Error is probable in any human activity, just because human actions are highly unforeseen and interactive in every context, thus creating the condition for errors to occur (El-Ladan & Turan 2012). The occurrence of a human behavior largely depends on the interpretation of the environment, the available information, the existing constraints and the motivation of the individual (Monferini et al. 2013). In this context, several definitions have been assigned to human error (Moriyama and Ohtani 2009, Kounavos 2012). A working definition in the context of this paper is that "human error is any human activity that solely or in combination with other activities increases the probability of occurrence or the consequence of a risk". It must be noted that this definition expands the usual interpretation of error from something directly associated to some sort of failure to something that could potentially result to a failure. This context allows considering as errors, all those actions that may not be perceived in this way at the time of their occurrence, but have an undoubted impact on the forthcoming failure. This is very valuable, especially, for the construction industry, where the lack of standardized production procedures often conceals the factors that contribute to the occurrence of an error.

Human error is classified based on type, consequence, failure modes, root-causes, etc. Some of those classes of error are (Moriyama & Ohtani, 2009, Kim & Park 2012, Kounavos 2012):

- Random vs. systemic, depending on whether the error is caused by random factors or the functional mode of the system.
- Internal vs. external, depending on whether the error is caused by cognitive functions or environmental factors.
- Obvious vs. hidden, depending on whether the error's consequence is directly perceived or in a relatively long period after the error's occurrence.
- Procedural vs. organizational, depending on whether the error is caused by a deviation from a course of action or organizational inefficiencies.
- Errors of Omission vs. Errors of Commission, depending on whether the error is caused by the omission of some planned actions or the commission of some redundant or inappropriate actions.

It is obvious that an error belongs simultaneously in various classes (i.e. systemic, internal, hidden, organizational, EoC) and that may be an obstacle for an efficient modeling in the context of HRA. This is the reason why these classifications constitute—in most of the cases—significant parameters in the development of a theoretical or methodological approach for HRA.

2.2 *Performance shaping factors*

Performance Shaping Factors (PSFs) are used to describe the various situational, organizational and personal causes that influence human behavior. They are defined and, even, named differently in the context of different HRA methods (Kim & Jung 2003, Petkov et al. 2004, Marhavilas et al. 2011) and this prevents from establishing a credible and widely accepted group of PSFs for general application. Therefore, it is common practice for researchers or practitioners to form the appropriate group of PSFs in a customized manner depending on the HRA model's requirements, the field of application and the analysts' approach (Kim & Jung 2003, Groth & Mosleh 2012).

While PSFs vary between different HRA methods, certain issues concerning the selection and use of them are quite common in every approach. These issues include (De Ambroggi & Trucco 2011):

- The definition of PSFs according to the level of analysis. In some cases, PSFs are not distinct in clarifying by definition whether they correspond to individual or team errors. This results to inclusion of PSFs of different level of analysis in the same model, which normally should be avoided.
- The interdependencies between PSFs. In all cases, many PSFs interact with other PSFs by affecting either their weights or directly their values. The type as well as the level of interdependency between two or more PSFs needs to be considered in the analysis.
- The existence of latent PSFs. Some PSFs are very hard to identify, mainly because they are hardly quantifiable. These latent PSFs can be measured indirectly through certain behaviors and actions that correspond to them.
- The connection between PSFs and failure mechanisms. In many cases, PSFs are, falsely, considered as error causes, while, in fact, they are measures of a condition.
- The scarcity of certain PSFs. In some cases, certain PSFs are met so rarely that no data exist for them with regard to their level of influence.

In these cases experts' judgments are the only source of useful information.
– The inherent properties of certain PSFs. In many cases, PSFs have by definition a positive or negative content that, respectively, influences the analysis; therefore, depending on the PSFs used in a particular method, this may be biased.

The knowledge of the issues concerning PSFs facilitates their proper introduction in the HRA method, which is proposed in this paper.

3 A METHOD FOR HUMAN RELIABILITY ASSESSMENT IN CONSTRUCTION

As mentioned in Sections 1 and 2, a major source of inefficiencies in HRA methods is the appropriate modeling of PSFs, which is a difficult task, in the first place. This research proposes: a) a systematic identification of the organizational, environmental and personal factors that have an impact on human errors in construction, and b) an evaluation procedure concerning the significance of each one of these factors. Subsections 3.1, 3.2 and 3.3 present the proposed method in this research.

3.1 *Identification and parameterization of performance shaping factors in construction*

In this research PSFs are organized in three major groups, namely organizational, situational and personal factors. This categorization is consistent with the standard approach for grouping PSFs, which has been applied in many previous cases (Marhavilas et al. 2011).

In complex situations the influences between PSFs may or may not be reciprocal. For example, while an organization factor affects the performance of a construction crew, the opposite does not happen. This means that, while the significance of the construction crew PSFs could be moderated by appropriate treatment of the organizational PSFs, the opposite is not feasible (Hallbert et al. 2004). Therefore, in the context of this research two types of influences are considered: a) those between PSFs in the same category, and b) those between PSFs from different categories according to the hierarchy shown in Figure 1.

The specific PSFs included in each one of those categories are not strictly defined. Unlike most other methods, it is considered that the PSFs set should not be standardized, but left free for the analyst to define it according to the situation in hand and a specific method, which is presented in subsection 3.3. This approach is considered effective given: a) the absolute lack in the literature of PSFs for the construction industry, and b) the characteristics of construction projects as presented in Section 1. As a working PSFs set, this research has adopted the one presented by Li et al. (2012), which with some slight modifications was evaluated as the most sufficient between the investigated sets for use in the construction industry.

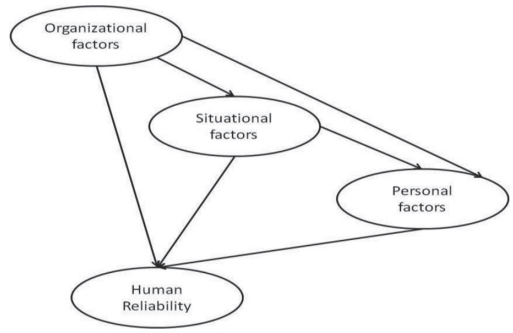

Figure 1. PSFs influence hierarchy.

3.2 *Construction of the performance shaping factors' influence tree*

PSFs influence the occurrence of a human error and their interaction determines the respective mode of failure. This can be represented by an influence tree, which requires the definition of the potential error. The selection of the appropriate PSFs from the respective set may follow the procedure of fault or event trees. The procedure has two stages, namely the pre-selection and the selection stages.

The pre-selection stage involves the selection of PSFs based on the evaluation of the analyst with regard to the influence they have to the investigated error. The following requirements must be met at this stage:

– All PSFs must refer to the same time band. The various PSFs present a different scale of reference in terms of development over time; however, it is ineffective for any method to include PSFs that are inaccurately defined in the analysis' period of reference.
– All PSFs are introduced to the analysis in a neutral state. This state is either the normally anticipated effect of the PSF or a state of zero effect, if the PSF does not fall in the first category.

The selection phase is conducted, based on the following assumptions:

– Human reliability has a high top boundary value. This assumption allows the consideration of behavior determinants (i.e. feelings, circadian rhythm), which are completely irrelevant to the

working environment, but, which may easily have an impact to an error occurrence.
– The error is known or considered as known in advance (i.e. prior to the analysis).
– The state of all PSFs can be evaluated; since the error is known or considered as known, a certain value for each influencing PSF should be, also, assigned to it.

The rules applied to select the appropriate PSFs in the analysis are the following:

– The selection includes only those PSFs, which have a direct impact to the downstream nodes. Those PSFs may be included in any one of the three categories as long as this category is prior (upstream) to the one where the node under investigation lies in.
– The selection includes only PSFs that at their final state, i.e. after the influences of other PSFs have been taken into account, is remote from the neutral state.

The selection follows a bottom-up approach, i.e. a direction from the error to the sources of its occurrence. When all PSFs of a certain category (e.g. personal) are identified, those of them, which have a negative influence to the error occurrence, are distinguished in two classes: a) Class A, which includes those PSFs that worsen the condition of the PSFs they affect, and b) Class B, which includes those PSFs that fail to exercise their positive influence to PSFs they affect. The transition to the upper PSFs level involves only those PSFs of the first class, while the rest PSFs are mapped for completeness but are not introduced into the network's calculations.

The final outcome of this process is a network like the one presented in Figure 2.

In the network of Figure 2: a) the circle represents a PSF with a positive influence to the connected PSF, while the rectangular represents a PSF with negative influence to the connected PSF, b) the solid line arrows represent a connection between PSFs of Class A, while the dashed arrow represents a connection of Class B.

Note that in Figure 2, PSF9 appears twice one with a negative and one with a positive effect to PSF7 and PSF4, respectively. The multiple appearance of a PSF in the network is feasible, since this PSF, in each repetition, is related with a different PSF. The potential of multiple appearances of a PSF at the same hierarchical level necessitates the measurement of the frequency of appearances at a certain condition (i.e. positive or negative) in the same time band.

Another issue is the importance of the influence a PSF exerts to another PSF. The importance measure of a PSF responds to the question of how much does one appearance of a PSF influences the frequency of appearance of the downstream PSF. The multiplication between a PSF's frequency and importance measures provides the measure of significance of this PSF.

The simple network described in Figure 2 could become much more complicated under specific circumstances, such as the following:

– A PSF could appear in multiple duplicates in several relations. All these duplicates are unified upstream at a single node as in Figure 3.
– Three PSFs could constitute a loop in the network. Loops should not appear in the network; therefore multiple duplicates of a node should be introduced, according to the example of Figure 4.
– A PSF could appear in multiple states in the network. In this case, the PSF is not introduced in duplicates, but for each state a different node is introduced.
– Several PSFs may have similar definition or function in the network. For example "Time Availability" may refer to several network parts with a different content in each one of these parts. This situation should be avoided by properly defining each PSF in the first place.

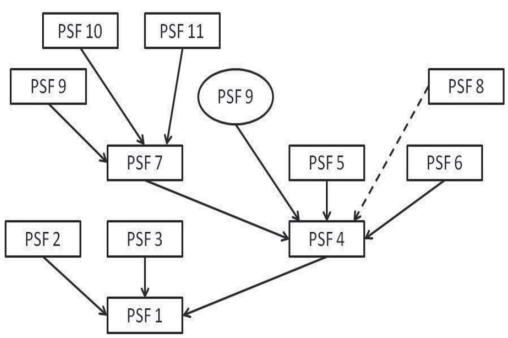

Figure 2. An example of a PSFs influence tree.

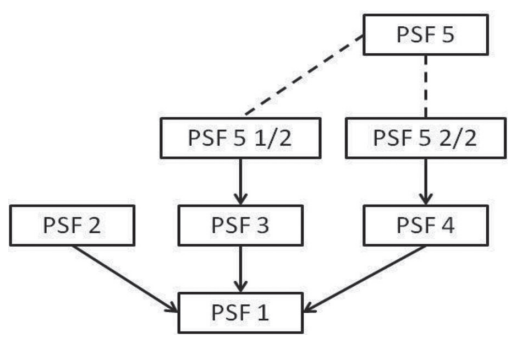

Figure 3. An example of a PSFs influence tree.

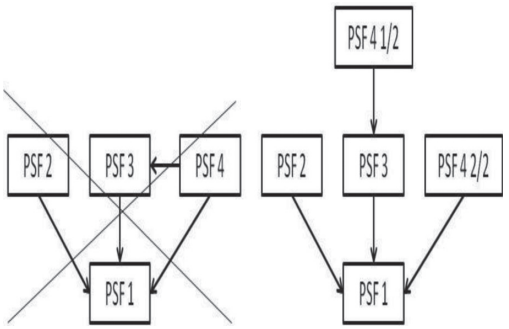

Figure 4. False and correct networks with regard to loops.

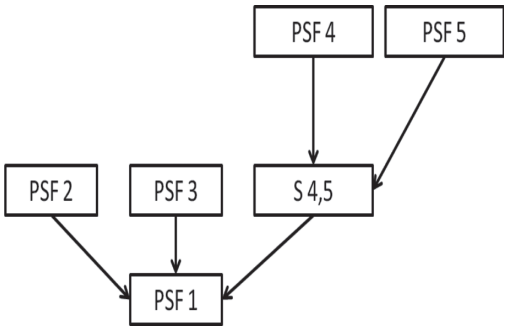

Figure 5. Representation of a situational node in the network.

– Several PSFs may have a decisive contribution to the failure mode of a downstream PSF, in such a way that their omission could automatically cancel this failure mode. This situation is tackled by introducing another type of node to the network, namely the "situational (S) node", whose frequency is the product of the multiplication of the frequencies of the converging nodes and importance is defined according to frequency measure. A case of a situational node in a network is presented schematically in Figure 5.

3.3 *Assessment of the significance of each performance shaping factor*

The quantification part of the proposed method is related to the assessment of the significance of the various PSFs that are included in the network. For this purpose an assessment card as shown in Figure 6 is filled for each PSF.

In the assessment card cells (1) to (3) are filled according to the developed network. It should be noted here that the copy number is the unique number of the specific duplicate of the PSF, which

(1) Ref. No	(2) PSF Name	(3) Duplicate Number
(4) Linguistic Description of Importance		(6) Linguistic Description of Frequency per Time Unit
(5) PSF State		(7) PSF Frequency per Time Unit
(8) Relative Importance (%)		(9) Product (7) x (8)
(10) Nodal Relative Significance		(11) Total Relative Significance

Figure 6. The PSF assessment card.

is presented in the form x/n, where x is the number of the duplicate and n is the amount of the duplicates for the particular PSF. Cells (4) to (7) are filled based on expert judgment, previous experience or available data, while cells (8) to (11) are calculated in the following way:

– The relative importance of a PSF (cell 8) is determined after the application of the AHP method, where experts compare the influence of a PSF to the downstream PSF's to determine which one of the latter is mostly influenced by the calculated PSF. The calculated influence, which has the form of a percentage, constitutes the relative importance of the PSFs that converge at a single node.
– The PSF's significance is calculated as the product of the values in cells (7) and (8), according to the proposed definition in subsection 3.2.
– The convergence of several PSFs at a node requires the determination of the specific PSF's significance; therefore, the calculated value in cell (9) is divided by the sum of all significance values of the PSFs that converge at the node. This new value (cell 10), which again has the form of a percentage, constitutes the PSF's nodal relative significance.
– The total relative significance for each PSF (cell 11) is calculated according to the network by multiplying each PSF's nodal relative significance with the total relative significance of the connected downstream PSF. In this way, the total significance of each PSF is determined up to the point of the error occurrence (the first node in the network).

In the assessment of the PSFs significance it should be noted that:

– The significance of a PSF with multiple duplicates is the sum of the values of significance of each duplicate.
– Situational nodes are also assessed with the same card, but the propagation of the total significance is inversely proportional to the parent nodes' frequency values. This is because of the method's orientation to the chances of dealing

with the potential error, which renders the rarest between, e.g. two causes of error, as more significant than the other.

4 AN APPLICATION EXAMPLE OF THE PROPOSED METHOD

The method's application is presented in a hypothetical example for demonstration.

Suppose that the seal of an equipment device, which is sensitive to water, is left open as a result of human negligence. This is the case of a human error that could evolve to a risk occurrence and the proposed method seeks to identify the reasons for this source of risk.

For the example, suppose that ten PSFs are identified as contributors to the human error occurrence. The time band is set to eight working hours, and the identified PSFs are presented in the corresponding network of interdependencies in Figure 7.

Each PSF is defined in terms of content and state. For example the "Maintenance planning" PSF's neutral state is set to "Normal operation", while the real state met, based on the example, is "Slightly problematic". All the PSFs in the network are defined in the same way.

The determination of the states for each PSF modifies the network as shown in Figure 8.

The updated network introduces the "Language understanding" PSF, as positive, instead of negative influencing factor for the downstream PSF.

Once the network is finalized, the next step is to fill the assessment cards of all active PSFs. An indicative card for the PSF "Level of Noise" is presented as an example in Figure 9.

The results of the total relative significance of all PSFs as they are derived from the assessment cards are summarized in Figure 10.

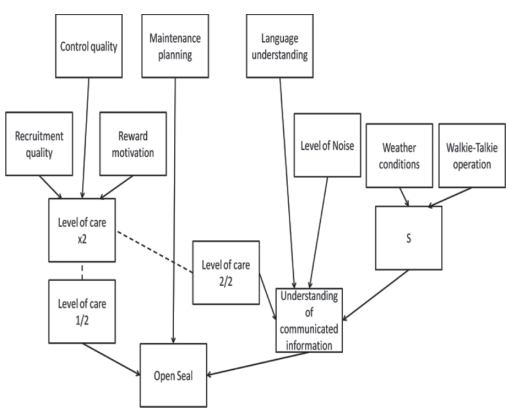

Figure 7. The network of the demonstration example.

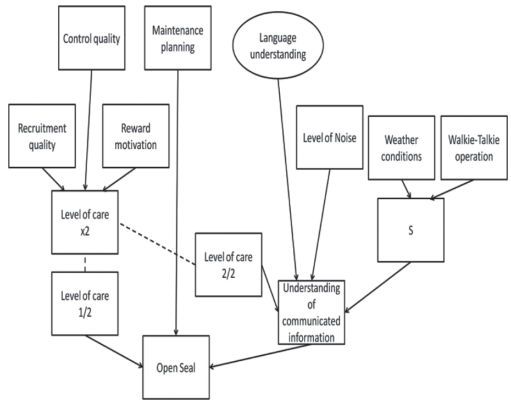

Figure 8. The modified network after the determination of states for each PSF.

4	Level of Noise	-
Noise often causes a slightly problematic communication		The site is noisy 4 hours per day
Noisy		0,5
39%		0,195
42%		19,95

Figure 9. An example of a filled assessment card.

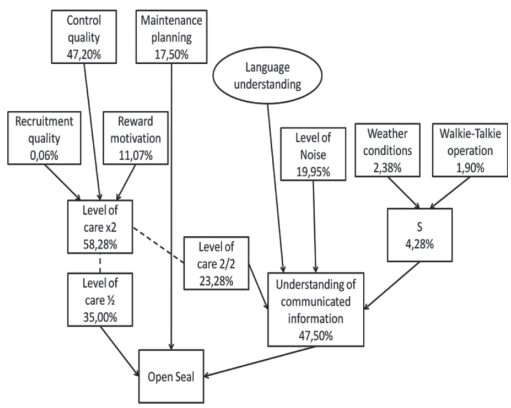

Figure 10. The final results of the PSFs' significance in the network.

As shown in Figure 10, the level of care is the most important factor and is mostly influenced by the quality of control in the site. Therefore, to avoid similar future human errors the construction manager should pay attention to the quality of control processes in the site, in order to minimize the risks from the lack of care on behalf of the workers.

5 CONCLUSIONS

Current HRA methods despite their evolution since the first generation are, still, far from being considered as accurate or generally applicable. Especially in the construction industry, which is characterized by complexity in the production process, current HRA methods are inefficient and, therefore, inadequate.

Taking into consideration the accumulated knowledge on the field, this paper proposes a method to model and assess performance safety factors in construction. The method comprises three basic steps, namely the identification of the PSFs, the creation of the network of interactions between the identified PSFs, and the assessment of the PSFs significance, in terms of impact to the downstream connected PSFs.

This method tries to tackle several issues that current HRA methods have inadequately treated; however, it still requires further development to achieve this goal. The method's current disadvantages are the heavy computational effort that may be required in the case of a very complicated network and the huge dependence on the initial development of the influence network. Moreover, a refinement of the assessment process may be required especially with regard to certain parts of the modeling, such as the copies or the situational factors.

Further improvements and research that will entail the method's performance in real cases and the algorithmic approach for the solving of the network are planned in this ongoing research, which intends to provide a new human reliability assessment method for application in the construction industry.

The impact of the use of subcontracting on organizational reliability and safety

C. Guers, C. Martin & J.L. Wybo
Centre de Recherche sur les Risques et les Crises (CRC), Mines ParisTech, Sophia Antipolis, France

ABSTRACT: Subcontracting has become very widespread in contemporary socio-technical systems. It takes many forms and leads us to think again about the nature of the workforce. This article takes a new look at organizational boundaries in terms of the concept of businesses that are extended through subcontracting and its implications for safety culture. First we present a comprehensive, state of the art typology of the current forms of subcontracting, which have been developed to meet the needs of productive organizations. Then we focus on the effects of this type of indirect management on the effectiveness and reliability of organizations and more specifically, the workforce.

1 INTRODUCTION

Since the beginning of the twentieth century, we have seen a change in the way businesses are organized. Until the end of the 1970s an integrative model dominated. Under this model companies themselves were responsible for most of the manufacturing of the final product and all production functions were integrated. In the early 1970s, companies became large corporate networks (a multi- or poly-cellular model). The contracting company headed the network; it was only responsible for a very limited part of production/manufacturing and was surrounded by a network of suppliers/partners.

This new model can be seen as offering the best prospects in an increasingly unstable economic context. Nowadays it takes many forms: the extended organization (Benchimol 1993; Capraro & Baglin 2002; Perez 2007; Defelix & Picq 2013), the fragmented organization (Hatzfeld 2000; Berger 2005), the network organization (Veltz 2000; Roy & Audet 2002; Rorive 2005; Morley 2005; Mazaud 2006; Pesqueux 2008), the shared organization (Abdul-Nour, Jacob, Julien & Raymond 2003), the enhanced organization (Moreau 2003) or the agile organization (Barrand, Gumb, Badot, Benameur, Blum *et al*. 2010). These new forms are all examples of not only a more flexible and efficient organization, but also new organizational boundaries, a new way of occupying space and new governance mechanisms. They consist of a national and international exterior space and an internal space that is fragmented due to the diversity of actors and skills. In this kind of organization, production is distributed in an orderly manner between partner companies.

These changes in the way businesses operate are fundamentally changing the organization. They are likely to accentuate certain types of organizational risks related to the management of a fragmented workforce distributed across a network, and extended by a constellation of actors (subcontractors, co-contractors or partners). It is important to understand these new organizational forms in order to be able to better predict these changes and anticipate the risks associated with them. The internal organization of a company can become a source of threat. Organizational reliability is based on the strategies of actors who shape production on a daily basis given the organizational constraints they face. In this context, this article examines how the constraints faced by the extended organization can be a source of reliability or risk. The aim is to help organizations that have decided to use subcontractors to improve reliability, and control safety- and security-related risks in the context of relevant research, particularly management systems.

Specifically, we ask how the strategies implemented by individuals shape the efficiency, reliability or risk of extended productive organizations. In the first part of the article we define subcontracting, its different forms and motivations. In the second part we define the extended organization, its characteristics and the risks that are associated with it. Finally, we show the impact of this ambivalent mode of organization on the effectiveness and reliability of the workforce.

2 SUBCONTRACTING

There is no question that subcontracting is one of the key characteristics of the operation of these new

productive organizations and the subcontractor can be thought of as a fully-fledged actor in the system. While the phenomenon of subcontracting is not new, its popularisation is. This phenomenon means two things: On the one hand it has become both widespread and commonplace; the subcontractor cascade has become common practice in many companies. On the other hand it has been extended into a growing number of business operations. In the 1970s it concerned simple tasks such as cleaning and security; since the 1980s it has extended in some companies to the entire production process (the hollow firm). The internal organization and working conditions of companies in many sectors have thus completely changed.

2.1 *Subcontracting and outsourcing*

Subcontracting is one form of outsourcing. A report by the French Social and Economic Council distinguishes between subcontracting and outsourcing in terms of the length of the relationship and the transfer of ownership (activity substitution), "It could therefore be said that subcontracting, unlike outsourcing, partially concerns the provision of a service in a given time and not necessarily over many years and—most importantly—does not imply that the activity was previously undertaken internally. Outsourcing is further distinguished from subcontracting in that it tends to lead to long-term change (by subtraction from the original company to an economic third party) in the boundaries of the company and the structural configuration of its resources. It could be called a 'contractualised' and 'monetised' handover of a function or activity previously included in the internal mode of governance."[1]

The concept of semi-integrated subcontracting (Houssiaux 1957) is based on the principle of substitution and the transfer of ownership of a specific piece of work; however it implies that there are ongoing and stable links. According to Barthélemy (2007, p. 12), the difference between subcontracting and outsourcing is based on the obligations of the service provider. Outsourcing is based on an obligation to provide results; the service provider takes entire responsibility for the management of the outsourced activity. In the case of subcontracting, the client is responsible for the management of the outsourced activity and the service provider merely provides production resources. Nevertheless, subcontractors are also obliged to produce results, and can be seen as the intervention of an external agent on at least three levels: the definition of work, its resources and the procedures put in place to achieve a specified outcome. In some cases, highly-qualified subcontractors may participate in drawing up specifications (Chaillou 1977).

Nevertheless, the difference between outsourcing and subcontracting remains ambiguous. Intercompany links are varied and in many cases go beyond official definitions, which give an incomplete picture of labour relations, "a little like concrete can mask the girders it supports" (Jounin 2006). In a very general and basic way, we define subcontracting[2] as an operation that consists, for a company A, of the delegation to a company B of a task or a function that Company A does not want to or cannot undertake itself.

2.2 *The various forms of subcontracting*

In order to understand the different forms that subcontracting can take within organizations, Chaillou (1977) proposed a typology, in which time is a fundamental characteristic for understanding the relationship between businesses. He distinguishes short-term subcontracting (comparable to occasional, cyclical troubleshooting) and long-term activities that can be compared to permanent, structural or semi-integrated subcontracting that is more akin to outsourcing (Houssiaux in Baudry 2013). The contract frames the length of the relationship between the client and the subcontractor.

At the same time, it is vital to identify areas where subcontracting can be used: on-site, internally or externally. External subcontracting may be local or abroad, known as offshore or delocalized outsourcing (Niang 2013). This practice runs the risks found in both outsourcing and offshoring (Geyer 2007) – loss of control and ownership of one or more delegated activities. In this case, it is up to the organization to decide whether it is in its interests to expand its borders. Ponnet (2011) also distinguishes between the activities carried out on the contractor's premises and those performed externally. She noted that maintenance work is semi-integrated and carried out at the contractor's production facilities.

In cases where subcontracting is carried out in the organization's country of residence, it is

[1]Social and Economic Council (*Conseil économique et social), Conséquences sur l'emploi et le travail des stratégies d'externalisation des activités,* The Official Journal (*Les éditions des journaux officiels*), 2005, p.92.

[2]The French law of 31 December 1975 defines subcontracting as "the operation by which a business entrusts, through a subcontract and under their responsibility, to another person called a subcontractor, all or part of the execution of a business contract or a public tender concluded with the client."

more like classical subcontracting or nearshore outsourcing (Quelin 2007).

When the work is carried out onsite by a foreign contractor, and the subcontractor's company is located in a different country to that of the client, the term onshore outsourcing is used (Samaganova 2008). *In situ* subcontracting is also subject to risk. Jounin (2006) gives examples of field observations where employees of various local companies coexist and work together to achieve the same production objectives. This is an illustration of a constellation of actors where the new interactions fundamentally change the organization's reliability, the division of work and teamwork modalities.

Although subcontracting practices vary from one organization to another, there are two main scenarios that are widely used. In the first scenario the company does not have sufficient production resources and therefore delegates certain functions that cannot be undertaken internally. This is known as 'speciality' subcontracting, where the contractor calls upon a specialist who has the equipment, materials and expertise that meets the needs of the purchaser, because the latter does not have or may not wish to acquire them, for their own strategic reasons[3]. Specialty subcontractors or specialised suppliers (Houssiaux in Baudry 2013) carry out specific operations using their own methods. Their activity is complementary to that of the organization. In the same vein, Barthélemy and Donada (2007) argue that companies are motivated by rapid access to resources and skills that are not available internally. It allows the organization to focus on its main activity (Mazaud & Lagasse 2009) and to delegate ancillary activities. Specialization is subjective and varies depending on the organization as, "their point of reference is their own technical ability" (Chaillou 1977). A specialist is someone who is as (or more) capable than the company itself, while others are seen as 'capacity' subcontractors (see below). Chaillou differentiates specialty subcontracting from 'supply' subcontracting which concerns, "the definition and study of methods to be used to perform a given piece of work." This type of subcontracting involves a high degree of specialization that makes it possible to define functions on the basis of specifications that target a specific need of the client company. This enables the client company to optimize its internal resources.

In the second scenario, the company is able to produce the good or service itself, but instead it delegates the work. This is called 'capacity' subcontracting. In this case, the contracting company, which can produce the product itself, employs another company (either occasionally due to a temporary spike in production or technical problem or on a more or less ongoing basis) because it wants to maintain its own capacity through the use of external production capacity[4]. These capacity subcontractors can also be called consignment manufacturers (Houssiaux in Baudry 2013); they perform simple tasks as directed by the contracting company or client and very often their activities compete with that of the organization.

Although in theory there are several types of subcontracting, in practice it is difficult to identify them. According to Jounin (2007), in the public construction sector, the boundary between capacity subcontracting and specialty subcontracting is blurred. For example, subcontracting in building industry activities is mainly based on workers and intermediate consumption, "some of the girders are supplied by the contractor, while their main tools are supplied by the general business" (such as the crane). In this case, Houssiaux talks about 'community' subcontracting, in which the activity, the execution of work or the finished product are collective.

2.3 *Motivations for the use of subcontracting*

We have highlighted the different forms of subcontracting, which correspond to the different needs and strategies of organizations. According to Houssiaux (in Baudry 2013) capacity subcontracting is mainly used to reduce or limit production costs. Business owners can create competition between different service providers to get better rates. This idea is not new; Williamson in 1975 looked at corporate collaboration through market relations from an economic point of view. Transaction costs theory (Ghertman 2003) argues that the organization chooses between doing things themselves, or having them done, depending on the cost of acquiring a product or service on the market compared to the cost of internal production. Barthélemy and Donada (2007) noted that the use of subcontracting allowed organizations to be more flexible by transforming fixed costs into variable costs, which made it easier for them to cope with market fluctuations. According to Quélin and Duhamel (2002) the economic factor is closely related to the quality function. A company delegates not only for reasons of quality and efficiency, but also cost.

[3]The French National Institute for Statistics and Economic Studies (INSEE) definition is as follows: Following the application of the *Nomenclature d'Activités Françaises* on 1 January 2008 (second revision), in the manufacturing sector primary contractors *sensu stricto* are only those who provide raw materials. Conversely, subcontractors *sensu stricto* are only those who receive raw materials.

[4] INSEE definition (op. cit.)

For some companies in some cases, subcontracting is primarily explained by performance issues in the workplace. Finally, subcontracting can be a way to transfer risks and responsibilities associated with production to a third party. Statistics show that accidents occur more often among the employees of subcontractors (Algava & Amiras 2011) compared to the employees of contractors, but it must not be forgotten that some companies outsource their riskier activities, particularly in the industrial sector (Thébaud-Mony 2000).

Other organizations transfer social risks through subcontracting (Puech 2004; Barthélemy 2007, p. 67). In this case, it is a way to avoid excessively high social costs; the imposition of new constraints, loss of benefits, lower wages and lack of resources can result in disenchantment with the organization. Subcontracting can enable the company, in deteriorating market conditions, to take measures that have a negative impact on the subcontractor without having to deal with the consequences. This is not an intentional process, but an adjustment mechanism in response to market fluctuations.

In addition to these quantitative, qualitative and social advantages of subcontracting, we can add a further strategic and opportunistic motivation. These concern situations where the company is faced with uncertainty concerning the market or its products and wishes to test a company or its staff before integrating them or buying the company. In practice, although the extended, outsourced organization has become a dominant trend, other organizations are moving in the opposite direction and are seeking to strengthen their classical "hierarchical and pyramidal centralization" through internalisation policies (Veltz 2000). This raises the question of the acquisition of certain subcontractors. The motivations for the use of subcontracting are not always rational, and are likely to be the result of poor strategic choices. Subcontracting is by nature ambivalent. While it offers various benefits to the organizations and can form part of an extension strategy, this extension can sometimes be a disadvantage and pose a risk to production.

3 ORGANIZATIONS EXTENDED BY THE SUBCONTRACTOR NETWORK

Rorive (2005) provides a typology of six types of corporate network. Of these six, five are driven by the use of partners, suppliers, joint contractors, subcontractors or distributors. It could therefore be said that many organizations extend themselves through outsourcing, and more specifically subcontracting.

For Veltz (2000, pp. 174–175) the term corporate network is both overly polysemic and restrictive. He defines this new form of organization as "a network of cellular models" made up of "a relatively compact and traditional central core surrounded by a periphery of suppliers and distributors structured in successive layers." Three elements characterize this type of organization and mark a break with the integrated organizational model: market-oriented decentralization, the contract and multi-functionality.

3.1 *Market-oriented decentralization*

Market-oriented decentralization concerns the distribution of activities across relatively autonomous units. These subsets are subject to strict targets coupled with the systematic evaluation of their results (rather than a precise definition of procedures). According to Veltz (2000) this management mode is a consequence of Taylorism where goals become more important than the means: "specialization according to goals and products impacts on specialization according to processes, resources and technical knowledge". This phenomenon can be observed in many organizations and has spread to many industries. This market-oriented decentralization can be a risk for organizations. If goals are too general and vague, they must be broken down into operational and individualisable sub-goals (Simon 1983). Otherwise, individuals may take decisions that have an adverse impact on the organization and it becomes difficult to control the consequences. Herbert Simon (1983) points out that the goals and objectives of an organization can be perceived differently by different members of the organization and these different perceptions are likely to harm the overall coherence of these new organizations.

3.2 *The contract*

The increasing use of the contract is a fundamental element of the relationships between the different units in the cellular network organization. For Veltz (2000) the contract leads to "very diverse relationships, legal forms, styles and constraints". He stresses that 'hierarchy' and 'contracts' are in no way antithetical" and takes the example of Japanese supplier chains. In these chains, the ability to mobilize networks of relationships is based on a clearly defined, prescribed hierarchy that forms the basis for the organization (Magaud & Sugita 1993).

An extension of the commercial function is found in new organizations through contracts that mobilise remote resources. The characteristic feature of this type of organization is that it is able to extend its scope for action while reducing its legal exposure. Many economists have highlighted the trend towards "vertical disintegration" (i.e. a reduction in direct production units legally owned by the company). This makes it possible to

indirectly extend and share production by mobilising a network of actors and skills. This market-driven vertical disintegration usually involves a reduction of the salaried workforce and non-strategic or ancillary activities (such as administration, cleaning or security) for the lead company.

Demmou (2011) noted that there has been a significant decrease in manufacturing jobs since the 1980s. The partial outsourcing of industrial activities to the service sector explains 20–25% of the decrease in the salaried workforce[5]. On the other hand, market orientation and the use of contracts have encouraged the creation of "complex mini-businesses rather than divisions created along the lines of traditional functional departments" in organizations (Veltz 2000, p. 178). Contractual relationships become one of the keys to the expansion of the organization. Coase (1937, p. 23) highlighted this point in other terms when he wrote, "a firm becomes larger as additional transactions (which could be exchange transactions co-ordinated through the price mechanism) are organized by the entrepreneur and becomes smaller as the abandons the organization of such transactions". The contract, whether between two individuals or two companies, allows the organization to expand both on a spatial and skills level. However, it cannot alone organize collective action, contrary to what the transactional approach (also known as agency theory) suggests[6].

There are a variety of mechanisms to coordinate production activities, the contract is not the only incentive mechanism (Baudry 1992). The mobilization of remote productive resources may pose management and control problems within the extended organization.

3.3 *Multi-functionality*

The organization distributes distinct functions across its network of partners, suppliers, joint contractors, subcontractors or distributors. This is the case at Airbus Toulouse (France), which divides tasks between Airbus and its network of suppliers. Production processes are distributed across the manufacturer's internal sites. Airbus is the prime example of the "lead network firm"; it delegates its non-strategic sub-functions in order to focus on its core activities.

However, the firm also uses strategic, lead subcontractors, who play an intermediate role and use their own subcontractors. Mazaud and Lagasse (2009) found "a high degree of segmentation" in Airbus suppliers. There is a division of labour between the company leading the network and its network of suppliers. Few authors have looked at its modalities. This multifunctional character of the organization means that it can carry out several simultaneous activities, improve performance and be more responsive to the needs of its customers. One example is the cooperation model that Airbus operates with its suppliers, which enables it to simultaneously develop several aircraft at different sites. However, while this multi-functionality enables organizations to focus on their specialty, it can also, in certain cases, lead to the loss of skills and control of overall production (Nogatchewsky & Donada 2005; Barthélemy 2007 p. 65).

These three features (market-oriented decentralisation, the contract, multi-functionality) make it possible to characterise and understand ambivalence in organizations that are extended by subcontracting. Such organizations grow around a base unit or an autonomous decision-making centre, which structures activities and their deployment, and ensures the overall coherence of peripheral activities.

The base unit forms the foundation for all other activities. This central core lies at the heart of direct and indirect cooperation with a constellation of partners, who undertake functions designed to achieve an ultimate goal. According to Capraro and Baglin (2002), the extended business "has to set the standard for all partners in design and production excellence, which must unite the efforts of numerous partners to achieve shared success in the extended company." The extended organization must therefore develop the capacity to re-think itself and quickly recompose itself in response to its environment and these new links.

We argue that one of the characteristics of the extended organization is that every action centre or mini-business forming the network has the potential to further extend the boundaries of the initial contractor, and to initiate new cooperation. Its potential extension, in terms of both skills and geography, is unlimited and can present risks. The strategic nature of the subcontractor cascade (shared responsibilities through a multiplication of subcontractors and contractors, the supply chain, value chain or overall logistics), which includes all of the actors and activities that enable the production of a final product (Sofiane, 2009) is specifically designed to offer organizational flexibility and geographic reach that the integrated model does not provide. Finally, there are at least two ways in which an organization becomes extended. The first is through a reduction in its direct production units, via market-driven decentralisation. Secondly, it can create new commercial and

[5]See Sauvy A., 1980. *La machine et le chômage*, DUNOD. The spillover theory argues that technical progress that improves productivity leads to a transfer (spillover) of jobs from one sector to another.

[6]The contract is seen as simply the act of giving consent and takes no account of authority and dependency relationships.

contractual relationships, and manage its resources through a network of partners.

While communication is one of the keys in the extended organization it enables them to manage their resources and partners—it can also represent a risk. In practice, the multitude of internal actors can also lead to the risk of leaked information about industrial processes or organizational strategies. The communication of information has strategic value as it makes it possible to gain power (Crozier & Friedberg, 1977). Individuals always have a degree of autonomy and pursue their own objectives, which are not necessarily compatible with those of the organization—especially when it consists of a fragmented constellation of partners (Vaughan, 2009). As much as it may try, the organization can never completely limit the autonomy of subcontractors. The opening up of extended organizations through market-oriented subcontracting networks can create a significant risk of information leak about resources and strategies in a given market, and lead to a loss of control with respect to its partners and competitors. For example, subcontractors from emerging countries can monopolize technical and organizational knowledge by copying processes before themselves developing high-tech industries that compete with those of industrialized countries. Faced with such a risk, the organization can take a strategic approach to the market, i.e. by subcontracting auxiliary functions while continuing to carry out core functions internally (Altersohn, 1997, p. 22). Otherwise, only the quality and strength of the links between the contractor and the subcontractor can reduce the risks associated with an organization's loss of confidential information.

4 THE EFFECTS OF THIS AMBIVALENT MODE OF ORGANIZATION ON THE RELIABILITY AND EFFICIENCY OF THE WORKFORCE

The motivations, forms of subcontracting and relations between contractors and service providers vary from one organization to another. In order to understand them better, it is useful to think of the subcontracting relationship as a form of employment relationship. Baudry (1992) argues that the two types of relationship are comparable. In both cases there is "quality economy", i.e. there is uncertainty about the work of the subcontractor, like that of the employee, in terms of productivity and results. The author shows that there is a plurality of mechanisms that govern inter-firm relations. Production is based not only on the contract and authority but also (and above all) on trust. Jounin (2006) also sees working relationships as going beyond purely mechanical aspects. Contracts "provide the framework, but within this framework actors build trust and informal loyalties [...]. Personality comes back into the game, loyalty is re-injected, tacit alliances are established that go beyond employment contracts and compensate for their fragility."

However, unlike the employment relationship, subcontractors are in a different, intermediate position. Paid work is very often a subordinate position, although being this position does not necessarily mean oppression and servitude. It can be a situation where work-related skills are made available to a third party or a contractor. The particular characteristic of subcontracting is that the company is no longer in a direct employer-employee relationship, but in an indirect relationship (Tinel *et al*. 2007). In practice, the commercial contract replaces the employment contract. The company continues to mobilise its productive effort remotely through subcontractors.

4.1 *Transformation of the workforce and risk management*

Subcontracting may affect teamwork. As it becomes commonplace the workforce is restructured into those who are directly and those who are indirectly mobilised. Jounin (2007) used a case study of a building site to demonstrate the importance of subcontracting in the construction industry. Out of 120 workers working on a large construction project, 80 were temporary workers employed by three subcontractors. Among the 40 who worked for the lead company, only 15 were direct hires. Therefore organizations need to create and cooperate with a fragmented workforce with different statuses, schedules and functions, united by a single goal. The SUMER 2003 survey (Hamont-Cholet & Sandret 2007) showed that the support of the workforce and the hierarchy protects against the risk of accident: the accident risk increases by 20% when workers cannot discuss with their bosses their concerns about how to do the job.

Similarly, Puech's analysis (2004) of a hotel's housekeeping staff identified two categories of workers, a fixed staff and subcontracted personnel, which highlighted the divided nature of the workforce. His case study showed that entire management of the workforce was tailored to meet the hotel's production requirements as closely as possible. The author noted significant differences in terms of employment conditions and wages in the two groups of staff (one employed by the hotel and the other employed by the subcontractor).

The first group worked full time, had a fixed number of rooms to clean and a fixed salary. The second group worked part time at a fixed pace: a certain number of rooms to be cleaned each hour. Their salaries were not fixed because their schedules varied between 20–30 hours per week.

The author observed a significant difference in salary conditions within the same occupational group. According to Peuch, "the use of subcontracting allows the group to compensate for variations in activity levels, a particular feature of the hospitality industry. The subcontractor's employment contracts are therefore established in order to respond to the needs of the company as far as possible, i.e. almost exclusively part time." The consequence was that around thirty subcontractors members of the housekeeping staff took strike action as a result of a collective sense of injustice. While working hours were their main motivation, above all, the subcontractor's staff demanded equal status with the hotel's staff. This study shows that the use of subcontractors is not without consequences and that the internal organization of a company can be a source of threat. The organization itself contains the necessary elements for both its growth and its death.

According to a 2006–2007 survey on organizational change and computerization (Algava & Amira, 2011, Table 1) subcontracting is widespread in the public construction and hospitality industries. However, most subcontractors are found in industry; both subcontractors who carry out the work themselves and those who in turn subcontract others (intermediate subcontractors).

4.2 *Subcontracting at the origin of both vulnerability and reliability*

In this section we focus on industrial organizations as a source of both risk (Perrow 1999) and reliability (La Porte & Consolini, 1991). These approaches are two sides of the same coin and we present them here as ways to understand the origins of reliability or risk within at-risk industrial organizations. Issues of reliability and unreliability are played out in the workforce (Bourrier 1999), and are particularly seen in strategies that locate actors depending on the constraints they are subject to. It is therefore important to understand the effect of the changes that organizations go through.

When subcontractors are used there is a multiplication of dual-source employment statuses (CEE 2008 pp. 57–68, p. 60 Table 1, p. 61 Table 2). In the 1980s, 63% of businesses used short-term contracts and 59.8% used subcontractors. In 2000, 70% of companies used short-term contracts and 85.3% used subcontractors.

Triangular subordination situations have spatially and temporally reshaped organizations. This is particularly seen in the widespread use of temporary employment contracts, flexible working hours and polyvalent/multi-skilled jobs. Alongside these changes in personnel management modes, power and the exercise of authority is changing. The need for results and constraints related to the pace, flexibility, objectives and the assessment of work are more visible in the subcontracting relationship.

According to a 2006–2007 survey on organizational change and computerization (Algava & Amira 2011), the employees of subcontractors were, on average, subject to greater constraints in terms of scheduling, pace, flexibility and objectives than those of prime contractors, and their working conditions were poorer. On the other hand employees of subcontractors had greater autonomy over their work than their colleagues with respect to initiatives taken to improve their workplace. The survey showed that non-intermediate subcontractors (those who carried out the work themselves and did not subcontract) received more direct instructions, but had fewer specific task-related targets to meet than both intermediate subcontractors and employees of the contractor. However, this formalisation of working practices does not seem to have reduced the autonomy of subcontractor's employees.

The increase in work carried out under constraints and the scope for autonomy has at least two consequences. First, the widespread use of management practices where individuals are closely monitored means that staff are motivated by the fact that their results are regularly evaluated. Secondly, they know that if their results are unsatisfactory there will

Table 1. The various forms of subcontracting.

Variable	Weight		
Duration of the activity of the subcontractor	Short	Moderate	Long
Place where the subcontractor carries out work	External	Intermediate	Internal
Share of the activity in the organization	Small	Average	Significant
Nature of the subcontracting activity	Simple and substitutable	Average	Complex, non-substitutable
Place of the subcontractor in the production process	Supply—intermediate production—final production		

be negative consequences. The client may not renew the contract; a decision which would have negative consequence for many of the subcontractor's employees. Results-based performance means that employees are subject to significant constraints. The hierarchy requires increased professionalism in order to be the best. The situation is one in which the hierarchy issues objectives that must be met without fail.

In an at-risk organization (for example in the nuclear sector), working under such constraints can be beneficial in terms of both efficiency and reliability. The work of Bourrier (1999, pp. 205–251) highlights the benefits of subcontracting. Although it may be normal to expect that subcontracting reduces transparency and leads to an increase in incidents, the author noted total transparency regarding outsourced activities at the Nogent nuclear power. Subcontractors did not hesitate to declare the slightest production deviation in order to protect themselves against certain incidents. The author explained this behaviour in terms of the significant economic and qualitative constraints subcontractors are subject to. Consequently, in order to secure the renewal of their contract they seek to guard against any incidents that may occur at the client's site and demonstrate their usefulness.

However, if these constraints on objectives and the pace of work can lead to more effective organizations, they are also likely to increase the risk of accidents. An analysis by the French Department for Research, Clinical Trials and Statistical Analysis (*Direction de l'animation de la recherche, des études et des statistiques analysis*, Dares) (Hamont-Cholet & Sandret 2007) confirmed that employees who report "always having to rush" increase their risk of an accident by 26%. A high workrate may also limit its effectiveness and quality. According to Vaughan (2009) the space shuttle Challenger accident occurred following a sequence of deviations from technical procedures in order to meet set deadlines. The technical culture of the aerospace industry is very sensitive to safety issues. According to the author, the politico-bureaucratic imperatives associated with a cost and time culture went against this technical culture.

5 CONCLUSION

This paper forms the first part of a sociological study. The different forms of subcontracting shown in these studies enable us to reflect on the impact of an increasingly widespread mode of governance that is having an effect on the workforce. The diversity of statuses present in productive organizations tends to change the organization of work. The use of subcontractors leads to both restructuring and tensions within the workforce. A better understanding of the composition of this workforce, and its reactions means that it becomes possible to anticipate events and shield productive organizations from certain risks associated with staff management. Sociological qualitative research methods are likely to provide us with a better insight into this scenario and help us to assess the associated risks.

ACKNOWLEDGEMENTS

We would particularly like to thank TOTAL, GDF SUEZ, SNCF and AFNOR, who are the partners of the Mines ParisTech Resilience Engineering Chair. These companies sponsored this research and thereby contributed to the creation of knowledge in the field of industrial risks.

Human error analysis: Review of past accidents and implications for improving robustness of system design

R. Moura*, M. Beer, E. Patelli & J. Lewis
Institute for Risk and Uncertainty, University of Liverpool, UK

F. Knoll
NCK Inc., Montreal, Canada

ABSTRACT: Since the establishment of the high-technology industry and industrial systems, developments of new materials and fabrication techniques, associated with cutting-edge structural and engineering assessments, are contributing to more reliable and consistent systems, thus reducing the likelihood of losses. However, recent accidents are acknowledged to be linked to human factors which led to catastrophic consequences. Therefore, the understanding of human behavioural characteristics interlaced with the actual technology aspects and organisational context is of paramount importance for the safety & reliability field. This study first approaches this multidisciplinary problem by classifying and reviewing 200 major accident data from insurance companies and regulatory authorities under the Cognitive Reliability and Error Analysis framework. Then, specific attention is dedicated to discuss the implications for improving robustness of system design and tackling the surrounding factors and tendencies that could lead to the manifestation of human errors.

1 INTRODUCTION

1.1 *The need for human reliability analysis*

Despite the evolution of engineering methods and fabrication techniques, recent accidents involving complex industrial systems within high-technology industries such as oil & gas, nuclear and aerospace were acknowledged to be consistently interrelated to human factors which led to tragic consequences (e.g. Rio-Paris Flight 447, Macondo and Fukushima). No one can deny the impact of human actions and decisions on the performance of engineering systems, hence justifying the need for evaluating the interaction between humans and systems through a suitable Human Reliability Analysis (HRA).

HRA is mainly a predictive tool, intended to estimate the probability of human errors and assess the human factors contribution to the overall risk through the use of qualitative and/or quantitative methods. Essentially, traditional HRA tools consist of (i) the identification of potential human erroneous actions, followed by (ii) the consideration of internal and external factors that could influence the human performance, finally resulting in (iii) the estimation of human error probabilities. The key step in this approach is defining possible tasks to be performed by a human operator, considered to be an element or component subjected to failure due to inborn characteristics, thus having an "inbuilt probability of failure". Modifiers known as performance shaping factors, error-forcing conditions, scaling factors or performance influencing factors, depending on the methodology, are then applied to adjust the likelihood of human failure when performing the assessed task.

On the other hand, some contemporary approaches to HRA such as "A Technique for Human Error Analysis"—ATHEANA (Barriere et al. 2000), the Connectionism Assessment of Human Reliability (CAHR) based on Sträter (2000) and the Cognitive Reliability and Error Analysis Method (CREAM) by Hollnagel (1998) were developed around the principle that the fundamental element is, in fact, the context in which the task is performed, reducing previous emphasis on the task characteristics *per se* and on a hypothetical inherent human error probability.

Several HRA methods comprising both "task-centred" and "context-centred" approaches are currently in use. Bell & Holroyd (2009) reported 72 different techniques to estimate human reliability and considered 35 as potentially relevant. Further analysis highlighted 17 of these HRA

*National Agency for Petroleum, Natural Gas and Biofuels (ANP), Brazil.

tools to be of potential use for major hazard directorates. For additional details on some of the existing methods, a summary of five commonly used HRA techniques in the offshore industry and other high-hazard facilities has been presented by Moura (2012), where the main features of the Human Error Assessment and Reduction Technique (HEART), the Technique for Human Error Rate Prediction (THERP), the Standardized Plant Analysis Risk (SPAR-HRA), the Justification of Human Error Data Information (JHEDI) and the Systematic Human Actions Reliability Procedure (SHARP-1) were reviewed.

Regardless of the variety of HRA methods available to enable practitioners to assess the risks associated with human error by estimating its probability, the substantially high uncertainties related to the human behavioural characteristics, interlaced with actual technology aspects and organisational context, turn this kind of evaluation into a very complicated matter, raising reasonable concern about the accuracy and practicality of such probabilities.

1.2 *The data collection problem*

Swain (1990) argues that the most serious problem for HRA is the unavailability of meaningful data (or less-than-adequate data) on human performance that could assist quantitative predictions of human behaviour in complex systems. Posing similar reservations, The International Atomic Energy Agency (1990) report on human error classification and data collection stressed this matter, claiming that a global data collection scheme would be *extremely difficult, if not impossible, to create*, justifying this unenthusiastic view by the amount of data related to each human error that should need to be generated in order to satisfy a wide range of objectives required by applications dependent on human performance databanks.

Indeed, in spite of some recent efforts to gather human performance data and overcome this issue, such as Gibson & Megaw (1999) CORE-DATA, the accessibility and usage of data is still very limited, due to four main reasons. Initially, human performance data collection usually begins within a specific domain, making the classification scheme or taxonomies closely associated with the industry where the issue was first raised. Trying to transpose terms and nomenclatures from one industry to another is challenging, thus human error information are likely to be captured under different frameworks.

Secondly, the insertion of the human performance data in a HRA, which would have to be subsequently combined with an equipment/system reliability analysis to finally reach a meaningful result in the probabilistic safety assessment, is complex and time consuming. Consequently, practitioners tend to use expert elicitation (or a qualitative approach) as a shortcut to include human error data in probabilistic risk/safety assessments, leaving the commitment to collect quantitative data behind.

In addition, the data collection and interpretation process could lead to significantly different results, depending on the data source and the acquisition method (field data, simulator data, HRA modelling, expert elicitation, operation observation, reporting methods, near misses, performance indicators, accident investigation reports etc.).

Lastly, despite the increasing complexity of engineering systems and safeguards reduced the possibility of accidents caused from a single failure, the exact interactions between human behaviour, technology and organisation currently required to produce the specific chain reaction leading to a disaster are very difficult to predict and highly associated with a specific work situation, thus unlikely to be repeatable.

2 CLASSIFICATION METHOD

2.1 *The Cognitive Reliability and Error Analysis Method (CREAM) taxonomy as a common framework to classify accidents*

An innovative use of the CREAM taxonomy was conceived as a common framework to classify accidents from different industries. Other classification methods such as The Human Factors Analysis and Classification System—HFACS (Shappell et al. 2007) and the Error Promoting Conditions (EPCs) from the Human Error Assessment and Reduction Technique (HEART) presented by Williams (1989) revealed good potential to be used as a classification scheme (in fact, it is one of the central functions of HFACS) and were also reviewed. However, the former taxonomy has deep associations with aviation accidents (e.g. crew resource management and personal readiness), and the latter does not differentiate between human, technological and organisation EPCs among the 39 nomenclatures available. In addition, HEART is designed to be used prospectively, i.e. to estimate human error probability, while HFACS main application is in retrospective analysis of accidents in the aviation field. Therefore, the use of both would have implied adjustments to the original taxonomies.

Conversely, the CREAM taxonomy (Figs. 1, 2 and 3) offers a very effective and clear division between human erroneous actions (phenotypes) and their possible causes or contributing factors

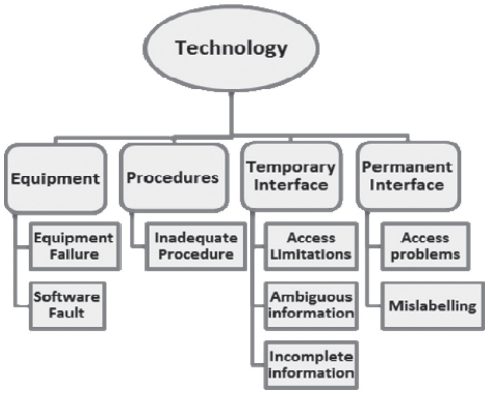

Figure 1. "Technology" taxonomy, adapted from Hollnagel (1998).

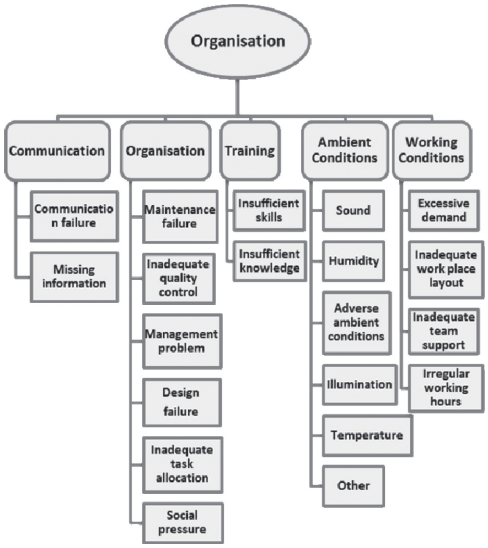

Figure 2. "Organisation" taxonomy, adapted from Hollnagel (1998).

(genotypes), grouped by three expressive categories: man, technology and organisation. Furthermore, the terminologies are generic and easily associated with most industrial sectors.

A noteworthy feature of CREAM's original application as a Human Reliability Analysis approach is the fact that the method was designed for both prospective and retrospective evaluations, whether supporting accident investigations aiming at the search for causes, or predicting events that are likely to occur. This flexibility enables the use of the CREAM HRA method as a data input to the chosen classification scheme, whether

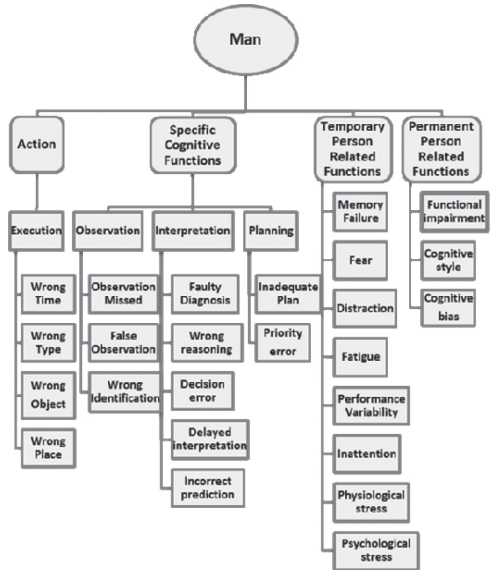

Figure 3. "Man" taxonomy, adapted from Hollnagel (1998).

prospectively, via simulation, or retrospectively, through the execution of accident analysis.

It is worth to notice that this work applies a "retrospective method" for data collection based on CREAM taxonomy, but certainly not following the procedures developed by Hollnagel to perform accident analysis. It means that the CREAM retrospective technique is not used whatsoever, considering that the accidents collected were submitted to extensive investigation and the causes and contributing factors are already exposed in the reports, being the current gap the need for interpretation and classification of the data under a common framework.

3 REVIEW OF 200 MAJOR ACCIDENTS DATA

3.1 *Data collection*

To deal with uncertainties related to data collection and overcome the "less-than-adequate" data problem in this research, factual data from accident investigation reports and case studies were interpreted and then organised to fit the scheme presented in Figures 1, 2 and 3. These accident reports were collected from insurance companies, regulatory bodies, commissions of inquiry, investigation boards and industry experts, such as MARSH Inc., the Australian Department of Industry and Resources (DoIR), the Australian National Petroleum Safety Authority (NOPSA), the Brazilian National

Petroleum Agency (ANP), the European Agency for Safety and Health at Work (EU-OSHA), the National Aeronautics and Space Administration (NASA), the Norwegian Foundation for Scientific and Industrial Research (SINTEF), the Petroleum Safety Authority Norway (PSA), the UK Department of Employment, the UK Health and Safety Executive, the US Bureau of Safety and Environmental Enforcement (BSEE), the US Chemical Safety and Hazard Investigation Board (CSB), the US Department of Energy (DoE), the US Environmental Protection Agency (EPA), the US Fire Administration (USFA), the US Minerals Management Service (MMS), the US National Transportation Safety Board and the US Occupational Safety and Health Agency (OSHA).

These events are listed in Table 1 by industrial activity.

3.2 *Relevance of the data sample*

The UK Control of Major Accident Hazards Regulations (1999) define "major accident" as *an occurrence (including in particular, a major emission, fire or explosion) resulting from uncontrolled developments in the course of the operation of any establishment and leading to serious danger to human health or the environment, immediate or delayed, inside or outside the establishment, and involving one or more dangerous substances. Most of the 200 accidents reviewed fit the United Kingdom's legal definition for major accident.*

Waste treatment plant	03	1.50
Waste water plant	01	0.50
Water supply	01	0.50

Forty four of the studied accidents accounted for 1,075 fatalities.

Of the events analysed, 91 reports included some cost information, thus it was possible to calculate a gross estimate (using cumulative inflation rate to update to 2013 values) of £20.25 billion in material losses. Furthermore, it is acknowledged that costs related to environmental recovery, litigation etc. would dramatically increase these figures. For example, in a Wall Street Journal article about the Macondo Oil Spill, which occurred in the Gulf of Mexico in April 2010, Fowler (2013) reported that BP had already paid around US$ 14 billion in spill clean-up; US$ 10 billion to individuals, businesses and governments; US$ 4 billion in a criminal settlement; and US$ 2 billion in environmental restoration and research. Not to mention the impact on the company's reputation/brand, reflected in the stock market: Bell (2012) reported a 35.00% drop of BP's stock price from 2010 to 2012.

Hence, these numbers highlight the significance of this research's data sample.

3.3 *Data collection and classification demonstration method*

To demonstrate exactly how the interpretation and classification of the data was performed, a heat exchanger rupture followed by an ammonia release, which occurred in a Tyre & Rubber Factory, will be scrutinised on Table 2. This is based on the study case publication from the US Chemical Safety and Hazard Investigation Board (2011).

Basically, on 11 June 2008, a heat exchanger containing ammonia has ruptured due to an overpressure, triggered by a failure during the maintenance process. One worker was killed and seven others were injured during this event.

Therefore, in the above example, the operator failed to perform the maintenance job sequence, skipping the reopening manoeuvre of a closed isolation valve after replacing a rupture disk. The investigation report did not provide further information about any person related function (memory failure, distraction, fatigue, inattention, stress etc.) that could have led to this specific phenotype (erroneous action). In the following day, another operator overlooked the status of the isolation valve (here we have a clear cogni-

Table 2. Tyre & Rubber factory classification example.

Group	Sub-group	Factor	Justification*
Man	Execution	Wrong place	Sequence, jump forward. One operator closed an isolation valve between the heat exchanger shell (ammonia cooling side) and a relief valve, to undertake a maintenance job, specifically a burst rupture disk replacement. However, after replacing the rupture disk, the reopening of the closed isolation valve was skipped, due to unknown reasons. On the following day, another operator closed a block valve to clean the pipe, isolating the ammonia pressure control valve from the heat exchange.
Man	Cognitive function (observation)	Observation missed	Second operator did not observe closed status of isolation valve and closed block valve, isolating the ammonia pressure control valve from the heat exchange. Afterwards, he started to steam the process line to clean the pipeline. The closed isolation and block valves prevented the increasing ammonia pressure from safely venting through either the ammonia pressure control valve or the rupture disk and relief valve.
Technology	Equipment	Software fault	Information delay. During the emergency, a malfunction in the computerized electronic badge-in/badge-out system delayed supervisors from immediately retrieving the list of personnel in their area.
Technology	Procedures	Inadequate procedures	Incomplete text/missing instructions. i) ASME Code requirement to have a competent person, capable of releasing the pressure, continuously monitoring pressure vessels with relief devices blocked or when there is a possibility of pressurisation above design limit, was not reflected in operating procedures. ii) Supervisors were to account for their employees using a master list generated from the computerized electronic badge-in/badge-out system, but there were no further instructions on how to compensate the expected absence of some members of the emergency response team. Therefore, the supervisors were unable to detect if there was a missing worker designed as a member of the emergency response team.
Organisation	Communication	Communication failure	Message not received. Turnover documents and sign-off procedures that should have alerted whether maintenance was completed or not, as well as the current status of the process, were not effective communication channels.
Organisation	Organisation	Maintenance failure	The relief system was not available due to a maintenance failure. Although maintenance workers had replaced the rupture disk, the valve isolating the rupture disk was not reopened thus the relief valve was not available.
Organisation	Organisation	Inadequate quality control	Inadequate quality control procedures. The information that the isolation valve on the safety relief vent remained in the closed position and locked-out was limited to a handwritten note. Although quality control measures (lockout/tag-out procedures to manage the work on the heat exchanger rupture disk were applied), the progress and current state of the maintenance job was not clearly documented. Moreover, there was not a post-maintenance quality check to verify if the service was properly concluded.
Organisation	Organisation	Design failure	Inadequate emergency system design, poor location of instruments and alarms. Alarm system was not fit for purpose due to a design failure. During emergency, operators were supposed to sound a location-specific alarm using pull-boxes located throughout the production unit. However, the water spray from the automatic water deluge system and the ammonia vapour prevented responders from reaching the alarm pull-box in the affected process unit.
Organisation	Organisation	Inadequate task allocation	Inadequate managerial rule (deficient organisation of work due to the lack of safety principles). After the conclusion of the maintenance job (rupture disk replacement), the work order system required the process operator to sign-off upon the completion of service. However, there was no evidence that this occurred (no signal of a signed copy of the work order was found).

(*Continued*)

Table 2. (*Continued*)

Group	Sub-group	Factor	Justification*
Organisation	Organisation	Social pressure	Group thinking. Although operating procedures required maintenance personnel to obtain production operators' signatures in work orders and keep these documents at production control stations, this was not regularly followed. Therefore, the blatant institutional disregard for procedures shows that the risk perception/understanding of the maintenance worker was clearly guided by the working practice among maintenance personnel.
Organisation	Training	Insufficient skills	Performance failure. Supervisors failed to perform workers headcount during emergency measures. Some employees had not been fully trained on partial and plant-wide evacuations procedures. Procedures established that plant-wide evacuation and shelter-in-place drills should be conducted at least four times a year, but such drills had not been conducted in the four years prior to the incident. Drills could have indicated problems with the worker headcount procedure.

*Inferred from evidences and descriptions from the US Chemical Safety and Hazard Investigation Board (2011) Study Case.

tive function failure—observation) and started to clean the process line. After classifying two man-related factors, one action error (wrong place, sequence, jump forward) and another specific cognitive function (observation missed), further two technology genotypes (equipment and procedures, linked to the escalation of the accident) and six organisation genotypes (communication, maintenance, quality control, design, task allocation, social pressure and training) were identified. The genotypes are the identified factors that caused or contributed to the accident or contributed to its escalation.

3.4 *Data classification results*

The examination of the 200 major accidents was similarly performed, and the following tables summarise the outcomes from these interpretations as well as the resulting categorisation.

Tables 3, 4 and 5 specify the number of appearances of the man-related, machine and organisations phenotypes and genotypes in the major accidents examined. Percentages relate to the total of events (200).

At least one human element was identified in 52.50% of the cases, with 50.00% of direct erroneous actions (phenotypes). Cognitive functions accounted for 45.50%, with the interpretation genotype appearing as the most relevant (31.50%). At least one technology genotype was recognised in 85.00% of the accidents, highlighting equipment failure (61.50%) and inadequate procedures (43.00%) as the foremost factors related to this group. Organisational issues appeared in 94.50% of the accidents, emphasising design failures (62.00%), inadequate quality control (57.00%) and inadequate task allocation (55.50%) as the most significant genotypes within the group.

A segregation analysis of the collected data shows that the prospect of a single group (man, machine or organisation) causing an accident is low. Of the examined events, only 1.00% show an erroneous action with a man-related genotype resulting in an accident. Technological factors were solely responsible for the undesirable outcome in

Man-technology-organisation	91	45.50

*Events where a single group or combinations appeared.

only 4.50% of the cases, while 8.00% of the accidents were due to exclusively organisational factors. Conversely, all combinations involving at least two groups featured significantly in the dataset. A Man-Technology arrangement appeared in 45.50% of the cases, while a Man-Organisation combination performed in 51.50%. The Technology-Organisation pair figured together in 80.50% of the events. In 45.50% of the cases, the three groups appeared together. Table 6 summarises these results.

It is important to notice that the design failure is the most significant single genotype from all three groups, appearing with an incidence of 62.00%, closely followed by equipment failure (61.50%).

There is also a close relationship between the design failure genotype and the man group: 69.00% of the erroneous actions (execution errors) were accompanied by a design failure. In addition, 58.62% of temporary and permanent person related functions and 71.43% of cognitive functions were also connected to design failures. Another interesting feature can be extracted from a tendency analysis along the years, considering the design failure genotype and the man group. Figure 4 suggests an increase on the percentage of the man group contribution along the years, while a stable behaviour of the design failure genotype is observed.

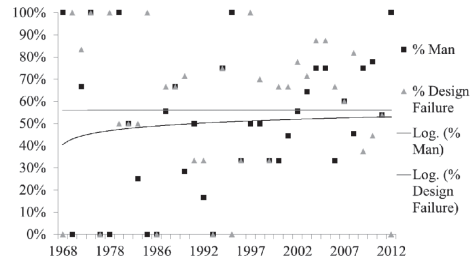

Figure 4. Man and design failure contribution along time.

4 DISCUSSION AND CONCLUSIONS

4.1 *Improving robustness of system design*

Even with the notable evolution of standards and regulations, the amount of design failures contributing to accidents does not appear to be reducing through time. The absence of a well-developed data source related to human performance in complex systems in addition to the diversity of human behavioural characteristics might be preventing reference documents and guidelines from containing unambiguous and direct design rules to deal with human interaction. This may, in turn, lead to this apparent inertia resisting a decrease in design failure. It could be explained by the fact that accidents are rare events, thus it is not an easy task to accumulate sufficient data to ascertain tendencies and improve robustness of system design. Therefore, data collection must be a long-term effort and needs to gather substantial evidence for it to be objectively converted into guidelines to be applied by designers.

This paper indicates that the use of taxonomies from a bi-dimensional approach such as CREAM to classify data is a potential solution to produce meaningful information from three different types of source using the same framework: (i) historical data, as demonstrated in this research, plus: (ii) incident investigations and (ii) prospective analysis, as in the original application of CREAM HRA. The common framework to conduct human reliability predictions as well as retrospective analysis of events during Human Reliability Analysis in a specific facility or industry is perfectly able to interface with the proposed classification scheme for past accidents, considering that they basically share the same taxonomy.

The increasing complexity of systems expanded the number of defences or barriers that needs to be breached in order to result in a major accident, explaining why accidents related to a single CREAM group are uncommon. During this study, the peripheral figures of one exact group

appearance (1.00%, 4.50% and 8.00% for man, technology and organisation, respectively), contrasting with the statistics of at least two groups (45.50% for man-technology, 51.50% for man-organisation and 80.50% for technology-organisation), showed that the presence of two or more CREAM groups is generally necessary to produce an accident. However, this complexity makes it almost impossible for one individual to anticipate all design nuances and connections with human and/or technological factors that could lead to undesirable outcomes. In addition, the relationship between design failures and the man group, explicitly the connection with cognitive functions (71.43% were associated to design failures) and execution errors (69.00% linked to design failures), shows that design failure and damage tolerance criteria must include (and be tested against) specific human related features highlighted by this study. This seems to be especially important with a failure in human interpretation of system status (wrong reasoning and faulty diagnosis), a potential observation missed and some execution errors (sequence, timing and type).

Therefore, the figures above indicate that reliability analyses should anticipate that cues, measurements or information originally intended to lead to a human action have a significant probability of being missed. Similarly, if system design allows situations in which some system analysis/diagnosis, interpretation or hypothesis formulation are required before taking an action, it is likely that specific cognitive functions (inferences, generalisations or deductions) will lead to undesirable outcomes. The design should also be tested against direct human execution errors, primarily focusing on: omissions; jumping forward a required action; performing a premature, delayed or wrong action; and performing a movement in the wrong direction, with inadequate speed or magnitude.

4.2 *Future developments*

The significance of the design failure genotype indicates a well-defined path for future investigation regarding the genesis and perpetuation of human errors.

Further research could also approach other data collection relevant features, due to the significant numbers observed in inadequate quality control (57.00%), equipment failure and maintenance failure (61.50% and 35.00%, respectively), inadequate task allocation (55.50%) and training (52.50%). Quality control guidelines could possibly join a comprehensive design robustness strategy as a failure identification and exclusion tool, while design failure prevention schemes might address both equipment reliability and maintenance efficiency. In addition, effective operational strategies appear to be connected to improved organisation of work by clear rules and principles and individual performance enhancement through workforce skills and knowledge improvements (to handle equipment/perform tasks and increase situation awareness).

Additional effort to expand the data sample is also desirable, whether to confirm or increase the robustness of the results.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support and insights of Christopher Price-Kuehne (MARSH Global Energy Risk Engineering Team), Gary Munley (Office for Nuclear Regulation), Steve Walker (HSE Energy Division—Offshore) and Nicola Stacey (Health and Safety Laboratory) during the development of this work. This study was partially funded by CAPES (Proc. nº 5959/13-6).

Operational and organizational barriers as means of enhancing safety and learning

T.J. Steiro, E. Hansson Blix, J. Seljelid, T.S. Johansen, R.J. Bye & H.N. Hansen
Safetec Nordic AS, Norway

A. Doumit
Saipem Norway AS, Norway

ABSTRACT: The Norwegian Petroleum Safety Authority (PSA) has put a strong demand on barrier management in order to avoid major accidents. Barriers can be seen as technical, operational or organizational aspects which by themselves or together are to prevent a defined sequence of events from occurring, or influence the sequence in a way that damages/losses are mitigated. Safety barriers are thus physical and/or non-physical means. Barrier management is the coordinated activities needed in order to establish and uphold barriers so they are maintained, monitored and functional at all times. In this article we will present findings demonstrating how the barrier management system is working. The focus is on the role of the individuals/operators and the learning aspects involved. Empirical data is based on ongoing barrier projects for drilling rig companies.

1 INTRODUCTION

In the aftermath of the Deepwater Horizon accident in 2010, the Norwegian Petroleum Safety Authority (PSA) and the industry have focused on barriers against major accidents. In their guideline, PSA states that:

The main purpose of barrier management is to establish and maintain barriers so that the risk faced at any given time can be handled by preventing an undesirable incident from occurring or by limiting the consequences given that such an incident has occurred. Barrier management includes the processes, systems, solutions and measures which must be in place to ensure the necessary risk reduction through the implementation and follow-up of barriers (PSA, 2013).

Safetec is currently developing barrier management systems for offshore rig companies operating on the Norwegian Continental Shelf. Promising models and concepts have been developed in close collaboration with rig companies and our aspiration is to have an integrated follow up system that helps the operators to maintain the integrity of their operations. The system will be related to various risk analysis and risk management studies.

2 BARRIER MANAGEMENT

2.1 *Introduction to barrier management*

The first step in implementation of barrier management for a facility as a rig company is to establish the barrier management system. The risk picture for offshore facilities is well defined and the regulations require risk analysis to be performed and updated from early design phases and throughout the lifetime of the operation.

The overall objective of the barrier management system is to protect the facility against the defined risk, either by preventing or limiting each of the specified major accident hazards. The barrier management system will be area specific or system specific, as the risk picture is differentiated throughout the areas of the facility. Major risk hazards such as blowout, gas leaks, fire and explosions, loss of stability and collisions are more or less generic. The handling of risk and the barrier systems may however be facility specific, especially when it comes to the barrier elements, representing the lower level of a barrier system.

There are different possibilities for the representation of barrier functions, but the usual way is to break down the barrier functions into barrier systems, sub-systems/sub-functions and barrier elements. As an example, the below diagram is an illustration of the barrier function "prevent blowout". Xue et al. (2013) points out that offshore drilling is a high-risk and high-cost operation, and blowout is one of the most serious accidents that a drilling rig and its crew might face. The Macondo blowout warns operators that the vigilance to blowouts should never be reduced.

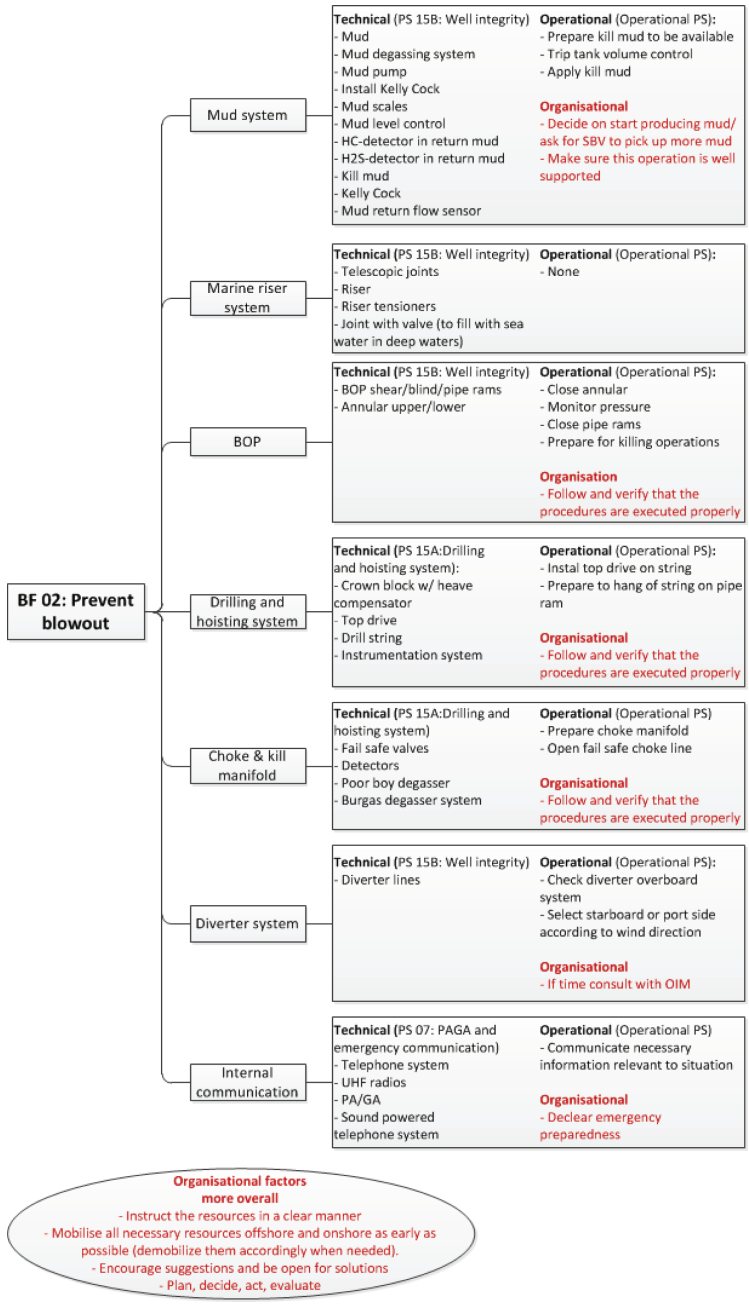

Figure 1. Barrier function with safety critical systems and barrier elements.

2.2 *Barrier management as an integrated part of the safety management*

For the barrier management system to play a role in the safety management of the company; work processes, integration in the operation routines and systematic approaches for following up the barrier status will be required. This will demand knowledge and training for both the onshore and offshore organization. Most companies operating in the oil and gas industry on the Norwegian

Continental Shelf are in the process of establishing and implementing barrier management systems, but we will claim that only a few have reached the final goal of having an integrated barrier management system where the status of the barriers is continuously monitored, maintained and controlled.

2.3 *Barriers—a theoretical foundation*

Sklet (2006 a) claims that the concept of safety barriers is related to the energy model developed by Gibson (1961). Haddon (1980) developed the model further as he provided ten strategies to prevent accidents. Barriers also play an important role in the Management Oversight and Risk Tree (MORT) concept (Johnson, 1980). Rosness et al. (2002) describe energy and barriers as one of the main overall perspectives on safety management. Reason (1997) articulated the barrier perspectives in the famous "Swiss cheese model" and opens up for the more human and organizational side of the barrier perspectives. However, Kjellén (2000) limits barriers to physical countermeasures to stopping or limiting an energy release. Hollnagel (2004) claims on the other hand that barriers are not restricted to the physical nature, but combine types of barriers from protecting against the release of energy to event report and safety policies.

Bolman and Deal (1989) claim there are four main perspectives in understanding organizations. These are the structural perspective, the human relation perspective, the political perspective and the symbolic perspective. The authors further state that the perspectives can be seen as complementary highlighting different aspects of the organization. Barrier management system can so far be seen as part of the structural framework. We will argue that in order to succeed, human relational aspects need to be included such as competence, learning and participation. In 2003, the operators on the Norwegian Continental Shelf were challenged by the PSA to set a target for reducing the frequency of hydrocarbon releases and to identify improvement measures (Sklet, 2006 b).

Several initiatives were conducted both with respect to hydrocarbon releases and barriers in process plants Sklet, Vinnem & Aven (2006) and safety barriers introduced to prevent hydrocarbon releases during wireline operations (Sklet, Steiro & Tjelta, 2005). Duijm (2009) states that the use of safety barriers diagram improves the quality of the risk analysis and the understanding of the role of safety barriers by identifying demand and failure condition for each safety barrier. This forces the analyst to consider the correct sequence, causal relationships in the diagram and further ensure that all safety barriers or safety functions are complete (Duijm, 2009). Rausand (2011) divides safety barrier functions into proactive and reactive functions regarding if they function before or after an undesired event. Hollnagel (2008) argue that barriers are necessary, but may represent a reactive approach which is insufficient by itself to guarantee safety. He further stresses the need for safety to be proactive and looking into the future (Hollnagel, 2008). This calls for more dynamic approaches to barrier management by linking barrier management to organizational learning. Organizational learning is part of the human relation perspective Bolman and Deal (1989).

2.4 *Operational and organizational aspects of barrier management*

The concept of barrier management and the approaches to it has been under constant debates and development both by the industry and by regulatory authorities such as the PSA. The understanding of the technical barriers has been comprehensive and unchanged. The understanding of operational barriers as the tasks to be performed by humans/operators to maintain, monitor and activate the technical barriers is well established while the concept of the organizational barriers is more challenging and difficult to grasp.

Hence, the PSA has reached an understanding of the organizational barriers as the roles that perform the operational barrier elements. This has been described in several presentations given by the PSA since the issuing of the latest version of barrier guideline in January 2013 (PSA, 2013). One example given by PSA (Ersdal, 2014) is the barrier function "detect and rebut" related to the major accident "ship collision".

Other actors have included in the definition of the organizational barriers aspects such as leadership, cooperation and competence. These are aspects that will influence the technical and opera-

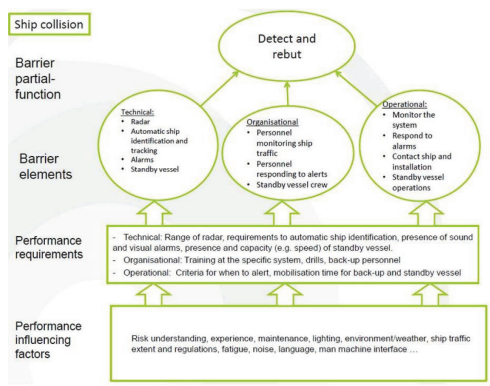

Figure 2 Barrier function for prevention of Ship Collision (Ersdal, 2014).

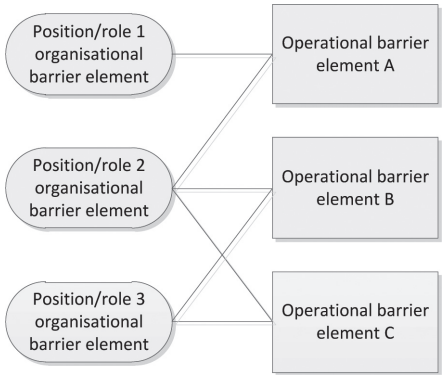

Figure 3. Illustration of some possible relations between position/roles and operational barrier elements.

tional barrier elements. In the PSA interpretation those are seen as performance influencing factors. The conceptualizations of respectively operational and organizational barrier elements as the human actions and the roles that perform the actions have however, some limitation in terms of providing a holistic overview for managing the barrier systems, because it may give an impression of a 1:1 relationship between operational (i.e. actions) and organizational (i.e. personnel/roles) barrier elements.

Operational barrier elements, i.e. *"Planned human actions or interventions that can actively stop an undesired sequence of events, or directly reduce the consequences of an undesired event"*, may consist of several sub-task that are carried out by several different persons in an organization (see Fig. 3). Further, some persons may perform tasks in their daily work that represent sub-tasks of several operational barrier elements.

The implication of this is that some personnel groups may be considered as more critical than others in terms of performing tasks that are necessary to maintain operational barrier elements. A mapping of the relationship between position and tasks related to operational barriers, denoted as *safety critical tasks*, are therefore considered to be important in order to ensure that the personnel in different positions are aware of their responsibility in relation to operational barrier elements, and actually receive the necessary resources (e.g. skills and knowledge, communication, workload/time pressure etc.) to perform their tasks.

3 CONCEPT FOR IDENTIFYING OPERATIONAL AND ORGANIZATIONAL BARRIERS

Safetec has developed a concept for identifying the relationship between operational and organizational barrier elements called "Safety Critical Tasks and Positions". In this section we will give an introduction to the concept and describe the use and result from a specific case.

3.1 *Safety critical tasks and positions—the concept*

The concept is based on examining all types of documentations such as; Quantitative Risk Analysis (QRA), job descriptions, operational duties and responsibilities, operational manuals and governing procedures and reviewing scenarios through workshops etc. In addition operational personnel are interviewed to examine and identify tasks and responsibilities connected to handling of the major accident risk identified for the installation. As a part of the interviews, the status of the performance influencing factors, i.e. skills and knowledge, communication, workload/time pressure etc. are explored as well. The next step is to link the safety critical tasks and personnel associated to them, and rating the position in terms of criticality. The concepts link safety critical tasks to the Major Accident Hazards.

The concept is illustrated in Figure 4.

In this concept we use the following defined Performance Influencing Factors:

1. Skills and knowledge (generic)
2. Site specific knowledge
3. Training
4. Procedures
5. Communication (with other actors relevant for the performance of the task)
6. Degree of redundancy (personnel)
7. Workload/time pressure
8. Supervision (offshore)
9. Onshore support provided for the offshore drilling operations.

Safety critical tasks are defined as:

"Specific action and tasks that must be performed to realize a certain technical or operational barrier function".

Safety critical personnel are defined as:

"Personnel with roles that involve the performance of safety-critical tasks. Safety critical personnel

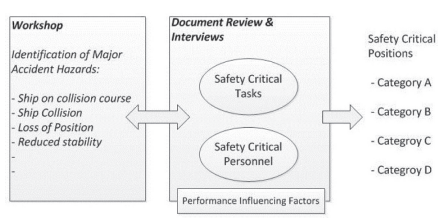

Figure 4. Safety critical tasks and positions.

represent organizational barrier elements which are necessary to realize certain barrier functions. The personnel are classified according to how they are critical for the maintenance of one or more operational barrier elements". Safety critical personnel represent organizational barrier elements.

Based on the definitions of safety critical tasks and safety critical positions, different positions will perform different types of safety critical tasks and thereby representing different influences on the functioning of the operational and/or technical barrier elements. Therefore we have classified four main categories of safety critical personnel (positions with associated safety critical tasks) and categorized roles according to this.

The positions are classified as A, B, C and D.

The classification of safety critical positions is illustrating the relationships between tasks, personnel and an undesired event. By having control of the relation between barrier elements and safety critical positions, barriers can be managed through the focus on safety critical tasks. Based on this, actions can be made to ensure that these positions comply with the necessary requirements for a certain safety critical position. Performance influencing factors are defined as conditions that are of importance for barriers functions and barriers elements ability to function as intended (PSA 2013).

A tool for identifying safety critical tasks and key operating personnel is a mean for both making the organization more conscious on principles regarding barrier management, to create a framework for the offshore drilling company to work continuously on barrier management linked to competence and to be able to better assess the competence. Consequently, it means that competence is better linked to the barrier management system and can function more proactively as stressed by Hollnagel (2008).

Table 1. Category A, B, C and D personnel.

Cat.	Description
A	Positions that imply main responsibility of performance of tasks that represents operational barrier elements, which may *directly* result into an escalation towards one or several hazard if carried out in an incorrect manner.
B	Positions that implies main responsibility of planning, coordinate, advise and control the performance of tasks related to *operational barrier elements* that may directly result into an escalation towards one or several hazards if carried out in an incorrect manner (tasks performed by category A).
C	Positions that implies main responsibility of planning, coordinate, advise and control of tasks related to *maintenance of technical barrier elements* that prevent escalation towards one or several hazards (tasks performed by category D).
D	Positions that imply main responsibility of performance of tasks related to *maintenance of technical barrier elements, and/or performance of other tasks that supports safety critical personnel of category A, B and C.*

3.2 *Case description*

The concept "Safety Critical Tasks and Positions" was applied on a drilling rig operating on the Norwegian continental shelf. The work started out by developing a barrier philosophy for the company and a barrier strategy for each of the drilling rigs. In parallel, the maintenance program for one of the rigs was updated performing criticality analysis. For the technical barriers the main source of testing and verification is covered by the maintenance program and an effort was made to link tests and other maintenance activities to the barrier system. The barrier diagram for "Prevent

	Hydraulic Engineer
	Rig Mechanic
	Technical Assistant
	Welder

Blowout" in Figure 2 is a part of the barrier system for this specific rig. This work was carried out mainly in 2013.

While the technical barriers may be more concrete and tangible, the organizational barriers and the role of the personnel are foreseen as more unclear. To overcome this challenge we aimed to identify a means to link tasks/positions to barrier management using the concept "Safety Critical Task and Positions". After a workshop with the onshore organization, two consultants spent four days onboard the rig interviewing personnel to examine the tasks and responsibilities they were handling. A total of 16 interviews were carried out. The table below presents the results from the study and categories of the positions onboard the rig during normal operation. The picture for an emergency preparedness situation will be different.

The aim is to link the positions onboard the drilling rig to their safety critical tasks and the impact on the hazard situations. Below are some examples.

The DPO (Dynamic Positioning Operator) performs the following tasks; control of the rig (heel/trim), ballast, monitor radar, cargo handling, fire- and gas detection, logging, tension on line (anchor draw work). For the DP- operator, the following major accident hazards are relevant to the failure in performing his tasks as intended:

- Ship on Collision Course
- Ship Collision
- Loss of Position (DP)
- Reduced Buoyancy/Stability

The failure of the DPO in performing his safety critical tasks, for instance dynamic positioning and stability calculation as needed, can lead to reduced buoyancy and stability or total loss of stability. If the DPO does not perform the required navigational tasks or communicate with vessels on collision course and relevant personnel onboard the rig, this may cause a ship collision. Mishandling of the DP-system may cause the rig to lose position on DP, and this may escalate to other hazards (kick or blow out caused by the rig moving out of position and the riser may be damaged or well is not shut in when the rig is starting to move out of position). Consequently, the DPO is defined to be in category A.

The Offshore Installation Manager (OIM) plays an important role of any offshore installation. In this setting the OIM is only categorized as B during normal operations; main responsibility of planning, coordinate, advise and control the performance of tasks related to operational barrier elements that may directly result into an escalation towards one or several hazards. In an emergency and preparedness situation the role of the OIM is different. The OIM also plays an important role in fostering a safe culture that is a reporting, just, flexible and learning culture (Reason, 1997). Kjellén (2000) points to the importance of top management commitment to safety.

4 DISCUSSION

4.1 *Humans as organizational barrier elements*

In this paper we have given an introduction to barrier management and different approaches to the organizational aspects. The presented concept "Safety Critical Tasks and Positions" has illustrated how operational positions can be classified as safety critical in relation to major accident hazards. It can be argued that defining operational personnel as organizational barriers may enhance the respect and understanding of importance of their roles, and hence their competence. On the other hand, it should be emphasised that this should not as a consequence put all responsibility for preventing accidents on the sharp end of the organization, the overall responsibilities lies within the management offshore and onshore.

We see that the approach presented in this paper is in line with the approach from PSA when it comes to defining organizational barrier elements as the roles or personnel onboard. We will however claim that our concept of safety critical functions has one major advantage when it comes to implementation of barrier management. The actual relationship between positions/roles (organizational barrier elements) and operational barrier elements has to be represented and understood in order to conduct a more holistic barrier management. Identifying safety critical tasks and positions and the relationship to operational and technical barrier elements makes it possible to:

- Control and monitor whether the positions in the organizations are able to handle their entire task portfolio related to operational barriers
- Identifying the degree of redundancy of personnel necessary to perform safety critical tasks
- Identify and monitor resources and conditions necessary for performing the tasks in a correct manner (e.g. skills and knowledge, communication, workload/ time pressure etc.)

PSA (2013) guideline as shown in Figure 5 illustrates the integration of the barrier management with the safety management. It can be argued that if the barrier management system is defined with all barriers being in the "sharp end", it is not sufficient to monitor and control the barriers to control major accident risk. Major accident risk will also be highly related to safety critical decisions, planning and communication, not only in the offshore

Figure 5. Integration of the barrier management with safety management (PSA, 2013).

organization and in the "sharp end" but in the entire organization. The illustration in Figure 5 may be misleading as it may indicate that risk is under control by barrier management alone.

Defining and describing a barrier management system is not sufficient for having a positive safety effect. The system needs to be implemented as part of the risk management system. The concept presented in this paper can be described as participatory and the advantage of a participatory approach is that the personnel themselves has defined and constructed the system. This ensures verification against real life and ownership and understanding. Employee participation and involvement in safety barrier analysis can serve as a vehicle for the development and maintenance of safety barriers (Kongsvik et al. 2014).

The way we have classified personnel may give surprising results, but will contribute to empowerment of the operational personnel.

4.2 *The learning perspective*

By mapping and representing the relationship between operational and organizational barrier elements by the concept "Safety Critical Tasks and Positions" one may identify organizational vulnerability or even organizational dysfunctional aspects, related to the organization of the personnel, tasks and manning (e.g. responsibilities, task portfolios, work load, lack of redundancy of personnel etc.). This information may be used to improve the organizational design in order to improve the barrier functions.

Further, the status of the performance influencing factors may be continuously followed up through assessments or when major organizational changes are implemented. This demonstrates that barrier management is not only a separate tool but also an important factor integrated to the management of the organization.

We believe that the following elements are central in barrier management as fundament for learning. That is competence, communication and workload, physical working environment and leadership.

4.2.1 *Competence*

It can be argued that competence (knowledge, skills, experience and attitudes) play a crucial role in upholding the barriers both in maintaining the system and to execute the tasks in a safe manner. The procedures and documentations are the structures that support and enable the operators to perform the tasks in accordance with best practice.

4.2.2 *Communication*

The quality of communication, i.e. asking and feeling comfortable with asking for a Safe Job Analysis to be performed, play an immediate effect on the performance of the operations. Open and clear communication is always important in high risk organizations. Open and direct communication has been identified as a key factor within High Reliability Organization thinking (Weick & Sutcliffe, 2007). Providing a language and a vocabulary for barriers are important in order for personnel to be aware and work proactively with barriers.

4.2.3 *Workload, physical working environment and leadership*

Reporting on the working environment should lead to improvements in the organization and therefore aligned to the work of barriers. It could in turn lead to management of change. The function of management of change is to contribute to the management of all technical, operational and organizational changes in order to avoid major accidents. Leadership is seen as more indirect, but playing a significant role in order to create and establish commitment to the barrier management philosophy and strategy. It covers both the onshore and offshore execution of leadership. It is also about establishing and environment to act safe and put safety before production (Reason, 1997). The rig focuses on the operational side and more on day-to-day activities. The onshore organization is more on to the long-term planning and monitoring of activities. Workload and the physical environment will typically play an important, but more indirect role, on the performances. Perceived not so good work environment has a negative impact on

performances. However, a perceived positive working environment do not necessary lead to higher performance. Psychosocial questionnaire should therefore be indicators for performances.

4.2.4 *Learning perspective from an offshore management viewpoint*

The implementation part is where the concept of barrier management succeeds or fails. The study presented in this paper identified the key safety critical positions, the challenge for the onshore management is for these positions to be made aware of what exactly is required of them in a barrier management terms and through the management system of the company.

In general, where there is found reluctance offshore to embrace new soft safety skills, it can be stated that this is often due to the concept and practical applications not being fully explained to, and hence understood, by the personnel in these positions. Hopefully this approach will make them see their clear contribution both directly and indirectly. In addition we see the interplay and interaction between different personnel better illustrated with this concept.

If, we can convince these key safety critical positions and call them 'barrier keepers', of the need for, and a good understanding of a more modern approach to operational barriers i.e. placing less reliance on the use Observation/ STOP Card type systems and greater emphasis on the maintenance of barriers, then this will be carried over to other crew members.

We believe that this concept can contribute to more learning to assess what the organization has learned and also identify gaps. It is also an opportunity to assess if there is need for adjustment and critical look into existing practice and executing double loop learning (Argyris & Schön, 1978). This should be done regularly and if changes are introduced. Other studies such as psychosocial evaluations covering important topics as demand, resources, expectations, stress, management and bullying will give valuable input and make the system dynamic.

5 CONCLUDING REMARKS

As we have discussed in this paper, establishing a barrier management system does not in itself improve the safety level. It may however be an excellent "tool" for understanding and controlling risks. How the concept is defined, for instance how and what we define as organizational barrier elements, is of less importance giving that the barrier systems is constructed for the specific risk of the asset. This requires a good understanding of risk and the frame conditions influencing it. In this paper we have emphasized the importance of identifying and representing the relationship between operational personnel and barrier elements. Including operational personnel in the development of the barrier system, as we have described in this paper, is important for a successful implementation of barrier management.

The concept "safety critical tasks and positions" needs further development and need to be strengthened by more input for the work to be properly aligned. The work on barrier management provide valuable input and in particular to the assessment of the different safety critical tasks.

We believe that the work presented in this paper will meet the PSA (2013) expectations in terms of barrier management. However, this is development work and improvements need to be done. Several rigs will be employed on the Norwegian Continental Shelf and it is believed that the next industry battle will be a "battle for competence", therefore focusing on barrier management is not only a tool to control risk but might also be a tool to demonstrate the importance of different categories and for people to see that *"I have an important role in this organization and I too contribute with regards to barrier management"*. This could help personnel to see their role and responsibilities in the organization and create a more holistic meaning for them and thereby also include more symbolic aspects of the barrier management to further elaborate on Bolman and Deal's (1989) taxonomy. In this article we have looked into structural and human resource (learning, participation) aspects and touched upon symbolic aspect (seeing your positions as part of a holistic system. However, following the thinking of Bolman and Deal (1989) further work and development should also address the issue of power. Kongsvik et al. (2014) has given some suggestions focusing on participation.

ACKNOWLEDGEMENT

We would like to express our sincere gratitude to all people in the rig company. We would also like to thank Synne-Emilie Bergersen & Lars-Erik Alstad Aas and two anonymous reviewers for providing us valuable and constructive comments on an earlier version of this paper.

Presumptions of culture: Applications and safety implications

F. Størseth
Safety Research, SINTEF Technology and Society, Norway

ABSTRACT: Contemporary safety thinking is saturated with cultural ideas. Culture is presumed important—for safety. Culture has become part of the convention, the normal scientific approach to understand and improve safety. It is part of the standard toolbox in terms of explanatory and interpretive repertoire. But, what is the nature of the culture conceptions? How is culture "applied" in terms of interpretations and explanations? Pursuing such questions, this paper identifies conceptions of culture by conferring source material pertaining to the Norwegian petroleum industry (official documents and an incident investigation reports). The analysis was performed by establishing a set of analytical dimensions or thematic axes: *The What, The How, The Where, and The Who* of safety culture. The results of these analyses are discussed. The core thesis of this paper is that the premises, presumptions, and implications of a given concept need active consideration. And, in a mode of efficient application, there is a danger of merely pointing towards "culture", and omitting the necessary "detour" of specifying suppositions and implications involved in the given cultural concept. This underscores the need to actively "apply" theory (Størseth and Grøtan, 2011). By addressing issues of theoretical underpinnings and presumptions concerning association, function and causality—a needed, additional layer of analysis and learning as application (Baumard, 1999; Størseth and Tinmannsvik, 2013) is forced into consideration, bringing awareness to the "directions" that silently influence interpretive and explanatory efforts to understand and improve safety.

1 INTRODUCTION

The text should fit exactly into the type area of 187 × Culture is part of the explanatory and interpretive repertoire. Culture is presumed important—for safety. But, what is the nature of the culture conceptions? How is culture "applied" in terms of interpretations and explanations? What are the implications of the chosen path? Inspired by such questions, this paper aims to identify theoretical underpinnings and conceptual building blocks of culture as it is described, defined and applied within the context of Norwegian Petroleum industry. This aim was specified by formulating a set of analytical dimensions or thematic axes. These are loosely formed themes and elements with the intention of creating an analytical platform, a defined approach for searching for ideas related to culture. The principal idea that is pursued here is the value of creating an angle, a reference point for thinking and analysis. The formulated analytical dimensions were:

Concept features: What are the presumed key features, dimensions and elements? This involves searching for definitions, operationalizations, characterizations, theories and philosophies. In short: What?

Concept model supposition: How is the concept interpreted, construed and explained? This involves looking for explanatory dynamics. How are core issues related to the concept explained? What are the advocated associations? In short: How?

Concept placement: Where is the concept (e.g. 'safety culture') placed? This involves looking for where—in given systems/organizations dimensions and dynamics of culture are thought located. In short: Where?

Concept actors defined: Who are defined and identified as concept actors and agents? This involves who is argued as the 'cultural creators' and/or 'cultural bearers'; i.e. who are pinpointed and argued as being responsible for acting out given cultural features. In short: Who?

2 METHOD

According to Bem and deJong, researchers and scientists must move beyond inspection, enumeration and description of the observed (Bem and deJong, 1997). The author concurs and derives from this that the scientific effort must involve elements of construction, in the sense of using our imagination, or pre-understandings, or theories with the intention of moving beyond the observable. The following reports how these efforts were pursued methodologically.

2.1 *Reflection as method*

The defined aim of the study was to explore and identify 'premises of culture'. The founding idea was to explore the workings of culture concepts and conceptions; how they develop, take form, move and have implications. To approach these issues, a set of documents were selected as analytical basis:

- An official Petroleum Safety Authority (PSA) investigation report (PSA, 2012)
- A PSA booklet on HSE and culture (PSA, 2002)
- A PSA article on principles of barrier management (PSA, 2013)

In a classical scientific sense, these documents served as the source material, the *empirical data*. However, my analytical approach, i.e. the way I made use of these data sources can be said to involve a blurring of the lines between data (observations) and going beyond the observables (theory). This is an old challenge for philosophers of science (Bem and de Jong, 1997). A variation of this "dilemma" has been addressed specifically by advocating the premise that "theory *is* method" (see Størseth and Grøtan, 2011).

My methodological approach can be denoted as *reflexive*. Specifically this involved a continuous oscillation between (document) analysis and collaborative reflection and discussion of findings with my research colleagues. To elaborate on this: We were four researchers involved in the research task that this study is part of; four different researchers each representing different scientific traditions and "denominations". My deliberate choice was to make use of this variety. Thus, I decided to approach the work in the following manner:

1. Individual analysis of selected material. A report/article/investigation report was selected for individual analysis. These individual analyses served as input/context for a reflection meeting reserved for discussing the findings.
2. Reflection meetings to test and develop hypotheses, conjectures and findings from my individual analyses. Through these reflection sessions, my working models, assumptions, as well as findings were tried, refuted, and—and developed. In turn, serving as the next step forward in terms of analytical efforts.
3. Application of the reflection meeting discoveries in subsequent individual document analysis. Here, my analytical effort shows its (hermeneutical) circular shape.

In this way, I deliberately opened up for a research approach that placed me (the researcher) as part of the process. This is close to what Alvesson and Sköldberg (2009) denote the principle of abduction.

2.2 *The principle of abduction*

Abduction denotes a process that blurs the lines between induction and deduction. Like induction, the abductive process begins with an empirical basis. But importantly, theoretical preconceptions are never rejected. They are accepted, and allowed to influence and "color" the analysis. In this sense, abduction is closer to deduction.

Analyzing empirical "facts" may here be both combined with, and preceded by various sets of theory and conjecture. This suggests an approach where theory may serve as an inspiration for how to observe, as well as vice versa; i.e. that the "facts" (the observables) may represent sources of inspiration for theory. *"Facts" "serve to occasion the theory, while continually plying the role of critical tuning instrument and fount of new ideas for the theory"* (Alvesson and Sköldberg, 2009, page 4). As noted by Alvesson and Sköldberg, the acknowledgement and application of pre-understanding is a similarity to hermeneutical method (e.g. Eco, 1990).

The principle of abduction illuminates the reflection process throughout my study. In other words, it shows how I (the researcher) applied and made use of the "facts" (documents). It also emphasizes the intentional alternation between data analysis, application of theory, and reflection processes that tested and developed conjectures along the line of the study.

My methodological approach is more about reflection than procedure. But, as shown above, the analytical process has been systematically pursued—by an intentionally designed work process, continually alternating between individual analysis, collaborative reflection and development of our results and conjectures.

3 RESULTS

3.1 *PSAs HSE culture booklet*

PSA defines culture as: "the knowledge, values, norms, ideas and attitudes which characterize a group of people" (PSA, 2002, page 5–6). This definition lists cultural components or dimensions and can thus be seen as the formal framing of 'The What'. According to PSA, culture is about technology, economics, law and regulation. This also resonates with 'The What'. It may be read to suggest the various spheres that (HSE) culture may be part of; or it may suggest various contexts of which it (HSE culture) is associated with. In any case, the context(s) that are suggested are vast and indefinite.

Norwegian regulations (from 2002) demands that companies possess what is described as a "sound HSE culture". However, as emphasized by PSA, these regulations offer no clear definition of culture. Consequently, PSA's intention (via the HSE culture booklet) is to provide approaches to understand culture, so that to enable "such a culture to be created" (PSA, 2002, page 3–4).

This aim is interesting in that it explicitly states that culture can be designed and shaped. In a very generic sense then, this relates to 'The How'; the HSE culture concept is possible by effort. It is presumed formable and shapeable. Furthermore, emphasis is put on the necessary connection between words and actions, a clear message underscoring the notion that culture is more than a dormant set of values. Culture is reflected in action, in what is done, and how. A similar point is made by underscoring that culture is more than some compound of knowledge, values and attitudes (PSA, 2002).

PSA states that a sound HSE culture is a reporting, just, flexible, and learning culture. For our purposes, the focus on learning is of particular interest, as it carries suggestions for both 'The Where' (i.e. concept placement in the form of where culture thought to be placed or positioned), as well as 'The Who' (i.e. the designated ambassadors of culture). PSA draw attention to issues regarding learning and conflicting objectives. They list a specific set of checkpoints in these regards, see Table 1.

The checkpoints (above) contain *a sense of direction*, a direction which also conveys information about 'The Where' and 'The Who'. There is a sense of u*ni-directionality* at play here, from somewhere (management?) to the operational. Do they (operational) have the sufficient criteria to realize or "live by" the culture? It is here to be argued that the checkpoint has a certain "flavor" of uni-direction that subtly suggests (1) where culture is "designed", and (2) who are thought to be the designated ambassadors of such culture. Although this conveys presumptions concerning a possible cultural design process, PSA put emphasis to the fact that cultural change is related to a range of factors. In fact, they present a model that encompasses a wide context for culture and cultural change.

PSA emphasize that *"Many factors can cause cultural change in an enterprise, as in the wider community. Some of these factors are listed in the cultural model (…). They represent the frame conditions for petroleum activities and offshore work. At the same time, we influence these frame conditions through our knowledge, values and norms"* (PSA, 2002, page 23–24). A rendition of the model as referred to in the quote is presented in Figure 1.

The figure illustrates forces of mutual interplay and influence. Discussing the cultural model, PSA point towards several challenges that needs careful consideration:

- Cultural variation and culture in plural form: sub-cultures, counter-cultures etc.
- The potential individual influence
- Power
- The danger of superficial culture diagnosis (no quick fix, neither with disciplining or bureaucratization/procedures)

PSA states clearly that there are no short-cuts. Building culture is demanding. But, who are the builders? Who are the creators of culture? Although the cultural model (Fig. 1) establishes reciprocity, there is a tone here that seems to further suggest that norms and values are to be adequately

Table 1. PSA checkpoints regarding conflicting objectives.

1	Are conflicting objectives discussed in a specific and constructive manner?
2	Have clear, realistic and accepted criteria been established for the way operational personnel should deal with normal conflicts between objectives?
3	Are procedures and job descriptions adjusted to ensure a balance between safety and efficient performance of the work?
4	Who decides the procedures? Do operational personnel participate in maintaining procedures and job descriptions?
5	Who decides the procedures? Do operational personnel participate in maintaining procedures and job descriptions?

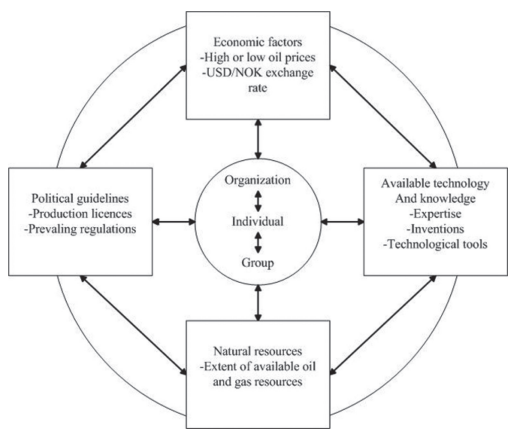

Figure 1. PSAs cultural model (PSA HSE culture thematic brochure, 2002, page 24).

established, and then released into the system for correct adherence and administration. Personnel must be trained, instructed or "prepared". The implication of the latter is that it is the personnel that are the designated "bearers" of culture—the actors defined as to adhere to the given culture.

This impression is strengthened considering the final section in the thematic brochure. The section is entitled "Section 6 Management and culture". Starting with a reference to an official publication on Norwegian framework regulations (Section 11; Report 7 2001–2002 to the Storting, specifying that what is given attention and priority by management becomes culture). It is stated that: *"The management plays a key role as the provider of the company's values and visions in the HSE area"* (PSA, 2002, page 31–32). The section holds several tips for how the manager/management, closing with the following: *"Managers who can take the pulse of their own organization and who pick up small but important nuances in the working climate have everything it takes to be a good culture-builder"* (ibid).

3.2 *PSAs principles for barrier management*

Barrier management refers to a systematic, ongoing effort to ensure that safety barriers are relevant, effective and robust. The main purpose is to establish risk handling barriers, aiming to prevent undesirable events or limiting their consequences, should they occur. Barrier management denotes the processes, systems, solutions and measures that are needed in order to ensure necessary risk reduction (PSA, 2013). These definitions provide insight into how barriers are managed (PSA, 2013, page 3):

Barrier: Technical, operational and organizational elements which are intended individually or collectively to reduce possibility for a specific error, hazard or accident to occur, or which limit its harm/disadvantages.

Barrier element: Technical, operational or organizational measures or solutions which play a part in realizing a barrier function. *Barrier function:* The task or role of a barrier. Examples include preventing leaks or ignition, reducing fire loads, ensuring acceptable evacuation and preventing hearing damage.

Performance influencing factors: Conditions which are significant for the ability of barrier functions and elements to perform as intended.

The following passage illustrates how these concepts are related: *"Personnel, equipment and systems are referred to or described not as barriers, but as barrier elements. Performance requirements must be set for the technical, operational or organisation elements required for the individual barrier to be effective (in other words, to realise its barrier function)" (PSA, 2013, page 5).*

Where do conceptions of culture fit into this? Although culture is referred to repeatedly, the purpose is not to include it into the barrier management as such. 'The Where' is defined as outside of the barrier management control scope; but—culture is still appointed as an important potential contributor. This suggests influence without further specification.

Is 'The How' left open? This is a question for the discussion section.

Attention is now turned to the Heimdal incident, as an example of where culture conceptions are put into application.

3.3 *The Heimdal incident*

The incident. On the 25th of May 2012 a hydro carbon leak occurred on the Heimdal installation (Statoil) during a testing of two emergency shutdown valves. The testing of the emergency valves was prepared by pressure releasing a pipeline towards the torch. In this pipeline, a ball valve is the final barrier against the torch. This valve was exposed to a pressure far beyond design, and it failed. A gas leak was a fact. The leak was estimated as 3500 kg with a leak rate on 16, 9 kg/s. Gas was detected in a wide area of the installation. PSA concludes that the event led to a very serious situation and that a major accident could have been the result with marginally changed circumstances (PSA, 2012).

Investigation report. PSA identified the immediate cause as a ball valve (final barrier towards torch) that was exposed to a pressure that far exceeded its design pressure. The valve failed.

Underlying causes. PSA identify weakened performance shaping factors are the most important underlying causes contributing to the incident (PSA, 2012, page 20). The most important incident causes were identified as inadequate design combined with inadequate risk assessments and procedures for valve opening/shutting (ibid, page 21). PSA build explanatory momentum in their investigation report by emphasizing connections between deficient leadership involvement and lack of experience transfer and learning:

Deficient leadership involvement. PSA argue for a discrepancy between the company's defined 'A-standard[1]' and the way that the work was performed. PSA also draws attention to the fact that in addition to the A-standard, the Statoil-book

[1]A "common performance pattern" defined by the company; meant to identify risk related to the activity and demands connected with the activity (formal demands, work method).

emphasizes the importance of compliance and leadership. This explicitly denotes leader responsibility as communicator, role model, instructor and guide/advisor in an A-standard. Also, continuous risk assessment en route in the work operations is to be performed. PSA states that they cannot see the leaders in the Heimdal organization, neither on—or offshore has functioned as role model, trainer or advisor for an execution of the A-standard performance pattern with accompanying risk assessments.

PSA point towards a range of factors that the associate with inadequate risk assessments concerning the task at hand:

- Lack of leadership involvement
- Lack of personnel involvement in planning the work
- Deficient communication to personnel (that were to execute the operation)
- Inadequate labeling of valves
- Unclear specification of how to perform the task in hard to read procedures

Lack of experience transfer and learning. PSA identifies a lack of using previous incidents for learning. Information from previous incidents are not processed, communicated and applied for learning purposes in the Heimdal organization. PSA provide several reasons for this. For instance, by reviewing the company's own incident reports, they find that several of the incidents has its background in a combination of technical failure, weak design and the operation of the installation/facility. It is also pointed out in several of these reports that there previously has been repeating similar incidents.

Still, this has according to PSA not lead to any measures to prevent repetition. PSA draws attention to PSAs yearly report "Risk level on the Norwegian shelf" (RNNP) which contains a major risk indicator for hydro carbon leaks. PSAs point is that it is the companies themselves that provide data from their own incidents here. In other words, the incidents should be known to Statoil and the parts of the organization they are relevant for. PSA also refer to a study concerning hydro carbon leakage causes on the Norwegian shelf that was performed by the RNNP in 2010. The study identified a range of hydro carbon leaks on due to human intervention in technical solutions with unfortunate design. The study identified a need to redesign these solutions to reduce risk. The study has been sent and communicated to Statoil. Still, there is according to PSA no trace of this knowledge been applied.

PSA identifies weaknesses in terms of necessary competence and risk understanding. PSA states that Statoil has not ensured that personnel (both land—and offshore) had the necessary competence and risk understanding for handling the work in a safe manner. PSA argues that the incident showed a deficiency on a wide range of levels (barrier elements and performance influencing factors. The culture reference is indirect here; via the emphasis on performance influencing factors.

But what discriminates the one from the other? Where is the line to be drawn, between performance influencing background factor and barrier element? With this we re-visit the challenges of barrier management. That is, the challenges concerning categories and classifications. Is culture by definition outside of the control scope? Or, is it "allowed" to appear and potentially affect barrier elements?

4 DISCUSSION

4.1 *The HSE culture booklet*

The operationalization and contextualization of the concept is theoretically thorough and has what can be denoted as "scholarly appeal" in terms of both depth and width. Further thoroughness is added considering how PSA acknowledges the complexity and challenges related to how the petroleum industry is organized (operators vs. contractors, sub-contracting). Still, the complexity and broad scope that is established serves as a strong reminder: How is this to be controlled? Shaped? Regulated?

Design by management? Is culture a management project? Is culture design a designated task for management? The culture booklet conjures up a kind of one-sided force of influence. In the checkpoints, both criteria and procedures are emphasized as important, to provide the operationals' with tools and judgment aids for safe and efficient operation. Although there is nothing inherently wrong with this, there is a unidirectional "flavor" to this that is strengthened by the fact that no emphasis is put on any complementing criteria or procedures in more distant corners (further away from operation).

Although not stated, it could be speculated that "operational" applies all over the system. However, as this is not stated explicitly, attention is somewhat drawn towards operational in the closer proximities to hazard. It must be noted however, that this unidirectional hint is moderated when PSA discuss factors that may affect HSE culture (page 23–30). But still, the management orchestration responsibilities are emphasized. Of course, pointing towards management responsibility can be said to be nothing but natural. But, given the potential role of such a document, there may be a risk of consolidating a view that establishes management as 'The Who' in terms of cultural shaping or design.

If so, an unfortunate effect could be that the mutual dynamics and reciprocity of cultural building is lost. In other words, that mutual responsibilities and possibilities of cultural development and performance are pushed out of scope.

4.2 *Barriers and the cultural backdrop*

Although the importance of culture is emphasized, the argumentation is that culture is outside of the barrier management scope. This is not to say that it is unimportant. Rather, culture is referred to as one of several more or less abstract background "conditions". Culture is placed within the category "performance influencing factors" group. These are factors held as potentially important. But, they are argued as not within range of being established as barrier elements accompanied by performance requirements. On page 26, PSA explicitly presents a reason for not bringing culture in as a barrier element: *"One of the stipulations for a barrier element is that performance requirements must be set for it, and that this performance must be verifiable. Investigations and surveys can be conducted into the culture in an enterprise, for example,* ***but it will be difficult to establish verifiable performance requirements for that culture****. So culture cannot be regarded as a barrier element" (emphasis added).*

Is culture omitted because it is impossible to control (performance requirements)? Or is it because culture, by default represents "something" too far from barrier realizing actions and decisions? No answer will be provided here. Still, it is interesting to note the distinction between what is presumed in the culture booklet in terms of a shapeable culture, and what is noted regarding barrier management: that culture is beyond the control scope.

It is here to be argued that by defining culture as outside the range of barrier element control; 'The How' of cultural influence may be at risk of being downplayed, if not ignored.

It is hard to disagree with a model that places culture in "the background"; as part of the context—something "back there". At the same time, features of culture may exert its influence in specific ways, in specific situations. Effects or (unwanted) side effects of a culture may indeed exert its specific influence. By categorically placing culture as "outside" there is a danger of letting cultural aspects pass unattended. Cultural aspects that potentially would be of critical importance in terms of realizing a barrier function.

Hopkins' (2012) analysis of the Macondo blowout is a strong example here (see National Commission report, 2011a, 2011b). Hopkins put emphasis to the fact that dynamics of e.g. consensus-mode, normalization of warnings (Vaughan, 2005), and groupthink were part of how signals were "effectively" ignored in the run-up to the blowout.

4.3 *The Heimdal incident*

Culture is not referred to by name here; that is, the concept is not explicitly referred to. Still, ideas permeated with culture are part of PSAs interpretation and suggested explanation. Culture dynamics are *applied* to build the thesis of the investigation.

PSA emphasize weakened performance influencing factors as the most important underlying causes. PSA defines performance influencing factors as "Conditions which are significant for the ability of barrier functions and elements to perform as intended" (PSA, 2012, page 3). As noted above (section on principles for barrier management), performance influencing factors are classified as outside of any specific barrier element.

Although the causes are defined as underlying, it is here to be suggested that they may quickly become linked to the three barrier elements. This is by "methodological default", as it is the barrier elements that are defined as within the control scope. In fact, the investigation can be said to implicitly build its case by showing how background cultural aspects (performance influencing factors) do exert active influence *within* the triad of barrier elements. If so, this stands in opposition to what PSA states regarding barrier management.

This underscores the challenges concerning "the cultural influence". If nothing else, it shows the importance of staying wary of the premises that concepts, methods and approaches are rested upon.

4.4 *Conclusions*

Before concluding, it must be emphasized that this study is no PSA witch-hunt. The heavy focus on PSA documents is however justified in light of their importance within the Norwegian context. PSAs role in the Norwegian petroleum industry is very active, not only in terms of their control mandate, but also in terms of setting the safety agenda. This is reflected in their communication and collaboration with various research organizations in Norway, but also with their focus on dialogue and communication with the industry.

The starting point for this study was to examine concepts and conceptions of culture in the Norwegian petroleum industry context. By analyzing a selected set of texts and documents, the study has put the foundational premises and assumptions to the fore front.

By focusing on presumptions and applications of the culture concept, the analysis has identified theoretical principles and ideas of association that

rests somewhat hidden within the culture concept; but that potentially influence interpretation and explanation.

Specifically, the study has identified:

- How theoretical premises contain ideas of unidirectional influence in terms of 'The What', 'The How', 'The Where', and 'The Who' of how culture is being designed and constructed.
- How culture in one sense is being defined by default as being outside the control scope; but that in terms of interpretation and explanation of an incident reveals ideas of how culture stretches into, and affects the barrier functions "up front". This demonstrates the challenges of applying static categories and classes that are kept controllable for methodological purposes.

The focus in this study was "locked on" the culture concept. However, the main message here is of concern for safety work and management in a generic sense.

The generic conclusion that should be derived from this is that theoretical and conceptual "building blocks" deserve constant attention as they exert influence in terms of interpretation and explanation of safety.

The Norwegian petroleum industry is efficient and professional, with highly skilled professionals involved: safety authorities, the industry themselves, researchers and consultants. But, it is precisely this efficient and professional work mode that creates a danger in that various concepts (like "culture") are eagerly taken aboard and efficiently installed as part of the prevailing, often tacit world views.

In this mode of efficient application, there is a danger of merely pointing towards "culture", and omitting the necessary "detour" of specifying suppositions and implications involved in the given concept (in this case: cultural concept). This underscores the need for a more active application of theory (Størseth and Grøtan, 2011). By addressing issues of theoretical underpinnings and presumptions concerning association, function and causality, a needed, additional layer of analysis and learning as application (Baumard, 1999; Størseth and Tinmannsvik, 2013) is forced into consideration, bringing awareness to the "directions" that silently influence interpretive and explanatory efforts to understand and improve safety.

ACKNOWLEDGEMENTS

This work has been carried out as part of the project entitled Translating HSE culture within the petroleum industry ('TRACULT'), led by Studio Apertura at NTNU Samfunnsforskning AS and funded by The Research Council of Norway. The paper represents the opinions of the author and does not necessarily reflect the opinions or policies of the above mentioned organizations.

Coding scheme to measure the operator's workload in advanced Main Control Room

S. Kim, Y. Kim & W. Jung
Korea Atomic Energy Research Institute, Daejeon, R.O. Korea

ABSTRACT: In an advanced main control room, the system operation is possible since the power plant facilities are controlled using the soft control embodied into the computerized procedures and distributed computers completely equipped with digital functions. Accordingly, though the task of the operators has been changed a great deal, due to a lack of appropriate guidelines on the role allocation or communication method of the operators, operators should follow the operating strategies of conventional MCR and the problem of an unbalanced workload for each operator can be raised. Thus, it is necessary to enhance the operation capability and improve the plant safety by developing guidelines on the role definition and communication of operators in an advanced MCR. In this research, to resolve this problem, we propose a COgnitive, Communicative and Operational Activities measurement approach (COCOA) to measure and evaluate the workload of operators in an advanced MCR. To check the applicability of COCOA, we evaluated the operator workload of an advanced MCR of a reference power plant through simulation training experiments. As a result, the amount of high workload of the Shift Supervisor (SS) was observed in relation to the computerized procedure system newly introduced into the environment of an advanced MCR. On the basis of these observations, it is necessary to reestablish the role and communication method of MCR operators suitable to the new operational environment and changed work and develop the appropriate operating guidelines.

1 INTRODUCTION

In a conventional Main Control Room (MCR) of a nuclear power plant, to operate the system facilities, the operators of each system operate various devices of the power plants by actuating the control switches on the board classified into each section. In an advanced main control room, however, the system operation is possible since the power plant facilities are controlled using the soft control embodied into the computerized procedures and distributed computers completely equipped with digital functions. Thus, for the operation of power plant facilities, while the operators of a conventional MCR can complete the work with the primary operation of the facilities, the operators under the environment of an advanced MCR need to additionally conduct such secondary operations as a GUI screen operation, which is not observed in a conventional MCR.

In addition, another feature of an advanced MCR is the use of computerized procedures [O'hara, 2002]. While the operators refer to the operating procedures written on a piece of paper in conventional power plants, the operators of an advanced MCR refer to the contents of relevant computerized operating procedures using computers. The execution of the computerized procedures of the advanced MCR includes logging of the step execution results of the procedures on computers in addition to the screen operation. As the feature of the computerized procedures of the advanced MCR, this requires the operators to conduct a new type of task.

Thus, the MMIS environment of the advanced MCR developed to improve the convenience of operation demands the operators to conduct more tasks on security of the exactness and convenience. Accordingly, though the work of operators has been changed a great deal, due to a lack of appropriate guidelines on the role allocation or communication method of operators, the problem of an unbalanced workload for each operator has been raised. Thus, it is necessary to enhance the operation capability by developing the guidelines on the role definition and communication of operators in an advanced MCR of NPPs. In order to resolve this problem, however, a method of measuring the workload according to the work execution of the operators is necessary, but the applicable method is not available at this time. In other words, due to the operational activities of operators characterized by the digital MMI environment of the advanced MCR, it is necessary to develop a framework

suitable to a measurement of the workload of the advanced MCR.

The objective of this research is to reestablish the role and communication method of MCR operators suitable to the new operational environment and changed work by developing an analytical system to evaluate the workload according to the work execution of the power plant operators in order to resolve the matters mentioned above and to contribute to a stable operation of NPPs by developing relevant operation guidelines and enhancing the operation capability in the new MMI operational environment.

In this research, we propose a COgnitive, Communicative and Operational Activities measurement approach (COCOA) to measure and evaluate the workload of operators in an advanced MCR.

2 BACKGROUND

2.1 *The necessity of workload measurement in the advanced MCR*

The basic requisite of the advanced MCR in nuclear power plants is to provide operators with the convenient factors for accurate and fast operations by equipping them with a variety of digital MMIS functions. The major functions that the advanced MCR should have are said to be Advanced Alarm System, Group-View Display on which operators can share the same screen and information, Soft Control in which electronic control is feasible by using computer GUI screens, Computer-based Procedure System to execute procedures using computer screens, and Computerized Operator Support System/Advanced Communication System to assist in situational awareness and decision making of operators [O'hara, 2002].

In other words, an advanced MCR is the design to which the state-of-the-art MMIS technology is introduced to display all the operations on monitors, showing a lot of differences from the board type of a conventional MCR in not only the work environment but also the task procedures and execution methods of the operators.

In particular, due to the use of Computer Based Procedures (CBPs), abnormal and emergency operations show large differences in the areas of information acquisition, operational control, role allocation of each assignment, and communication of operators in comparison with the task conducted with paper procedures under the environment of the conventional MCR. For example, in the board type of the conventional MCR, the operators actuate switches by moving, to operate the facilities of power plants, to the board on which the switches of relevant facilities are arranged, but in an advanced MCR, the operators can operate relevant facilities without locational shift using the Soft Controls of computers.

Thus, the work processing method of an advanced control room makes big differences in two aspects from that of conventional nuclear power plants.

First, there is a big difference in the information acquisition method on the conditions of the power plants and physical operation variables. Though in conventional MCR the Shift Supervisor (SS) in total charge of the operation can confirm the system conditions and operation variables of the power plants through communication with the Board Operator (BO) as Reactor Operator (RO), Turbine Operator (TO), and Electrical Operator (EO), in the advanced control room the entire operators including the SS can acquire and confirm the entire operation information through the Large Display Panel (LDP) and each operator's monitor.

Second, the advanced control room uses CBPs instead of paper document procedures. In the conventional MCR, SS conducts procedures while providing order and confirmation to BO with Paper Based Procedures (PBPs). On the other hand, in the advanced MCR, SS can confirm the necessary operation information through the LDP and his own monitor while conducting CBPs. Of course, SS instructs relevant operators to operate the instruments and equipment. It is a big difference that SS must operate for a conduction of procedures the system called CBPs in the advanced control room.

Table 1 shows the major differences in the operational environment of operators between the advanced main control room and the main control room of conventional nuclear power plants.

In this way, the environmental change of the MCR has caused the operation principles and roles of operators.

First of all, SS can confirm/check the conduction of procedures and the execution actions of RO/TO/EO while confirming directly operation variables without relying on RO/TO/EO. Second, the entire operators added to their work the use of a new system called CBPs and Soft Controls, increasing the procedural workload. Third, direct confirmation of operation information enabled the contents and methods of communication between operators can be changed.

Such changes in the control room environment affect the information acquisition and operation method of operators and eventually cannot but have an influence on the role and communication method of operators. According to what was observed at the time of verifying human engineering conducted during the design process of an

Table 1. Major differences in the operational environment of operators between conventional MCR and advanced MCR.

	Conventional MCR		Advanced MCR	
	SS	BO	SS	BO
Direct plant information gathering	X (SS can't get the plant operational variables without relying on board operators)	O	O	O
Using emergency operating procedure	O	X (BO performs the countermeasures according to SS's order without EOP)	O	O

advanced main control room, however, various types of operation methods were observed due to a lack of sufficient operational guidelines in such field.

Even though CBPs include such a support function as a supply of operational information, the workload of SS and BOs tend to increase since they have to use the new system called CBPs in order to execute the procedures.

Therefore, it is necessary to evaluate the effect of an advanced control room environment on the role and communication of operators, reestablish the role of each assignment in case of using CBPs and Soft Controls in comparison with the operational task of conventional standard nuclear power plants, and develop the guidelines on communication methods.

2.2 *Related work*

Since the operators in the Main Control Room (MCR) of NPPs or chemical plants may severely decrease their work performance in case they have a severe cognitive workload, methods to measure cognitive workload have been studied for a long time. The cognitive workload is in general defined from the difference between the capability of operators and the required resource for conduction of their tasks [Eggemeier et al., 1991][Gopher et al., 1986]. Basically, the method to calculate the cognitive workload is classified into four approaches of work performance-based measures, subjective workload method, task load analysis method and physiological monitoring method [Embrey et al., 2006].

The work performance-based measures analyze the workloads from the speed, accuracy, or error rate of the demanded tasks. In some cases, one or two additional tasks are required to the subjects for deeply understanding the availability of the cognitive resources [Cain, 2007].

The subjective workload measures evaluate the workloads on the basis of subjective experience for the demanded tasks. It primarily uses self-reporting questionnaires which ask the beliefs, values, preferences, and attitudes of the respondents. MCH (Modified Cooper-Harper), NASA TLX (Task Load Index) and SWAT (Subjective Workload Assessment Technique) are developed for evaluation of subjective cognitive workload measurement method [Wierwille and Casali, 1983][Hart and Staveland, 1988][Reid and Nygren, 1988].

The task load analysis approach calculates the requirements of target tasks as they are which may provide the psychological influence of the operators. This approach measures the workload by estimating the resources used for tasks [Mitchell, 2000a].

The physiological measures record the physiological signals that are strongly associated with the subjective experience of the operators. Electroencephalogram (EEG) is a record of voltage difference between various points on the head surface[Humphrey and Kramer, 1994]. Electrocardiography (ECG) is the most widely used method to measure the electrical activity within the heart. [Meshkati, 1988]. Electrodermal Activity (EDA) is a technique to measure electrical phenomena on the skin, and is used to understand the psychological state including the mental load. In addition, Electrooculography (EOG) is a technique to measure the movement of the eyeballs. High workload requirements cause a response delay in eyeball flickering and show a response to decrease the closed time of the eyes [Kramer, 1991].

Finally, the task load analysis approach calculates the requirements of target tasks as they are which may provide the psychological influence of the operators. This approach measures the workload by estimating the resources used for tasks [Mitchell, 2000a][Mitchell, 2000b]. It also evaluates the psychological and environmental factors that may affect the performance of the operators.

3 A PROPOSAL ON METHODOLOGIES FOR EVALUATION OF WORKLOAD OF OPERATORS

3.1 *Framework for evaluation of workload*

As explained in the previous section, in order to determine the workload of operators in the advanced MCR, both the communicative behavior between operators and the operational behavior for operation of MMIS-based control equipment should be considered in addition to a measurement of the cognitive workload. In order to resolve this problem, this research is based on the workload measurement method used in various existing fields, and it was realized in the way of integration with the workload analysis method required additionally.

The framework for operator workload measurement presented in this research is Cognitive, Communicative and Operational Activities Measurement Approach (COCOA), the method judged on the basis of the three-dimensional classification of cognitive task, communicative task and operational task.

First of all, the cognitive task represents the cognitive activities of operators conducted for operation and situation handling of the power plants. For classification of the cognitive task, we used the task classification scheme proposed by Hollnagel. [Hollnagel, 1996].

The communicative task represents the communicative activities of operators conducted for operation and situation handling of the power plants, such as information exchange between operators and instructions. The communicative classification table presented in the Extended Speech Act Coding Scheme developed by Kim was used for classification of the communicative task. [Kim et al., 2010]. Finally, the operational task represents the behavior which operators take to conduct the cognitive activities and it was newly defined in this research depending on the necessity.

Figure 1 shows the framework for 3 activities-based COCOA workload measurement used in this analysis.

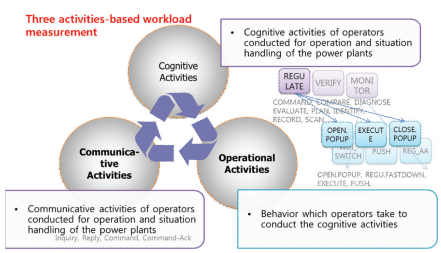

Figure 1. COCOA workload measurement framework.

As shown in Figure 1, it may be found that the task conducted by operators in the MCR of NPPs consists of cognitive activities, communicative activities, and operational activities. This is the area applied to the situations of not only normal operation but also abnormal/emergency operations of the power plants. In other words, though the 3 major task behaviors are the task behaviors classified independently depending on the task characteristic behavior, it may be considered that each individual task behavior itself does not represent the entire task but shows the task characteristics of operators most appropriately when the task behaviors are integrated.

Table 2 shows the taxonomy of three dimensions of operator activities (COCOA): cognition, communication, and operative activities.

3.2 *Workload evaluation process*

The data for an analysis of task load should be acquired to evaluate the workload. In general, the evaluation data are obtained by video-recording for the simulation experiments of operators. The acquired data are first classified into the procedures and procedural numbers, and the analysis was conducted. At the task analysis step for each procedural number, the kind of task is first selected from cognitive activities (diagnosis/decision-making), communicative activities, and operational activities. For each classified task, the relevant task behavior is judged and arranged, and the relevant tasks are then integrated to complete the workload evaluation. The workload evaluation results with the completed analysis show the execution results for the cognitive task, communicative task, and operational task of each operator. When an adjustment is needed to balance the workload from the results analyzed in this way, the workload of each operator is adjusted and averaged to raise the task conduction efficiency and satisfaction of each operator. Figure 2 is a block diagram of the workload evaluation process of operators in an advanced MCR.

3.3 *Workload evaluation example*

If it is assumed that the emergency operation procedures to be conducted by operators in an advanced MCR are the same as shown in Figure 3, the logic for an execution of the workload evaluation may be composed of the following. First, after procedural steps 1 through 4 are completed, the case where the conditions of detailed step 4.1 are satisfied and the case where they are not satisfied may be investigated. When the conditions are satisfied, detailed step 4.1 is skipped, and detailed step 4.3 is executed. When they are not

Table 2. Taxonomy of COCOA classification.

Dimension	Activity	Description
Cognitive activity	COMPARE	Comparing two or more entities of system states.
	DIAGNOSE	Recognizing or determining the cause of the system states by signals or parameters.
	EVALUATE	Checking a system state with consideration of other system parameters or states.
	EXECUTE	Performing a single prescribed action (ex. open, close, turn on, etc.)
	MAINTAIN	Sustaining a specific system state by executing or regulating systems.
	MONITOR	Continuously observing the system states or parameter.
	RECORD	Writing down or logging the system states or events.
	REGULATE	Changing the quantity, speed, or direction of the system parameters or states.
	VERIFY	Checking an entity of system states.
	SCAN	Briefly reviewing specific system states by displays or other information.
	PLAN	Formulating a path to achieve specific goals.
	IDENTIFY	Recognizing the overall state of a specific system.
Communicative activity*	COMMAND	Ordering an operator to execute or regulate a system or component.
	COMMAND-ACK	Informing whether a listener understood a command.
	INQUIRY	Asking about system states or parameters.
	REPLY	Answering a question.
Operational activity	SWITCH_SCR	Altering a display screen to read or operate specific parameters or states.
	OPEN_CTRLPNL	Opening a control panel to operate a specific system.
	CLOSE_CTRLPNL	Closing a control panel that has been opened.
	CLICK_EXECUTE	Pushing a button to operate a single entity (ex. opening a valve).
	CLICK_REGU_ UPDN	Pushing a direction button to regulate a system parameter or state (ex. opening a valve).
	CLICK_REGU_ FASTUPDN	Pushing a double-direction button to regulate a system parameter or state (ex. opening a valve).
	CLICK_ENABLED	Pushing a button to enable a control panel to be usable.
	CLICK_MANNUAL	Pushing a button to manually operate a single entity.
	CONF_STEP	Clicking a button confirming that all instructions of a step have been completed.
	CONF_SUBSTEP	Clicking a button confirming that an instruction of a step has been completed.
	ACK_ALARM	Checking and silencing a notifying alarm.
	CONF_CHANN	Pushing a button to verify the channel of an entity to be operated.

* The most frequently used communicative activities quoted in the table.

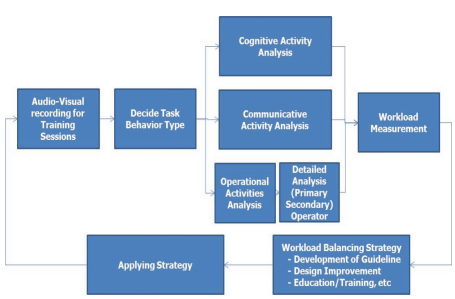

Figure 2. Workload evaluation process.

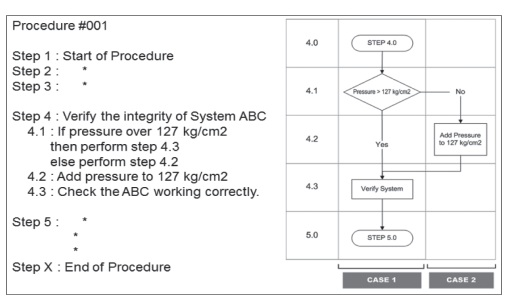

Figure 3. Emergency operation procedure (assumed).

Table 3. Workload analysis (dissatisfied condition).

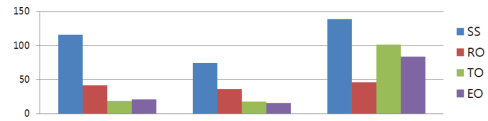
Task ID	Step	Type of activity	Task activity	Operator (SS)	Operator (RO)
1	4.1	COMMUNICATION	INQUIRY	"Is the pressure of the pressurizer 127 kg/cm²?"	
2	4.1	COGNITION	COMPARE		Compare the pressure of the pressurizer.
3	4.1	COMMUNICATION	REPLY		"The pressure of the pressurizer is below 127 kg/cm²."
4	4.1	COGNITION	VERIFY	Confirm that the pressure of the pressurize is below 127 kg/cm².	
5	4.1	OPERATION	CONF_SUBSTE P	Confirm steps and check dissatisfaction.	
6	4.2	COMMUNICATION	COMMAND	"Maintain the pressure of the pressurizer above 127 kg/cm² by controlling valve AA."	
7	4.2	COMMUNICATION	COMMAND-ACK		"OK"
8	4.2	OPERATION	OPEN_CTRLPNL		Open the window for control of valve AA.
9	4.2	OPERATION	CLICK_REGU_UPDN		Control the opening of valve AA.
10	4.2	OPERATION	CLOSE_CTRLP NL		Close the window for control of valve AA.
11	4.2	COMMUNICATION	OBSERVATION		"I've completed the valve control."
12	4.2	COMMUNICATION	OBSERVATION_ACK	"OK"	
13	4.3	COGNITION	SCAN	Check if all the relevant steps are executed	
14	4	OPERATION	CONF_STEP	Check for move to the next step	

Number of activities: 14 (Cognition: 3, Communication: 6, Operation: 5).

satisfied, detailed step 4.2 is executed to control the pressure of the pressurizer, and the procedure execution then moves to the next step (detailed step 4.3).

When the conditions of detailed step 4.1 are not satisfied, the task behavior analysis results for procedural step 4.1 are the task activities between an SS and RO, and they are composed of 14 steps, as shown in Table 3. As the conditions of step 4.1 are not satisfied, an SS orders an RO to control the valve opening through the execution of step 4.2 (Task Id #6), and RO opens the control window for a valve opening to execute procedural step 4.2 and maintains the pressure by controlling the valve opening (Task Id #7—Task Id #12). The steps after this consist of the RO's report for control completion, and SS's confirmation of the system conditions.

As shown in the table, the results of the workload analysis for step 4 of the procedures indicate that step 4 consists of 3 cognitive tasks (two for SS, one for RO), 6 communicative tasks (three for SS, three for RO), and 5 operational tasks (two for SS, three for RO).



4 WORKLOAD EVALUATION USING COCOA ANALYSIS

To verify the validity for the workload evaluation framework of operators proposed in this research, the workload evaluation was conducted on the basis of the operator practice data used in the simulator of the training center of the reference plant, which was installed in the advanced MCR under an MMIS environment. The environment for acquisition of the task load evaluation data is given in Table 4.

The analysis results for the workload of operators in the advanced MCR of a reference plant are shown in Figure 4. The graph shows the total frequency of cognitive activities, communicative activities, and operational activities used during the process of executing a Standard Post Trip

Table 4. Environment for acquisition of workload evaluation data.

Items	Detailed contents
Scenario	LOCA(SPTAP + DP + ORP(LOCA)) SGTR(SPTAP + DP + ORP(SGTR))
Team	3 Training teams (advanced MCR operation teams)
Acquisition method	Video recording individual recording for each operator (SS, RO, TO, EO)

Procedure		Cognitive Activities				Communicative Activities				Operational Activities			
		SS	RO	TO	EO	SS	RO	TO	EO	SS	RO	TO	EO
1	SPTAP	38.6	14.1	4.4	12	25.6	12	5	7.6	52.6	12.3	16.6	36.3
2	DP	19.6	4.3	2.9	3.4	10.4	2.6	2.8	3.4	23.4	3.9	4	15.4
3	ORP	57.8	22.7	11.3	5.1	38.4	21.5	10	4.8	62.4	30.1	80.3	32
Sum		116	41.1	18.6	20.5	74.4	36.1	17.8	15.8	138.4	46.3	100.9	83.7

Figure 4. Workload analysis results.

Action Procedure (SPTAP), Diagnosis Procedure (DP), and correspondence procedures (Optimal Recovery Procedure (ORP) for Loss of Coolant Accident (LOCA) and Steam Generator Tube Rupture (SGTR)). Figure 4 shows the average total number of activities that appear when the LOCA and SGTR scenarios are executed, and the table at the bottom of Figure 4 shows the frequency of cognitive tasks conducted by operators for each procedure and each activity.

The results for the workload analysis indicate that the cognitive activities of SS are far more than those of other operators. It was found that as the communicative activities of SS are also the most, SS leads the entire MCR. Not only that, but SS is also found to conduct more operational activities than other operators. This shows that SS increases the frequency of operational activities by executing diagnostic procedures (SPTAP + DP) and Optimum Operation Procedures (ORP), using the CBPs, under the operation environment of an advanced MCR.

5 GENERAL CONCULSTION

In this research, we proposed a framework to measure and evaluate the workload of operators in an advanced MCR and the workload was measured through the simulator training experiment of the advanced MCR of a reference plant to verify the validity of the framework.

The workload analysis results of operators in the advanced MCR of the reference plant show that the cognitive and communicative activities of SS are more than those of other operators. This is because SS is responsible for confirming the accuracy of the procedural execution in the case of an emergency and should continue to conduct the operational guidance and surveillance activities. Though the CBPs and personal information processing system basically provide a variety of information on the status of the power plants, SS has a high amount of cognitive activities and also has a high amount of communicative activities for understanding of the operators' behavior and plant status since SS should judge and decide whether all the instructions are executed or not in the CBPs.

Not only that, but these analysis results also show that the workload for operational activities of the SS is heavier than that of other operators. Whenever the SS, who operates the CBPs, executes each instruction and step, the SS should mark in the CBPs whether they are executed and whether they are satisfactory. Thus, many operational activities are required for the execution. It is easy to understand that SS, who has to conduct a high amount of cognitive and communicative activities due to the workload caused by such operational activities, is more overloaded. It may be predicted that SS will be given an additional workload due to the operational activities increased in comparison with the workload under the environment of a conventional MCR.

The COCOA developed in this research presents the framework suitable to a workload analysis of the operators in an advanced MCR. This also presents the taxonomy for additional operation activities of operators to use the computerized procedures and soft control added to the advanced MCR, and it enables an integrated measurement of the operator workload in various dimensions of cognition, communication, and operation. Of course, even though it is impossible to get an arithmetic average of the load values measured in each dimension, additional research is needed to present a comprehensive measure in consideration of the weighed values between factors (dimensions). In addition, the measurement method presented in COCOA is regarded as a calculation method to enable a comparison between operators.

On the basis of these observations, it is necessary to reestablish the role and communication method of MCR operators suitable to the new operational environment and changed work and develop the appropriate operating guidelines.

As additional research, it is judged that the evaluation of operator workload through more experiments is needed to prove the validity of COCOA,

and in-depth research on an equalization plan for the workload unbalance of operators analyzed through COCOA is also needed.

A survey of Bayesian Belief Network Applications in Human Reliability Analysis

L. Mkrtchyan, L. Podofillini & V.N. Dang
Paul Scherrer Institute, Switzerland

ABSTRACT: Applications of Bayesian Belief Networks (BBNs) to Human Reliability Analysis (HRA) are receiving increasing attention. This paper surveys these applications, aiming at identifying the areas of HRA for which BBNs can be attractive. The survey is based on an extensive search of the literature (2006–2013). The literature is divided into groups depending on the HRA aspect primarily addressed with the use of BBNs. Five groups are identified and analysed: modelling of organizational factors, analysis of the relationships among Performance Shaping Factors (PSFs), extensions of existing HRA methods (in practice, SPAR-H and CREAM), HRA dependence assessment, and the assessment of situation awareness. Each application emphasizes a different BBN feature: e.g. ability to deal with scarce data, to incorporate diverse information, to model complex multi-layer relationships. This survey focusses on how the BBN framework is used to capture the different HRA aspects. An important aspect outside the scope of the present paper is how the BBNs are built, i.e. the incorporation of available data and/or expert judgment in the construction of the models and the determination of their parameters—this aspect will be addressed in future work.

1 INTRODUCTION

Human Reliability Analysis (HRA) is the area of risk analysis aimed at analysing the human contribution to system reliability and safety. A number of HRA methods have been developed, different in their scope, approaches for analysing the human performance conditions, and human error quantification approaches. An overview of methods can be found in Kirwan (1994).

An important class of HRA methods is based on models, which typically represent and quantify the relationships among the factors influencing the human failure probability. Examples of these models are those underlying SPAR-H (Gertman et al. 2005), CREAM (Hollnagel, 1998) and the recently developed causal models such as in Groth & Mosleh (2012). Generally, the relationships between influencing factors and human failure probabilities are challenging to capture. The influencing factors can be many and interdependent (correlated and with dependent effects on the failure probability); the data available to inform these relationship is limited and, if present, it is challenging to use.

In this context, modelling frameworks able to represent complex, non-deterministic relationships with limited information are attractive for HRA. In particular, recently, Bayesian Belief Networks (BBNs) (Jensen & Nielsen, 2007) are increasingly being explored, developed and applied for HRA. Use of BBNs in risk and reliability analysis is relatively established, while their use for HRA is quite recent (mostly from the last five years). In addition to the features already mentioned, BBNs are especially suitable for HRA for the following reasons. First, BBNs handle both causal and evidential reasoning: this allows not only the estimation of Human Error Probabilities (HEPs) given the contributing factors but also the analysis of the most dominant factors given a human failure. Second, BBNs can incorporate information of different nature from different types of evidence sources—a key feature in case comprehensive data is not available. Third, because of their straightforward graphical representation of cause-effect relationships, BBNs are easy to use for both domain experts and analysts, and the results are easy to interpret for non-experts. Finally, the probabilistic nature of BBNs allows them to be integrated with other mathematical models such as fault trees and event trees; therefore the results can be used in Probabilistic Safety Assessment (PSA).

The present paper systematically surveys HRA applications of BBNs. The review is based on an extensive search of the academic literature (2006–2013). The literature is divided into

five groups depending on the HRA aspect primarily addressed. Each application emphasizes a different BBN feature: e.g. ability to deal with scarce data, to incorporate diverse information, to model complex multi-layer relationships. After a brief introduction of BBNs (Section 2), Section 3 gives the overview of the surveyed papers and of their grouping. The studies are discussed in detail by group in Sections 4–7; a brief overview of the individual studies is provided in the Appendix. The conclusions from the survey are given at closure.

2 BAYESIAN BELIEF NETWORKS

BBNs model probabilistic relationships among variables, with variables and relationships represented as nodes and links of the network (Jensen & Nielsen, 2007). Graphically, BBNs are represented as directed acyclic graphs (therefore, the feedback cycles cannot be modelled) connecting nodes with links. The quantitative relationships among the connected nodes are represented as conditional probability distributions for each variable (node) in the network.

For BBNs with discrete nodes, the conditional probability distributions are stored in Conditional Probability Tables (CPTs). The CPTs are obtained either from data, expert judgment or both. The automatic quantification of CPTs from data typically requires large data samples. This is the case of some data-rich applications, e.g. in molecular biology, medical diagnostics, or financial economics. In these applications, typically, both the BBN structure and relationships are learnt from data: in these, BBNs are used to identify the important factors, their relationships (correlations and causal relationships) and their quantitative influence on the variables of interest.

In the risk analysis domain, BBNs are used to represent uncertain knowledge about factors and relationships. With few exceptions, data is scarce (if at all available), so that the CPTs are obtained by expert elicitation. For these applications, the development of processes to avoid biases and efficiently elicit large number of probabilities is an important area of research and a key element for successful application of BBNs (Jensen & Nielsen, 2007).

Once the BBNs are built, they can be used both for diagnostic and predictive applications by making inference about the variables in the network. Inference in BBNs is based on the concept of belief propagation which refers to computing posterior marginal probability distributions of a set of variables of interest, after obtaining some observations of variables in the model.

3 BAYESIAN BELIEF NETWORKS IN HRA: OVERVIEW OF THE SURVEYED STUDIES

The surveyed studies of HRA-related BBNs were grouped according to the HRA aspect they address (Table 1). Namely, these are studies using BBNs: 1) to represent the possible impact of Management and Organizational Factors (MOFs) on HEPs; 2) to analyze the relationships between interdependent Performance Shaping/Influencing Factors (PSFs/PIFs); 3) to extend existing HRA models to capture additional features allowed by the BBN modelling framework; 4) to model HRA dependence; 5) to assess situation awareness. These HRA aspects are strongly inter-related. For example, representing the impact of organizational factors would also explicitly capture the dependence across multiple human failure events introduced by MOFs. In the compilation of in Table 1, whenever a study fits into multiple groups, the study was classified according to the most representative HRA aspect treated.

The subsequent sections discuss each of these groups of contributions in detail. A short description and summary of the individual contributions is presented in the Appendix. The contributions related to situation assessment are inspired by the application of BBNs as diagnostic tools; their aim is to identify opportunities for misdiagnosis and predict their probabilities in the frame of simulation-based risk assessment. Due to this specificity and space limitations, further discussion of this group is omitted.

4 BBNS TO MODEL ORGANIZATIONAL FACTORS

There are significant challenges to the incorporation of MOFs in quantitative risk assessment.

Table 1. HRA aspects addressed by the reviewed works.

HRA aspect	Contributions
Organizational factors impact assessment	(Martins & Maturana, 2013), (Cai et al. 2013), (Vinnem, et al. 2012), (Gran et al. 2012), (Trucco et al. 2008)
PSF/PIF relationship assessment	(Sundarmurthi & Smidts, 2013), (Stempfel & Dang, 2011), (Dang & Stempfel, 2012), (Podofillini et al. 2013), (Musharraf et al. 2013), (Groth & Mosleh, 2012)
Situation assessment	(Lee & Seong, 2009), (Kim & Seong, 2006a), (Kim & Seong, 2006b)
HRA method extensions	(Groth and Swiler, 2013), (Kim et al. 2006)
Dependence assessment	(Baraldi et al. 2009), (Ekanem & Mosleh, 2013), (Mosleh et al. 2012)

MOFs by their nature are difficult to define and classify; the link between MOFs and their impact on safety can be subtle and long-term; data is hard to obtain because of the difficulty to establish appropriate taxonomies. The lack of an established set of MOFs and corresponding definitions hinders comparisons and benchmarking analyses across different studies. The reader can refer to (Mohaghegh et al. 2009), (Mohaghegh & Mosleh, 2009) for a comprehensive discussion on the issue.

Generally, the use of BBNs to model the impact of MOFs aims to explicitly model their multi-level and hierarchical influences on the HEPs, as discussed in Li et al. (2012), Cai et al. (2013) and Martins & Maturana (2013). Many of the influencing factors typically considered by HRA methods can be thought of having direct influence on the HEP, e.g. the quality of the human machine interface and the time available for the personnel to carry out their tasks. In contrast, many of those referred to as MOFs have indirect effects: for example the management's commitment to safety influences the quality of personnel training, which then directly influences the HEP. The BBN ability to represent multi-level relations helps to model these types of hierarchies. Figure 1 shows an example of the hierarchical influences.

Trucco et al. (2008) use BBNs to model the dependence among multiple failure events introduced by organizational factors. The effect of the organizational factors is to modify the probability of each basic event through the corresponding organizational variable; in this way, the same organizational factor may impact multiple basic events. The study combines two frameworks; namely fault trees and BBNs. As advocated by Mohaghegh et al. (2009) this combination appears to be the most promising approach for integrating organizational influences in risk assessment. Figure 2, taken from Mohaghegh et al. (2009) shows the concept for the integration of the BBN, event tree, and fault tree modelling techniques.

In general, the surveyed studies focus on the potential advantages of BBNs to model the subjective, hierarchical, and "soft" relationships characterizing MOFs. A key element for the development of these models is the assessment of the quantitative relationships underlying them. The assessment is based on expert judgment, given the absence of empirical data: the process for the elicitation of the judgments becomes a fundamental component of the model development and of its acceptance. Therefore, approaches to effectively elicit expert judgment, while avoiding biases, are generally sought in the surveyed studies. A survey of these approaches is outside the scope of the present paper.

A concern related with the surveyed studies is their limited emphasis on the operationalization of the factors. For the quantitative incorporation in safety analysis, MOFs require clear definitions, operationalizations and measuring techniques. As mentioned, an important contribution in this sense comes from the modelling principles in Mohaghegh & Mosleh (2009). Also, Vinnem et al. (2012) discusses how the measuring of influencing factors was approached: the scoring of each factor (a six-point scale is used, from A to F, see Table 2) is assessed via questionnaires and interviews. However, in most of the references, MOFs are presented as BBN nodes with their states (typically, binary), with no guidance on how to assess the states (i.e., how an analyst should decide between "Organizational Culture" being "Appropriate" or "Non Appropriate" taking one example from Table 2).

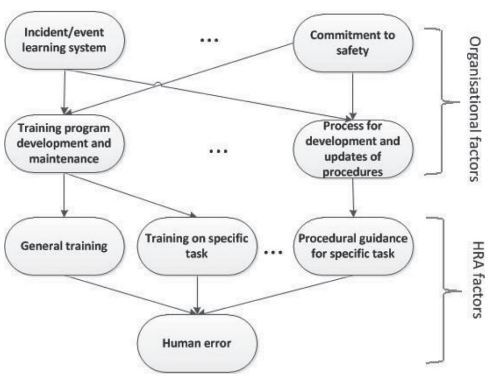

Figure 1. Example of multi-level influences typically modelled by BBNs: direct and indirect influences of the error probability.

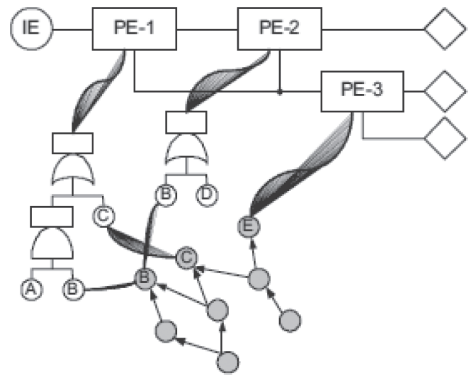

Figure 2. Concept for the integration of MOFs in probabilistic safety assessment, combining the BBN, the event trees, and fault tree frameworks (Mohaghegh et al. 2009).

Table 2. Some of MOFs and states used in BBNs.

5 BBNS TO MODEL THE RELATIONSHIPS AMONG PSFS

Most HRA methods use PSFs to support the analysis of the contextual conditions under which human failure may occur. In the qualitative HRA, PSFs help analysts to systematically address all factors believed to be important to human performance. In the quantitative HRA, PFSs are frequently used to modify a generic error probability to capture the effect of the context in which the task of interest is carried out.

Typically, when multiple PSFs are assumed to influence the HEP, HRA methods model the PSF joint influence by cumulating the effect of each factor, as if each of them would act independently on the HEP. However, PSFs can have interacting effects: good performance conditions (e.g. support from the procedural guidance or highly experienced personnel) can compensate for the difficulty of a highly complex task; on the other hand, a complex task carried out under limited procedural guidance support, by unexperienced personnel would be characterized by a very high failure probability, much higher than if these three factors would be present alone.

BBNs are naturally suited to model the effects of interacting PSFs. Indeed, the key practical problems are to identify the interacting factors and quantify their joint effects. This is the common issue addressed by the studies included in this category in the survey (Sundarmurthi & Smidts, 2013), (Stempfel & Dang, 2011), (Dang & Stempfel, 2012), (Podofillini et al. 2013), (Groth & Mosleh, 2012). All papers address identification and quantification of the interactions as these emerge from data (see Fig. 3 for a typical view of the BBN structure for these applications): empirical data in Groth & Mosleh (2012) and Sundarmurthi & Smidts (2013); artificial data in Stempfel & Dang, (2011), Dang & Stempfel (2012), Podofillini et al. (2013).

A unique feature of the work in Groth and Mosleh (2012) is the use of empirical data to inform the BBN development, both for the graphical and quantitative parts: data analysis (correlation and factor analysis) allows identifying the causal relationships among the PSF, their interaction to produce errors and some of the BBN conditional probabilities. The uniqueness relates to the fact that, as mentioned in the introduction, the typical approach for BBN applications in field with poor data availability is to use expert judgment for building the structure of the networks and then the available data for quantifying the relationships.

A primary aspect of the work by Groth & Mosleh (2012) is the exploration of the Error Contexts (ECs), which are certain combinations of PSFs (Fig. 3) which are more likely to produce a human error (Groth & Mosleh, 2012). ECs

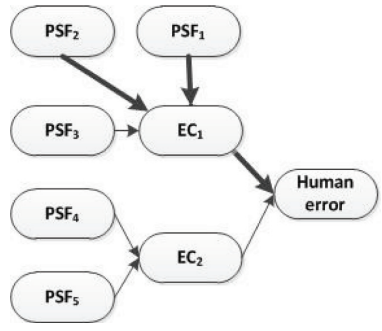

Figure 3. An example of PSFs hierarchical structure and influence on human error (the line style depends on the importance and strength of the link).

are identified from the data patterns, via Factor Analysis. For example, one of the ECs emerging from the data is the combination of inadequate teamwork and training to respond to a complex, dynamic situation (involving three PSF, "Team", "Training" and "Complexity"). The probability of an error occurring when this combination occurs is much larger than when these factors act alone. This suggests the importance of teamwork and training to cope with complex tasks (good teamwork and training can compensate the challenges of complex situations so that the probability of error can significantly decrease).

The main aim of Sundarmurthi & Smidts (2013) is to develop an HRA model suitable for the dynamic PSA simulation environment integrating plant physical models and operating crew models into stochastic simulation engines. The relationship among PSFs is first represented with causal graphs as an initial structure of BBNs. The relationship between two elements/nodes in causal graphs is expressed in terms of statistical correlation calculated from data or with expert judgment. In the causal graphs the importance of each PSF is explored in terms of its influence by other factors.

The main aim of the work presented in Stempfel & Dang (2011), Dang & Stempfel (2012), Podofillini et al. (2013), is to examine the BBNs as a modelling tool to capture the relationships among the PSF as these emerge from data. The artificial data (generated, with known properties) is used to evaluate the capability of the BBN models to reproduce the known properties. A key assumption of the artificial data was that in addition to their individual effects on performance, some PSFs interacted producing an additional contribution to the HEP. In other words, their joint effect was more than the sum of their individual effects. The formalism of the BBN clearly supports the modelling of such interactions. Stempfel & Dang (2011) investigated how the BBN model compared to a model where this interaction term is neglected: a multiplicative model was fitted to the data. As expected, it performed poorly on all configurations where more than one PSF was present. The references analyse the BBN performance under different modelling conditions: reduced data sets (Stempfel & Dang, 2011), missing and/or incorrect data values (Dang & Stempfel, 2012), different BBN structures (Stempfel & Dang, 2011 and Dang & Stempfel, 2012), uncertainty in the BBN parameters (Podofillini et al. 2013). As expected, the BBN performance degrades as the size and quality of the data set decreases. Combination with expert judgment can be sought to improve the BBN performance in these cases.

6 BBN-BASED EXTENSIONS OF HRA METHODS

Among the reviewed studies two contributions present BBN versions of the HRA methods SPAR-H and CREAM. In Groth & Swiler (2013) the authors state that the reason for using the BBN version of a known and widely used HRA method is to demonstrate the benefits of using BBNs on a method with which practitioners are familiar. This is believed to help in "bridging the gap" between the development of HRA methods by researchers and its adoption by the practitioners.

The study in Groth & Swiler (2013) presents a BBN version of the SPAR-H method. The network structure consists of the eight PSFs of SPAR-H and the human error (all PSF nodes directed into the human error node). Being a BBN replica of SPAR-H, the CPTs are given by the SPAR-H relationships between PSFs and error probabilities. Building on the BBN version of a familiar method, the study shows how the BBN framework can accommodate analyses with perfect, partial or no information on the PSF states as well as evidential reasoning (i.e. about the PSFs states given error occurrence). Finally, possible modifications to the model are discussed by adding additional PSFs and discussing the interdependency among PSFs.

The study in Kim et al. (2006) is based on the HRA CREAM method. BBNs are used for the probabilistic assessment of the control mode, different from the original CREAM formulation in which the control mode is deterministically determined. The control mode represents the degree of control that the personnel has over a situational context. The situational context is captured by the state of nine Common Performance Conditions (CPCs), each having three or four possible ratings. Depending on the ratings, CREAM suggests a basic diagram to decide the control modes. The BBN developed in Kim et al. (2006) study is used to extend the described deterministic approach in CREAM and it calculates the probability distribution of control modes given the probability distributions of nine CPC nodes.

7 BBNS FOR DEPENDENCE ASSESSMENT

In HRA, dependence analysis refers to assessing the influence of the failure of the operators to perform one task on the failure probabilities of subsequent tasks (Swain, 1983).

The THERP handbook (Swain, 1983) suggests general rules to determine the dependence, qualified in terms of levels (from zero to complete) providing a formula for computing the dependent, conditional probability for each dependence level.

In current HRA practice, dependence assessment is generally supported by decision trees that guide analysts through the assessment of the different factors influencing dependence (e.g. closeness in time between two successive tasks, similarity of the cues related to the two tasks).

Two lines of research have addressed the use of BBNs for dependence assessment in HRA. The first one investigates the use of BBNs (Baraldi et al. 2009) as expert models, to increase the repeatability and the transparency of the dependence assessment. The BBN nodes in this study are based on the dependence factors described in THERP (Fig. 4). The lack of traceability in the development of the decision trees used for dependence analysis is one of the main motivations behind the work by Baraldi et al. (2009). The consequence is that the fundamental assumptions behind the influence of factors (e.g. which factors are important and how much each influences the model output) are not directly linkable to the developed model. The work in Baraldi et al. (2009) generally is included in the larger activity of the authors of the present paper to improve traceability and transparency of model development in HRA via systematic expert elicitation approaches (cf. Podofillini and Dang, 2010).

The second line of research aims at using BBNs to more explicitly capture the causal dependencies between different human failure events (Ekanem & Mosleh, 2013), (Mosleh et al. 2012). The causal dependencies are originated by the fact that the same PSFs influence multiple HFEs: BBNs are used to explicitly model these influences. In terms of structure, BBNs developed for these applications would have multiple HFE nodes and different factors influencing the different HFE nodes as necessary. Note that this line of research for capturing HFE dependences has a strong connection with the uses of BBNs for incorporating organizational factors in the PSA framework: organizational factors constitute fundamental, common causes of human failures.

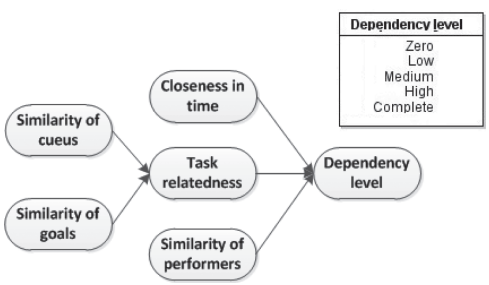

Figure 4. HRA dependence modelling with BBNs (Baraldi et al. 2009).

8 CONCLUSIONS

This paper has surveyed recent applications of BBNs for HRA application—a recently increasing trend for HRA. The applications have been grouped into five categories, four of which are discussed in this review.

BBNs have been used for incorporating MOFs in probabilistic safety assessment. The BBN attractiveness for this aim is in their ability to capture "soft" relationships, typical of the influences of these factors. In addition, their graphical interface largely facilitates the discussion on the identification and definition of the influencing factors behind the model development phase. This feature appears particularly interesting for the modelling of MOFs because the procedures for their identification and definition are relatively unestablished so that any tool able to improve the process transparency is beneficial. BBNs are embedded in the classical fault tree and event tree frameworks to capture the overarching effect of MOFs over multiple failure events (possibly explicitly modeling the dependence effect introduced by the MOFs).

The second group of applications addressed BBNs to model the relationships among PSFs, intended as how PSFs interact to determine the human failure probability. These applications demonstrate the superiority of BBNs to reproduce these relationships compared to the simplified models more typically used in HRA, i.e. in which the factors independently influence the HEP. Ideally, the relationships should be captured by the BBNs as these emerge from empirical data. However, the amount of data available still does not allow the construction of BBNs solely on empirical grounds, so that elements of expert judgment are always present.

The third group of applications applies BBN to modify existing HRA methods, to provide additional modelling capabilities that the methods would not support. For example, these relate to introduction of interdependencies in the PSF and/or multiple layers. As pointed out by Groth and Swiler (2013), the introduction of BBNs into existing HRA models can foster the acceptability of BBNs by the HRA community. Indeed, practitioners would be more willing to accept a new model when this is embedded in a familiar framework (such as SPAR-H or CREAM as in the surveyed works). Also, the possibility offered by BBNs to incorporate new information would allow enhancing existing HRA methods with new data, via the BBN learning mechanism.

The fourth group of applications dealt with dependence assessment. Dependence assessment is an area of HRA characterized, in practice, by the absence of quantitative empirical data. In this

framework, BBNs have been used as a modelling tool to improve the traceability of the models supporting the assessment. This necessarily implies the adoption of a systematic framework for eliciting expert judgement and converting it into a quantitative model. Indeed, the need for systematic treatment of expert judgments to develop BBNs is not specific to dependence assessment and not to HRA. Still within the domain of dependence assessment, BBNs have been used to explicitly model the impact of common factors among multiple human failure events. This has been done exploit the possibility to incorporate the BBN framework with fault and event trees, similarly to how the MOFs in PSA is envisioned.

This paper has surveyed how BBNs model each aspect of HRA. However, an important element for BBN applications has been left out: the process for BBN development. The analysis of the process of model development is key for the acceptability of the BBN framework in HRA where the transparency of the adopted models is very important: models need to be understood, reviewed, and accepted. This requires a systematic process to utilize available data and expert judgment in the model development phase. The next phase of this survey will be to analyse how these elements are incorporated in the BBN development.

Aggregating expert-elicited error probabilities to build HRA models

L. Podofillini, L. Mkrtchyan & V.N. Dang
Paul Scherrer Institute, Villigen PSI, Switzerland

ABSTRACT: Models for Human Reliability Analysis (HRA) applications are characterized by a strong component of expert judgment. With the increasing attention to the empirical basis of HRA, it becomes important that, whenever expert judgment is used as a source for the method development, this is done rigorously. The present paper represents one step further in that direction, dealing with the development of Bayesian Belief Networks (BBNs) models for HRA. Expert assessments of selected error probabilities are formally aggregated and converted into BBN relationships. An approach is then proposed to fill in the missing relationships. This overcomes the need to elicit all model relationships, which in many cases is impractical. The approach is demonstrated on a very simple HRA model, which suits well the illustration purposes. Given the importance of this issue for HRA (and several other applications), it seems worthwhile to systematically investigate the attractiveness of alternative approaches to develop BBN models based on elicitation of partial information.

1 INTRODUCTION

The increasing use of Probabilistic Safety Assessment (PSA) to support regulatory and operational decisions requires that methods be developed to the extent possible on an empirically sound basis. For Human Reliability Analysis (HRA), this means that methods should be based on data from operational experience, studies in simulator environments, as well as theoretical cognitive models. A significant step in this direction has been achieved with the International and US HRA Empirical Studies, which aimed at an empirically-based understanding of the strengths and weaknesses of a number of HRA methods (Forester et al. 2013).

Bayesian Belief Networks (BBN) have demonstrated promising features for HRA application (Groth & Mosleh 2012, Mkrtchyan et al. 2014). BBNs are models representing and quantifying probabilistic relationships among factors. Their primary use is the representation of knowledge and decision support under uncertainty; their application is established in diverse areas such as medical diagnosis and prognosis, engineering, finance, information technology, natural sciences (Jensen and Nielsen 2007). In HRA, BBN applications have addressed the incorporation of management and organizational factors, investigation of the relationships among the performance shaping factors, dependence analysis, situation assessment and diverse extensions of existing HRA methods (See Mkrtchyan et al. 2014 for a survey of these applications).

Ideally, the increased attention to the empirical basis of HRA methods should be seen in BBN applications as well. Examples are Groth & Mosleh (2012) and Sundarmurthi & Smidts (2013): these references propose methodologies to develop BBNs based on the combination of data, expert judgment and cognitive models. Expert judgment is required because of the difficulty of collecting data covering the entire scope and situations addressed by HRA models. Indeed, despite important efforts in the collection of HRA data, the challenges underlying the collection and the use of this type of data are such that statistically significant data to fully construct HRA models is currently not available. A rigorous integration of data, theoretical models and expert knowledge is seen as the way ahead for enhancing HRA models (Groth & Mosleh 2012).

The present paper focuses on the use of expert knowledge to construct HRA models. Rigorous treatment of expert judgment is seen as necessary before tackling the integration of the three main sources for HRA (data, theoretical models, judgment). The first aspect addressed by the present paper is the aggregation of expert estimates to inform the quantitative relationships of a BBN (the Conditional Probability Distributions, CPDs). In particular, the Bayesian approach recently presented in Podofillini & Dang (2013) is adopted, which allows formally and transparently aggregating expert estimates, so that both the inherent variability of the human error probability and the experts' variability are represented and distinguished in the final probability distribution.

The second aspect relates to the difficulty to directly elicit all CPDs from one or more experts.

When many assessments need to be made, possible biases in the elicitation of probabilities and inconsistencies arise. For a comprehensive discussion of possible biases and inconsistencies, see (Cooke, 1991). An attractive alternative, the subject of the present paper, is to elicit selected model relationships or, more generally, partial model information, and then complete the rest of the relationships with algorithms. This approach is attractive for HRA because of the large number of relationships to be assessed (a medium-size HRA model is characterized by probability distributions numbering on the order of 20–50 to fully characterize the model). Some approaches for developing a complete set of BBN relationships from a limited number of elicitations have been proposed and applied in the literature (Fenton et al. 2007) but their application to HRA has been limited. Some examples are (Martins & Maturana 2013, Cai et al. 2013); however, these required the assumption of independence in the factor influences. This assumption can be problematic for HRA applications because of the factor interactions: these are indeed a motivation for the application of BBNs in HRA. Recently, Podofillini et al. (2014) have applied the approach developed by Fenton et al. (2007), which allows capturing some degree of dependence among the factors. With the developed BBN, it was possible to represent different levels of error forcing impact (therefore, of associated error probability). The study by Podofillini et al. (2014) underscores the attractiveness of combining limited information with algorithms to complete the model relationships. A difficulty in the application of the algorithm by Fenton et al. (2007) is that the choice of the functions and their parameters needed for the development of the BBN can be quite subjective (no hard rules connecting the elicited information and these functions exist).

This paper presents a new concept to fill in the missing CPDs in a BBN by interpolating among the available ones (i.e. those elicited from the experts). In particular, the available CPDs are approximated by parametrized functions. The parameters of the missing CPDs are obtained by interpolating those corresponding to the available ones. The idea behind the approach is to decrease the subjectivity in the development of the model: the parameters of the approximating functions are calculated from those of the available ones, as opposed to being determined by the model developer.

The paper is organized as follows. The next section briefly introduces BBNs in general and, specifically, the BBN used to demonstrate the approaches. A two-input, one output BBN is used: this is certainly a strongly simplified model, but it well-suited for illustration because the behaviors of the algorithms and outputs are easy to interpret. Section 3 briefly presents the approach from Podofillini & Dang (2013) to inform CPDs by Bayesian aggregation of expert estimates and applies it to determine the selected relationships on the simple example. The interpolation approach to fill in the rest of the relationships is then presented and applied in Section 4. The conclusion section will underscore some elements for discussion.

2 BAYESIAN BELIEF NETWORK (BBN)

2.1 *Introduction*

BBNs model probabilistic relationships among variables, with variables and relationships represented as nodes and links of the network (Jensen & Nielsen, 2007). Graphically, BBNs are represented as directed acyclic graphs connecting nodes with links (consequently, feedback cycles cannot be modeled). The quantitative relationships among the connected nodes are represented as Conditional Probability Distributions (CPDs) for each variable (node) in the network. The CPDs are determined either from data or by expert judgment, or both. In the risk analysis domain, BBNs are used to represent uncertain knowledge about factors and relationships. In many cases, data are scarce (if at all available), so that the CPDs are obtained by expert elicitation. For these applications, the development of processes to avoid biases and efficiently elicit large number of probabilities is an important area of research and a key element for successful application of BBNs (Jensen & Nielsen, 2007).

2.2 *A BBN for a simplified HRA model*

As mentioned, for illustration purposes, a very simple BBN is used (Fig. 1). The BBN has two input nodes, representing the factors Human-Machine Interface (HMI) and task complexity. The output node models the Human Error Probability (HEP). The states of the nodes are given in Tables 1 and 2. Note that the definition of the output node (Table 2), modeling the HEP, is rather different than in typical HRA applications of BBNs. In these, the output

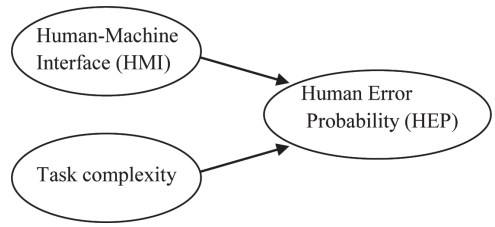

Figure 1. The BBN of the simplified HRA model.

Table 1. Definition of the BBN input nodes and states.

Node	States
Human-Machine Interface (HMI)	Strongly Success Forcing (SSF) Nominal (N) Less Than Adequate (LTA) Error Forcing (EF)
Task complexity	Very Low (VL) Nominal (N) Very High (VH)

Table 2. Definition of the BBN output state (HEP).

State #	State label	Reference probability value	Probability range
1	Very high	1	>3.2e-1
2	High	1e-1	(3.2e-2, 3.2e-1)
3	Moderate	1e-2	(3.2e-3, 3.2e-2)
4	Low	1e-3	(3.2e-4, 3.2e-3)
5	Very low	1e-4	<3.2e-4

node generally models whether the Human Failure Event (HFE) occurs: therefore the node is binary and the probability of the failed state is the HEP. In the present application, a multi-state node is used, with the states modeling different levels of error probability (from very low to very high, Table 2). This allows modeling the uncertainty in the HEP assessment, by assigning different probabilities to each HEP state. Indeed, the precision of the assessment is related to the probability interval covered by each state. The present application basically considers the case in which the BBN is used to predict the order of magnitude of the HEP (each state covers a factor of 10 in the HEP range from 1 to 1e-4). As reported in Table 2 each state is assigned a qualitative label as well as a reference probability value and range. The values determining the probability range associated to each reference value are the geometric mean of the reference HEPs of two successive intervals. The combination of qualitative labels and numerical values is often used in the elicitation of probabilities (e.g. Forester et al. 2007). The association of probability ranges to each state will be used in the application of the approach to aggregate the expert estimates (Section 3.2).

3 ELICITING SELECTED CPDS: A BAYESIAN APPROACH

3.1 *Bayesian aggregation of expert estimates*

The Bayesian approach to aggregate expert estimates entails that the estimates concerning an unknown quantity (e.g. a probability value) are used to update a prior belief concerning that quantity.

The basic assumption for the approach used in the present paper is that the quantity of interest (e.g. the HEP in the HRA case) is distributed according to a known distribution family (e.g. a normal, lognormal, beta), with unknown parameters (Mosleh, 1994). The expert opinion is then used to update the knowledge on the values of these parameters. Following the model presented by Mosleh (1994), the expert opinion comes as estimates of specific realizations of the quantity of interest.

As noted by Podofillini & Dang (2013), an element that challenges the direct elicitation of CPDs for HRA applications follows from the fact that these CPDs generally correspond to HEPs for combinations of factor states. For example, in the simple case considered in the present paper (Tables 1 and 2), one would need to elicit the applicable HEP in case the HMI is "nominal" and the task complexity is "very high" (indeed, more realistic HRA models would involve more factors and intermediate nodes). Generally, the factor labels and operationalizations may be felt as too generic and abstract: it may be difficult for experts to contextualize these factors and provide HEPs. To address this issue, Podofillini & Dang (2013) proposed an approach in which experts would be provided specific performance conditions, corresponding for example to PSA actions. These performance conditions are represented by the pattern of factor ratings under investigation. Continuing the example above, this may be in the form of a specific PSA Human Failure Event (HFE), in which the human-machine interface is "nominal" and the task complexity is "very high". Once the experts have analyzed the HFEs and provided their estimates, the output of the approach in Podofillini & Dang (2013) is the probability distribution (continuous or discrete, depending on the cases) of the HEP for the specific factor configuration under analysis.

The situation of interest for BBNs with discrete nodes is the one presented by Podofillini & Dang (2013), in which experts provide their estimate on a discrete scale, say on an n-point scale, $x_1, x_2, \ldots, x_n$. The scale can be expressed with numerical values (e.g. $x_1 = 1, x_2 = 0.1, x_3 = 0.01, x_4 = 0.001$ and the like), or representing reference values (e.g. the mean, the median or just an indication of the expected order of magnitude) for the human error probability. As shown in Table 2, each point of the scale can be also expressed with qualitative judgments (e.g. x_1 = "very likely", x_2 = "likely", x_3 = "possible", x_4 = "very unlikely"). When dealing with discrete

probability distributions, the Bayesian model can be written as:

$$\pi_j = k^{-1} L(\boldsymbol{E}/j)\pi_j^0 \quad j = 1,2,...,n \tag{1}$$

where π_j is the j-th element of the posterior probability distribution, $\boldsymbol{\pi} \equiv \{\pi_1, \pi_2, \ldots, \pi_n\}$, of the variable of interest, x (e.g. the HEP); $\boldsymbol{\pi^0} \equiv \{\pi_1^0, \pi_2^0, \ldots, \pi_n^0\}$ is the prior distribution, updated in light of the evidence $\boldsymbol{E} \equiv \{i_1^*, i_2^*, \ldots, i_N^*\}$, where N is the number of experts. Each element of the evidence i_h^* represents the expert assessment that the i_h^*-th point in the scale applies to the HFE under consideration. Factor k normalizes (over j) the expression to a probability distribution.

The likelihood term $L(\boldsymbol{E}/j)$ is interpreted as the probability of evidence $\boldsymbol{E}$, given that the actual value of x is x_j. This is a function of two elements.

- Matrix F, representing the inherent variability of the HEP.
- Matrix G, representing the confidence that the expert provides the correct HEP value.

In particular, element f_{ij} is the probability that the realization of the HEP of the specific HFE considered by the expert is within the interval represented by x_i, when the applicable (or reference value or reference judgment, depending on how the variable x is expressed) probability is represented by x_j (x_j being for example the mean, the median, or just an indication of the order of magnitude).

Element g_{ij} is the probability that the expert assesses $X = x_i$, when attempting to estimate x_j (i.e. when attempting to quantify the HEP of an HFE with HEP represented by x_j). G represents the confidence in the expert assessing the true value for X. For example, a "perfect" expert would asses the real value of the HEP: the G matrix would be the unity matrix. An unbiased expert would be modeled by a probability distribution centered on the correct value: the narrower the distribution, the higher the confidence on the expert. The next Section 3.2 provides an example of how to determine the values of the f_{ij}'s and the g_{ij}'s. Podofillini & Dang (2013) derive expressions of the likelihood term in (1), in the cases of dependent and independent expert assessments. The expressions are omitted here for brevity.

3.2 *Application to the simple HRA model*

As mentioned, for the analyses of this paper, we assume that the experts analyze specific HFEs with factor combinations corresponding to selected BBN relationships. The judgments are provided on the scale presented in Table 2. The expert assessments are then converted into corresponding CPDs. Then, these CPDs are used as interpolation anchors to fill in the rest of the CPDs.

The elements of the matrices F and G are calculated as follows. Each reference value x_i i = 1, 2, …, 5, of Table 2 is interpreted as the median of an HEP uncertainty distribution. Therefore, the HEP assessment problem becomes that of assessing which of the five x_i's best represents the median, based on the expert estimates. The error factor (square root of the 95th and 5th percentiles) of the uncertainty distribution is assumed to be known and equal to 5; this significantly simplifies the assessment procedures, because only one parameter has to be assessed (the median). Indeed, the value of 5 for the error factor represents a commonly accepted confidence range for HEPs (Podofillini & Dang 2013).

Under the above assumptions, the elements of the F matrix (Table 3) are interpreted as: f_{ij} = probability that the realization of the HEP is within interval i, given the median HEP is x_j. For example, element f_{12} is the probability that the HEP would realize within interval 1 (> 3.2e-1) given its median is x_2 (1e-2).

For the G matrix, a lognormal distribution with an error factor of 10 is assumed the confidence in the expert providing the correct value of the HEP. This corresponds to being 90% confident that the expert estimate would deviate within less than a factor of 10 above and below the correct value. The elements of the G matrix (Table 4) are therefore interpreted as follows: g_{ij} = probability that the expert assessment of the HEP is x_i, when the realization is x_j. For example, element g_{12} is the probability that the expert would assess the HEP as x_1 (>3.2e-1), when its realization is x_2 (1e-2). For use in the calculation, the elements of the matrix G are then modified to avoid too low probabilities (i.e. below ~ 1e-2) of expert estimates deviating

Table 3. Elements of matrix F, f_{ij} = probability that the realization of the HEP is within interval i, given the median HEP is x_j.

	j				
i	1	2	3	4	5

VH	Anchor 3			Anchor 4

by more than two intervals from the appropriate one, as suggested in Podofillini & Dang (2013). Therefore, elements with values below 1e-2 are set to 1e-2 as reported in Table 4.

The assumptions made in the present paper on the distributions underlying the F and G matrices, although reasonable, may be subject to further investigation in future work.

3.3 *Cases of expert assessment*

Two (hypothetical) cases are assumed: assessments from a single expert and from multiple (four) experts. The anchor assessments are provided on the four factor combinations corresponding to the extremes of the ranges for HMI and task complexity (Table 5). The anchor combinations and corresponding expert assessments are provided in Table 6.

Note that, in the single expert case, the assessments reported in Table 6 would represent the expert belief that the two factors HMI and Task complexity influence the HEP to different degrees. Indeed, an error-forcing HMI leads to very high error probability, independently of the task complexity (anchors 2 and 4 in Table 6); on the other hand, very high task complexity does not necessarily results in very high error probability (see anchors 3 and 4 in Table 6). This different importance is reflected as well in the assessments by the four experts. However, these are characterized by different levels of agreement (for example, the assessments for anchor 4 show a high degree of consistency among the experts compared to those for anchor 3). The different importance of the two factors and the different levels of agreement have implications of the final CPDs, as discussed in Section 4.

Table 6. Anchor combinations and corresponding expert assessment (hypothetical).

		Assessment of HEP	
Anchor	Factor combination HMI/task complexity	Single expert	Multiple experts *
1	Strongly success forcing/ very easy	VL	Ex1: VL ** Ex2: VL Ex3: VL Ex4: L
2	Error-forcing/ very easy	VH	Ex1: VH Ex2: H Ex3: VH Ex4: VH
3	Strongly success forcing/ very high	H	Ex1: L Ex2: H Ex3: VH Ex4: M
4	Error-forcing/ very high	VH	Ex1: VH Ex2: VH Ex3: VH Ex4: VH

* The four experts are indicated as Ex1, …, Ex4.
** VL: Very Low; L: Low; M: Moderate; H: High; VH: Very High.

By using the approach from Podofillini & Dang (2013), the judgments are converted into probability distributions of the different probability ranges, (Figs. 2 and 3). In the single expert case, the probability distributions have their maxima on the value assessed by the expert (Fig. 2 vs. Table 6). As presented in detail in Podofillini & Dang (2013), the uncertainty on the distributions combines the level of confidence in the expert estimates and the intrinsic variability of the HEP.

In the multiple expert case, the probability distributions reflect the aggregated assessments: e.g. the pronounced maximum in case of expert agreement and larger uncertainty as the level of disagreement increases. For example, comparing the distribution for anchor 4 in the single and multiple expert cases (bottom right plots in Figs. 2 and 3), the more pronounced maximum on Very High ($i = 5$) is the result of the agreement among the four experts that the applicable HEP range is $i = 5$ (Table 6); in the

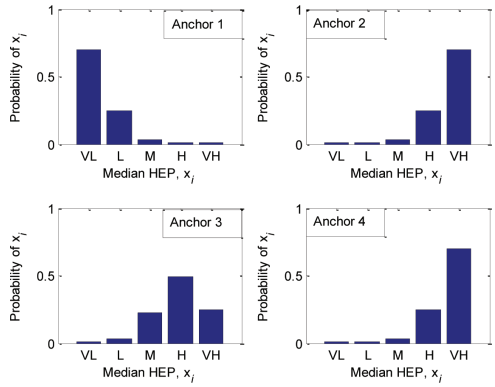

Figure 2. Conversion of the expert assessments (Table 6) in probability distributions—single expert.

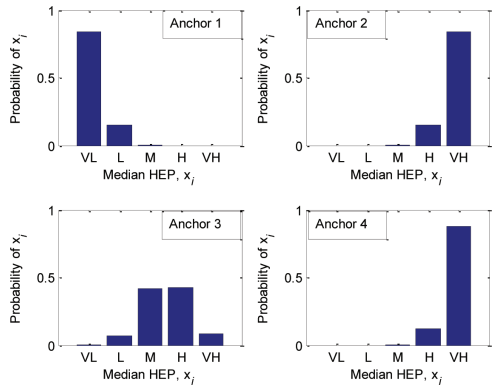

Figure 3. Conversion of the expert assessments (Table 6) in probability distributions—four experts.

single expert case shown in Figure 2, the less pronounced maximum for anchor 4 reflects the lower confidence that $i = 5$, given that it is based only on a single assessment. In contrast, the disagreement among the experts on the applicable value for Anchor 3 (Table 5) translates into two HEP values with practically equal likelihood (Moderate, $i = 3$ and High, $i = 4$).

4 THE CONCEPT FOR DERIVING THE MISSING RELATIONSHIPS: APPROXIMATE & INTERPOLATE

The expert assessments cover a selected subset of the BBN relationships. The rest have to be determined based on the properties emerging from the available judgments.

The concept presented in this paper is to fill in the missing CPDs by interpolating among the available ones. In other words, referring to Figures 3 and 4, the CPD from anchor 1 would gradually move to that for anchor 3 as task complexity changes from very easy to very difficult and to that for anchor 2 as HMI becomes error-forcing; likewise for the other factor combinations. The approach has two main elements:

– The available CPDs are approximated by functions, described by parameters
– The parameters of the missing CPDs are obtained by interpolating among the available ones CPDs

Of course, two key assumptions are required: on the approximating functions and on the interpolation rule. In the present paper, Normal functions are used (therefore the parameters would be the mean and the standard deviation) and the interpolation is linear on the factor states.

4.1 *Approximating the anchor distributions*

Assuming normal functions for the approximation, the first step is to determine the parameters of the functions approximating the probability distributions obtained from the elicitation (e.g. Figs. 2 and 3). This was done by minimizing the sum of the squared difference between each value of the distributions assessed for the anchors and the corresponding value of the Normal function (appropriately normalized so that the values sum to 1). As example, Figure 4 shows the result for the single expert assessment, anchor 3. In Figure 4, the bars replicate the anchor 3 distribution of Figure 2. The dotted line shows the Normal function that best approximate the distribution; the circles show the values of the Normal function in correspondence of each value of the distribution. Note that the Normal function should not be interpreted as a probability density: it is just used to approximate the discrete probability distribution in its five values

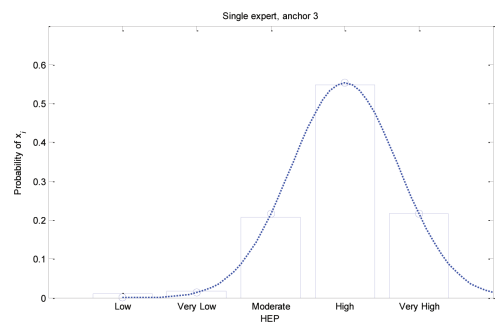

Figure 4. Example of approximation of anchor distributions by a Normal function—single expert, anchor 3.

(as shown in Fig. 4). Generally, the Normal distribution was found to approximate well all anchor distributions. This is not surprising because of the assumption made in Section 3.2 of lognormal uncertainty distributions for the HEP realizations and for the expert deviation from the correct value: these distributions become normal in the log-scale of the probability introduced by Table 2. However, the Normal distributions fail to represent the tails introduced by the residuals of 1e-2 introduced to modify the elements of the G matrix (see in Fig. 4 the underestimation of the probability of the Low and Very Low probability intervals). Indeed, studying alternative approximating functions can be expected to represent an important subject of future work.

Indeed, in order to evaluate the Normal function, the states of the output node HEP are assigned a numerical scale (the Normal function is truncated within the scale). The scale 1 to 5 was used (1: for "very low" to 5 "very high"). Note the choice of the scale has no influence on the resulting approximating function because of the normalization. The values of the resulting parameters of the approximating function are reported in Table 7.

4.2 *Obtaining the missing CPDs by interpolation*

Once the anchor parameters are obtained (Table 7), it becomes easy to obtain the missing values by linear interpolation (Tables 8 to 10).

The tables show that the interpolation approach gradually changes the parameter values across the anchors. For example, the parameter μ in the single expert assessment case (Table 8) is interpolated across the values corresponding to the anchor statements. The latter values are exactly matching the expert assessments of Table 6. This is indeed expected because the anchor distributions have maxima on the expert assessments as discussed with reference to Figure 2. For the multiple expert case, the anchor values of μ represent "in-between" assessment (e.g. 3.5 for anchor 3, HMI being "Strongly Success Forcing" and Complexity "Very High", Table 6), resulting from the aggregation of the different expert evaluations.

Table 7. Parameters of the normal functions approximating the anchor distributions from expert assessments (Table 6).

	Single expert		Multiple experts	
Anchor	μ	σ	μ	σ
1	1	0.72	1.2	0.42
2	5	0.72	4.8	0.42
3	4	0.84	3.5	0.77
4	5	0.72	4.7	0.32

Note that μ and σ are to be intended as descriptive parameters for the approximating Normal function. They are not related to the mean and standard deviation of the corresponding discretized function.

Table 8. Values of the parameter μ (single expert). Shaded cells: anchor values; white cells: interpolated values.

	HMI			
	SSF	Nominal	LTA	EF
Complexity				
Very low	1.0	2.3	3.7	5.0
Nominal	2.5	3.3	4.2	5.0
Very high	4.0	4.3	4.7	5.0

Table 9. Values of the parameter σ (single expert). Shaded cells: anchor values; white cells: interpolated values.

	HMI			
	SSF	Nominal	LTA	EF

Nominal	2.4	3.2	4.0	4.8
Very high	3.5	3.9	4.3	4.7

Table 11. Values of the parameter σ (multiple experts). Shaded cells: anchor values; white cells: interpolated values.

	HMI			
	SSF	Nominal	LTA	EF
Complexity				
Very low	0.42	0.42	0.42	0.42
Nominal	0.60	0.52	0.45	0.37
Very high	0.77	0.62	0.47	0.32

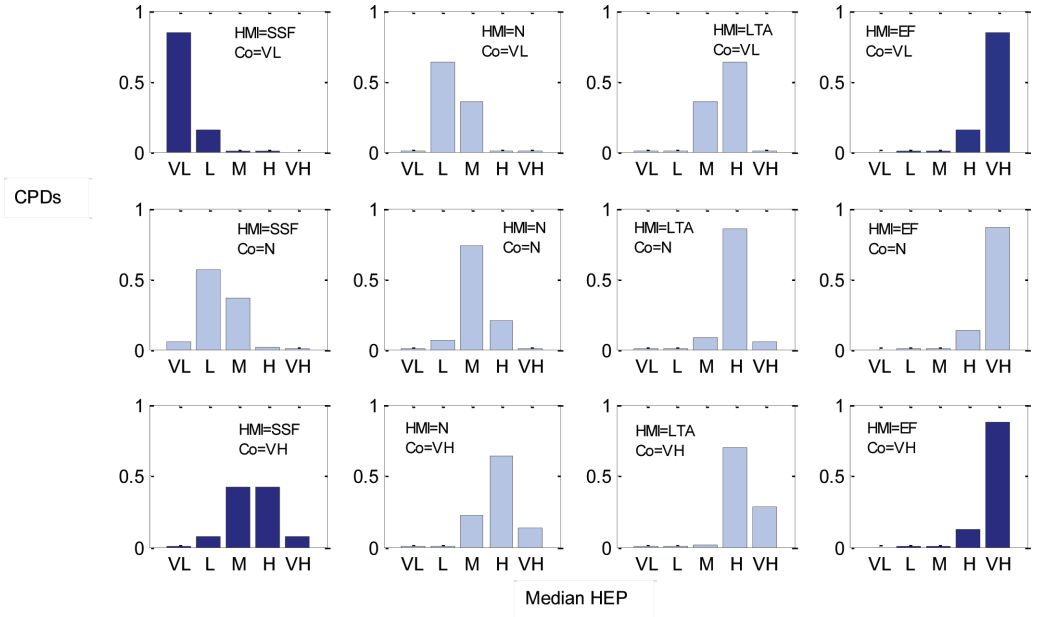

Figure 5. CPDs for the simple BBN model (multiple expert elicitation): dark blue: anchors CPDs; light blue: derived from interpolation approach.

Concerning σ, it is interesting to note how the different levels of uncertainty are reflected in the multiple expert case. The smallest value of σ corresponds to anchor 4 in which all experts agree that the HEP should be "very high", ie. $i = 5$. The largest value corresponds to anchor 3, where the largest disagreement is seen (Table 6).

Finally, Figure 5 shows all the CPDs obtained by applying the proposed approach: as desired, in the approach development, the CPDs gradually shift across the anchors.

5 DISCUSSION AND CONCLUSIONS

The present paper has dealt with the development of BBN models for HRA. Expert assessments on HEPs are formally aggregated and converted into CPDs for selected BBN relationships. An approach is proposed to fill-in the missing relationships. This allows overcoming the elicitation of all model relationships, which in many cases can be impractical.

The aim of the fill-in approach is to limit the level of judgment required to determine the rest of the model relationships. The parameters defining the missing relationships are calculated from those elicited from the expert. The approach assumes that the CPDs are discretizations of underlying Normal distributions (as it is the case, for example in the literature approach by Fenton et al. 2007). The linear interpolation of the CPD parameters allows to automatically build the missing relationships without additional subjectivity injected in the model. This contrasts with the approach in Fenton et al. (2007) in which the parameters of the missing relationships need to be determined by the model developer.

Indeed, one element of subjectivity in the presented approach is the choice of the Normal functions as well as of the interpolation function (linear). However, the applicability to HRA of these or possibly alternative choices can be tested in different applications. Once (if) a best choice is identified, this element of subjectivity would be removed.

An important feature of the combination of the aggregation and fill-in approaches is the treatment of uncertainties. The aggregation approach allows to formally and transparently consider the possibly different confidence in the assessed CPDs. Then, the fill-in approach maintains this information and, by interpolation, the CPDs gradually move across the areas of the model with different levels.

It is worth finally noting that different alternative approaches exist to develop BBNs based on limited elicited information. Given the importance of this issue for HRA (and several other applications), it seems worthwhile to systematically investigate the attractiveness of these alternatives for their application to HRA, addressing different aspects such

as the type and amount of information required from the expert, handling of uncertainties, possible limitations on the number of node states, and the like.

Organizational factor inclusion in Human Reliability Analysis (HRA) tools

N. Balfe & S. Cromie
Centre for Innovative Human Systems, Trinity College Dublin, Dublin, Ireland

ABSTRACT: There is an increasing recognition of the role played by organizational factors in major accidents and incidents, but many of the tools available for human factors analysis focus on the specific factors related to the task. This study used the STAMINA model to assess the scope of the Performance Shaping Factors (PSF) in five HRA tools. The goal was to understand the extent to which team and organizational factors are accounted for in different HRA tools as compared to the more traditionally recognized task and individual factors. The analysis highlights the mismatch between the increasing understanding of the importance of organizational factors and the relative lack of account of these factors in traditional HRA methods.

1 INTRODUCTION

The causes of accidents have moved from predominantly mechanical faults or failures in past decades to a current situation where human and organizational factors are recognized as root causes of major accidents. Taking aviation for example, the Comet disasters in the 1940s were due to a lack of understanding of metal fatigue in pressurized aircraft hulls. More recent aviation accidents, such as the Air France Flight 447 which crashed in the Atlantic following incorrect pilot reactions to inconsistent air speed indications, and even the Tenerife air accident in 1977 have listed human error as a contributing factor or leading cause. Outside of aviation, human error has also been associated with major accidents in the oil and gas (e.g. Piper Alpha in 1988, Deepwater Horizon in 2010), rail (e.g. Clapham in 1988, Eschede in 1998), and maritime (e.g. Herald of Free Enterprise in 1987, Costa Concordia in 2012) industries.

Human error is a term subject to increasing debate with the main argument against its use pointing towards the negative connotations it holds for the individual who had the misfortune to commit an error in the chain of events leading to an accident. This is especially true considering that the same action may have been appropriate and even applauded under a different set of circumstances. Dekker (2006) points out that systems are not intrinsically safe and individuals are often required to make trade-offs between safety goals and the other goals of the organization. As well as placing inappropriate blame on an individual, who may have acted in an entirely understandable manner, the term serves to deflect attention from more fundamental socio-technical issues and the ability to seek out and appropriately control variability in human performance (Hollnagel and Amalberti, 2001).

The recent train derailment in Santiago de Compostela is a case study in this—media reports firmly established human error as the accident cause early on in the investigation (e.g. Topham, 2013; Dowsett & Larraz, 2013), and this was followed by reports of previous reckless behaviors by the driver involved. Later accounts of his reputation for cautious behavior were not as widely reported. But the debate in the media over the possible culpability of the driver distracted from the more serious issues involved: the poor design of the track at that location and the consequent need for a serious reduction in speed combined with the lack of supervisory automation systems for monitoring speed—a system which was in place for the rest of the line (Burgen, 2013). These design flaws created a situation in which human error was far more likely, and the right set of circumstances occurred when the driver was distracted by a work related call. The organizational factors that allowed these to take place have not yet been fully investigated and/or reported to the authors' knowledge, however the rail infrastructure manager has already moved to install speed controls on the section of track, as well as reviewing protocols governing communications between drivers, control center staff and train crews in light of the accident.

Other examples of organization contributions to accidents include the degradation of the safety management system in the Bhopal chemical accident in 1984 (Gupta, 2002), poor equipment and job design in the Herald of Free Enterprise

maritime accident in 1987 (Sheen, 1987), poor signal design and lack of safety controls in the Ladbroke Grove rail accident in 1999 (Cullen, 2001). These, and other accidents, serve to illustrate that while the immediate cause of an accident may lie in an individual's actions, the control of these factors often lies with the organization in the design of the system and the implementation of controls that support human performance.

The motivation behind this research is the idea that organizational factors are not well accounted for and there are limited methods and tools available to assess how well an organization is working to control risks relating to human performance. The Human Factors discipline provides trained professionals and a range of methods and techniques to assess systems for human performance, but it is still a minority discipline and human factors assessments can sometimes be regarded as a tick-box exercise rather than a critical part of the engineering design and company operations.

The IEA defines human factors as "the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data and methods to design in order to optimize human well-being and overall system performance." (IEA, 2000). The discipline has developed tools to assess operator workload, the design of human-machine interfaces, the design of the working environment, including thermal, lighting, and noise factors, etc. However, some industries still focus on controlling individual behaviors through training, and rewarding safety behaviors. These are both valid approaches, but without any recognition of the role of the organization and the potential improvements at the design level, it is unlikely to be optimal.

1.1 *STAMINA model*

The STAMINA Model of human performance was developed to underpin human factors training, primarily in the aircraft maintenance industry, but it has also been applied in the pharmaceutical sector (Konstantinos et al., 2011). It adopts the EASA definition of human factors as 'anything that affects an individual's performance" (EHFAG, 2012). The model is composed of four elements:

- Task—characteristics of the task itself that can promote or reduce error;
- Individual—the strengths and limitations of humans performing the task;
- Team—effectiveness of team interaction, e.g. communication, peer pressure, etc.;
- Organization—factors that can limit or promote the effectiveness of the organization as a whole, e.g. design of roles, management of resources, etc.

This model has proved to be a useful tool, both in structuring human factors training and in analyzing the requirements of legislation and the current status of organizations (Konstantinos et al., 2011). The model is used in this research to structure the analysis of the factors considered in Human Reliability Analysis tools.

2 HUMAN RELIABILITY ANALYSIS

Techniques for the identification and evaluation of human error are typically labeled Human Reliability Assessments (HRA). A complete HRA starts with a definition of the problem and development of a task analysis to support the HRA (Kirwan, 2005). The core of HRA is the Human Error Identification (HEI) and Human Error Quantification (HEQ) stages, and several methods have been developed to specifically focus on these two areas. From these, control measures can be identified to reduce the overall system risk.

The task analysis is the human factors equivalent of the functional analysis in systems engineering. Functional analysis is a description of system functions achieved by arranging functions in logical sequences. Decomposition of higher-level functions adds more detail and allows system objectives to be allocated to lower-level functions. Similarly, task analysis identifies and examines the tasks performed by human operators when interacting with the system (Kirwan & Ainsworth, 1992). Without these representations of the tasks and activities it would not be possible to correctly analyze the task, identify and evaluate all the relevant risks. Common task analysis representations include Hierarchical Task Analysis (HTA; Annett & Duncan, 1967), Link Analysis (Chapanis, 1996), Operational Sequence Diagrams (Kirwan & Ainsworth, 1992), Cognitive Task Analysis (CTA; Stanton et al., 2005) as well as more general process and flow-chart techniques. The data for these representations are usually captured through observations, analysis of documentation, and/or interviews.

Specific methods have been developed to support human factors analysis with regard to HEI or HEQ. HEI tools include TRACER (Shorrock and Kirwan, 1998), SHERPA (Embrey, 1986), and GEMS (Reason, 1990) while HEQ tools include SLIM (Embrey et al., 1984), APJ (Seaver and Stillwell, 1983), and TESEO (Bello and Colombari, 1980). HEI techniques consider what errors are possible (the External Error Mode; EEM), why that error might occur (the Performance Shaping Factors; PSFs), and the psychological mechanism responsible for the error. Despite the number of HEI techniques developed, Kirwan (1992),

in a comparison of techniques, found that HEI is more of an art than a science, and relies to a large extent upon the expertise of the human factors professional.

HEQ techniques focus on calculating the Human Error Probability using a basic formula of the number of errors occurring divided by the number of opportunities for error (Kirwan, 1996). All HEQ techniques share the same difficulty—access to reliable data on human error rates. Typically, a base error rate is identified for a particular type of task and this is modified according to the circumstances to account for factors in a particular environment that may increase the probability of error. The base error rates can be based on task observation or recording, incident data, simulator data or expert judgement. Many HEQ tools include base error rates, which have been collected either from specific domains (e.g. nuclear simulation data used in THERP) or generic domains (e.g. generic tasks in HEART) but it is usually recommended, where possible, to use task specific information. This information can be extremely difficult to collect. Even where detailed accident and incident data is available, the number of opportunities for that error to occur may not be available, the number of opportunities for that error to occur may not be available and so it is not possible to calculate an accurate error rate.

The final step of the HRA process, control measure identification, largely relies upon the human factors practitioner's general knowledge and skill, supported by applicable standards and validated methods where possible. Where possible, control measures should make the design inherently safer, but in some cases the best available mitigation may be to generate new procedures or provide operator training.

Complete HRA methods cover both HEI and HEQ and these are the methods analyzed in this research. The tools covered are THERP, HEART, SPAR-H, CREAM, and ATHEANA.

2.1 *THERP*

The Technique for Human Error Rate Prediction (THERP) was developed by Swain and Guttman (1983) to evaluate the probability of human error within specific tasks. THERP uses a fault tree approach to model Human Error Probabilities (HEP), but also attempts to account for other factors in the environment that may influence these probabilities. These factors are referred to as Performance Shaping Factors (PSF). The probabilities used in THERP can either be generated by the analyst, usually from simulator data, or can be taken from tables generated by Swain and Guttman from available data and expert judgement.

Kirwan (1996) lists the key elements of the THERP process as:

- Decomposition of tasks into elements;
- Assignment of nominal HEPs to each element;
- Determination of effects of PSF on each element;
- Calculation of effects of dependence between tasks;
- Modelling in a HRA Event Tree;
- Quantification of total task HEP.

THERP is a complete methodology, from generation of task analyses, through error identification and representation, to quantification of human error probability. The documentation associated with the technique contains methods, models and tables of estimated human error probability to inform the analysis.

2.2 *HEART*

The Human Error Assessment and Reduction Technique (HEART) structures PSF considerations for the analyst who uses these to modify basic error probabilities. It assumes that human reliability is dependent on the generic nature of the task and that the level of reliability will be consistent (given a likelihood within probabilistic limits) under 'perfect' conditions. The reliability can be varied for non-perfect conditions using Error Producing Conditions (EPCs).

Kirwan (1996) lists the key elements of the HEART process as:

- Classify a task into one of the generic categories;
- Assign a nominal HEP to the task;
- Determine which Error Producing Conditions (EPCs: effectively PSFs) may affect task reliability;
- Determine the Assessed Proportion Of Affect (APOA) for each EPC;
- Calculate the task HEP.

Eight generic categories are provided within HEART and are related to the level of familiarity an operator has with the task as well as the task complexity/difficulty. Each generic category has a nominal human unreliability score associated with it. EPCs are listed within the tool, each with an associated multiplier to be applied to the unreliability score; however, the analyst must use their judgment to decide how much of a negative effect each EPC has on the task and calculate appropriately.

2.3 *SPAR-H*

The Simplified Plant Analysis Risk Human Reliability Assessment (SPAR-H) was developed in 1999 from a previous method (ASP/SPAR). This

method classifies tasks as either action tasks or diagnosis tasks and assigns a generic error rate based on this. Potential benefit or detriment is included through eight PSFs:

- Available time;
- Stress and stressors;
- Experience and training;
- Complexity;
- Ergonomics (and HMI);
- Procedures;
- Fitness for duty;
- Work process.

2.4 *ATHEANA*

A Technique for Human Event ANAlysis (ATHEANA) was developed by the nuclear industry due to a perceived need for a human error analysis tool that more closely modeled actual operational events and which put a stronger focus on contextual factors. The quantification is based around three calculations. First, calculating the probability of an 'Error Forcing Condition' (EFC; i.e. the probability that the plant will be in a state which may induce an error). This is determined by a combination of plant conditions and PSFs. Second, the probability of an Unsafe Action (UA). And third, the probability of not recovering from the initial UA. This third area incorporates the possibility of alarms and/or feedback to the operator allowing them to correct the UA.

Key steps in the process are:

- Integration of the issues of concern into the ATHEANA HRA/PRA perspective;
- Identification of human failure events and unsafe actions that are relevant to the issue of concern;
- For each human failure event or unsafe action, identification of (through a structured and controlled approach) the reasons why such events occur (i.e. elements of an EFC—plant conditions and performance shaping factors);
- Quantification of the EFCs and the probability of each unsafe action, given its context;
- Evaluation of the results of the analysis in terms of the issue for which the analysis was performed.

EPCs are identified using structured search schemes regarding plant conditions and rules and error types.

2.5 *CREAM*

The Cognitive Reliability Error Analysis Method (CREAM) is a second-generation error analysis method developed by Hollnagel (1998) which can be used both predictively and retrospectively. The technique involves identifying the importance of human performance in a given context and application of a cognitive model. In contrast to other techniques, CREAM focuses the analysis on the context of the task rather than the task itself.

Four basic control modes are represented within the cognitive model taken from Hollnagel's Contextual Control Model (COCOM), and the reliability is generated from these:

- Scrambled control: the choice of the forthcoming action is unpredictable or haphazard. The situation in question may be portraying rapid alterations in unexpected ways thus eliminating the operator's ability or opportunity to make deductions about the next action required;
- Opportunistic control: the next action is determined by superficial characteristics of the situation, possibly through habit or similarity matching. The situation is characterised by lack of planning and this may possibly be due to the lack of available time;
- Tactical control: performance typically follows planned procedures while some ad hoc deviations are still possible;
- Strategic control: plentiful time is available to consider actions to be taken in the light of wider objectives to be fulfilled and within the given context.

The assessment should commence with the generation of a task analysis to facilitate further analysis. Common Performance Conditions (CPCs) are then used to determine which mode the system is operating under. A count of positive CPCs (improving reliability) against negative CPCs (reducing reliability) for the system under analysis allows the control mode to be determined. If the potential for error is sufficiently low, the analysis may stop at this point, or it may be necessary to continue with a more detailed analysis.

3 ORGANIZATIONAL FACTORS

Direct human factors contributions to accidents and incidents tend to be described as human errors (Reason, 1990). Various factors including biological factors (e.g. age, gender, size, handicaps), physical condition, mental condition, competence, and personality may all contribute to human performance. All of these can be managed to some degree by the organization, and the failure to do so can be regarded as an organizational contribution to an accident.

Organizational factors are those areas under the control of the company management that can contribute to a safer working environment. Organizational factors may not be as readily identified during an accident investigation, as they tend

to require a deeper level of analysis than is always performed following an accident/incident. Leveson (2011) suggests that organizational factors are frequently not identified because traditional accident investigation models stop once an immediate causal event has been identified. Therefore, the factors leading an operator towards an error are not analyzed. Similarly, organizational factors may not be well accounted for in risk assessments where the focus has been on identifying possible human errors. Organizational factors can include management commitment to safety, training, communications, stability of the workforce, supervison and teamwork, among others (Gordon, 1998).

The organizational element of human performance management has often been measured in terms of its safety culture, which Reason (1997) describes as an engine driving an organization towards increasing safety and is composed of

- an informed culture, in which managers have the information needed to manage safety;
- a reporting culture, in which people are prepared to report their errors and near misses;
- a just culture, in which people are encouraged to provide information on genuine errors but willful violations are punished;
- a flexible culture, one which can adapt to meet changing circumstances;
- a learning culture, one which has the ability to analyze and draw the correct conclusions from safety data and act upon it.

The research into safety culture has led to the use of safety climate measurement tools as a Safety Performance Indicator (Guldenmund, 2000) but the results are largely intangible and may not help organizations identify where they need to focus attention in order to improve safety (Sorenson, 2002). The lack of a generally accepted definition for safety culture or safety climate also limits their usefulness as concepts since they do not support a systemic methodology for their measurement (Zhang et al., 2002).

In contrast, organizational factors cover more tangible areas, such as the provision of appropriate training and development of procedures, human factors input to the design of HMI, and appropriate design of job roles. These are often included in HRA techniques as performance shaping factors or error producing conditions. However, there is no comprehensive framework defining organizational factors and their measurement, despite their recognized importance in managing safety.

4 METHOD

This study used the STAMINA model to categorize the performance shaping factors in five HRA tools: HEART, THERP, SPAR-H, CREAM, and ATHEANA. The performance shaping factors were taken from available literature on the five methods (Swain & Guttman, 1983; Gertman et al., 2005; Hollnagel, 1998; Cooper et al., 1996), and in the case of HEART, the railway adaptation by Gibson (2012) was used.

The STAMINA model was supplemented by an 'Environment' category to capture factors relating specifically to the physical environment in which the task is performed. There were therefore five categories for the analysis: Task, Environment, Individual, Team, and Organization. Each PSF (or equivalent) was assessed to determine to which category it should be assigned.

The aim of the study was to understand how the factors influencing human performance within available HRA methods are spread across the five different areas. A review of the literature in the area did not identify any similar studies, and although some studies have highlighted the lack of a standard set of PSFs (e.g. Groth & Mosleh, 2012), the choice of PSFs within HRA tools has largely been unchallenged. This study was designed to give an insight in to possible gaps in the tools available for the analysis of human performance, particularly in terms of recognition of the possible impact of the organization on individuals' safety performance.

5 RESULTS

5.1 *Performance shaping factors*

THERP had the largest set of PSFs across the five tools analyzed, and contained 69 PSFs across three categories of External PSFs, Stressors, and Internal PSFs. Within the external PSFs, situational characteristics such as the environment in which the task is conducted, the work hours and organizational structure were covered. External PSFs also included job and task instructions, and equipment and task characteristics. Stressors were both psychological (e.g. task speed, distractions) and physiological (e.g. fatigue, hunger, radiation). The final category of internal PSFs included training and experience, motivation, and sex differences. SPAR-H contained eight PSFs, including available time, stress/stressors, complexity, experience/training, procedures, ergonomics/HMI, fitness for duty, and work processes. HEART contained 27 Error Producing Conditions (EPCs) across six categories of task design, interface, competence management, procedures, person, and environment. CREAM contained nine Common Performance Conditions (CPCs) including adequacy of organization, working conditions, adequacy of MMI and operational support, availability of procedures/plans, number of simultaneous goals, available

time, time of day, adequacy of training and experience, and crew collaboration quality. CREAM also contains a set of antecedents under the broad categories of person-related, technology-related, and organization-related. However, these are not included in the application of the HRA tool and have not been included in the analysis. Finally, ATHEANA contained nine PSFs of procedures, training, communications, supervision, staffing, human-system interface, organizational factors, stress, and environmental conditions.

5.2 *Analysis*

Figure 1 describes the results of the analysis. In total, 47% of the factors in the five HRA tools related to the specific task being analyzed, 11% to the environment, 17% to the individual, 8% to the team, and 18% to the organization.

There was considerable variation in the tools in terms of the extent to which they addressed different areas of the STAMINA model; however, all tools had a primary focus on the task, with the exception of ATHEANA which had a majority of elements focused on the organization. Environmental factors were also not widely accounted for, despite being a key influencer on task performance, and often under the control of the organization. Team factors also failed to play a major role in many of the tools.

HEART and CREAM featured the largest number of task-related PSFs as a proportion of the total number of PSFs in each tool (59% and 56% respectively). The most common task-related PSFs were procedures and HMI, which appeared in all five HRA tools, and available time appeared in four tools. THERP and HEART had the highest number of PSFs related to the task, as they also had the highest overall number of PSFs. THERP included a number of PSFs related to the requirements of the task, such as memory requirements and decision-making, while HEART featured PSFs relating to conflicting goals.

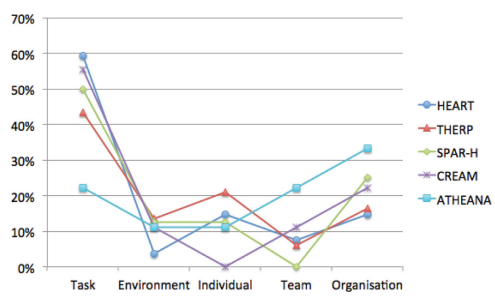

Figure 1. Analysis of the PSF according to the STAMINA model.

All five tools included environmental stressors but apart from THERP, none went in to any detail, i.e. the four remaining HRA tools simply listed environmental conditions as a PSF. THERP provided more specific PSFs including temperature extremes, radiation, oxygen insufficiency, and vibration. However, THERP did not cover less extreme environmental conditions such as lighting levels, glare, and noise.

HEART and THERP featured a higher number of individual related factors as compared to the other tools. SPAR-H simply included a broad 'fitness for duty' PSF while ATHEANA listed 'Stress'; CREAM did not feature any individual related factors. HEART and THERP both covered factors relating to individual experience and previous training, emotional stress, and physical condition. THERP was the most comprehensive, also including factors relating to fatigue, pain, motivation, attitudes, and sex differences.

Team related factors was the smallest group, with only nine PSFs appearing across all five tools and SPAR-H did not contain any team factors. Quality of communications was the most common team factor, featuring in three of the tools. There was no agreement between the tools across the remaining six factors classified as team related. These covered actions by others, team structure, group identifications (THERP), crew collaboration (HEART), and supervision (ATHEANA).

The proportion of organizational factors represented in the five tools ranged from 15% (HEART) to 33% (ATHEANA). There was considerable variation in the factors covered within the organizational category. Experience and training provided by the organization appeared in three tools, organizational structure/role design, fatigue management, staffing, and work processes/policies all appeared in two tools. Both CREAM and ATHEANA had a generic PSF of 'Organization' while THERP included a number of more specific factors related to reinforcement of behaviors.

6 DISCUSSION

The analysis of the results found that, as expected, there is a stronger focus on task and individual factors than on team and organizational. The strong focus on the task element within all five HRA tools is to be expected, since HRA is typically used to analyze the probability of failure of a particular task. However, the focus of the HRA tools is not compatible with the acknowledged role of organizational factors in major accidents.

The role of human error in safety analysis is increasingly considered outdated and unhelpful in creating a cooperative socio-technical system.

New methods for assessing events, such as the Event Risk Classification (ERC) element of the ARMS methodology (ARMS, 2010) have moved towards a focus on effectiveness of the preventative and recovery barriers in relation to an undesirable event. This helps focus the organization on the positive measures it can take to promote safety. A similar concept is needed to support human performance through the identification, measurement and management of the relevant organizational factors.

Existing safety culture surveys provide organizations with information on how mature they are in terms of safety, but the elements measured are largely intangible and provide organizations with the knowledge that they need to improve, but not necessarily what and how they should improve. A tool developed to allow an organization to analyze its strengths and weaknesses in terms of supporting human performance could help the organization focus on tangible areas for improvement. This could be achieved either through the strengthening of the role of organizational factors within the existing HRA paradigm, or through the creation of a new approach with a stronger focus on the organization. The development of a tool in this area would also serve to provide more support for the critical task of control measure identification within existing HRA approaches.

Task factors, are by nature, very variable and can be difficult to identify and quantify, particularly early on in the design of a new system. In contrast, organizational factors are more stable and are by definition, within the control of the organization. Our suggestion is that more can be achieved by focusing efforts on improving organizational factors to support human performance. To achieve this, the set of organizational factors will need to be expanded to include those that will directly influence the task, environment, individual and team factors. Examples of this might be the existence of a standard within the organization for an ergonomic review of the environment and equipment, explicit role design and function allocation, selection and recruitment activities explicitly related to the job requirements, and an assessment of the quality of procedures design rather than the quality of the individual procedures related to a particular task.

7 CONCLUSION

Hollnagel et al. (2013) in a white paper for the air traffic control industry suggest that the focus should be moved from viewing human activities in a system as a liability or hazard to recognizing that human activity is an intrinsic part of the system and is subject to variability. Supporting human performance enables a system to become more flexible and resilient, and development of better tools and measures for managing and controlling organizational factors will be critical for supporting human performance.

The study reported here has shown that the traditional HRA factors do take account of some organizational factors, but these are relatively limited in comparison to the task factors. The next steps for this research will be to draw together a coherent framework of tangible organizational factors that will help organizations assess their strengths and weaknesses in terms of supporting human performance. A tool based on this framework could facilitate organizations in continuously improving safety.

Design methods of reducing human error in practice

M. Butlewski, M. Jasiulewicz-Kaczmarek, A. Misztal & M. Sławińska
Chair of Ergonomics and Quality Management, Poznan University of Technology, Poznań, Poland

ABSTRACT: Optimization of reliability in work systems and the often complex, technical objects contained within them, results in a large elimination of technical faults. But due to the significant role played by the human in causing damage, enforcing limitations to manage only the technical components of the system will not bring about the desired effect. Depending on the type of industry, the human factor is recognized as the cause of up to 80% of failures. This means that the human more or less directly contributes to a significant part of the failures. In order to reduce this problem there are many different methods and approaches that are used for obtaining the fallibility of the human—technical system operator at a sufficiently low level. The following article analyzes the construction methods for assessing and reducing human error and analyzes their scope of application, together with some practical examples. As a method to solve the problem, comparison of methods was done together with an analysis of their applicability and event models. As a result of the work it was found that in practical applications the best results in terms of reduction in the number of undesirable events were achieved with the application of selected methods. A comparison of the causes of undesired actions allowed to determine the most common problems for example: rule violations and mistakes, a lack of knowledge, and omission. The most common remedial measure for human error in the field of simple production situations was workers' awareness. The proposed method consists of the measurement of the relationship between symptoms, phase of the human error, and means of preventing that error under specified organizational and technical conditions.

1 INTRODUCTION

The issue of human error has for many years constituted the subject of scientific research and practical activities. In view of the improvement of production methods and a general increase in quality, naturally human error became the object of an even greater interest, since it has an impact in a greater degree than ever before on the efficiency of production systems and safety during use of machinery and equipment.

The research on the problem of human error can be differentiated based on the approach to the problem of error, and more specifically its elementary character. For researchers related to ergonomics, human error is in first order the result of a specific sequence of events and not the cause. This assumption allows on the one hand to disclose the diversity of the character of human error, while on the other hand allows for its increased elimination. Applying ergonomic design properly oriented to human error, one can obtain much more reliable anthropometric systems (Hankiewicz 2012).

2 SPECIFICS OF THE HUMAN ERROR PHENOMENON

Human error is a concept so well-known worldwide that it is often cited but not actually defined. It should be noted that this term is understood as an action that is not intended; not desired by a set of rules or an external observer; or that led the task or system outside its acceptable limits (Senders & Moray 1991). Human error is not connected with the accident, and thus the result, because it is independent (the same error in other circumstances may lead to different results) and can be simultaneously the result of other circumstances causing the error. However, very often it is considered from the point of view of an accident, due to the fact that it is only after the accident that an analysis is performed which reveals the existence of a specific human error. Another limitation of the category of human error is to specify that human error is understood as only such action, which was not purposely intended by the human (and therefore an action done in good faith, not a deliberate violation of the established rules) (Reason 1990).

For this reason, under the category of human error should fall activities such as: failure to perform an action, or a modified performance as a result of inattention, forgetfulness, or misunderstanding the instruction (Wrzesińska 2012).

Most common classification of types of human error is presented in Figure 1.

The classification presented in Figure 1 does not reveal, however, a number of specific causes of human error which have their source in a large part in psychological factors in decision-making (Więcek-Janka 2011) that will eventually take the form of the following causes:

– lack or inadequate procedure
– poor hazard identification
– poor or lack of training
– poor design and lack of ergonomic assessment
– overload, workload
– fatigue, lack of rest, stress at work
– vague or unclear roles and responsibilities
– different distortion

Human error is always one element in a whole sequence of events, the outcome of which determines whether it will be considered serious, and if it will ultimately be classified as an error on the part of the human.

Human error can occur at any of the three basic stages of the operator's work (receiving information, its processing and adequate performance—Fig. 2), and it can always be seen as a lack of balance between the demands of work and human capabilities in the specified function of time. This allows the conclusion that the prevention of human error can be associated with the appropriate control of the above-mentioned balance by adapting it to the level of the expected interference (Fig. 3).

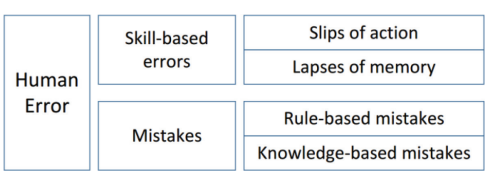

Figure 1. Human error classification (HSG48).

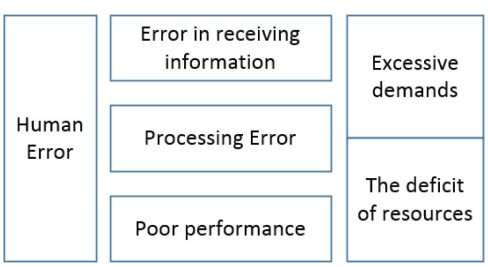

Figure 2. Human error root cause (own preparation).

The scheme of the formation of human error arising from external causes is presented (Fig. 3). Based on the presented scheme, one can conclude that reducing error can be achieved by reducing the impact of distractions from the material environment as well as the technical and organizational factors of distraction. Among the factors of the material environment can be mentioned such factors as noise, vibration, lighting, and microclimate. In contrast, technical and organizational distractions include factors such as the pace of work, organization, supervision, etc. The use of the cybernetic scheme human-technical object thus provides significant opportunities to reduce human error by identifying the different categories of distracters. Moreover, based on the presented model (Fig. 3) it can be seen that the last step (performance) is critical in the absence of security for unintentional action, because there are no following steps in which to correct the error. This also raises another solution for methods of reducing human error—reserving, which despite its costliness brings about the best results. Considering the chain of events would indicate the diverse possibility of solutions identifying the error in an specified phase. It would therefore be more indicative of determinants its creation and based on them determine its probability. The specified level of probability should activate further levels of precautions. Finally, it should also be noted that an important function in controlling the possibility of human error is the magnitude of the impact in the event of its occurrence, which is a stimulus whose effect depends again on the balance between individual ability and the strength of the stressor.

The next and very important group of factors includes the psychological basis of committing errors such as: long-term ability to comply with the rules, the perception of risk, resistance to stress, locus of control, and social patterns. At the macro-social level, determinants of psychological error will also be factors such as the ability

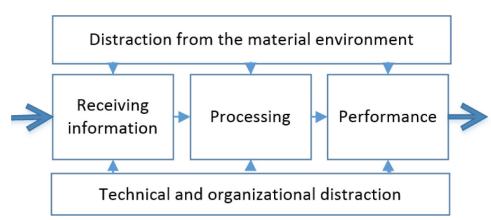

Figure 3. External human error scheme (based on Tytyk 2001).

to work in groups, taking on a specific role, and competitiveness.

To sum up, it should be noted that only some of the issues cited in the field of human error indicate the applicability of ergonomic models to know its character. Due to the limited capacity of this publication as well as the fairly extensive literature on this topic, and also the fairly obvious relationships between variables, the issue will not be considered to a greater extent when describing the practical methods of reducing human error, except for design proceedings targeted to human infallibility.

3 METHODS, FACTORS, AND INDICATORS OF PREDICTION OF HUMAN ERROR

Connected with the concept of human error are mainly those situations where there is a large responsibility for the committed error. This increased responsibility is particularly true in the case of operating work (operators of vehicles and machines) (Butlewski & Sławińska 2014). To the most commonly used in calculations indicators of reliability of the human-operator are included the following four quantitative indicators: infallibility, preparedness, restitution and timeliness. Indicator of infallibility is the probability of flawless operation of the operator, which can be determined with respect to the distinguished operation and the entire algorithm of actions. This ratio is expressed by the following formula (Sławińska 2011)

$$P_j = (N_j - n_j)/N_j, \tag{1}$$

where:

P_j—probability of flawless execution of operations;

N_j—total number of operations performed;

n_j—number of errors.

Indicator of preparedness of the operator is the probability that the operator will join operations at any time (Sławińska 2011).

$$K = 1 - (T_0/T), \tag{2}$$

where:

K—preparedness indicator;

T_0—operator's "time off," operator's absence in a given period at a given workstation;

T—total work time of the operator.

Indicator of restitution relates to the possibility of self-assessment by the operator and making adjustments in own actions. This indicator expresses the probability of correcting errors committed by the operator (Sławińska 2011).

$$P_{pop} = P_k \cdot P_{wyk} \cdot P_p, \tag{3}$$

where:

P_{pop}—probability the operator will act after the appearance of an error with the aim of correction;

P_k—probability of sending a signal from the control device;

P_p—probability of correcting erroneous operations during repeated performance of the task;

P_{wyk}—probability of correctly performing the task.

Indicator of timeliness (time adequacy of the operator's actions) is introduced due to the fact that actions that are correct but taken at the wrong time, do not lead to the goal. It expresses the probability of execution of the tasks in time (Sławińska 2011).

$$P_a = P\{\tau < t_1\} = \int_0^{t_1} f(\tau) d\tau \tag{4}$$

where:

P_a—probability of timeliness;

$f(\tau)$—function of time distribution of execution

t_1 constant value

In summary, human reliability indicators are based on the creation of a particular probability of leaving the operator and the factors which influence him/her in terms of a function of time. It can therefore be noted that for this reason they are based on the theory of homeostasis, which contains both the appropriate conditions and the appropriate resistance to interference.

4 DESIGN METHODS DIRECTED AT LIMITING HUMAN ERROR

The nature of the problem of human error caused a broad interest from scientists from different disciplines, which allowed the development of a range of methodological approaches. Here should be distinguished the trend of cognitive psychology which allows the identification of factors responsible for specific human activity (Fedota & Parasuraman 2010). In this framework, examined are the circumstances of making wrong decisions and the factors that encourage this, for which is used for example the Stroop test (Stroop 1935). These studies have a cognitive character and contribute to the development of guidelines for anthropotechnical systems that limit errors. Another group of methods of a cognitive character are methods of investigating both errors and failures (McBride et al. 2013). These methods are used to determine the causes of accidents in real operating conditions, after their occurrence. In turn, simulations are used to model the circumstances of human error

and to determine the scale of the consequences. All of these methods are the basis for the development of management methods to allow for the reduction of human error, from which a particular interest is put on ergonomic methods. They have a meta-method character, which form a combination of methods of action in terms of a number of factors. Due to the methodical difficulty of disconnecting them from the others they have been reported in the next chapter of this publication. It must therefore be noted that ergonomic predictors of human error lead to the conclusion that all efforts to improve the ergonomic quality of work lead to the reduction of exposure to man-made errors in the humanocentric system (Jasiulewicz-Kaczmarek 2009). This statement is, however, despite its accuracy unsuitable because of its excessive generality. It is therefore necessary to define that for ergonomic methods of reducing human error we will consider these approaches, which will be directed at reducing the vulnerability of the human-operator to make mistakes, by identification and limitation of the factor responsible to the greatest extent for the mistake.

More precise measures and calculations of ways to reduce human error arise when one points to five basic ways of reducing error (Kariuki & Lowe 2007):

- Training—48%
- Procedures—20%
- Supervision—13%
- Displays—13%
- Skills and knowledge—6%

Percentages given indicate the involvement of a particular method in preventing human errors.

However, there is concern that the prediction error of the method that is burdened with an error in the classification of the cause. Relative weights of factors affecting a human error event may also vary depending on the conditions in which the error is considered.

Human fallibility may be limited, but these are costly actions that must be justified as a specific economic result. These approaches can be divided into specialized, taking into account only the specific situation, and universal, which are methodologies that relatively quickly are used in the following areas of human functioning such as poka yoke, which as a design approach has been adapted to management activities (Pakdil et al. 2009). Methods of design are also developed that cause manufactured items to be more resistant to interference, including by limiting the human impact on the efficiency of the manufacturing system (Mrugalska 2013). Design methods can also be divided due to the site of action in the event of an error sequence. With the growth of computer technology there is a clear shift of techniques from the limiting of the effects of error to detection and limiting of the causes. An example of such an approach can be found in the automobile industry which after implementing systems limiting the effects of error (safety belts, airbags) began to increasingly develop driver anomalous behavior detection systems. Examples of such systems are: Driver Alert Control (DAC), which prevents drivers from falling asleep while driving, Lane Departure Warning (LDW) which oversees that the vehicle stays on an adequate track, and Collision Warning system, which consists of a set of radars registering the appearance of obstacles in the vehicle's path, warning of a possible collision, and in critical cases capable of activating the automobile's brakes (Menes 2011).

In the case of the more general situation, when there is no known mechanism of error, one should follow the procedure of specifying the circumstances of error and allowing to implement mitigation methodologies. We can mention here such methods as:

- HAZOP—human error hazard and operability study (Swann & Preston 1995)
- HEART—human error assessment and reduction technique (Kirwan 1996)
- HEIST—human error identification in systems tool (Kirwan 1994)
- HET—human error template (Stanton et al. 2006)
- HERCA—human error root cause analyses (Ławniczak et al. 2014)
- HRA—human reliability assessment
- THEA—technique for human error assessment early in design (Pocock et al. 2000)
- THERP—technique for human error rate prediction (Swain & Guttmann 1983)
- SHERPA—systematic human error reduction and prediction (Baber & Stanton 1996)

Many methods of reducing human error are also based on the determination of whether human error actually occurred. Therefore, among these methods are included fault tree analysis and MORT event analysis.

An analysis of methods allows one to focus the method of action to the following activities (modules):

- human error identification (determination of what can go wrong?, taxonomy of errors)
- human error quantification (an estimate of how often a human error will occur?)
- human error or its impact reduction (determination of how human error can be pre-vented from reoccurring or its impact on the system be reduced?).

Many methods are an improvement over the previous ones taking into account certain factors or extending the scope of the analyzed reality. For this reason, the use of only one method does not allow for a complete picture, and the selection of methods should be preceded by an in-depth analysis.

5 CASE STUDIES—SOME PRACTICAL EXAMPLES

As a basis for the analysis of human error, utilized are illustrative examples of accidents at work, in which the direct or indirect cause was human error. The cause was adopted from the findings of the post-accident teams which determine the cause of the accidents. As part of the identification of the causes of human error, used were SHERPA and HERCA classification methods.

As the examples show, every human error is the result of at least several factors, the combination of which results in an adverse effect. All cases point to an additional factor—failure to follow instructions and the accepted principles of operation.

On the basis of event analysis using a variety of methods it is indicated that the classification offered by them can be used for both analytical and design goals. Although one can point to direct evidence for errors in design when looking at the operator's error, a significant part of the responsibility is on the side of the operator, his/her training and the attitude to compliance with the rules.

Human error is therefore not the reason, but the effect of specific circumstances under which is an user. Still the deficit of specified human resources is a factor of the error. This deficit can be attention, ability to make decisions under stress or performance, regardless of the degree to assess whether he was the reason the chain of events.

The use of different methods for the study of human error, not used for the purpose of design, can bring a benefit in the form of a greater visibility of the range of possible preventive measures. Still, a big problem are situations arising from multiple causes, especially in non-standard cases—such as emergencies (Bajda et al. 2011), which are the biggest source of accidents caused by human error.

In the presence of insufficient resources describing human error, it seems advisable to apply a combination of factors not only describing the categories of human error but also the way of its limitation (Fig. 4). Such an approach would allow for the development of groups of symptoms that would describe the probability of the occurrence of a specific human error. The model structure allows to determine the strength with which a particular factor affects the other categories (spatial arrangement of cube), at the same time not pointing at single factor dependencies, which in reality de facto do not exist. Identification of human error in the proposed system could be based on the estimation of the relationship between deficits in the field of cube walls in combination with deficits of the environment—the ambient of the cube. This combination may in the future allow the prediction of human errors before they occur.

Table 1. Human error causes comparison (own elaboration on the basis of www.poznan.oip.pl).

No.	Cause according to national labor inspectorate	SHERPA behavior taxonomy	HERCA cause
1	Improper work methods applied by the victim, involving the improper hand position during machining of the object, at the level of the knife shaft, and omitting checking the device	Action: omitted	Forgetfulness and inattention
2	Operator used the wrong equipment for the particular part of the depot	Action: right action, wrong object	Attitude and behavior
3	Operator was not careful while driving under the roof of the depot with a raised load	Action: omitted	Behavior: error caused by lack of attention
4	Improper application of equipment, lack of coordination	Action: wrong action, right object	Forgetfulness and inattention

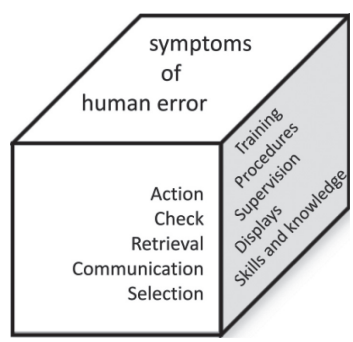

Figure 4. Human error cube.

6 CONCLUSION

Design with an increased resistance to human error will increasingly translate to the success of manufacturing complicated technical objects. It is enough to imagine a car incapable of having an accident or a completely safe machine. Achieving this goal requires a transition to the next level ergonomic quality, which will have a dynamic character and be responsive to the currently existing methods of prevention and thus static methods. Dynamic methods allow for the anticipation of an error made by a human, which will allow avoiding the substantial consequences in accordance with the principle that prevention is better than treatment.

A hierarchical framework for the measurement of maintenance efficacy and efficiency using performance indicators

G.M. Galante, R. Inghilleri & C.M. La Fata
Dipartimento di Ingegneria Chimica, Gestionale, Informatica, Meccanica (DICGIM), Università degli Studi di Palermo, Palermo, Italy

ABSTRACT: Maintenance plays an important role in achieving the organizational goals so that the measurement of its effectiveness and efficiency has become an essential element of industrial strategy. In literature several Maintenance Key Performance Indicators (MKPIs) are proposed but none structured approach is suggested to select the best set of MKPIs able to synthetically describe a specific maintenance context. The paper proposes a structured methodology for the maintenance performance measurement by means of MKPIs. Firstly, a multi-level hierarchical framework able to synthesize the most meaningful perspectives affecting the performance of the maintenance process is designed. Successively, some MKPIs proposed in the literature are assigned to the hierarchical framework and ranked by an Analytic Hierarchy Process-based approach. A procedure to deal with incomplete and inconsistent pair-wise comparison matrices is proposed. Finally, a mathematical model is formulated to select the set of MKPIs representing the best compromise between the completeness and the conciseness of the returned information.

1 INTRODUCTION

Nowadays, maintenance is more and more considered as an important support function in business with significant investments in physical assets and plays an important role in achieving the organizational goals (Tsang 2002). As a consequence, the measurement of the maintenance performance has become an essential element of strategic thinking of asset owners and managers to be utilized for identifying business processes, areas and departments that need to be improved to achieve the organizational goals (Parida 2006). Over the last two decades, a large number of performance measurement frameworks has been suggested as regards the evaluation of the overall organizational performance. To the contrary, the area of maintenance performance and management is still in need of more future systematic research efforts (Simões et al. 2011). Nowadays, literature on Maintenance Performance Measurement (MPM) models and Maintenance Key Performance Indicators (MKPIs) principally lacks on two aspects. Firstly, proposed MPM frameworks are generic, without considering the business specific environment of the company where these tools should be applied in. Secondly, the available literature mainly proposes a huge list of MKPIs but lacks an agreed-upon methodological approach for selecting specific MKPIs from the listed indicators. With this recognition, the present paper aims at proposing a structured methodology for the maintenance performance measurement by means of a restricted and comprehensive list of MKPIs. The organizational context which the present paper is focused on is that of a high risk process plant where the way maintenance is managed and performed is fundamental to prevent the occurrence of hazardous events. The whole methodology has been designed and implemented in cooperation with the maintenance staff of a refinery plant in order to allow to the maintenance manager to measure, check and communicate the maintenance process performance on the base of different perspectives. The methodology consists of several steps. Firstly, a *customized hierarchical framework* capable of synthesizing the most meaningful aspects affecting the effectiveness and the efficiency of the maintenance process is designed. The stakeholder of the hierarchical framework is the company's maintenance manager that needs to communicate the maintenance process results to both the top management and the maintenance technicians. As a consequence, the hierarchical framework is thought in such a way to incorporate all those perspectives that the maintenance manager deems to be fundamental in order to *vertically* communicate and eventually improve the maintenance performance. It consists of multiple levels so that information returned by each level provide a greater detail on a particular aspect of the immediately higher one. Successively, MKPIs already proposed in the technical and scientific literature are

collected in order to obtain a comprehensive list of MKPIs. Among them, indicators deemed to be the most appropriate to describe the specific maintenance process are selected and then assigned to the hierarchical framework. Then, an Analytic Hierarchy Process (AHP)-based approach (Saaty 1994) is proposed to rank the assigned MKPIs. In particular, the decision maker is asked to supply just pair-wise comparison judgments on which he/she is confident. Namely, incomplete pair-wise comparison matrices could be supplied and then need to be opportunely handled. Finally, a mathematical programming model is formulated and solved in order to select the *optimal set* of MKPIs by means of which measuring the maintenance performance. Actually, managing a large number of MKPIs can be counterproductive in terms of lack of conciseness of the returned information. In addition, calculating a large number of MKPIs requires a considerable effort in terms of input data to be recorded. As a consequence, MKPIs to be used need to be carefully selected among those assigned so that if on the one hand they synthesize the needed information in the best possible way, on the other hand their number is not too large.

The paper is organized as follows. The literature review is supplied in Section 2. The whole methodology is synthesized in Section 3, the classical AHP method is presented in Section 4, whereas its application to the maintenance performance measurement problem is detailed in Section 5. The mathematical model is reported in Section 6. A case study is reported in Section 7 and conclusions finally drawn in Section 8.

2 LITERATURE REVIEW

The most widely used business performance model is the Balanced SCorecard (BSC) of Kaplan & Norton (1996). The classical BSC model has been also used for the maintenance performance measurement (Visser & Pretorius 2003) but the feasibility of its application for managing the performance of a specific function, as maintenance, is still an uncharted area which needs researching (Tsang et al. 1999). In fact, the classical BSC model is not able to capture all facets of the maintenance function because of the several interrelationships between the maintenance and the other organizational functions. As a consequence, several contributions have been proposed aiming at adapting the BSC to the maintenance performance measurement problem (Mather 2005, Alsyouf 2006, Bakhtiar et al. 2009, Wireman 1998). Nevertheless, to the authors opinion the BSC model is not easily understandable by the maintenance staff. Furthermore, each organization is unique in its structure, function and business position so that a performance measurement framework may be suitable for one organization and may not be suitable for another one. With this recognition, a maintenance performance measurement model should be focused on the specific organizational context so that critical (key) factors influencing the overall maintenance effectiveness and efficiency are identified.

The common way of measuring the performance of key factors is that of making use of indicators. As regards the maintenance function, numerous MKPIs have been already defined in the scientific and technical literature principally with relation to the manufacturing sector (EN:15341 2007). In addition, several contributions have been proposed over the last few years as regards the problem of ranking *a priori* defined set of KPIs in order to evaluate the overall organizational performance (Wua et al. 2009). To the contrary, few contributions exist with relation to the ranking of MKPIs. Amodeo (2005) starts from the BSC concept to define the fundamental aspects (pillars) upon which the overall maintenance operation rests. From these basic pillars, a hierarchical decomposition is proposed in order to arrive to the lowest measurable function, whereby obtaining the fundamental attributes to be used to manage the general goal. A conceptual framework that provides a guideline for choosing maintenance performance indicators is developed by Muchiri et al. (2011). Authors emphasize that further research work is recommended on the methodological approach of choosing the right MKPIs among the given indicators listed in literature. Van Horenbeek & Pintelon (2014) develop a generic hierarchical framework which is based on the corporate and maintenance strategy and incorporates all organizational levels (i.e. strategic, tactical and operational). Then, authors suggest an ANP-based method to customize the proposed framework.

3 PROPOSED METHODOLOGY

A structured methodology for the measurement of the maintenance process performance by means of a restricted number of MKPIs is here proposed. It comprises the following steps:

1. Definition of a *customized* hierarchical framework able to synthesize all those aspects that affect the maintenance performance of the specific organization.
2. Collection of MKPIs already proposed in the scientific and technical literature.
3. Selection of MKPIs deemed to be the most appropriate to be used in the specific organizational context.

4. Assignment of selected MKPIs to each aspect of the hierarchical framework.
5. Application of the AHP-based approach to rank the assigned MKPIs.
6. Formulation of a mathematical programming model to identify the optimal set of MKPIs among those assigned that represents the best compromise between the conciseness and the completeness of the returned information.

3.1 *Definition of the customized hierarchical framework*

The hereafter presented hierarchical framework (Fig. 1) takes into account the way maintenance process is performed within the organization and has been designed in cooperation with the subject company maintenance staff. It comprises more levels and *nodes*. Each node represents a particular aspect on the base of which measuring the maintenance performance and, whenever deemed to be necessary, it is further branched in order to detail the considered aspect. In such a way, the highest level nodes are representative of more generic aspects of maintenance and return information potentially of interest to the company's top management. To the contrary, the lower level nodes are more detailed and specific so that returned information are mainly addressed to maintenance technicians. The proposed hierarchical framework is explained in the following.

The first level (i.e. the level zero) represents the goal, namely the *measurement of the maintenance process performance*. The next level (i.e. the level 1) comprises all those aspects deemed to be critical in terms of their influence on maintenance effectiveness and efficiency. Particularly, the following five aspects are considered at the first level of the hierarchical framework:

1. Technical (node 1). It aims at highlighting the influence on plant reliability and availability of *how* maintenance actions are performed within the organization.
2. Economical (node 2). It aims at giving evidence to the economical aspects of maintenance (maintenance efficiency), from the budgeting to the expenditure phase.
3. Organizational (node 3). It regards the way maintenance activities are planned, scheduled and carried out. In addition, it includes all those issues related to the management and training of maintenance personnel.
4. Health, Safety and Environment (HSE) (node 4). It highlights the impact of maintenance actions on the health and safety of inner and outer maintenance personnel, as well as on the environment.
5. Warehousing (node 5). It aims at describing the efficacy and the efficiency of the maintenance spare parts management.

Successively, each one of the level-1 nodes is further branched in order to detail the expected information. Referring to the Technical node (node 1), it is branched into the Reliability (node 1.1) and the Availability (node 1.2) nodes. Actually, reliability and availability are two different and common measures relating to the maintenance process effectiveness. The node Availability (node 1.2) is further branched into the nodes Corrective Maintenance (node 1.2.1), Preventive Maintenance (node 1.2.2) and General (node 1.2.3). Namely, the attention is firstly focused on the two main maintenance policies performed in the plant in order to detail how the way they are carried out affects the plant's availability. The General node aims at including the measures describing general aspects that do not regard a particular maintenance policy. The Economical node (node 2) is branched into the Corrective Maintenance (node 2.1), Preventive Maintenance (node 2.2) and General (node 2.3) nodes. Nodes 2.1 and 2.2 aim at focusing the attention on the efficiency of corrective and preventive maintenance actions, whereas the node 2.3 returns information on the whole maintenance process efficiency disregarding the type of maintenance policy. The Organizational node (node 3) firstly includes an aspect (node 3.1) related to the maintenance actions planning, scheduling and execution in order to highlight if maintenance work is opportunely planned, scheduled and carried out on-time.

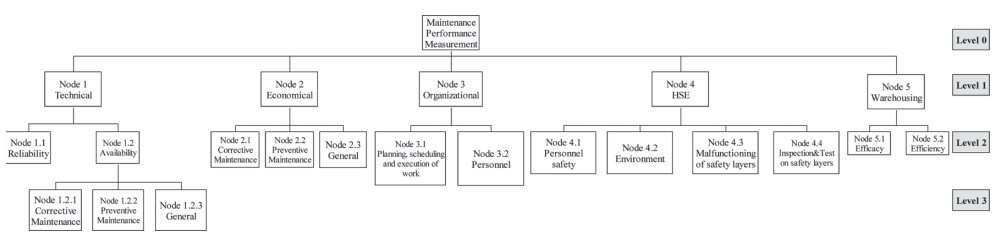

Figure 1. Hierarchical framework.

Secondly, the node Personnel (node 3.2) relates to *what* the organization makes for the maintenance personnel improvement by the training activities. The HSE node (node 4) involves an aspect related to the safety of inner and outer maintenance personnel (node 4.1), and a further node (node 4.2) that focuses the attention on the environmental impact of the maintenance process. In addition, taking into account the particular organizational context, two further aspects are detailed. The first one (node 4.3) concerns the failure due to a wrong maintenance on safety barriers installed to prevent the occurrence of hazardous situations or to mitigate the related consequences. The second one (node 4.4) aims at highlighting the correct execution of inspection activities on such safety barriers. Finally, the node Warehousing (node 5) concerns the management of maintenance spare parts both on the effectiveness and efficiency point of view.

3.2 *Maintenance Key Performance Indicators (MKPIs) collection and assignment*

A specific function as the maintenance one requires specific indicators to measure its performance. Scientific and technical contributions propose a huge number of MKPIs, even if the main part of them relates to manufacturing industries. Aiming at measuring the influence of each specific aspect of the designed hierarchical framework on the whole maintenance process performance, MKPIs already proposed in the literature have been collected and analyzed in cooperation with the subject company maintenance staff. Therefore, the significance of each MKPI has been evaluated in terms of its applicability to the particular organizational context as well as in terms of its easiness of comprehension and importance to describe a specific aspect. Among those collected, just those indicators deemed to be useful to describe the maintenance process have been selected and then opportunely assigned by a top-down procedure. A total number of 116 MKPIs has been collected from the existing literature. Among them, 58 MKPIs have been selected and assigned to the lowest level nodes of the hierarchical framework. The next step of the designed methodology consists in ranking such MKPIs on the basis of their capability in measuring the maintenance process performance. The AHP-based approach here proposed is detailed in Section 5, whereas the classical AHP method is synthesized in the following Section 4.

4 ANALYTIC HIERARCHY PROCESS (AHP)

Proposed by Saaty in the late of 70's, the AHP is a multi-criteria decision making method that supports the decision maker in the evaluation and selection of alternatives through the use of pair-wise comparison judgments. It comprises the following five steps:

1. Problem decomposition. It comprises the individuation of the goal (i.e. the decisional problem to be solved), of the criteria/sub-criteria on the base of which evaluating alternatives, and of the alternatives to be ranked in respect to the goal, eventually to select the best one.
2. Expression of pair-wise comparison judgments with relation to each pair of elements belonging to the same hierarchical level in respect to the immediately higher element. Evaluations are expressed through the use of appropriate semantic scales. The most used one is that proposed by Saaty (2008).
3. If n is the number of items (criteria, sub-criteria or alternatives) to be compared with relation to a specific element of the immediately higher level, the total number of judgments required to the decision maker is $[n \cdot (n - 1)/2]$. Each pair-wise comparison judgment constitutes the element a_{ij} of the so-called reciprocal pair-wise comparisons matrix.
4. Local priorities computation. The local priority (or relative importance) that each element of the hierarchical structure takes in respect to the immediately higher level is calculated by one of the techniques proposed in the literature. Among them, the most used one is the eigenvector method (Saaty 1977).
5. Consistency evaluation. As stated by Saaty, local priorities make sense only if arising from consistent or near consistent matrices. As a consequence, a consistency check on opinions expressed by the decision maker needs to be performed. Saaty proposed a Consistency Index (CI) calculated as follows (1):

$$\mathrm{CI} = \frac{\lambda_{max} - n}{n - 1} \tag{1}$$

where n is the size of the pair-wise comparison matrix and λ_{max} is the corresponding maximum eigenvalue. Then, the Consistency Ratio (CR) is given by the following expression (2):

$$\mathrm{CR} = \frac{\mathrm{CI}}{\mathrm{RI}} \tag{2}$$

where RI is the random index calculated by Saaty (Saaty 1977) as the mean value of the CIs of 500 randomly filled matrices of the same size. If CR is less than 0.1, then the matrix can be considered as acceptably inconsistent. Otherwise, the decision maker is commonly asked to provide

again his/her own judgments until an acceptably inconsistent pair-wise matrix is obtained.
6. Global priority computation. It consists in synthesizing the local priorities across all criteria and sub-criteria in order to determine the global priority of alternatives in respect to the goal. The most used method is the distributive mode that is an additive aggregation with normalization of the sum of local priorities to the unity. Alternatively, the ideal method (Belton & Gear 1983) normalizes by dividing the score of each alternative by the score of the best alternative under each criteria.

5 AHP-BASED APPROACH TO RANK MKPIS

5.1 *Gathering pair-wise comparison judgments from the decision maker*

An AHP-based approach is here proposed to derive the weights of MKPIs assigned to nodes of the hierarchical framework. With relation to the specific organizational context, the decisional problem is the maintenance performance measurement (goal) that is hierarchically structured as previously described in Section 3.1. Alternatives to be evaluated and ranked are the assigned MKPIs. Commonly, the AHP hierarchical structure includes criteria and sub-criteria on the base of which ranking the available alternatives. Instead, the here proposed hierarchical framework comprises those perspectives on the base of which evaluating the maintenance process performance. The AHP can be used to determine their relative importance in respect to the immediately above hierarchical level. For instance, let suppose to compare the Technical aspect (i.e. Node 1) with the Economical one (i.e. Node 2) in respect to the immediately higher level, namely the goal. Then, expressing a pair-wise comparison judgment means answering the question "*how much more or less important the Technical aspect is than the Economical one of the same level in measuring the maintenance performance?*". It is obvious that such a relative importance strictly depends on stakeholders whom the information is addressed to.

In the classical AHP method, alternatives are pair-wise compared on the base of the selected criteria/sub-criteria. Generally, all alternatives can be evaluated on all criteria/sub-criteria. Referring to the specific application, alternatives to be compared are the MKPIs assigned to a specific aspect. Then, for each aspect, the assigned alternatives are pair-wise compared on the basis of their description capability. For instance, let KPI_1 and KPI_2 are two indicators assigned to a generic node not branched. Then, expressing a pair-wise comparison between the KPI_1 and the KPI_2 means answering the question "*how much do you believe the* KPI_1 *better or worst describes the aspect represented in the considered node than the* KPI_2?". However, the decision maker might not have a strong opinion on a comparison judgment so that he/she is not able to express any evaluation. That is particularly true with relation to pair-wise comparison judgments concerning the MKPIs because of a real difficulty of the decision maker to fully appreciate the different description capability. In such a situation, one could alternatively proceed as follows:

1. Forcing the decision maker to express all pair-wise comparisons required by the AHP method.
2. Allowing the decision maker to express only pair-wise comparisons on which he/she is confident and eventually force him/her so that judgments span all elements of the pair-wise comparison matrix.

To the author's opinion, referring to pair-wise comparison judgments among MKPIs, the best way to proceed in the light of the previous considerations is that described at point 2, namely allowing the decision maker to provide from $(n–1)$ to $[n\cdot(n–1)/2]$ judgments that span all elements of the pair-wise comparison matrix. Each evaluation represents the relative capability of MKPIs in describing the aspect they belong to. Whether a pair-wise comparison matrix includes less than $[n\cdot(n–1)/2]$ comparison judgments as here allowed, such a kind of matrix is commonly defined *incomplete*. As a consequence, missing judgments need to be determined in order to continue with the application of the classical steps of the AHP. Several approaches have been proposed in the literature to deal with incomplete pair-wise comparison matrices (Fedrizzi & Giove 2007, Gomez-Ruiz et al. 2010). Such methods determine the missing values so that the matrix inconsistency is minimized. Among them, the most mentioned and applied completion method is the Revised Geometric Mean of Harker (1987) synthesized in the following Section 5.2. As regards the pair-wise comparisons of the aspects needed by the classical AHP for the computation of their relative weights, one believes that the problem of the matrix incompleteness cannot occur. As a consequence, pair-wise comparison matrices concerning the relative importance of each aspect of level i in respect to the aspect of level $(i–1)$ are here assumed to be complete.

5.2 *Revised Geometric Mean (RGM) method*

Let assume the decision maker provides an incomplete pair-wise comparison matrix $\boldsymbol{C}$, which the generic element is c_{ij}. Then, Harker states that

computing the principal eigenvector $\boldsymbol{W}$ of the matrix $\boldsymbol{C}$ coincides with solving the same problem with relation to the quasi-reciprocal matrix $\boldsymbol{A}$ which elements a_{ij} are obtained as follows:

- $a_{ij} = 0$ if c_{ij} is a missing judgment, with $i \neq j$;
- $a_{ij} = c_{ij}$ if c_{ij} is not a missing judgment, with $i \neq j$;
- $a_{ij} = 1 + m_i$ if $i = j$;

where m_i is the number of missing judgments in the row i of the incomplete matrix $\boldsymbol{C}$. Namely, $\boldsymbol{C}$ and $\boldsymbol{A}$ have the same eigenvector $\boldsymbol{W}$, and the relation $\boldsymbol{A} \cdot \boldsymbol{W} = \boldsymbol{C} \cdot \boldsymbol{W}$ holds. Therefore, once decision maker pair-wise comparisons have been collected, all incomplete matrices are here completed by the Harker's method. Then, the methodology continues with the measurement of the inconsistency of all complete (or completed by Harker) matrices, namely the classical consistency check described in Section 4 needs to be performed. Therefore:

1. if the checked matrix is acceptably inconsistent, then local priorities of aspects and MKPIs can be calculated by means of the eigenvector method.
2. if the checked matrix is unacceptably inconsistent, then such an inconsistency needs to be reduced. The common way to proceed is to ask the decision maker to supply again his/her judgments and recalculate the CR of the new pair-wise comparison matrix. The procedure is reiterated aiming at reaching an acceptable consistency. Alternatively, different methods have been proposed in literature to reduce matrices inconsistency. The procedure here used is detailed in the following Section.

5.3 *Consistency improvement of complete matrices*

Several techniques have been proposed in literature to improve the matrix consistency (Obata et al. 1999, Hu et al. 2006). They firstly identify the comparison judgment that results in a greater inconsistency and then suggest a value to replace it. When changes are made, the CR is calculated again and the process is repeated until an acceptable CR is obtained. The method here used to improve the pair-wise comparison matrix consistency is that suggested by Saaty (2003). It uses the following relationship:

$$n \cdot \lambda_{max} - n = \sum_{\substack{i,j=1 \\ i \neq j}}^{n} (\varepsilon_{ij} + \varepsilon_{ij}^{-1}) \tag{3}$$

where λ_{max} is the maximum eigenvalue of the matrix $\boldsymbol{A} = [a_{ij}]$, and ε_{ij} is a generic element of the matrix $\boldsymbol{E}$ determined by the Hadamard product $\boldsymbol{A} = \boldsymbol{W} \cdot \boldsymbol{E}$, being $\boldsymbol{W} = [w_i/w_j]$ the vector of local priorities of the unacceptable inconsistent matrix $\boldsymbol{A}$. Therefore, the matrix $\boldsymbol{E} = [\varepsilon_{ij}]$ is obtained as $\boldsymbol{E} = \boldsymbol{W}^{-1} \cdot \boldsymbol{A}$. The ε_{ij} farthest from one implies the greatest inconsistency arising from a_{ij}. Then, the corresponding a_{ij} and a_{ji} are deleted from the matrix $\boldsymbol{A}$ that is completed by the Harker method. The new eigenvector is calculated and the previous a_{ij} is replaced by the Saaty scale value nearest to the w_i/w_j obtained by the new eigenvector.

If the decision maker has not been able to express all judgments, the procedure here proposed preliminary utilizes the Harker method to complete the pair-wise comparison matrix. Then, aiming at reducing the matrix inconsistency if necessary, the aforementioned ε-method to identify the most inconsistent judgment is employed. In order to replace it, the decision maker is one more time involved to reformulate such a judgment provided that it was originally supplied by the decision maker. To the contrary, namely the judgment found to be the most inconsistent one has not been previously expressed by the decision maker, then it arises from the application of the Harker method. Therefore, at the first iteration of the procedure, it cannot be the most inconsistent one. Instead, during next iterations, even a judgment obtained by Harker could be the most inconsistent one. In such a case, it is erased and the Harker's method applied again. The same procedure is used when the most inconsistent judgment coincides with one of those already reformulated by the decision maker. The described methodology is iterated until an acceptable matrix inconsistency is reached. Summing up, the proposed procedure tries to reduce the matrix inconsistency by involving again the decision maker just on that judgment that he/she was previously able to express if it results to be the most inconsistent one. However, even if reformulated, such a judgment could successively result to be the most inconsistent so that it could be erased. The flow-chart of the whole methodology is synthesized in Figure 2.

Once all pair-wise comparison matrices related to aspects and MKPIs are acceptably inconsistent, the final local priority vectors are obtained. The final step of the AHP-based approach is the computation of the MKPIs global priority vector in respect to the goal. The ideal method mentioned in Section 4 is here applied. The ideal mode is preferred to the distributive one because it avoids that the best MKPI belonging to a more numerous group is disadvantaged in respect to that assigned to a smaller group. Actually, referring to a generic node of the hierarchical framework, using the distributive mode leads to divide the corresponding weight to MKPIs assigned to it. Therefore, the more the number of assigned MKPIs is, the smaller the local

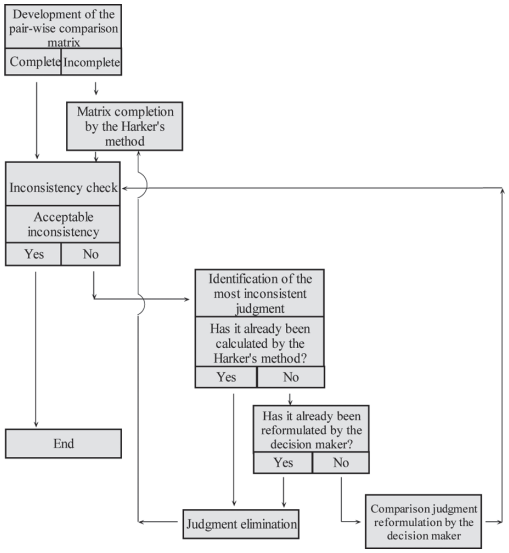

Figure 2. Iterative procedure for the improvement of the pair-wise comparison matrix inconsistency.

priority of each MKPI becomes. However, applying the ideal method leads to global priorities that do not sum to one. As a consequence, if deemed to be necessary, one can renormalize by using a normalization method among them already proposed in the literature.

6 MATHEMATICAL PROGRAMMING MODEL

Once global priorities of MKPIs in respect to the goal are calculated, the problem of choosing the optimal set of MKPIs still holds. Actually, calculating and monitoring over the time more and more MKPIs could result time-consuming in computational terms and amount of input data to be recorded. As a consequence, the optimal set of MKPIs needs to be selected among all those previously assigned to the hierarchical framework and ranked by the AHP-based method. Such a set is asked to be the best compromise between the information completeness and its conciseness. To this purpose, a mathematical model is formulated. The used nomenclature is reported below:

- i generic indicator of the list of MKPIs, with $i = 1, \ldots, N$.
- j generic node of the level 1 of the hierarchical framework, with $j = 1, \ldots, M$.
- g_i global priority of MKPI i arising from the application of AHP-based method.
- p_j local priority of the node j belonging to the level 1 of the hierarchical framework and calculated by the AHP.
- n_{min} minimum number of MKPIs to be selected for each node of level 1.
- α_{ij} numerical value that takes 1 if the MKPI i belongs to the node j, 0 otherwise.
- x_i Boolean variable that takes 1 if the MKPI i is selected, 0 otherwise.

The problem is formulated as follows.

$$max\ F(x) = max\left[k_1 \sum_{i=1}^{N} x_i \cdot g_i - k_2 \frac{\sum_{i=1}^{N} x_i}{N} \right] \tag{4}$$

Subject to:

$$(1 - p_j) \cdot \sum_{i=1}^{N} x_i \cdot \alpha_{ij} \geq n_{min} \qquad \forall j \tag{5}$$

$$k_1 + k_2 = 1 \tag{6}$$

The first term of the expression (4) aims at choosing those MKPIs having the highest global priority (i.e. a greater capability of description), whereas the second term represents the number of indicators to be selected. Both terms of the objective function range from 0 to 1. The parameters k_1 and k_2 are the weights representing the relative importance that the analyst attributes to each term of the objective function. Constraint (5) forces the model to choose at least a fixed number of MKPIs with relation to each level-1 node.

7 CASE STUDY

The proposed methodology has been implemented on a refinery plant. The subject company maintenance staff has been actively involved for the customization of the maintenance hierarchical framework, for the selection of the most meaningful MKPIs among those already proposed in the literature and for the expression of pair-wise comparison judgments needed by the designed methodology. Specifically, a total number of 116 MKPIs has been collected from the scientific and technical literature and supplied to the maintenance staff. Among them, 58 MKPIs have been selected on the base of their significance and applicability to the specific organizational context and assigned to each node of the designed maintenance framework.

The software Expert Choice has been used as a support tool to implement the AHP-based approach to rank the assigned MKPIs. The

mathematical programming model has been solved by means of Lingo fixing k_1 equal to 0.6 and k_2 equal to 0.4, whereas n_{min} has been set equal to 2 for each level-1 node. Twenty-nine MKPIs have been finally selected.

8 CONCLUSIONS

Nowadays, existing literature on Maintenance Performance Measurement (MPM) and Maintenance Key Performance Indicators (MKPIs) principally lacks on two aspects. Firstly, proposed MPM frameworks are generic and disregard the business specific environment of the company where these tools should be applied in. Secondly, the available literature mainly proposes a huge list of MKPIs but lacks a methodological approach for selecting specific MKPIs from the listed indicators. With this recognition, a structured methodology for the maintenance performance measurement by means of a restricted and comprehensive list of MKPIs has been proposed. The approach has been thought with relation to a high risk process plant where the way maintenance is managed and performed is fundamental to prevent the occurrence of hazardous events. The subject company maintenance staff has been involved in the definition and implementation of the whole methodology that actually arises from a real need of the maintenance manager to measure, check and communicate the maintenance performance on the base of different perspectives. Firstly, a *customized hierarchical framework* capable of synthesizing the most meaningful aspects affecting the effectiveness and the efficiency of the maintenance process has been designed. It comprises multiple levels and nodes so that information useful for all organizational levels are incorporated. Actually, each node represents a particular aspect on the base of which measuring the maintenance performance and, whenever deemed to be necessary, each node has been further branched in order to detail the considered aspect. Then, MKPIs already proposed in the literature have been collected and analyzed in cooperation with the subject company maintenance staff in order to select the most appropriate to describe the specific maintenance process. Then, an Analytic Hierarchy Process (AHP)-based approach has been implemented to rank MKPIs previously assigned to nodes of the hierarchical framework. MKPIs to be evaluated are not compared in respect to any criteria or sub-criteria but in respect to their relative capability in describing the specific aspect which they have been assigned to. In addition, the decision maker has been asked to supply just pair-wise comparison judgments on which he/she was confident so leading to *incomplete* pair-wise comparison matrices. The latter have been opportunely completed and checked in terms of resulting consistency. Then, an iterative procedure to improve the pair-wise comparison matrices consistency has been implemented. Finally, taking into account that calculating a large number of MKPIs requires a considerable effort in terms of input data to be recorded as well as leads to a lack of conciseness of the resulting information, a mathematical programming model has been formulated and solved to select the *optimal set* of MKPIs.

Even if designed with relation to a high risk process plant, the proposed methodology can be implemented in different contexts. Actually, it constitutes a structured approach that supports maintenance managers in measuring the maintenance process performance.

State of the art in Operation and Maintenance planning of offshore wind farms

M. Asgarpour
Department of Civil Engineering, Aalborg University, Denmark
Energy Research Centre of the Netherlands (ECN), Unit Wind Energy, The Netherlands

J.D. Sørensen
Department of Civil Engineering, Aalborg University, Denmark

ABSTRACT: Operation and Maintenance (O&M) costs of offshore wind farms are large contributors to the cost of energy. During last decades, methods have been developed for assessing the corrective maintenance costs, and many studies have been published for planning of preventive maintenance, but yet maintenance is not planned using advanced methods by taking all available information into account in a consistent manner. In this paper first a short literature review in O&M models for cost calculation of corrective maintenance and planning of preventive maintenance is given. Furthermore, an O&M study for a reference offshore wind farm is presented to illustrate the average costs and downtime for a typical offshore wind farm and to justify the necessity and potential of further development of current O&M models. At the end, a discussion on optimal O&M planning of offshore wind farms is given.

1 INTRODUCTION

Offshore wind energy is rapidly growing, but it's not yet competitive with conventional power plants due to its high cost of energy. By the end of 2013, more than 2000 offshore wind turbines were installed in Europe, making a cumulative total of 6.5 GW in 69 offshore wind farms (Corbetta et al., 2014).

Operational costs are one the main cost drivers of offshore wind energy and contribute approximately to 25% of the levelized cost of energy (*Offshore Wind Cost Reduction—Pathways Study*, 2012).

In order to fully exploit the offshore wind energy it is essential to reduce the levelized cost of energy from 17 to 12 ¢€/kWh by 2020 that can be partially achieved by reducing operational expenses of offshore wind farms.

Operational expenses of offshore wind farms are mostly caused by failure of wind farm components. In general the following maintenance actions can be considered for an offshore wind farm:

- Calendar based maintenance, once or two times per year and scheduled by the wind turbine manufacturer;
- Preventive maintenance actions to prevent failure of wind farm components scheduled by wind farm operator using information obtained from inspections, SCADA and condition monitoring system;
- Corrective maintenance actions after a component fails, such as repair or replacement, performed by wind turbine manufacturer during the guaranty period and performed by wind farm operator afterwards.

The purpose of the calendar based maintenance and preventive maintenance is to prevent the high costs of corrective maintenance and preserve the system functionality.

During the past decades of offshore wind energy, several studies have been performed on the following subjects:

- Estimation of corrective maintenance costs;
- Planning of preventive maintenance actions.

In the following sections first a short literature review in O&M models of offshore wind farms is given and then, an O&M study for a reference wind farm is presented. Furthermore, a discussion on optimal operation and maintenance planning of offshore wind farms is given.

2 ESTIMATION OF CORRECTIVE MAINTENANCE COSTS

When a wind farm component fails, the functionality of one or several wind turbines will be affected and therefore, it should be repaired or replaced as soon as possible.

If a wind turbine component fails F times in elapsed time T, then the estimated failure frequency is:

$$\lambda = F/T \quad (1)$$

The estimated failure frequency determined from equation (1) is based on the historical data and can't be used to determine the actual damage state of the component.

In Figure 1 the state of a component is illustrated. The figure presents a simple state model of a component and demonstrates two failures. Assuming there is no redundancy in the design, after each failure the whole system, in this example the wind turbine, stops functioning and a suitable maintenance action should be performed to repair or replace the failed component.

The average functioning time of a component is known as 'availability' and the average downtime of a component is known as 'unavailability'.

In other words, availability is the probability that a component is functioning and unavailability is the probability that the component is not functioning.

From the Figure 1 the unavailability can be calculated as:

$$U = MDT/(MDT + MTTF) \approx MDT/MTTF = \lambda/\mu \quad (2)$$

where MDT is 'Mean DownTime' and MTTF is 'Mean Time To Failure'.

Equation (3) also describes the relation between λ, which is the failure rate and μ, which is the repair rate with MDT and MTTF.

$$\lambda = 1/MTTF$$
$$\mu = 1/MDT \quad (3)$$

Furthermore, it can be easily seen that the sum of availability (A) and unavailability (U) is equal to 1 or 100%, therefore availability can be calculated easily from unavailability equations.

$$A = 1 - U = 1 - MDT/MTTF = 1 - \lambda/\mu \quad (4)$$

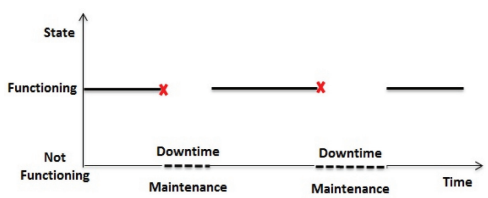

Figure 1. State of a component.

Estimation of corrective maintenance costs of a wind farm is essential, especially in the planning phase of the farm and can be derived from the equation (5):

annual corrective maintenance costs per component = annual failure frequency of the component × repair costs of the component (5)

In early operational years of a wind farm, accurate annual failure rate of the components is not available yet and therefore, data from a generic reliability database, like Reliawind database, will be used. After first years of operation, the annual failure rates of the components can be updated using the actual failure statistics in the farm.

Repair costs of the component include the costs of access vessels, spare parts and technicians to perform initial inspection, repair or replacement. Moreover, lost production and revenue losses due to the disturbed functionality of the wind turbine(s) are a part of the corrective maintenance costs.

In order to estimate the revenue losses, the total downtime of wind turbine(s) during the corrective maintenance should be estimated and to do so, expected waiting times for weather windows of given length are needed for each type of access vessel.

There are two methods to calculate the annual corrective maintenance costs of offshore wind farms:

- Mean value method used in ECN O&M Tool;
- Monte Carlo simulation in time domain used in ECN O&M Calculator, NOWIcob, O2M, MWCOST, and CONTOFAX.

2.1 *Mean value method*

The ECN O&M Tool developed by Energy Research Center of the Netherlands (ECN) is an Excel based tool to estimate overall expected costs of corrective maintenance actions based on the historical failure rates of wind farm components.

The ECN O&M Tool processes the time series of wind speed and significant wave height and then, calculates the mean wait time for a number of weather window lengths.

Furthermore, a polynomial is fitted to describe the mean waiting time as function of the needed weather window and then, these curves are used to calculate the lost production and revenue loss associated with each failure (Rademakers et al., 2008b).

2.2 *Monte Carlo simulation in time domain*

ECN O&M Calculator (Rademakers et al., 2008a) and NOWIcob (Norwegian offshore wind cost and benefit model) developed by NOWITECH

(Hofmann and Sperstad, 2013) both are simulation based tools to calculate the costs of inspections, preventive and corrective maintenance. Both tools take system effects into account and give also insight about required access vessels, technicians and spare parts for maintenance actions.

ECN O&M Calculator, NOWIcob, O2M developed by GarradHassan (Phillips et al.), MWCOST developed by BMT (Stratford) and CONTOFAX developed by Delft University of Technology (Van Bussel and Bierbooms, 2003) are similar in failure modeling and different in weather modeling. In all models failures can be simulated from a Poisson process with constant failure rate, which corresponds to random failures. In MWCOST it's also possible to define time dependent failure rates.

As discussed before, the models are different in processing the weather data. In ECN O&M Calculator and MWCOST historical time series of wind speed and significant wave height are used as input directly in the simulations.

In NOWIcob weather time series are generated by applying a Markov chain process and historical weather data are used to estimate transition matrices from one weather state to the next one (Hofmann and Sperstad, 2013).

The O2M model generates pseudo random time series of the significant wave height using FFT based on input time series, and then, inverse FFT to create artificial time series (Phillips et al.).

In CONTOFAX time series of accessible and inaccessible periods for each access vessel type are generated based on the Weibull distributions for accessible and inaccessible weather windows, which are found based on real time series. Therefore, in CONTOFAX only the availability is calculated because the wind speed is not included in the model and production loss cannot be calculated (Van Bussel and Bierbooms, 2003).

ECN has also developed ECN O&M Analyzer, which can be used to process operational data and study the components failure behavior. After first years of operation, failure rates defined in ECN O&M Calculator can be updated using the output of ECN O&M Analyzer to have an even more accurate estimation of corrective maintenance costs (van de Pieterman et al., 2014).

3 PLANNING OF PREVENTIVE MAINTENANCE ACTIONS

Preventive maintenance actions are performed to preserve system functionality and reduce the failure of components. There are several approaches for planning of preventive maintenance actions trough the life time of an offshore wind farm:

- Based on the predicted life time;
- Based on optimal preventive inspection intervals;
- Based on Reliability Centered Maintenance (RCM).

These approaches are described in the followings.

3.1 *Based on the predicted life time*

The simplest approach for preventive maintenance planning of offshore wind farms is based on only the predicted life time of components and not based on information obtained from inspections and condition monitoring.

The mentioned approach has been used in (Bharadwaj et al., 2007) which describes a simple probabilistic damage model for general corrosion of the tower structure. Assuming this to be the only damage mechanism causing failure of the structure, the remaining lifetime of the structure is calculated by the following model:

$$RL = (T_c - MAT)/C \tag{6}$$

where RL is the remaining lifetime in years, T_c is the current thickness of the structure in mm, MAT is the minimum allowable thickness in mm and CR is the corrosion rate in mm/year.

3.2 *Based on the optimal preventive inspection intervals*

Determining the optimal inspection intervals could be a challenge since long inspection intervals increases the corrective maintenance costs and short inspection intervals increases preventive maintenance costs and revenue losses due to the production lost.

This approach can be applied for the period when a defect in a component becomes detectable and failure occurs, known as delay time. In this approach optimal preventive inspection intervals are found to prevent the failure of components using rate of arising defects, delay time distribution, and cost and duration of preventive inspection.

In (Andrawus et al., 2008) a hybrid of Failure Modes and Effect Criticality Analysis (FMECA) and Delay-Time Maintenance Model (DTMM) is used to find optimal inspection intervals for selected critical components. The failure modes of the turbines are determined by FMECA approach and then mean delay time are derived by DTMM approach.

3.3 *Based on the reliability centered maintenance*

Reliability Centered Maintenance (RCM) is a systematic approach develop in aircraft industry that determines what to do to preserve system

functionality by balancing between corrective and preventive maintenance for critical components.

In (Andrawus et al., 2006) a hybrid of an RCM approach and Asset Life Cycle Analysis technique is used to find the optimal maintenance strategy for a wind turbine. In this paper possible failure modes and their causes and consequences are determined by RCM approach and it is concluded that condition based maintenance is the most cost effective option for the selected wind turbine.

In (Nilsson and Bertling, 2007) a reliability centered asset management approach is introduced to investigate how much decrease in amount of corrective maintenance actions justifies using a condition monitoring system for wind farms. In this paper it is concluded that a change from unplanned to planned maintenance of 47% is enough to make a condition monitoring system profitable.

In the followings first an O&M study will be presented and then, a discussion on optimal O&M planning of offshore wind farms is given.

4 O&M STUDY FOR A REFERENCE WIND FARM

In order to illustrate the average costs and downtime of a typical offshore wind farm and to justify the necessity of further development of current O&M models for offshore wind farms, an O&M study for a hypothetical offshore wind farm is performed. In the following sections, first the reference wind farm is discussed and then, the assumptions for the baseline O&M strategy are given. Furthermore, the results of O&M study for the reference wind farm are presented.

4.1 *Reference wind farm*

The reference wind farm used in this O&M study is a hypothetical 400 MW offshore wind farm. This wind farm consists of 80 NREL offshore 5 MW baseline wind turbines.

The wind farm is assumed to be located in vicinity of meteorological mast FINO3, approximately 80 km west of the German island of Sylt.

The water depth at the location of the wind farm is approximately 30 m. For the weather modeling the wind speed and significant wave height of FINO meteorological mast in the vicinity of the wind farm is used. The wind farm is illustrated in Figure 2.

Figure 2. Location of the reference wind farm in the vicinity of FINO3 meteorological mast [www.fino3.de].

4.2 *Theoretical wind turbine*

The 5 MW NREL offshore baseline wind turbine is a theoretical wind turbine representing the typical multi-megawatt offshore wind turbines used in the reference wind farm. The power curve of the turbine is illustrated in Figure 3.

The wind turbine is using a pitch control system with 90 m hub height and 126 m rotor diameter.

The NREL 5MW offshore baseline wind turbine is equipped with an internal crane with 2000 kg hoisting capacity, which can be used for hoisting of small components like pitch motors or yaw drives. For hoisting large components such as generator or nacelle a large external crane on a jack up vessel is required (Jonkman et al., 2009).

4.3 *Assumptions for baseline O&M strategy*

In order to calculate the annual maintenance costs and revenue losses ECN O&M Calculator developed by Energy Research of Netherlands (Rademakers et al., 2008a) is used. The baseline O&M strategy is defined based on default model available in ECN O&M Calculator.

In the baseline O&M strategy it is assumed that personnel will work only in one single shift during daylight periods for all possible maintenance to ensure a safe working environment. On average personnel work from 7:00 h to 19:00, which means the total workday length is set at 12 hours on average. Maintenance will only be initiated if the technicians can spend a minimum of 2 hours to the repair onsite.

In the baseline O&M strategy mostly main components are defined on a system level, except the rotor system and drive train, where the major subsystems are included in the breakdown. The failure

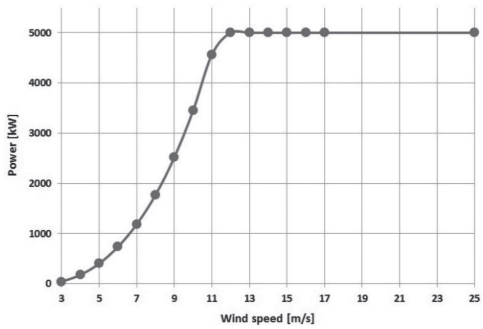

Figure 3. Power curve of theoretical wind turbine used in the NORCOWE reference wind farm.

frequencies of wind farm components are derived from the result of Reliawind project (Wilkinson and Hendriks, 2011).

For calendar based maintenance, all wind turbines in the wind farm will be maintained once per year with three technicians. Moreover, every five years a larger preventive maintenance campaign is carried out additional to the yearly maintenance.

A mother vessel is located in the proximity of the wind farm. This vessel offers accommodation for technicians to stay overnight. All year long, two crews of technicians are employed, who are exchanged from the mother vessel on a 2-weekly basis. Besides the mother vessel, the following vessels are used to transfer personnel and spare parts, and for hoisting of components: three workboats permanently leased of fixed contract, one chartered jack-up vessel when required, one chartered cable laying vessel when required, one chartered diving support vessel when required and one helicopter to transport technicians to the balance of plant structure when required.

Results of the O&M study.

As results of the simulation in the time domain, the following costs are calculated:

- Total maintenance costs M€ 66.5/year;
- Total revenue losses due to the lost production: M€ 28.7/year;
- Sum of total maintenance costs and revenue losses due to the lost production: M€ 95.2/year;
- Total maintenance costs per kWh produced: ¢€/kWh 3.92.

Form the summary of results it can be seen that the total cost of maintenance is about 23% of the price of energy, which demonstrates the necessity of an optimal model for O&M planning of offshore wind farms to contribute in cost of energy reduction.

From the breakdown of O&M costs and total down time per type of maintenance it can be seen that 89% of the total O&M costs and 95% of the total downtime is caused by unplanned corrective maintenance, which can be significantly reduced by using condition monitoring systems and an optimal preventive maintenance planning model to perform cost effective preventive maintenance actions.

In Figure 4 the breakdown of the total O&M costs is illustrated and it can be observed that most of the O&M costs are caused by equipment costs (43%) and revenue losses (30%) due to the lost production.

Furthermore, in Figure 5 the breakdown of the total downtime is illustrated. In Figure 5 it can be observed that about half (51%) of the total downtime is caused by weather delays that corresponds to long waiting time before a suitable weather window can be found.

It is of great interest to observe that only 15% of the total downtime is caused by the actual maintenance actions on wind farm components.

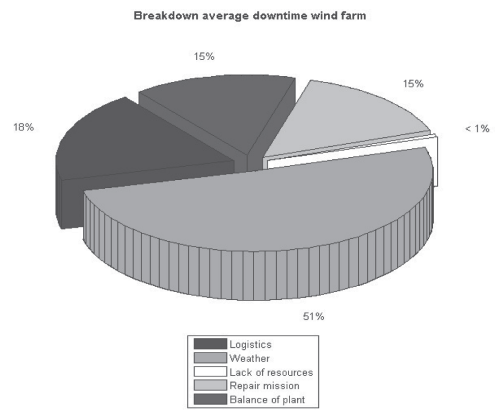

Figure 4. Breakdown of the total O&M costs.

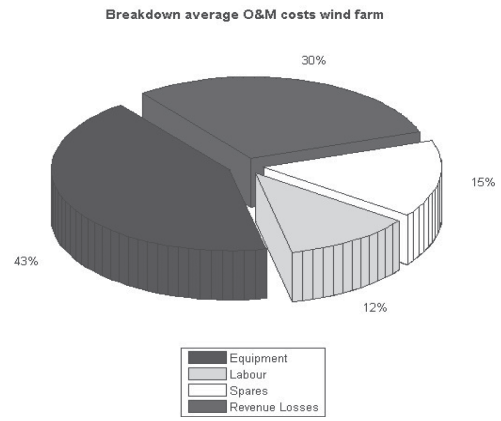

Figure 5. Break down of the total downtime.

5 DISCUSSION ON OPTIMAL PLANNING OF PREVENTIVE MAINTENANCE

As illustrated in the O&M study, corrective maintenance actions are the main contributors to operational expenses of offshore wind farms and they can be reduced significantly by using an optimal O&M model to support the wind farm operator in long term planning and short term decision making.

During the last decades several simulation based methods have been developed to estimate the maintenance costs, but they are mostly cost calculators and can't be used as an optimal short and long term planning tool.

In Figure 6 an optimal O&M planning model is illustrated which is consisting of the following parts:

- Inputs: inspection and maintenance results, SCADA, condition monitoring system and climate data;
- Processors: indicator model, deterioration model of critical components, risk based cost model and risk based decision model;
- Output: long term planning and short term decision support.

The model in Figure 6 includes the deterioration model of the critical components instead of the historical failure frequencies. The deterioration models should also continuously get updated by using an indicator model to determine the component failures more accurately.

The indicator model is obtaining direct and indirect information from inspection and maintenance results, condition monitoring systems and SCADA to update continuously the deterioration model of the components.

The model illustrated in Figure 6 also includes a decision model, which is consisting of risk based decision rules and decision criteria to process all input data and determine the optimal O&M planning.

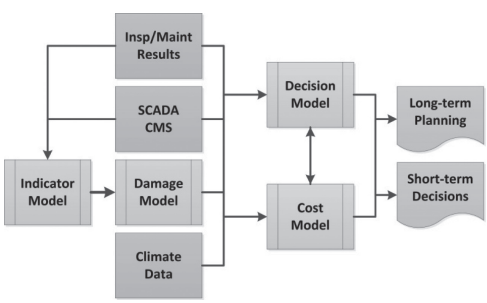

Figure 6. Model of an optimal risk and reliability based O&M planning tool.

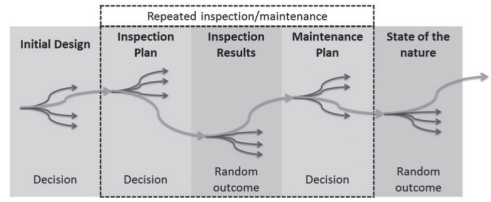

Figure 7. Decision tree for optimal O&M planning.

The developed decision rules and criteria should continuously get updated whenever new information is being available. Then, based on the feedback from the system all calculations are redone and the updated O&M plan is determined.

In (Sørensen, 2009) a risk based life cycle approach for optimal planning of preventive maintenance actions is described.

The approach is theoretically based on pre-posterior Bayesian decision theory and can be used when deterioration mechanisms such as fatigue, corrosion, wear and erosion are present and can be observed by inspection and monitoring before failure of the component occur. The decision tree described in this paper is illustrated in Figure 7.

The described risk and reliability based approach in Figure 6 can rationally take into account the uncertainty related to the deterioration and the future costs related to inspections and maintenance of offshore wind farms.

6 CONCLUSIONS AND FUTURE WORK

Through a case study for a reference offshore wind farm it was illustrated that O&M costs are about one quarter of the cost of energy. Furthermore, it was seen that a major part of the total costs and downtime of O&M actions are caused by unplanned corrective maintenance, which can be significantly reduced by using a risk and reliability based O&M model to support the wind farm operator in long term preventive maintenance planning and short term decision making.

As illustrated in Figure 6, in order to develop an optimal O&M model a risk based decision model and deterioration models of critical components should be developed.

Additionally, a short literature review in O&M models for cost calculation of corrective maintenance and planning of preventive maintenance was given. It is also of great interest to study the existing risk based O&M models for maintenance planning of offshore wind farms.

ACKNOWLEDGMENT

This work has been (partially) funded by Norwegian Centre for Offshore Wind Energy (NORCOWE) under grant 193821/S60 from Research Council of Norway (RCN). NORCOWE is a consortium with partners from industry and science, hosted by Christian Michelsen Research. The work presented in this paper has been made also possible by the Energy research Centre of the Netherlands (ECN).

Maintenance of power systems considering time-dependent uncertainty

T. Iesmantas & R. Alzbutas
Lithuanian Energy Institute, Kaunas, Lithuania

ABSTRACT: There are a lot of different infrastructure maintenance approaches. One of it is Markov processes, which take into consideration changing states of the maintained object. However, the uncertainty of data is a forgotten matter when things turn to the maintenance modeling. The practice is to plug in points estimates and proceed with maintenance analysis. We take a Bayesian view on the power transformer maintenance modeling to take into account the uncertainties and to propagate it through the model. We will concentrate on theoretical models rather than applications to real data. Such a restriction is necessary as our foremost intention is to build a solid background, which will serve then as a framework for real world applications.

1 INTRODUCTION

Maintenance concept, especially when related to the context of power grid, is of great importance. As time is passing by the reliability requirements for systems are increasing, while the maintenance cost are not getting any cheaper (IEEE/PES Task Force, 1999). However, the common practice is to use time independent mathematical model for maintenance and parameter values are just point estimates obtained from the historical data—and it doesn't really matter what kind problem we might consider. Whether it is a power grid maintenance/inspection optimization task, or reliability predictions under the influence of maintenance/inspection rates, the "tradition" is the same—obtain point estimates and don't bother oneself by the data any more. In addition, uncertainty of data is almost never taken into consideration, or event when it is—not as the central part of the whole picture. We demonstrate in this paper that Bayesian framework is applicable to propagate data uncertainty through all the maintenance analysis aspects.

Surely, with Bayesian methods penetrating into every engineering problem, there is already some work in maintenance modelling field, like application of Bayesian networks (Khakzad, 2011). However, it is basically for modelling decision processes of maintenance under data uncertainty and the time-dependent maintenance specificity of power grid components was never (at least authors do not know of it) widely considered. On the other hand, mathematical modelling literature on maintenance of power grid components is not so vast in general.

In this paper we take a look at the problem of power transformers and as a reference model of their maintenance will be a Markov process (see Section 2). We provide complete picture on how transition rates between different states of transformer degradation can be estimated and present a view on how to do it sequentially, i.e. update parameters once new data arrives without recalculating everything starting with old data (Section 3). We also show how such updating makes life easier when taking into consideration optimization of the maintenance rates. In addition, Bayesian parameter updating abilities are applied to update the optimal maintenance policies sequentially (Section 4). All calculations are done with parameters not necessarily representing some specific set of transformers, as our intentions are to demonstrate theoretical analysis rather than some specific case calculations.

2 TIME-DEPENDENT MAINTENANCE OF POWER TRANSFORMERS

Since we do not seek some specific case investigation, we will start from general model of maintenance (without the cost consideration), which is a slight modification of the one considered in (Jirutitijaroen, 2004; Beehler, 1997). The general scheme of the Markov model is presented in Figure 1.

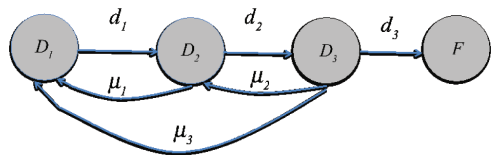

Figure 1. Markov model for maintenance.

For example, using it we may assume three states D_i, which approximate the deterioration of power transformer, while the last state F represents a complete failure and inability to carry through electricity. We consider the F state as an absorbing. The states after deterioration can be repaired at the rates μ_1, μ_2 and μ_3.

We assume that if the transformer fails (i.e. it is in state F), lines going through it cannot transmit electricity, i.e. failure of the transformer is equivalent to the outage of connected lines.

In this model the maintenance rates μ_i are assumed to be fixed. As we will investigate its effect on the reliability of the grid, so the estimation of these rates is out of the scope of this investigation.

A note about the deterioration is required here. Any transition rate d_i between the deterioration states does not reflect exactly the ageing process. Ageing during long time period generally weakens all system—components of power transformers fractures, cracks, etc. Thus, as time goes by, more often transitions between D_1, D_2, D_3 and F states will occur and transition rates may increase. In order to be able to model this effect age-dependent transition rates should be employed, i.e. time-inhomogeneous Markov processes should be considered. However, we will not use this kind of modelling here.

3 BAYESIAN INFERENCE AND SEQUANTIAL UPDATING

One of the purposes of this paper is to stress the importance of properly handling uncertainty in the maintenance-inspection modelling and the influence on overall network reliability. The prevailing practice in maintenance modelling is to plug-in point estimates of the parameters (in our case we have 6 unknown transition rates) and go along with it. However, estimates are uncertain, i.e. we do not have infinite amount of information in order to be able to have absolute certainty about their values. Thus, by blindly using point estimates without any consideration of uncertainty bounds we can make inspection or maintenance decisions, which are not very well informed. For example, there is a significant difference between the 95% confidence intervals [400; 700] and [200; 1300] of the MTTF (Mean Time To Failure), even though the expectations of MTTF may be equal in both cases. Quantified uncertainty allows to have a more informed insight on possible variations of parameters and their impact on considered result e.g. cost.

Bayesian framework is perfectly suited for such purposes and we will stick to it. In this section we'll briefly present Bayesian inference for Markov chain parameters. More in depth and more general considerations can be found in (Billingsley, 1961; Jacobsen, 1982; Bladt, 2005).

For the ease of general presentation we denote transition rate matrix by $Q=(q_{ij})$. Then the likelihood function can be expressed as follows (Bladt, 2005):

$$L_t(Q)=\prod_{i=1}^{n}\prod_{k=1} q_{ij}^{N_{ij}} \exp\{-q_{ij}R_i(t)\}, \tag{1}$$

where n is a number of states, N_{ij} is the number of transitions from state $\boldsymbol{i}$ to state $\boldsymbol{j}$ in the time interval [0,t], whereas $R_i(t)$ is the time that is spent in state i before time t.

As we seek to estimate the transition rates, according to Bayesian framework they have to have a prior distribution. For each unknown parameter we place a uniform distribution, so that the posterior distribution is proportional to the likelihood.

Since we do not assume any prior dependencies between the transition rates, we have a very nice simplification. Namely, the likelihood function (1) can be decomposed into likelihood functions for each separate transition rate q_{ij}, and the posterior distribution for each transition rate given data X is propotional to the following expression:

$$q_{ij}^{N_{ij}} \exp\{-q_{ij}R_i(t)\} \tag{2}$$

which is (after renormalization) a gamma distribution:

$$q_{ij} \mid X \sim Gamma(N_{ij}+1, R_i) \tag{3}$$

Having posterior distribution for the unknown transition rates, we can now perform inspection schedule analysis and its influence on the reliability. Suppose we decided on some optimal value of the inspection rates. As time goes by, additional data will become available and it would be reasonable to adjust our optimal inspection and maintenance plans. Fortunately, Bayesian approach allows performing such updating in a very natural way.

If the new data is X' and if we consider previous posterior distributions $\pi(q_{ij}\mid X)$ as our prior distribution, we obtain updated posterior distribution, which is expressed again as a gamma distribution:

$$q_{ij} \mid X \sim Gamma(N_{ij}+1+N'_{ij}, R_i+R''_i) \tag{4}$$

where N'_{ij} and R'' are calculated for the new data.

Since parameters might change considerably (especially in case of initially small samples), we can reconsider inspection rate and find another optimum. Thus, we propose, that Bayesian framework in addition to being the most natural way of propagating uncertainty in model parameters,

allows us a kind of sequential updating of not just parameters, but optimal inspection plans as well.

Since changes of parameters, as supported by the new data, are allowed, the sequential parameter updating has another useful feature—if due to ageing effect the transition rates do in fact change, this will partially be reflected in updated posterior distributions. Even though expectations of parameters might not change very much, uncertainty bounds will react to the additional information. Hence, this is another important reason for the uncertainty consideration.

4 POWER TRANSFORMER RELIABILITY UNDER UNCERTAINTY

Let's assume that we have observed some data sample over the time period of 10 years. The sample is such that data for posterior distributions of transition rates (except the maintenance intensity, as those will be assumed to be known) are as presented in Table 1.

Figure 2 represents 100 realisations of failure probability (unreliability) curves within 95% credibility belt. These curves represent the uncertainty level as is encoded in the gamma distributions of transition rates. Example clearly shows, how uncertain our decisions might be if we just use some point estimates.

The uncertainty directly can be transferred to other measures of interest, like the Mean Time To Failure (MTTF). For example using the collection of the parameters as above, the 95% credibility interval of MTTF is [47; 192] years. This interval is very wide and it is not encouraging that there is a 0.95 probability that the MTTF lies somewhere in that range. So, for better decision making, say in optimal maintenance scheduling, or in optimal cost analysis, we would suggest to take into account this uncertainty.

Table 1. Data for gamma distributions of uncertain parameters.

Parameter	N_{ij}	R_i	Expectation
d_1	83	177	0.47
d_2	6	20	0.30
d_3	1	3	0.33

Let's fix μ_1 and μ_2 parameters to the values to 0.5 and 0.7 accordingly and vary and μ_3 over the interval [0,20]. The MTTF and its upper/lower bound for 95% credibility interval changes as represented in Figure 3.

MTTF dependence on the maintenance rate can be used in the maintenance optimisation. However, the same problem with uncertainty as in unreliability case remains—uncertainty bounds shows that application of point estimates can be not the best choice.

And once again, uncertainty bounds can be used to make better informed decisions—maintenance cost evaluation when uncertainty is taken into account should serve as a better money allocation tool. From the plot we can see how wide MTTF uncertainty bounds can be and making decisions purely by means of expected values might lead to under or over estimation.

Let's assume in our further investigation, that maintenance optimization is equivalent to choosing maintenance rate μ_2 such that the upper bound of power transformer failure in the next 4 years probability (i.e. transition rate d_3) is not higher than 0.07, i.e. we want to choose such maintenance rate, so that in the next 4 years, the probability of transformer failure will not be higher that the value 0.07. The choice of time period and probability threshold is purely arbitrary and is only for the purposes of possible strategy demonstration rather than to imply some existing practice. Figure 4 illustrates the dependence on the maintenance μ_2 of 95% bound for the probability of failure in the next 4 years.

Now, let's assume, we want to update every 4 years our optimal maintenance (i.e. reflect changes of data in the adjustable maintenance rate μ_2). Due to the convenience of Bayesian updating procedure and the resulting gamma posterior

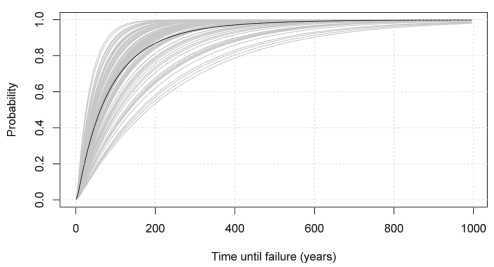

Figure 2. Uncertainty of unreliability function.

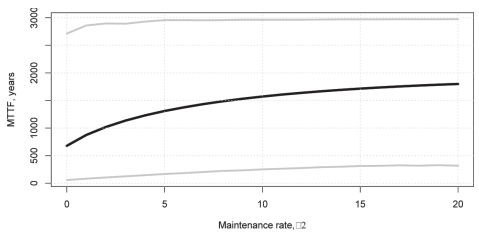

Figure 3. MTTF and its 95% confidence interval dependence on the maintenance rate.

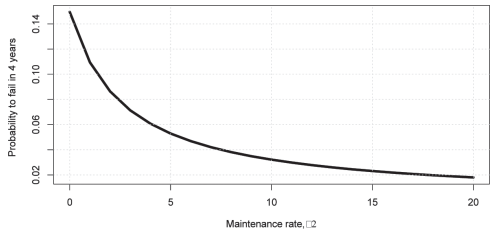

Figure 4. Upper 95% confidence bound of probability to fail in the next 4 years.

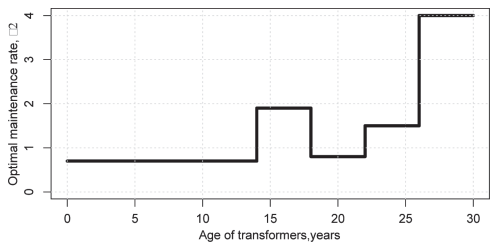

Figure 5. Change of optimal maintenance rate after updating every 4 years.

distribution, such maintenance corrections can be done without any recalculations of the previous analysis. All one needs to do is to update posterior gamma distribution with new data and then find another maintenance rate so that the probability in another 4 years is kept lower than 0.07.

Markov chains generate time-dependent probability distribution of transitions (even though it will eventually approach some steady state value) and we show optimal maintenance μ_2 or MTTF (Mean Time To Failure) to change each time we update transition rates as well. Figure 5 demonstrates, how this optimal maintenance rate changes when we update the model parameters (i.e. update deterioration rates) every 4 years.

The initial maintenance rate was 0.7. Since the upper bound of probability to fail in next 4 years was lower than the 0.07 value, there was no need to increase the maintenance rate. That is the reason for going 14 years with the same maintenance rate. Then, since the probability to fail increases with time, we have to update our maintenance with optimal schedules. As we update transition rates every 4 years, we update the optimal maintenance as well. However, after certain age the corrections of only one maintenance rate will not be enough, since to keep the upper bound of probability to fail in the next 4 years lower than 0.07 value, the maintenance rate will have to be extremely high (at the age of 30 years, it has to be approximately equal to 58 in order to keep the probability below 0.07).

If we would consider age-dependent transition rates (i.e. time inhomogeneous Markov chains), the easy transition rate updating procedure by gamma posterior distribution would not work, as the posterior distribution would be much more complicated and the analytical expression would not be known. Thus, in order to obtain posterior estimates one would have to employ numerical methods, like Markov Chain Monte Carlo methods (Gilks, 1996).

5 CONCLUSIONS AND FURTHER DISCUSSIONS

In this paper we have demonstrated how uncertainty in the data can be easily incorporated into the problem of maintenance optimization and how sequential updating of parameters using Bayesian approach can be applied when maintenance is adjusted according to the available information and possible uncertainty.

Bayesian updating of model parameters allows straightforwardly deal with uncertainty in data which is directly transferred to the decision about the optimal maintenance schedule. In addition sequential nature of the problem enables (at least at some degree) to deal with uncertainty in transition between transformer degradation states.

We have left the aspect of power transformer reliability influence on overall power grid reliability unexplored. It is very common approach to consider power grid nodes as perfectly reliable and just proceed further with failing electricity transmission lines. However, even thought the MTTF's are much longer for power transformers as compared to transmission lines, transformer have much more significant influence on the connectivity of the network and hence on the overall reliability. We showed, that reliability bounds for transformer can be very wide (especially when data sample is small).

Our previous work (Iešmantas, 2014) have provided some evidence that power lines do not follow identical distribution. Heterogeneity due to geographical locations, different weather conditions, etc. results to heterogeneity in failure rates of transmission lines. Since power transformers functions in different geographical areas as well, we can expect the same heterogeneity in their reliability to be present as well. This brings into picture additional level of uncertainty, so called between source uncertainty.

ABSTRACT: The purpose of this study is to help GRTgaz optimising the maintenance of its natural gas compressor stations. Availability stations modelling is therefore proposed, taking the probability of failure of Basic Functional Elements (BFE) and preventive and corrective maintenance actions into account. It also includes maintenance and system downtime costs. The system modelling was created in stochastic Petri nets with predicates.

1 INTRODUCTION

GRTgaz manages a gas transmission network in France and uses databases related to the technical features and operation data of its facilities.

CRIGEN, the GDF SUEZ Research and Technologies Division for Gas and New Energies, provides its methodological support to GRTgaz for the development of policies in the fields of asset and industrial safety management.

The present study deals with the asset management of Basic Functional Elements (BFE) at natural gas compressor stations, using feedback data. The purpose is to help GRTgaz optimising the frequency of its preventive maintenance. Consequently, a proposal was made to model BFE availability at compressor stations, taking the failure probabilities (with effect of ageing) and preventive and corrective maintenance into account. The modelling also incorporates the downtime costs of the system and the maintenance costs.

The modelling was carried out with stochastic Petri nets with predicates and the software used was the Petri net module of GRIF, developed by SATODEV. The results obtained in terms of frequency of failure, percentage of planned and unplanned downtime, and especially costs, make it possible to suggest areas where preventive maintenance frequencies can be optimised.

This study also provides an evaluation of the available data and a scientific approach combining feedback data and expert judgement.

2 DEFINITIONS AND HYPOTHESES

Only those components deemed to be critical in terms of downtime are taken into account in this study. Accordingly, the Basic Functional Elements (BFE) of natural gas compressor stations were broken down into nine parts, each of them having sub-components:

- Ultimate security system, comprising filters, instrumentation and valves;
- Process valves, comprising instrumentation, continuous valves, and on-demand valves;
- Filtration system, comprising filters;
- Natural Gas Compressor (NGC), comprising control systems and NGC with auxiliaries;
- Turbine, comprising a turbine with auxiliaries;
- Cooling tower;
- Safety valve;
- Air admissible circuit, comprising a filter;
- Oil circuit, comprising filters, a lubrication pump system, and aero oil.

Subsequently, the sub-components (note that there might be multiple instances of a given sub-component) will themselves be broken down into maintainable units. Note also that he input data, modelling, and results presented here pertain to one particular station (confidential).

2.1 *Series system*

BFE of natural gas compressor stations is considered as a series system (Procaccia et al. 2011)

with respect to its nine parts identified as critical, just like each of these parts with respect to its sub-components, and each of these sub-components with respect to its maintainable units. Accordingly, the downtime of any maintainable unit can itself cause BFE downtime.

2.2 *Two modes of operation*

Each maintainable unit has two modes of operation:

- "Continuous" mode, when the failure in the maintainable unit has an impact on the compressor station as soon as it appears;
- "On-demand" mode, when the failure in the maintainable unit only has an impact on the compressor station as of the moment when a demand is actually made upon the maintainable unit.

In the case of "on-demand" mode, it is considered that the (random) time between two demands made upon the maintainable unit follows an exponential distribution. The frequencies of demand are defined at the level of the sub-component and are therefore applicable to all its maintainable units.

When a demand is made upon a maintainable unit that is in operation, the duration of said demand is assumed to be negligible. On the other hand, when a demand is made upon a failing maintainable unit, the effect of said failure (which starts as of the moment of demand) lasts until the maintainable unit is put back into operation, regardless of the duration of said demand.

2.3 *Mean Time To Failure (MTTF)*

It is considered that the time between placing/replacing a maintainable unit "in operation" and its next failure follows a Weibull distribution of parameters η and β. The Mean Time To Failure (MTTF) without preventive maintenance of a maintainable unit is given by (Lannoy & Procaccia 2006):

$$MTTF = \eta \cdot \Gamma(1 + 1/\beta) \tag{1}$$

with the Gamma function defined by:

$$\Gamma(x) = \int_0^{-} u^{x-1} \cdot e^{-u} \cdot du \tag{2}$$

Parameter η is the scale parameter (in time units) and parameter β is the form parameter (without unit).

2.4 *Preventive maintenance*

For each maintainable unit, these two parameters define the preventive maintenance actions:

- Preventive maintenance period τ, with the preventive maintenance actions performed at times $t0+\tau$, $t0+2 \times \tau$, $t0+3 \times \tau$, etc. (provided the corresponding maintenance resources are available), defined by failure as of $t0 = 0$;
- Duration of preventive maintenance d (as of the moment when the corresponding maintenance resources are available), including supply times and inactivity times due, for instance, to the stopping of maintenance actions during nights and weekends.

These preventive maintenance action parameters are defined for each maintainable unit. Indeed, the maintainable units have been defined in such a way that each preventive maintenance action corresponds to a maintainable unit. Nevertheless, when the preventive maintenance actions do not cover the entire sub-component, the result is a "residual" maintainable unit which is not subject to preventive maintenance action.

Each preventive maintenance action on a maintainable unit has the effect of rendering that unit (and therefore the system) unavailable for a duration equal to the corresponding preventive maintenance duration to which is added any waiting time for the availability of the corresponding maintenance resources.

At the end of a preventive maintenance action, the maintainable unit in question is restored to a state that is "as good as new," i.e. any ageing effects of the maintainable unit are "reinitialised."

2.5 *Corrective maintenance*

The corrective maintenance actions start as soon as the failure in a maintainable unit is detected (provided the corresponding maintenance resources are available).

- When a maintainable unit is in "continuous" mode, the failure is detected as soon as it appears.
- When the maintainable unit is in "on-demand" mode, this happens as soon as a demand is placed upon the failing maintainable unit, or following a preventive maintenance action on it.

It is assumed that the (random) time between the start (as of the moment when the corresponding maintenance resources are available) and the end of the corrective maintenance action of a maintainable unit follows an exponential distribution. The Mean Times To Repair (MTTR) are defined at the level of the sub-component and are therefore applicable to all of the maintainable units that comprise it.

Each corrective maintenance action on a maintainable unit has the effect of rendering that unit, and therefore the system, unavailable for a duration equal to the corresponding corrective maintenance duration to which is added any waiting time for

the availability of the corresponding maintenance resources.

At the end of a corrective maintenance action, the maintainable unit in question is restored to a state that is "as good as new", i.e. any ageing effects of the maintainable unit are "reinitialised".

2.6 *Maintenance resources*

The maintenance resources used to perform preventive and corrective maintenance actions are limited in such a way that at any time, the number of resources used to perform any maintenance action may not exceed a certain value.

When the maintenance resources that are needed to perform a desired maintenance action are not available, the maintenance action in question is put on hold until the necessary maintenance resources are available. In the case of "conflict" (i.e. when multiple maintenance actions on hold could start at the same time), priority is given to corrective maintenance actions and, secondly, the choice is made in an equiprobable manner. All maintenance actions in progress must be terminated before releasing the corresponding maintenance resources.

The maintenance resources that are needed to perform corrective maintenance actions are defined at the level of the sub-component and are therefore applicable to all of the maintainable units that comprise it.

The maintenance resources that are needed to perform preventive maintenance actions are defined for each maintainable unit.

2.7 *Costs*

System downtime implies a cost per time unit. This cost is independent of the cause of the downtime (corrective maintenance or preventive maintenance).

Each corrective maintenance action implies a fixed cost. These costs are defined at the level of the sub-component and are therefore applicable to all of the maintainable units that comprise it.

Each preventive maintenance action implies a fixed cost. These costs are defined for each maintainable unit.

3 METHODOLOGY

3.1 *Reliability input data*

The first step consists of estimating the associated failure rates for each piece of equipment on the basis of feedback data.

According to Lannoy (1996), the Bayesian approach applies when:

– There is not much feedback data;
– Such data are "contaminated" by changes to the design, by changes to operation or by maintenance;
– It is desired to re-update previous estimates if new feedback observations become available.

In this case, there is not much feedback data, or even none at all for certain equipment families for which no failures were observed. This high level of reliability invalidates the frequency-based approach and does not make it possible to obtain an accurate estimate. The Bayesian approach is an alternative that makes it possible to take all of the available knowledge into account in order to attain the best and most accurate possible estimate.

The Bayesian approach (Procaccia 2008) was therefore applied for those equipment families with little feedback:

– Either by using offshore reliability data (OREDA);
– Or by consolidating local data (specific to a particular site) via national data (considered as prior in this case).

When OREDA data were used, Fisher Information weighting was performed in order to ensure a balance between prior and likelihood, with respect to information contribution.

In addition, it was necessary to ensure a correct match between the feedback and prior knowledge. It was sometimes necessary to weight the data according to the match level.

Expert data (Lannoy & Procaccia 2001) was also collected in order to compare the expert assessment to the results obtained. Accordingly, a questionnaire was used to collect two expert assessments: one from an expert in reliability and maintenance of the equipment studied, and the other from an expert in the operation of compressor stations.

As can be seen in Figure 1, for six equipment families, the result of the assessments is in line with the result of the feedback. Expert 1 was the more

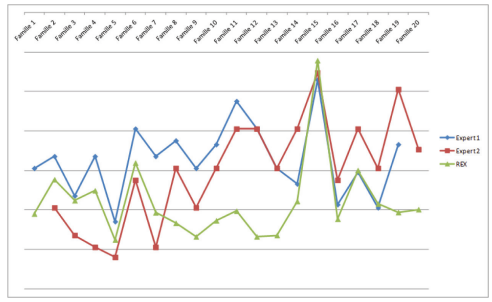

Figure 1. Failure rates provided by each expert compared to the GRTgaz feedback data (the values are masked for confidentiality reasons).

pessimistic in terms of reliability and expert 2 was more optimistic.

For the other families, the two experts were more pessimistic, giving higher failure rates than the feedback data.

The two expert assessments were incorporated using the Bayesian approach by giving equal weight to both experts.

All of the Bayesian calculations were performed using REXPERT software.

Organising the failure data into a hierarchy subsequently made it possible to identify critical equipment families according to their impact on the downtime of the facility (total for the site or partial for a workshop, for example).

The demand frequencies and the MTTF come from feedback data. (It should be noted that the MTTF were defined taking account of the current preventive maintenance periods and the formal parameters applicable to Weibull distributions.)

3.2 *Maintenance input data*

The periods (expressed in years) and the durations (expressed in hours) of preventive maintenance actions come from the current GRTgaz maintenance policy.

The average repair durations (expressed in hours), the costs of preventive maintenance actions and corrective maintenance actions, the maintenance resources needed to perform preventive maintenance actions and corrective maintenance actions, as well as the form parameters applicable to the Weibull distributions (β) come from expert judgement, based on GRTgaz's expertise.

The maximum number of maintenance resources that can be used at any given time is defined at four maintenance operatives, on the basis of GRTgaz's expertise.

The system downtime cost per time unit was estimated via GRTgaz's expertise.

3.3 *Modelling*

The modelling was carried out in stochastic Petri nets with predicates (Dutuit et al. 1997), using the Petri net module from GRIF software. This TOTAL software is developed by SATODEV (www.satodev.com).

Each maintainable unit was modelled separately. The architecture of the model presented in Figure 2 shows all the "groups" which each contain the model of a maintainable unit as presented in Figure 3.

Places 185 to 188 in Figure 3 make it possible to model the failure of the maintainable unit in question, the detection of said failure, and the associated corrective maintenance action.

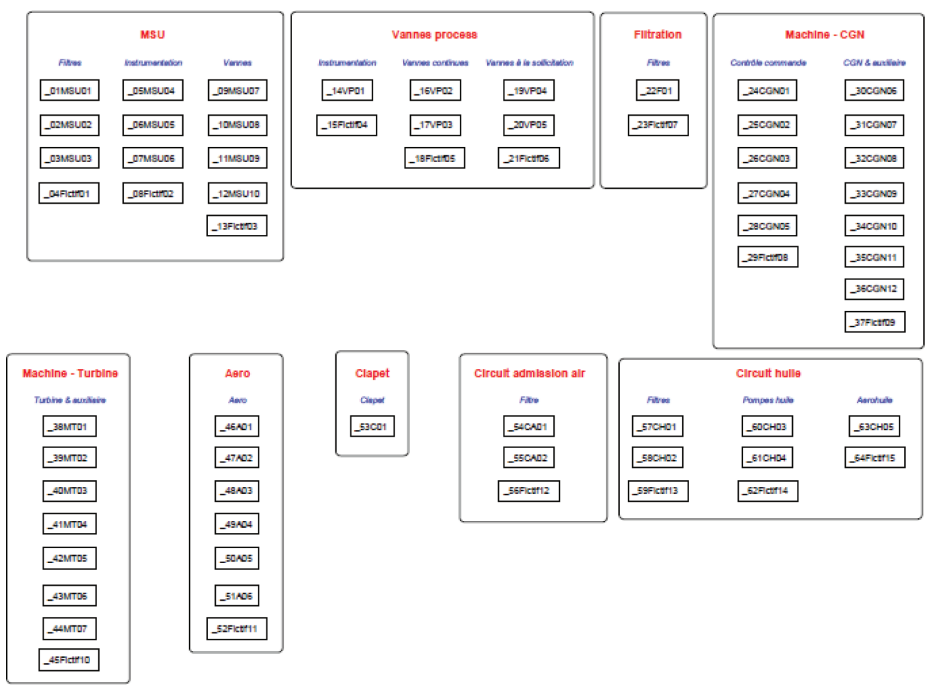

Figure 2. Architecture of the model.

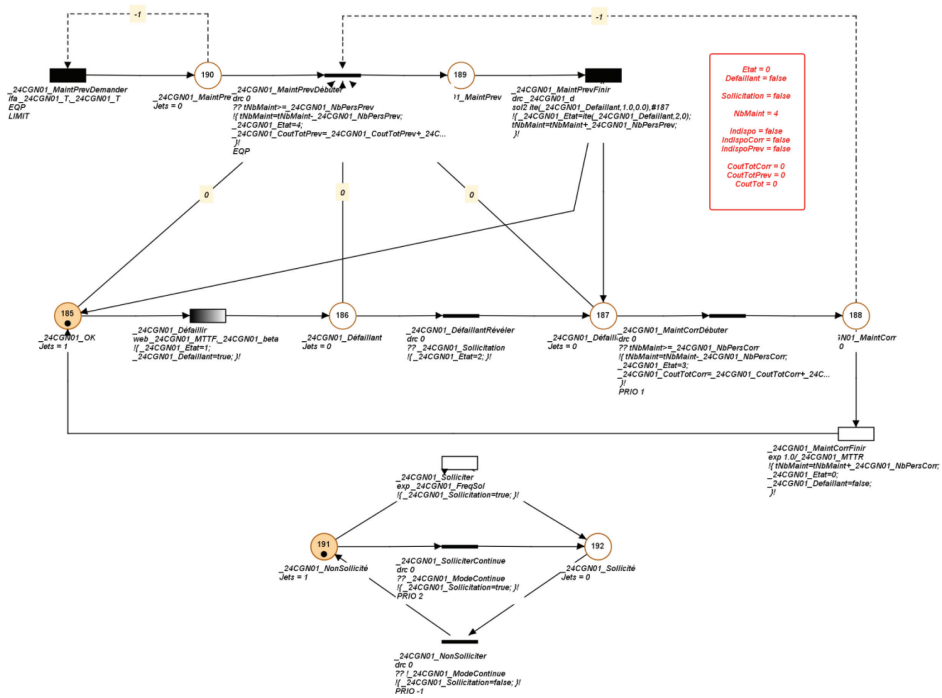

Figure 3. Model of a maintainable unit.

– The failure occurs according to the Weibull law defined in the hypotheses.
– The failure is detected as soon as a demand is placed upon the maintainable unit.
– Lastly, the corrective maintenance action begins as soon as the required maintenance resources are available, and ends according to the duration defined in the hypotheses. During the corrective maintenance action, the number of maintenance resources defined by the hypotheses is subtracted from the number of available resources, then added once the action is terminated. In addition, each time a corrective maintenance action starts, the total cost is increased by the cost defined by the hypotheses.

Places 189 to 190 in Figure 3 make it possible to model the preventive maintenance action of the maintainable unit in question.

– The request for such a maintenance action happens according to the period defined in the hypotheses.
– An "on demand" maintenance action then begins as soon as the required maintenance resources are available, and ends depending on the duration defined in the hypotheses.
– During the preventive maintenance action, the number of maintenance resources defined by the hypotheses is subtracted from the number of resources available, then added once the action is over. In addition, every time a preventive maintenance action begins, the total cost is increased by the cost defined by the hypotheses.

A variable state of the maintainable unit is defined with the following values:

– 0 when the maintainable unit is operational (initial state);
– 1 when the maintainable unit is failing and said failure has not been detected;
– 2 when the maintainable unit is failing and said failure has been detected;
– 3 when the maintainable unit is undergoing corrective maintenance;
– 4 when the maintainable unit is undergoing preventive maintenance;

Accordingly, the maintainable unit is failing when said status variable is not 0 and causes downtime of the sub-system to which it belongs when the status variable is equal to or greater than 2.

It should be noted that a preventive maintenance action may not begin while a corrective maintenance action is in progress. In addition, if a preventive maintenance action begins while the maintainable unit is failing and if said failure is not

detected, then said failure becomes detected once the preventive maintenance action is terminated.

Places 191 to 192 in Figure 3 make it possible to model the demand on the maintainable unit in question. Said demand is permanent in the event of "continuous" demand on the maintainable unit, or it is then defined according to the demand frequency stipulated in the hypotheses.

3.4 *Results*

The results were obtained from 10,000 simulations over an analysis period of 30 years. We can site the following types of results:

- The annual average failure frequency of the entire system;
- The main contributors to failure frequencies;
- The average unplanned downtime percentage of the entire system (due to failures);
- The main contributor to unplanned downtime;
- The average planned downtime percentage of the entire system (due to preventive maintenance actions);
- The main contributor to planned downtime;
- The average total downtime percentage of the system;
- The main contributor to total downtime.

Figure 4 shows the contribution of planned and unplanned downtime to total downtime.

3.5 *Modelling validation*

The simulations carried out on the basis of the Petri net models under the observed reliability and maintenance conditions make it possible to find the availability data observed in the system. This matching between the results of the simulations and the observed availability makes it possible to validate the proposed model.

Based on this model, changes to the preventive maintenance frequencies were made: +50%, +100%, +150%, +200% of the initial period.

In order to evaluate the effects of the maintenance policy modification, different simulations were realised with different values of the β parameter. In addition to the simulations based on the initial values of β, two others sets of simulations considered β+0.5 and β+1. These important values of the β parameter, corresponding to a more important materials ageing, leads to more failures. The different simulations allow the validation of the modelling as the given results confirm experts opinion.

Figure 5 below shows the change in total availability of the system, planned downtime (due to preventive maintenance) and unplanned downtime (due to corrective maintenance) as a function of these various frequencies.

In one hand, a drop in downtime due to preventive maintenance results of the increase in frequencies. In the other hand, the corrective maintenance, and thus the number of failures, increases. These two observations also make it possible to validate the model that restores the expected behaviour of the system.

In term of results, this figure shows also that total downtime remains stable, with the two abovementioned trends cancelling each other out. An increase was also observed in total downtime when preventive maintenance frequencies were doubled. This gives a limit that cannot be exceeded if we wish to maintain the same level of availability while reducing preventive maintenance.

Indeed, the initial results show that preventive maintenance frequencies can be doubled, thus reducing preventive maintenance costs by 50%, while maintaining the same level of system availability. However, a more refined analysis is needed in order to identify the optimum frequency for critical equipment in terms of availability and cost.

As presented here in a global approach, a similar analysis is carried out for each sub-system. The results show that for certain equipment the preventive maintenance reduction margin is less important. A more refined analysis is in progress

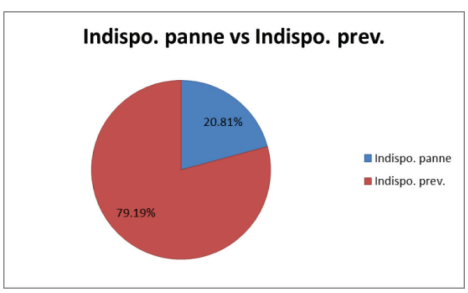

Figure 4. Contribution of planned and unplanned downtime to total downtime.

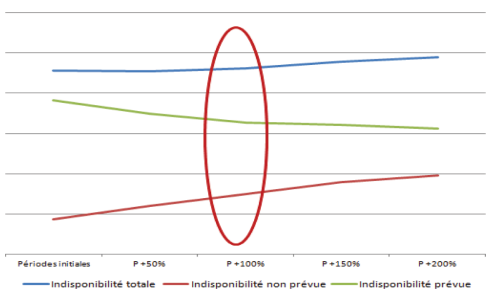

Figure 5. Change in downtime as a function of the frequency of preventive maintenance.

to identify the optimum maintenance frequency for critical equipment. This analysis incorporates the costs related to maintenance and downtime. It is important to note that the sub-systems concerned by safety challenges and for which there are statutory maintenance actions are taken into account in the model, but are not the subject of changes to maintenance policy.

4 CONCLUSIONS

This study made it possible to highly the value of using Petri nets to model an industrial facility. Taking into account the reliability and maintenance characteristics of the system (MTTF, MTTR, preventive maintenance actions, etc.) as well as the organisational constraints on maintenance (number of operators, work priorities, etc.) is essential.

The modelling is possible for a whole system (compressor station), but also for sub-systems (equipment), that makes it flexible.

The simulations based on this model make it possible to compare multiple scenarios on the basis of a group of performance and cost indicators. Consequently, they provide important and reliable decision-making support for maintenance optimisation.

This modelling, already implemented at one station, is being deployed at all GRTgaz stations. The possibility of reusing the model's building blocks and adapting them to the specific data and architecture of each station facilitate and optimise the study duration and cost.

To conclude, this study allowed the improvement of the maintenance approach and gives interesting gains perspectives.

Optimization of maintenance and operational policies of an offshore wind farm subject to stochastic wind conditions

B. Castanier, C. Pehlivan & T.G. Yeung
École des Mines de Nantes—IRCCyN, Nantes, France

ABSTRACT: Offshore wind power has recently become a highly sought after source of sustainable energy. It consists of the generation of electricity through wind turbine farms located in bodies of water off the coast. While offshore wind farms have the advantage of greater wind availability and not taking up land space, they are also challenging to maintain do to their harsh environment and accessibility issues. We propose a Markov decision process to determine the optimal maintenance and operational policy of an offshore wind farm. The maintenance decision determines which subset of the wind turbines to maintain while the operation decision yields the optimal braking speed of the wind turbine in order to reduce deterioration on the system. Our model takes into account the stochastic wind and weather conditions through both the current conditions and a longer-term forecast in order to reduce the risk of taking wind turbines offline during high production periods. Furthermore, we model the accessibility and maintenance resource issues through a fixed maintenance duration period. The deterioration of the wind turbines is modeled via a stationary gamma process which eliminates the need for a complex physical model or a large amount of historical data. A numerical example is presented to highlight the effectiveness of our model.

1 INTRODUCTION

Offshore wind power has recently become a highly sought after source of sustainable energy. It consists of the generation of electricity through wind turbine farms located in bodies of water off the coast. Wind farms are increasingly proposed offshore as there are higher wind speeds available and they do not take up valuable land space.

In 2013 the wind energy sector in Europe had a production capacity of 117 GW and represented 8% of Europe's electricity consumption, doubling since 2008. This rapid rise is expected to increase even further with a more than tripling of production by 2030 to 25% of the European Union's consumption. Furthermore, all but six European countries generated at least some amount of electricity from wind (European Wind Technology Platform 2014).

In addition to increasing consumption, the key goal of the first ever Strategic Research Agenda and Market Deployment Strategy by TPWind was to significantly reduce the cost of wind energy (European Wind Technology Platform 2014). Given that operating and maintenance costs for wind farms comprise up to 30% of the cost of energy produced (Engels *et al.* 2009), the optimization of maintenance policies is a key factor in helping to realize this goal. Moreover, Van Bussel (1997) states that "a different approach to the maintenance strategy is needed that diverts from the existing practices and a technical re-design for the offshore wind turbines is essential to achieve a financially viable project for offshore wind farms."

Compared to land-based wind farms, offshore production presents several maintenance challenges. First, offshore wind turbines are significantly larger than their land counterparts are not as easily accessible. This creates the need for non-traditional maintenance resources such as cranes attached to vessels, helicopters and dedicated crews (Haddad *et al.* 2010) Furthermore, corrosion is a much greater risk due to the humidity and salinity of the sea or ocean. Secondly, the sea itself imposes constraints due to wave and wind conditions which can render the farm inaccessible for significant periods of time. For these reasons realistic, condition-based maintenance optimization models that take into account the unique features of offshore wind farms in order to help reduce cost and make this sustainable form of energy even more attractive. Therefore, in this paper we propose a new condition-based maintenance and operation optimization model for the entire offshore wind farm that takes into account the aforementioned challenges in order to give managers a clear and robust policy to implement.

2 LITERATURE REVIEW

A conceptual overview of operation and maintenance aspects of large offshore wind farms can be found in Bussel (1997, 2001), Bussel and Handerson (2001), and Bussel (2009).

In more focused work, there have been a few models which take a statistical approach to measure failure data to evaluate the reliability level of several critical components (Andrawus *et al*. 2007, Tavner *et al.* 2006, Guo *et al*. 2009). These models are primarily based on the Weibull distribution to model the failure rate.

Several simulation models also exist for analyzing the behavior of land-based single wind turbines (Tawner *et al*. 2006, Negra *et al*. 2007, Foley and Gutowski 2008) and McMillan and Ault (2008) use Monte Carlo simulation to quantify the cost effective ness of a condition-based maintenance strategy on a wind turbine. There have also been a few works using simulation to evaluate maintenance strategies for offshore wind farms. Rademakers *et al*. (2003) consider corrective maintenance strategies while Jacquemin *et al*. (2007) examined the interdependencies between key parameters of operating and maintenance practices such as transportation means, accessibility methods, and the number of maintenance personnel. Byon *et al*. (2011) investigated via simulation the effect of different maintenance strategies on the reliability of *onshore* wind farms using performance indices such as the number of failures, operating and maintenance costs, and availability. Karyotakis (2011) used variability in various input parameters to predict the performance of a planned intervention maintenance policy. These models do not address simultaneously condition based maintenance strategies for an offshore wind farm.

Finally, there are a few analytical models in the literature that deal with wind turbines. Byon *et al.* (2010) consider use a Markov Decision Process (MDP) to determine the optimal maintenance strategy under stochastic weather conditions. To our knowledge, this is the first mathematical model for wind turbine maintenance; however, it is in a land-based context. Haddand *et al.* (2010) use a MDP based on real options for the availability maximization of an offshore wind farm. This model takes a condition-based maintenance approach to identify the optimal combination of turbines to be maintained in the wind farm. Besnard *et al*. (2011) formulate a stochastic model for opportunistic maintenance planning of offshore wind farms. They use stochastic optimization to optimize the planning of service maintenance activities to take advantage of low wind periods in order to reduce production loss while the turbines are offline. Besnard *et al.* (2013) also consider the optimization for the maintenance support of offshore wind farms such as the location of maintenance accommodations, the number of technicians needed, the choice of transfer vessel, and the use of a helicopter. Finally, Byon (2013) extend their previous work to formulate a more tractable approximation of the dynamic decision making model. The approximation links external (e.g. weather) and internal (e.g., system health) conditions to linear decision rules. The advantages of the decision rules of the static condition-based model were used to derive a new set of decision rules. Improvements were then proposed to make the decision rules more adaptive to rapid changes in weather conditions.

In this paper, we propose a Markov decision process to optimize the optimal maintenance and operational decisions for an offshore wind farm subject to stochastic wind conditions. The maintenance decision consists of a form of selective maintenance to determine which subset of wind turbines, based on their degradation level, to maintain. The operational decision determines the optimal blade speed reduction or braking to use for the online wind turbines. Restricting or reducing the turbine speed will lead to less energy production, but also less deterioration on the system. Furthermore we consider an extended downtime period due to maintenance that takes into account the accessibility and resource issues related to offshore wind farms.

Our model further contributes to the existing literature in several key ways. First, rather than relying on a tremendous amount of historical data to derive a statistical model for the reliability or failure rate of the wind turbines, we present a stochastic process based approach utilizing the stationary gamma process to model the degradation of the wind turbines. This model has the advantage of needing only two parameters to model the degradation.

Byon *et al.* (2010) note that there are three stochastic factors that should be considered when modeling wind turbine maintenance: 1) weather conditions and wind speed, 2) repair interruption and delay, and 3) the long lead time for assembling maintenance crews and obtaining spare parts. Our model considers (1) by incorporating both the current wind speed and long-term wind speed forecast. This allows us to take into account the future weather conditions that will impact energy production should some wind turbines be taken offline for maintenance. We consider points (2) and (3) above through the implementation of a fixed maintenance duration during which the maintained turbines will be offline and unavailable for energy production. Moreover, our analytical MDP formulation considers the network or park of wind

turbines to optimize both condition based maintenance decisions for the farm as well as operational decisions. To our knowledge this is the first model to consider both types of decisions. The simultaneous optimization is valuable as the blade speed has a significant impact on wind turbine degradation as well as energy production output. We are then able to derive an optimal policy of which turbines to maintain and the blade speed of those in operation based on the current state of the wind farm and both current and expected future weather conditions.

3 MODEL FORMULATION

We consider an offshore wind farm comprised of N independent and identical wind turbines, each with a continuous deterioration index X_t. A deterioration index $X_t = 0$ represents a perfectly functioning wind turbine and $X_t \geq L$ represents the failed state (no production of energy). We assume that M different maintenances are available. We define an interval where the maintenance i is applicable by the degradation index interval (x_i, x_{i+1}). Hereafter, we refer to degradation state i such an interval. Let n_i represent the number of wind turbines in degradation state i. We also consider the current average wind speed w.

At each decision epoch we decide what selective maintenance actions to take as well as if any reduction in the wind turbine blade speed should be employed. Let i' be the selective maintenance threshold such that all wind turbines with a degradation state $\geq i'$ will be maintained. The operational decision of the wind turbine speed coefficient ρ denotes the reduction or braking of wind turbine blade speed for all wind turbines in operation where $0 \leq \rho \leq 1$. We assume that the maintenance duration is constant and always last δ time periods. Implicitly, this also assumes that all possible maintenance actions may be completed within δ time periods. δ is considered to be the amount of time necessary to assemble the necessary human and other resource, transport them to the farm, and perform all maintenance necessary. A maintenance cost c_i is incurred for each wind turbine under maintenance in state i as well as a fixed cost γ whenever maintenance is performed. We further assume that any wind turbine in maintenance is not functional during the maintenance period and therefore unable to produce energy. The maintenance action is considered to be "perfect," returning the wind turbine to a state "as good as new" i.e., $i = 0$. Once a maintenance period has begun no new maintenance may be initiated until the current maintenance period has been completed. The decision is given by the combination $D = (i', \rho)$.

In addition to the current average wind speed w, we also consider a wind forecast w_δ which is a long term wind forecast of the expected average wind speed over the next δ time periods. The incorporation of this parameter allows us to the take into account potential loss of energy production during periods of high wind while performing maintenance.

The degradation state space of the wind turbines can be expressed as

$$\bigcup_{i=1}^{M} n_i$$

And the complete system state space as

$$S = \left\{ \bigcup_{i=1}^{M} n_i, w, w_\delta, k \right\}$$

where $k = \{0, 1, \ldots, \delta\}$ is the number of periods remaining in the maintenance duration. $k = 0$ denotes that no maintenance is currently in progress, while $k = \delta$ indicates that maintenance has just begun.

We now present the complete Markov decision process formulation. Let $V(S)$ be the maximum expected discounted cost-to-go over the infinite horizon starting from this state. Then

$$V(S) = \max_{(i',\rho)} \left\{ -MX + PR - PL + \lambda \sum_{S'} p_{s'} V(S') \right\}$$

where

$$MX = \gamma + \sum_{i=i'}^{M} c_i n_i$$

$$PR = \sum_{i=0}^{i'-1} f(w, \rho) n_i$$

$$PL = \sum_{i=i'}^{M} g(w_\delta, \delta) n_i$$

λ is a discount factor, $0 \leq \lambda < 1$ and S' represents all possible future states of the system.

MX represents the maintenance cost. PR is the production reward. The energy production is a function of the wind turbine blade speed and the wind speed and given by the function $f(w, \rho)$ that we suppose is a linear function of the number of wind turbines that are operation. PL is the production loss due to wind turbines in maintenance and is given the function $g(w_\delta, \delta)$ and supposed as a linear function of the number of wind turbines currently offline due to maintenance.

A stationary gamma process is used to model the degradation index of each individual wind turbine. We use the gamma process as a general model of aggregate degradation due to its mathematical convenience and strictly increasing property (Van Noortwijk 2009). We have considered only a general deterioration metric rather than trying to model individual components or failure modes which would lead to an intractability for the complex network problem. By discretizing the process we are able to derive the transition probabilities of a wind turbine moving from state i to state a state $\geq i$. Then, using these individual transition probabilities we can then calculate the transition probabilities of the farm. The transition probabilities of the wind speed and wind forecast are assumed to be exogenous and known *a priori*.

4 NUMERICAL EXAMPLE

As a numerical example, we consider an offshore wind farm of size $N = 5$ and four failure mode levels, $i = \{0, 1, 2, 3\}$. We set the maintenance duration $\delta = 3$, so we therefore have $k = \{0, 1, 2, 3\}$. The maintenance decision is given as $i = \{1, 2, 3, 4\}$; $i = 4$ corresponds to no maintenance being performed. The results are displayed in Table 1. We consider three possible values for the braking factor of the turbines $\rho = \{0, 0.5, 1\}$. This corresponds to a complete stoppage of the turbines, half braking, and no braking, respectively. The maintenance costs used were $\gamma = 10$ and $c_i = \{8, 12, 30\}$. Note that this represents a nonlinear increase in the maintenance cost as the degradation level increases. The experiments were evaluated under three possible levels of current wind conditions $w = \{1, 2, 3\}$ and two wind forecasts $w_\delta = \{1, 2\}$.

For the energy production we choose a simple linear function

$$f(w, \rho) = 2w\rho$$

where 2 is an energy production coefficient. Similarly, the energy loss function is a simply a function of the wind forecast

$$g(w_\delta) = w_\delta.$$

We solve for the optimal policy using value iteration with $\lambda = 0.99$.

The transition probabilities were generated using a stationary gamma process with shape function parameters 2 and 1 and scale parameter equal to 10. The degradation indices were defined as $x_i = \{0, 2, 3, 5\}$. In order to simplify the evaluation of the stationary law, we assumed $\rho = 0.8$ as the average braking.

Table 1. Maintenance (Mx) decisions.

n_0	n_1	n_2	n_3	w	w_δ	Mx (i)	ρ
0	0	0	5	1	1	3	1
1	0	0	4	1	1	3	1
1	0	1	3	1	1	2	1
0	0	5	0	1	1	2	1
0	0	4	1	1	1	2	1
0	0	3	2	1	1	2	1
0	0	2	3	1	1	2	1
0	0	1	4	1	1	2	1
0	1	3	1	1	1	1	1
0	1	2	2	1	1	1	1
0	1	1	3	1	1	1	1
0	1	0	4	1	1	1	1
0	0	0	5	2	1	3	1
1	0	0	4	2	1	3	1
0	0	4	1	2	1	2	1
0	0	3	2	2	1	2	1
0	0	2	3	2	1	2	1
0	0	1	4	2	1	2	1
0	1	2	2	2	1	1	1
0	1	1	3	2	1	1	1
0	1	0	4	2	1	1	1
0	0	0	5	3	1	3	1
1	0	0	4	3	1	3	1
0	0	3	2	3	1	2	1
0	0	2	3	3	1	2	1
0	0	1	4	3	1	2	1
0	2	1	2	3	1	1	1
0	2	0	3	3	1	1	1
0	1	2	2	3	1	1	1
0	1	1	3	3	1	1	1
0	1	0	4	3	1	1	1

For the numerical results, we first analyze the maintenance decisions which are presented in Table 1. Note that Table 1 only shows those states and wind conditions in which maintenance (Mx) is prescribed. The complete policy is much too large to present in its entirety. We see from the table that both preventive ($i = 1, 2$) and corrective ($i = 3$) actions are taken by the model and that maintenance is only prescribed when the wind forecast is low. Generally, we find that maintenance is performed when there are only one or less wind turbines in perfect condition ($n_0 \leq 1$) or where $n_2 + n_3 \geq 4$. We also only see corrective maintenance performed when all or almost all of the wind turbines are failed.

The results also seem to indicate a threshold policy. We see that no maintenance is performed if $n_0 \geq 2$ or $n_1 \geq 2$. Interestingly, maintenance is still not prescribed at $n_1 \geq 2$ even when $n_0 = 0$.

Finally, we see that maintenance decisions are much more sensitive to the wind forecast than the current wind conditions. As noted we only

see maintenance when the wind forecast is low, however we do not see a significant change in the policy between different current wind conditions. The braking decisions, however, are sensitive to the current wind conditions.

We now analyze the braking decisions for the wind turbines. We see in Table 1 that at the beginning of the maintenance period, no braking is ever employed in the farm. This is intuitive as remaining wind turbines should be in sufficient condition such that braking is not warranted. Table 2 shows the portion of the policy where $\rho = 0.5$. Note that there is no maintenance prescribed here for any of these cases. This only occurs at the highest wind level ($w = 3$), but may be with either a high or low wind forecast.

Table 2. Turbine braking decisions.

n_0	n_1	n_2	n_3	w	w_δ	Mx (i)	ρ

2	2	0	1	3	2	4	0.5
2	1	0	2	3	2	4	0.5
1	4	0	0	3	2	4	0.5
1	3	1	0	3	2	4	0.5
1	3	0	1	3	2	4	0.5
1	2	0	2	3	2	4	0.5
1	1	0	3	3	2	4	0.5
0	5	0	0	3	2	4	0.5
0	4	1	0	3	2	4	0.5
0	4	0	1	3	2	4	0.5
0	3	1	1	3	2	4	0.5
0	3	0	2	3	2	4	0.5
0	2	0	3	3	2	4	0.5
0	1	0	4	3	2	4	0.5

There are many other possible states in which no maintenance is prescribed, and due to space limitations it is not possible to list them all. However, we can summarize our findings on the braking policy as a function of w and k. For low and medium wind levels ($w = 1, 2$) no braking is ever utilized by the model. Braking to half speed ($\rho = 0.5$) may be employed when $w = 3$ as noted in Table 2. The results do not show a strong sensitivity of the braking policy to the wind forecast.

In general, we find that the model proposes braking in states when there is a small number of functioning wind turbines in the farm, regardless of their degradation level, and also when the functioning wind turbines are highly degraded, regardless of the number of wind turbines in operation.

An interesting numerical result is the relationship between ρ and k. We find that as k decreases (i.e., as the maintenance duration becomes closer to completion), ρ also decreases. For example, when $k = 3, 2$, the model suggests half braking when $w = 3$ in order to keep the operating wind turbines functioning longer, however when $k = 1$ the model mostly proposes full braking (i.e., stopping the wind turbines). One would intuitively expect braking to decrease as the opportunity for maintenance becomes closer, but the model suggests otherwise. This could perhaps be due to the non-linear jump in maintenance cost for higher degradation levels. The model is choosing to stop the wind turbines rather than face a very high maintenance cost if they are further degraded.

5 SUMMARY AND CONCLUSIONS

We have formulated a Markov decision process model to jointly optimize the maintenance and operational decisions of an offshore wind turbine farm. We have incorporated many key aspects of this problem including extended maintenance durations and changing wind conditions.

Our model provides farm managers with an easy to implement policy based on the condition of the park while taking into account the evolution of degradation and both current and future wind conditions. Understanding the maintenance policy in relationship to the state of the farm can help managers to anticipate upcoming maintenance actions and therefore ensure that the necessary resources are in place. Furthermore, incorporating the breaking decisions allows extending the life of the turbine before maintenance is needed. Providing a tool to manage such a complex system of systems well help to reduce maintenance and

operating costs and allow offshore wind energy to become a more viable alternative in the future.

The optimal policy of our model seems to have appealing structure and it would be interesting to investigate this further to demonstrate the existence of various threshold or control-limit policies. We would also like to emphasize that this is a preliminary work to gain an initial understanding on the impact of various factors on the optimal policy. We have provided a small-scale numerical example and understand that, as always with dynamic programming, the curse of dimensionality comes into play as the size of the farm grows. The development of more efficient algorithms or heuristics, that perhaps take advantage of the policy structure, will be needed in evaluating real world offshore wind farms.

An age-based preventive maintenance for offshore wind turbines

F.P. Santos, A.P. Teixeira & C. Guedes Soares
Centre for Marine Technology and Engineering (CENTEC), Instituto Superior Técnico, Universidade de Lisboa, Portugal

ABSTRACT: In this paper a strategy is presented for combining corrective maintenance replacements with age-based imperfect preventive maintenance repairs. Preventive maintenance actions are performed considering the components' age thresholds and an age reduction ratio, q. An offshore wind turbine consisting of several degraded components is considered. Failure models are based on onshore ones and derived through an empirical approach based on stress factors for mechanical systems. Generalized Stochastic Petri Nets with predicates and Monte Carlo simulation are used to model and simulate operation and maintenance activities considering logistic resources, times and costs, and weather constraints. A preventive maintenance repair cost function dependent on the age reduction effort, q, and on the age of the components is proposed and compared with an age independent cost function, in terms of their effect on the operation and maintenance costs and revenues.

1 INTRODUCTION

The Operation and Maintenance (O&M) of offshore wind farms faces more challenges than the onshore one given that the harsher offshore conditions limit, for example, the accessibility for routine servicing and maintenance. Even in favourable weather conditions, the O&M activities are still more costly than in onshore as they are influenced by the offshore distances, site exposure, wind farm size, wind turbine reliability and maintenance strategies. Moreover, offshore O&M tasks need special lifting equipment for the installation or change of major turbine components, which are not always available at short notice. Thus, for some European offshore wind farms the cost of energy is approximately 33% more than in onshore installations (Tavner 2012) and the O&M costs which are major contributors to the cost of energy can reach up to 30% of such cost (Nielsen & Sørensen 2011).

The Corrective Maintenance (CM) is widely used but as a reactive approach does not prevent costly repairs or replacements. This is a general problem (Guedes Soares et al. 2010) but in the offshore context failures often occur during seasons of the year when the accessibility to the turbine is limited due to the weather conditions leading to production losses (Nielsen & Sørensen 2011). In contrast, Preventive Maintenance (PM) can be planned in time so that the risk of major failures and downtimes is minimized and, the logistics and maintenance costs along with the system operability are optimized.

When modelling the maintenance and optimization of complex and real systems one is faced with the challenge of capturing the realistic aspects of a system's performance and the dynamics of the interactions among numerous subsystems or components (Guedes Soares et al. 2010, Zio et al. 2009). Simulation approaches are often essential for such purpose even when dealing with condition monitoring (Barata et al. 2002), which is being considered also for wind turbines (Van Horenbeek et al. 2013).

The offshore wind energy industry is quite recent not having reached the maturity of other industries such as the one of oil and gas production. Consequently, there has been a need to develop and adapt specific maintenance strategies for optimization, even though such strategies are broadly used in many fields.

In this paper a maintenance strategy combining CM replacements with age-based imperfect PM repairs is modelled and assessed. The PM is performed when the repair threshold age of the components is equalled or exceeded. A PM repair cost function having an age reduction ratio, q, and the age of the components as parameters is proposed. This is compared with an age independent cost function—already used in the literature (Ding & Tian 2012)—in terms of the effect on the O&M costs and revenues of an offshore wind turbine.

Four degraded components of the wind turbine are considered. The failure models are based on onshore ones and derived using an empirical approach based on stress factors for mechanical systems. Generalized Stochastic Petri Nets (GSPN)

and Monte Carlo Simulation (MCS) are used to model and simulate the O&M activities and the dynamics of the interactions between components considering the logistics, times and costs, and weather constraints.

2 LOGISTICS AND WEATHER CONSTRAINTS

A set of four components, rotor, gearbox, generator and pitch system of a 5 MW offshore wind turbine is considered for maintenance modelling and simulation. The turbine is located in a North Sea wind farm about 45 km from German shore. A capacitor factor of 50.8% has been reported by Lindoe (2011).

According to the International Energy Agency (2012), the German tariff for wind energy produced by offshore wind turbines is €0.15/kWh (€150/MWh) and is the reference value considered in the present study.

Three different maintenance categories based on Rademakers & Braam (2002) are used depending on the weight (BVG associates) of the component being replaced (CM) or repaired (PM), thus according to the vessel involved as is shown in Table 1.

The supply vessel is the only one docked at the harbour and used to perform PM actions. It transports a maintenance crew of 4 technicians and spares up to 1 ton [t] such as the pitch system. The maintenance crew has a 12 hour shift per day, 7 days a week, which includes the travelling times to and from the turbine when is to be maintained. Besides, it can start at any time of the day as long as all the logistics are available and there is a weather window allowing the performance of a full maintenance action.

At each maintenance, the sailing of the supply vessel with the maintenance crew is done every day up to its ending. This is valid for all maintenance categories. On the other hand, the jack-up and crane vessels stay at the turbine location. The supply vessel is set to arrive at the turbine at the same time as the jack-up or the crane vessel, so that the maintenance team can start working immediately.

Table 1. Maintenance categories.

	Turbine's components			
Categories (vessels)	Gearbox ≤ 65[t]	Generator ≤ 20[t]	Pitch syst. ≤ 1[t]	Rotor 90–150[t]
Supply	PM	PM	PM, CM	PM
Crane	CM	CM		
Jack-up				CM

The velocity values of each vessel and respective travelling times from the harbour to the turbine are shown in Table 2.

The times larger vessels take to arrive at the harbour and the delay for a spare pitch system to be available are presented in Table 3. The values of Table 2 and Table 3 are based on Rademakers & Braam (2002).

The costs of the turbine's components presented in Table 4 are approximate values retrieved from an offshore wind farm guide (BVG Associates) on 5 MW turbines. The cost of transporting a spare from the manufacturer to the harbour is assumed to be included in the components' unit cost.

The costs associated with the vessels and maintenance technicians are in Table 5, being approximate values based on Rademakers & Braam (2002).

Table 2. Velocity and traveling times of each vessel.

Vessel	Velocity [knots]/[kmh^{-1}]	Travelling time (one way) [h]/[day]
Supply	10.8/20	2.25/0.09
Crane	8.1/15	3.0/0.13
Jack-up	5.4/10	4.5/0.19

Table 3. Vessels' logistic times.

Maintenance category	Logistic time [h]/[day]
Supply	48/2
Crane	160/6.67
Jack-up	504/21

Table 4. Cost of components.

Component	Cost/unit [€]
Gearbox	863,000
Generator	247,000
Pitch system	123,300
Rotor	1,849,000

Table 5. Hourly rates and mobilization costs.

	Cost [€]
Supply vessel (hourly rate)	600
Crane vessel	
Hourly rate (0.04 days)	6250
Mobilization/demobilization	45,000
Jack-up vessel	
Hourly rate	6250
Mobilization/demobilization	57,000
Technician (hourly rate)	70

Table 6. Probabilities of weather windows and waiting times.

Season	Weather window probability	Waiting time for a weather window [day]
Winter	0.30	60
Autumn	0.50	30
Spring	0.60	10
Summer	0.80	3

The probabilities of occurrence of weather windows, i.e. of wind speed and significant wave heights within the O&M limits, and the waiting times for such windows (i.e. when weather conditions are over the O&M limits) to perform maintenance actions are given in Table 6 for each season of the year. These values are merely illustrative examples and do not represent real data statistics, which can be obtained only from real weather data when available.

3 STRESS FACTORS AND FAILURE MODELS

Offshore wind turbines endure higher stresses than onshore wind turbines such as environmental and power utilizations ones, due to being located in the marine environment. Thus, they experience higher failure rates (Karyotakis & Bucknall 2010) and for this reason onshore failure distributions are not adequate for modelling the behaviour and performance of an offshore wind turbine. However, there is a lack of available reliability data of offshore wind turbines (Karyotakis & Bucknall 2010), in fact only a few field data exists in the public domain (Tavner 2012). Consequently, power rating and environmental stress factors for mechanical systems (Davidson 1994) are considered in the present study as an empirical approach to derive failure distributions for the offshore wind turbine components from the typical onshore failure models (Ding & Tian 2012) of Table 7.

The "failure" in this context refers to the component's loss of function that leads to its replacement.

Failures rates of components of onshore wind turbines were used by Karyotakis & Bucknall (2010) in a reliability model based on stress factors for mechanical systems (Davidson 1994) to estimate a range of failure rates for offshore wind turbines. To do so, one has to assume that both onshore and offshore wind turbines are of the same type and also account for the higher environmental and power utilization stresses that offshore wind turbines are subject to (Karyotakis & Bucknall 2010).

Table 7. Failure parameters of onshore turbine components.

Component	Distribution	Scale parameter α [day]	Shape parameter β
Rotor	Weibull	3000	3
Gearbox		2400	3
Generator		3300	2
Pitch		1858*	3

*Parameter derived from Ribrant (2006) and Durstewitz (2005).

According to Davidson (1994) the reliability model is based on the linear Equation 1.

$$\lambda_{offshore} = \lambda_{onshore} \cdot (K_1 \cdot K_2) \cdot p(A) \quad (1)$$

where one has the following:

- $\lambda_{offshore}$ is the estimated offshore wind turbine failure rate for failure mode A;
- $\lambda_{onshore}$ is the failure rate of the system subjected to ideal conditions of minimal stresses (e.g. onshore);
- K_1 and K_2 are the environmental and power utilization stress factors, respectively. They represent the different conditions in which a system is used. In offshore conditions, they refer to the influence of weather and marine environment and, the effect of different operating power ranges on the reliability of the offshore wind turbine;
- $p(A)$ is a measure of the failure rate's proportion for failure mode A of the system. In this case, only a failure rate and failure mode is considered for each component and therefore $p(A) = 1$.

The empirical values of the environmental and power rating stress factors for mechanical systems (Davidson 1994) are shown in Tables 8 and 9, respectively.

The four components of the turbine are considered to be *marine, sheltered*, i.e. are within the nacelle but not exposed to the marine environment directly. Accordingly, $K_1 = 1.5$.

The values of Table 9 are graphically represented in Figure 1. The trend line shows that K_2 increases exponentially as a component rating is increased over its nominal rating.

The power rating stress factor represents the possible effect of different operation power ranges on the reliability of a wind turbine. Given that an offshore turbine is subjected to higher winds than an equivalent onshore one the percentage of power available relatively to the turbine's nominal rating is higher. Therefore, K_2 can be considered

Table 8. Environmental stress factors for mech. systems.

General environmental conditions	Environmental stress factor K_1
Ideal, static conditions	0.1
Vibration free, controlled conditions	0.5
General-purpose, ground-based	1
Marine, sheltered	1.5
Marine, exposed	2
Road	3
Rail	4
Air	10
Missile	100

Table 9. Power rating stress factors for mechanical systems.

Percentage of component nominal rating	Power rating stress factor K_2
140	4
120	2
100	1
80	0.6
60	0.3
40	0.2
20	0.1

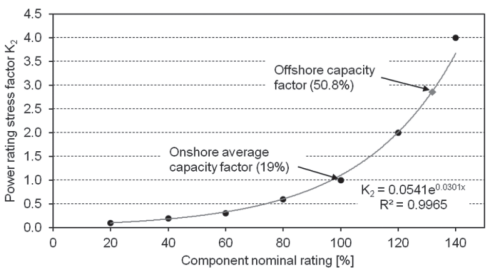

Figure 1. Power rating stress factor vs. component nominal rating [%].

as dependent on the capacity factor of a turbine. Consequently, the power rating stress factor of an offshore wind turbine can be calculated from the capacity factor of a specific installation. Moreover, K_2 when applied to failures rates accounts for the difference in the capacitor factors between offshore and onshore wind turbines (Karyotakis & Bucknall 2010; Karyotakis 2011).

By the end of 2011 the average capacity factor of wind turbines in Germany was 19% for a total of 29,075 MW of installed wind capacity of which 200 MW were offshore. The total number of turbines was 22,297 and of the 55 offshore wind turbines installed 33 were only connected to the grid in December of 2011 (International Energy Agency 2012). Therefore, it is reasonable to consider 19% as the onshore average capacity factor. Considering this value for onshore wind turbines and that it is assumed to represent 100% of component nominal rating, it can be seen in Figure 1 that $K_2 = 1$. Additionally, assuming 50.8% as the equivalent offshore wind turbine capacity factor, and inserting the value 50.8% – 19% + 100% = 131.8% in the exponential equation of Figure 1 one gets $K_2 = 2.86$.

Karyotakis & Bucknall (2010) consider constant failure rates in Equation 1 while in the present paper the failure rates of the components increase with time, following two-parameters Weibull distributions. Thus, substituting $\lambda_{onshore}$ in Equation 1 by the expression of a Weibull failure rate one obtains Equation 2.

$$\lambda_{offshore} = \frac{\beta_{onshore}}{\alpha_{onshore}}\left(\frac{t}{\alpha_{onshore}}\right)^{\beta_{onshore}-1} \cdot K_1 \cdot K_2 \qquad (2)$$

Having only one equation (i.e. Equation 2) for two parameters (α and β) it is assumed that one parameter has to be kept the same for onshore and offshore turbines. Consequently, taking as example the failure model of the rotor (see Table 7) for which the Mean Time To Failure (MTTF) is 7.34 years, a variation of –10% in the shape parameter, β, yields a MTTF of 7.31 years, whereas the same variation in the scale parameter, α, returns a MTTF of 6.61 years. In other words, the reliability distribution of a degraded component is more sensitive to variations in the values of α than to the variation of β. Therefore, considering the same β for onshore and offshore failure models, Equation 2 turns into Equation 3.

$$\frac{\beta \cdot t^{\beta-1}}{\alpha_{offshore}^{\beta}} = \frac{\beta \cdot t^{\beta-1}}{\alpha_{onshore}^{\beta}} \cdot K_1 \cdot K_2$$
$$\Leftrightarrow \frac{1}{\alpha_{offshore}^{\beta}} = \frac{K_1 \cdot K_2}{\alpha_{onshore}^{\beta}} \qquad (3)$$

Solving for $\alpha_{offshore}$ and substituting K_1 and K_2 by the previously obtained values one gets Equation 4.

$$\alpha_{offshore} = \frac{\alpha_{onshore}}{(K_1 \cdot K_2)^{\frac{1}{\beta}}} = \frac{\alpha_{onshore}}{4.29^{\frac{1}{\beta}}} = 4.29^{-\frac{1}{\beta}} \cdot \alpha_{onshore} \qquad (4)$$

Using Equation 4 with each of the components' failure models of Table 7 one obtains, according to the stress factors' approach, the failure distributions of the same components but for

Table 10. Failure parameters of the offshore turbine components.

Generator		1594	2
Pitch		1144	3

the equivalent offshore wind turbine as shown in Table 10.

4 O&M STRATEGY

The O&M strategy consists of CM and PM actions. The CM tasks entail only unplanned replacements whereas PM activities are age-based and imperfect, being performed considering an age reduction ratio, q ($0 < q < 1$) when the age of a component is equal to or larger than some predefined time $p \times MTTF$, where $0 < p < 1$. The component after PM is therefore q younger, i.e. the age is reduced by q percent. The value, p, is a preventive repair threshold parameter which is the same for all components.

The age of a component after a maintenance action is given by Equation 5.

$$Age_i = \underbrace{\left[t_i - t_{i-1} + Age_{i-1}\right]}_{Age_i^{acc}} \cdot (1-q) \tag{5}$$

where Age_i and Age_{i-1} are the component's consecutive ages after the ith and $i-1$th maintenance tasks, respectively; Age_i^{acc} is the age at the beginning of the ith maintenance action, accumulated from the $i-1$th maintenance task; t_i and t_{i-1} are the calendar times at the beginning of the ith and at the end of the $i-1$th maintenance actions, respectively. The CM is always perfect since it replaces the component by a new one (as if $q = 1$), thus $Age_i = 0$. Since the age reduction effort is $0 < q < 1$ then all PM are imperfect repairs.

The CM is performed when necessary whereas PM is carried out only in the summer given to more favourable weather conditions, thus higher accessibility to the turbine. A PM is performed when Equation 6 is valid.

$$t_i - t_{i-1} + Age_{i-1} \geq p \cdot MTTF \tag{6}$$

Notice that t_i is a summer calendar time. The failure distributions and, repair and replacement times of the components are considered to be independent.

Ding & Tian (2012) used the age reduction ratio, q, for the opportunistic maintenance of an onshore wind farm, considering the cost of the imperfect maintenance actions as a function of q^2 times a variable preventive replacement cost plus a fixed maintenance cost. In the present paper each PM is stochastically driven so no fixed maintenance cost is considered. Although the maintenance cost function, Equation 7, is also based on q it additionally increases, however, as the age of the component increases at each PM.

$$C_M = \begin{cases} q^{\frac{MTTF}{Age_i^{acc}}} \cdot C_r & 0 < q < 1 \ \wedge \ Age_i^{acc} > 0 \\ 1 & q = 1 \ for \ CM \Rightarrow Age_i = 0 \end{cases} \tag{7}$$

where C_r is the cost of a new component (see Table 4).

Figure 2 shows the plot of the maintenance cost function in terms of the age reduction effort q and of the age of a component, Age_i^{acc}, at the beginning of a PM and accumulated from the previous maintenance task. The PM cost (in terms of C_r) for a fixed q increases with the age of the component, i.e. it is reasonable to consider that putting the same effort on PM actions, say $q = 50\%$, to improve the condition of a component with an age of 100% of its MTTF is more costly than if its age were to be 75% × MTTF. Thus, a component which is aging even with consecutive PM has increasing maintenance costs. Also, it may be as preventively costly to slightly reduce the age of an old component as significantly improving its condition when it is much younger.

The effective duration times of the CM replacements and PM repairs follow exponential and

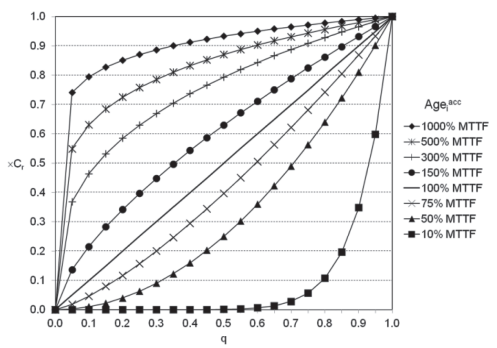

Figure 2. Effect of age and reduction effort on the PM cost.

Table 11. Distributions' parameters of the effective duration of CM and PM actions.

Maintenance category	CM (exponential)	PM (lognormal)	
	λ [day^{-1}]	MTTR [day]	St. dev. [day]
Supply	2.381	0.420	0.126
Crane	0.481	2.079	0.624
Jack-up	0.599	1.669	0.501

lognormal distributions, respectively. Their parameters are given in Table 11 for each maintenance category.

The logistics, weather constraints and the O&M tasks are modelled and simulated using Generalized Stochastic Petri Nets with predicates and Monte Carlo simulation. The q and age dependent cost function for PM repairs (Equation 7) is compared with the q^2 cost function in terms of the effect on the turbine's O&M costs and revenues.

5 GENERALIZED STOCHASTIC PETRI NETS MODEL

Petri nets are a tool that combines graphical with mathematical modelling to analyse discrete event systems. They are adequate to represent the dynamics and behaviour of systems and its maintenance, providing performance outputs (Zio 2009). The GSPN with predicates coupled with MCS are a recent extension of Petri nets and have been proven to be powerful and efficient in modelling the complexity of real systems (Dutuit et al. 1997, 2008, Santos et al. 2012, 2013a, b). The transitions of the GSPN can fire stochastically and deterministically. The predicates can be guards or assignments. The first are preconditions to enable or inhibit the transitions while the second are post-condition messages to update variables when a transition fires. Not to be too extensive, only the GSPN of the PM of the rotor presented in Figure 3 is briefly explained.

The rotor imperfect PM is performed only in the summer, if it is functioning (i.e. *??Rotor_avail*==1 is *true*) and its age is equal to or larger than the predefined age $p \times MTTFrotor$ (i.e. when the *if then else PerformRotor_PM=ite((time()-max(Rotor_lastCM, Rotor_lastPM)+Rotor_age)>=(p×Rotor_MTTF), true,false)*). If so, and the supply vessel is on standby along with the maintenance crew and no other component is in replacement/repair a weather window is generated. Meanwhile, if the rotor fails or the summer ends the PM is aborted (i.e. *NoRotorPM* fires).

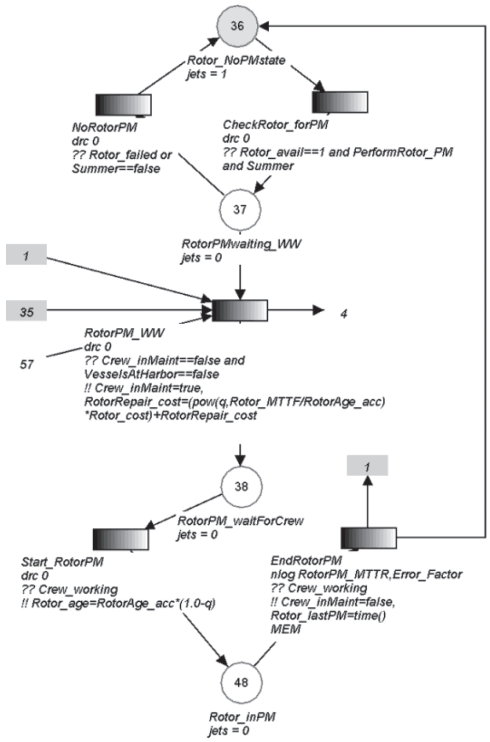

Figure 3. GSPN model of the rotor's PM.

Given that an age reduction ratio, q, is used the rotor's age after the PM is $1 - q$ times its accumulated age since the last maintenance, i.e. $Rotor_age = RotorAge_acc \times (1.0\text{-}q)$ and the accumulated repair cost is $RotorRepair_cost = (pow(q, Rotor_MTTF / RotorAge_acc) \times Rotor_cost) + RotorRepair_cost$ (see Equation 7). The stochastic law of the repair time is lognormal as shown in the transition *EndRotorPM*.

6 RESULTS

To begin with, a convergence analysis of the MCS was performed on the GSPN model considering all of the relevant statistics. The simulations were of 10,950 *days* (i.e. 30 *years*). The convergence of the statistics was achieved when the variation of their values was equal to or less than 0.1%. This occurred when increasing the number of simulations from 9000 to 15,000.

For simplification purposes the models with the q and age dependent, and q-dependent cost functions will be referred from now on as *q^age* and *q^2*, respectively. They were compared in terms of the effect on the turbine's O&M costs and revenues.

For such, a fixed $q = 0.4$ and a set of p-values ranging from 0.1 to 0.9 in steps of 0.1 were considered. The total simulation times were 4.02 and 4.58 minutes for the models with q^2 and q^*age* cost functions, respectively.

Figure 4 shows the mean CM costs incurred with the replacements: new components, mobilizations and demobilizations of the larger vessels (i.e. crane and jack-up), their times at the harbour, going to and staying at the turbine, and to demobilize. The second curve is related with the turbine mean loss of production. The other curve represents the supplier vessel and maintenance crew mean costs due to the CM and PM actions. Since what drives such costs are the failure and repair rates, the logistic times and weather constraints, which are common to both models and do not result from the q^*age* and q^2 cost functions, the models have the same mean costs (i.e. curves).

As the preventive repair threshold parameter, p, is increased until 0.9, the mean times between PM get larger. Accordingly, the failure rates increase giving rise to more failures, thus increasing the mean CM costs as shown in Figure 4. Moreover, the mean costs with the supplier vessel and maintenance crew used in the CM and PM tasks decrease, since the drop in the mean number of PM is larger than the increase in the mean number of CM. However, the rate at which these CM and PM costs decrease is lower than that of the increasing CM costs given that the supplier and crew hourly costs are much smaller than the replacements, but specially than the hourly costs of the larger vessels. Finally, the loss production costs due to the turbine unavailability decrease until $p = 0.5$, stabilizing after that, mainly due to the reduction in the mean number of PM actions.

The q^2 and q^*age* cost functions have only effect on the mean PM repair costs (see Equation 7) as shown in Figure 5.

Considering that the age reduction ratio, q, has a fixed value the mean cost of each PM repair,

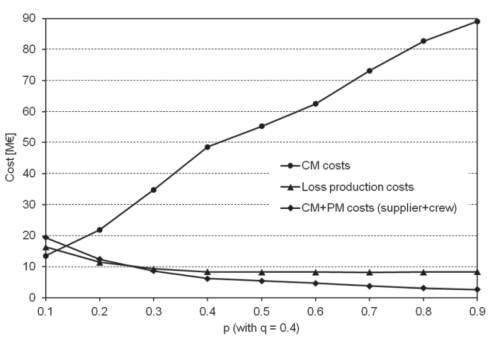

Figure 4. CM and PM costs for both models.

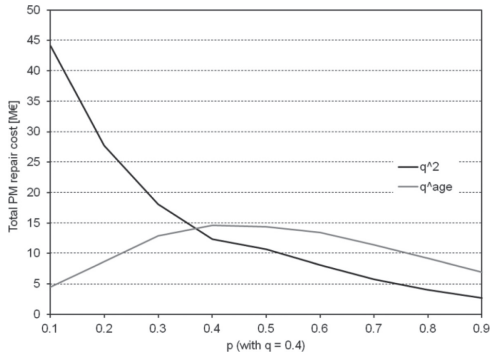

Figure 5. PM repair costs using the two cost functions.

according to the q^2 approach, is always the same for a component independently of its age. In other words, one can vary the time between PM actions (by varying p) that the PM repairs costs "behave" as if the component did not age. This seems counterintuitive, however. The only reason for the decrease in the mean total PM repair costs is the reduction of the mean number of PM repairs due to the increase in the time between PM actions.

On the other hand, the q^*age* cost function is sensitive to the age reduction effort and to the age of a component at each PM. Therefore, although the mean number of PM tasks decreases, as the time between PM increases, the total mean costs get higher due to the aging of the components, reaching is maximum value at $p = 0.4$. As the time between repairs continues to increase the total repair costs decrease given that the impact of the decrease in the mean number of repairs outweighs that of the increasing ages of the components. Also, the aging between consecutive PM repairs is accounted for in the maintenance costs. It seems reasonable that an effort to reduce, for example, the age of a young component by 40% should be less costly than improving its condition in the same percentage when it is older. Also, it may be realistic to consider that is as costly to slightly reduce preventively the age of an old component as is to considerably improve its condition when it is quite younger.

Figure 6 shows the mean total maintenance costs and revenues by varying the p-values. The availability curve is independent of the two cost functions by the same reasons given for the results in Figure 4.

The mean optimal revenues are 20 M€ ($p = 0.3$) and 34.48 M€ ($p = 0.2$), the mean number of PM repairs are 1.33 and 1.94 per component/year, and the turbine's mean availabilities are 90.7% and 88.6% when using the q^2 and q^*age* cost functions, respectively. These availability figures are

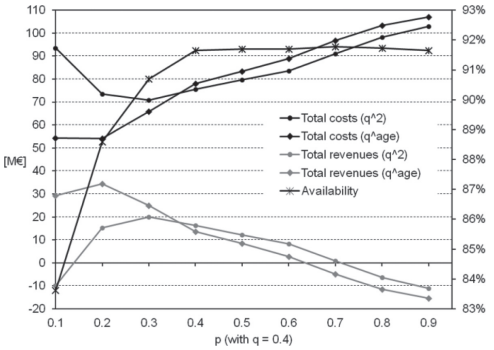

Figure 6. Total maintenance costs and availability using the two cost functions.

somewhat in line with the current offshore wind turbines availability values of 90–95% achieved by the industry (Tavner 2012). All in all, it seems at least as reasonable and realistic to consider the PM cost function that takes into account the age reduction effort and the age of the components.

Despite having been modelled only one offshore wind turbine, the considered maintenance strategy and cost function can be used for a wind farm provided that the dependencies between wind turbines due to sharing common logistic resources are modelled. In such case, the failure and repair models can be assumed the same for equal components in all wind turbines; more repair teams, different numbers of vessels and the use of an helicopter for harsh weather conditions could be introduced in the model to evaluate the impact in the costs, revenues and availability of the wind farm. Also, the use of opportunistic maintenance should be evaluated since it is reasonable to expect that the "simultaneous" maintenance of several wind turbines would be less costly.

7 CONCLUSION

An age-based imperfect PM combined with CM replacements was modelled for an offshore wind turbine using GSPN with predicates coupled with MCS and considering the logistics, times and costs, and weather constraints. The PM repairs were modelled to be performed after a repair threshold age, $p \times MTTF$, of the components. The failure models of the components were obtained from onshore ones using an empirical approach based on stress factors for mechanical systems.

A PM repair cost function dependent on an age reduction ratio, q, and on the age of the components was proposed and compared with a q-dependent cost function in terms of the effect on the O&M costs and revenues of the wind turbine.

Since the cost function is sensitive to the age of the components the total mean repair costs increase with their aging as the time between PM increases up to a point when the impact of the decreasing number of repairs on the costs outweighs that of the aging. This way the aging between consecutive PM repairs is accounted for in the maintenance costs. This approach seems reasonable when compared with the one based only on q given that an effort, in percentage terms (q), to reduce the age of a young component should be less costly than when applying the same effort once the component is older.

Considering a fixed q and varying the time between PM repairs (i.e. varying p-values) the mean optimal revenues were higher for the model with the age-dependent cost function.

Availability modelling and analysis of an offshore wind turbine using Extended Coloured Stochastic Petri Nets

P. Zeiler & B. Bertsche
Institute of Machine Components, University of Stuttgart, Stuttgart, Germany

ABSTRACT: Wind turbines for power generation will be further developed and constructed worldwide. The trend goes towards offshore locations due to the higher wind speeds at sea. For an operator of a wind turbine its technical availability is the crucial factor for a cost-effective operation. In this paper, the availability modelling and analysis of an offshore wind turbine is done based on Extended Coloured Stochastic Petri Nets (ECSPN). The merits of ECSPN in modelling complex, multi-state and multi-component systems with age evolution based on time-dependent failure rates are shown. Corrective, preventive and condition-based maintenance measures as well as periodic replacements are modelled—each with individual age reduction effects. Two different maintenance categories differentiated by the size and weight of the spare parts and logistics involved such as ships and floating cranes are included in the model. The spare parts inventory and the order policy are modelled. The weather windows for accessing the turbine as well as the wind loads of the turbine are also modelled. Numerous interactions and dependencies are included in the model. The influences of different maintenance and logistics strategies on the availability are investigated. Based on the results, the reliability goals and the necessary maintenance strategy for achieving a desired availability can be specified.

1 INTRODUCTION

Wind power is one of the most important forms of renewable energy production. The German Wind Energy Association (BWE) reported in 2013 the construction of wind turbines with a total capacity of approximately 3,000 MW in Germany. In order to operate such a plant economically, despite the high investment costs, life times of about 20 years are provided (IWES 2009). This results in high demands on the reliability of a wind turbine.

In recent years, the trend goes towards offshore wind farms that promise a higher energy yield due to the higher wind speed at sea. These exposed locations provide new challenges on maintenance and repair for operators of wind turbines. Due to meteorological conditions—in particular by wind and waves—the access to offshore wind turbines is significantly limited compared to onshore wind turbines. Therefore, the maintenance strategy is of particular significance.

For the operator of a wind turbine the crucial factor for the cost-effective operation is the technical availability of the system, which results from the reliability and maintenance strategy. Therefore, powerful methods need to be applied to the specification of wind turbine availability.

In the past years many papers have been published in the context of maintenance and logistics modelling as well as availability analysis. Several papers are especially focusing on offshore wind turbines. A recent paper already including a variety of modelling aspects is Santos et al. (2013). It aims for the planning of operation and maintenance activities based on Generalized Stochastic Petri Nets (GSPN). It includes corrective and preventive maintenance but does not consider condition-based maintenance and periodic replacements. The global age evolution of the components in their different load states cannot be modelled due to the limitations of the GSPN. Kahrobaee & Asgarpoor (2013) focuses on maintenance optimization of deteriorating equipment of offshore wind turbines by applying a hybrid analytical-simulation approach. The developed model is limited to constant failure and repair rates and is neglecting the maintenance logistics and resources. The influence of the weather on the turbine load and accessibility is not considered. Roux et al. (2013) investigate the optimization of preventive maintenance through a combined maintenance-production simulation model applying timed Petri nets. The developed model is able to describe a multi-component system, but it is not possible to consider multi-states of the components.

In this paper, the availability of an offshore wind turbine is modelled and analysed based on Extended Coloured Stochastic Petri Nets (ECSPN).

The merits of ECSPN in modelling complex, multi-state and multi-component systems with age evolution based on time-dependent failure rates are shown. Corrective, preventive and condition-based maintenance measures as well as periodic replacements are modelled—each with individual age reduction effects. Two different maintenance categories differentiated by the size and weight of the spare parts and logistics involved such as ships and floating cranes are included in the model. The spare part inventory and the order policy are modelled. The weather windows for accessing the turbine as well as the wind loads of the turbine are also modelled. Numerous interactions and dependencies are included in the model. They need to be considered for a close-to-reality analysis which will serve as a base for the specification of the wind turbine reliability and the supporting maintenance process.

This paper is organized as follows: In section 2 Petri nets are presented, which serve for the modelling and analysis. Modelling availability and complex maintenance strategies is covered by section 3. In section 4 the influence of the specified reliability and maintenance strategy on the achieved technical availability will be investigated in a case study.

2 PETRI NETS

2.1 *Low-level Petri nets*

In (Petri 1962) Carl Adam Petri developed Petri nets as a graphical modelling formalism for state-discrete systems. Petri nets consist of the following basic elements:

- Places, pictured as circles, represent possible states and can contain tokens.
- Transitions, pictured as squares, model possible state changes and therefore the dynamics within the model following specific rules. After a certain precondition, the activation, a transition can fire. The transition then deletes and creates new tokens in the places connected to it. If the transition is a so called timed transition, there is a time delay between activation and firing; otherwise it is called an immediate transition. Within a stochastic Petri net, the time delay can be stochastically distributed.
- Arcs are direct connections between transitions and places and vice versa. They map the logical interrelations.
- Tokens, pictured as filled out circles, are the only dynamic elements within a Petri net. The marking of a Petri net is the assignment of tokens of all places. A marking describes the current state of the modelled system and therefore changes with a firing of a transition.

A simple Petri net model of a repairable component is shown in Figure 1. It consists of two places, representing the states 'operational' and 'failed', and two timed transitions representing the stochastic life time of the component and its maintenance time.

At the beginning the component is in the operational state. This initial marking is shown in the figure. The transition 'Component failure' is activated with the initial marking. After a stochastic delay it fires, which means the component fails. When it fires the token in the place 'Component operational' is deleted and a new token is created in the place 'Component failed'. The new token then activates the following transition 'Component repair' and it fires after a stochastic repair delay. This deletes the token in the input place 'Component failed' and creates a new token in the output place 'Component operational'. The original marking is restored and the lifecycle starts again. The time slice of the token being in the place 'Component operational' is equivalent to the operational availability of the component. The analysis of the model is done by applying a Monte Carlo simulation.

Since the introduction of the original Petri net, many new extended classes of Petri nets have been developed to improve their modelling abilities (see e.g. extended stochastic Petri nets, Pozsgai 2006).

2.2 *Coloured Petri nets*

The class of Coloured Petri Nets (CPN) was developed in (Jensen 1996). In a CPN the anonymous token can carry information therefore they are distinguishable (coloured). The information within the token may affect the activation of transitions and thus influences the dynamic of the Petri net model. The information within the tokens can be passed on and/or can be modified by a firing transition. As the tokens are distinguishable

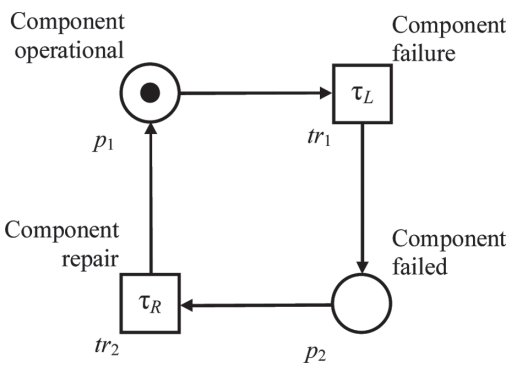

Figure 1. A simple stochastic Petri net model of a repairable component.

identical net parts can be reused for tokens with different colours and models become more compact. On the other hand, coloured Petri nets require textual declarations and additional text inscriptions in the graph to depict the flow of information within the model. Tokens are represented by a text inscription beside the place in a CPN.

Pozsgai developed a Conjoint System Model (CSM) focusing on the close-to-reality modelling of complex technical systems in Pozsgai (2004) and Pozsgai (2006). It consists of a class of Extended Coloured Stochastic Petri Nets (ECSPN) and a Reliability Block Diagram (RBD). An ECSPN allows the modelling of:

- arbitrarily stochastically distributed and/or deterministic time characteristics (life times, maintenance durations),
- various system states and component states including passive states, hot/warm/cold standby redundancies and load sharing,
- manifold dependencies between components, the system and the system's environment, for example common mode failures or failure propagation,
- complex maintenance strategies with corrective and preventive maintenance actions including condition-based maintenance actions,
- failure and maintenance behaviour of pre-aged components,
- queuing behaviour of maintenance/logistic processes and
- activity- and state-dependent operational costs.

Figure 2 shows a CSM version of the anonymous PN model from Figure 1. The system RBD

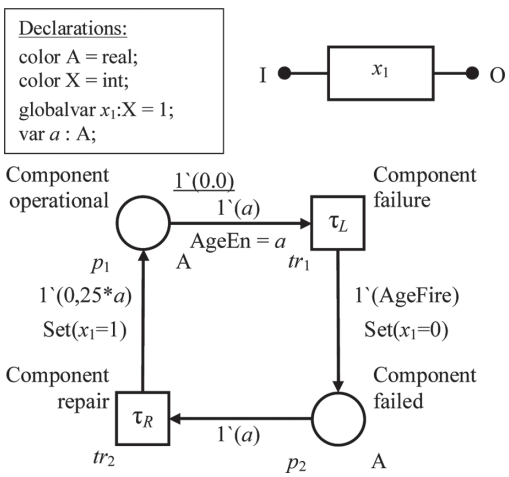

Figure 2. Conjoint system model of a repairable component with age influence.

model can be seen in the upper right corner and the ECSPN component model is located below. In the upper left corner the declarations of the ECSPN model can be seen. The token within the model contains the pre-age of the component, which is considered when calculating the component's stochastic life time. This can be seen in the depiction of the arc inscription 'AgeEn = a'. The arc inscription '0.25*a' represents an age reduction of 75% of the repair measure. The interface between the RBD and the ECSPN is the global component state-variable x_1 which is modified by the arc expression 'Set()'.

Certain advancements and supplements have been implemented and published, whose preliminary last status is represented by (Buck et al. 2011).

3 MODELLING AVAILABILITY AND COMPLEX MAINTENANCE STRATEGIES

The availability modelling based on Petri nets is very powerful. This method allows a comprehensive analysis of an offshore wind turbine. Based on a realistic model, relevant effects on the availability can be taken into account. These are on the one hand, the reliability of the wind turbine and its components, and on the other hand, the maintenance strategy that is being implemented for the system.

The reliability of the system results mainly from the so-called inherent reliability, which basically is the constructive and technically implemented reliability. It results from the relevant structural reliability of the system and the reliability of its components. The inherent reliability is strongly influenced by actual stress of the components during the operation of the plant. Main factor to this are the meteorological conditions, especially the prevailing wind strength.

A failure of one component usually leads to the shut-down of the entire wind turbine. As a result the intact components are usually set in a safe passive state in which they are considerably less strained in comparison to usual operation. This is referred to as a failure dependency, as the failure of one component has influence on the reliability of the other components.

The maintenance strategy includes the type and planning of the intended maintenance activities, as well as the necessary resources. This also includes the related logistics in the form of equipment, maintenance personnel and spare parts. Frequently, dependencies between the maintenance and the availability of a system exist. For example, a maintenance action requires a standstill

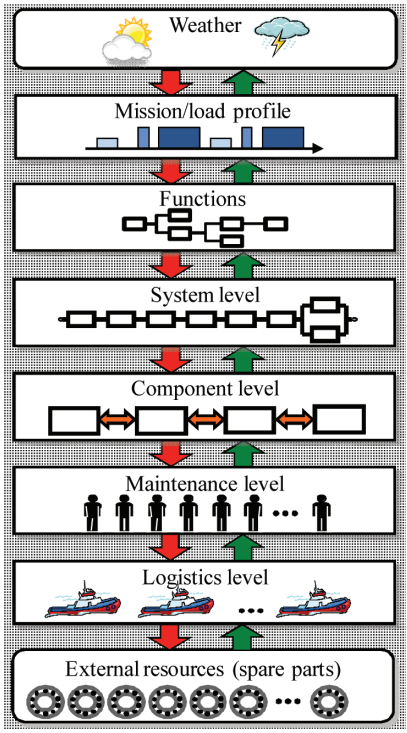

Figure 3. Numerous aspects of availability modelling.

of a plant, which cannot continue to produce during that period. Mostly the available resources are also limited or not available immediately, leading to extended plant downtimes. Therefore, it has to be possible to represent the maintenance process on the one hand and the resulting interdependencies on the other hand in the model.

The numerous aspects of modelling the availability of an offshore wind turbine are illustrated in Figure 3. It can be seen how the different modelling levels are interdependent.

4 AVAILABILITY ANALYSIS OF AN OFFSHORE WIND TURBINE

Especially in the field of wind energy technology availability is a parameter that is used to assess a wind turbine. The availability is defined as the probability that a system is operating satisfactorily at time t (Bertsche 2008). In simple terms, availability is the ratio of the period with full operability to the observation period. In the wind energy industry, mainly the technical availability and energetic availability are used. In particular, the technical availability takes the influence of the reliability and maintenance policy on the availability of the plant into account and is therefore considered in the following.

In the following case study it is shown how an offshore wind turbine can be analysed and evaluated right from the planning phase. The CSM (refer to section 2) is applied to model the turbine and its maintenance process. The Monte Carlo simulation (Pozsgai 2006 and Zio 2013) is used for analysing the model. It allows the analysis of the technical availability using statistical methods. The case study was carried out by using the modelling and simulation package REALIST, which has been developed at the Institute of machine components of the University of Stuttgart. The principal procedure is illustrated in Figure 4.

As a part of the joint project "Increasing the availability of wind turbines" operational data and experience of wind turbines were processed and analysed (IWES 2009). The life times and maintenance periods in this availability analysis are generic but were mainly based on the values shown there. The Weibull distribution was always chosen as the life time distribution.

4.1 *Specification of the wind turbine*

The specification of the wind turbine is done based on its five main components: Rotor System (RS), Gear Transmission (GT), Pitch Control (PC), Hydraulic System (HS) and Control unit and Safety equipment (CS). The turbine system comprises a series structure, i.e. one failed component leads to a shut-down of the turbine.

As noted in section 3, the reliability of wind turbines or their components is mainly influenced by the prevailing wind strength. Therefore, different inherent reliabilities depending on the wind strength were used as a basis for the components: reliability during normal operation (see Table 1), during calm and during a safety shut-down (caused by exceptionally high wind speeds). Additionally a

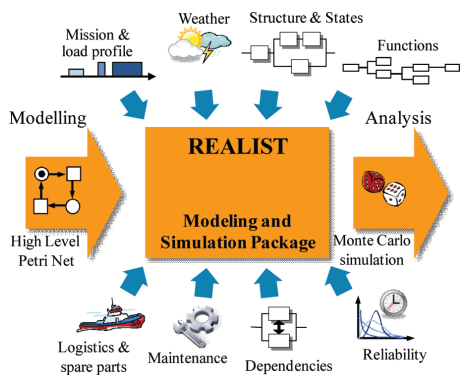

Figure 4. Procedure of availability analysis.

Table 1. Parameter of life time distributions for inherent reliability in "normal" operation.

Component	Scale parameter [h]	Shape parameter
Rotor system	32,000	1.5
Gear transmission	15,000	1.5
Pitch control	12,000	1.5
Hydraulic system	20,000	1.5
Control unit and safety equipment	1,460	1.0

separate reliability has been chosen for the passive state of a component. Each component can fail in each of its states.

During calm (see Table 2) each component would be operational, but operation is not possible due to too low wind speeds.

During safety shut-down (see Table 3) components would be operational, but turbine operation is interrupted caused by exceptionally high wind speeds.

A failure of one component leads to the shut-down of the entire wind turbine. As a result the intact components are set in a safe passive state (during the maintenance of the failed component) in which they are considerably less strained in comparison to usual operation (see Table 4). Components would be operational, but operation is not requested by the system.

Therefore, the reliability model of the turbine is based on multi-level components with individual time-dependent failure rates in each state.

4.2 *Weather model*

The influence of weather on the stress states of the components as well as on the accessibility of the turbine is considered in a weather model.

The duration of the maintenance measures on a wind turbine depends to a significant degree on the accessibility to the system. Very strong winds, storms or swell may prevent or complicate the accessibility. Special equipment is needed for maintenance work. Repairs of rotor blades or replacements of the transmission usually require large floating cranes. These can only be used in moderate weather. Apart from helicopter operations, the accessibility of offshore wind turbines is directly influenced by the wave height (indirectly of the wind speed). During weather conditions with a wave height of more than 1.5 m, called the "weather days", a wind turbine cannot be reached without danger. These boundary conditions were considered in the model of the wind turbine.

The weather conditions are divided into two seasons: winter and summer half year. With the modelled weather parameter, the following weather data (exemplary shown for the winter half year in Table 5) were considered in the analysis.

Table 2. Parameter of life time distributions for inherent reliability in "calm" state (caused by too low wind speed).

Component	Scale parameter [h]	Shape parameter
Rotor system	128,000	1.2
Gear transmission	60,000	1.2
Pitch control	48,000	1.2
Hydraulic system	80,000	1.2
Control unit and safety equipment	1,460	1.0

Table 3. Parameter of life time distributions for inherent reliability in "safety shut-down" state.

Component	Scale parameter [h]	Shape parameter
Rotor system	35,000 h	1.5
Gear transmission	28,000 h	1.2
Pitch control	20,000 h	1.2
Hydraulic system	20,000 h	1.5
Control unit and safety equipment	1,460 h	1.0

Table 4. Parameter of life time distributions for inherent reliability in "passive" state.

Component	Scale parameter [h]	Shape parameter
Rotor system	50,000	1.3
Gear transmission	28,000	1.3
Pitch control	25,000	1.3
Hydraulic system	25,000	1.3
Control unit and safety equipment	1,460	1.0

4.3 *Maintenance strategy & logistics*

The maintenance strategy defines the type and planning of the intended maintenance activities, as well as the necessary resources and logistics.

4.3.1 *Maintenance strategy*

Four different maintenance strategies have been investigated:

– Option 1—Corrective Maintenance (CM): Only corrective measures (i.e. repairs) performed after a failure

Table 5. Weather data for winter half year.

Phase condition	Days/phase	Phases/month
Operation	2.4	10
Operation (with access to turbine)	1.4	10
Operation (w/o access to turbine)	1.0	10
Calm (too low wind speed)	1.1	3
Wind speed too high	0.5	6

- Option 2—Condition-based maintenance (CM+CBM): In addition to option 1, also measures depending on the detectable state (i.e. by a condition monitoring system) are carried out
- Option 3—Preventive Maintenance (CM+PM): In addition to option 1, preventive measures at defined intervals are performed
- Option 4—Combined maintenance strategy (CM+CBM+PM): Includes the corrective, preventive and condition-based measures of the options 1 to 3

The duration of repair time is modelled by a Weibull distribution for each component as listed in Table 6. Each repair requires a spare part. Depending on the spare part size, a ship or a floating crane is required (see section 4.3.2 and 4.3.3).

The preventive and condition-based measures have constant time duration of 12 h. It is assumed that all necessary planned measures can be performed in parallel within one common maintenance action. The maintenance interval is 1,200 h, which is globally defined for all components. A ship is required for a preventive and condition-based measure (see section 4.3.3).

Over the analysed wind turbine life time of 20 years its components are replaced completely at least once and considered as new after that (see Table 7). This planned component replacement is carried out for all four strategy options. This means that maintenance measures aim to keep downtime as a result of unplanned outages or maintenance as low as possible. A component replacement is not possible during the winter half year. If a replacement is due in a winter half year, it is waited until the summer half year begins to start the replacement. A replacement of a component requires a floating crane.

The maintenance actions yield a specific reduction of the component age. A degree of renewal describes a factor. The component age after maintenance is the age before the action multiplied by this factor (see Table 8).

Table 6. Parameter of repair time distributions.

Component	Scale parameter [h]	Shape parameter
Rotor system	48	3.5
Gear transmission	90	3.5
Pitch control	12	3.5
Hydraulic system	12	3.5
Control unit and safety equipment	2	3.5

Table 7. Interval between component replacements.

Component	Replacement interval [h]
Rotor system	87,600
Gear transmission	70,080
Pitch control	105,120
Hydraulic system	87,600
Control unit and safety equip.	87,600

Table 8. Degree of renewal of maintenance actions.

Maintenance action	Degree of renewal
Repair (CM)	0.3
Maintenance (PM or CBM)	0.5
Replacement	0.0

4.3.2 *Spare part logistics*

Spare parts are necessary for each repair of a failed component. Preventive maintenance does not require a spare part. Two spare part policies are considered in the case study:

- Policy 1—Order policy: Without spare part inventory; spare parts are ordered at the supplier only when needed; Spare part delivery has a specific lead time according Table 9.
- Policy 2—Spare part inventory: A spare part inventory is available onshore; if the inventory level falls below a specified value an order for new spare parts is placed.

The spare parts have two different sizes. The share of small and large spare parts for each component is given in Table 10.

4.3.3 *Special equipment*

For the availability analysis the logistics of floating cranes and ships for the transport of spare parts and the implementation of measures has been integrated into the model.

- Ship: Necessary for delivery of small spare parts to the turbine and for performing planned or condition-based maintenance.

Table 9. Spare part lead times.

Component	Lead time [week]
Rotor system	4
Gear transmission	8
Pitch control	4
Hydraulic system	4
Control unit and safety equipment	2

Table 10. Share of spare part size.

Component	Small spare part [%]	Large spare part [%]
Rotor system	65	35
Gear transmission	80	20
Pitch control	92	8
Hydraulic system	94	6
Control unit and safety equipment	100	0

– Floating crane: Necessary for delivery of large spare parts to the turbine and for component replacements.

A ship or a floating crane is only sent to the turbine if the wind is calm. If the wind is not calm, it is waited until it is calm. The trip duration is according to the weather condition. If the turbine is not accessible when the ship or crane arrives, it needs to idle nearby the turbine until it is accessible again. The return trip to the service harbour starts only if the weather condition is well.

4.4 *Turbine model*

The entire model which has been developed based on the values and boundary conditions as described in the sections 4.1 to 4.3 is shown in Figure 5. It is realised by the CSM modelling method. The tool REALIST offers a graphical editor to develop the model.

The model it is thematically decomposed i.e. the model is separated visually into sub models by applying reference places. This allows avoiding a spider web like crossing of connecting arcs all over the model. The model is kept traceable which supports the modelling process especially for such complex scenarios.

In the following the modelling aspects which are implemented by using the ECSPN are shortly described in an overview. In the top part of the model the different operational states and the conditional state transitions are modelled which include also the processing of the pre-age when leaving a state and entering a new one. Therefore,

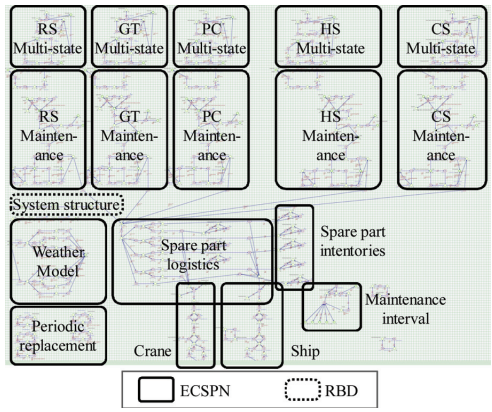

Figure 5. Entire model structured into main modelling topics.

the turbine model is a multi-component system with multi-state components. The components have an individual age evolution in each state based on time-dependent failure rates.

Below the state model, the maintenance process is modelled including the corrective, preventive and condition-based measures as well as component replacements. In the lower part of the model the spare part logistics including the spare part inventories and the special equipment is modelled. The logistic process of two different maintenance categories requiring a ship or a floating crane can be seen. Two auxiliary sub models for generating the trigger for the overall periodic maintenance as well as the periodic replacements are included, too. On the left side the weather model which is simulating the weather phases in summer and winter half year can be observed. By this, the weather windows for accessing the wind turbine and the load states of the turbine components are generated.

Finally the system structure of the turbine is implemented by using a RBD which allows for an efficient generation of the turbine system state.

In Figure 6 a detail of a ship proceeding to the turbine is shown. After a repair order which is put in place p34 an available ship will be sent to the turbine with the spare part after a preparation time modelled by transition tr60. If no ship is available, the repair order needs to wait until one is available. The ship is only sent to the turbine, if the turbine is currently accessible which is modelled by the transition tr65 using the global accessibility variable of the weather model. The trip duration to the turbine is depending on the weather condition. If it is calm, the trip duration is shorter compared to strong wind, which is realised by the two transitions tr67 and tr68 and specific guards, which use the value of the global wind variable of the weather model.

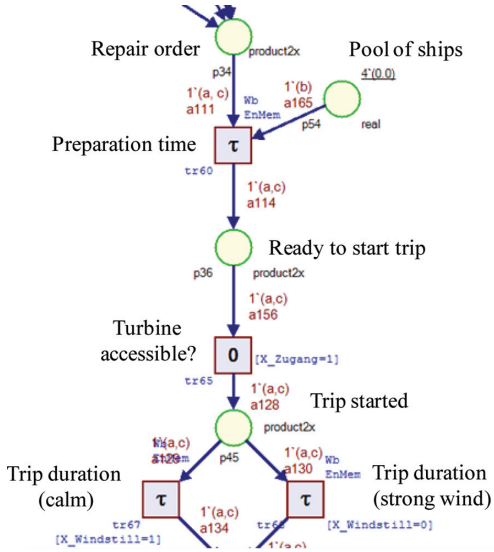

Figure 6. Ship driving with spare part to turbine.

4.5 *Availability without spare part inventory*

The availability analysis has been carried out for all maintenance strategy options described in section 4.3.1. The analysis was done by applying the REALIST simulation and evaluation module.

The spare part logistic is organized according policy 1 (i.e. without spare part, see section 4.3.2). The results of the analysis are given in Table 11. They show the lowest technical availability of 89.5% for option 1. If condition-based measures are carried out in addition to the purely corrective measures, there is a slight increase to 90.1%. In option 3 with additional preventive measures the result is 91.2%. If all measures are combined like in option 4 there is the highest achievable availability of 92.0%.

A technical availability of 98% for an onshore wind turbine can be considered as reference for a comparison with the values in Table 11. Compared to this reference value, the analysed availability of the offshore turbine is considerably lower. That means the higher energy yield of an offshore turbine should at least compensate the lower operation time. It should be mentioned here that the analysed availability of the variants is purely depending on the modelled scenario. Different specification parameters may lead to a different availability or variant ranking.

4.6 *Availability with spare part inventory*

In the second step, all maintenance strategy options are considered in combination with spare part policy 2. The results of the analysis are given in Table 12. They show the benefit of an onshore part inventory on the availability compared to the results in the previous section. Again option 4 achieves the highest availability with a value of 95.9%. That means the onshore inventory increases the availability by almost 4%.

Table 11. Technical availability without spare part inventory.

Maintenance strategy	Technical availability [%]
Option 1 (CM)	89.5
Option 2 (CM+CBM)	90.1
Option 3 (CM+PM)	91.2
Option 4 (CM+CBM+PM)	92.0

Table 12. Technical availability with spare part inventory.

Maintenance strategy	Technical availability [%]
Option 1 (CM)	94.5
Option 2 (CM+CBM)	95.1
Option 3 (CM+PM)	95.7
Option 4 (CM+CBM+PM)	95.9

Table 13. Mean number of failures per component.

Strategy	RS	GT	PC	HS	CS
Option 1	3.3	7.5	8.9	4.9	62.6
Option 2	2.9	6.7	8.7	4.8	62.5
Option 3	1.5	3.3	4.5	2.3	62.5
Option 4	1.4	3.2	4.5	2.2	62.1

The effect of component failures to the turbine availability is quite significant compared to the preventive and condition-based maintenance measures. The time between failure and finished repair depends strongly on the weather and the accessibility of the turbine. In contrary the turbine is still operating until a preventive or condition-based maintenance measure begins. It is important to note, that an instantaneous component failure can also lead to expansive damage on the component or the surrounding elements.

Besides the availability the mean number of failures per component has been investigated during the study in order to further evaluate the different strategy options (results are shown in Table 13).

Compared to the corrective maintenance strategy (option 1), the number of failures can be considerably reduced especially by option 3 and 4. The number of failures for the control unit and safety equipment is relatively high and remains almost

constant in all strategy options. The different maintenance options do not have an effect on the failure number. This stems from the random failure behaviour of these electric and electronic components (modelled by a constant failure rate). The situation can only be improved by a design change, which leads to a significant lower failure rate.

5 CONCLUSIONS

The analysis showed the high influence of the weather on the maintenance logistics. Both the trip duration and the accessibility of the turbine depend on the weather condition. The effect of sudden failures on the availability is higher compared to maintenance actions, as the turbine stands still until the spare part is available and the repair is finished.

Furthermore, the analysis results showed that the control unit and safety equipment causes much more failures compared to the other components. It was shown that it is not possible to reduce these failures by maintenance. Therefore, from reliability specification point of view, the reliability target of the control unit and safety equipment needs to be increased considerably.

The bottleneck of the maintenance strategy is the spare part supply and the accessibility of the turbine. It was shown how an additional spare part inventory contributes to a higher availability. As the accessibility is strongly depending on the weather, the maintenance accesses to the turbine should be reduced to a minimum. This can be achieved by reducing the number of unplanned failures by additional preventive and condition-based maintenance actions.

The availability analysis based on Petri nets allows the consideration of many factors and interactions, and can be performed at an early development stage. Based on the results, the reliability goals and the necessary maintenance strategy for achieving a desired availability can be specified. Many variations can be analysed, compared and optimized. The model enables sensitivity analysis to determine, e.g. how the maintenance periods or condition monitoring quality influences the turbine availability.

Additionally the risk-based development of services for the turbine, e.g. maintenance contracts, can be done based on the analysis results (Zeiler & Bertsche 2014).

For the analysed maintenance strategies further studies for optimizing the maintenance strategy and the supporting logistics as well as the cost aspects will be carried out. Furthermore, the research activities will be extended to an entire wind farm.

Maintenance in availability of weapon systems under combat operation—optimization possibilities

T. Smal
Faculty of Security Affairs, Wroclaw, Poland

ABSTRACT: Availability is a parameter which determines (together with credibility) dependability of any technical object including weapon systems. High availability of a weapon system means that such system has high reliability and maintainability and it can be increased due to modelling its survivability and vulnerability. In context of a combat operation, weapon system availability can be improved at the stage of design and production and at the stage of maintenance. An effective systems of service, evacuation and repair are of crucial importance when we consider availability of a weapon system under combat operations. Therefore, maintenance is one of the solutions which can improve availability of a weapon system. The paper presents analysis of functional elements of maintenance system that influence weapon systems' availability under combat operations. The following components were discussed: purchasing of weapon systems, organization of maintenance system, human resources and technical resources connected with maintenance. On the basis of numerous references and personal experience some new optimization possibilities were offered like: *taking into account new factors when purchasing equipment,* modification of maintenance services structures, introducing modern IT platform, reduction and destination of currently used mobile workshops and introducing system of expedient repairs in the field.

1 INTRODUCTION

Logistic system under combat operations is called combat service support and they include: supply, movement and transportation, maintenance, infrastructure and medical support (ALP-4.2(A), 2010). Weapon systems belong to a group of technical objects used in task (random) mode and they require a specific maintenance system, which should be aimed at executing tasks in a specific place and time regardless of circumstances. The properly developed maintenance system can create advantage over an enemy, that is why, the new and diverse solutions should be searched for in order to ensure fighting units availability of weapon systems. Diversification of various solutions and adequate designing of equipment will support logistics units in recovering of weapon systems and can help to create advantage over an enemy by increasing availability of weapon systems.

Availability can be defined as a system ability to fulfil the required functions in certain time and conditions. High availability of a weapon system means that such system has high reliability and maintainability and it can be increased due to proper modelling its survivability and vulnerability (Nowakowski, 2011).

In context of a combat operation, weapon system availability can be improved at the stage of design and production and at the stage of maintenance. Firstly, we can take into account: lessons learned from previous military operations and current and upcoming means of combat and protection systems as well as we can apply modern on board diagnostic systems in order to design and manufacture military equipment which has higher survivability and maintainability and lower vulnerability. Secondly, we can introduce effective systems of service, evacuation and repair in order to increase maintainability of a weapon system (Furch, 2010).

2 WEAPON SYSTEMS AVAILABILITY

There are several definitions of a system (Nowakowski, 2011; Backlund, 2005). One of them says that each complex object, which can be distinguished in researching reality can be called a system given that it determines integrity created by a set of elementary objects and relations between them (Sienkiewicz, 1983). Another one, runs that a system is an existence displaying its existing by the synergetic cooperation of its elements (Bellinger, 2002). A mathematical complement of the mentioned definition is represented by the following equation:

$$S = (E, A, R),\ E = [E_1 \ldots E_n],$$
$$A = [A_1 \ldots A_m],\ R = [R_1 \ldots R_k]$$

where: S—system, E—a set of elements, A—a set of attributes (properties), R—a set of the relation between elements and attributes.

A system can consist of $n > 1$ elements—E, which can have $m \geq n$ attributes, participating in $r \geq n - 1$ relations (equality for the series system). The possible spectrum of elements of some systems could be: physical, energetic, symbolic, computerized, living, conscious, self-conscious. Additionally, they are set in the any configuration of types and elements.

The main aim of logistics should be providing a commander with adequate quantity of means in order to fulfil particular task. To meet this aim it is necessary to implement the latest organizational and technical solutions to the battlefield maintenance system, which proper installation should maximize activities performed by logistics elements. Among components which are essential for trouble-free functioning of maintenance system one can distinguish:

– purchasing of weapon systems;
– organization of system;
– human resources connected with the system;
– technical resources assigned to weapon systems' maintenance.

3 PURCHASING OF MILITARY EQUIPMENT

The first phase in a new model during which new equipment is obtained is called needs defining. From the logistic point of view, one of the important problems is designing maintenance system according to the newly acquired military technology. It should be commenced at the stage, during which the ability to fulfil the needs is analysed. Project of this type of system should contain; among other things, such elements as maintenance (together with repair) and supply systems. Moreover, it should be able to determine accessibility and designing of service appliances altogether with courses and trainings, not to mention that transport devices and IT implementation should be also enclosed within it. Considering the above-mentioned issues will have a great impact on logistical susceptibility of particular object during its maintenance, which consists not only of technical susceptibility (diagnostic, service, evacuation, repair and transport) but also its maintenance needs (Smal & Szukalski, 2009).

Modification of system, which is aimed at acquisition of weapon systems in accordance with its availability, should be carried out by increasing life cycle and combat lifespan of newly manufactured or modernized objects (Vališ & Vintr, 2006), and by designing them on the basis of carried out tests, methodology of quick verification of damages, and last but not least, according to a propose of its recovery and repair methods on battlefield (Vališ & Vintr & Malach, 2012). Determining survivability of the equipment may be conducted by practical tests (Jackson, 2009) or by computer simulations (Wasmund, 2009; Vališ & Vintr, 2006). However, the most reliable results might be obtained only during an experiment. For example, each weapon system purchased by US Army must pass adequate procedures, which reflect its survivability—so called "live fire tests" done by means of live ammunition. Such tests have been done e.g. for F/A-22 plane. It passed and the damages turned out to be far less considerable than it had been assumed. After that, wing, which was built of composite and titanium skeleton, was repaired and it was an excellent opportunity of improving repair methods by using standard BDR kit (Fig. 1).

U.S.A. experiences in that matter have shown that the best solution is to create adequate technologies and algorithms of proceeding, which would be dedicated to particular family or type of equipment (FM 4-30.31, 2006). A positive example of this kind of philosophy of an approach to designing is HMMWV vehicle. In this vehicle, the driver, without any repair kits, is able to carry out particular gears or assemblies with help of Battle Damage Assessment and Repair (BDAR) instruction (TM 9-2320-280-20-1/2/3, 1996).

To sum up, as long as obtaining of new equipment is concerned, requirements of maintenance system should be taken into account. The susceptibility to restore a weapon system availability is higher when an object is:

– designed observing the modularity of assemblies,
– equipped with quick-mounting joints that provide quick assembly and disassembly.

Figure 1. Combat logistics support squadron's personnel cutting expedient repair of F/A-22 plane (Surviac Bulletin, 2002).

– equipped with a possibility of using standard devices and tools in a process of assembly and disassembly,
– secured with base surfaces (openings) of the components in order to use them in a repair process,
– labelled in a way that enables easy and proper assembly of cooperative components of the object,
– constructed in a way that makes an access to the most often damaged assemblies easy and; simultaneously, that enables easy mounting of damaged subassemblies or their repair without a necessity of disassembly,
– designed in a way that gives a possibility to use modern technologies and repair materials in a repair process,
– equipped with dedicated repair manuals in conditions of combat operations, and with special repair kits.

4 ORGANIZATION OF SYSTEM

Maintenance tasks should be conducted by means of recovery and repair mobile elements which are equipped with adequate procedures, tools and materials. Although the fundamental problem is that maintenance services during peacetime usually train and perform tasks as logistic forces and they use stationary maintenance infrastructure, but for the combat purpose they convert themselves into mobile maintenance elements such as: recovery teams, evacuation-repair sections, evacuation teams, etc. (DD/4.2, 2007). In addition to that, because of gradual spending cuts tactical exercises are being abandoned; therefore, above mentioned elements are not executed and there is no opportunity for training and synchronization similar to real environment.

Another organization issue concerns division of military equipment into two groups. The first group is in use to conduct current tasks and training of military units. The second group is stored to support mobilization and war time. A huge part of mobile workshop is assigned to a stored group; therefore, military regulation doesn't allow to use them during peace time. Military mechanics execute service and repair of military equipment during peace using different stuff, thus they don't use specialist tools sets. This fact can lead in the future to the situation where maintenance units act ineffectively during combat operations, because of lack of experience. Having regard to the above, the proposition is to shift almost all mobile workshops to the group in use, and that is going to allow mechanics to gain more experience in using their equipment, as well as, to interchange their tools and materials. These undertakings should give certainty that mechanics will be well-prepared for their tasks (Smal & Smoła, 2011).

The allied countries implement organizational solutions, which facilitate incorporation of system solutions in the scope of maintenance tasks. Such system should be organized in a way which give assistance, as quickly as possible, by entire or partial removal of consumption effects, as well as, damages or malfunctions, of restoration of task capability of military equipment. Time devoted for those actions, in combat conditions, should be sufficiently short. Conducting it, one should try to restore as many of the vehicles as it would be manageable in the shortest time possible. According to this, one should repair, as the main priority, those of vehicles, which cause fewest problems (DD/4.2, 2007 & Stanag 2406, 1995). It is permitted to demount parts from those which are non-operational in order to mount them in those which are still useful. It is also allowed to mend them so they would be able to perform a single task or so they could be used but with some limitations (Smal & Rośkowicz, 2009).

The exchange of information about the occurred problems and previously executed operations is an efficient method of simplifying maintenances tasks (Vališ & Mlynczak & Nowakowski, 2011). The Polish Armed Forces do not have a unified IT system, which would support the maintenance process under combat operations. Furthermore, the units do not gather information on defect statistics of the equipment or the methods of damage elimination. Thus today, there is no way of implementing modern strategies, such as Reliability Cantered Maintenance (RCM) or strategy based on RBI diagnostics or RBM safety oriented strategy in the maintenance of military equipment (Uhl, 1999), as well Prognostics and Health Management (PHM) Technologies (Song & Li, 2009) or Condition Based Maintenance Plus (CBM+). The last mentioned concept seems to be very useful, especially in context of weapon systems sustainment. CBM+ is the application and integration of appropriate processes, technologies, and knowledge-based capabilities to achieve the target availability, reliability, and operation and support costs of weapon systems and components across their life cycle (Fig. 2). CBM+ uses a systems engineering approach to collect data, enable analysis, and support the decision-making processes for system acquisition, modernization, sustainment, and operations (Gang & Bo-Suk & Pecht, 2010).

An additional setback in implementing the above strategies in the usage of military equipment of the Polish Armed Forces, would not only be the lack of knowledge on damage characteristics, but also the shortage of specialized equipment

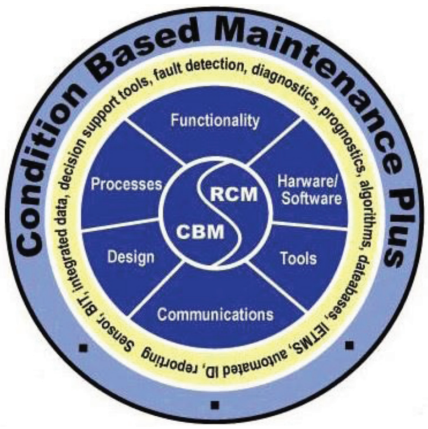

Figure 2. Condition based maintenance plus (http://www.acq.osd.mil/log/mpp/cbm+.html, 2014).

for controlling the state and software, especially with older versions of devices and vehicles and the necessity of baring significant costs of service investments, which would affect the total cost of maintenance (Niziński, 2002).

The leading armies of NATO are ordered to keep a regular repair documentation. For instance, the Armed Forces of USA have a special damage evaluation and executed repairs form, which is transmitted to Survivability/Vulnerability Information Analysis Centre (SURVIAC). An analogical temporary repair realization form was implemented by the NATO standardization document on the basis of American experiences (Stanag 2418, 2009). Gathering and distributing information on combat damages and the methods of dealing with those damages through interactive internet sites is an interesting and useful idea for transferring information on damages and executed repairs. The project was created by the Joint Combat Assessment Team (JCAT) and implemented by SURVIAC to support the reporting system of combat damages of aircrafts (Egner & Mullins, 2009). A web page under the name Combat Damage Incident Reporting System (CDIRS) was used as a data base for all documented combat damages during the operation "Iraqi Freedom". Initially, the page was a source of statistical data, currently it is an interactive data base operating in actual time, thus it can be used directly during combat operations. Additionally, it contains tools enabling data analysis, its distribution to all the involved subdivisions, data search according to specified criteria, e.g. damaged component or the damage's occurrence date etc.

By combining the knowledge and experience of maintenance specialists with the data gathered

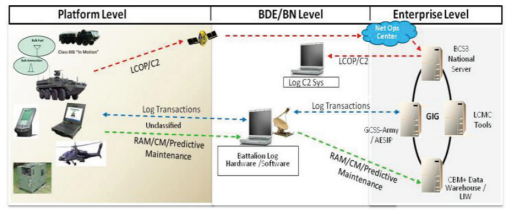

Figure 3. Telemetry combat service support system under combat operation (Presentation obtained from U.S. Army Logistics Innovation Agency, 2012).

in electronic bases, we could develop availability of weapon systems, including remote technical service i.e. telemaintenance. Telemaintenance, in some publications called "Remote Diagnostics & Maintenance (RD&M)", are based on wireless transitions of utilization data of the vehicle (You & Krage & Jalics, 2005). These systems are usually used by companies, which provide long distance transportation and by the military. Considering combat operation circumstances, the telemaintenance system may be very useful, especially in: vehicle's diagnostics performed by the driver, gathering vehicle's diagnostic data by the logistic support line, planning and organizing vehicle's utilization, remote technical support for the driver and the crew, especially in special situations (combat damages, breakdowns) as well as perfecting the construction and the utilization process in order to improve the reliability and efficiency of repairs (Fig. 3).

In sum, functioning organization of the maintenance systems could be significantly improved by:

- modification of maintenance service structures, which realize services and repairs;
- developing and implementing equipment procedures and manuals within the scope of recovery and quick temporary repairs of weapon systems directly within operation zone;
- utilizing modern IT tools to support the service and repair works;
- constant monitoring of the system's functioning and searching for optimization possibilities.

5 HUMAN RESOURCES

Regardless of the type of activity, a man and his intellect is the most significant element of every system. Thus, while discussing the availability of weapon system, we cannot ignore the problem of effective gathering, processing and repeated usage of the experiences of specialists in this field.

Due to permanent restructuring of the Polish Armed Forces, especially the logistic system and

logistic structures, the issue of system usage of the experts' knowledge and experience in the field of military technology repairs is highly neglected. The aging mechanic and engineering staff is another problem. Introducing regular army and recruiting young and inexperienced privates and officers to repair divisions causes them to often not be able to handle the tasks that they are given. A similar situation occurs during trainings for future officers—future commanders of platoons. Their knowledge on the structure and usage of military equipment constantly decreases. This is most likely caused by the fact that they are usually graduates of humanities at high schools, and the number of hours for technical subjects in the military schools is permanently decreased. The problem of experienced mechanics shortage in repair subdivisions is solved by hiring former professional soldiers, who served in such formations. Their knowledge and competences are priceless, but besides current usage of their work, is someone gathering and utilizing their experience? Furthermore, as interviews conducted with commanders of repair battalions indicate, the average age of persons employed as mechanics is constantly increasing. Replacing vacant mechanic positions with positions from the National Reserve Forces program is an additional hindrance in filling the generation gap (Smal & Smoła & Stankiewicz & Szukalski, 2010).

The experiences of allied countries clearly indicate that proper preparation of maintenance personnel is a very significant element of technical support of weapon systems. An appropriate level of training for persons responsible for eliminating damages during combat operations is acquired through permanent conduction of trainings—theoretical and, first and foremost, practical [19, 25] (Fig. 4).

The experiences of other armies indicate that we cannot waste the massive intellectual potential concerning the practical realization of maintenance tasks, which is usually lodged in the older and more experienced mechanics. For example, technologies and field repair systems of technical objects evolve along with the intellectual thought and human imagination. The same techniques, equipment and materials could be used in varied situations and circumstances. It is important that these experiences are gathered, verified and that the fastest and most efficient methods are proposed for usage. This however, will not be possible without proper system solutions.

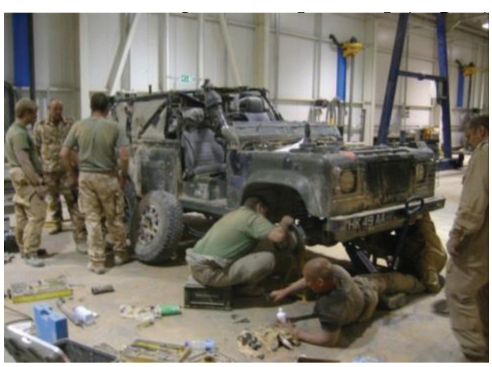

Figure 4. British team practicing expedient repairs (Photo obtained from Combat Service Support Group of NATO Standardization Agency, 2012).

In sum, we must conclude that proper usage of human potential within maintenance of weapon systems at appropriate level of availability should consist in:

- creating or appointing a centre that deals with training and studying technology applications;
- developing a digital platform of gathering, processing and popularizing information on maintenance technologies and procedures with the use of a form proposed in the standardization document common for the entire Armed Forces;
- organizing periodic trainings about maintenance tasks with the participation of experienced instructors—repair specialists in an appointed centre;
- inviting researches and public companies, occupied with the problems of military technology sustainment to participate in distributing the experiences and propagating knowledge on weapon systems availability;
- distributing information on techniques and methods of recovery and repairs among the staff of repair subdivisions, e.g. via periodical bulletins.

6 TECHNICAL RESOURCES

The system of weapon systems maintenance requires usage of technical resources, which differ significantly from the ones commonly used in other fields of economy. Technical potential of maintenance system under combat operations is based on four main elements: recovery vehicles, mobile workshops with universal equipment, specialist tools sets and spare parts kits (Smal & Smoła, 2011).

Recovery vehicles should provide evacuation and repairs of damaged equipment in field conditions. Trucked combat vehicle of Polish Army Land Forces are supported with special recovery vehicles like WZT-2, WZT-3, WPT Mors and Bergepanzer 2A2 (Fig. 5).

The presented vehicles perform well during large scale combat operations with the use of heavy

Figure 5. Recovery vehicle Bergepanzer 2A2 during lifting power pack of tank.

caterpillar equipment. However, the experiences of the components of the Polish Armed Forces from recent abroad operations and equipping the units with AMV Rosomak, indicates that there is a gap concerning wheeled combat vehicles. So far, maintained vehicle KRAZ 255 is being withdrawn from the Army as obsolete and TATRA 815 is being used mostly as semitrailer evacuation vehicle. Due to this, there is a necessity to purchase a new type of vehicle, which will be able to recover wheeled combat vehicles like BRDM or AMV Rosomak and conduct second level BDR for them (Smal & Stankiewicz, 2010). The tasks of such a vehicle would include: sling towing damaged vehicles, evacuation of mired down vehicles, supporting medical services in rescuing people out of damaged vehicles, executing expedient repairs of damaged vehicles in order to restore independent movement, standing overturned vehicles, reloading pallet containers, car bodies and weaponry system modules in field conditions.

In relation to the above, the future vehicle should be designed on a 8×8 basis chassis with large load capacity and increased mobility, furthermore, it should be equipped with among others (Smal & Smoła & Stankiewicz & Szukalski, 2010): an armoured cabin adjusted for weaponry installation, main and supporting winch, a winch for self-evacuation, a hydraulic crane, a hydraulic device for lifting and towing, a hydraulically steered plowshare, a system of supports and anchor bolts ensuring the vehicle's stability during the crane's and winches' operation and specialized equipment for repair works and rescues as well as a power generating unit with a combustion drive and communication means.

By combining the concept of a properly equipped wheeled recovery vehicle with battle damage repair technology, adequate for equipping our army, we could create an evacuation/repair vehicle, which would serve as an evacuation tractor and a repair sets carrier. Thus, the vehicle could prove useful in technical rescue as well as executing expedient on-the-spot repairs. Additionally, such a vehicle would be endued with road rescue equipment and could also be used during civil level crisis operations. At this point, we should again consider qualifications and experience of such a vehicle's crew, which would play a key part in proper realization of the entire element's tasks.

The mobile repair and service workshops located on chassis were designed in order to secure the operation of logistic subdivisions, which secure military actions in field conditions. There are some problems connected with contemporary mobile workshops, which are maintained in land forces, and those are types of workshops, dimensions of bodywork and equipment of workshops.

Currently there are two basic and eight auxiliary workshops maintained in Polish Armed Forces to conduct service and repair of wheeled and trucked vehicles. Basic workshops are supplemented with specialist tools sets at level 1, 2 or 3 dedicated to a given type of vehicle and; as the result, the workshops turn into specialist workshops. There are following kinds of basic mobile workshop: WOP—workshop designed for vehicle service that can be equipped with 5 box of KOR and WRP—workshop designed for vehicle repair that can be equipped with 7 box of KOR. Basic workshops make it possible to conduct a full range of service and repair but only with exchanging of units and parts. They aren't equipped enough to provide full diagnosis, verification, and regeneration of damage units and parts, therefore, there are used as additional auxiliary mobile workshops, among which we include: cylinders filling station, battery recharge station, machining workshop, electromechanical workshop, welding-tin workshop, engine repair workshop, fuel gear workshop, lubrication workshop, evacuation vehicles.

According to the literature the following trends might be considered when talking about the development of mobile workshops (Šafr & Chladil, 2005):

- lowering the types and the number of mobile workshops;
- providing basic technical parameters for land, air and rail transport, and shipment;
- using the functional bodies of a container type for higher organizational logistic levels, providing the maintenance of land combat vehicles used in missions.

Technical solutions examples in allied armies confirm the trend of mobile repair workshops development on the basis of loading containers (Furch & Smal, 2011). Repair subunits of the Land Forces of USA made use of the experiences gathered during utilization of M984 vehicles and PLS and devel-

oped equipment adjusted for executing overhauls and repairs in field conditions (M7 Forward Repair System—FRS). Basing on the solutions for PLS, FRS was created on a flat rack platform and can be moved with HEMTT trucks (Fig. 6). The presented solution significantly optimizes the operation of technical services ensuring higher weapon systems' availability and possibility of reacting to occurring threats under combat operations. FRS is ready to undertake tasks within 5 minutes from the stoppage of the basic vehicle (FRS, 2009). Execution of repairs is possible due to such equipment as: hydraulic crane with 5t load capacity, power generating unit, compressor, combustion unit, power tools, hand tools (ca. 560) and diagnostic devices sets. Constant development of technical solutions for field repair systems of military equipment is a characteristic feature of leading armies.

Having regard to the above and the unification of bolted and pivot connections, as well as, the use of standardized bearing and covering the differences between higher and lower services and repair, there is a proposition to replace the two basic workshops mentioned above with one mobile workshop designed to vehicle service and repair (Smal & Smoła, 2013). Additionally, considering the current trend to minimize parts regeneration, the number of auxiliary workshops should be reduced. The table below shows new configuration of mobile workshops maintained in Land Forces of the Polish Army (Table 1).

The workshops maintained in Polish Army are constructed on the basis of bodywork called "Sarna II" which is totally incompatible with very popular standardized containers (Šafr & Chladil, 2005). The standardized containers are cheap in manufacturing and transport, multi-role and compatible with many kinds means of transport. In most countries of NATO, containers are used as bodyworks for many sorts of workshops (Connors, 2003). The Polish Army will not avoid the same future; still, considering the costs; first of all, exchange and modernization of equipment in currently used workshops should be executed.

Discussing the unification of mobile workshops, basic logistic vehicle-carriers should be considered because there is no understandable reason for vehicles like STAR MAN 944 or 1466 to be purchased as the universal logistic carriers. The analysis of vehicles used by other armies has shown that universal vehicles should be equipped with jib hook to load every cargo in container outlines (all means of transport base on standardized containers). Universal vehicle should also be the basis for semi-trailer evacuation vehicle (Fig. 7). We can obtain high military equipment susceptibility to service and repair thanks to considering the mentioned facts (Smal & Szukalski, 2009).

Figure 6. FRS on a HEMTT-type vehicle during transportation (left), working post after removing from the vehicle (middle) and FRS during repair works (right) (Gray, 2007).

Table 1. Proposition of reducing mobile workshops number and types.

Current status	Proposed changes
WOP—workshop designed for vehicle service	WOR—workshop designed for vehicle service and repair
WRP—workshop designed for vehicle repair	
SŁB—cylinders filling station	SŁB—cylinders filling station
SŁA—battery recharge station	WEM—electromechanical workshop
WEM—electromechanical workshop	
WOM—machining workshop	WOMC—machining and heat treatment workshop
WSB—welding-tin workshop	
WRS—engine repair workshop	WRPP—power packs workshop
WAP—fuel gear workshop	WRUD—additional devices workshop
WOS—lubrication workshop	

Figure 7. The example of universal logistic vehicles which are able to load container cargos.

There are many propositions of solving the problem above. One of them is a container workshop constructed by 52 repair battalions (Fig. 8), but there also are some issues which should be improved. The workshop should be equipped with handle for jib hook to make it possible to load it on universal carrier; a side tent should be replaced by mechanical awning, and drawers should be replaced by mobile workshop wheelchair. Similar workshops effectively operate in other armies of NATO or are being currently created by them (Furch & Těšík & Glos & Marek, 2008).

Similar conditions to stationary should be created for mechanics who are conducting tasks in field conditions; therefore, they should execute service and repair in the same teams, with the same tools, and

Figure 8. The proposition of a new workshop for the Polish Armed Forces.

using the same procedures. The equipment of currently maintained mobile workshops is far different from stationary workshops. The modernization of it was terminated at the end of the 80's, hence over 20 years of technology gap (Smal & Smoła, 2010). The example of that is soldiering iron, which is very obsolete and cannot be used to repair complicated and delicate electronic systems. It is not possible to exchange all mobile workshops with modern container workshops taking into consideration the current economic situation of our country. Therefore, transition solution should be adopted, which main effort would be focused on equipment modernization of currently used workshops including the fact that the modernized equipment will be moved to a new container workshops in the future. Additionally, the purchased tools would be used in stationary workshops at the same time, which should allow to reduce costs. The tools and equipment of mobile workshops should be placed in special mobile workshop wheelchairs or boxes taking into account the specific conditions of maintaining sections activities, especially in the field conditions. It would facilitate moving them between stationary and mobile workshops and during field operation at the damaged vehicles (Smal & Smoła, 2011).

Specialized repair equipment is another element, which may significantly improve the conditions and efficiency of repairs and shorten the time of execution. The contemporary market of power tools and hand tools is very developed. This allows for very precise selection of equipment, according to the needs. Besides the standard durability, anti-corrosive or aesthetic properties, military tools should have several additional features, such as: permissible black colour (oxidation) or khaki green, low weight, multi-functionality, a higher safety coefficient during construction of tools, high ergonomics of the handle enabling longer work and greater torque (Fig. 9).

Pneumatic lifts are incredibly useful tools, which should be at the disposal of maintenance services. They may significantly improve realization of enterprises connected with lifting damaged vehicles in the workshop as well as in the field and facilitate recovery of vehicles mired down during operation. The lifts are elastic containers (bags), filled with exhaust fumes by a hose connected to the exhaust pipe of the repaired or neighbouring vehicles (Fig. 10). The fact that such lifts can be

Figure 9. The example of modern tools: power wrench (left), hammer screwdriver (middle), small gas welder (right).

Figure 10. Using pneumatic lifts for lifting vehicles (www.arbusa.com).

placed directly on the ground (e.g. snow, dirt, etc.), without the necessity of searching for hardened places (places of direct damage) is a significant advantage over the "classic" solutions. Lifting lopsided vehicles is possible, thus unsteadiness of traditional siphons is eliminated, which in turn decreases the probability of injuries.

Proper repair sets enabling elimination of military equipment's damages when access to specialized tools and spare parts is limited is another aspect of maintenance services proper functioning in the context of weapon systems availability (Fig. 11) (Smal & Smoła, 2010). The equipment of our repair subdivisions is mainly the one used during the former "Warsaw Pact" and is not adjusted to contemporary reality, nor the expeditionary character of actions. The ER/BDR repair sets should include the following groups of repair materials: glue composites, materials for eliminating damages of pneumatic, hydraulic and electric installations and plastic elements. They should also include universal repair materials, such as: regeneration tapes, tie bands, fan belts, seals, simmerings, etc. Completing sets should be based on scientific research and years of practical experience, the process should be continuous (Smal & Furch, 2011).

To sum up, modification of technical resources of the weapon system maintenance should include:

– purchasing a new type of recovery vehicle, which will be able to recover wheeled combat vehicle like AMV Rosomak and conduct recovery and repair tasks;

Figure 11. Level 1. BDR kits used by the Dutch (left) and Norwegian (right) armies.

– reduction and destination of mobile workshops type so they are more up-to-date concerning current challenges and needs facing land forces;
– in the first step, an exchange and modernization of equipment should be executed in currently used workshops, and in the second step a new type of container workshops should be introduced;
– proper temporary repairs kits should be introduced to the crews of fighting and recovery vehicles.

7 CONCLUSIONS

The crucial role of efficient and effective maintenance system in the field conditions is highlighted not only in the allied doctrines and rules but also in numerous publications concerning recently conducted combat operations. The appropriate documents allow for execution of improvised and temporary repairs in order to fast restore damaged weapon systems to battle area.

The conducted analysis of maintenance systems in other NATO armies indicates that it is a crucial element of any combat operations. Considering its complexity and significance, the system is being permanently improved and developed by numerous research, analysis and implementation of new concepts and solutions. Therefore, it seems that the process of new weapon systems acquiring should be modified in order to fulfil operation and logistics needs. As far as the battlefield maintenance of weapon systems at the appropriate level of task efficiency is concerned, it is very profitable to the weapon system since it would be characterized by high level of survivability, vulnerability and reparability in case of any damage. Additionally, there are necessary well-trained specialists, appropriate procedures and technologies in order to quickly execute maintenance tasks during combat operations.

It should be highlighted that the mobile repair system and equipment of the Polish Land Forces maintain units is largely obsolete and not adequate to requirements of contemporary battlefield. The rational organizing of maintain system of equipment used in the task mode seems to be matter of urgency. The division of maintain equipment and organization structure into peace and war time seems to be not rational and economic, especially if lack of sources for regular training is taken into consideration. It should be mentioned that the organization and technical solutions adopted in the Polish Land Forces do not fit into an expeditionary nature of operations conducted recently by Polish troops. As the analysis of numerous references have indicated, there are; commonly used by the allied armies, and easy to redeployment, mobile workshops and expedient repairs technologies, as well as, materials during expeditionary operations conducted in the remote battle areas. Another issue concerns a proper personnel preparation to battle damage assessment and repair, which can be achieved by providing permanent trainings for each maintain level personnel and including the gained experiences in handbooks, manuals and digital platforms. Finally, it should be claimed that the changes and modifications concerning the Polish Land Forces mentioned in the chapter are very slow, although they follow trends observed in allied armies.

There are many modern and efficient methods and technologies on the market that can be successfully applied to perform services and repairs of military equipment in the field. Taking this fact into account, an accessible solutions should be searched for by the military by means of numerous comparative experimental studies, as well as, economical and application analysis in order to find the best products and technologies considering specific requirements of a contemporary battlefield.

Statistics is an invaluable tool for collecting, processing and using of all information referring to maintenance of weapon systems, in particular, special computer systems designed for supporting maintenance and supply management like for example Condition Based Maintenance Plus. The use of these systems in the future should allow to eliminate a large portion of faults and defects resulting from faulty design, production technology or used materials and any other engineers solutions, as well as, take advantage of experiences and reports from executed already repairs. The implementation of computer system would support not only current maintenance planning and execution but also: permanent weapon systems improvement, design of new weapon systems, prediction of battle and maintenance faults, planning of recovery and repair operations, as well as, technical potential assessment, cost of repair calculation and stocks record to conducting repairs.

ABSTRACT: The focus of this paper is to provide decision support for the selection of a Crew Transfer Vessel (CTV) fleet for the offshore wind farm maintenance operations. This is achieved through analyses of environmental conditions, investigation of failures, and assessment of vessel operations. The developed methodology and analysis enable operators to decide the specification of CTVs which will bring the optimum financial benefit, considering both the enhancement of the offshore wind farm power generation as well as the minimisation of the total O&M cost.

1 INTRODCUTION

Offshore wind is becoming increasingly attractive to developers due to a number of advantages over the onshore environment. These include the availability of offshore areas in which major projects can be developed, the lack of limitations associated with the visual impact and noise of the wind turbines, higher wind speeds, and the lower turbulence levels in the offshore environment. Contrary to these advantages there are a number of increased challenges when moving offshore; wind turbines are situated in the highly corrosive sea environment, and subject to loads that are not often experienced onshore; therefore offshore wind farm operators suffer from greater maintenance issues. Harsher wind and wave conditions limit the operability of these vessels and eventually the accessibility of offshore wind farms. Currently, onshore wind energy costs £74/MWh, alternatively offshore wind energy costs £150/MWh, which the industry has to commit to bringing the cost of offshore wind down to £100/MWh in order to sustain the competiveness and the development in the offshore industry (WindPower Offshore, 2012).

According to a report prepared by WindPower Offshore (2013), the proportion of the CTVs to the number of vessels in the entire offshore wind market is 40.6%, while cabling vessels, jack-up vessels, heavy lift vessels and other vessel account for 21.3%, 16%, 12%, and 10%, respectively. Despite the dominance of the CTVs, there is no regulation specifically for offshore wind farm service vessels (WorldWind Technology, 2013). Technicians performing offshore maintenance are classed as passengers, and therefore if there are more than 12 technicians on-board, this specific vessel is classified as passenger vessel, which introduces extensive safety legislation and decrease operational flexibility. Furthermore, weather conditions restrict access of the CTVs; larger vessel may have better operational capabilities but charter rates escalate quickly. In this respect, it is essential to use the optimal vessels for the jobs involved, but also charter them at the right time at the minimal price.

It has been identified that the minimisation of the vessel costs has significant potential to reduce the overall Operation and Maintenance (O&M) expenditure. Although, CTVs are highly utilised within an offshore project lifecycle, the influence of CTVs on the entire O&M lifecycle cost has not been considered thoroughly. Considering current offshore wind O&M models, it has been identified that the CTV related operations are generally

neglected or modelled in a crude way. As such, the focus of this research is the investigation of optimum CTV fleet size and the examination of different CTV types which bring economic and operational benefits. Considering different climate parameters, failure characteristics of the turbine components, and the operational characteristic of the CTVs, an exhaustive model is presented which provides support for the long term offshore wind O&M planning.

The paper is structured as follows; in Section 2, the common procedures, aspects and issues associated with maintenance of offshore wind farms are presented. Through the observations in that section, a modelling methodology is specified in Section 3. A case study is presented in Section 4 in order to validate the proposed model. In Section 5, the results of the case study are evaluated. Final recommendations are provided in Section 6.

2 LITERATURE REVIEW

2.1 *Economic assessment*

O&M activities represent a significant share of the expenses during the lifecycle of the projects (Kaldellis and Kapsali, 2013). O&M costs can be considered to comprise of labour costs, material costs, access vessels & lifting vessels costs and potential revenue losses. In this respect, it is important to identify the critical elements that can significantly reduce overall costs.

Previous studies have identified that the development of new O&M vessels is particularly important; since the costs for vessels make up 73% of the total O&M costs (Fingersh et al., 2006, Junginger et al., 2004, Krohn et al., 2009, Lazakis et al., 2013). Van Bussel and Zaaijer (2001) showed that irrespective of wind turbine design, the cost of lifting operations by using a vessel accounted for more than 50% of the overall O&M costs. Dinwoodie et al. (2013) evidenced that the proportion of vessel associated costs to the total O&M costs is the largest; therefore optimisation of vessel costs is the key to minimise the overall project costs; considering the fact that economic benefit from producing more energy by increasing the availability does not always leads to higher profits since it may not compensate the increase in the total O&M costs (Santos et al., 2014).

2.2 *O&M activities and available vessels*

Minor failures occur frequently but lead to shorter downtimes and the cost of repairs are cheaper; however, numerous minor failures have the potential to contribute significant downtime. In this respect, Faulstich et al. (2011) studied the failure rates of wind turbine components identifying that the minor failures account for 75% of all turbine failures. In the case of minor failures such as; electrical system, electronic control, sensor and hydraulic system failures, vessels for minor maintenance are utilised in the repair operations. CTVs are used for wind turbine repairs, which do not require heavy equipment transport or heavy crane operations. CTVs can be equipped with dynamic positioning and motion-compensating gangways in order to improve the operability and accessibility but these technologies currently have a high associated cost.

Monohull boats, small catamaran vessels and Small Waterplane Area Twin Hull (SWATH) vessels are generally utilised in minor maintenance operations, which allow operators to keep the cost of minor maintenance operations at acceptable levels. Catamaran configurations are often the preferred choice but operations are restricted to relatively low wave heights (Tavner, 2012). The most distinctive characteristics of these vessels are high speed, small deck spaces, small crane capacities and safe access to wind turbine structures that will allow operators to take quick actions in case of urgent repairs.

3 METHODOLOGY

The developed methodology is illustrated in Figure 1. The overall model consist of four blocks. The inputs of the model are introduced in the Inputs block. The inputs are processed in the Data Process block and then considered for the Simulations block. In the Simulations block, processed climate series, forecasted failure behaviours and vessel accessibility and operability values are synthesised and OPEX calculations are performed. The cost elements which influence offshore O&M activities are then employed along with these results to support the decision making. Final decision choices are determined not only from a power production point of view, but also in terms of cost, revenue and profit.

3.1 *Inputs block*

Wind speed, wave height and wave period observations constitute the climate parameters. Whilst all the climate parameters influence vessel operations, wind speed has also impact on power generation. Failure rates and repair times denote the sequence of minor failures and the time required to repair these failures. The repair time values are the periods associated with actual repairs, excluding the reaction time. Wind farm related attributes represent the number of turbines in the farm, individual turbine capacity

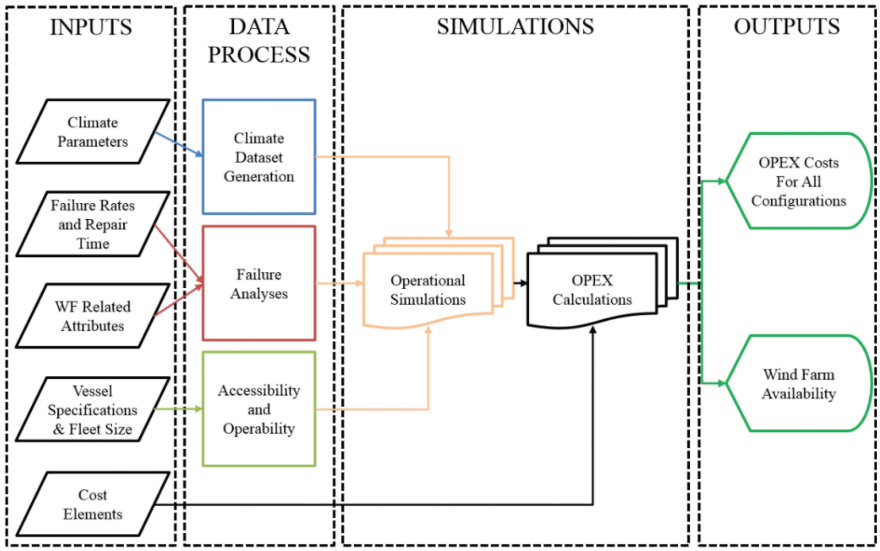

Figure 1. Proposed methodology.

and average distance from O&M port. Vessel specifications and fleet size denote the number of vessels in the fleet; also structural and mechanical properties of these vessels. Cost elements symbolise daily charter cost of vessels, fuel cost, electricity price, and technician annual salaries.

3.2 *Data process block*

Data process block where the datasets from inputs block will be organised and evaluated. In this respect, climate dataset generation, failure analyses, and accessibility & operability calculations are performed prior to the simulations and OPEX calculations. In the following sections, these analyses will be explained in details.

3.2.1 *Climate dataset generation*

The climate dataset for simulation comprises of a synthetic wind speed, significant wave height and wave period time series. These are generated using a Multivariate Auto-Regressive (MAR) model, shown in Equation 1, normalised by the mean of the data μ where X_t is the simulated wind speed at time-step t, n is the number of variables, X_n is a variable state vector, A_n is a matrix of the MAR model coefficients and ε_n is a noise vector with mean zero and covariance matrix of the data, order p (Box and Jenkins, 1970).

$$X_t = \mu + \varepsilon_n + \sum_{i=1}^{p} A_n (X_{n-i} - \mu) \quad (1)$$

In order to apply Equation 1 to a wind and wave data set a transformation must be applied in order that the data set mean and variance are stationary and approximate a Gaussian distribution. It is necessary to apply the Box-Cox transformation described in Equations 2 and 3, where Y_t is the transformed series, Hs is significant wave height and Λ is the transform coefficient. A Fourier series fit of the seasonality observed in the transformed data can then be removed (Soares et al., 1996). The transfer coefficient value that minimises skewness is identified and used to give the closest approximation of a normal data set.

$$Y_t = \frac{Hs_t^{\Lambda-1}}{\Lambda}, \quad for\ \Lambda \neq 0 \quad (2)$$

$$Y_t = T(Hs_t) = ln(Hs_t), \quad for\ \Lambda = 1 \quad (3)$$

Having transformed the data, Equation 1 can be applied to both wind and wave data. The determination of MAR coefficients and model generation is implemented using the arfit algorithm in MATLAB (Schneider and Neumaier, 2001). Order is chosen by optimising Schwarz's Bayesian Criterion and coefficients are estimated using a stepwise least squares estimation process. In order to preserve the variability in performance driven by climate, a unique synthetic time series is generated for each simulation. Using the described methodology the key characteristics of mean and variance as well as annual distribution, access window duration periods and inter-time step correlation are

preserved. In addition, correlation between different climate parameters are preserved.

3.2.2 *Failure analyses*

The wind turbine system failure process is implemented using the methodology developed in (Billinton, 1970). The wind turbine is characterised as a series of subsystems that can each exist in a discrete state during each simulation time-step. The probability of moving from an operating state to a failed or reduced operating state is governed by the hazard rate h(t), which is defined as the probability of observing a failure in a specified time interval. The hazard rate through the life cycle can be represented using the Weibull function shown in Equation 4, where the shape parameter β determines the gradient of the hazard rate and scale parameter ρ corresponds to the frequency of observed failures. This methodology allows for changing hazard function throughout the simulated life time. As a greater understanding of offshore wind turbine failure behaviour is developed through operator experience it will become possible to represent design life changes or impacts of climate and maintenance.

$$h(t) = \rho\beta t^{\beta-1}, \ for \ t \geq 0 \tag{4}$$

At each time-step a uniformly distributed random number, R, in the interval 0 to 1 is generated and used to determine if a failure has occurred using the criteria in Equation 5. Failure transition if:

$$R > (1 - h(t)) \cdot \frac{\Delta t}{8760} \tag{5}$$

Repair is then simulated based on the climate time series. If a turbine is in a failed state it will return to a working state when sufficient access time has been observed or when a series of repair actions have been performed corresponding to a completed maintenance action.

3.2.3 *Accessibility and operability*

CTVs operate in waves; through analysing wind speed and significant wave height values, it is possible to identify the time-steps/days in which the CTVs can operate or stay in the specified port. In the proposed methodology, the transit time delays due to speed reduction under different climate conditions are considered by also analysing the wave period values. In this context, accessibility and operability analyses are constituted from 5 sequential steps;

- Calculation of total calm water resistance
- Calculation of additional wave resistance
- Calculation of total resistance
- Calculation of speed loss in wavy sea
- Calculation of transit time

The total calm water resistance $R_{T\text{-}Calm}$ of the CTVs can be calculated from the Equation 6 and 7;

$$P_E = P_B / \eta_T \tag{6}$$

$$R_{T\text{-}Calm} = P_E / V \tag{7}$$

where P_B = break power; P_E = effective power; η_T = total efficiency of the vessel; and V = vessel speed. In the Equations above, effective power is the necessary power to move the vessel through water, and break power is the power output of the engine without power loss caused by gears, transmissions or friction force.

In heavy seas, waves cause additional resistance on the vessel hull. The most accurate method to calculate additional resistance due to waves is model testing; alternatively, Jinkine and Ferdinande (1973) developed an empirical formulation for predicting the added resistance for fast cargo ships in head seas. The dimensional added resistance is related to the non-dimensional added resistance coefficient by Equation 8,

$$R_{AW} = \sigma_{AW} \ (\rho g \zeta_A^2 B^2 / L) \tag{8}$$

where R_{AW} is non-dimensional added resistant coefficient, σ_{AW} is non-dimensional added resistant coefficient, and ζ_A is wave amplitude; ρ is density of water, g is acceleration due to gravity, B breadth of CTV, and L is length of CTV. The total resistance of the vessel, R_T is the summation of calm water resistance and added resistance due to waves in the ocean (Equation 9).

$$R_T = R_{AW} + R_{T\text{-}Calm} \tag{9}$$

Due to the fact that time-step approach is utilised in the simulations, wave height and wave period values in each time-step will be different which creates variation in added resistance and eventually total resistance of the CTVs. Therefore, the equations above have to be applied to every time-step of the simulations.

Whilst a CTV is traveling in a wavy sea, skipper can keep the power constant and decrease the speed or keep the speed constant and increase the power. In this study the power and thrust of the CTVs will be kept constant and speed will change with the influence of added resistance. In order to calculate the speed loss in each time-step under the condition of constant power and thrust, Equations 10 and 11 derived by Berlekom et al. (1974) and Berlekom (1981) can be utilised.

$$\frac{\Delta V_i}{V_0} = \sqrt{1 + \frac{R_{AW_i}}{R_{T_i}}} \quad (10)$$

$$V_{A_i} = V_0 - \Delta V_i \quad (11)$$

where R_{AWi} = Added resistance at time-step i; R_{Ti} = Total resistance at time-step i, V_0 = Operational speed of CTV; ΔV_i = Speed loss at time-step i; V_{Ai} = Achievable speed at time-step i.

Transit time is calculated through adding the individual distances that are logged in each time-step, which are the multiplication of achievable speed at time-step i and interval (Equation 12). When the summation of these distances become equal to the total distance between port and offshore wind farm, it is accepted that the vessel has approached to the wind farm site (Equation 13).

$$Distance_i = Time\ Step\ interval \times V_{A_i} \quad (12)$$

$$Total\ Distance = \sum_{0}^{i} Distance_i \quad (13)$$

3.3 *Simulations block*

The simulations are performed through synthesising all the processed climate, failure and operational information received from data process block. At the first stage, the failure types and time-steps are identified and assigned to the specified turbines. In the repair strategy, climate parameters and accessibility calculations are considered together. Following the failure identification and allocation, accessible & operable days are identified. Due to the fact that current operational practices are on shift bases, the same approach is adapted in this study; therefore working hours are limited by a specified shift duration. However, climate parameters may not allow CTVs to leave the port or transport technicians to wind farm within specified shift or allow only a limited period in the shift. In this respect, the maximum weather window is calculated in the shift in order to identify the maximum period that the technicians can work.

Additionally, there may be cases that the time spent on the journey might be substantially longer. Therefore, a 'minimum working limit' has to be defined for making a working shift acceptable and cost-effective. The 'minimum working limit' will create an extra constraint for the O&M activities. If the maximum weather window is shorter than the minimum working hour, this specific day is considered as inaccessible day.

The repair simulations are performed on daily bases. After identifying the day that the repair can be performed, a CTV is allocated to the failed turbine. The repairs are cumulative, which means if the repair cannot be completed within a single shift, the remaining part can be completed in the following accessible day. When a repair day is completed, the following day is simulated. If there is failure in that day, the same approach is implemented. Otherwise, the following day is simulated. The simulations are completed when the days simulated reaches the length of the simulations.

3.4 *Outputs block*

Outputs of this study are the average MTTR for all turbine components, average availability, the ratio of completed scheduled maintenance, power produced, power loss, revenue loss, and profit values due to the change of fleet size and CTV capabilities. These outputs provide sufficient information in order to assess the influences of changes and bring a solution for the fleet optimisation problem. Through considering all the parameters, the optimal fleet size and CTV type are decided. Potential alternatives, such as increase in crew size, improvement in failure characteristics, can be investigated following the decision of fleet size and CTV type.

4 CASE STUDY

In order to validate the proposed model, a case study which captures the influence of fleet size variation on MTTR, power production, availability, and profit values, was performed. In the simulations, two different CTVs were examined, which provide not only the flexibility of comparison between the size of fleets, but also the selection of CTVs which brings the most economic advantage. Table 1 shows the specifications of CTVs; CTV-1 has better capability than CTV-2, on the other hand daily charter rate and fuel consumption

Table 1. CTV specifications.

	CTV-1	CTV-2
Vessel type	Catamaran	Catamaran
Length (m)	26	19.1
Demi-hull breadth (m)	3	2
Draught (m)	2.05	1.3
Displacement (tons)	145.7	50
Speed (knots)	24	24
Installed power (kW)	1790	1418
Op. wave height (m)	1.5	1.25
Op. wind speed (m/s)	25	25
Fuel cons. (l/h)	446	316
Charter rate (£/day)	3250	2000
Technician capacity	12	12

values of CTV-2 are less than the values associated with CTV-1.

Tables 2 and 3 represent the failure rates, cost of repairs, required time and the technicians that will be allocated to the turbines. These values are adapted from the reports prepared by Poore and Walford (2008) a Wilkinson and Hendriks (2007). At this stage, it is important to highlight that the knowledge related to failure rates of offshore wind turbines are very limited, therefore, it will be possible to utilise more accurate offshore wind failure rates in the future using the developed modelling framework.

Table 2. Failure rates and repair costs of components.

No.	Failure types	Failure rate (times/year)	Repair cost (£)
1	Manual restart	8.79	–
2	Blade	1.48	20300
3	Pitch system	0.08	7150
4	Hub	0.185	4300
5	Main shaft & bearings	0.185	14000
6	Gearbox	0.08	3250
7	High-speed shaft	0.19	3250
8	Mechanical brake	0.04	2500
9	Generator	0.08	12000
10	Control system	0.24	4150
11	Yaw system	0.12	10800
12	Hydraulic services	0.12	1300
13	Power electrics	0.24	4150
14	Transformer	0.02	15400
15	Tower	0.19	5000

Table 3. Required time and technicians for repairs.

No.	Failure category	Repair time (Hours)	Required tech.
1	Manual restart	1	2
2	Blade	8	2
3	Pitch system	5	2
4	Hub	4	2
5	Main shaft & bearings	4	2
6	Gearbox	4	2
7	High-speed shaft	3	2
8	Mechanical brake	2	2
9	Generator	4	2
10	Control system	4	2
11	Yaw system	3	2
12	Hydraulic services	3	2
13	Power electrics	3	2
14	Transformer	5	2
15	Tower	8	2

Table 4. Additional attributes.

No.	Failure category	
1	Number of simulations	100
2	Number of years	20
4	Number of turbines	100×5 MW
6	Scheduled maintenance	100 man-hour/ year/turbine
7	Electricity price	0.137 £/kWh
8	Staff cost	60000 £/year
9	Fuel cost	0.83 £/litre
10	Distance to shore	20 nmiles
11	Minimum working	2 hours
12	Daily shift	8am–8pm

Table 4 represents the additional attributes required to run the simulations. Due to the fact, the generated climate datasets show variations, 100 different climate datasets are generated prior to the simulations, and these generated climate dataset are utilised for each fleet size. Therefore, the climate influence is captured by running 100 simulations for each fleet size, on the other hand consistency is secured by utilising the same climate datasets for each fleet size.

5 RESULTS

This section presents the simulated results for the specified case studies. Figure 2 demonstrates the annual availability simulated across different CTV configurations. There is an inherent inter-annual variability driven principally by the climate and failure rates which both have significant variability between years. It can be seen that increasing the number and capability of the CTV fleet reduces the degree to which inter annual variation occurs as well as improving average availability. This result is explained due to the increased operational threshold reducing the observed inaccessibility and consequently reducing uncertainty in performance from climate. Increasing the access threshold of CTV fleet further will reduce the variability from climate further but there are practical technology limits and associated costs with improved vessel design.

Figure 3 shows the downtimes of offshore wind turbine components due to minor failures under the influence of fleet size increase. Whilst the left vertical axis represents the component MTTR values, the right vertical axis represent the mean MTTR values for the entire offshore wind turbine system. The values on the horizontal axis is the size of fleet and the values ‘1’ and ‘2’ denote the category of CTV in the fleet. Due to the fact that

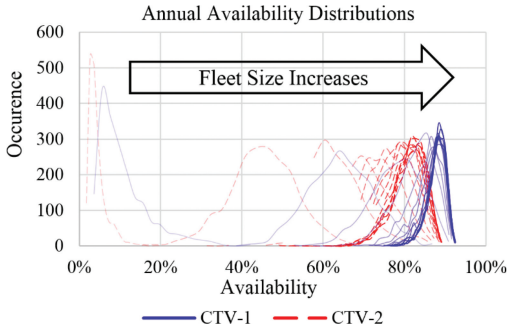

Figure 2. Annual availability distributions.

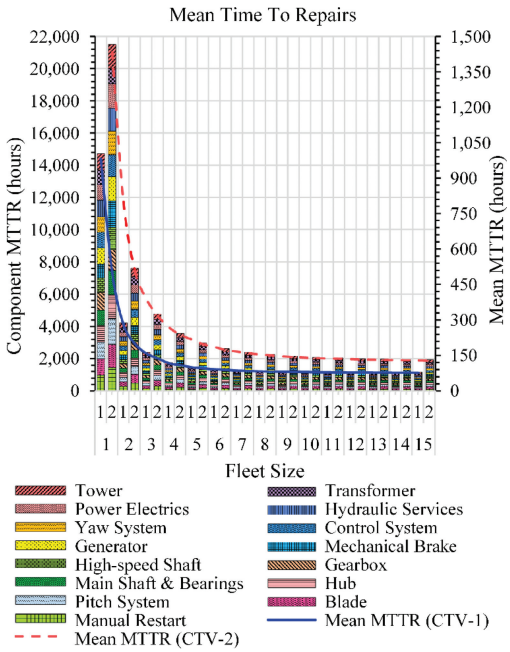

Figure 3. MTTR values for different fleet compositions.

increase in the fleet size provides more flexibility in the O&M activities, the reaction times to failures and eventually the downtimes of the minor failures decrease substantially. As explained in the previous section, the operational capabilities of CTV-2 are lower than CTV-1; therefore, MTTR values are higher for the fleets which consist of CTV-2. Additionally, the improvement on MTTR values decreases with the increase in the size of fleet for both CTV categories.

In contrast to the MTTR values, the power production values escalate with the increase of fleet size regardless of CTV category (Fig. 4). Due to the fact that maximum theoretical power that

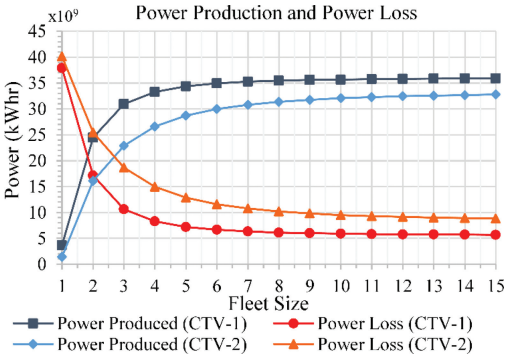

Figure 4. Power produced and power loss.

can be generated is unrelated to the fleet size or CTV capabilities, the power loss values decrease proportional to the increase in power production. The reason that all the graphs in Figure 4 become approximately straight after a critical fleet size is the maximum accessibility has been achieved by the specified vessels.

Wind farm availability and completed scheduled maintenance values are shown in Figure 5. Availability values show similar trends to the power production values and increase when the fleet size becomes larger. For all fleet compositions, the availability values are lower for the fleets with CTV-2. The reason is the number of accessible days within a year for CTV-2 is lower than the number of accessible days for CTV-1. Therefore, it will not be possible to reach equivalent productivity by chartering a larger number of CTV-2 s. With regard to completed scheduled maintenance values, it can be seen that scheduled maintenance tasks can be completed within simulation period in both cases; however the size of the CTV-2 fleet has to be larger to achieve comparable performance with the CTV-1 fleet.

When the distribution of costs that contribute to total O&M cost is analysed, the transport cost which is the summation of fuel cost and daily charter rate cost, dominates the total O&M cost as shown in Figure 6. The vertical axis represents the costs associated with each cost attribute; the values on the horizontal axis is the size of fleet and the values '1' and '2' denote the category of CTV in the fleet. At this stage, it is important to highlight that the O&M tasks in this study are the repairs due to minor failures of the turbine components; therefore the values in Figure 6 represent the costs associated with minor O&M activities. The staff cost is directly proportional to the fleet size; therefore the staff cost increases £720,000/per-year when a new CTV is added to the existing fleet. The red and blue lines show the total O&M cost which is always

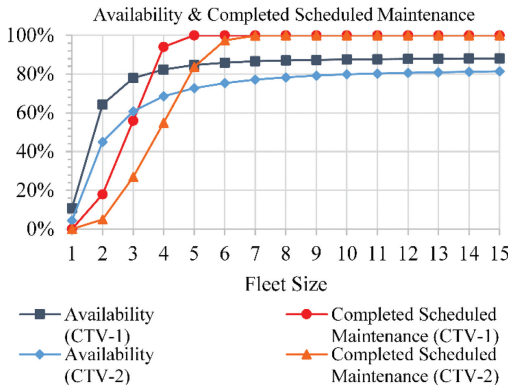

Figure 5. Availability and completed scheduled maintenance.

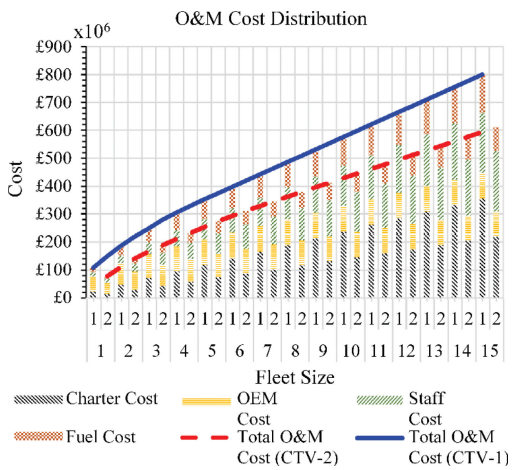

Figure 6. O&M cost distribution.

higher for the CTV-1 fleets than CTV-2 fleets due to higher daily charter rate and fuel consumption of CTV-1.

Considering these results, the escalation of fleet size brings a reduction in MTTR and lost revenue, increased power production, availability, and completion of scheduled maintenance values; however, there is a corresponding increase in all aspects of the costs. In this context, the optimum size of the fleet has to be defined through assessing the revenue loss and profit values; because the revenue and profit values reflect the level of economic benefits achieved through increasing the fleet size. In this respect, Figure 7 shows how these features are formed. For the CTV-1 fleets, financial loss decreases and profit increases until fleet size reaches a fleet of 7 vessels. If the CTV-1

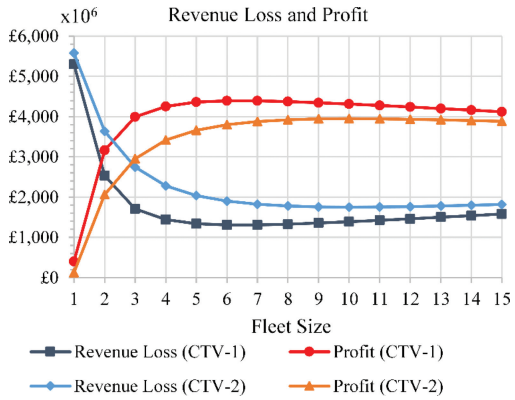

Figure 7. Revenue loss and profit.

fleet size becomes larger than 7, the profit starts to decrease and therefore revenue loss increases. This is because, extra costs cannot be covered anymore by the production increase. From the CTV-2 point of view, optimum fleet size is 10 vessels. As for the CTV-1 fleet, revenue loss decreases and profit increases until fleet size reaches 10. Therefore, the optimum fleet sizes for CTV-1 is 7, for CTV-2 is 10.

When the simulation results are compared between CTV categories, CTV-1 clearly shows both operational and economic benefits. Although, CTV-2 has lower fuel consumption and daily charter rate, the number of days accessible by CTV-2 is significantly low; thus the utilisation of CTV-2 is low. This situation causes a substantial decrease in the availability and profit values.

6 FINAL DISCUSSION AND CONCLUSION

This article relates to the current issues of the offshore wind O&M cost optimisation; considering the influence of varying fleet sizes and CTV characteristics. A model was introduced with the objective of identifying the most cost effective CTV and the optimum fleet which brings economic and operational benefits. In order to assess the accuracy of the proposed model and to generate realistic results, the model was applied to a case study wind farm.

The results indicate that a CTV with better capability brings great economic and operational advantages, even though that CTV has higher daily OPEX cost. It is also identified that the profit increases and the financial loss decreases until the fleet size is reached an optimum level. On the other hand, the fleets that are larger than optimum result

in an increase in the total O&M cost which cannot be compensated by the economic benefit from producing more energy.

Practical aspects of the application of RCM to select optimal maintenance policy of the production line

M. Jasiulewicz-Kaczmarek
Poznan University of Technology, Poznan, Poland

ABSTRACT: The most known and diffused third generation maintenance management systems is the Reliability-Centered Maintenance (RCM). RCM focuses on the system functions and directs maintenance efforts at those parts and units where reliability is critical. One of the issues with the conventional RCM process is that the analysis takes time and consequently, the results of the program accrue after a substantial period of time. Considering the fact that there is not enough time nor money to follow the full RCM procedure, the approach to the methodology has been modified. In the paper the case is introduced to present application of modified RCM to determine the optimal maintenance strategies mix for an equipment in the way more efficient comparing to classic RCM approach.

1 INTRODUCTION

1.1 *Technical object*

Profitability improvement is one of the most important tasks for the industry. This improvement can be achieved by increasing the availability of the system and by reducing the total associated maintenance costs. In pursuit of continuous improvement, two complementary methodologies that reflect various focuses are available (uptime) of physical assets, these methodologies are (Jardine & Tsang 2013): Total Productive Maintenance (TPM)—a people-centered methodology and Reliability-Centered Maintenance (RCM)—an asset-centered methodology. These methodologies require the maintenance and production departments to operate with synergy to discern and avoid potential problems. The maintenance objectives are focused on production needs, i.e. to reduce manufacturing lead-times and increase flexibility. TPM emphasizes integration between production and maintenance practices and the systematic and continuous improvement, in order to maximize the Overall Equipment Effectiveness (OEE) performance index. RCM focuses on the system functions and directs maintenance efforts at those parts and units where reliability is critical (Garg & Deshmukh 2006).

In the paper, the author presents a case study of RCM implementation in one of the manufacturing companies in order to improve the maintenance scheduling and maintenance strategy in the production line. The implementation of RCM was carried out in 4 stages; preparation, system analysis, decision making, implementing and feedback. In order to determine system functions, functional requirements, functional failures, as well as cause and consequences of functional failures, the FMECA technique can be adopted.

2 MAINTENANCE

Nowadays along with the rapid development of industries in the world and organizations attempt for the continuity of production and also the increase of influence in the market, the decrease of the production cost and the attempt to set up the process of production, have turned to the most important challenges of production organizations. To reach to this goal continuity of production and also decrease of operation costs are set on the high agenda of production managers. (Swanson 1997). Maintenance costs are a major part of the operating costs of all manufacturing or production plants. Depending on the specific industry, maintenance costs can represent between 10 and 40% of the costs of goods produced.

Today, maintenance has become a management issue, with its function as a contributor towards profit (Jasiulewicz-Kaczmarek 2013a). This indicates the need for the maintenance operation to align with the business objectives and increase value for the enterprise. Thus, the choice of the right maintenance strategies, i.e. the best mix of corrective, preventive, condition-based, and proactive maintenance for the equipment is fundamental. Throughout the years several approaches to enhance the maintenance management have been developed and applied to a wide variety of organizations and systems (Bevilacqua & Braglia 2000;

Pun et al. 2002; Jafari et al. 2008; Selvik & Aven 2011; Wang et al. 2012). The most known and diffused third generation maintenance management systems is the Reliability-Centered Maintenance.

3 RELIABILITY-CENTERED MAINTENANCE

3.1 *RCM history*

Reliability-Centered Maintenance is one of the well-established systematic methods for selecting applicable and suitable maintenance operation types (Kumar et al. 2007). It originated in the civil aircraft industry in the 1960s with the introduction of the Boeing 747 series, and the need to lower PM costs in attaining a certain level of reliability. The results were successful and the methodology was developed further. In 1975, the U.S. Department of Commerce defined the concept RCM and declared that it should be used in all major military systems (Nowlan & Heap 1978). In the 1980s, the Electric Power Research Institute (EPRI) introduced RCM into the nuclear power industry. Today RCM is used or being now expanded to several industry fields (Abdulrohim et al. 2000; Deshpande & Modak 2002; Afefy 2010; Ramli & Arffin 2012; Narnaware et al. 2014).

3.2 *RCM approach and methodology*

Moubray (1997) defines RCM as "a process used to determine what must be done to ensure that any physical asset continues to do what its users want it to do in its present operating context", characterizing RCM as a process to establish the safe minimum levels of maintenance. The definition however is quite general. The more detailed approach is presented in IEC 60300-3-11 standard, in which RCM is defined as "a method to identify and select failure management policies to efficiently and effectively achieve the required safety, availability and economy of operation" (IEC 60300-3-11:2009). RCM methodology has three major goals (Moubray 1997):

- to increase safety and reliability of systems by focusing on the most significant functions (RCM is concerned mainly with what we want the equipment to do, not what it actually does),
- to prevent or to mitigate the consequences of failures, not to prevent the failures themselves (the consequences of a failure disagree depending on where and how items are installed and operated),
- to decrease maintenance costs by escaping or removing maintenance actions that are not strictly necessary.

Hence, determining the operating context and what the user wants the equipment to do is the starting point for the RCM process, which is applied by asking and answering the following seven questions (Moubray 1997):

- What are the functions and associated performance standards of the machine in its present operating context?
- In what way does it fail to fulfil its functions?
- What causes each functional failure?
- What happens when each failure occurs?
- In what way does each failure matter in respect of the environment, human safety, losses, and expenses?
- What can be done to predict or prevent each failure?
- What should be done if a suitable proactive task cannot be found?

To perform RCM analysis are employed the following tools and expertise:

- design, engineering and operational knowledge of the system,
- condition-monitoring techniques,
- risk-based decision making (the frequency and the consequence of a failure in terms of its impact on safety, the environment and operations),
- Failure Modes, Effects and Criticality Analysis (FMECA), this analytical tool helps answer questions 1 through 5 (the FMECA is composed of two separate analyses: the Failure Mode and Effects Analysis (FMEA) and the Criticality Analysis (CA); the FMEA analyzes different failure modes and their effects on the system while the CA classifies or prioritizes their level of importance based on failure rate and severity of the effect of failure; the ranking process of the CA can be accomplished by utilizing existing failure data),
- RCM decision flow diagram, this diagram helps answer questions 6 and 7.

The aim of RCM is to optimize, in a systematic way, the mix of the main maintenance practices, i.e. corrective, preventive, condition-based, and proactive, that must be adopted by the maintenance staff of a firm. These main maintenance policies, rather than being applied independently, are integrated to take advantage of their respective strengths in order to maximize facility and equipment reliability while minimizing life-cycle costs.

Successful application of RCM requires a good understanding of the equipment and structure, as well as the operational environment, operating context and the associated systems, together with the possible failures and their consequences. It means that running RCM analysis in a company requires some specific knowledge and experience from the

Table 1. Classification of streamlined RCM concepts (Pintelon & Parodi-Herz 2008).

Example	Characteristics	Pitfalls
Retro-active approach	Starts from the existing maintenance plan. Determines the failure mode for all maintenance tasks and implements the last RCM steps for these.	Quite time-consuming to find the failure modes for all tasks. "Functions" are detected on ad hoc basis. It Implies that the existing maintenance plan is good.
Criticality approach	Limits the implementation to critical functions and/or failures for these a full RCM analysis is performed.	Often determines criticality on an ad hoc basis or uses criticality tools which are less reliable than the RCM approach.
Troublemaker approach	Carries out a full RCM analysis for critical equipment only. Critical equipment is defined here as bottleneck equipment, which had a lot of maintenance problems in the past or is critical in terms of safety hazards.	Idem as above, although here all RCM steps are followed which guarantees a "full picture".

members of the team responsible for the analysis. The IEC 60300-3-11:2009 standard introduces requirements within this area, especially stressing:

– knowledge of and experience with the RCM process,
– detailed knowledge of the item and the appropriate design features,
– specialist knowledge of constraints, such as safety and environmental legislation, regulation, etc.
– knowledge of the maintenance techniques and tools,
– knowledge of costs.

3.3 *RCM related concepts*

In the 1970s, and still today, RCM was a major challenge in many industries because it changed the focus of PM from bringing back the systems to a "perfect" state to maintaining the system in a good "functional" state. RCM as such has proven to be a very valuable concept, focusing on reliability and paying attention to safety and environment. Its structured approach ensures asset sustainability. However, there are some drawbacks that should be kept in mind and, if possible, remedied. RCM implementation is complex, time consuming and is not straightforward. Hence, it should be implemented in a controlled fashion with total support of all levels of the organizations. In the literature one can find many RCM-related concepts such as Gits, Coetzee, BCM, RBCM, streamlined RCM, and so forth (Pintelon & Parodi-Herz 2008). All of them adopt RCM principles with the intention of solving some of its shortcomings. Although streamlining sounds attractive it should be carefully applied, in order to keep the RCM benefits. Table 1 provides a picture of popular streamlined RCM approaches.

In many enterprises RCM methodology is an element of TPM approach realization (Ben-Daya

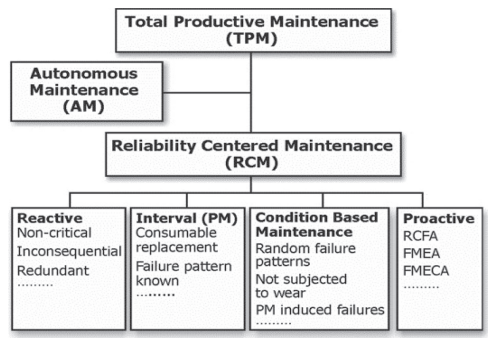

Figure 1. Relation between TPM, RCM and other maintenance approaches.

2000). TPM is a holistic approach building technical culture, based on team work and common goals. Simultaneous application of TPM and RCM contributes to synergy effect within maintenance area. The effect is possible thanks to combination of knowledge of maintenance engineers (RCM) and machines operators (TPM)—participation in striving for a common goals. The relations between TPM and RCM is introduced in the Figure 1.

4 CASE STUDY

The RCM practice was used to assist the company in focusing their maintenance activities based on the criticalities of the equipment by applying the FMECA. For over six years the company benefits from TPM approach application. Predefined pillars of TPM are being developed according to general methodology developed by JIPM, with respect to needs and constraints identified in a company. Regular training sessions concerning methods and techniques for continuous improvement are organized periodically for managers and operators in a

production process, as well as for maintenance staff, new standards for performance are being developed and procedures and instructions applied so far are inspected and modified whenever needed.

The aim of RCM was to reduce the number of maintenance checklist and to improve significantly the integrity of maintenance practice, by, among others, optimization of performance of maintenance staff and of operators realizing technical services within Autonomous Maintenance (AM) pillar.

RCM analysis was to be conducted for one of the production lines composed of 11 machines. The line works in three-shifts system and breakdown of any of the machines results in stoppage of the entire line.

One of the issues with the conventional RCM process is that the analysis takes time and consequently, the results of the program accrue after a substantial period of time. Considering the fact that there is not enough time nor money to follow the full RCM procedure, the approach to the methodology has been modified. The modification introduces one basic change into the process. Instead of looking forward, into the future and thinking about "potential breakdowns", their causes and consequences, it is necessary to look into the past, at breakdowns which has already happened. The benefit from the approach is substantial decrease in time and costs of analysis, making it practically applicable in the company.

The implementation of RCM was carried out in 4 stages; preparation, system analysis, decision making, implementing and feedback.

At the beginning of preparation stage, a project group was established from various departments and all relevant equipment documentations are collected such as breakdown reports, maintenance history records, current maintenance checklists, operation manuals, safety and environmental incident reports, production and quality reports and service reports. Also the equipment was listed accordingly to their respective shop in order to clarify the status of every parts availability. Analysis of data on production line covered two years period. The goal of analysis was to identify machines characterized with the greatest unreliability, as well as time and cost consuming repair process (failure removing and production losses). Identification of a machine to be subject of further analysis is based on Pareto analysis, according to which in each set or group of objects there is a small subset much more important than others. Basing on the data gathered on failures of production lines resulting from failures of all the machines Pareto graph was made (Fig. 2). In the chart, the columns represent the number and downtime connected with removing failures detected. Analysis of the two parameters proves that the machine critical for the line is M1, for which average time of repair was calculated as t = 0,61 h. Furthermore, analysis of costs emerging from failures removal was conducted for every machines. Taking into consideration the number of failures, time and cost of their removal the decision was taken to conduct further analysis for M1 machine.

In the next stage analysis of failures of M1 workstation was conducted. The goal of the analysis was identification of a component of the machine causing the greatest losses. Decomposition of the machine was conducted and basing on historical data on number of failures and downtime caused by failures of each component Pareto chart was drawn, as presented in the Figure (Fig. 3).

The area critical for M1 is foiling subsystem M1U1. Decomposition of M1U1 to basic components was conducted as presented in the Figure 4.

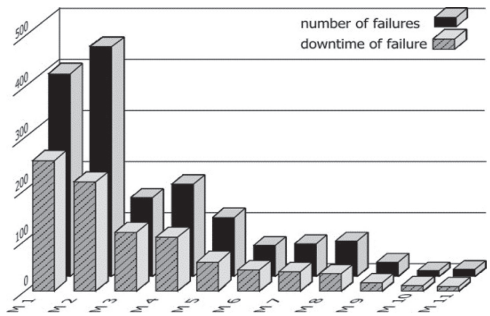

Figure 2. Pareto chart for a production line.

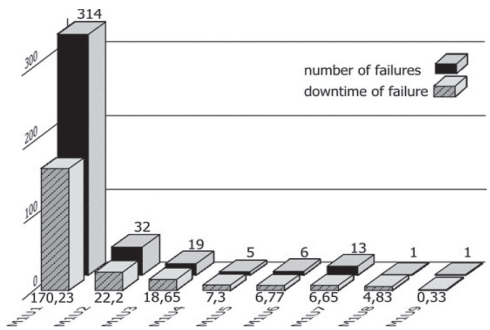

Figure 3. Pareto analysis for M1.

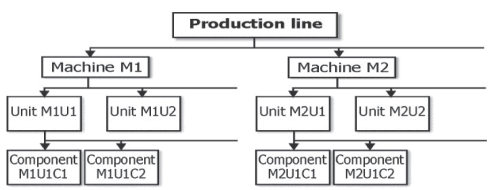

Figure 4. Decomposition of M1 to subassemblies and components.

Based on maps of losses (Pareto analysis) the 8 most critical components of the device were selected. In the next step functions of components were identified for all the components (F), which was followed by characterization of all possible Functional Failures (FF), described all possible Failure Mode (FM) and the effects of each failure mode were specified in reference to: line downtime, spare parts purchase costs and working time purchase costs for maintenance staff (Table 2).

In the next step, criticality of each failure was assessed. Methodology applied for the assessment was FMECA. FMECA is a tool used to help on setting priorities for the definition of maintenance tasks based on the analysis of the failure modes of components and their respective effects in a system. The effects of a failure depend on:

- the consequences (impact) of the failure in the operational environment,
- the conditions (occurrence) under which the failure happens.

Failure of a machine potentially influences performance, quality of a product, safety and many others. Hence, gravity of consequences of failures influences mostly which actions are to be taken to avoid predefined failures. That is why the following factors determining the impact of failures were identified in the company:

- safety (S)—analyze the impact of the failure mode on the safety of the workers in the area of occurrence (risk of accidents due to the failure),
- environment (E)—analyze the impact of the failure mode on the environment on its area of occurrence (risk of environmental accidents due to the failure),
- quality (Q)—analyse the impact of the failure mode on the quality of product (risk of quality defects due to the failure),
- production (P)—analyze the impact of the failure mode on the production, productivity or efficiency of processes (risk of time/material losses due to the failure etc.).

Assessment of impact of a failure on each of predefined factors was based on four levels scale, where 0—no impact; 1—low impact, 2—medium impact, 3—high impact. The example of assessment of influence of a failure on production is introduced in the Table 3.

It needs to be stressed that downtime parameters "a" and "b" presented in the table are individual for each company, hence each team should assess them by itself. Taking general data based on literature analysis may lead to mistaken decisions in some cases. In the next step the team conducted assessment of influence of the failure mode on the safety, environment, quality and production.

Table 2. Definition of function, functional failures and possible failure mode for M1U1C1 component—the example.

Component/code	F	FF code	FM code
Gum covered cylinders/ M1U1C1	Keeping foil strained while cutting	No cutting M1U1C1.1	Contaminated cylinders M1U1C1.1.1
		Foil creasing M1U1C1.2	Cylinders pressure wrongly adjusted M1U1C1.2.1
		Foil creasing M1U1C1.2	Used surfaces of cylinders M1U1C1.2.2
		Cutting impossible M1U1C1.3	Change in properties M1U1C1.3.1
		Foil got stuck in between cylinders M1U1C1.4	Leading rods wrongly adjusted M1U1C1.4.1

Table 3. Impact of a failure on production.

Index	Description
0	The occurrence of the failure has no effect at all
1	The occurrence of the failure can cause stoppages < "a" min
2	The occurrence of the failure can cause stoppages between "a" min and "b" hours and/or small increment in materials consumption
3	The occurrence of the failure can cause stoppages > "b" hours and/or significantly increase materials consumption

Table 4. Impact of a failure—M1U1C1 component.

Component code	FM code	Impact (I) S	E	Q	P	S + E + Q + P
M1U1C1	M1U1C1.1.1	0	0	1	1	2
	M1U1C1.2.1	0	0	1	1	2
	M1U1C1.2.2	0	0	1	3	4
	M1U1C1.3.1	0	0	1	3	4
	M1U1C1.4.1	0	0	1	2	3

Table 5. The occurrence of failure defined by frequency.

Index	Description
0	Potential failure: MTBF = ∞
1	MTBF > "m" operating hours
2	"n" < MTBF < "m" operating hours
3	MTBF < "n" operating hours

Table 6. Occurrence and criticality—M1U1C1 component.

Component code	FM code	Occurrence (O) P	R	D	C = I + O	Cause
M1U1C1	M1U1C1.1.1	3	1	1	7	No sensorial inspection
	M1U1C1.2.1	3	1	2	8	No sensorial inspection
	M1U1C1.2.2	3	3	2	10	No CBM
	M1U1C1.3.1	3	3	2	10	No modification
	M1U1C1.4.1	1	2	2	8	No sensorial inspection

The example of the assessment of influence of M1U1C1 is introduced in the Table 4.

After influence analysis, occurrence was assessed. The occurrence of failures was defined through:

- frequency (F)—analyse how often the failure mode occurs in the equipment (MTBF of the failure mode), (Table 5),
- repair (R)—analyse how difficult the repair/restoration of the failure is (time and cost),
- detection (D)—analyse how difficult it is to detect in advance the occurrence of the failure (before it happens).

The Criticality (C) of the failures can be defined based on the analysis of all of their effects (impact and occurrence) and the interaction of those factor.

In the company criticality was assessed as a sum of all components of impact and occurrence. The example of occurrence and criticality assessment for M1U1C1 and causes for the situation identified are presented in the Table 6.

The analysis of the Criticality index provides organization with ability to prioritize action in order to reduce the effect of the failure modes on the equipment. The principle followed by the company is that analysis has to be continued for influence values are identified in the given range (S or E ≥ 2) or (P or Q = 3) or criticality C ≥ 7, for the other cases it is necessary to examine whether performance standards are satisfactory and keep

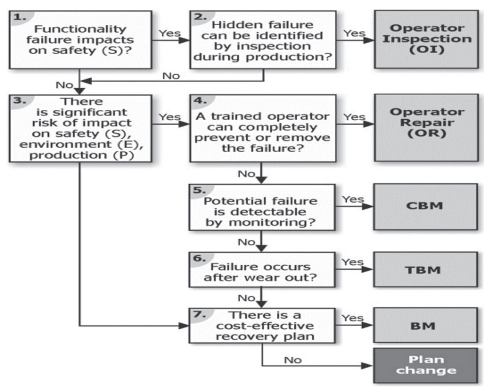

Figure 5. Decision-making process diagram.

them, in the other cases it is necessary to develop new or verify existing standards.

The next task of the team was definition of actions which have to be performed for each failure. Based on the diagram (Fig. 5), the team chose a PM effective tasks (Table 7).

In the next step, results of analyses conducted were translated into actions on operative level. Operative actions were assigned to their performers (depending on to whom the job is assigned: operators (AM)/maintenance staff (PM)), scheduled and resources necessary for their execution were identified as well. Considering changes of performers responsible for predefined actions,

Table 7. Maintenance tasks selection.

Function	FF code	FM code	Questions 1	2	3	4	5	6	7	Task
Keeping strained foil during cutting	M1U1C1.1	M1U1C1.1.1	N		P	Y				OR
	M1U1C1.2	M1U1C1.2.1	N		P	Y				OR
	M1U1C1.2	M1U1C1.2.1	N		P	N	Y			CBM
	M1U1C1.3	M1U1C1.3.1	N		P	N	Y			CBM
	M1U1C1.4	M1U1C1.4.1	N		P	Y				OR

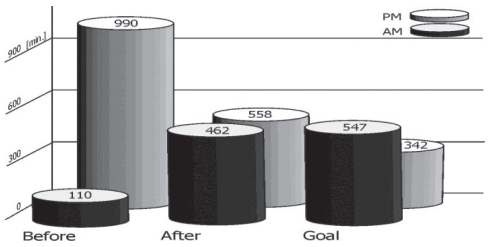

Figure 6. Inspection AM-PM/month.

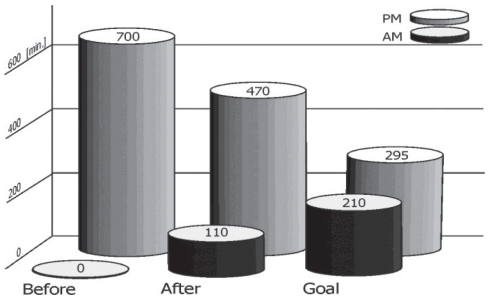

Figure 7. Lubrication AM-PM/month.

competence gaps were identified and training sessions were scheduled, supported by documents (procedures and instructions) developed to provide correct realization actions. To cope with new challenges considering lead time the analysis of availability of spare parts and exploitation materials was conducted.

The next stage was implementation of changes developed for previously binding standards of repairs planning, inspections conducting and smearing followed by assessment of changes efficiency.

It was confirmed that the implementation of RCM gave great success. Changes in number of breakdowns were noticed three months after implementation of the program. Comparing the number of breakdowns observed within three months

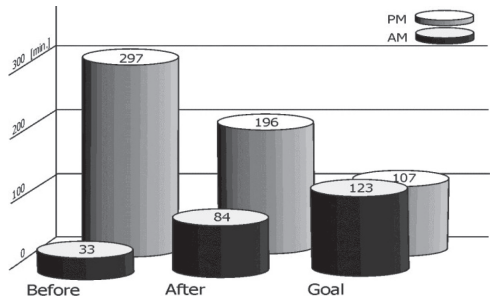

Figure 8. Overhauls AM-PM/month.

after implementation of the program to equivalent period of the last year the decrease percentage was 38%. Major improvements were also obtained in: structure of the work execution (Figs. 6–8), maintenance costs, unscheduled machine failures, repair downtime, and spare parts inventory.

RCM is a living process, therefore the practices applied have to be systematically analyzed and verified adequately to needs of an organization. programs monitoring machines condition and training sessions improving skills and knowledge of employees support solutions an organization benefits from and provide current and periodical information enabling assessment of their efficiency. The proposal and example of comprehensive maintenance assessment, based on the values of standardized and aggregated ranks of technical objects, in the context of exploitation measurements is included in (Młyńczak 2007; Loska 2013; Pourjavad et al. 2011).

5 CONCLUSION

Analysis of contemporary approaches to maintenance of technical objects leads to the conclusion that they represent approach to identification and solving problems, as well as interpretation of maintenance place different comparing to the one promoted in previous years. The new approach is

characterized mainly by (Jasiulewicz-Kaczmarek 2005; Młyńczak & Nowakowski 2006; Laskowski & Łubkowki 2013; Jasiulewicz-Kaczmarek 2013b):

– Preserving functions realized by machines and equipment instead of maintaining them only,
– Avoiding, reducing or eliminating failures instead of preventing them,
– Defining frequency of maintenance actions based on failure symptoms instead of relying on indexes of unreliability of machines and equipment,
– Self-reliant development of maintenance program at reasonable consideration of producer instructions instead of making producer the only party responsible for their definition,
– accepting uncertainty as an element of decision making when selecting maintenance methodology,
– common use of IT tools for identification.

The most known and diffused third generation maintenance management systems is the Reliability-Centered Maintenance. The primary focus of RCM is to achieve a high level of understanding of the failure modes/causes, the likelihood of occurrence and the related effects, then to define a maintenance plan that prevents or proactively addresses the potential causes of failure in such a way that the overall cost of doing business is reduced.

The selection of the maintenance policies mix is a very important task for a firm. This job is often carried out on the basis of qualitative and subjective choices, thus relying only on the human factor. This fact may lead to the adoption of the wrong maintenance strategies, reducing productivity as well as profitability. Methodology applied for RCM limits subjectivism in decision making process.

The study was carried out at one of manufacturing plant in Poland which has implemented RCM to improve their current PM task. The RCM practice has been implemented directly in order to improve maintenance scheduling and maintenance strategy in their production line. Prepared maintenance scheduled leads to saving in maintenance cost in each category (e.g. cost of downtime, cost of maintenance labor, cost of parts, etc.). It is concluded that Reliability Centered Maintenance is effective maintenance ensuring all through that maintenance induced failures are either eliminated or minimized. It did not require complex numerical calculation. The important factor enhancing success of the program was the fact that it was established as an element of TPM system already functioning in the company. Hence, the decision was premeditated and its realization was properly provisioned in terms of resources, including human resources, knowledge, data and information, now and before meticulously collected and available. To some extent, it limited potential problems emerging from RCM methodology application. However, there were some limitations identified in a company and related with application range as it was to be applied for all the production lines and machines. The first problem identified was high labor-consumption of the methodology (even though there were some simplifications introduced), thus its application should be the consequence of thorough analysis of enterprise's needs. Secondly, methodology is not useful for typical equipment, including gears or clutches, thirdly, it requires highly qualified staff, fourthly, it should be applied for devices and components of high criticality and finally, each enterprise should develop its own plan with respect to strategy, goals and problems specific for a company, production process and condition of machines.

Hidden Markov Models for diagnostics and prognostics of systems under multiple deterioration modes

Thanh Trung Le, Florent Chatelain & Christophe Bérenguer
GIPSA-Lab, University of Grenoble Alpes, Grenoble, France
GIPSA-Lab, CNRS, Grenoble, France

ABSTRACT: Multi-state systems have recently attracted a great deal of interest with regards to reliability and maintenance. Since most mechanical equipment operates under some sorts of stress or load, it tends to degrade over time, thus possibly resultingin discrete degradation states (damage degrees), ranging from perfect functioning to complete failure. Over recent years, Hidden Markov Models (HMMs) have been applied to model these discrete degradation states for diagnostic and prognostic purposes. However, most of the reported researches on HMMs for multi-state equipment in the literature consider only one degradation mechanism of degradation processes. The present paper proposes a novel model called Multi-Branch HMM (MB-HMM) to deal with deterioration processes modeling under multiple competing modes. To illustrate the proposed approach, a numerical study is given.

1 INTRODUCTION

Condition-Based Maintenance (CBM) plays nowadays an important role in the maintenance of engineering systems since it has the ability to recommend in advance proper maintenance actions by basing on the information collected from condition monitoring (Jardine et al. 2006).. Within a CBM program, diagnostics and prognostics are two important aspects where the former deals with fault detection, isolation and identification when it occurs and the latter helps to assess the current health state of the system and predict the remaining time before a failure occurs. An accurate prediction of the Remaining Useful Life (RUL) could provide ample time for maintenance engineers to schedule a repair, and to acquire replacement components before they actually fail (Zhang et al. 2005). Due to the stochastic nature of the deterioration, stochastic processes have been adapted to model the deterioration processes and have shown the promising results within the CBM framework (Van Noortwijk 2009, Le Son et al. 2012, Wang and Wang 2012).

As a stochastic process, Hidden Markov Model (HMM) has been successfully applied in many domains, such as Speech recognition, genes and Deoxyribonucleic acid (DNA) analysis (Rabiner 1989) thanks to its strong mathematical basis. In the CBM context, HMMs can divide equipment conditions into several meaningful states, such as "good", "minor defect", "maintenance required" and "failure" and therefore easy to understand (Si et al. 2011). They can also characterize the stochastic relationship between the features extracted from condition monitoring data and the actual health states of the equipment. For these reasons, HMMs, in the recent year, are being more and more investigated to be used as an efficient tool for the deterioration modeling and the RUL estimation (Wang and Wang 2012). For example, Baruah et al. employed HMMs for carrying out both the diagnostics and the prognostics for metal cutting tools (Baruah and Chinnam 2005). In (Zhang et al. 2005), the authors used the HMMs to construct a health/degradation index representing the current system health status. This index was then fed into an adaptive prognostic scheme in order to estimate the RUL of a bearing. In order to better represent the real degradation mechanism, several extensions of HMMs have being adopted in the literature, such as Mixture of Gaussian HMM (Tobon-Mejia et al. 2012), age-based HMM (Peng and Dong 2011), segmented HMM (Geramifard et al. 2012), segmented Hidden Semi-Markov Model (Dong and He 2007), etc.

To our best knowledge, almost all of the HMM-based frameworks in the literature consider only the mono-mode case, meaning that there is only one degradation mode occurring at one time. In practice, however, multiple degradation modes could exist in competition. In this paper, we propose a new HMM-based structure called Multi-Branch Hidden Markov Model (MB-HMM) to deal with this problem. In order to evaluate the effectiveness of the proposed model with respect

to a traditional mono-branch HMM, a simulation study is implemented.

The remainder of the paper is organized as follows. Section 2 is devoted to review some basic theories of HMMs. Section 3 describes the extension to MB-HMM and its application for diagnostics and prognostics. To illustrate the methodology, a comparative study is introduced in the section 4. Conclusion follows in Section 5.

2 METHODOLOGY

2.1 *Basic theory of Hidden Markov Model*

Hidden Markov Model is an extension of the Markov chain in which the state process are latent and can be only revealed through an observation process. This is where the word "hidden" comes from. In the deterioration modeling framework, the hidden state process represents the health states of the equipment, while the observations can be measurable signals such as the vibration signals or the features extracted from condition monitoring data. The relation between these two processes is represented by a probabilistic model. Figure 1 illustrates an example of an HMM model.

Mathematically, the complete specification of an HMM consists of the following elements (Rabiner 1989)

- N, the number of states in the model
- M, the number of distinct observation symbols per state, i.e., the discrete alphabet size
- A finite set of hidden states, i.e., $S = \{S_1, S_2, ..., S_N\}$
- A state transition probability distribution, i.e., $A = \{a_{ij}\}$, where $a_{ij} = P(q_{t+1} = S_j | q_t = S_i)$
- An observation symbol probability distribution, i.e., $B = \{b_j(k)\}$ where $b_j(k) = P(Y_k | q_t = S_j)$, $1 \le k \le M$
- An initial state probability distribution, i.e., $\pi = \{\pi_i\}$ where $\pi_i = P\{q_t = S_i\}$, $1 \le i \le N$

For convenience, in this study, an HMM is represented by a compact notation $\lambda = (A, B, \pi)$.

2.2 *HMM topology selection*

In order to apply the HMM model for the deterioration modeling framework, one question is naturally raised: Given the observations, how one can choose/select a proper topology of the model. For instance, how can we choose the type of the model, how many states should be used or which observation probability distribution is suitable? These questions will be answered in this subsection.

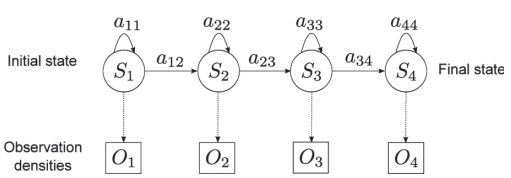

Figure 1. A five state left-right HMM.

2.2.1 *HMM type selection*

There are several types of HMMs existing in the literature, such as the ergodic HMM or the left-right (Bakis) model (Rabiner 1989). Since the deterioration processes are often irreversible in reality, components cannot come back from a bad health state to a better one as time progresses. For this reason, the left-right HMM model is chosen to be investigated. More precisely, the used left-right model in this study has the characteristic that the state index can either stay the same or increase by one. In other words, the components can only stay in the current health state or move to the next one. In this case, the coefficients of the transition matrix of the model satisfy the following properties:

$$\begin{aligned} a_{ij} &= 0, \qquad j < i \\ a_{ji} &= 0, \qquad j > i+1 \\ a_{NN} &= 1, \\ a_{Ni} &= 0, \qquad i < N \end{aligned}$$

The state S_N is considered as the final (failure) state.

2.2.2 *Observation model selection*

The observations are usually considered as discrete symbols, hence discrete probability densities are used to model the observation probabilities. However, in the framework of machine condition monitoring, the observations obtained are typically continuous signals (Tobon-Mejia et al. 2012). In this case, the continuous HMM possessing a continuous probability density function (pdf) to model the emission probabilities could give a better accuracy in diagnostics, compared to the discrete HMM (Wang and Wang 2012). However, to ensure that the parameters of the HMM can be estimated in a convenient way, the observation pdf should be elliptically symmetric densities or mixtures of elliptically symmetric pdf (Rabiner et al. 1985). For this reason, the Gaussian pdf is used in this study as the observation model:

$$b_j(O) = \mathcal{N}(O, \mu_j, \Sigma_j), \qquad 1 \le j \le N$$

where μ_j and Σ_j are the mean vector and covariance matrix in state S_j.

2.2.3 *Number of states selection*

Selecting the number of states in an HMM model is always an interesting but difficult question. It exists several methods as well as criteria for this selection purpose, such as Akaike Information Criterion (AIC), Bayes Information Criterion (BIC), Cross-validation, etc. (Knoblauch 2004). In this study, we investigate the use of BIC for selecting the number of state N.

The Bayes Information Criterion (BIC) is defined as follow

$$BIC = -2\mathcal{L} + k\log N \tag{1}$$

where $\mathcal{L}$ is the log-likelihood function; k is the number of free parameters to be estimated and N is the number of data points in observation sequences $\mathbf{O}$. The chosen model will be the one having the minimum BIC value.

3 EXTENSION TO MULTI-BRANCH HIDDEN MARKOV MODEL

3.1 *General principles*

The idea of the multi-branch HMM have been appeared in the literature and have mainly been applied for the applications of handwriting recognition (Lee, Kim, & Kim 2001, Wang, Brakensiek, Kosmala, & Rigoll 2001). In this section, we will present the general principle of MB-HMM for modeling degradation processes under different modes. An example of a two-branch HMM is presented in the Figure 2.

Such a multi-branch model is suitable to model the equipment deterioration process which could follow different modes due to different changes of the operating condition. Considering the propagation of the crack appearing in a bearing. In a normal condition, the bearing operates normally. However, when more stress is applied on it, the crack could initiate and then propagate with different rates. The more stress applied, the more quickly the crack propagates. In the MB-HMM model, each constituent branch is dedicated to model a different deterioration mode. It is worth noting that the observations emitted from the corresponding states in different constituent branches could be similar (e.g. having the same probability distributions). The only thing that distinguishes the branches is the rate of deterioration which is represented by the transition probabilities.

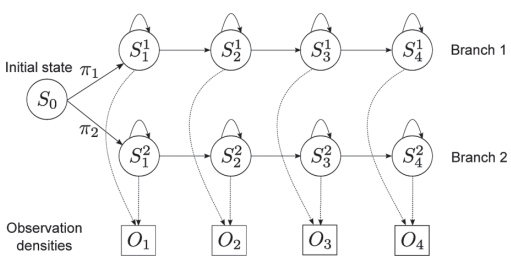

Figure 2. Example of a two-branch HMM.

There are some important assumptions that must be made in constructing the model. Firstly, once the equipment has degraded following one mode, it will follow that mode until it reaches the end of its life. There is hence no connection between the branches. The second assumption is that, the normal condition can last very long with no special characteristics in the measurement. We are interested in the deterioration process, with the purpose of assessing the deterioration level of equipment as well as predict its residual lifetime when it has suffered a problem. For this reason, the initial state can be assumed as a dummy state with no emission of observation. Each branch can therefore be seen as a single model and is assigned an *a priori* probability π_k as shown in the Figure 2. These *a priori* probabilities satisfy:

$$\pi_k = P(\lambda_k) = K_k/K, \qquad \sum_{k=1}^{M} \pi_k = 1 \tag{2}$$

where λ_k denotes the constituent HMM for branch k, K_k is the number of training data sequences corresponding to mode k, K is the total number of training data sequences and M is the total number of branches of the MB-HMM.

3.2 *MB-HMM for diagnostics and prognostics*

The application of MB-HMM for diagnostics and prognostics can be implemented in two phases, as shown in Figure 3.

In the off-line phase, the training data is classified into M different groups and then, each constituent HMM model is trained individually with the data in the corresponding group. At this step, the well-known Baum-Welch algorithm can be used without any modifications. In the next step, the number of data in each group is used to assign the *a priori* probabilities for each model (equation (2)). Finally, a trained MB-HMM model is obtained.

In the online phase, the diagnostics involves two sessions. In the first session, the mode that the equipment is following must to be identified. This goal can be achieved by using the decision theory. For instance, the model that has the maximum *a posterior* probability, given the data, can be chosen

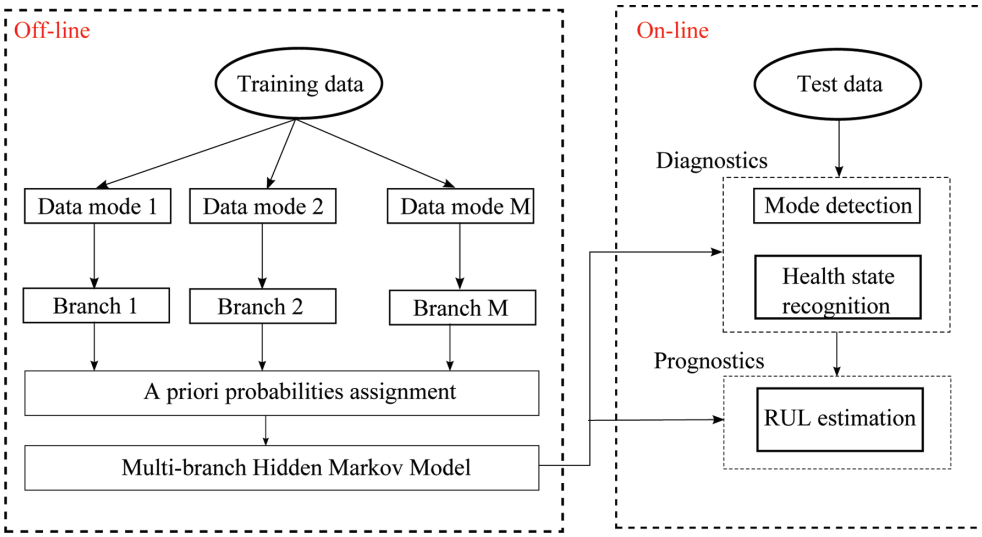

Figure 3. Proposed MB-HMM framework for diagnostics and prognostics.

in order to minimize the misclassification rate, (Bishop et al. 2006). That is:

$$\hat{k} = \arg\max_{k} P\left(\lambda_k | \mathbf{O}\right) \tag{3}$$

Note that, using Bayes' theorem, these *a posteriori* probabilities can be calculated as follows:

$$P(\lambda_k | \mathbf{O}) = \frac{P\left(\mathbf{O} \mid \lambda_k\right) P\left(\lambda_k\right)}{\sum_{k=1}^{M} P\left(\mathbf{O} \mid \lambda_k\right) P\left(\lambda_k\right)} \tag{4}$$

where $P\left(\mathbf{O}|\lambda_k\right)$ is the likelihood of the model λ_i given the data $\mathbf{O}$ and can be calculated thanks to the popular forward-backward algorithm. $P(\lambda_k)$ is calculated from equation (2).

After having identified the deterioration mode, the next stage of the diagnostics is to recognize the actual health state of the equipment. This is carried out in two steps consisting of finding the single state sequence (path) which is the most probable one representing the given test data, and considering the final state as the actual health state. The first step is done thanks to the well-known Viterbi algorithm. Let q_t denote the equipment state at time t and $Q = (q_1, q_2, \ldots, q_t)$ denote a path till the current time. Given the estimated mode, the most probable path is the one that gives the maximum joint probability of the path and the observation:

$$Q^* = \arg\max_{Q_{\hat{k}}} P\left(\mathbf{O}, Q_{\hat{k}} \mid \lambda_{\hat{k}}\right) \tag{5}$$

where Q_i represents a possible path within the mode i. The actual health state of the equipment is the final one of the path Q^*.

3.2.1 *RUL calculation*

Given the deterioration mode and the current health state estimated from the diagnostic stage, the RUL estimation can be conducted the same as in a single HMM case and is straightforward. In the MB-HMM framework, this estimation, however, strongly dependson the mode detection. Indeed, a wrong deterioration mode detection may result in a large bias in the RUL estimation. For example, if a crack propagates with a high rate, the detection of a low rate mode may lead to an extremely larger value of the RUL than the actual one. This phenomenon often occurs at the beginning of a defect propagation since the observations are insufficient to show an obvious deterioration trend. In this study, the Bayesian Model Averaging (BMA) technique (Hoeting et al. 1999) is implemented to tackle this problem. The RUL distribution is calculated as an average of the posterior distributions under each constituent model, weighted by their posterior model probability:

$$P\left(\mathrm{RUL}|\mathbf{O}\right) = \sum_{k=1}^{M} P\left(\mathrm{RUL}|\lambda_k, \mathbf{O}\right) P\left(\lambda_k|\mathbf{O}\right) \tag{6}$$

where $P(\lambda_k|\mathbf{O})$ is calculated from the equation (4).

The RUL estimation now turns to the estimation of the individual RULs under each constituent HMM, which is straightforward and can be

computed in a recursive way as follows. Given the test data, the health state of equipment is identified thanks to the Viterbi algorithm. The RUL can be defined as the necessary time steps to reach for the first time the final state S_N from the current state S_i ($i < N$):

$$\mathrm{RUL} = min\{ n \geq 0 : q_{t+n} = S_N \mid q_t = S_i \} \tag{7}$$

where q_t denote the health state at the time t. By this definition, the RUL can be seen as a discrete variable and its probability mass function is given by

$$P(RUL = n | q_t = S_i) = P(q_{t+n} = S_N, \\ q_{t+n-1} \neq S_N, \ldots, q_{t+1} \neq S_N | q_t = S_i) \tag{8}$$

Denote $h_i^{(n)} = P(RUL = n \mid q_t = S_i)$. Since the model is strictly one-order left-right topology HMM, the RUL can be calculated by the following backward recursive equations:

At state S_{N-1}:

$$h_{N-1}^{(1)} = a_{(N-1)N} \tag{9}$$

$$h_{N-1}^{(n)} = a_{(N-1)(N-1)} h_{N-1}^{(n-1)} \tag{10}$$

At state S_{N-2}:

$$h_{N-2}^{(1)} = a_{(N-2)N} \tag{11}$$

$$h_{N-2}^{(n)} = a_{(N-2)(N-2)} h_{N-2}^{(n-1)} + a_{(N-2)(N-1)} h_{N-1}^{(n-1)} \tag{12}$$

……

At state S_i

$$h_i^{(1)} = a_{iN} \tag{13}$$

$$h_i^{(n)} = a_{ii} h_i^{(n-1)} + a_{i(i+1)} h_{i+1}^{(n-1)} \tag{14}$$

where a_{ij} is the transition probability from state S_i to state S_j and is obtained from the transition matrix A.

After calculating all the individual components, the RUL estimation under the MB-HMM can be accomplished by the equation (6).

4 NUMERICAL EXAMPLES

4.1 *Fatigue Crack Growth model for data generation*

To evaluate the proposed MB-HMM-based diagnostic and prognostic framework performance, it is necessary to have the data which represent several different deterioration modes. In this section, the Fatigue Crack Growth (FCG) model is used to model the crack appearing and propagating within a bearing and to generate both the training as well as the testing data. The FCG is chosen since it has been widely used to describe the crack propagation in the literature (Huynh et al. 2012, Myotyri et al. 2006). The bearing is supposed to operate under different operation conditions so that the crack will propagate with different rates which represent different deterioration modes for our purpose.

4.1.1 *Fatigue Crack model*

The FCG model is constructed based on the popular Paris-Erdogan equation to express the crack growth rate:

$$\frac{dx}{dt} = C(\Delta K)^n \tag{15}$$

where x is the crack depth, t is the time, ΔK is the stress intensity amplitude and C and n are constant depending on the material property. It is shown that ΔK is roughly proportional to square root of crack depth x by a factor β: $\Delta K = \beta\sqrt{x}$ (Myotyri et al. 2006).

To take into account the stochastic aspect of the crack propagation, equation (15) could be discretized and then randomized by adding a multiplicative factor following a log-normal distribution as follows:

$$x_{t_i} = x_{t_{i-1}} + e^{w_{t_i}} C\left(\beta e \sqrt{x_{t_{i-1}}}\right)^n \Delta t \tag{16}$$

where w_{t_i} are independent and identically distributed according to a Normal distribution $\mathcal{N}(0, \sigma_w^2)$, $0 < x_{t_{i-1}} < x_{t_i} < \infty$. This discretized and randomized model allows us to determine recursively the crack depth x_{t_i} at time t_i given the previous depth $x_{t_{i-1}}$ and the model parameters. By this way, the deterioration data can be generated.

For modeling different deterioration modes, the factor β is considered to be a function $\beta(e)$ of the operating environment state e as below (Huynh et al. 2012):

$$\beta(e) = \beta_b \cdot e^{\gamma_e} \tag{17}$$

where β_b is the base stress level of system, the values $\gamma_e \geq 0$, $e = 1, 2, \ldots, M$ determine the level of extra stress linking with the state e of the environment. Obviously, from the equations (16) and (17), the propagation rate is directly proportional to the parameters γ_e: the greater the value of γ_e is, the more quickly the crack propagates.

4.1.2 *Observation model*

The actual crack depth is difficult to be directly and accurately measured because of several different reasons (Huynh et al. 2012). Hence, we need an observation model to represent the relationship between these actual values and the measure ones. In this study, the measurement is assumed to be the sum of the actual crack depth and a zero-mean Gaussian noise. Let X denote the crack depth and Y denote the corresponding measurement, the observation model is:

$$Y = X + \xi \tag{18}$$

where $\xi \sim N\left(0, \sigma_\xi^2\right)$ is the measurement error.

4.2 *Application of MB-HMM for FCG data*

In this section, the bearing is supposed to operate under two different environments and therefore the crack propagates in two different rates. A two-branch HMM is chosen to represent these two deterioration modes. The following parameters of the FCG model are chosen: $C = 0.005$, $n = 1.3$, $\beta_b = 1$, $\sigma_w = 1.7$, $\Delta t = 1$, $\gamma_e = [0\ 0.75]^T$, $\sigma_\xi^2 = [5 \quad 10]^T$ where the subscript T denotes the transpose of a vector. The different variance values of σ_ξ^2 mean that the measurement error may depend slightly on the operating condition.

The bearing is supposed to be failed once the crack depth reaches a critical level $d = 100$. 100 data curves have been generated by using the FCG model with the above parameters and used as the training data. Figure 4 illustrates this training data set.

In this study, the number of deterioration modes is assumed to be known beforehand. Therefore, "kmeans" tool is used to classify the failure times into 2 "clusters". Based on this, the training data can be separated into two groups, which is then used to train different branches of the MB-HMM.

In order to train each constituent model, it is necessary to determine the number of states of each model. This task is done by using the BIC criterion. Figure 5 illustrates the BIC values with respect to different state numbers for a branch of the MB-HMM.

Since the crack propagation herein is a continuous process, the increase in the states number N will obviously reduce the BIC value. To avoid the overfitting situation, it is sufficient to take the "knee" point on the BIC curve. The value $N_{statesmode1} = 10$ is hence chosen for this example.

After having determined the number of states, each model is trained thanks to the Baum-Welch algorithm. The next step is to assign the *a priori* probability for each branch (equation (2)) and the result are: $\pi_1 = 0.41$ and $\pi_2 = 0.59$.

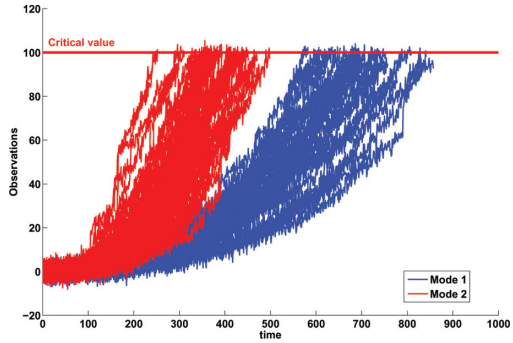

Figure 4. Two-mode training data.

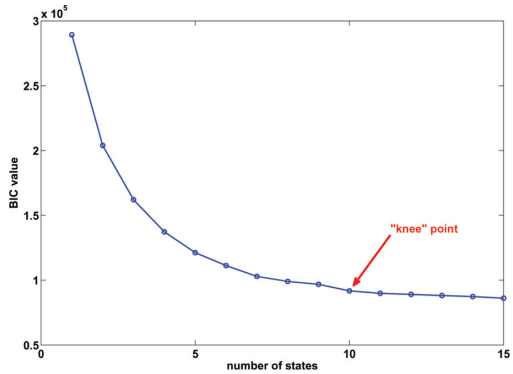

Figure 5. BIC for number of state selection.

An MB-HMM is obtained and the offline phase is terminated.

We now move to the on-line phase. One data curve representing the propagation of the crack depth from the beginning to the end of bearing life is also generated by the FCG model. This curve serves as the test data and is shown in the Figure 6 (upper sub-figure). Only the red part till the actual time $t_{act} = 100\ h$ are assumed to be observable. The estimated RUL pdf is illustrated in the lower sub-figure of the Figure 6.

To simulate the on-line RUL estimation problem, the actual time t_{act} is gradually replaced by 30 h towards the failure. After each replacement, more information about the deterioration is achieved and the diagnostic and prognostic procedures are re-implemented. Figure 7 represents the mean value of the estimated RUL associated with the 95% confidence interval. It can be realized that, at the early instances, the lack of information due to the limited observations results inthe bias and large variance in the RUL estimation. However, the actual values always lie within the 95% confidence interval. As the time passes, the length of the

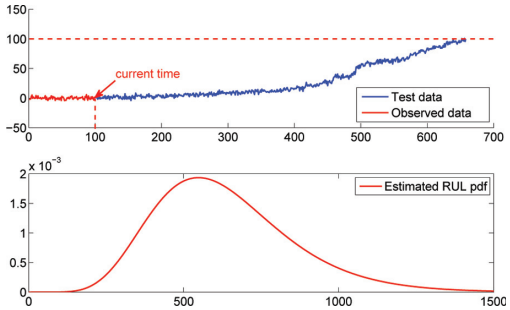

Figure 6. Observations and RUL estimation at t_{act} = 100 *h*.

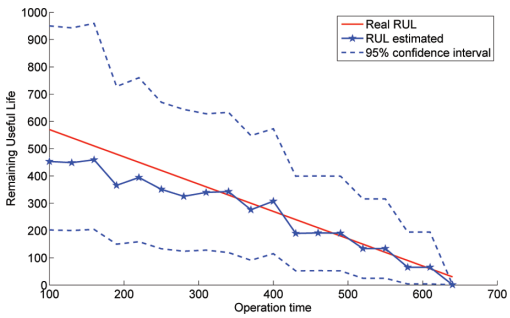

Figure 7. RUL estimation at different time instances.

confidence interval significantly decreases and the estimated RUL converges to the real value. This demonstrates demonstrates the accuracy of the proposed RUL estimation method.

4.2.1 *MB-HMM vs average HMM*

Investigating the advantage of the proposed approach naturally raises a question: given the same data set, which method between the one using the proposed MB-HMM and the one using only an "average" HMM will give the better performance in RUL prediction. To answer such question, a comparative study is given in this section with 100 test data curves. The prognostic performance of each method is characterized by the Root Mean Squared Error (RMSE) metric.

For notation convenience, we denote the average HMM by AVG-HMM. In the training phase, the training data set in the previous section is not grouped and is used as a whole to train only one AVG-HMM. This model is then used in the online phase to estimate the RUL. At $t_{act} = 100\ h$, we obtain $\mathrm{RMSE}_{\mathrm{AVG-HMM}} = 74.4$. Compared to the corresponding result of the MB-HMM: $RMSE_{MB-HMM} = 52.5$, it can be concluded that the MB-HMM give a better performance in RUL

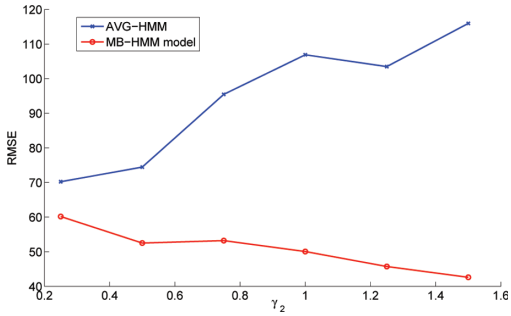

Figure 8. Prediction RMSE vs γ_2.

estimation compared with the AVG-HMM for this case.

Another interesting question raised in evaluating the advantages of the proposed MB-HMM is: does the above conclusion still hold in case that the two propagation rates are not quite different, or in case that there are two obvious trends in the training data? To answer this question, it is necessary to define a "distance" between two deterioration modes. In this study, the "mode distance" is defined by the gap between the two propagation rates and can be changed through the parameter γ_e of the FCG model. Indeed, as indicated in the section 4.1.1, the propagation rate of a crack is directly proportional to γ_e. The greater the value of γ_e is, the more quickly the crack propagates. Therefore, by fixing γ_1 and do varying γ_2, the mode distance is changed. Figure 8 shows that, when the distance between modes increases, the RMSE given by MB-HMM approach decreases while with AVG-HMM, the RUL prediction error increases. It can be concluded that the larger the distance between deterioration modes is, the better performance in RUL estimation it is given by the proposed MB-HMM approach, in comparison to an "average" HMM.

5 CONCLUSION

The present paper proposes a novel model called multi-branch Hidden Markov Model (MB-HMM) to deal with the deterioration modeling problem in case that there are several competing modes existing in deterioration mechanism of equipment. A diagnostic and prognostic framework based on the proposed model is also given. The actual health state recognition and the RUL estimation can be implemented in the same way as the traditional HMM. However, by using different HMM models for different modes, together with the *a priori* probabilities of each model, the MB-HMM shows a very promising result in dealing with the multi-mode deterioration mechanism.

Future research will be focused on the extension of the MB-HMM to a multi-branch Hidden semi-Markov Model (MB-HSMM) due to the fact that the state sojourn time of an HMM follows an exponential distribution, which may not be hold in practice. Another possible extension of the model is the ability of transition between the states of the different branches. The proposed model and the extension should also be validated on the data of real systems.

ABSTRACT: Recently, Bayesian Networks (BNs) have been discussed in the field of maintenance management. The purpose of this paper is to present the results of the BN application to maintenance models of Nuclear Power Plant (NPP) safety systems. The Maintenance Rule (MR) is a methodology to check the effectiveness of maintenance carried out in NPPs and plant configuration control. An expert panel determines the relationship between the selected Structures, Systems and Components (SSCs) and the plant safety within the MR scope. The SSCs are monitored to verify whether their performance meets the established criteria or whether they need undergo a specific maintenance program. For analyzing the adequacy of the methodology, a case study was developed concerning the Emergency Diesel Generators (EDGs) and compared with previous studies. The results have been achieved faster and satisfactorily when experts' opinions are required. This study demonstrates the flexibility of this framework when applied to reliability evaluations of systems under the MR.

1 INTRODUCTION

The Brazilian Monitoring Program for Maintenance Effectiveness (PMEM) is based on the NRC Maintenance Rule (MR) NRC (2012).

The purpose of this paper is to model through a Bayesian Network, BN, a safety system of a German nuclear power plant design within the scope of MR, allowing for making decisions based on the BN probabilities as to which components and subsystems might undergo dependent failures.

The use of BNs in this context aims at assessing their ability to present the modeling of a safety system failure, considering the dependent failure events that might be involved.

The reliability considering the whole set of subsystems through the BN makes it possible to identify subsystems that require more effective actions, thus seeking to keep the reliability index within the required limit.

The BN allows the production of new results, in accordance with the demand of information, assuming the addition of new variables, updated data and hence update the reliability calculation.

For analyzing the methodology adequacy, a case study was developed concerning the emergency diesel generators and compared with previous studies.

The calculations for the modeled BN were carried out through the Netica™ (2014) program. The obtained results were satisfactory and demonstrated that modeling by means of BNs is adequate for classification of MR categories for equipment having several subsystems, such as EDGs. The analysis can be performed more consistently by monitoring the system performance through its operational tests and also the results can help set operational testing for its subsystems.

2 SURVEY OF MAINTENANCE RULE

The Maintenance Rule (MR) is a requirement established by the U.S. Nuclear Regulatory Commission (NRC) to check the effectiveness of maintenance carried out in nuclear plants, and to plant configuration control. The control of plant configuration is necessary to verify the impact of the maintenance of an out of service safety device on plant safety. The MR technique was consolidated in the U.S. in 1996. MR classifies Structures, System or Components (SSCs) into two

categories: Category (a)(2), the SSCs that reach the intended performance demonstrate that the preventive maintenance is being appropriately performed, and Category (a)(1), which stands for the SSCs that do not fulfill Category (a)(2), and must have established goals, so that the discrepancies can be revised and then return to Category (a)(2).

NRC requirements establish that all SSCs can be evaluated to verify the pertinence of their inclusion in MR. If the SSC is directly related to safety, can mitigate accidents or transients, is part of Emergency Operational Procedures (EOPs), can prevent other SSC of performing their safety functions, or causes a reactor shutdown or a safety system actuation, the SSC will be put within the MR scope. Otherwise, it remains under the existing maintenance program, outside the MR scope. The MR simplified flowchart may be found in (NRC, 2014).

The MR also requires that before performing maintenance activities the licensee shall assess and manage the increase in risk that may result from the proposed maintenance activities. The scope of the assessment may be limited to those structures, systems, and components that a risk-informed evaluation process has shown to be significant to public health and safety.

The Nuclear Engineering Institute (NEI) issued the report NEI (1996). This document is a guideline for applying the Maintenance Rule to Nuclear Power Plants. Section 11.0 of NEI (1996) consolidates the assessment and management of the increase in risk that may result from the proposed maintenance activities.

An expert panel determines the relationship between the selected SSC and plant safety within the MR scope (high or low significance). Finally, SSCs are monitored to verify whether their performance meets the established criteria or whether they can undergo a Maintenance Preventable Functional Failure (MPFF).

A periodic evaluation of the reliability and unavailability balance is scheduled, according to the MR, at each refueling cycle or every two years.

3 GENERAL ASPECTS OF BAYESIAN NETWORKS

One of the most attractive features of the Bayesian formulation in causal models is the ease of making predictions as to future events, such as the outcome of a social episode, the outcome of a given test and the prognosis of a disease, Pearl (1998).

The modeling using Bayesian Networks (BN) allows the organization of knowledge in a given area, or in a given system to map causes and effects, automatically generating predictions or decisions, even with sparse data. Bayesian inference also enables the production of new results, in accordance with the demand of information, assuming the addition of new variables, data update and aggregation of expert opinion when needed.

Bayesian networks consist of a qualitative part (an acyclic directed graph, where nodes represent stochastic variables) and a quantitative part (a set of conditional probability functions), Langseth et al. (2009).

A Bayesian network is a directed acyclic graph, where the nodes represent the system variables and arrows symbolize dependencies or cause-effect relationships between variables. A BN is defined by a set of nodes and a set of directed arcs. A probability is associated with each node state. This probability is defined a priori for a root node and is calculated by inference for the others, Weber et al. (2012).

Celeux et al. (2006) define a Bayesian network as:

- a set of variables V, defining the vertices, and a set of edges between variables;
- each variable has a finite number of unique states;
- variables and edges define an acyclic directed graph, denoted by $G = (V,E)$;
- each variable Y with parents $X_1, \ldots, X_n$, is associated with a conditional probability $P(Y|X_1, \ldots, X_n)$. When a variable has no parents, a marginal probability $P(Y)$ is associated to it.

The name Bayesian network stems from the known Bayes theorem. In a BN, the joint probability can be written as

$$P(X_1, \ldots, X_n) = \prod_{i=1}^{n} P(X_i \mid pa(X_i)) \quad (1)$$

where $pa(X_i)$ is the set of parents of vertex X_i, Celeux et al. (2006).

The modeling using Bayesian networks has become increasingly common to treat problems in which the joint use of information from the monitoring and evaluation of a system are fundamental. It allows the creation of diagrams to organize data through a mapping between causes and effects, thus enabling the automatic generation of predictions or decisions even with incomplete knowledge.

Bayesian networks are a brief way to represent conjunctions of probabilities, presenting in a direct and structured way the dependencies between the variables of a domain, Martins (2013).

Cai et al. (2013) discuss the use of BNs to assess the maintenance of subsea Blowout Preventer (BOP) control systems. Neil & Marquez (2012) discuss the use of hybrid BNs the estimate the availability of renewable systems. Jones et al. (2010) apply BN modelling for maintenance planning in a manufacturing industry, while Melo & Sanchez (2008)

discuss delays related to software maintenance by BNs. Celeux et al. (2006) use a BN modeling to discuss preventive maintenance from expert opinions related to a nuclear plant mechanical systems degradation.

4 CASE STUDY

The case study was developed concerning the Emergency Diesel Generators (EDG) and was prepared considering data from published operating experience, according to NRC (1999), Brazilian NPPs operational experience, and the Joint Research Centre, JRC, a reference center of science and technology for the European Union, JRC (2013) concerning plant start-up, load run and subsystems failures. The failures recorded in JRC (2013) for EDG tests can be raised by the cycle operation. For subsystems, the survey could be done only by the accumulation of failures considering the entire period. Thus, the results can only be compared by the failures accumulated in the total period. Each cycle lasts 450 days approximately, with downtime intervals of 30 days for the reactor core refueling and plant maintenance.

The EDG has five auxiliary systems (KWU, 1984). Figure 1 shows the boundary and support systems of EDG:

1. Cooling Water System (XJG), which is designed to remove the heat generated in the engine, in the air for combustion system and in the lube oil system;
2. Lube Oil System (XJV), which is designed to supply oil to lubricate the moving parts of the engine and dissipate heat (while the diesel unit is on standby, this system is preheated and kept in constant recirculation);
3. Fuel System Oil (XJN) provides fuel for engine operation and also executes speed control and engine shutdown;
4. Start Air System (XJP) stores pressurized air tanks and when the start-up is requested, injects air into the engine, with a tank capacity of seven sequential starts;
5. Combustion Air and Exhaust Gas Systems (XJQ/XJR), the XJQ collects, and filters and stores the combustion air and XJR controls the air temperature and extracts the gas from the combustion engine.

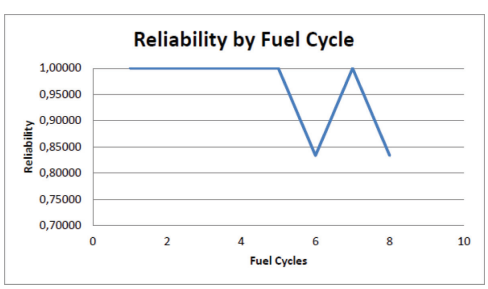

Figure 1. EDG reliability profile during the cycles 1 to 8.

The EDG operate in standby. The reliability and availability assessment are performed through operational tests (or periodical or surveillance tests) or actual demands (cases of postulated events). For this case study, the failures recorded in the operational tests as unsuccessful tests were considered, ETN (2013).

The reliability of emergency diesel generators is one of the major factors affecting the core damage probability in the event of a blackout. Therefore, it is necessary to achieve high reliability and keep it, in order to significantly contribute to ensuring the supply of emergency power to safety systems during blackout. The reliability must be hold within a range of not less than 5%, the minimum acceptable reliability is 95%. Another performance criterion is the maximum acceptable unavailability of 5%, NRC (2007). In this case study, only the criterion on the minimum acceptable reliability is used.

The reliabilities of EDGs are verified through the operating tests demands at intervals of 30 days. Reliabilities are considered at starting and under load run, according to, Vajgel (2009):

$$R_i = 1 - \left({}^{n^o SF}/_{n^o TT} + {}^{n^o RF}/_{n^o TT} \right) \quad (2)$$

– nºSF number of stating failures in operational tests
– nºRF number of loading run failures in operational tests
– nºTT number of total operational tests

1. Sub-Systems; 2. Failures by Surveillance Tests (ST) demands; 3. Demands by ST considering Cycle-1 to Cycle-8 period; 4. Failure Probability (total); 5. Reliability; 6. Maintenance Rule Category.

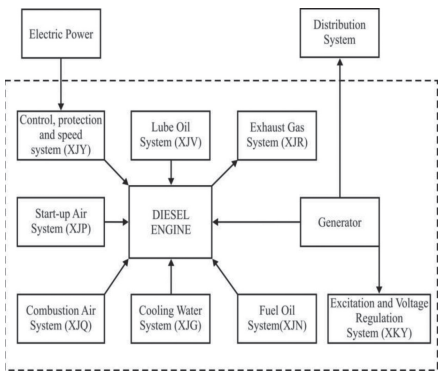

Figure 2. Boundary and support systems (sub-systems) of emergency diesel generator.

The failures were considered in parts, subsystems and systems, which required the maintenance crew intervention. According to NRC (1987), failures can be defined as: critical (they cause the finish of one or more functions of equipment); degraded (they occur gradually and partially, but the equipment/component continues operating); and incipient (they are imperfections that describe the state or condition of an item). Failures considered in the case study were those (critical or degraded) that prevented the continuity of operational tests.

Table 1 presents per cycle the results of EDG tests without success (per cycle), the reliability loss and MR categorization. The reliability loss is calculated according to Eq. (2). Figure 1 shows the reliability profile. The EGD showed a cumulative reliability of 95.7% considering the eight cycles, being classified as a(2). Note that at the end of Cycle 8, its reliability was 85.7%.

Table 2 shows the failures of operational testing (testing without success) for EDG subsystems, considering the eight fuel cycles and the same number of operational tests performed. The subsystem XJN presented a reliability lower than 95% and was classified as a(1), according to the MR requirements. All other subsystems analyzed met the established criteria and were classified as a(2).

With the information from Table 2 and the structure of Figure 2 (boundary and sub-systems of emergency diesel generators), a BN modeling was performed in order to measure the joint probability (the reliability of EDG calculated considering the influence of the subsystems behavior).

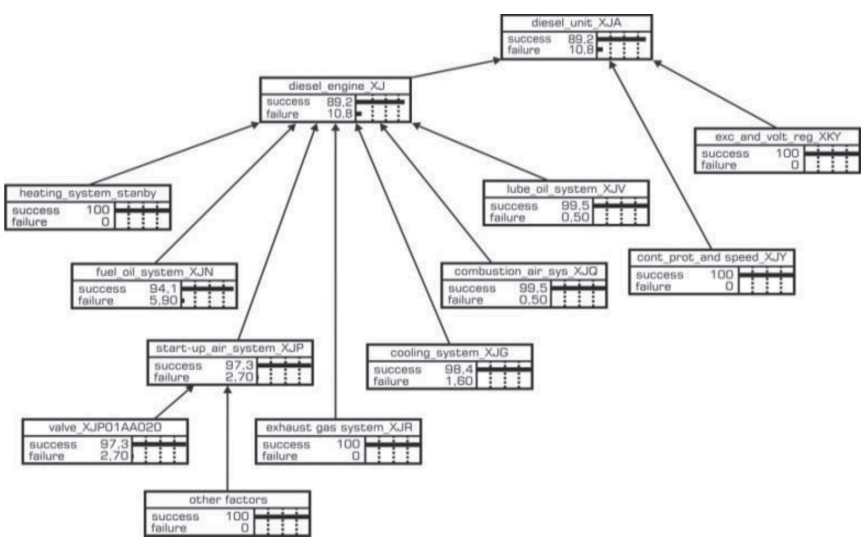

Figure 3. Bayesian network of EDG.

Table 3. Probabilities computed by the Bayesian network.

System	Success	Failure
XJY	1.000	0.000
XKY	1.000	0.000
Diesel motor XJ	0.892	0.108
Others factors	1.000	0.000
Standby heat system	1.000	0.000
XJQ	0.995	0.005
XJN	0.941	0.059
XJR	1.000	0.000
XJG	0.984	0.016
XJV	0.995	0.005
XJP	0.973	0.027
XJA	0.892	0.108
Valve XJP01AA020	0.973	0.027

The probability of failure and reliability were calculated using data obtained from selected publications, JRC (2013) and NRC (1987).

The reliabilities for the subsystem were used as input data for the Bayesian network.

The reliabilities per cycle were used for comparison purposes with the EDG reliability from the BN. The BN was generated through the Netica™ (2014) program. Figure 3 shows the BN and Table 3 shows the calculated probabilities from the BN.

5 CONCLUSIONS

The advantage of the use of a Bayesian Network, in this case, consisted in the fact that it allowed evaluating all the variables involved in the process, the dependency relationships between them and the estimated joint system reliability (considering that perfect EDG functionality depends on the reliability of each subsystem).

The EDG had an accumulated reliability for 8 cycles of 95.7% and was classified as a(2), but its reliability in the end of cycle 8 was 85.7% and would, thus, be classified as a(1) (reliability < 95%). The reliability presented in the last cycle is a more realistic estimate than the accumulated reliability of 8 cycles.

The reliability considering the whole set of subsystems through the BN makes it possible to identify subsystems that require more effective actions, thus helping keep the reliability index within the required limit.

The BN allows the production of new results, in accordance with the information demand, assuming the addition of new variables and updated data and hence update the reliability calculation.

Thus, classification of Maintenance Rule as a(2) or a(1) for equipment having several subsystems, such as the EDG, can be performed more consistently by monitoring their performance through their operational tests and also as a the result set operational testing of its subsystems.

ABSTRACT: This paper presents the experience obtained on the application of Allowed Outage Times (AOT) changes due to planned maintenance to safety systems of the $n + 2$ ($4 \times 50\%$) redundancy design criteria. With the unit in power, Technical Specifications (TS) state that the AOT for one emergency diesel generator is 14 days. After this period, the unit should go to cold shutdown if the emergency diesel generator still remains unavailable. However, 30 days are necessary for planned maintenance. It focuses on the evaluation of Risk-Managed Technical Specifications by EPRI (2006) methodology with risk informed decision making of changes to allowed outage times as a result of planned maintenance observing the Maintenance Rule requirements, and it is supported by the US Nuclear Regulatory Commission requirements. The results show that the maintenance of emergency diesel generators for 30 days does not cause a significant increase of plant risk.

1 INTRODUCTION

Over the last fifteen years a Probabilistic Safety Analysis (PSA) has been issued for most nuclear power plants in the world. General guidelines for issuing these PSAs have been followed both by guidance of the International Atomic Energy Agency (IAEA) and also of the U.S. Nuclear Regulatory Commission (NRC), so that these analyses are of sufficiently high quality to be used.

The modern approach is to apply an integrated decision-making process that combines the insights from the deterministic approach and the probabilistic analysis with further requirements, where applicable (legal, regulatory, cost-benefit, etc) in making decisions. This approach is being increasingly applied by regulatory bodies in making decisions about safety issues (including plant licensing) at nuclear facilities and in organizing their activities so that their resources are more efficiently used and there is a reduction in the unnecessary burden on licensees without compromising safety.

The use of risk information by a regulatory body as part of an integrated decision making process addresses the way in which risk information is being used as part of an integrated process in making decisions about safety issues at nuclear plants—commonly referred to as risk-informed decision making, and how risk information is being used by regulatory bodies as an input into the activities that they carry out—sometimes referred to as risk-informed regulation.

The risk-informed approach aims to integrate in a systematic manner quantitative and qualitative, deterministic and probabilistic safety considerations to obtain a balanced decision. In particular, there is explicit consideration of both the chances of events and their potential consequences together with such factors as good engineering practice and sound managerial arrangements. The basic components of risk, chances of occurrence and consequence, are based on sound knowledge or data from experience, or derived from a formal, structured analysis such as a PSA.

This paper focuses on the evaluation of Risk-Managed Technical Specifications by EPRI (2006) methodology with risk informed decision making of changes to allowed outage times as a result of planned maintenance observing the Maintenance Rule (supported by the US Nuclear Regulatory Commission requirements) The case study is related to plan emergency diesel generator maintenance.

The results show that the maintenance of emergency diesel generators for 30 days does not cause a significant increase of plant risk.

2 REGULATORY DOCUMENTATION CONCERNING RIDM

PSA is a methodology that can be applied to provide a structured analysis process to evaluate the frequency and consequences of accidents scenarios in nuclear power plants. NRC first applied PSA in the Reactor Safety Study (NRC, 1975). An important initiative (NRC, 1988) was the issuance of Generic Letter GL-88-20, which originated the program known as IPE, Individual Plant Examination, NRC (1988). This is because the Reactor Safety Study did not consider each plant individually in the risk assessment.

Since that time, NRC has been using risk assessment and directing the issuance of decisions on complex items associated with or related to safety, such as: (a) total loss of power (station blackout); (b) Anticipated Transients Without reactor Shutdown (ATWS); (c) Pressurized Thermal Shock events (PTS); and (e) Maintenance Rule.

NRC issued the Probabilistic Safety Assessment Policy Statement (NRC, 1995), which incorporated risk assessment as a tool in the regulatory process. It consists of elements that have originated the Risk-Informed Decision Making (RIDM) and the Performance Based Regulation (PD).

The following PSA-based RIDM regulatory guides were issued: (a) changes in the bases of the specific plant licensing, RG-1.174 (NRC, 2011a); (b) assessment of changes and implementation of technical specifications, RG-1.177 (NRC, 2011b); (c) in-service inspections in pipes, RG-1.175 (NRC, 1998) and RG-1.178 (NRC, 2003); (d) an approach to determine the technical quality of PSA results for RIDM, RG 1.200 (NRC, 2009a) (e) fire protection, RG 1.205 (NRC, 2009b). Many of the current regulations, based on deterministic requirements, cannot be quickly replaced.

Regulatory Guide 1.174 (NRC, 2011a) describes the approach accepted by NRC to assess the nature and impact of Licensing Basis Conditions (LBC) by considering engineering aspects and application of risk insights.

Regulatory Guide 1.200 (NRC, 2009a) describes the approach accepted by NRC to determine that PSA quality, in part or in whole, is sufficient to assure its results so that they can be used in regulatory decision making. Figures 1 and 2 show, respectively, the role of NRC regulatory guides in RIDM and NRC approach for RIDM.

The International Atomic Energy Agency, IAEA, has, over the past year, sponsored and promoted activities and issued technical documents related to RIDM. Among the latest highlights are IAEA (2010) and IAEA (2011).

IAEA (2010) was prepared with the participation and contributions of experts from Belgium,

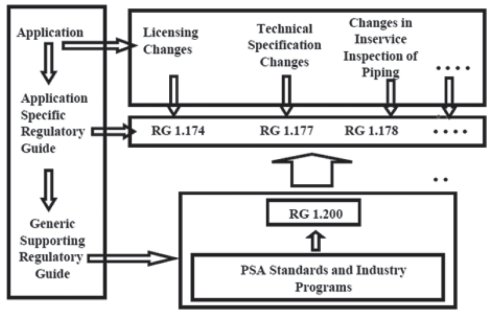

Figure 1. Role of NRC regulatory guides in RIDM.

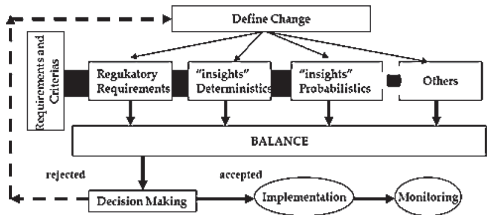

Figure 2. NRC approach for RIDM.

the Czech Republic, Finland, the Netherlands, Sweden, Switzerland and the United States of America. In-service inspection is an integral part of defense in depth programs for nuclear power plants, to ensure safe and reliable operation. Traditional in-service inspection programs were developed using deterministic approaches. However, as probabilistic approaches are being developed, risk insights are being used to optimize in-service inspection programs by focusing in-service inspection resources on most risk significant locations.

IAEA (2011) is intended to promote a common understanding among the international nuclear community (designers, suppliers, constructors, licensees, support organizations and regulators) of how the concept of risk can be used in making safety decisions relating to nuclear installations. The integration of operating experience, deterministic considerations, probabilistic considerations, consideration of uncertainties and other factors serves to help ensure coherent and balanced decisions.

3 TECHNICAL SPECIFICATION, MAINTENANCE RULE AND RISK-MANAGED TS

Technical Specifications are specifications regarding the characteristics of nuclear power plants (variables,

systems or components) of overriding importance to nuclear safety and radiation protection, which is an integral part of plant operation authorization. The technical proposal should be accompanied by a summary of the bases, including the following topics: 1) safety limits, 2) setting limits safety system, 3) limiting conditions of operation, 4) requirements for inspections and periodic tests, 5) design features not included in previous topics, 6) administrative controls, and 7) radioactive effluents.

Limiting Conditions of Operation (LCO) are the minimum levels of performance or capacity or operating system components required for the safe operation of nuclear plants, as defined in technical specifications. The requirements for inspections and periodic (or surveillance) tests (SR) are conditions for the test, calibration or inspection, to ensure: (a) maintaining the necessary quality of systems and components of a plant, (b) facility operation within safe limits, and (c) meeting the boundary conditions of operation.

According Martorell et al. (2012), safe operation of nuclear power plants depends on the Technical Specifications (TS), so that TS are part of the Licensee Basis (LB) to operate a NPP, which were established taking into account mainly deterministic criteria. The development of PRA (Probabilistic Risk Assessment) and its application since the early 80's to analyze TS changes has brought the opportunity to review TS consistency from a risk viewpoint, i.e., addressing the impact of the changes on plant safety on the basis of the risk information provided by the PSA, with particular attention to the role of the Allowed Outage Times (AOT) included within the Limiting Conditions of Operation (LCO). Martorell et al. (2012) focus on the use of importance analysis. A case study that focuses on an AOT change of the accumulators system of a nuclear power plant using a Level 1 PSA is provided.

The Maintenance Rule (MR) is a requirement established by the U.S. Nuclear Regulatory Commission (NRC) to check the effectiveness of maintenance carried out in nuclear plants, and to plant configuration control. The control of plant configuration is necessary to verify the impact of the maintenance of a safety device out of service on plant safety. The MR technique was consolidated in the U.S. in 1996.

MR classifies Structures, System or Components (SSC) into two categories: Category (a)(2), the SSCs that reach the intended performance demonstrate that the preventive maintenance is being appropriately performed, and Category (a)(1), which stands for the SSCs that do not fulfill Category (a)(2), and must have established goals, so that the discrepancies can be revised and then return to Category (a)(2).

NRC requirements establish that all SSCs can be evaluated to verify the pertinence of their inclusion in a MR. If the SSC is directly related to safety, can mitigate accidents or transients, is part of Emergency Operational Procedures (EOP), can prevent other SSC of performing their safety functions, or causes a reactor shutdown or a safety system actuation, the SSC will be put within the MR scope. Otherwise, it remains under the existing maintenance program, outside the MR scope. The MR also requires that before performing maintenance activities the licensee shall assess and manage the increase in risk that may result from the proposed maintenance activities. The scope of the assessment may be limited to those structures, systems, and components that a risk-informed evaluation process has shown to be significant to public health and safety.

The Nuclear Engineering Institute (NEI) issued the report NEI (1996). This document is a guideline for applying the Maintenance Rule at Nuclear Power Plants. Section 11.0 of NEI (1996) consolidates the assessment and management of the increase in risk that may result from the proposed maintenance activities.

The Electric Power Research Institute (EPRI) has assessed the role of probabilistic safety analysis in the regulation of nuclear power plant Technical Specification, EPRI (2006). This report presents a framework and associated general guidance for implementing Risk-Managed Technical Specifications, RMTS, as a partial replacement for existing Technical Specification, with the following objectives: a) to provide utilities with an approach for developing and implementing nuclear power station Risk-Managed Technical Specifications programs; and b) to complement and supplement existing successful configuration risk management applications such as the Maintenance Rule.

The guidance, EPRI (2006), is applicable to the determination of Risk-Informed Completion Time (RICTs), Risk-Management Action Times (RMATs) and specification of appropriate compensatory Risk-Management Actions (RMAS) applicable to Technical Specification requirements.

Risk management thresholds for RMTS program application are established quantitatively by considering the magnitude of the instantaneous Core Damage Frequency (CDF) and the Incremental Core Damage Frequency (ICDF) for the plant configuration of interest. The incremental frequency values are measured from their respective "no-maintenance" or "zero-maintenance" baseline frequencies as determined via PSA.

Thresholds for risk management actions may be established quantitatively by considering the magnitude of increase of the core damage frequency for the maintenance configuration. This is defined as the incremental CDF. The incremental CDF,

ICDF, is the difference in the "configuration-specific" CDF_s and the baseline (or the zero maintenance) CDF_{ZM}. The configuration-specific CDF_s is the annualized risk rate considering with the out-of-service equipment unavailability:

$$ICDP = (CDF_S - CDF_{ZM})/yr \quad (1)$$

This reflects more closely the plant actual configuration during the maintenance activity. Plants should consider duration factors when setting risk management thresholds. This may be either the duration of a particular out-of-service condition, or a specific defined work interval (e.g. shift, week, etc). The product of the incremental CDF and duration is expressed as a probability (e.g., Incremental Core Damage Probability—ICDP).

Guidance for evaluating temporary risk increases by considering configuration-specific risk is provided in NEI (1996). The risk management thresholds presented in Table 1 provides the basis for RMTS program implementation, the quantitative risk management thresholds and RMTS action guidance as well as a comparison of the respective applicable Maintenance Rule thresholds.

By EPRI (2006), in a RMTS program the 10^{-6} threshold for ICDP, is referred to as Risk Management Action (RMA) threshold and the RMAT is the corresponding risk management action time. The 10^{-5} threshold for ICDP is referred to as Risk Informed Completion Time (RICT) Thresholds. These thresholds are deemed appropriate for RMTS programs because they relate to integrated plant risk impacts that are occasional and temporary in nature and are consistent with NRC (2011a) and NRC (2011b).

Table 1. RMTS quantitative risk management thresholds.

Criterion	MR RMG*	RMTS RMG**
CDF		
$\geq 10^{-3}$ events/yr	Careful consideration before entering the configuration	Voluntary entrance into configuration prohibited. If in configuration due to emergent event, implement appropriate risk management actions
ICDP		
$\geq 10^{-5}$	Configuration should not normally be entered voluntarily	Follow technical specification requirements for required action not met
$\geq 10^{-6}$	Assess non-quantifiable factors; and establish compensatory risk management actions	RMAT and RICT requirements apply; Assess non-quantifiable factors; and Implement compensatory risk management actions
$<10^{-6}$	Normal work controls	Normal work controls

*Maintenance Rule Risk Management Guidance; **RMTS Risk Management Guidance.

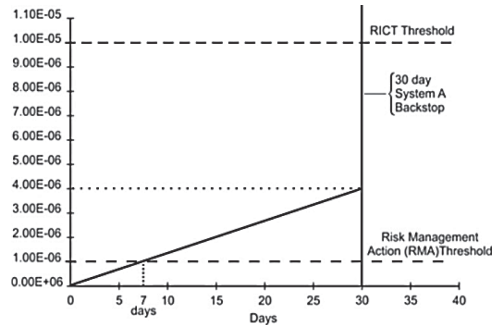

Figure 3. Configuration of risk management RMAT and RICT calculation.

Figure 3 provides a simple example of the RMTS process for inoperability of equipment followed by an emergent event which modifies the risk profile causing changes in the plant configuration RMAT and RICT values.

This example is intended to demonstrate the application of these values in a RMTS program. At $t = 0$, the RMTS equipment becomes inoperable for a duration anticipated to exceed the front-stop CT. In this configuration, RMAT and RICT are calculated.

4 RISK MANAGEMENT NPP

Risk management in nuclear power plants owned by Utility, aims at the monitoring and control of operational settings (unavailability of equipment and/or alignment systems) that imply risks to industrial installation of plants, the ownership and general public, or not directly involved in operating activities.

Risk management adopts the figure of merit frequency of damage to the reactor core to any interference on the tolerability of operational risk.

Risk management by APS during power operation covers: the testing activities; routine or planned corrective maintenance; and the activities of unplanned corrective maintenance.

The CDF calculated for a given plant configuration, in which one set of components is maintenance activities, is compared to the background risk to CDF. The acceptance criteria are defined for the instantaneous and the cumulative risks.

Table 2. Risk ranges depending on CDF.

CDF	Range	Tolerability
CDF < 10^{-4}	GREEN	Usual risk—controls work and usual tasks are developed without constraint having as principle prevent entry into YELLOW range.
$10^{-4} \leq$ CDF < 10^{-3}	YELLOW	Tolerable risk—risk management actions should be implemented seeking to limit the time spent in this band having as principle prevent entry into the RED.
CDF ≥ 10^{-3}	RED	Intolerable risk—risk management actions should be implemented seeking to limit the length of stay in this range for more severe levels as set out for the YELLOW band, under the guidance and strict permission of the Plant Supervisor, having in principle the immediate return the ranges or YELLOW or GREEN.

For the instantaneous risk, the based CDF should be calculated by assuming that all the components considered in the PSA are available to perform their functions (all basic events in test and maintenance should be considered as zero).

The configuration is classified by a criterion of range represented by a color, as the level of risk: GREEN, YELLOW or RED.

The values associated with the boundaries between the stripes and the tolerability of the risk posed is shown in Table 2.

Risk assessment of maintenance for the Unit in power activities are carried out with EOOS software, EPRI (2004), based on the model developed with the EPRI (2005).

The criteria adopted for the management of risk are based on the core damage frequency, CDF. The value of the CDF for PSA Level 1 is 2.3 10^{-5}/year.

5 CASE STUDY

The case study is related to planning maintenance whose completion time exceeds the established Allowable Outage Time of TS and to evaluate the application of EPRI (2006). The NPP is typical nuclear power plant of Siemens/KWU design. This design applies for safety systems of the *n*+2 (4 × 50%) redundancy design criteria.

With the unit in power, the TS states that unavailability (out of service) of one emergency diesel generator is 14 days (AOT or CT).

After this period, the unit should go to cold shutdown if the condition of the emergency diesel generator still remains unavailable.

With the application of the requirements of EPRI (2006) and NEI (1996) and using compensatory measures, the completion time was extended to 30 days for the emergency diesel generator maintenance. Table 3 and Figure 4 show the results for each emergency diesel generator.

It can be seen that risk management actions are necessary to complete the required AOT extension for DG-A, DG-B and DG-D. For DG-C RMAT is 30 days.

With the results of the quantitative evaluation, the monitoring conditions of maintenance activities were established.

The maintenance activities were authorized by the regulatory body that followed the services during the 30 days and has considered satisfactory in meeting the requirements established.

Maintenance activities were conducted in two GDs. These were performed on time and meeting the established criteria. The results demonstrate that

Table 3. Results of case study quantitative risk management thresholds.

Eq.	CDF_S	CDF_{ZM}	ICDP	$ICDP_{30}$	NWC	RMA

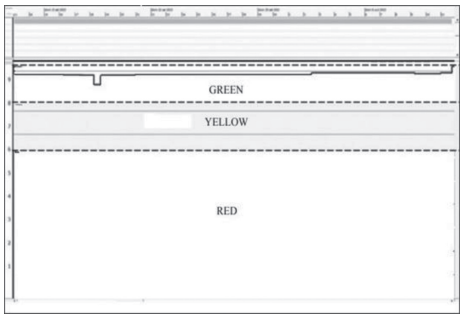

Figure 5. Case study CDF configuration profile during the 30 days maintenance of GD-B.

maintenance of the emergency diesel generators for 30 days does not cause a significant increase on plant risk. Figure 5 shows the profile of the CDF of the plant during the maintenance GD-B period.

6 CONCLUSIONS

Whereas PSA follows the requirements for an integrated decision-making process, the EPRI methodology is appropriate, allowing for consistent decision making.

According to EPRI (2006), a particular configuration change shall be limited to a period of 30 days by technical specifications.

This period was judged by EPRI as an administrative boundary prudently conservative risk management in maintenance activities.

It is noteworthy that, according to the use of risk management for the unit risk assessment, any other component/equipment that is declared inoperable simultaneously with maintaining a given DG and that affects the configuration of the unit may be returned to the original TS completion time.

Maintenance activities were conducted in two GDs. These were performed on time and meeting the established criteria. The results demonstrate that maintenance of the emergency diesel generators for 30 days does not cause a significant increase on plant risk.

Expert system for means of transport maintenance processes performance. A comparative analysis for various types of rail vehicles

T. Nowakowski & S. Werbińska-Wojciechowska
Wroclaw University of Technology, Wroclaw, Poland

ABSTRACT: In the presented paper, the authors' research work is focused on the comparative analysis of developed expert system for transportation means' maintenance processes performance implementation in various rail buses exploitation processes performance. As a result, in the Introduction section, the transportation means' maintenance processes issues and a briefly literature overview in the research area are discussed. In the next Sections, the decision support system and expert system for means of transport maintenance processes performance are described. Following this, the case studies of transportation systems performing in Lower Silesia province, Poland is provided. The work ends up with summary and directions for further research.

1 INTRODUCTION

Effective performance of transportation systems needs proper operational management performance on the one hand, and adequate maintenance performance determination on the other. The decision relevance strictly depends on their accuracy and dedicated decision time. Moreover, it influences the dependability state of the system (Babiarz 2006, Kierzkowski 2010, Valis and Vintr 2006).

The maintenance strategy selection is a complex process, thus it may be supported by decision support systems implementation (Nowakowski & Werbińska-Wojciechowska 2013, 2012a). Such systems can support chosen or every step of manager's decision making process, such as: data gathering, problem definition, problem classification, information model designing, model solution, or optimization process performance (Grobarek et al. 2007).

The Decision Support System (DSS) concept is extremely broad and its definitions may vary depending on the author's point of view and the way of its use (DSS 2002). It may be defined as "… *an interactive computer-based system that helps decision makers utilizes data and models to solve unstructured problems*" (Despres & Rosenthal-Sabroux 1992). The literature review in the research area of DSS designing and applications issues may be found e.g. in (Arnott & Pervan 2008, Asemi et al. 2011, Despres & Rosenthal-Sabroux 1992, Eom 2001, Grobarek et al. 2007, Jankowski & Laskowski 2012, Jodejko-Pietruczuk & Plewa 2012, Lubkowski & Laskowski 2013, Power 2008, Sharda et al. 1988, Vintr & Valis 2012, Zhengmeng & Haoxiang 2011).

In the literature, there can be found a lot of works dedicated to DSS developed for means of transport maintenance processes (see e.g. (Bojda et al. 2010, Kacprzak et al. 2011, Martland et al. 1990, Wachnik & Drzewiecki 2011, Zhang et al. 2011, Zhu 1996)).

In the area of passenger transportation processes performance, the DSS issues being analysed in the literature regarded to e.g. timetable adjustments (e.g. (Mendes-Moreira et al. 2009)), transportation system planning process supporting (e.g. (Burla et al. 2009, Han 2006, Kamath et al. 2011)), traffic control (e.g. (Borne et al. 2003, Ossowski et al. 2005, 2004)), or transportation system safety during emergencies (e.g. (Yoon et al. 2008)).

The convenient approach for solving the maintenance management problems is expert system implementation. The expert system may be defined as an *intelligent computer program that uses knowledge and inference procedures to solve problems that are difficult enough to require significant human expertise for their solution* (Angeli 2010). The main components in an expert system development include: knowledge acquisition, choice of knowledge representation, the coding of knowledge in a knowledge base, the development of inference procedures for diagnostic reasoning, and the development of input-output interfaces (Venkatasubramanian et al. 2003).

Following this, the authors have investigated the problem of decision support system for transportation means' maintenance process performance by development of DSS conception (see e.g. (Bojda & Werbińska-Wojciechowska 2012)), expert system definition (see e.g. (Nowakowski & Werbińska-Wojciechowska 2012a)), data uncertainty analysis (see e.g. (Nowakowski & Werbińska-Wojciechowska 2012b)), or initial analysis of

expert system implementation possibilities (see e.g. (Bojda et al. 2014)). As a result, the focus of this study is to investigate the implementation possibilities of developed expert system for different types of means of transport when their exploitation databases differ. Thus, in the next Sections, the conception of DSS for means of transport maintenance processes performance and Expert system are investigated. The work ends up with discussion about analysis results of expert system implementation in the case companies maintenance decision processes performance.

2 DECISION SUPPORT SYSTEM IN MEANS OF TRANSPORT MAINTENANCE PROCESSES PERFORMANCE

The purpose of the developed DSS performance is connected with possible maintenance strategy (traditional/DTA based) for technical object definition based on chosen maintenance and dependability indicators' values. The solution is based on decision rules implementation. These decision rules are the base for computer procedure of decision support definition.

The general decision support program's structure is given in the Figure 1. The example of decision rules edition process is given in (Nowakowski, 1999). For more information we recommend reading e.g. in (Bojda et al. 2014, Bojda & Werbińska-Wojciechowska 2012, Nowakowski & Werbińska-Wojciechowska 2014, 2013).

The main *assumptions* taken during the DSS development encompass (Bojda & Werbińska-Wojciechowska 2012):

- performance of a multi-component (or complex), repairable transportation system investigation,
- investigation of maintenance strategies for systems with and without components dependence,
- corrective maintenance strategy omission,
- condition-based maintenance models omission,
- maintenance information management models omission,
- cannibalization maintenance models omission.

Following these considerations, in the DSS development process we examine various types

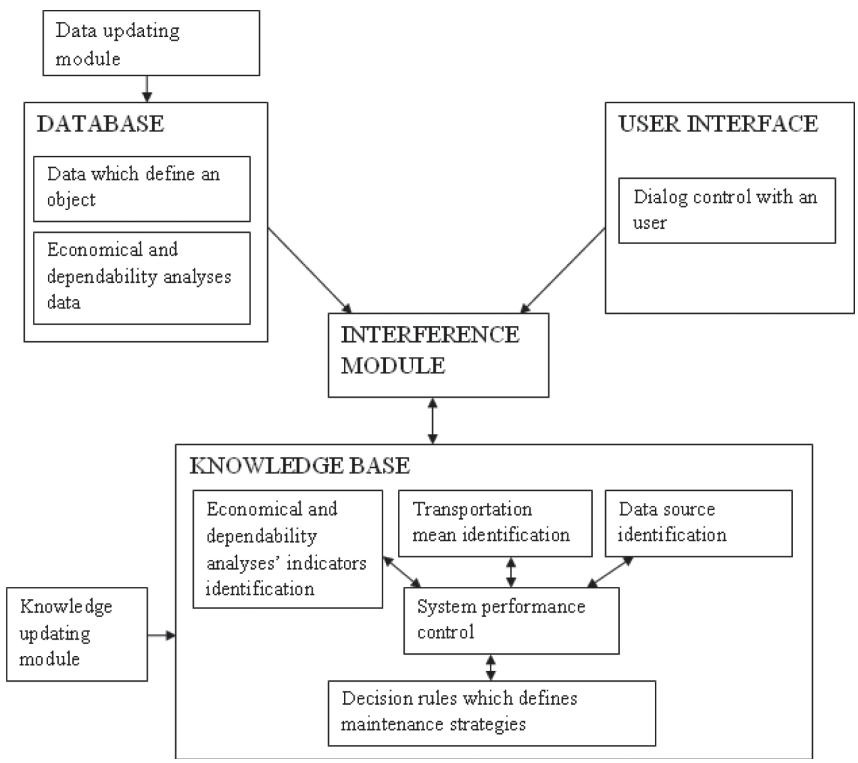

Figure 1. The structure of DSS for means of transport maintenance process performance (Nowakowski & Werbińska-Wojciechowska, 2012).

of maintenance policies for multiunit or complex systems, which are the most commonly used (for review see e.g. (Nowakowski & Werbińska, 2009)).

The development of DSS in the analysed area regards input data, conclusions and decision rules definition. The main *input data* which are necessary to be used in a DSS performance can be classified into three groups (Bojda & Werbińska-Wojciechowska 2012):

- general data, which describe transportation system performance,
- data which describe the actual state of transportation system,
- data which describe the maintenance costs of transportation system performance.

The decisions are made based on the information about the state of a system, maintenance costs and data accessibility. These input data being defined more precisely and quantified are used to develop *decision rules*, which are the simple logical sentences. More information can be found in (Bojda et al. 2014, Bojda & Werbińska-Wojciechowska 2012, Nowakowski & Werbińska-Wojciechowska 2014, 2013).

Table 1 shows a list of basic maintenance strategies included in the DSS with the main information necessary to be gathered to implement the DSS in the area of real-life transportation systems performance. In the Table 2, there are defined main input data.

Table 1. List of maintenance strategies included in the DSS (with index) (Bojda & Werbińska-Wojciechowska 2012).

Table 2. The necessary input data for DSS implementation.

Index	Input data definition
Np	Number of means of transport in a system
TE	Time horizon of observation performance
L	Type of components dependency
RS	Type of system's reliability structure
Z_F	Type of system failure
t_f	Time moments of failure occurrence
ZM	Type of maintenance processes performance
t_{RT}	Time moments of maintenance actions finishing
T_p	Time of preventive maintenance performance
T_c	Time of corrective maintenance performance
T_{nm}	Time of minimal repair performance
T_{in}	Time of inspection action performance
T_{dw}	Downtime of a system
$E[h]$	Expected value of delay time
c_{cor}	Cost of corrective action performance
c_{op}	Operational cost per unit of time
c_w	Cost per unit of preventive action performance
c_p	Penalty cost
c_{dw}	Cost of system downtime
c_{nm}	Cost per unit of minimal repair performance
c_i	Cost of inspection performance
$C_{mn}^{\max}$	Maximal acceptable cost of corrective action performance

3 EXPERT SYSTEM APPLICATION

The expert system is based on EXSYS Professional system implementation. Exsys Corvid, is a

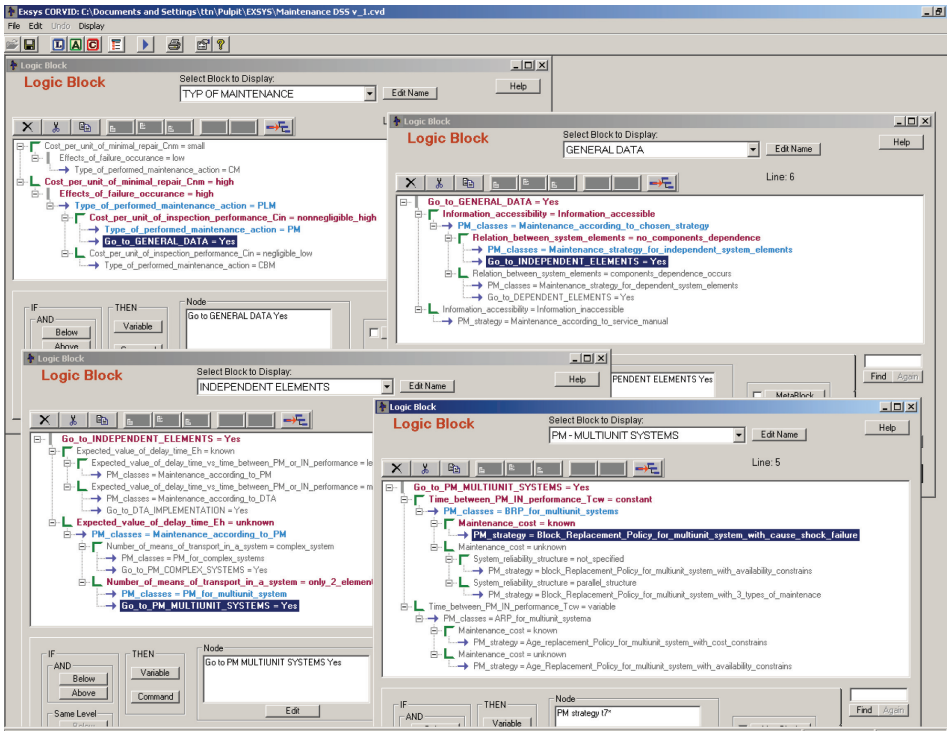

Figure 2. Rule decision window for t_7 strategy selection.

development environment suitable for any type of knowledge automation system project—anywhere expert advice and answers need to be distributed or accessed (Exsys 2011). The example of decision rules edition process is given in (Nowakowski 1999, Nowakowski & Werbińska-Wojciechowska 2014) and the introduction to the presented problem is given e.g. in (Bojda & Werbińska-Wojciechowska 2012, Nowakowski & Werbińska-Wojciechowska 2012a, b). The detailed description of DSS building process is given in (Bojda et al. 2014, Bojda & Werbińska-Wojciechowska 2012, Nowakowski & Werbińska-Wojciechowska 2014, 2013, 2012a, b).

An exemplary DSS screen of Rule decision window is given in Figure 2.

4 EXPERT SYSTEM IMPLEMENTATION

4.1 *Case studies—regional and local passenger transportation systems*

The developed expert system was applied to select maintenance strategies for two types of rail vehicles being operated in two different passenger transportation systems located in Lower Silesia, Poland.

The first type of rail vehicles—rail buses are used in regional passenger transportation system. The operator puts into service small- and middle-sized diesel rail vehicles, running mostly as single train sets, rarely coupled. Currently 21 rail buses dating from 2004 to 2011 are used, being built mostly by one manufacturer or his subsidiaries. The research analysis covered 8 single car rail buses of particular type X.

The system covers several routes operated daily by Lower Silesian Railways Company on mixed-traffic railway infrastructure which is partially single and double track. The network is of irregular form with central station in Legnica, supplemented by the only service depot for the car fleet located nearby. More information can be found e.g. in (Bojda et al. 2014).

The second type of rail vehicles—trams by Skoda are used in city transportation system performing in Wroclaw city, Poland. The municipal transport services are provided by a common carrier. In March 2012, the city carrier had a total of 416 passenger tram cars (*Urban* …, 2012), including 48 cars of Skoda (17 cars of Skoda 16T and 31 cars of Skoda 19T).

The tram network covers the most area of the city, and is supplemented by four service depots. More

information can be found e.g. in (Nowakowski & Werbińska-Wojciechowska in prep.).

4.2 *Maintenance data for presented case companies' rail vehicles*

To implement expert system in the area of maintenance management decision process performance, there were collected data about rail buses' and trams operational processes performance. In the case of rail carriers, the period of research analysis encompasses 43 months (152 568 working hours), from December 2008 to June 2012. The operational data are taken from their operational books which are prepared by department of tram maintenance employees. These operational books are located in every rail buses, and are filled in by engine drivers, warehousemen, and service engineers.

Every engine driver should fill in the date, hour and place of beginning/finishing his work. Moreover, some additional information should be taken into account, like e.g. all failures and irregularities detected during operational process performance.

In the case of trams performance, the period of research analysis covers time from January to December of 2011. The operational data include the recording of all events associated with the operational process of rail vehicles (Skoda 16T, 19T) and their maintenance actions that have been recorded in the technical book and emergency exits book.

The gathered data contain e.g. the information about the date of the event, the number of the wagon; failure information, maintenance information (e.g. type of repair, date of repair). In some cases, there are given extra information about a time of incident notification, time of damaged tram substitution, but such contributions was less (about 30%).

The collected data give the authors information e.g. about types of failures occurred in the system, their occurrence frequency. There were also obtained information about maintenance actions performance (planned/unplanned). Following this, the transportation system characteristics can be obtained. The exemplary transportation systems characteristics for time between failures of defined types of rail vehicles are presented in Figures 3–5.

For more deeply analysis of obtained operational data and rail cars dependability characteristics we recommend reading e.g. (Bojda et al. 2014, Nowakowski & Werbińska-Wojciechowska in prep.).

Another problem regards to economical parameters estimation. There were obtainable corrective and preventive maintenance actions' costs only for one case company—regional carrier. More information can be found in (Bojda et al. 2014). In the second case, maintenance manager has to base only on operational input data to select maintenance strategy.

To sum up, the analysis of rail cars operational processes performance gives the possibility to gather

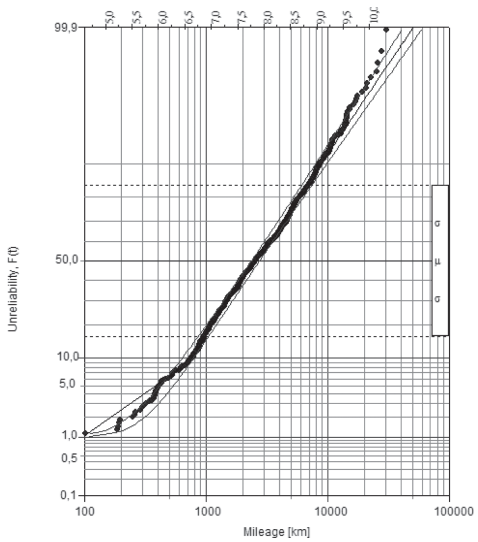

Figure 3. The cumulative distribution function of rail buses time between failures [mileage] (Log-normal distribution: $\mu = 7.8517$, $\sigma = 0.9673$) (Nowakowski & Werbińska-Wojciechowska 2014).

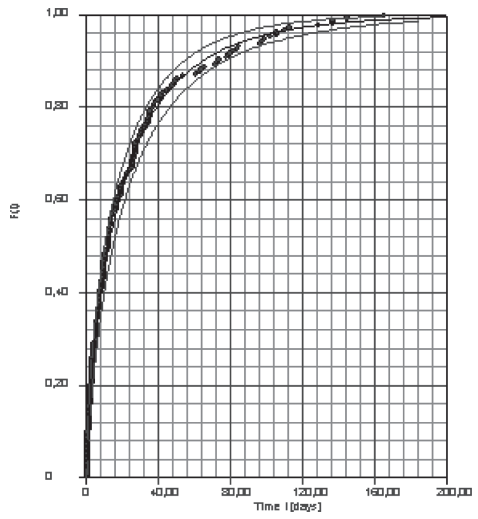

Figure 4. The cumulative distribution function of rail buses Skoda 16T time between failures [days] (Weibull distribution with parameters: $k = 0.7144$, $\lambda = 19.9665$, $\gamma = 0.7800$, $\rho = 0.9739$) (Nowakowski & Werbińska-Wojciechowska in prep.).

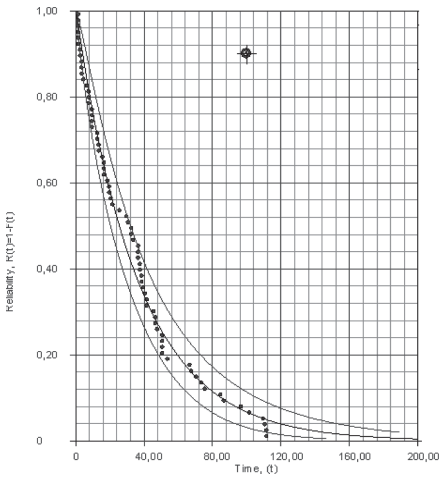

Figure 5. The reliability function of rail buses Skoda 19T [days] (Weibull distribution with parameters: k = 0.9881, λ = 36.4833, γ = 0.3750, ρ = 0.9771) (Nowakowski & Werbińska-Wojciechowska in prep.).

main operational and maintenance data, necessary for maintenance strategy selection process. However, not all necessary DSS's input parameters (presented in the Table 2) were defined during research analysis performance. The comparison of accessible for case companies input data is presented in the Table 3.

In the Table 4, there is presented the correlation between necessary input data and maintenance strategies defined in the expert system (where system reliability structure: 0—a series structure, 1—a parallel structure, 2—a k-out-of-n structure, 3—not specified). For more information see (Bojda & Werbińska-Wojciechowska 2012).

For example, for both the analysed transportation systems there were no possibility to define if, and what kind of components dependency occur. The system reliability structure wasn't also defined. Additionally, there were also no possibilities of delay time parameter estimation. The problem with economic data gathering process is also visible for the case of Skoda trams.

Following this, in the next Section, there is presented the developed expert system implementation in rail cars' maintenance strategy selection process.

4.3 *Maintenance strategy selection for case companies' rail vehicles with expert system application*

In the next step of research analysis authors have implemented the developed expert system for one of the defined maintenance strategies selection process performance. During the decision process, there has to be answered few questions regarding e.g. types

Table 3. The accessibility of necessary input data for DSS implementation for the analysed rail cars.

of the performed maintenances, types of occurred failures, or components dependency occurrences.

For the case of rail buses, the expert system indicates, that the best maintenance strategy for analysed transportation system is t_8—*Block Replacement Policy for multi-unit system with availability constrains*. This result is connected with e.g. lack of information about system reliability structure. Another simplification regards to impossibility of delay time and elements dependency definition. As a result, authors underline, that the rail cars operational process performance should be broadly analysed in order to gather the necessary but not obtained input data for expert system fully implementation.

For the case of Skoda trams, the maintenance strategy selection process is limited to those policies, which uses reliability/availability as optimization criteria. In that case, expert system support maintenance manager with choosing the same maintenance strategy—t_8—*Block Replacement Policy for multi-unit system with availability constrains*. This is also connected with the time between planned maintenance actions performance which is suggested to be constant.

5 CONCLUSIONS

The discussed issue is a continuation of research work connected with developing a decision support system for transportation means' maintenance processes performance. The system gives decision makers a hint which one from the defined maintenance strategies is the most advisable to implement in a defined circumstances. However, the conclusions are strictly determined by the type and likelihood of obtained operational data. In the presented case studies not all the necessary information can be put into the system. Following this, the decision process cannot be conducted in a proper manner.

Moreover, there is a problem with data uncertainty. Some research works which consider uncertainty problem in decision support system performance are given in (Nowakowski & Werbińska-Wojciechowska 2012b). As a result, the discussion about the input data reliability and its influence on decision process results will be the point of authors' further research works.

ABSTRACT: Track fault may cause the derailment and it is one of the major contributors to railway maintenance costs. Gauge spread is one of the track faults. Maintenance and speed restriction should be taken according to the inspection results. Visual Inspection (VI) can only detect poor fastening and static gauge spread. Train Recording Vehicle (TRV) detects the loaded gauge spread. The inspection frequencies are required in Standards, but they should happen at a greater frequency if the recommendations are insufficient. Two inspection schemes are introduced for a railway section. One scheme considers that VI and TRV are periodic; another assumes that TRV interval depends on the number of identified defects. In this paper we propose a risk and maintenance model based on a hierarchical Colored Petri Net (CPN) for a railway section, since CPN is flexible enough to model the component deterioration process and the different inspection schemes. The CPN model considers not only the maintenance process for observed component states but also the accident scenarios. According to Monte Carlo simulation results, the model can be used to evaluate the inspection policies.

1 INTRODUCTION

Railway industry concerns the performance of railway system and railway assets management tries to reduce the railway accidents and the maintenance cost. Derailment is one of railway accidents leading to fatalities and a high corrective maintenance cost. On plain line, derailment may occur when a train travels along a poor condition track. Track inspections and maintenances should be carried out to maintain track condition. Traffic control such as speed restriction cooperates with track maintenance to decrease accident frequencies or reduce accident consequences. Track maintenances cost a lot of money and traffic controls always reduce line availability. System risk metrics, railway line availability and management cost are required to decide when and how to maintain the track and when to perform speed restriction to get fewer accidents with higher availability and lower cost.

1.1 *Track quality and its modeling*

According to derailment investigations, around 74% of derailments occur due to track problems; in the track issues, track geometry fault (i.e. gauge spread, twist, cyclic top and buckle) is the major contribution to derailment. Wheels on one side may climbs the rail flange and wheels on the other side drop down the rails due to track faults (Lupton 2003).

Since the track faults are unrevealed, track condition data is collected for the one-eighth mile section by inspection methods (GC/RT 5021 2011) (GC/RT 5010 1998). Track faults can be described using track deterioration models. In the literature, deterministic model and stochastic model are used to model track degradation. Deterministic methods focus on the factors related to track quality, these factors can be materials, loads, speed and so on (Zwanenburg 2008) (Westgeest, Dekker, & Fischer 2012) (Sadeghi & Askarinejad 2010). However, track deterioration varies at different time, that is important to be considered in maintenance decision making, so stochastic models are introduced to describe these variations (Meier-Hirmer, Riboulet, Sourget, & Roussignol 2009) (Quiroga & Schnieder 2011).

This paper focus on gauge spread and assumes it is a stochastic process. Gauge spread is defined as the tendency of the maintained track gauge to become greater. It occurs due to poor fastening system or poor sleepering condition, such as

baseplate shuffle, chair shuffle, rotten sleepers and chair screws losing their grip in the sleepers, these events might be identified by visual inspection and fixed by refastening (Ellis 2006). Track gauge is classified to be static and dynamic regarding to the loading on track. The standard static track gauge is 1430 mm, the allowed maximum dynamic gauge is 1480 mm. The static gauge can be measured by visual inspection; once the static gauge exceeds 1450 mm, dynamic gauge should be measured by train recording vehicle. If static gauge is over 1430 and below 1450 mm, gauge spread can be controlled by speed restriction or tie-bar. If the gauge exceeds 1450 mm and below 1480 mm, speed restriction and tie bar should be carried out at the same time. If the gauge spread is high (the loaded gauge is over 1480 mm), the line should be closed until re-sleepering restores track gauge (GC/RT 5021 2011).

A multi-stage deterioration model is adopted to describe the process of gauge spread. Corresponding repairs are carried out for each observed deterioration stages. In this paper the component deterioration and the corresponding maintenance and control methods are assumed as shown in Table 1.

1.2 *Railway risk model*

Risk analysis is required to evaluate the accident frequency and consequences. In railway industry, Safety Risk Model (SRM) is used to estimate system risk, SRM consists of Fault Tree Analysis (FTA) and Event Tree Analysis (ETA). Fault tree estimates accident frequency considering system failure logic (Muttram 2002). It calculates top event frequency or probability using minimal cut sets. Basic events in fault tree describe the component failures; they can model revealed repairable failure, revealed unrepairable failure and unrevealed repairable failure with periodic inspection (Andrews & Moss 2002). The above failure models for basic event are not enough to consider the effects of maintenances on risk as these models cannot describe multi-level repairsor inspections in details.

Petri nets are used in the railway risk model due to their capability to describe concurrent events in accident scenarios (Zheng, Mueller, Slovak, & Schnieder 2009). Furthermore Petri nets can describe the combined process of stochastic deterioration and maintenance in details (Andrews 2012) (Prescott & Andrews 2013). Petri nets estimate accident frequency or probability by thousands of Monte Carlo simulations. Colored Petri nets are a kind of high level Petri nets. They introduce colored set into the Petri nets, so it is possible to build an object-oriented Petri net model for complex systems.

A railway block section is chosen in this paper which is a railway plain line segment including 8 track components, an entry signal and an exit signal. The section is open for the waiting trains if there is no inspection, no maintenance and no train in the section. A derailment is assumed to occur once a train is passing along a track which exceeds dynamic gauge limitation (1480 mm). Train speed restriction might be carried out to control the corresponding stage of failure. Train speed in this section is informed by the entry signal and train will pass the whole section with the permissible speed. This paper presents a hierarchical CPN model for a railway block section to estimate the railway system derailment frequency due to gauge spread.

1.2.1 *Colored Petri Nets*

A Colored Petri net consists of places, transitions, arcs, color sets, variables, color set functions, guard, arc expression function and initialization functions. A CPN is defined as:

$$CPN_t = (P, T, A, \Sigma, V, C, G, E, I) \tag{1}$$

CPN_t is a timed CPN, P is the set of places, T is the set of transitions, A is the set of arcs, Σ is the set of colored set, V represents the set of variables. G is the set of guard functions, I is the initial marking of the net, C is the set of colored set functions and E is the set of the arc expression functions (Jensen, Kristensen, & Wells 2007).

Table 1. Repair assumption for different component states.

Component state	Inspection	Repair	Effect	Waiting time	Duration
Level 1	–	N/A	–	–	–
Level 2	VI	Refastening	Level 1	τ_{f2}	μ_{f2}
Level 3	VI	Tie bar	Level 2	τ_{f3}	μ_{f3}
Level 4	VI/TRV	Tie bar & speed restriction	Level 3 (TSR)	τ_{f4}	μ_{f4}
Level 5	TRV	Re-sleepering	Level 1	τ_{f5}	μ_{f5}
Accident	–	Renewal	Level 1	τ_{f6}	μ_A

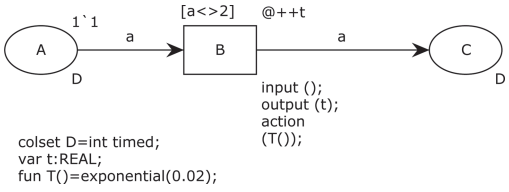

Figure 1. Colored Petri Net concept.

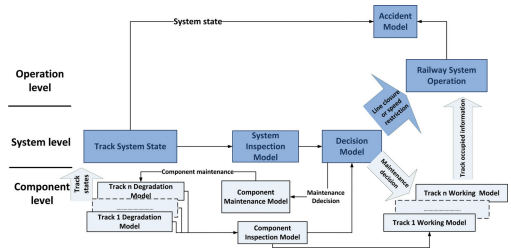

Figure 2. Modeling framework.

Figure 1 shows a simple timed CPN example, 'D' is defined to be colored set, colored set can be defined to be any data type, for example, in this figure, colored set D is defined to be integer type. Place A and Place C belong to coloredset D. Transition B transfers variable *a* from place 'A' to place 'C'. Function $T()$ defines a stochastic function and assigns the value to variable *t*. It means variable 'a' is transferred from place 'A' to place 'C' at time 0, the token in place 'C' is valid at time *t*. At place 'A', '1' 1' is the initial token.

For a complex system, it is impractical to build a CPN model as a single net. Therefore, a hierarchical CPN model introduces the concept of modules and the interfaces. A module is related to a substitution transition, which is represented by a rectangularbox with double line borders. There are input and output places in the substitution transition to connect different modules. A complex system can be modeled in a modular manner thus we can work at different abstraction levels and use component models repeatedly.

2 MODELING FRAMEWORK & ASSUMPTIONS

A modeling framework for the chosen section is proposed to combine risk modeling and track deterioration modeling. The framework can be described as shown in Figure 2, including three levels: Component level, System level and Operation level.

The component level describes track component deterioration and component working status. Inspection is needed to detect the unrevealed track degradation, then maintenance activities are carried out for the defective components. At component level, component working status contains: being inspected, being maintained, occupied by train, available.

The system level consists of the system state, the system inspection and the decision model. System state depends on track component deterioration and system structure. Any component failure will lead to system failure state, thus system is considered to be a series system. A system inspection is carried out for the entire chosen section, then the decision making model decides maintenance activities according to system and component inspection results.

Operation level contains the system operation model and the accident model. Operation model describes two system statuses: available and unavailable. When there is a train, an inspection or a repair, the system is unavailable for a waiting train; otherwise it is available. Accident model describes possible event sequences which might lead to derailment.

2.1 *Component modeling*

In this framework, the model of maintained component is shown in Figure 3. The component degradation process is divided into k stages, this process is shown in the grey rectangle area in Figure 3. The time distribution of each level is assumed to be an exponential distribution with rate λ_i, when the component deteriorates to level k, it may cause an accident.

Each level can be identified by inspections *INSPi*, then the component state is observed and a corresponding repair *Mi* controls the observed deterioration. Unfortunately, the repair arrives in a delay time and the component keeps degrading when this defective component is waiting for the repairs, hence the arriving repair may not fix the defects. Figure 4 shows an example of these situations. Level 5 is assumed to be the failure state in this example. When level 3 arrives and it is identified by the *i*-th inspection, there is a waiting time for the repairs R_i. Before the *i*-th repair R_i arrives, the level 3 defect may degrade to be level 5, in this case, a derailment accident may happen. If R_i arrives between T_{l4} and T_{l5}, level 4 may be observed. Therefore, the dash arrows from 'observed deterioration level 3' in Figure 3 show the possible situations that the repair waiting time exceeds deterioration time to the other stages.

The component working model is used to model a component having the different working states. In the chosen section, track component working states

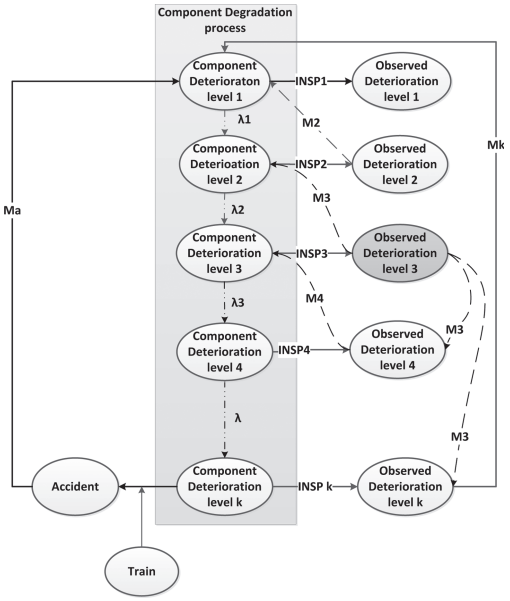

Figure 3. The maintained component model.

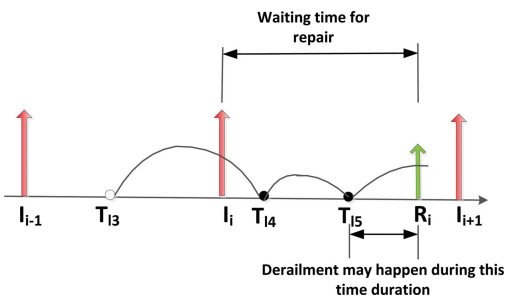

Figure 4. Repair waiting time exceeds deterioration time.

include 'available', 'being inspected', 'being maintained' and 'occupied by train'. Figure 5 shows the relationship of these working states. For example the track is being inspected if an inspection arrives when the track is available and track becomes available once inspection leaves.

2.2 *System operation and accident model*

System operation model describes railway section behaviors. There are two operation modes for the chosen section. Normally, trains may pass the section with normal speed; if there is a defect, train may be required to pass the section with a speed restriction; if there is an identified failure, an inspection or a maintenance, the railway

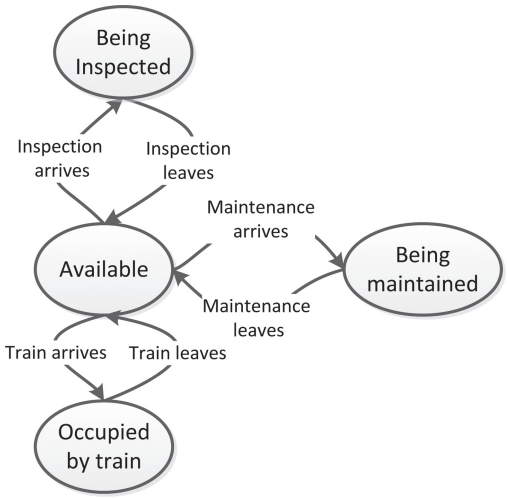

Figure 5. Track component working status model.

line is closed. An accident will occurs when a train passes a poor condition track with normal speed or speed restriction.

3 CPN MODEL FOR THE RAILWAY SECTION

A plain line block section is modeled in this paper to evaluate inspection and maintenance strategies. According to the above modeling framework, a hierarchical CPN model is built to estimate derailment frequency, system availability and maintenance cost. The CPN model contains several parts: component deterioration model, component working model, operation and accident model.

The CPN model evaluates two inspection schemes:

- Visual inspection and Train Recording Vehicle for gauge spread are taken periodically;
- Visual inspection is carried out periodically, Train Recording Vehicle has a maximum planned interval but its interval decreases if the number of identified defects increases.

3.1 *Component CPN model*

The component CPN model contains the CPN model of component working states and the CPN model of inspection and maintenance.

3.1.1 *Component deterioration CPN model*

According to the deterioration process in Figure 3, a component deterioration model is built as shown in Figure 6.

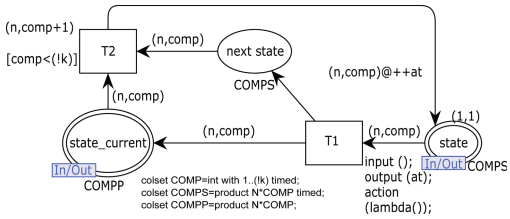

Figure 6. CPN component deterioration model for track component 1.

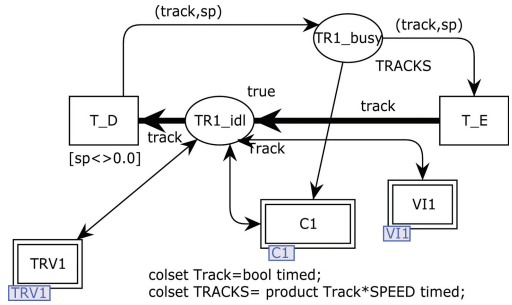

Figure 7. CPN component working model for track 1.

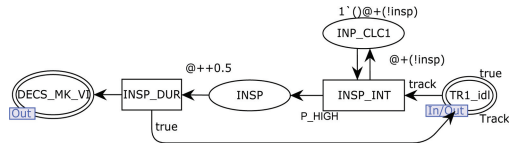

Figure 8. Visual inspection model.

Place 'state' represents the initial state, place 'state_current' represents the current track state. Variable *comp* represents the defect level, there are *k* component deterioration levels. Transition T1 samples deterioration time to next state by function *lambda*() and it assigns the deterioration time to 'next state' by variable *at* in arc inscription, place 'next state' records the next state arriving time in its token time stamp. Once the token in 'next state' is valid, transition T2 fires, the component state degrades.

3.1.2 *Component working CPN model*

Figure 7 shows the CPN model, which describes the component working process.

The working model considers existence of train, inspection and maintenance. The place *TR*1*_busy* represents a track occupied by train, the place *TR*1*_idl* represents the component being available. Transition *T_D* means that a train enters this track component. *T_E* represents train leaving. Substitution transitions *TRV*1 and *VI*1 represent the inspection arrivals. Substitution transition *C*1 combines the component deteriorations and the maintenances.

3.1.3 *Component inspection CPN model*

Visual inspection is considered to be the component level inspection in this paper, it is assumed to be taken periodically.

The substitution transition 'VI1' in Figure 7 is extended as shown in Figure 8. When a track is available (the token in Place 'TR1_idl' is valid) and the cycled inspection time arrives (token in place 'INP_CLC1' is valid), a visual inspection takes place (transition *INP_INT* fires). In Figure 7 there may be the conflicts among substitution transition TRV1, C1 and VI1 if they are enabled at the same time. In this paper the inspections are assumed tohave a higher priority, therefore the priority of transition 'INSP_INT' is set to be 'P_HIGH' (high priority). The inspection lasts 0.5 unit time and the transition INSP_DUR assigns the inspection duration and represents a finished inspection; then a decision is made (the place 'DECS_MK_VI') and the track becomes available (TR1_idl).

3.1.4 *Component maintenance CPN model*

Maintenances are carried out according to the visual inspection result. Table 1 lists the repair activities for the identified component degradation levels, these degradation levels are defined by global reference values *!j* = 2, *!m* = 3, *!l* = 4 and *!k* = 5. There are four repair activities for identified track gauge spread: refastening, tie bar, re-sleepering and renewal. These repair processes for level '!k','!l' and '!m' are described in substitution transition *C*1.

Figure 9 illustrates the repair CPN model for the observed component deterioration level *!j*. Substitution transition deterioration describes the deterioration process, which is shown in Figure 6. Token in place DECS_MK_VI is valid when visual inspection is completed at time *t*, at this moment, the value of the token in place 'state_current' is level *j*, according to this state, transition 'Tmm_D' fires. After 'rdelay2' time, the token in place 'WTmm' is valid, whichmeans the planned repair arrives. Transition Tmm fires which means repair for level *!j* is carried out, according to the maintained model in Figure 3, if the current state is the same as the observed state, repair maintains track state to be '*comp*—1 in place 'state', the repair takes '!mu2' unit time; if the current state degrades to be the failure state *!k*, a token is put in place 'WTMM' which means waiting for maintenance for level *!k*. If the current state is *!l* or *!m*, a token is put in place 'WTMm' and the track component will wait for another level repair (repair for level *!l* and *!m*).

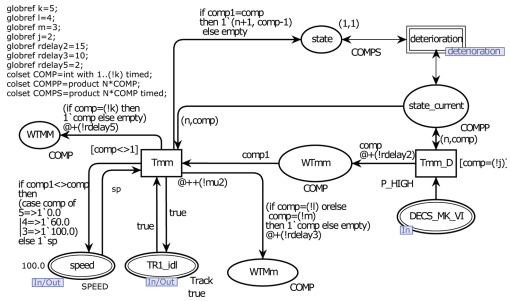

Figure 9. Repair model of observed level '!j' for track component 1.

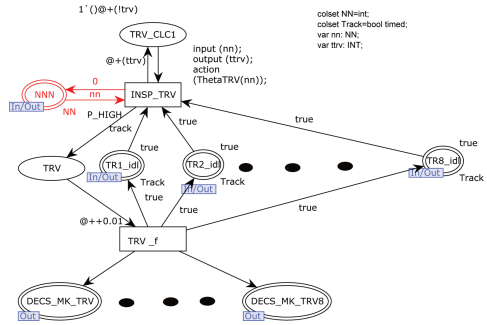

Figure 10. Train recording car inspection model.

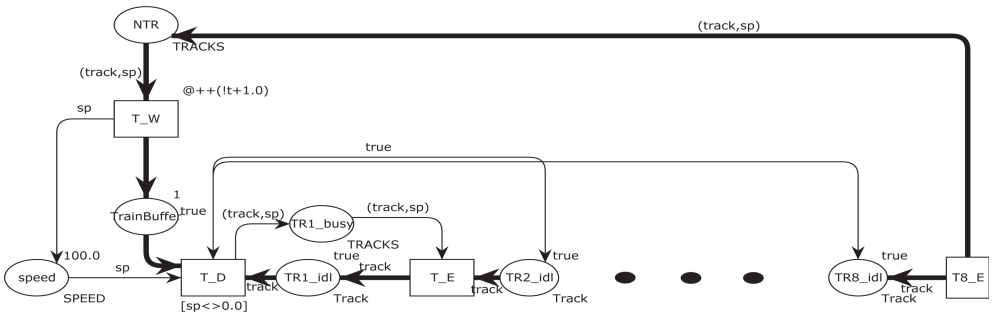

Figure 11. System operation model.

3.2 *System inspection CPN model*

Train Recording Vehicle can be carried out once there is no train, no maintenance and visual inspections in the section.

A CPN model of the Train recording car is shown in Figure 10. If all of the places 'TR*i*_idl' have a token when it is time for TRV (a token at place 'TRV_CLC1' is enabled), transition 'INSP_TRV' fires and a token arrives at place 'TRV' and the decisions for track components (places 'DECS_MK_TRVi') are made.

The TRV CPN can model two inspection schemes using function *ThetaTRV*(*nn*). Function *ThetaTRV*(*nn*) controls the interval of train recording car by variables *ttrv*. If TRV is periodic, function *ThetaTRV*(*nn*) = *!trv*, where *!trv* is defined as the planned maximum TRV interval. If TRV depends on the number of observed defects, place NNN collects the number of defects in the section, then function *ThetaTRV* defines 'ttrv' according to 'nn'.

3.3 *System operation and accident CPN model*

The track system operation model is shown in Figure 11. Place TrainBuffer represents a waiting train at the entry of the section. Place 'Speed' controls train operation modes due to the track

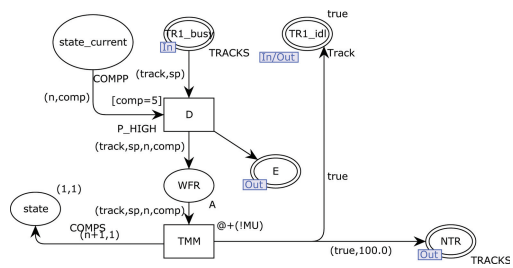

Figure 12. Accident model at track component 1.

gauge spread. Train can pass the section normally with speed 100, or in a degraded mode with speed 60; if the extreme failure exists, traffic must be stopped (speed is 0). Transition 'T_D' describes a train entering the section; it fires if all of the places 'TR*i*_idl' have tokens and variable *sp* of place 'Speed' is not zero. 'T_D' fires and it takes token from place 'TR*i*_idl' to 'TR*i*_busy', which means that track component is occupied by train, thus 'T_D' is not enabled and another train is not allowed to enter.

Figure 12 shows the derailment model: a derailment happens (transition D fires) when train is

passing along the component (the place 'TRi_busy' has a token), where a track failure exists (place 'state current' has a value 5). After the accident, a renewal ('TMM' fires) is carried out and the track is restored (the variable *track* is 1 in place 'state') in '!MU' time (μ_A in Table 1).

4 SIMULATION RESULTS

The CPN model can be used to evaluate different inspection policies of the two inspection schemes. Four inspection policies are assumed in this paper:

- Policy 1: Two level periodical inspections, Visual Inspection interval $\theta_{vi} = 40$ units;
- Policy 2: Visual Inspection interval is $\theta_{vi} = 40$ units while Train Recording cars interval depends on the number of defects.
- Policy 3: Two level periodical inspections, Visual Inspection interval $\theta_{vi} = 50$ units;
- Policy 4: Visual inspection interval is $\theta_{vi} = 50$ units while Train Recording cars interval depends on the number of defects.

For these inspection policies, the planned Train Recording car interval ranges from 5 to 2000 units. The parameters for maintenance in Table 1 are assumed to be: $\tau_{f2} = 15$, $\mu_{f2} = 1$, $\tau_{f3} = 10$, $\mu_{f3} = 4$, $\tau_{f4} = 5$, $\mu_{f4} = 4$, $\tau_{f5} = 2$, $\mu_{f5} = 10$, $\tau_{f6} = 0$, $\mu_A = 70$.

The system performance index 'Scheduled line availability A_{sch}', 'Line availability A_{uns}', 'Line Scheduled cost C_{sch}', 'Total cost C_{uns}' and 'The number of availability $N_{derilment}$' are used to compare these four inspection policies.

$N_{derilment}$ is counted by monitoring transition D in Accident model. The scheduled availability A_{sch} and the line availability A_{uns} are obtained by monitoring transition T_D and T_i_E according to Equation 2 and Equation 3. $T_{avilable}$ is the line available time, T_{total} is the total time, DT_{uns} is the unscheduled down time.

$$A_{sch} = \frac{T_{available}}{T_{total} - DT_{uns}} \tag{2}$$

$$A_{uns} = \frac{T_{available}}{T_{total}} \tag{3}$$

C_{sch} and C_{uns} are calculated by Equation 4 and 5. C_M is maintenance cost, C_{trv} is the cost of each Train Recording car, C_{vi} is the cost of each visual inspection and $C_{Accident}$ is the cost of each accident. The number of Train Recording cars N_{trv}, the number of Visual Inspections N_{vi} are counted by monitoring the transition *INSP_TRV* and transition *INSP_INT*. The number of maintenances N_M are obtained by monitoring transition *Tmms*(refastening), *TMms* (tie bar) and *TMMs* (re-sleepering) in the CPN model.

$$C_{sch} = C_M N_M + C_{trv} N_{trv} + C_{vi} N_{vi} \tag{4}$$

$$C_{uns} = C_{sch} + C_{Accident} N_{derailment} \tag{5}$$

20000 simulations are carried out to check how many simulations are required to observe a convergence in the results. A plot of the average line availability against the number of simulations is shown in Figure 13. The middle curve is the average availability result, the curve below it and above it are the 99% confidence results. It shows the simulation converges at around 2000 simulations. If the number of simulations is less than 2000, the results have larger deviations. Therefore, at least 2000 simulations are needed to get the solution of CPN model.

Figure 14 shows the normalized number of derailments against TRV interval per year. The derailment frequency increases when either Visual Inspection interval or Train recording Vehicle interval increases.

If the Train Recording car interval increases, the scheduled availability increases as shown in Figure 15. However, the line availability decreases if TRV interval increases as shown in Figure 16.

The scheduled cost and unscheduled cost are shown in Figures 17 and 18. All of the inspection policies have the minimum total cost as shown in Figure 18. For policy 1 and policy 3, the minimum maintenance cost can be obtained for a Train Recording vehicle interval of 65 units. For policy 2 and policy 4, the minimum total cost can be obtained if the train recording car interval is 125 units.

In the plot of derailment, if TRV interval ranges from 0 to 300 units, policy 2 and 4 exhibit fewer

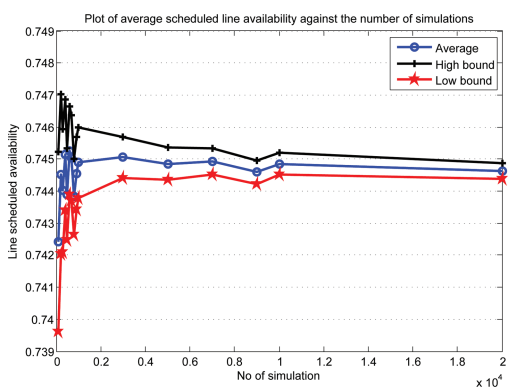

Figure 13. The number of simulation against the availability.

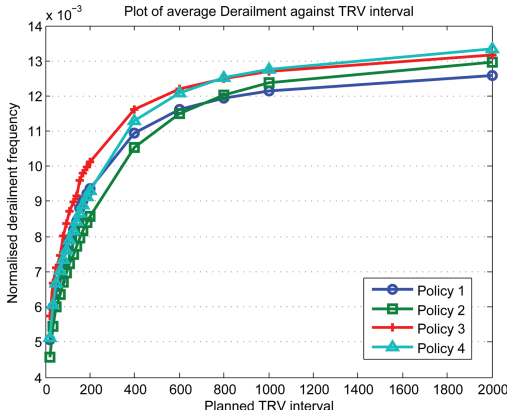

Figure 14. The number of derailment against TRV interval in one year.

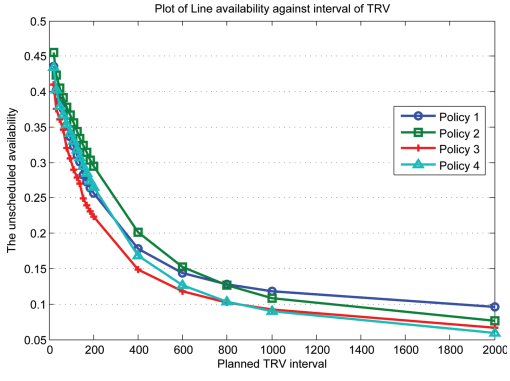

Figure 16. Unscheduled availabilities against TRV intervals.

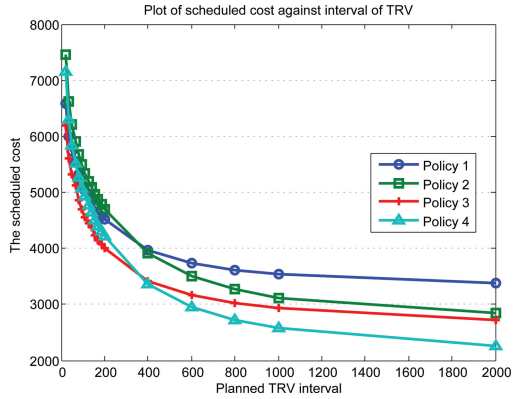

Figure 17. Scheduled cost against TRV intervals.

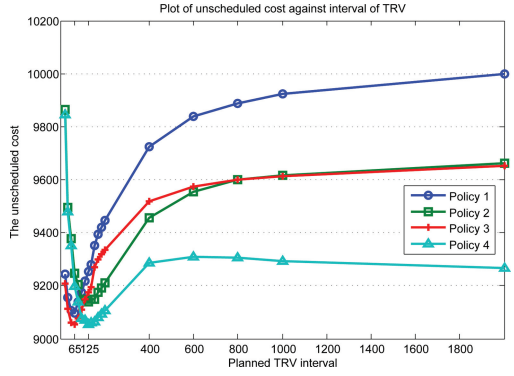

Figure 18. Total cost against TRV intervals.

derailments and a shorter visual inspection interval can lead to a lower number of derailments. If TRV interval is within range from 300 units to 700 units, policy 1 and policy 2 are better than policy 3 and policy 4, policy 2 has a lower number of derailments than policy 1; if TRV interval exceeds 700 units, policy 1 is better than policy 2.

5 CONCLUSIONS

A modeling framework is presented for a track block section. System degradation and system operation are taken into account for the system performance evaluation. A hierarchical CPN model is built according to this framework, which consists of component working model, deterioration model, inspection model and maintenance model. Monte Carlo simulations are carried out to obtain the solutions.

CPN is a flexible modeling tool due to the concept of color set, for example, the track deg-

radation states are defined by color set COMP as shown in Figure 6, the preventive maintenance thresholds (the parameter 'k', 'l' and 'm' in Fig. 9) are defined by global references. In addition, function *ThetaTRV* can be defined as an input of the CPN model to combine the different inspection schemes.

The model can be used to evaluate the strategies for risk-based maintenance and cost-effective maintenance. It can also evaluate the performance measures according to the practical inspection requirements, that requires visual inspection to be 168 hours and the maximum train recording car interval to be 3 months.

Analysis of the process of unloading containers at the inland container terminal

M. Zając & J. Świeboda
Wroclaw University of Technology, Wroclaw, Poland

ABSTRACT: Intermodal transport is a complicated way of transportation, where there is usually over a dozen means of transportation and many modes of transportation. As can be easily seen cargo is subjected redoubled number of transshipments in comparison to the number of vehicles, which is transported. Very popular transport relation Asia—Europe shipping takes around 25 days, while terminal operations take up 17% of the time transferring cargo container. In all decisive importance to the planning of operations to plan the operation of machinery—planning is affected by the resulting time. The purpose of this article is to demonstrate the direct impact duration elements of the service on the total time of the process.

1 INTRODUCTION

After the difficult years of 2008–2010 container transport becomes stronger. In Poland it is visible seeing more and more new container handling transshipment points. Currently, the total container turnover in the market of intermodal transport is estimated by the owners of intermodal companies over 2.5 million TEUs per year (for comparison, in 2007, there are approximately 1.7 million TEU).

Modern combined transport terminal is more than a simple transshipment point. It develops in the creation of centers freight with a wide range of services (Braekers, 2011 and Jakubowski, 2009). Sea terminals are to be run in such a way as to reduce to a minimum residence time of the loading units within the terminal. Using sophisticated technology, handling, such as full automation of the process can substantially reduce the time of cargo handling, eliminate errors, increase the level of safety and reliability (*Ambrosino & Caballini & Siri, 2013 and* Boysen & Fliedner & Jaehn, 2011 and Gambardella & Rizzoli & Zaffalon, 1998). Problems of vulnerability was mentioned also in (Vališ & Koucký & Žák, 2012 and Vališ & Pietrucha-Urbanik, 2014). These technologies are extremely expensive and are not widely used. In smaller ports, high throughput is achieved by streamlining operations. The inland terminals link transport and storage functions. Problem in intermodal transshipment hubs is linked with choosing appropriate method of container warehousing (Zajac, 2011a and 2011b). Very often it is necessary to move container several times from one point to another during process of storage. The results are more expensive container service and probability that containers can't be easy available then are needed.

The increase in intermodal transport is a natural phenomenon in the face of the *White Paper on Transport* recommendations. Nevertheless, intermodal transport as a logistics process requires scientific work and research, the effect of which is to strengthen the competitiveness of intermodal transport to the traditional road to the carriage of highly processed goods.

Intermodal technology functioning is mainly based on experience in Poland. Over the years, intermodal transport was underrated way of transporting goods. Its principal advantage lies in combining functionality with the ability to cargo transport and storing in intermodal transshipment point. Intermodal transport technologies are shown in (Nowakowski & Kwaśniowski & Zając, 2008). Design rules container terminals are presented in the (Steenken & Voss & Stahlbock, 2004). Both publications are land-based container terminal.

Both the technology and design rules terminals do not show know how to manage the movement of cargo units inside the terminal. However, the functioning of the inland container terminals is far different from the typical container ports on which there is a lot of information in foreign literature (Vatanabe, 2005).

Sea terminals are to be run in such a way as to reduce to a minimum residence time of the loading units within the terminal [8]. This is due to the need for high bandwidth as a result of the conditions established infrastructure and container turnover. Using sophisticated technology, handling, such as full automation of the process can substantially reduce the time cargo handling, eliminate errors, increase the level of safety of the process. These technologies are extremely expensive and are not

widely used. In smaller ports, high throughput is achieved by streamlining operations. One of the solution is increasing tariff for storage of cargo at the port (Vis & Koster, 2003).

Intermodal technology is mainly based on experience in Poland. Over the years, intermodal transport was underrated way of transporting goods. Its principal advantage lies in combining functionality with the ability to cargo transport and storage in intermodal transshipment point. Intermodal transport technologies are shown for example in the development of (Nowakowski & Kwaśniowski & Zając, 2008).

Both the technology and design rules terminals do not show know how to manage the movement of cargo units inside the terminal. However, the functioning of the inland container terminals is far different from the typical container ports on which there is a lot of information in literature (Braekers, 2011). There are some element of terminal operation management and reliability (Nowakowski & Werbinska-Wojciechowska, 2012). There are also some technical aspects described in (Vališ & Vintr & Malach, 2012 and Vališ & Žak & Pokora, 2014).

Sea terminals are to be run in such a way as to reduce to a minimum residence time of the loading units within the terminal. This is due to the need for high bandwidth as a result of the conditions established infrastructure and container turnover. Using sophisticated technology, handling, such as full automation of the process can substantially reduce the time cargo handling, eliminate errors, increase the level of safety of the process. These technologies are extremely expensive and are not widely used. In smaller ports, high throughput is achieved by streamlining operations. One of the solution is increasing tariff for storage of cargo at the port.

The inland terminals, as mentioned previously, links Transport and storage functions. In this case, the tariff for the storage of empty containers or loaded is decreasing. Both types of containers are stored within a storage space. Problem in intermodal transhipment hubs to adopt an appropriate method of storage of intermodal units, the implementation process container depots, so that there was no need of their translocation to another storage location. In reality Polish intermodal hubs, stacking containers and large volume of financial and intuitive decision-making, such situations often occur. This is the reason for the formation of additional costs and sometimes even necessary, adjusting the container several times.

In the international literature, little space is devoted to the theme of inland terminals. Generally it is a showcase of new technologies intermodal attempt to analyze their applicability, detailed technical solutions. There is no literature on the process of storage. There have been no analysis of the arguments has to be taken into account when storing. Do not analyzed the information contained in the transport documents for their use in the management of places components in intermodal transshipment node. We can say that this area of knowledge is not recognized, and the practice sets the rules in force here. The article presents the characteristics of unloading operations of containers in relation rail wagon—yard. Presented times perform the duties of the components and their impact on the whole process.

2 PROCEDURES CHARACTERISTICS

The inland terminals storage containers usually up to three layers to four layers vain. The storage yard in a terminal is usually divided into rectangular regions called storage blocks or blocks. Each row typically Consists of over twenty 20 -ft container stacks stored lengthwise end to end. For storing a 40 -ft container stack, two 20 -ft stack spaces are used. Load distribution and hence the allocation of storage is done by machine operators. This is done on the basis of their experience and relying on the information derived from public goods. Basic information to be taken when allocating loads are:

- whether the container is empty, loaded, refrigerated, tank, ADR/RID;
- the size of the container,
- the expected storage time charge on the terminal,
- the recipient,
- the gross mass,
- operator.

The essential part of machine operator's work is to memorize and consistently putting in a storage container so as not to turn the download does not require adjustment of the upper layers of containers. This task is difficult and involves unreliability. This problem increases the lack of information from one of the main customers of schedule downloads terminal at the time of arrival of containers by rail to unload the cargo units. As a result, the containers are unloaded in free space components (cached), and after being informed of the date of delivery segregated and placed in the correct order.

Schedules cargo operations are difficult to define because they vary depending on the sender or recipient, traffic conditions, etc., although this time the service should be as short as possible. Therefore, previous planning manual handling is often very difficult, if not impossible, due to random factors beyond the control of the operator terminal. To transfer the containers in the number

of hours between scheduled transport services large batches, the temporary storage of containers is essential. Meets the buffer function terminals. Unfortunately, the container terminal is limited capacity and technology used transport units, thus piling up more layers to increase capacity. This increases the number of containers in the landfill, but very often difficult to locate the container, and the effective execution of transhipment operations on it. As the number of handled cargo units, there are new problems. With little turnover of the cargo container to find the company was not a problem for those involved in the physical handling of cargo. Today, however, the terminal supports more load and hence there is a possibility of a problem to locate the container that is to be assigned. During the deployment analyze intermodal cargo transshipment node can watch two indicators:

- rotation ratio,
- the intensity of use of the component.

Rotation ratio is the number of operations performed per unit time with respect to one component of the terminal. This means that the residence time of the free—space component may be relatively short, but the number of containers in a given location may be large. This means that the area is heavily used, but due to the large rotation load. Achieving high turnover ratio is desirable for marine terminals, where it counts the technical efficiency of the transport process and land-based terminals, where the number of occupied seats begins to cause complications in the implementation of the basic functions of transport. The intensity of the storage is a busy time of the landfill by the same unit load per unit of time. The smaller the value of this ratio the greater the rotation of the loading unit is characterized by a terminal.

3 CHARACTERISTICS OF THE STUDY AREA

The observations were done in 2014 on one of container terminals in Poland. Observations treat handling relation wagon-yard at the container terminal. Containers were taken from the first or second rail track, then put at the free space on the storage yard in one of the 4 levels. The aim of the research was to characterize the relationships binding site to download and postpone load. Observations were including duration of operation and the distance moved both with load and without.

Figure 1 presents transshipment cycle.

It was assumed that the unloading of the container from the train starts from the application to the operating system needs to perform an operation. Then crane begins the process of setting the drive.

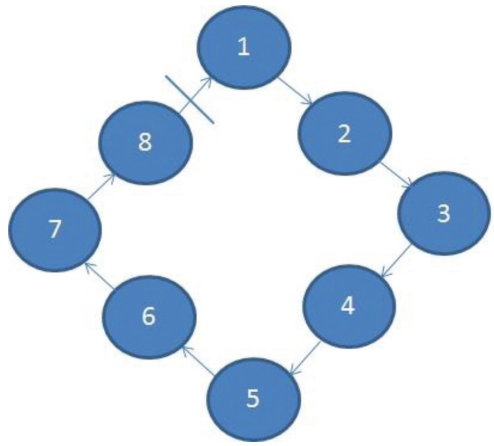

Figure 1. Container transhshipment cycle. 1—setting up the dribe, 2—drive, 3—setting to catch, 4—lifting the container, 5—settitng up the drive, 6—drive, 7—setting for unloading, 8—unloading.

After arriving at the wagon with maneuvering to capture the correct container. Then retrieves the container, and when set to begin driving transport to postpone. The final step is to set aside container at the storage location.

4 THE RESULTS

During the more than 800 observations the distance of transportation was measured and time recorded. Table 1 shows summary information for the group of observations.

As can be seen from the data presented in Table 1 most of the time during the execution of the discharge cycle takes a ride with the cargo, immediately after driving without a load. The total cycle takes an average 133 s reloading while driving is more than 62 s. It can be seen here that one of the fundamental option of shortening the cycle is shortened drive to and with the container. Reloading cycle-times differ depending on the relationship of handling. The Table 2 and Table 3 present results for handling relationships and track—first floor, and track—the fourth floor.

In relationships I track—I floor the average operating time was 123 s. Like the collective results are also driving time was the largest (total 55 s). Due to the experience of the operators turned out to be a very short time—away containers. Due to the visibility of the container, and no need for very precise withdrawal of the unit load on the already standing—another—this time was the shortest of all possible relationships.

Table 1. The overall results of the observation.

Operation	Mean value	Std deviation	Variance
Setting up the drive [s]	17.98	8.48	71.94
Drive [s]	28.45	20.49	419.87
Distance (without) [m]	54.04	38.37	1472.23
Setting to download and download [s]	15.57	6.00	36.02
Setting up the drive [s]	18.57	10.34	106.90
Drive [s]	33.64	17.24	297.12
Distance (with) [m]	65.45	39.82	1585.83
The setting for unloading and unloading [s]	19.00	11.00	121.08

Table 2. Results of the unloading in relation I track—I floor.

Operation	Mean value	Std deviation	Variance
Setting up the drive [s]	16.76	8.86	78.44
Drive [s]	25.29	20.18	407.22
Distance (without load) [m]	45.47	31.99	1023.14
Setting to download and download [s]	14.71	5.16	26.60
Setting up the drive [s]	20.88	17.20	295.74
Drive [s]	30.12	18.98	360.11
Distance (with load) [m]	62.00	42.39	1796.50
The setting for unloading and unloading [s]	15.29	7.74	59.97

Table 3. Results of the unloading in relation I track—IV floor.

Operation	Mean value
Setting up the drive [s]	22.00
Drive [s]	31.50
Distance (without load) [m]	50.00
Setting to download and download [s]	11.00
Setting up the drive [s]	14.00
Drive [s]	26.50
Distance (with load) [m]	20.00
The setting for unloading and unloading [s]	45.50

Unloading on the fourth floor proved to be far more time-consuming. The average duration of the operation was over 150 s., in this case, almost one third the time it took defer the load on a high level. Driving time with load were similar to those obtained with the unloading of the first floor: a little over 55 s. Table 4 contains the time and speed of the crane with load. The observations can be noted that the experience led operators overcome the greatest distance putting the container on the third layer. Regardless of the level of deposition of the load, the speed obtained without charge are—as expected—higher than the load.

Table 4. Time and distance with and without load.

Without load	Time		Distance	
Floor	I track	II track	I track	II track
1	30.12	21.25	62.00	32.50
2	34.45	26.67	71.68	43.33
3	40.64	26.83	71.18	46.50
4	26.50	26.00	20.00	30.60

The studies lead to the following general conclusions:

- If taking account time of operations it does not matter whether the container is deposited on level 1 or level 2.
- Postpone the level 3 lasts longer than half the level of 1–2.

  Putting container on level 4 in comparison to the level 1 is three times longer.
- The difference between putting on levels 1–2 and level 3 allows for passing around 5–10 m.
- The difference between putting on levels 1–2 and level 4 allows the passing of about 50–60 m.

5 SUMMARY

As practice shows decision problem applies to most containers. In addition, during the work simulation should pay attention not only to the time of transhipment single container, but also groups: there may be a situation where it is worth to lose a few seconds for one to gain even a few minutes in subsequent operations.

Implementation of the described research is related to the development of effective methods of reducing the operative time for the container terminal cranes. The result, which seeks to provide the following effects:

- reducing the number of meter hours by shortening cycles of loading.
- reducing the number of operations by 10%.

It is worth noting that the assumption that the cycle will be shorter loading only 1 minute obtain savings in the form of one review per year (terminal, where the project is implemented annually performs about 150 thousand cycles). When reducing the number of operations by 5% we obtain a reduction of another review annually. By reducing the cycle of 1 minute and reduction cycles by 10% saving on fuel inspections and within five years will amount to nearly EUR 550 000.

ACKNOWLEDGEMENTS

The results presented in this paper have been obtained within the project "The model of operations in intermodal terminal" (contract no. POIG.01.03.01-02-068/12 with the Polish Ministry of Science and Higher Education) in the framework of the Innovative Economy Operational Programme 2007–2013.

Reliability based model of the cost effective product reusing policy

A. Jodejko-Pietruczuk & M. Plewa
Wroclaw University of Technology, Wroclaw, Poland

ABSTRACT: Recently it has been a remarkable growth of interest in processes that supports recapturing value from used goods, waste and objects moving in the opposite direction of the supply chain. Minimization of waste production has become an important element of the smart economy. Reusing of products has become a factor of competitiveness for modern companies. This will accelerate the change of the linear production model to circular one where demand can be partially satisfied with new items manufacture or returned products recovery. Reuse of products can bring direct advantages because company uses recycled materials instead of expensive raw materials. The main goal of this paper is to create a reliability based model of the cost effective product reusing policy.

1 INTRODUCTION

Recently it has been a remarkable growth of interest in processes that supports recapturing value from used goods, waste and objects moving in the opposite direction of the supply chain. Minimization of waste production has become an important element of the smart economy. Reusing of products has become a factor of competitiveness for modern companies. This will accelerate the change of the linear production model to circular one where demand can be partially satisfied with new items manufacture or returned products recovery. Reuse of products can bring direct advantages because company uses recycled materials instead of expensive raw materials. The first part of the article contains literature survey, which is a summary of work that has been done around the theme of research.

Based on the studied literature [e.g. Dekker et al. 2004, Fleischmann et al. 1997, Rogers & Tibben-Lembke 1999, Thierry et al. 1995] it is possible to define the area of interest, which includes the following products:

– returns of raw materials, intermediates and final products from the production phase (surplus raw materials, defective products rejected by quality control, by-products and wastes generated in the production process);
– product returns and packaging from the phase of distribution (products damaged during transport, reusable packaging, excess inventory, unsold products);
– decommissioned objects (products returned because of changing the purchasing decision or a qualitative defect, parts replaced during the maintenance process, products that fail during warranty period which repair was impossible and other and waste).

Based on the classification presented in [Thierry et al. 1995] it is possible to specify the following types of recovery:

– direct reuse/resale,
– repair,
– refurbish,
– remanufacturing,
– cannibalization,
– recycling.

Description of the different recovery options was presented in (Fleischmann et al. 1997, Guide 2000, Rogers & Tibben-Lembke 1999, Thierry et al. 1995). Cannibalism has been described in (Fisher et al. 1986, Fisher, 1990, Hirsch et al. 1968, Hochberg 1973, Ormon & Cassady 2004, Simon 1972).

The problem of the design of products suitable for the recovery has been widely discussed in the literature, for example in the following articles (Hoffmann 2001, Ijomah 2007, Jiang 2000, Kang & Jung 2001). Design of recovery-oriented includes avoiding the creation of irregular shaped objects, which are more easily damaged in the distribution phase and the reduction and standardization of connectors to facilitate the process of removal.

Forecasting the number of returns is also an important part of planning the production process and recovery. In papers [Murayama & Shu 2001, Murayama et al. 2004, Murayama et al. 2005, Murayama et al. 2006] authors present a model of planning the production process, which is in predicting the number of returns based on reliability theory. In the present model, the demand for new products does not depend on the number of returned products. The authors describe the method on the example of a

product consisting of components forming serial reliability structure. The analyzed product can be taken out of service if any component fails or the user finds the product's useless. Object withdrawn from service is disassembled. Components that are suitable for reuse, are sent to the manufacturer of the product.

In the literature one can also find the other models describing the planning and implementation of production and the recovery processes (eg, [Clegg et al. 1995, Dekker et al. 2004, Guide et al. 1997, Guide 1996, Gupta & Taleb 1994]). Review of the literature relating to production planning systems that use remanufacturing as the method of recovery are shown in [Kennedy et al. 2002].

In the literature on is also possible to identify other areas of interest of scientists. In [Zikopoulos & Tagaras 2007] the authors analyze the impact of the quality of the returned products on the costs of recovery processes. In [Kimura et al. 1998] the authors convince the reader of the benefits of shortening product life cycle. They believe that products with short life cycles, such as Single Use Cameras can be easily re-used, because their components do not undergo aging process.

Literature review that have been done so far allowed to define the main shortages of existing reverse logistics models:

- most of models assume single-component product,
- they usually are based on the assumption that recovered products are as good as new ones,
- very few articles optimize the threshold age of returns, but none of them gives any guidelines what kind of recovery technology or method should be applied.

On the base of literature overview the aims of the paper were established. It proposes the model that use reliability theory to optimize manufacturing policy parameters for the case when:

- a new, multi-component object is produced from the mix of new and reused components,
- reused elements are not good as new,
- depending on the age of returns and its reliability characteristics, various actions may be undertaken:
- a direct reusing of the component,
- an element repair, which allows to improve its condition with additional cost, disposal.

2 MODEL OF REUSING POLICY

The model that is presented in the paper is based on the following assumptions:

- A company produces an object composed of two elements (A and B) being in the series reliability structure, so the object fails after any components failure.
- A failure of components occurs independently.
- If the product fails during the warranty period, it is returned to the manufacturer and he has to pay some penalty cost (e.g. the cost of a new product).
- The components may be reused in a new production if are upstate after return and were not reused before (twice reusing is allowable). Thus, every component returned, capable to further work may be:
  - reused without any activities,
  - recovered in order to improve its condition with an additional cost,
  - disposed.

To indicate if the returns should be reused, a producer should estimate the expected profit resulting from using mix of new and old elements instead of the new ones:

$$P(T,\Delta T,T_W) = C_B - C_R(T,\Delta T) - C_M - C_O(T,\Delta T,T_W) \quad (1)$$

$$C_O(T,\Delta T,T_W) = c_o\left[F_1(T,\Delta T,T_W) - F_2(T_W)\right] \quad (2)$$

where: $P(T, \Delta T, T_W)$ = the total expected profit resulting from the components' reusing, T = age of a returned element, ΔT = the period by which the item will be rejuvenated by additional recovery operations, T_W = the warranty period of the object, C_B = the cost of a new element B, C_R = the total cost of all activities including additional recovery operations: decomposition, cleaning, preparing of the returned B element to reusing in a new production, C_M = the cost of element indication before reusing, C_O = the expected cost of claims resulting from lower reliability of the product in the warranty period, c_O = the unit cost of a product failure during warranty period, $F_1(t)$ = unreliability function of the product with a reused component, $F_2(t)$ = unreliability function of the object comprised of all new elements.

The cost model of the reusing policy (Eq. 1) includes potential savings and losses of a producer. The savings are the effect of a lower cost of returned element than a new one but the price difference has to cover all the costs necessary to reuse product components: cost of elements identification, recovery activities and cost of lower reliability of a reused element in a warranty period. A manufacturer may consider four basic options:

- to make a new product from new elements,
- to produce the new object from the mix of new and old components,
- to manufacture the product composed of "old" elements but offered as "new" one at the market,

– to manufacture the product composed of "old" elements and offer it with another warranty or pricing conditions than the new product at the market.

Moreover, in some cases a producer deciding to reuse returns may take some additional operations "changing" the age of a returned component understood as the age from the reliability point of view. Usually, these operations generate some additional costs which should be included when one consider the profitability of the reusing policy.

Following the assumptions presented at the start of the chapter, when a product with reused components has the series reliability structure, its unreliability functions $F_1(t)$, $F_2(t)$ should be expressed:

– for the case when both elements installed in a product are new:

$$F_2(T,T_W) = 1 - R_B(T_W) \cdot R_A(T_W) \tag{3}$$

– for the case when single element (B) is reused without any rejuvenation operations after return:

$$F_1(T,T_W) = 1 - \frac{R_B(T+T_W)}{R_B(T)} \cdot R_A(T_W) \tag{4}$$

– for the case when A and B elements are reused without any rejuvenation operations after return:

$$F_1(T,T_W) = 1 - \frac{R_B(T+T_W)}{R_B(T)} \cdot \frac{R_A(T+T_W)}{R_A(T)} \tag{5}$$

– for the case when returned and reused element B has been rejuvenated for ΔT:

$$F_1(T,\Delta T,T_W) = 1 - \frac{R_B(T-\Delta T+T_W)}{R_B(T-\Delta T)} \cdot R_A(T_W) \tag{6}$$

– for the case when both (A and B) returned and reused elements have been rejuvenated for ΔT:

$$F_1(T,\Delta T,T_W) = 1 - \frac{R_B(T-\Delta T+T_W)}{R_B(T-\Delta T)} \cdot \frac{R_A(T-\Delta T+T_W)}{R_A(T-\Delta T)} \tag{7}$$

where: $R_A(t)$ = reliability function of the element A, $R_B(t)$ = reliability function of the element B.

The formulas 3–7 describe all the production possibilities: new components, mix of new-old, old components used in a new product. If a producer has sufficient data required to estimate the reliability functions of product elements, the calculations of potential profit from the reusing policy should not be very difficult for a given cost components and the length of a warranty period.

The issue that may raise objections is an estimation of the returns' age T, whose value must be assumed in calculations. The age of returned element T in equations 3–7 may be approximated by its expected value, according to the following formula:

$$E(T_B) = \int_0^{T_W} t \cdot f_A(t) \cdot R_B(t) \cdot dt \tag{8}$$

where: $E(T_B)$ = the expected age of returned B elements, $f_A(t)$ = probability density function of the time to failure of the A element.

The probability of the return of a reusable B component during a warranty period is equal zero for products, whose lifetime is longer than the warranty (element B is not returned) as well as for products returned because of a failure of B element (element B is downstate and cannot be reused). For this reason in some cases the better estimation of the expected age of a reusable component is given by equation:

$$E(T_B) = \frac{\int_0^{T_W} t \cdot f_A(t) \cdot R_B(t) \cdot dt}{\int_0^{T_W} f_A(t) \cdot R_B(t) \cdot dt} \tag{9}$$

3 THE AGE OF REUSABLE COMPONENTS

The cost model presented in the previous part of the paper may be applied in the profitability analysis of various options of the reusing policy, nevertheless it requires to know or assume all the parameters of the policy Most of them are decision variables of a producer or depends on market environment, e.g. warranty period length, cost components, etc. and may be determined more or less precisely. The hardest to estimate are parameters pertaining to reliability characteristics of manufactured product components. Moreover, in combination with warranty features, they have direct impact on the number and the age of reusable returns and thus—on the efficiency of the reusing policy.

Undoubtedly the fact whether reusable components appear in a manufacturing system is the key factor for potential of a reusing policy application. The aim of this chapter is to present the most significant factors of the reusing policy, which determine the ability of a production system to reuse elements, i.e.: the length of a warranty period, reliability characteristics of co-components and resulting from the both: the expected age of reusable returns.

The influence of a warranty period length on the expected age of a reusable component appearing in a production system may be observable in Figures 1–2. The longer warranty period causes growing probability of return as well as the growing age of elements which may be reused. The Figure 1 also depicts the relationship between the expected age and the mean time to failure of the element which may be reused (MTTFB), whereas the

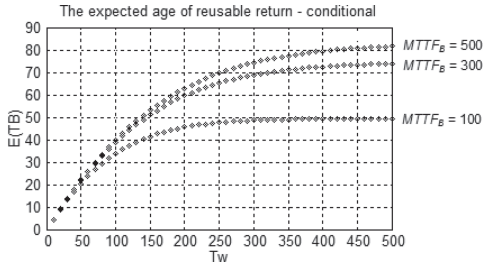

Figure 1. The expected age of a reusable element B (Eq. 9) for various warranty periods (T_W) and mean time to failure ($MTTF_B$) of the element ($MTTF_A = 100$).

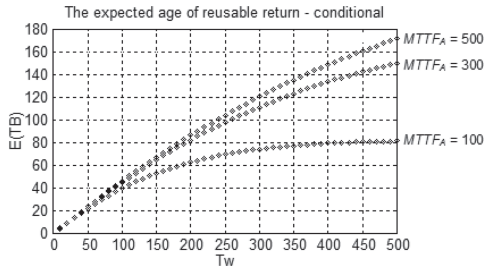

Figure 2. The expected age of a reusable element B (Eq. 9) for various warranty periods (T_W) and mean time to failure of its co-component ($MTTF_A$), ($MTTF_B = 500$).

Figure 2—between the age and the mean time to failure of its co-component (MTTFA). It may be clearly seen that MTTFA is the main determinant of the expected age of returns (E(TB)) for the same warranty conditions: an element may be reused in a new production only if it returns from a market because of a failure of an another component according the assumption of the series reliability structure. The same result was observed while study of relationship of the expected age of a reusable element and its failure rate as well as a failure rate of a co-components. A change of a failure rate of co-component A caused more rapid changes in the number and the age of reusable elements than similar changes in reusable element B.

The second study conducted in this part of the paper pertains the better estimation of the expected age of reusable returns elements which may be used in profitability model of the reusing policy (Eq. 1–7). The equation 8 describes the expected age of returned elements unconditionally, whilst equation 9 determine the expected age of elements conditionally, considering only those which are returned. For the majority of cases the conditional way (Eq. 9) gives much higher results than the another. In order to assess usefulness of the both approaches in the analysis of the reusing policy profitability, simple Monte Carlo simulation has been done and convergence of obtained results was tested for a chosen set of numerical experiments.

The figures below present the residual reliability of a reusable component B, understood as the conditional reliability of the reused element during the next warranty period. Figures 3 and 4 depict two cases characteristic for the all research results: the unconditional expected age of the reused element is more adequate to predict reliability of product containing "old" elements. The fact has been confirmed for constant failure rate of product components, independently on their MTTF or the warranty length (Fig. 3). The conditional expected age of a return (eq. 9) is better to use (Fig. 4, TW < 150) when one wants to predict the residual reliability of the mixed product comprised of elements under the two conditions:

– elements have a rising failure rate,
– reusable element has a comparable or lower MTTF than its co-components.

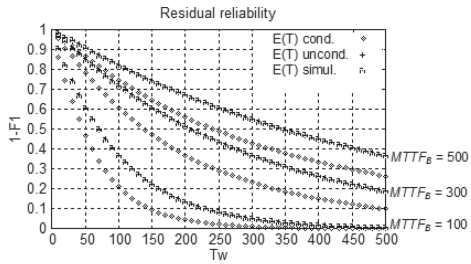

Figure 3. The expected age of a reusable element B obtained according to Eq. 9 (E(T) cond.), Eq. 8 (E(T) uncond.) and from Monte Carlo simulation (E(T) simul.) for constant failure rate of both co-components ($MTTF_A = 100$).

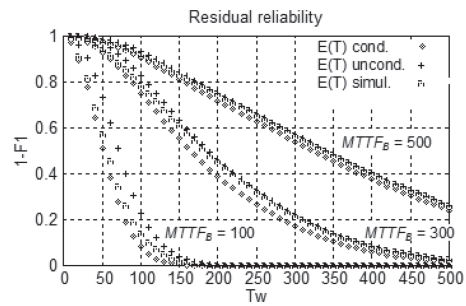

Figure 4. The expected age of a reusable element B obtained according to Eq. 9 (E(T) cond.), Eq. 8 (E(T) uncond.) and from Monte Carlo simulation (E(T) simul.) for rising failure rate of both co-components ($MTTF_A = 100$).

4 DIFFERENT RECOVERY OPTIONS

The conclusions drown in the previous chapter may be applied when a producer considers various recovery options of returned element. One of them is to mix new and old components in a product and offer it in the market as if it was the new one. In this part of the paper some results of such strategy will be shown.

The cost model of the reusing policy (Eq. 1) assumes the two cost components directly combined with recovery options of reusable returns: the cost of recovery operations and the expected cost of increased product unreliability during the next warranty period of a product. The relationship between them is inversely proportional, but not necessarily linear and continuous. The first cost component depends only on the range of recovery operations and is some function of the period by which the item will may be rejuvenated (ΔT). The second—the cost of increased reliability depends on the same factor (ΔT), the age of retuned component and a length of a warranty period. On the foundation given in the previous chapter, the age of reusable element may be estimated as a function of the length of a warranty period, thus the recovery options may be quite easily analyzed. If one considers any rejuvenating operations, should calculate the following costs' relation:

$$P_R(\Delta T, T_W) = \left[F_1(\Delta T, T_W) - F_2(T_W) \cdot c_o - C_R(\Delta T) \right] \tag{10}$$

where: P_R = the profitability of element recovery.

If the above coefficient (PR) is positive for any value of ΔT, recovery operations should be taken when it comes to cost minimization. Figures 5, 6 present the profitability analysis for exemplary cases of recovery actions which may be applied in the case of reusable return installed in a new product. The Figure 5 shows profitability for the element rejuvenation reused in a product, composed of two series elements, while Figure 6 depict the same rejuvenation possibilities but for the element, which is single in a new one-element product. Because the warranty period for the both analyzed cases is chosen to be very long (TW = 200, MTTFA = 100, MTTFB = 500), the profitability of recovery is very high when B element is installed in as an one-element product (Fig. 6), whereas there is almost no point in recovering element in the two-component, series system (Fig. 5). Neither restoring activities will be useful because of the low reliability of the co-component during a warranty period, thus it is extremely important to study the potential of the reusability policy considering its comprehensive influence on the production results.

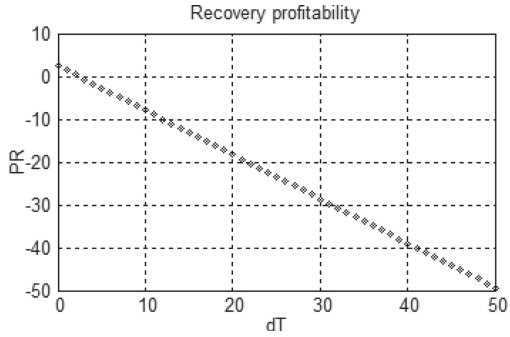

Figure 5. The profitability of rejuvenation of returned B component (of dT period) in a product composed of the mix of new and old elements.

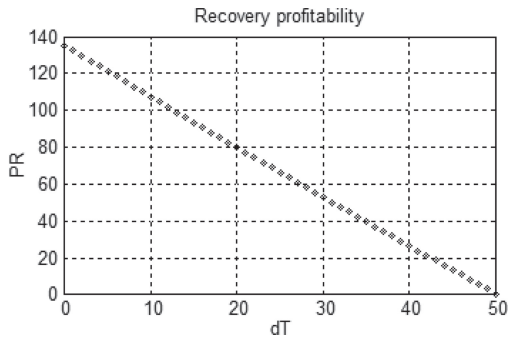

Figure 6. The profitability of rejuvenation of returned component (of *dT* period) in one—element product (assumed unit costs: $c_o = 1000$, $c_r = 1$ dT).

5 SUMMARY

The cost model has been presented and developed to the cases of various production options (Eq. 1–7).

In the next step the analysis of the expected age of reusable returns has been proposed. On this foundation two alternative estimations of the age have been formulated and used in the subsequent part of the paper. The paper ends up with the proposition on how to assess the profitability of various recovery options and the exemplary results of the assessment.

Asset maintenance optimization: The case-study of an offshore wind farm

Y. Bot & D. Azoulay
BQR Reliability Engineering, Israel

ABSTRACT: Offshore wind farms are very expensive assets, not only to design and build, but also to operate and maintain. Their remote location, coupled with weather's constraints and harsh marine environment, and the lack of adapted access equipment, make their maintenance complicated and expensive due to high repair costs, high transportations costs and painful production losses due to high downtime.

More generally, the offshore wind technology is in a stage of development where its economic worthiness has still to be fully demonstrated, and numerous projects are largely supported by governmental subsidies (European 2011). This lack of maturity is evident, for example, through the numerous reliability problems of wind turbines components.

This article aim is to explain this industry challenges and a new technology that can help to reduce maintenance cost.

1 INTRODUCTION

1.1 *Summary*

Offshore Wind Farms are very expensive assets, not only to design and build, but also to operate and maintain. Their remote location, coupled with weather's constraints and harsh marine environment, and the lack of adapted access equipment, make their maintenance complicated and expensive due to high repair costs, high transportations costs and painful production losses due to high downtime.

More generally, the offshore wind technology is in a stage of development where its economic worthiness has still to be fully demonstrated, and numerous projects are largely supported by governmental subsidies (European 2011). This lack of maturity is evident, for example, through the numerous reliability problems of wind turbines components.

Both the inherent aspects of the offshore wind industry and the reliability problems it is facing contribute to the high Operation and Maintenance (O&M) costs and eventually hinder its competitiveness compared to other sources of energy. It is commonly assumed that up to 25% of the cost of energy produced by offshore wind turbines is due to O&M activities, which is twice as expensive as onshore installations (Sonderkar 2013).

This paper describes a methodology to optimize the maintenance strategy of offshore wind farms in order to minimize life cycle costs and maximize availability and performance. The ApmOptimizer, developed by BQR Reliability Engineering (BQR) is the software tool used for modelling, reliability analysis, cost and performance estimations and maintenance optimization.

For the purpose of the demonstration, a case study of a typical wind farm is defined. A detailed model is built that accounts for numerous operational, cost and maintenance parameters. The ApmOptimizer optimization modules are then implemented for optimizing the preventive maintenance, periodical inspections, condition-based maintenance, and spares levels. Starting from a baseline scenario, several optimization steps are investigated, following a typical RAM/LCC analysis assessment procedure: Operational Availability, Operational Downtime, Lifecycle O&M Costs and produced Energy are used as the main metrics. The optimal maintenance strategy is obtained from an exact optimization process and not from Monte Carlo simulations that can provide only an approximate assessment for a user-inputted strategy.

The study shows that by following several optimization steps, the wind farm performances can be significantly increased, to a level that makes the cost of produced energy more competitive. The influence of modelling parameters like failure distribution and degradation process is also investigated.

1.2 *Background on the apmOptimizer*

The apmOptimizer is a Modelling, Analysis and Optimization tool designed to bring Asset

maintenance to an optimal state, maximize Availability and minimize Cost of Ownership over lifetime. Optimization algorithms are implemented to find the optimal solution among all possible outcomes, according to the problem constraints and targets. The apmOptimizer is not based on Monte Carlo method whose results accuracy is function of the number of calculated simulations and dependent on user's best guess, but instead performs exact analytical computations from the input data, including failure rate distribution and reliability model (serial, parallel, standby redundancy, K out of N). The optimization process itself is not user-driven since the space of possible solutions is built from these exact computations. This guarantees that even non-evident solutions can be found out.

In this work, the ApmOptimizer is used to build the model of a typical wind farm and calculate its Reliability Availability Maintainability (RAM) parameters, as well as Lifecycle Costs (LCC). The Energetic Performance of the wind farm is also computed and the cost of energy extracted. The apmOptimizer model can integrate the most specific features of a wind farm and of its maintenance operations: accessibility limitations, weather variability, high cost of downtime, planned and unplanned maintenance etc. Although this is not done in the present work, operational data from actual wind farm (maintenance records, log book, sensors readings) can also be used for a better assessment of failure distribution.

After defining and characterizing a baseline model, several scenarios have been created that successively investigate the influence of the preventive inspections, preventive replacements, and inventory level. Each of these scenarios is provided to the ApmOptimizer for optimization and RAM/LCC and Performance Metrics are compared.

2 DESCRIPTION OF MODEL

A complete description of the input parameters being out of the scope of this paper, only a brief review of the main elements is provided here. The authors would like to highlight the fact that data used in this work was obtained from publicly available sources and unavailable data was assessed by engineering judgment.

2.1 *Wind farm elements*

The considered system is a 240 MW wind farm composed of 80 generic wind turbines each one having a rated power of 3 MW, one offshore substation and submarine cables. Turbines are grouped in 8 clusters (radials) that each contains 10 WT and cables. The farm is located at a medium distance of 30 km from shore. The Wind Farm (WF) is operating on a 24/7 basis, with an expected lifetime of 20 years. Since this paper is focused on evaluating the costs related to O&M activities only, it is assumed that the WF is completely operational from year 1 and that commissioning and decommissioning phases are not considered for cost analysis.

It is assumed that each 3 MW wind turbine is pitch-regulated, variable speed, with gearbox installed and is modelled by a breakdown structure—see Figure 1, adapted from the Reliawind project (Relia 2010). For the sake of simplicity, the breakdown tree is limited to assembly level and sub-assemblies and components are not modelled.

2.2 *Failure and reliability parameters*

The global WT failure rate was assumed to be 3.8 failures/turbine/year, based on an initial onshore value of 1.5 and conversion coefficients K1 = 1.75 and K2 = 1.447 for environmental stress and near shore location respectively (Karyotakis 2011). The components contribution to total wind turbine failure rate was then obtained from (Reliawind 2010), where exponential distribution is assumed.

In accordance with (Maples 2013) approach, we define for each element of the wind turbine several generic Failure Modes (FM) and for each failure mode a Failure Ratio (FR). For example, the Gear Box (GB) has 3 failure modes defined as shown in Table 1.

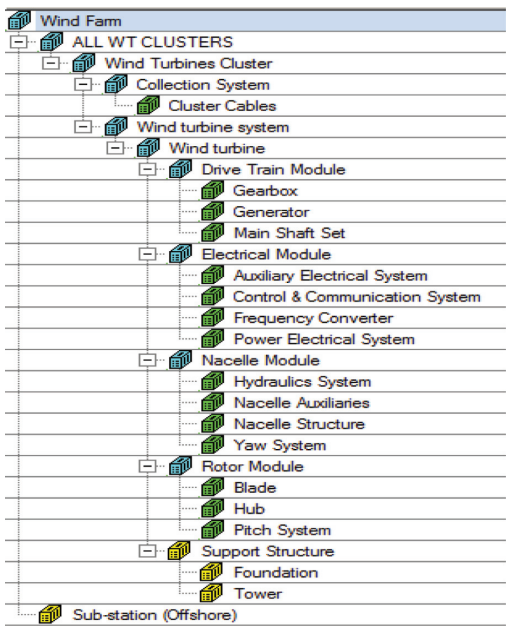

Figure 1. Wind farm breakdown (screenshot).

Table 1. Gearbox failure modes.

Name	FR	Detectability	Type	Degradation to failure, hrs	Deviation
GB-1	0.45	Evident	–		
GB-2	0.45	Hidden	Gradual	20000	+/–50%
GB-3	0.1	Evident	–		

The failure modes having some inspection tasks are defined as hidden (others are evident failure modes), meaning the failure cannot be detected until an inspection is performed. Failures detected by condition monitoring equipment are considered as evident. Additionally, the degradation process of hidden failure modes is modelled by defining a "mean time from degradation start to failure", as well as a "deviation" parameter representing the uncertainty on the degradation process.

2.3 *Maintenance tasks and resources*

The failure modes are assigned some maintenance tasks and maintenance resources required to restore the equipment in accordance with (Maples 2013).

The costs of personnel, support equipment, materials and other resources are defined in libraries and allocated to maintenance tasks. The wind farm is maintained by 20 Maintenance technicians that work 12 hr per day, 350 days a year with a cost of 70€/hour. Operations personnel (located in a control room) is composed of 3 teams of 3 operators (8-hr shift) with a cost of 50 Euros/hr.

2.4 *Maintenance locations*

Most of the maintenance tasks are performed on-site and only the heaviest repair tasks like blade or gearbox repair are performed at an on-shore maintenance facility. Spare parts are also stored in this facility, where they arrive from different suppliers or after repair. Spares procurement is "on-demand" and a time delay that accounts for production and/or administrative delays are defined for every replaceable item. For example, the blades procurement delay is 6 days. The maintenance locations and transportation between them are defined in the ApmOptimizer through the maintenance map shown in Figure 2.

Between the wind farm and the maintenance facility, several access vessels are defined:

– A cable laying vessel is used for cables,
– A Jack-up vessel for large parts
– A workboat access vessel for transporting personnel
– Diving support vessel for inspecting foundations

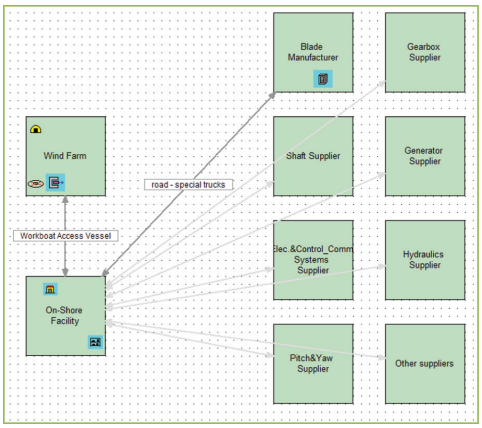

Figure 2. Maintenance synoptic map (screenshot).

Wind turbines are equipped with an internal crane that can handle small parts, while larger parts require use of the Jack-up vessel.

Supply of spare parts to maintenance facility is assured by regular truck with an average transportation time of 20 hours except for the blades where a special truck is assumed with a time of 120 hours.

2.5 *Environmental parameters*

The Wind variability is the most influential factor on the energy production. Its variation is mostly seasonal and largely studied in the literature (Morgan 2011). In the present case study, wind speed variability is accounted on a yearly basis in the energy production module by assuming a wind speed density function of Weibull type, with scale parameter $A = 8.09$, and shape parameter $k = 1.96$ (Redemakers 2002) and a rated power output curve of the Vestas V90 3 MW WT, as shown in Figure 3. By combining this data with the reliability metrics of the Wind farm components, the total produced energy at wind farm level and its cost can be extracted.

An Initial performance computation yields an ideal (no failures) annual energy production of 960096 MWh.

The second major impact of the wind variability is its delaying of maintenance operations. This is

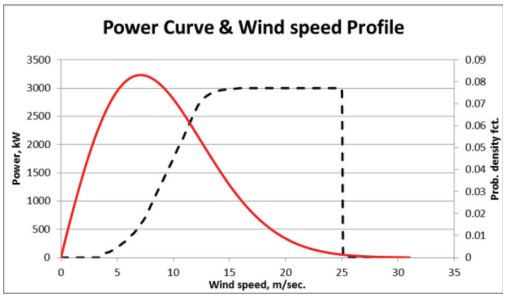

Figure 3. Assumed WT power curve and wind speed distribution.

accounted in our study by additional mean transportation time delays depending on the transportation vessels.

3 BASELINE SCENARIO

3.1 *Initial maintenance strategy*

The basic assumptions of the initial maintenance strategy are described hereunder:

- Inspections of all components are performed once a year for all components.
- When an inspected item has a too high degradation or has failed, a spare is ordered from stock.
- If spare is available in stock, it is sent to wind farm with required maintenance resources by using the appropriate vessel; if not, it is ordered from supplier.
- Stock delay due to administrative constraints is assumed to be 24 hrs.
- Suppliers delays are item dependent (several days in all cases)

Transportation delays incorporate: mobilization time, transportation time, positioning time, and an assumed weather variability delay:

- When spare arrives at the wind farm, item is removed and replaced by the new one
- Failed item is taken back onshore for repair at repair facility according to defined tasks. A repair delay (for administrative procedures) of 2 days is assumed in addition to repair time.
- Repaired item is made available in stock.
- Some items have repair condemnation, meaning they can be repaired only a limited number of times, before they are disposed of. In that case, a new spare is ordered.

3.2 *Analysis results*

Computations are performed to extract the main characteristics of the wind turbine: Reliability metrics, Performance Metrics and Cost Metrics. Figures 4 and 5 show the contribution of each component to the total failure rate and to the total computed downtime.

The pitch and yaw systems are clearly the main contributors to the downtime, along with the generator and gearbox. This is mostly due to a relatively high failure rate combined with a high turnaround time: when a part has to be replaced, the time for the jack-up vessel to be available and to reach the wind farm is very high and in the meantime, the wind turbine is not operational. On the other side, components with similar failure rates like frequency converter contribute much less to the downtime since spare parts are brought to site by faster workboat vessels. In addition, the limited number of spares in stock is also a cause for downtime since more spares may be necessary for repair than available at stock, thus creating a spare waiting time. The spares problem is addressed in §4.3.

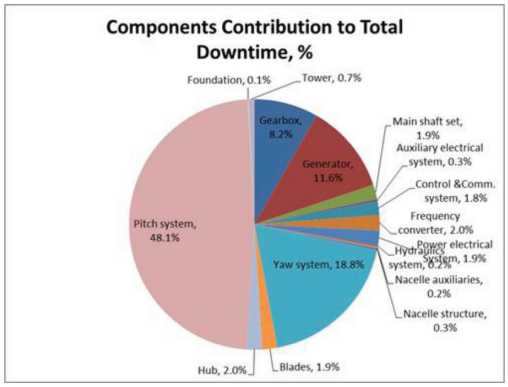

Figure 4. Components contribution to total failure rate.

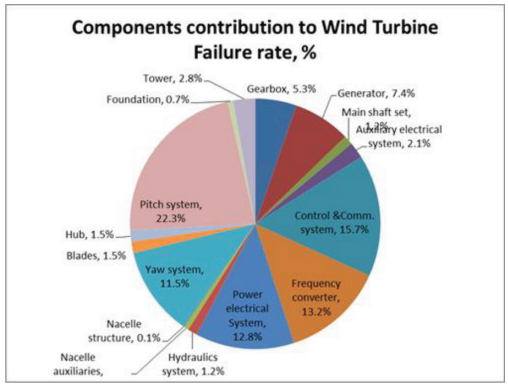

Figure 5. Components contribution to total downtime.

Table 2. Summary of baseline and optimized scenarios results.

Scenario	Availability	Number of inspections per turbine	Energy produced, MWh	Capacity factor, %	O&M costs, M€	CM costs, M€	PM costs, M€	Revenue losses, M€	Cost of energy, €/MWh
1	80.0	20	763697	36.3	23.4	20.0	2.0	18.6	31
2	87.3	115	833426	39.6	16.9	14.7	0.9	12.0	20
3	91.4	79	880117	41.9	13.4	10.9	0.9	7.59	15
4	93.6	79	889666	42.3	12.3	9.8	0.9	6.7	14

The resulting WT availability is 80%, and the energy produced by the whole Wind Farm is 763697 MWh/year at a cost of 23.4 M€ (O&M only). The resulting cost of energy is 31€/MWh produced, and the capacity factor of the wind farm is 36.3%. See Scenario 1 in Table 2.

4 OPTIMIZATION SCENARIOS

4.1 *Inspections optimization*

The inspection schedule of the baseline scenario gives an identical weight to each WT component. While this approach is not unusual in existing installations, it is somewhat unjustified. An adapted inspection schedule should be able to improve the system availability by accounting for the different reliability rates and degradation process. The Inspection Optimization module of the ApmOptimizer is used for performing the optimization, where optimization objective is the minimization of total costs, i.e. maintenance costs, failure damage costs and downtime costs (revenue losses). Optionally, it is possible to define minimal required availability or reliability at component or system level. Since inspections are planned in advance, required spares can also be ordered in advance and provided on time.

The optimization results in the optimal inspections schedule shown in Table 3.

The interval unit is weeks, such that for example the optimization recommends performing inspection on the yaw system every 30 weeks. User is free to accept these recommendations or not, according to its own judgment. When possible, inspections are grouped in order to reduce cost. After accepting the recommendations, the resulting RAM/LCC and Production parameters are computed, see scenario 2 in Table 2. Optimization yields very significant results: the WT availability increases by 7.3 points, which translates in a 9% increase in energy production. From the cost perspective, the effect is even more evident through a 26.5% reduction in corrective maintenance costs, as well as a reduction in preventive maintenance costs due to better oriented inspections although much more inspections are performed (inspections cost depends on equipment). Overall, the cost of produced energy is reduced by about 30%.

Table 3. Optimal inspections schedule.

Inspections Schedule

Inspection interval (in PMU)	Interval in operation hours	Inspection session name
14	2352	Pitch System
30	5040	Yaw System
35	5880	Control & Communication System
40	6720	Frequency Converter
45	7560	Generator, Power Electrical System
63	10584	Gearbox
200	33600	Tower
210	35280	Blade, Hub
270	45360	Main Shaft Set
300	50400	Auxiliary Electrical System
540	90720	Nacelle Structure
600	100800	Nacelle Auxiliaries

The advantage of performing an optimization through an optimization algorithm, versus using Monte Carlo type simulations is clearly seen by looking at the proposed inspections schedule. Optimization algorithm is powerful enough to yield original solutions that provide the strongest cost reductions and performance improvements.

4.2 *Condition monitoring system scenario—preventive maintenance optimization*

The effectiveness of implementing a CMS system is investigated here. CMS systems are useful in the case of offshore farms since they provide operator failure detection and identification, and enable to schedule a repair/replacement with much more precision. However, these systems are still expensive and do not always give a clear picture on what is really happening in the turbine.

In the present scenario, we assume that a CMS is installed on the following items: gearbox, pitch system and yaw system (the main downtime drivers) and that their degradation is continuously measured. Coupled with an assumed prediction model, they enable to predict the Time-To-Failure

(TTF) density distribution at a given time, and from then decide for an optimal maintenance planning that best accounts for maintenance costs and other maintenance tasks.

In our model, we assume that the monitored equipment now have a normally distributed failure time (instead of exponential) with an unchanged mean value, thus reflecting the results of the condition monitoring and prediction analysis. The previously defined inspections for the 3 items are cancelled and the Preventive Maintenance Optimization module is now used to find the best schedule to perform preventive replacement.

Again, the optimization objective is a minimization of the total lifecycle costs. Inspections optimization is then updated to adapt the new maintenance schedule. The preventive replacement and updated inspections schedule recommended by the apmOptimizer are shown in Tables 4 and 5.

The three instrumented systems are now subject to replacement only, and it can be observed that the inspections schedule has been adjusted to account for these replacements.

The resulting reliability, performance and cost metrics are summarized in scenario 3 of Table 2.

For the sake of comparison, an average investment cost of 1200€ per CMS system (total CMS cost of 288000€) has been included in the cost computations. Even with this additional cost, the implementation of CMS remains worthwhile and brings a reduction in O&M costs of more than 3.5 M€ per year compared to the previous scenario. However, this improvement has to be tempered by the fact that:

– The introduction of the CMS systems in the wind turbine does affect its reliability, since the CMS may fail as well,

Table 4. Optimal preventive maintenance schedule.

Preventive Maintenance Schedule

	Interval in PMU	Interval in calendar hours	Interval in operation hours	PM session name
	21	3528	3528	Pitch System
	50	8400	8400	Yaw System
	70	11760	11760	Gearbox

Table 5. Updated inspections schedule.

Inspections Schedule

	Inspection interval (in PMU)	Interval in calendar hours	Interval in operation hours	Inspection session name
	32	5376	5376	Control & Communication System
	40	6720	6720	Frequency Converter, Power Electrical S
	42	7056	7056	Generator
	160	26880	26880	Tower
	210	35280	35280	Blade, Hub
	270	45360	45360	Main Shaft Set, Hydraulics System
	300	50400	50400	Auxiliary Electrical System
	540	90720	90720	Nacelle Structure
	600	100800	100800	Nacelle Auxiliaries

– It was assumed here that 100% of the degradations are clearly detected, though there are cases where signals cannot be clearly interpreted, or not sufficient to draw conclusions.

4.3 *Spares level optimization*

Optimizing the inventory level of spare parts is an important stage in order to reduce downtime, especially for parts that have very long lead or turnaround time. After the inspections and preventive maintenance have been optimized, the requirement for spares is modified and should be also optimized. For that purpose, we use the spares optimization module of the ApmOptimizer. The optimization algorithm objective is to minimize the total costs and damage. The program provides the optimal initial spares quantity as well as the required spares that must be ordered during lifetime in order to replenish stocks of condemned parts.

As a result of the spare optimization, availability increases to 93.6%, as well as the energy produced. The reduction in corrective maintenance costs reflects a decrease in revenue losses due to downtime. The cost of energy produced decreases a little more to 14€/MWh. See scenario 4 in Table 2.

5 CONCLUSIONS AND FUTURE WORK

This case study has demonstrated the capabilities of the ApmOptimizer to efficiently model an offshore wind farm, and propose original maintenance configurations to bring significant downtime and O&M cost reductions. Starting from a hypothetical though representative baseline model, the inspection, preventive maintenance and spares modules have successively reduced the downtime and improved the total energy produced. It has been shown that the knowledge of the failure modes of each component, and especially of the associated degradation process enables to define the optimal inspection schedule and reduce the overall downtime.

The interest of using Condition monitoring systems in order to detect as early as possible the degradation process has been highlighted, and was proven to be worth the investment. Moreover, the use of failure distributions extracted from on-site measurements has been proven to be profitable for optimization of preventive replacements.

In a future work, more detailed model of the wind turbine components, as well as field data from real wind farms installations will be used to extract accurate reliability figures. This field data will be used to evaluate real failure distributions for all components instead of the usual assumptions.

Maintenance planning for drum shearer machine based on its reliability characteristics and economical sensitivity analysis

S.H. Hoseinie, B. Ghodrati & U. Kumar
Division of Operation, Maintenance and Acoustics, Luleå University of Technology, Luleå, Sweden

ABSTRACT: Cutting arms are the main productive units of coal shearer machine that contact directly with coal seam. More importantly, the cutting arms operate under a high stress environment. In this paper, in order to suggest an optimum maintenance plan for the subsystem of shearer machine, firstly, we conducted a failure and reliability analysis using the data acquired from the Parvadeh coal mine Iran over the last two years. In doing so, we applied estimated distribution functions and calculated cost parameters to identify the cost-based optimum preventive maintenance interval. The analysis shows that the Power Law Process model provides a good fit to the failure data. Accordingly, the preventive maintenance operation can improve the reliability of the system by 53.5%. Furthermore, we conducted a sensitivity analysis of the studied machine and identified that if we consider the variation of the world price of the raw coal then the maintenance plan is sensitive to the price, however the effects of this change on reliability improvement is almost zero.

NOTATIONS

C_C:	Cost of the consequence of failure or production loos
C_{CM}:	Cost of corrective maintenance
C_{CMi}:	Cost of failure when the preventive maintenance is used
C_i:	Cost of inspection
CM:	Corrective Maintenance
C_{PM}:	Cost of a pre-planned preventive maintenance
C_{pm}:	Cost of preventive maintenance can be carried out in the scheduled intervals during inspections
C_{PMi}:	Expected cost of inspection and preventive maintenance
C_R:	Cost of repair
k:	Number of events
MCSPPM:	Mean cost of spare parts for preventive maintenance
MCSPR:	Cost of spare part during the inspection operation
MTTR:	Mean time to repair
MTBF:	Mean time between failures
NHPP:	Non-Homogeneous Poisson Process
N_t:	Cumulative number of failures up to time t
PLP:	Power Law Process
P_e:	Probability that inspection will indicate the potential failure
P_f:	Probability of the failure occurring
Pp:	Probability of the failure being detected
PM:	Preventive Maintenance
RP:	Renewal Process
R(t):	Reliability function
TBF:	Time between failures
t_k:	Total running time
t_i:	Running time of the ith event

θ:	Scale parameters

1 INTRODUCTION

The high productivity and lean operation are critical factors which should be addressed in the management and production strategies of mines. In this regard, longwall mining is one of the special mining methods that use high technology, high mechanization and automation process. The basic types of equipment that are used in modern longwall mining are: coal cutting machine (drum shearer), armored face conveyor and powered supports (Stefanko 1983, Ramani 1981, Mandal & Banik 1996). A mine production system demands a sequential operation of the equipment that can be used in cutting-loading and transport operations. Therefore, it is important that each subsystem should perform well during the time of requirement, likewise achieve the goal production during subsystem failures (Bhatacharaya et al., 1991).

As explained above, shearer is the first component of production chain in longwall face; therefore

its operational characteristics can seriously affect the rest of production process as well as mine productivity. The reliable and efficient performance of this machine can lead the system to achieve the target production effectively.

Similarly, cutting head (cutting system) is one of the important and critical subsystems of longwall shearers. It plays direct role in coal cutting and production and has a close relation to other subsystems such as electrical, water and hydraulic systems. Any failure to this unit directly affects the drum performance and leads to immediate stoppage of the machine. Therefore, the reliability study of this subsystem of shearers is essential to prevent the machine from unpredictable break downs.

In this paper, we analyze the reliability of cutting arms of drum shearer and furthermore, we calculate the optimum preventive maintenance planning based on cost parameters and reliability characteristics. Finally, we discuss the effects of the international coal price on maintenance planning of machine and amount of reliability improvement.

2 RELIABILITY ANALYSIS

Common occurrence of failures in the repairable systems is the result of discrete events that happens over time. These processes are often called stochastic point processes (Modarres, 2006). The stochastic point process is used to model reliability of the repairable systems. The analysis in this process includes renewal process, homogeneous Poison process, and non-homogeneous Poison process.

Before any reliability analysis is started, tests for trends and serial correlations must be performed to evaluate the type of the available TBF data and to select the best analysis method. If there is a trend in the dataset, this means that the data are not identically distributed. The presence of serial correlation shows that the data are not independent. In the case of no trend and no serial correlation, data are called iid (independent and identically distributed) and the RP method is the best method for reliability analysis, while in the case of having trend and serial correlation, the NHPP method is used for modelling.

The PLP is a well-known NHPP model used to study the reliability of the repairable systems. Duane (1964) was the first to report that the cumulative number of failures of such systems up to time t, N_t, often have a "power-law" growth pattern. Then, Crow (1974) formulated the corresponding model as a nonhomogeneous Poisson process model. The reliability function at time t are defined by the following equation:

$$R(t) = \exp\left[-\left(\frac{t}{\theta}\right)^{\beta}\right] \tag{1}$$

The θ and β parameters can be estimated by the following expressions as suggested by Crow (1974);

$$\hat{\beta} = \frac{k}{\sum_{i=1}^{k-1} \ln(t_k / t_i)} \tag{2}$$

$$\hat{\theta} = \frac{t_k}{k^{1/\beta}} \tag{3}$$

A simple graphical method for testing the goodness-of-fit is to simply plot $\ln(N(t))$ against $\ln(t)$ on a square graph paper. If a straight line is observed, it means the power law process model is a suitable model for reliability analysis (Klefsjö & Kumar, 1992, Crow, 1974).

3 MAINTENANCE PLANNING AND OPTIMIZATION

There are two primary types of maintenance actions: PM and CM. When the system is in a wear-out condition that is represented by increasing failure rate, in many cases, the preventive maintenance may be a suitable policy for improving the operational condition of machine.

The important goal of this study is to find the optimal preventive maintenance policies that can minimize the total cost of operation, at the same time, improve the reliability of the cutting arms of shearer. In this paper, we will use the analytical method for estimation of optimal overhaul intervals. The suggested method will minimize the long-run cost per unit of operation time given the system is modeled by the power law process.

In this case, the cost per unit of time can be calculated by Equation 4:

$$C(T) = \frac{(C_{CM} + C_{PM})\left(\frac{T}{\theta}\right)^{\beta} + C_{PM}}{T} \tag{4}$$

The Equation 4 has minimum value at T_{PM}, where;

$$T_{PM} = \theta\left(\frac{C_{PM}}{(C_{CM} + C_{PM})(\beta - 1)}\right)^{\frac{1}{\beta}} \tag{5}$$

Therefore, one possibility of estimating the optimal time interval T_{PM} between complete overhauls

is to use Equation 6 where $\hat{\beta}$ and $\hat{\theta}$ are estimates of β and θ.

$$\hat{T_{PM}} = \hat{\theta}\left(\frac{C_{PM}}{(C_{CM}+C_{PM})(\hat{\beta}-1)}\right)^{\frac{1}{\hat{\beta}}} \quad (6)$$

If a component/subsystem runs to failure, the expected cost of CM over a given time interval includes the product of P_f and $(C_C + C_R)$ (Barabady & Kumar, 2007):

$$C_{CM} = (C_C + C_R) \times P_f \quad (7)$$

The expected cost of maintenance over a given time interval includes two main parts (Barabady & Kumar, 2007):

a. C_{CMi}: It is not possible to remove all failures by using PM, but the number of failure could be decreased. The C_{CMi} applied in this case, can be calculated as follows:

$$C_{CMi} = (C_C + C_R) \times P_f \times (1 - P_p) \quad (8)$$

b. C_{PMi}: The C_{PMi} can be calculated by using the Equation 8.

$$C_{PMi} = C_i + (C_{pm} \times P_f \times P_p) + (C_{pm} \times (1 - P_f) \times P_e) \quad (9)$$

Finally, the C_{PM} is the sum of Equation 8 and 9:

$$C_{PM} = C_{CMi} + C_{PMi} \quad (10)$$

4 CASE STUDY: PARVADEH COAL MINE, IRAN

In this paper, the shearer machine of Parvadeh coal mine in the central Iran was selected for case study and data collection. The extracted coal seam of this mine has 1.8 m thicknesses and is mined by retreat longwall method using a double-drum shearer (Fig. 1).

As shown in Figure 1, each side of studied shearer machine has a ranging arm and a cutting drum. The arm is fixed to drive unit and electric system block by means of the articulated joint and pins. The arm can be lifted and lowered down in steeples way, and maintained at desired height by means of hydraulic servo.

4.1 *Failure data analysis*

The required data for this research was collected from operation and maintenance reports and direct field observations over a period of two years. Many of the desired information, such as failure occurrence times, reasons of failure, types of repair actions and time to repair were available in mine database, therefore only TBFs values were calculated. All needed calculations related to data analysis and reliability modeling were carried out using Easy*fit* and Microsoft Excel software.

According to the results of trend and serial correlation tests, a trend was noticed as interpreted from the convexity of the curve. The test for the serial correlation showed no correlation in general. Therefore, non-homogeneous Poison process it the best way for reliability analysis. In this research, the

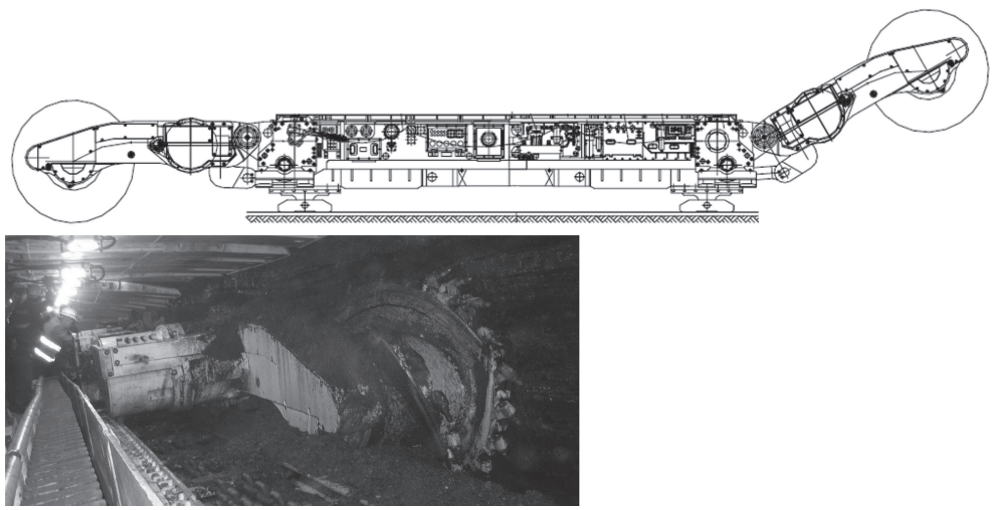

Figure 1. Drum shearer of Parvadeh coal mine.

power law process, as a certain form of nonhomogeneous Poisson process, was tested and selected for analyzing the reliability of cutting system of drum shearer.

4.2 *Reliability analysis*

After validation of the PLP assumption, the parameters of the PLP model were estimated analytically using the Equation 2 and 3. The calculations showed that β is 1.58 and θ is 443.8. According to achieved reliability model, the reliability curve was plotted as shown in Figure 2. The plot shows that the reliability of cutting arms of drum shearer reaches the zero after about 1300 hours of operation. There are 80% and 50% chance that this system can work without any failure after 170 hour and 350 hour respectively.

Since β is greater than one, the cutting arms of shearer machine have increasing failure rate. Therefore, this system needs a preventive maintenance operation to prevent the system from reaching the high failure rates and serious breakdown.

4.3 *Maintenance planning and reliability improvement*

As depicted in Equation 4, calculation of the costs of corrective and preventive maintenances is essential to find the optimum maintenance interval of a system. The cost parameters which were presented in Equations 4 to 9 are calculated as follows:

C_C: To calculate this parameter, statistical analysis was done on the available data so that we can find the average production hour per shift and average cutting rate (advance speed) of drum shearer. The results showed that, the shearer of Parvadeh mine works 2.71 hours per shift in average, likewise the average cutting rate of machine in working condition was 1.16 m/min. Considering the all available information and the density of 1.6 g/t for extracted coal, the total production per minute was 2.67 tons in average. If we assume that the raw coal price is 55$/t in average then the value of the produced coal per minute will be 146.85$/min. It means any breakdowns in the production can cost around 146.85$/min in Tabs coal mine. Using this information, if we know MTTR of the cutting arms of shearer, we can calculate the C_C by multiplying 146.85$ with the MTTR. Therefore, in the Parvadeh mine case, first, the MTTR of the system was calculated, and then the C_C of the system was calculated.

C_R: To calculate the cost of repair, two main costs were considered:

a. MCSPR: the cost of spare parts and tools is directly depending on the type of subsystem and maintenance operation. According to the available financial data and spare part usage reports of the Parvadeh mine, an average value was considered for the cutting arms of the subsystem. The considered value is presented in Table 1.
b. Labor cost: this cost represents all human works done on machine during the maintenance operation. The labor cost for the maintenance operation in Parvadeh mine is ≈0.23$/min according to the salary and working hours for each worker per day. These values can be used to calculate the labor cost, supposing the MTTR of system is given, by multiplying the 0.23 with MTTR.

Finally, the above cost can be added to calculate the C_R. Calculated value of C_R is presented in Table 1.

P_f: To calculate this parameter, we need to consider initial intervals for maintenance operations and then calculate the failure probability based on cumulative failure distribution function (F(x)), which is the outcome of TBF data analysis. In his paper, MTBF was used as an initial maintenance intervals; therefore using the MTBF value the

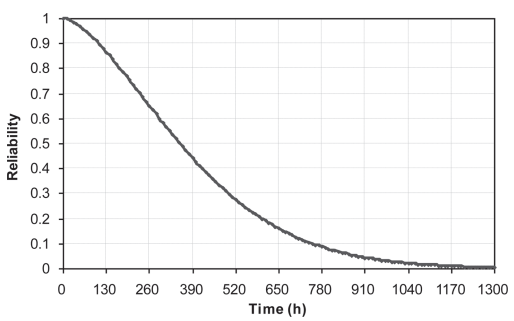

Figure 2. Reliability plot of cutting arms of drum shearer.

Table 1. Cost parameters of cutting arms of drum shearer of Parvadeh coal mine.

Parameters	Values
MTTR (min)	42.5
C_C ($)	6247.3
MCSPR ($)	150
C_R ($)	165.3
P_f	2.35%
P_e	30%
C_i ($)	5.4
MCSPPM ($)	65
C_{pm} ($)	78.5
C_{PMi} ($)	29.7
C_{CM} ($)	150.7
C_{PM} ($)	74.9

failure probability was calculated. The result is presented in Table 1.

C_i: the rate of inspection consists of two main costs: labor costs and tool/test costs. Parvadeh mine, usually, conduct visual inspection because of the specific working condition, for instance limited space and light and low accessibility to machine parts. Therefore the cost of tools and tests was negligible. The calculated labor cost in Parvadeh mine was 0.125$/min. Using this cost, if we know the mean time of inspection then we can calculate the labor cost. The inspections usually take in average 25 minutes for cutting arms. As a result, the inspection cost calculated for this system is 3.125$.

C_{pm}: the preventive maintenance can be carried out in the scheduled intervals during inspections. In this study, the scheduled PM is considered for the cost estimation. Therefore, PM is done in real operation and uses real duration and tasks. To calculate the total of PM, we used two costs: MCSPPM and labor cost. The final value of C_{pm} is calculated by adding these two costs. The result is presented in Table 1.

P_e and P_p: maintenance operation has special difficulties in mining. The operation is also seriously affected by the environment. Cutting arms had so many mechanical parts which are not easily visible. Therefore, 30% has been assigned to the probability that inspection will falsely indicate the potential failure of cutting arms. Thus, the probability that the failure can be detected by inspections (P_p) is 70%.

With regard to previous explanations, the input data for calculating the C_{PM} and C_{CM} of the cutting arms of the drum shearer of Parvadeh coal mine is shown in Table 1.

According to the cost parameters as presented in Table 1, Equation 6 can be used for calculating the optimum preventive maintenance interval of cutting arms of drum shearer as shown below:

$$\hat{T}_{PM} = 443.8\left(\frac{74.9}{(150.7+74.9)(1.58-1)}\right)^{\frac{1}{1.58}} \approx 289 \tag{11}$$

Therefore, preventive maintenance tasks should be done in intervals equal to $T_{PM} = 289$ hours.

5 SENSITIVITY ANALYSIS OF MAINTENANCE PLAN

All the time most of the mining companies are afraid of the effects of raw material price on operation and benefits of their mines. As can be seen in Table 1, the highest cost of maintenance is related to the C_c which represents the cost of production loss. This value directly depends on the price of raw coal in international market.

In this study, the basic price of raw coal was assumed 55$/ton in average. For sensitivity analysis, the whole calculations have been repeated by 40, 50, 60 and 70 $/ton. The result of the calculations is shown in Figure 3. As can be seen in Figure 3, the T_{PM} is very little affected by raw coal price. It means that, 35$ change in coal price changes the T_{PM} only by 6 hours.

Figure 4 shows the improved reliability plots for different T_{PM}. As can be see, due to very little

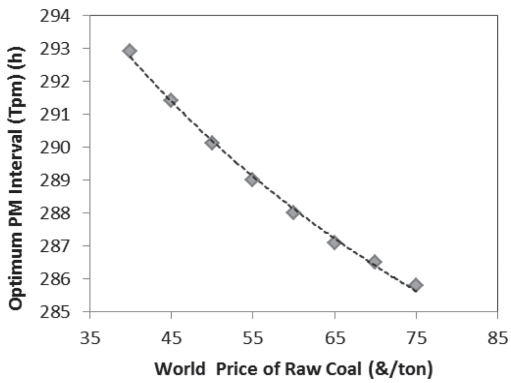

Figure 3. Effect of world price of raw coal on optimum maintenance interval (TPM).

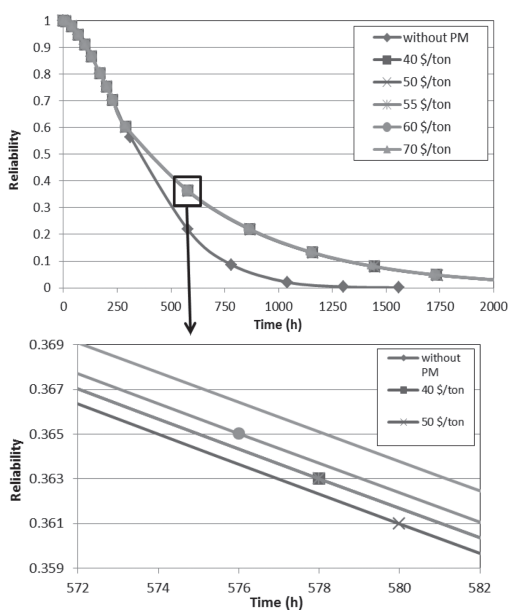

Figure 4. Effect of world price of raw coal on improved reliability plots resulted from PM.

differences in optimum maintenance intervals, the reliability of machine is not much sensitive to raw coal price and all the reliability plots are lay in a same way. The zoomed out part of plots are clearly shows that, the difference among the reliability plots are negligible. Therefore, as a clear result, the mine managers and planners should not be afraid of the world price of coal and its effects on their maintenance plan and operation.

The sensitivity analysis of maintenance plan showed that the big changes in world price of raw coal are not so effective on maintenance plan of the drum shearer, especially on cutting arms of the machine. This matter can be checked in other subsystems of machine and also other equipment of longwall mining. Then, we can come to an exact statement about the operational effects of unstable international market of coal on longwall operation.

6 CONCLUSION

According to the results of trend analysis and test for the serial correlation, it is clear that the assumption of iid is normally not valid for the TBFs of the cutting arms of the drum shearer machine. The assumption that the power law process adequately describes the TBFs of this system was validated and confirmed by graphical method. Since the failure rate of this system is increasing, the preventive maintenance is suitable strategy for this system.

The cost parameters that have been calculated based on case study data were used for calculating the optimal preventive maintenance interval for this system. The calculation showed that approximately 289 hour is optimum value for PM intervals. It is predicted that if we conduct the preventive maintenances in 289 intervals then the reliability of cutting arms of drum shearer will improve by minimum 53.5%, which is a noticeable positive change in operational and economical condition of machine performance.

The sensitivity analysis showed that by changing the world price of coal from 40$ to 75$/ton, the optimal maintenance interval can decrease from 293 hours to 286 hours. In this case, however, the difference is not so significant. One of the reasons for this little difference can be that with the increase of the coal price, the C_C also increase, which in turns leads to C_{CM} increase, consequently, that leads to T_{PM} decrease. In practice it means that, when the coal price is high, we are more concerned about our machine because any unpredictable failure can result in a higher revenue loss (or higher production loss). Therefore to reduce the probability of breakdown occurrence, the preventive maintenance in a shorter period is advised. However, in this particular case of mine, there was no significant difference between the PM intervals of various coal prices. On the other hand, the reductive trend was obvious (Fig. 3).

Because of the low changes in T_{PM}, the amounts of reliability improvements in different intervals were very low or almost negligible. The implication of the result to the Parvadeh coal mine is that the international coal prices don't have any serious effect on maintenance program of the coal shearer machine, and may not be the real risk factor.

ACKNOWLEDGEMENT

The authors are grateful to employees and managers of Parvade Coal Complex in Iran for their kind cooperation during data collection. The financial support of the Center for Advanced Mining and Metallurgy (CAMM) of Lulea University of Technology is also acknowledged.

A guide for Block Inspection Policy implementation

A. Jodejko-Pietruczuk & S. Werbińska-Wojciechowska
Wroclaw University of Technology, Wroclaw, Poland

ABSTRACT: In the presented paper, authors focus on the investigation of Block-Inspection (BI) policy implementation possibilities. They provide the synthetic approach to the results on BI policy research which gives the possibility to define guidelines for determining its use. Thus, there is provided a comprehensive literature review covering the issues on inspection policy parameters modelling and optimization or implementation. This gives the possibility to present the approach for maintenance inspection selection problem from engineering point of view. The research work is aimed at summarizing some authors developments in the analysed research area.

1 INTRODUCTION

The main maintenance problems which face maintenance managers mostly regard to the definition of a problem/disruption occurred in the area of operational processes performance, and identification of its nature, locations and possible maintenance actions (Valis and Vintr 2006). Following this, maintenance problems of technical systems have been of significant importance for the past fifty years, especially because of the applications in industry, aviation, transportation systems, or medicine (see e.g. (Babiarz 2006, Bajda et al. 2011, Kierzkowski 2010, Kierzkowski et al. 2012, Kierzkowski and Zając 2012)). During that time, there have been developed many conceptions and models in the area of technical objects maintenance performance, which are aimed at maintenance tasks scheduling and optimization, taking into account economical and reliability criteria (Nowakowski and Werbińka 2009).

Moreover, the two approaches have evolved from performing maintenance actions. First, there are known models in which a system or its components fail and there are no visible symptoms about the forthcoming failure (assuming that it is a sudden failure). The majority of the maintenance modelling concepts, being discussed in the literature since the early 1960s, regards to this kind of a problem investigation. For more information we recommend reading e.g. (Młyńczak et al. 2014, Nowakowski and Werbińka 2009, Werbińska-Wojciechowska 2014).

The second approach involves the modelling problems of systems/its components, when assuming that it is not a sudden failure. In this approach, before a component breaks down, there will be some sings of reduced performance or abnormalities. The time between the first identification of abnormalities (called initial point) and the actual failure time (failure point) will vary depending on the deterioration rate of the component. This concept (delay time concept), which provides useful means of modelling the effect of periodic inspections on the failure rate of repairable technical systems, was developed by Christer et al., see e.g. (Christer 1987, Christer 1982, Christer & Waller 1987, 1984a, 1984b, Christer & Whitelaw 1983).

However, the identification of the best maintenance strategy and its parameters for real-life systems is a complex problem. On the one side, there is a problem to define if and what kind of signal of forthcoming failure may occur. On the other, some signals about system defects cannot strictly indicate what kind of problem occur in the system.

For example, the squealing of vehicle belt during its operation process performance indicates the need for its preventive replacement. However, the occurred noise during operation processes performance of construction machines (e.g. wheel loader) will only indicate a problem in the drive system, which may regard to e.g. differential problems or transmission problems (e.g. propeller shaft).

One of the examples, which serves to illustrate the difficulty and complexity of proper maintenance action definition my regard to the problem, which occurred during operational processes performance by a loader which worked at different surfaces. In the analysed case, at a speed of 17.5 km/h, the construction machine fall in the resonance which even make its correct operation impossible. After a long search for the cause of the problem (e.g. assessment of the potential damage to the front axle and rear), it turned out that the tires have been wrongly selected what caused such the problems.

Taking one step further, even the preventive maintenance policy selection (e.g. Block Replacement Policy) for exploitation or operational materials may be complicated and determined e.g. by changeable

working conditions. An example here would be the replacement of teeth in a loader's bucket. The time between successive replacements will depend on the class of abrasion of excavated materials.

Another problem is that some inspection (diagnostic) actions may be performed only during planned maintenance actions performance. A good example here is the planned replacement of engine oil in construction machines. During this maintenance operation performance, one can use a sample of used oil and examined it for the content of metallic elements. The increased level of their content may attest to the usage of certain engine system components, such as wear out of cylinders, piston rings or bearings.

There is also possible continuous control of some signals which indicate for defects. The example here may be the control process of temperature or pressure of engine oil, transmission oil or axles oil. This control allows for ongoing assessment if there appears in the system too high friction or leakage.

The given example indicate the need for research work in the area of maintenance decision process support tools development and definition of methods of maintenance strategy and its parameters selection.

Following the above considerations, authors focus on the investigation of given Block-Inspection (BI) Policy implementation possibilities. They provide the synthetic approach to the results on BI policy research which gives the possibility to define guidelines for determining its use and setting out the questions to be answered:

- When to use the BIP policy?
- What kind of data to estimate?
- How to choose the optimal period T?

Thus, in the next Section, there is provided a comprehensive literature review covering the issues on inspection policy parameters modelling and optimization as well as its implementation. This gives the possibility to present the approach for maintenance inspection selection problem from engineering point of view. The research work is the continuation of investigations presented e.g. in (Jodejko-Pietruczuk et al. 2013a, Jodejko-Pietruczuk and Werbińska-Wojciechowska 2014b, 2012a, 2012b) and is aimed at summarizing some authors developments in the analysed research area. The work ends up with summary and directions for further research.

2 INSPECTION POLICY MODELLING— LITERATURE REVIEW

Ones of the first works dedicated to the inspection problems literature review are (Barlow et al. 1963), where authors investigated the issues of periodic inspections, and (Sherif 1982), where author reviewed about 818 international papers aimed at optimal inspection and maintenance schedules of failing systems. More related studies on optimal inspection issues can be found e.g. in (Abdel-Hameed 1995, Cui et al. 2004, Kaio and Osaki 1988, Luss 1983, Onoufriou and Frangopol 2002).

In the recent literature, one can find models of inspection frequency optimization with the use e.g. simulation processes (see e.g. (Alfares 1999, Vaghefi and Sarhangian 2009)), probability analysis (see e.g. (Baohe 2002)), Bayes or quasi-Bayes approach (see e.g. (Durango-Cohen and Madanat 2008, Jones et al. 2010)), or Markov processes (see e.g. (Kenzin and Frostig 2009)). Moreover, the analysed problems include e.g. the periodic inspection optimization for systems with failure interaction (see e.g. (Golmakani and Moakedi 2012, Zequeira and Berenguer 2005)), or the introduction of imperfect inspection (see e.g. (Berrade et al. 2013, Zhao et al. 2007)).

There are also many papers dedicated to inspection policy implementation e.g. in the area of industrial systems performance (see e.g. (Duffaa and El-Ga'aly 2013, Yun and Nakagawa 2010)), railway systems maintenance (see e.g. (Podofillini et al. 2006)), or cargo container reliability analysis (see e.g. (Ramirez-Marquez 2008)).

The basic inspection models are extended by using a technique called Delay Time Analysis (DTA), which has been developed for modelling the consequences of an inspection policy for any systems (Christer 1982). A literature review, in which delay-time models are investigated along with other PM models are given e.g. in (Dekker & Scarf 1998, Mazzuchi et al. 2007, Ozekici 1996, Thomas 1986, Valdez-Flores & Feldman 1989). The state of art works, dedicated strictly to DT modelling are given in e.g. (Alzubaidi 1993, Baker & Christer 1994, Christer 2002, 1999, Christer & Redmond 1992, 1990, Lee 1999, Nowakowski & Werbińska-Wojciechowska 2012, Redmond 1997, Wang 2012).

In the case of a repairable component, it is possible to model the reliability, operating cost and availability functions when pdf $f_h(h)$ and $g(u)$ are known.

The basic multi-component system delay-time model is given in e.g. (Christer & Redmond 1992, Christer & Waller 1984a, 1984c, Wang 2003). The basic assumptions include perfect inspection case, independent system components, the number of defects arising over T following a HPP with a constant rate λ per unit time, known pdf $f_h(h)$, regular inspection actions performance which requires a constant time d. Following these assumptions, probability of defect arising as a failure $P_b(T)$ and downtime per unit time $E_D(T)$ may be estimated.

The basic extensions for analysed delay time model regard to the non-perfect inspection case (see

e.g. (Christer 1999, Wang 2009)), multiple nested inspections case (see e.g. (Wang 2000, Wang et al. 2012)), imperfect inspections performance (see e.g. (Cai & Zhu 2011, Wang 2010)), or NHPP defect arrival process (see e.g. (Christer 1999, Christer & Wang 1995)).

The presented above maintenance models regard to PM policy consideration. The implementation of condition monitoring policy in delay-time models for complex systems is given e.g. in (Chilcott & Christer 1991, Jalani Naini et al. 2009, Wang 1992).

Delay time modelling applied to industrial maintenance problems can be traced back to (Christer 1982). Since then, there has been developed a lot of maintenance models that use the delay-time concept. Many works have been carried out on the DT modelling to production plants (e.g. (Akbarov et al. 2008, Jones et al. 2009)). Other works include the application to gearbox failure process (see e.g. (Leung & Kit-leung 1996)), modelling PM for a vehicle fleet (see e.g. (Christer & Waller 1984b, Desa & Christer 2001, Jardine & Hassounah 1990, Scarf & Bouamra 1995)), PM process for a coal face machinery (Chillcott & Christer 1991), wind turbine maintenance optimization (see e.g. (Andrawus et al. 2007)), modelling maintenance of fishing vessel equipment (see e.g. (Pillay et al. 2001)), medical equipment (see e.g. (Christer & Scarf 1994)), or application to concrete structures (see e.g. (Redmond 1997)). Moreover, well known models base on time-based PM or condition-based maintenance (e.g. (Chilcott & Christer 1991, Jalani Naini et al. 2009, Wang 1992)). Additionally, Cui in his work (Cui 2002) provides a semi-automated DTM tool, which is based on models developed till the 2002 and enables engineers to themselves undertake e.g. model based decision making.

All the presented works give the model of optimal period between inspections estimation. However, they do not address the issues of selection of the type of maintenance strategy which should be use depending on the analysed technical system and its operational process. These issues are one of the scope of maintenance management systems or decision support systems developed in the analysed research area. For more information we recommend reading e.g. (Bojda et al. 2014, Laskowski and Bylak 2013, Vintr and Valis 2012).

3 MAINTENANCE MODELLING METHODOLOGY FOR TECHNICAL SYSTEMS

3.1 *Block Inspection policy*

The analysed methodology of DT concept use in maintenance modelling of technical systems is developed for implementation of Block Inspection Policy. This maintenance policy assumes, that inspections take place at regular time intervals of T, and each requires a constant time. Usually components are prone to become defective independently of each other when the system is in operating. All defects which may have arisen in the system, deteriorate over an operating time. Later, all elements with identified defects will be replaced within the inspection period. However, the inspection actions may be perfect or imperfect ones what affect the optimization process.

3.2 *Developed methodology*

There is no simple decision rule which maintenance policy should be taken to provide the best effectiveness of technical systems during their life span. While developing the methodology for modelling the processes of technical systems maintenance, taking into account the DT concept, it should be noted that the purpose of the model is usually to minimize the expected duration of system downstate $E_d(T)$, the expected maintenance costs $C(T)$, or maximize the system availability function $A(T)$. At the same time, the impact of their components failures on its environment is also important. The level of this impact can be expressed by the function of the expected failure consequences costs $C_C(T)$. On the other hand, further considerations omit the possibility of performing a multi-criteria analysis.

Following this, the algorithm for the determination of the optimal period between the inspection actions performance T should contain the following steps (Fig. 1) (Cunningham et al. 2011, Jones et al. 2009, Wang and Christer 2003):

- understanding the process of maintaining the selected system (e.g. determining the type of the involved maintenance operation, the relationship between the system's components, definition of the types of obtainable data),
- identifying the problems in the selected system exploitation process (e.g. long-term repair operations, frequent damage),
- analysis if there is a possibility of expected delay time $E(h)$ or characteristics of initial point u estimation,
- data collection and analysis—based on using subjective and objective methods;
- determining the assumptions of the model—based on the data and knowledge about the operation processes in effect (e.g. single-/multi-element system),
- estimating the basic parameters of the model—for example, functions $f_h(h)$ and $F_h(h)$ for the time delay parameter h, selecting the probability distribution for the time between failures or the repair time,

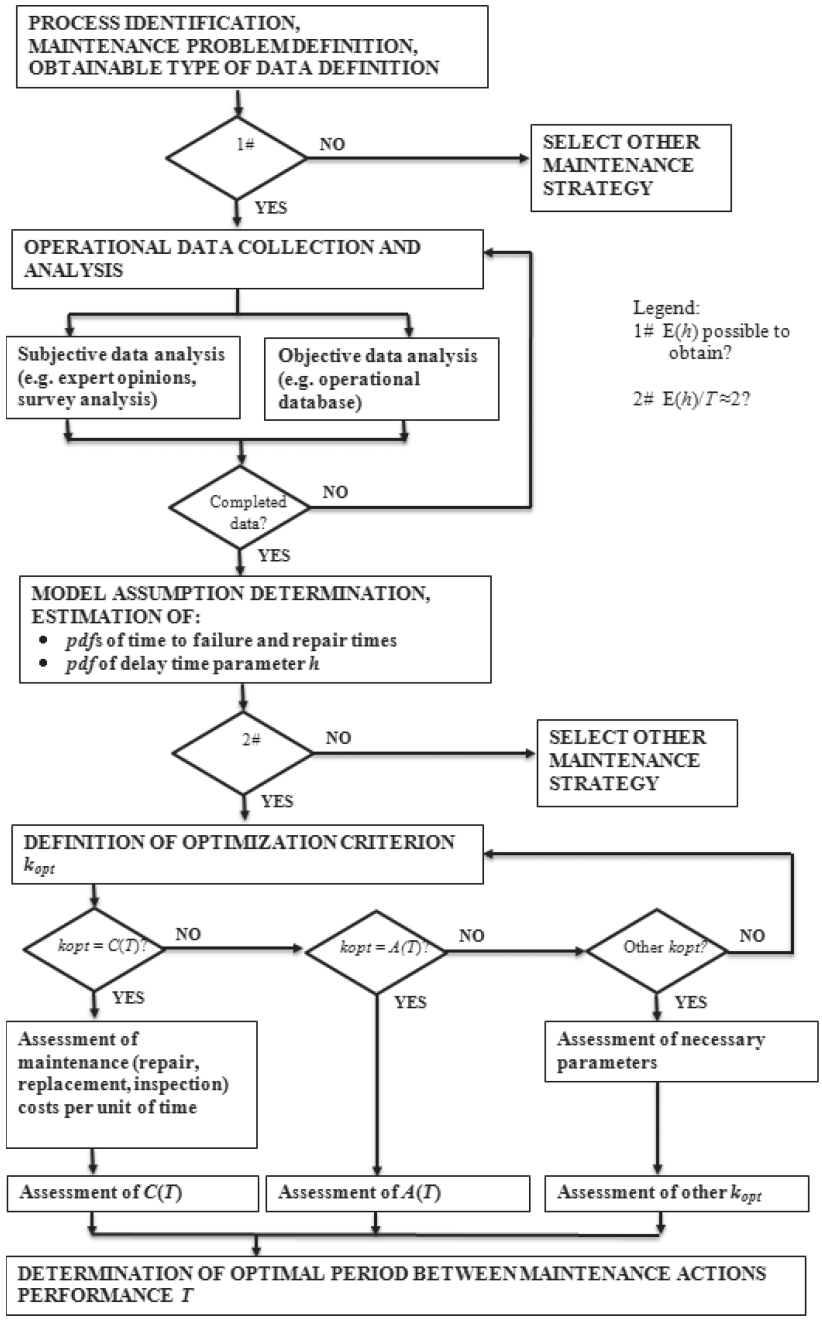

Figure 1. The algorithm for assessment of optimal period T using the concept of DT.

- determining the relationship between the expected value of the time delay parameter h and the optimal period T—in order to determine whether the DT concept allows for optimum solution obtainment (more info e.g. in (Jodejko-Pietruczuk and Werbińska-Wojciechowska 2012a, 2012b)),
- defining optimization criteria—depending on the available operational data and model assumptions,

- estimating the function of the optimization criterion, designating the optimal period T.

3.3 *The main guidelines for optimal period T assessment with the use of BI policy*

The previous authors' research works was aimed at investigation of BI policy modelling and implementation for technical systems performing in various reliability structures (see e.g. (Jodejko-Pietruczuk and Werbińska-Wojciechowska 2014a, 2014b, 2012a, 2012b). Thus, there were developed some rules for definition of the principal relations between the system performance under given PM policy and chosen PM policy parameters.

3.3.1 *Perfect inspection case*

Let's consider the system comprised of 3 identical elements, in a k-out-of-n reliability structure, working independently under the same conditions. The performance of the investigated system, being illustrated in Figure 2, is also defined by the additional assumptions:

- the system is a three state system where, over its service life, it can be either operating, operating acceptably or down for necessary repair or planned maintenance,
- maintenance actions restores system to as good as new condition,
- the system can remain functioning in an acceptable manner until breakdown (despite having defects),
- the breakdown will be assumed to have been caused by two of the defects which has deteriorated sufficiently to affect the operating performance of the system as a whole,

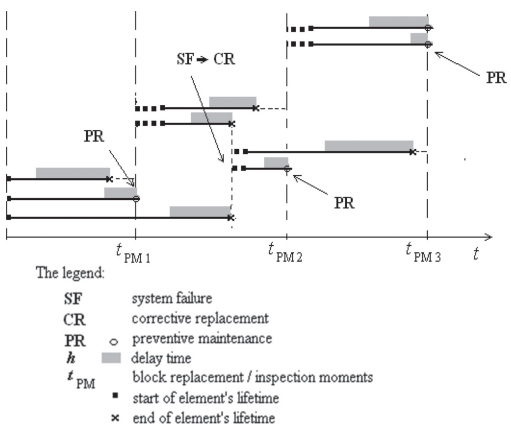

Figure 2. Block inspection policy for the investigated system (2-out-of-3 reliability structure).

- failures of the system are identified immediately, and repairs or replacements are made as soon as possible,
- system incurs costs of: new elements, when they are replaced, inspection costs, and some additional, consequence costs, when system fails,
- time of defects occurrence defined by u is a random variable described by its probability distribution functions $g(u)$ and $G(u)$
- elements' lifetime, repair time, replacement time and the length of the delay time before element's failure are random and their probability distributions are known.

The performance of the chosen system is modelled with the use of simulation processes. The modelling process was based on the use of *GNU* Octave software. More information can be found e.g. in (Jodejko-Pietruczuk and Werbinska-Wojciechowska 2012a, 2012b). The modelled system parameters are given in Table 1.

Following the carried out research analyses results, some decision rules on when to use BI policy can be defined for technical systems performing in various reliability structures.

Observation of the modeled operating process' simple scheme (Fig. 2) leads to believe that the main variables affecting the BI maintenance policy performance are: an element's time to failure (T_p) and a delay time (h). Thus, according

Table 1. Modelled system parameters.

Notation	Description	Tested values
n	Number of elements of the system	3
k	Minimal number of up-stated elements for having system in an operational state	1, 2, 3
c_r	The cost of new element	1
c_i	The cost of an inspection	1
c_f	The cost of a system failure	10 000
T_i	The time required for inspection	0
$F(t)$	C.d.f. of elements' lifetime	$F(t) = 1 - e^{-(t/100)^{3,5}}$
$G_r(t)$	C.d.f. of single elements' repair time (resulting from a system failure)	$G_r(t) = 1 - e^{-(t/100)^{2,3}}$
$G_p(t)$	C.d.f of single element's replacement time (resulting from preventive replacement)	$G_p(t) = 1 - e^{-(t/10)^{2,3}}$
$F_h(h)$	C.d.f. of elements' delay time	$F_h(h) = 1 - e^{-(h/35)^{3,5}}$

to the research works (Jodejko-Pietruczuk and Werbińska-Wojciechowska 2012a, 2012b), which investigated the BIP policy in multi-unit systems performance implementation, there is possible to determine the relationship between time T and the expected value of the variable h in systems with serial reliability structure, which is obtained for the lowest maintenance cost and highest system availability:

$$\frac{E(h)}{T} \approx 2 \tag{1}$$

$$4 \le \frac{T_p}{T} \le 6 \tag{2}$$

where: T—the period between inspections, T_p—the $MTTF$ of system elements, h—the mean delay time value.

System with parallel reliability structure may be inspected even at longer time intervals because of its higher resistance to single element failures ($E(h)/T \approx 1$).

Figure 3 shows the example of the economic results of analysed system depending on the expected value $E(h)$ and the length of the period T. The presented analysis results for "*1- out-of t 3*" reliability structure (the parallel reliability structure) are indicated as bright markers and for "*3*-out-of-*3*" reliability structure (serial reliability structure)—as dark markers. The relationship given by Eq. (1) is presented in Figure 3 as an additional line, near which are the best solutions for the economic and availability criteria and analysed expected values $E(h)$.

The results presented in the Figure show that "nearly optimal" period between inspections of the series system performed according to BIP strategy should be determined on the basis of information about the expected value of the delay time. The expected maintenance costs of system C_{BI} reaches a minimum at the values of the $E(h)/T \approx 2$ for technical system performing in series reliability structure. The optimal values of costs C_{BI} for the system operating in parallel reliability structure are observed for the smaller value of the relationship $E(h)/T$. In the case, where $E(h)/T >> 2$, maintenance costs are still low what is connected with the "safe" maintenance variant including frequent system elements inspections performance.

For more information we recommend reading e.g. ((Jodejko-Pietruczuk and Werbińska-Wojciechowska 2014a, 2014b, 2012a, 2012b).

3.3.2 *Imperfect inspection case*

To complete the research analysis, there should be investigated case of imperfect inspection performance. For this purpose, *Inspection precision* is understood as the ability of system to detect (and correctly interpret) its elements' defects during inspection if their symptoms may be observable. This ability is given by p factor describing the probability that an element defect will not be noticed by maintenance service. The greater value of p means more difficult diagnosis of a real state of system during Inspection (Jodejko-Pietruczuk and Werbińska-Wojciechowska 2012c).

To analyze how the expressions (1) and (2) should be changed when inspection becomes less precise, additional assumption has been made to the system. Any component's defect, which occurred in the system till the moment of inspection, will be unnoticed with probability p or correctly identified with probability 1-p. All elements with identified defects will be replaced within the inspection period. The performance of the investigated system with additional assumptions, is illustrated in Figure 4.

The system in the Figure 4 is inspected at t_{PM} moments. Diagnosis of defect symptoms is imperfect thus elements 2 and 7 are allowed to further work although their defects might be noticed. Because of the fact, during one of following periods between inspections (t_{PM1}–t_{PM2}) two consecutive

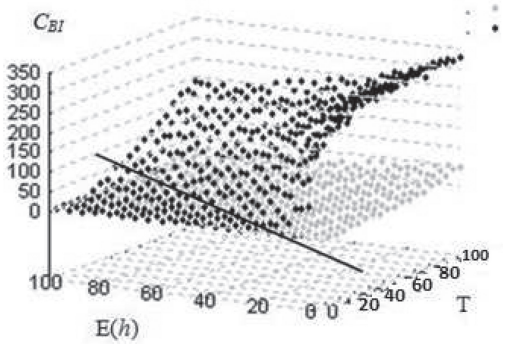

Figure 3. The total cost C_{BI} for various relations $E(h)/T$ (for $c_c = 10\,000$).

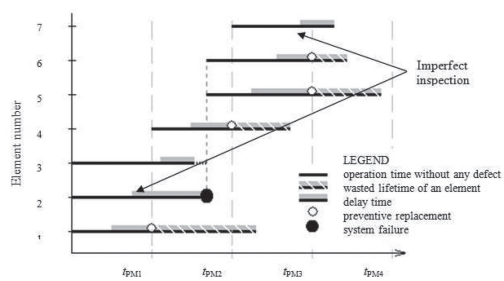

Figure 4. Idea of the block inspection policy with imperfect inspection (2-out-of-3 reliability structure).

elements fail what causes a system failure. On the other hand, some elements' defects are properly diagnosed at the first possible inspection (elements: 1,4,5,6) and the components are preventively replaced but their potential lifetime is wasted.

Figures 5 and 6 present chosen BI results obtained for various levels of inspection imprecision p and various lengths of period T in relation to mean element's lifetime (T_p/T) and to mean delay time (h/T), presented for two system's reliability structures. To save the space of the paper, the outcomes are presented at the same time as the function of p, T_p/T, h/T.

Presented in Figure 6 cost results are unequivocal for the analyzed series reliability structured system—the period between inspections set according to Eq. (1) and (2) generates low system costs when inspection is perfect. When diagnosis becomes less reliable (higher p value) the system should be inspected much more often ($T_p/T > 4$, $h/T > 2$) but explicit optimum T cannot be specified for any level of p. The result is the effect of significant role of the system failure consequence cost in the total cost of the maintained system and makes profitable

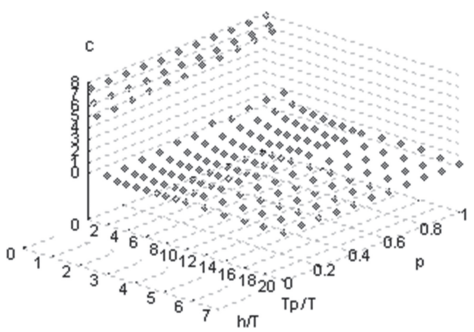

Figure 5. The total costs of the parallel system for various levels of inspection precision p, relations T_p/T and h/T.

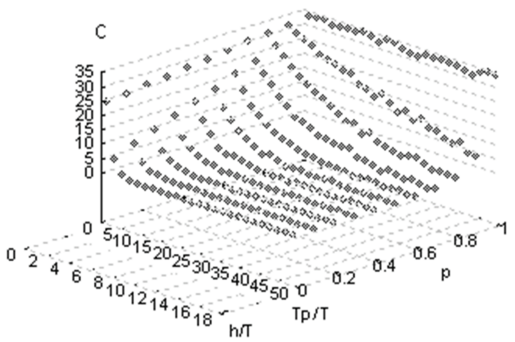

Figure 6. The total costs of the series system for various levels of inspection precision p, relations T_p/T and h/T.

every maintenance strategy with no system failure. The same effect of higher (but comparable) profitability of shorter periods T, is observable in *1-out-of-3* system (parallel) but for lower values of T_p/T and h/T. Thus one cannot to precisely determine explicit optimum relation of period T to elements' lifetime or delay time.

For more information we recommend reading (Jodejko-Pietruczuk et al. 2013b, Jodejko-Pietruczuk and Werbińska-Wojciechowska 2012c), where also the optimization analysis, bases on simulation model use, was made.

3.4 *Optimization of T parameter*

To provide a comprehensive optimization of time period T, the analytical model was developed (for the case of perfect inspection). Taking into account the additional assumption, that inspection action performance begins the new maintenance cycle for the analyzed system, the expected costs of n-element system maintenance in one inspection cycle are defined (Jodejko-Pietruczuk and Werbińska-Wojciechowska, in press):

$$C(T_i) = C(t_{i-1}, t_i) = \frac{c_f F(t_i) + c_r\left(1 - F(t_i)\right)\left(\sum_{j=1}^{n} G_j(t_i)\right) + c_i\left(1 - F(t_i)\right)}{\prod_{j=1}^{n}\left(1 - G_j(t_{i-1})\right)} \tag{3}$$

The formulae may be used under the condition that all the system elements were as good as new at the beginning of the cycle. When system performs in a series reliability structure, there is a possibility to define the *C.d.f.* of time to failure, $F(x)$, as the convolution of u and h such that $u + h \leq x$ (Jodejko-Pietruczuk and Werbińska-Wojciechowska, in press):

$$F(x) = 1 - \prod_{j=1}^{n}\left[1 - \int_{u=0}^{x} g_j(u) F_{h_j}(x-u)du\right] \tag{4}$$

When the system elements work in a parallel reliability structure, the *C.d.f.* of time to failure, $F(x)$, given by the formulae (4) may be estimated as (Jodejko-Pietruczuk and Werbińska-Wojciechowska, in press):

$$F(x) = \prod_{j=1}^{n}\int_{u=0}^{x} g_j(u) F_{h_j}(x-u)du \tag{5}$$

The strong convergence of simulation and analytical results of the presented maintenance model was investigated in (Jodejko-Pietruczuk and Werbińska-Wojciechowska, in press). Both the models, simulation and analytical one yield the

same results, what may be the foundation to confirm their correctness. This conclusion gives the possibility to define the optimum (or at list good) period between two consecutive system inspections, which may be determined on the base of minimization of the difference of the failure and elements' replacement costs:

$$K = CF - CE \tag{6}$$

The plot of the K value in the function of period between inspections (T) for various *k-out-of-n* systems is presented in the Figure 7.

The results presented in the Figure 7 shows different optimum periods between inspections for *k-out-of-n* system, dependently on the k value. When system is liable to every component failures (3-*out-of-* 3), it should be inspected much more often than systems being more resistant for elements' unreliability ($k < 3$). The presented effect exemplifies the usability of the analytical maintenance model for the general case of system with *k-out-of-n* reliability structure.

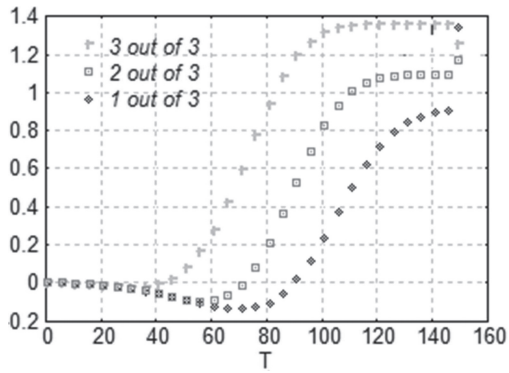

Figure 7. Function K according to Eq. (6) (for the case: $c_r = 5$, $c_i = 1$, and $c_f = 100$).

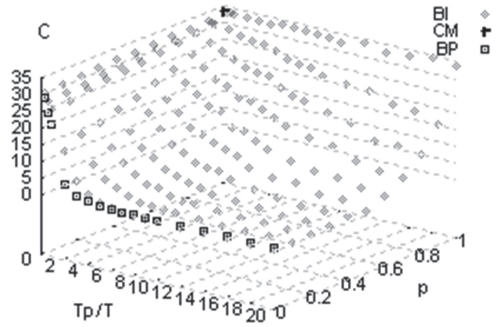

Figure 9. The total costs of the series system for BI, CM, BP maintenance policies.

4 CONCLUSIONS

The discussed issues give the possibility to obtain some rules for definition of the principal relations between the system performance under given PM policy with perfect/imperfect maintenance and chosen PM policy parameters.

The obtained analysis results indicate that the cost-effectiveness of maintenance policy implementation depends on the lengths of T time period and delay time period h. Taking into account these facts together and earlier performed analyses, there can be stated a conclusion that the best results of the BI maintenance policy may be achieved when the period between inspections T is shorter than the system elements' $MTTF$ and their mean delay time h.

To summarize the presented research work, there could be made answer the question if the BI maintenance policy is more profitable in comparison to other maintenance policies when its inspection precision drops. For this reason the system has been tested assuming BI policy, corrective maintenance policy (CM) ($T \to \infty$) and BP policy ($h_i = T_{pi}$, $p = 0$). The chosen results are presented in Figures 8 and 9.

As one can see, the results show some general rules valid for the modelled system:

- the corrective maintenance policy is the worst of all the analysed policies.
- cost results of the BP policy obtained in the research are better than BI effects (or mostly the same) for every tested case of inspection precision. Such a situation happens because preventive replacement of all system elements ensures the lowest consequence cost, which is the dominant cost component. Another relation of new element and system failure costs may make the BI policy more profitable in comparison to the BP policy.

Availability model of technical objects—block inspection policy implementation

A. Jodejko-Pietruczuk & S. Werbińska-Wojciechowska
Wroclaw University of Technology, Wroclaw, Poland

ABSTRACT: In the presented paper, authors focus on development of mathematical delay-time model for single-unit technical systems liable to costly failure. Failure is taken here to mean a breakdown or catastrophic event, after which the system is unusable until repaired or replaced. Thus, the briefly literature review in the area of delay-time modelling is provided. Later the analytical model of expected system availability is investigated. Authors also discuss the sensitivity analysis of given simulation model. The directions for further research work are defined.

1 INTRODUCTION

One of the basic targets of maintenance services is to ensure the proper and uninterrupted performance of technical systems. This is of particular importance because any unforeseeable and unreasonable disruption of a technical system performance may entail huge costs associated with e.g. the interruption of production or the occurrence of catastrophic events (see e.g. (Babiarz 2006, Kierzkowski 2010, Kierzkowski et al. 2012, Kierzkowski and Zając 2012)). Unplanned downtime can be prevented through the use of appropriate maintenance strategies or diagnostics. Tasks are designed to forecasting upcoming moments of repair or replacement of wearing parts during their operation and to shorten the duration of taken maintenance processes (Valis and Vintr 2006, Vintr and Valis 2012).

The technical objects performance is strictly connected with aging process. The wear processes are the most common cause of damage (about 70–80% of all the occurred failures) in mechanical devices (Boda 1999, Ickiewicz and Ickiewicz 1998, Laskowski and Bylak 2013). One of the possible solutions aimed at improving operational processes is inspection policies applying. Moreover, authors focus on investigation of technique called delay time analysis, which has been developed for modeling the consequences of an inspection policy implementation for any systems (Christer 2002).

Most of the known in literature delay-time models regard to single-unit systems performance optimization issues (Frostig 2003, Valdez-Florez and Feldman 1989, Wang 2002). Moreover, widely investigated inspection models are dedicated for new elements maintenance performance (Jodejko-Pietruczuk et al. 2013). However, when assuming that the working element is not defected at the point of inspection maintenance time, the optimization model for time between next inspections performance is not investigated.

Following the above considerations, authors focus on the development of analytical maintenance model of single-unit technical objects with taking into account availability criteria. Thus, in the next Section, there is provided a briefly literature review in the investigated research area. This gives the possibility to present the maintenance model for the case of one-component system. Following this, in the next step, authors examine the sensitivity analysis of obtained model. The work ends up with summary and directions for further research.

In conclusion, this article is to be the continuation of consideration about mathematical modelling of technical objects with time delay maintenance. The analytical model with cost constraints is given in (Jodejko-Pietruczuk et al. 2013), the cases of multi-unit systems performing in different reliability structures are investigated in (Jodejko-Pietruczuk and Werbińska-Wojciechowska, in prep.).

2 BLOCK INSPECTION POLICY MODELLING—LITERATURE REVIEW

The delay-time concept is widely known in the literature since the 70 s. of XX century (Christer 2002). The literature review works strictly dedicated to the issues of DT modelling and implementations are given mostly in (Alzubaidi 1993, Baker and Christer 1994, Christer 2002, 1999, Christer and Redmond 1992, 1990, Lee 1999, Nowakowski and Werbińska-Wojciechowska 2012, Wang and Christer 2003, Wang 2012). There should be also

underlined the state of art work, in which delay-time models are presented along with other PM models (see e.g. (Cho and Parlar 1991, Dekker and Scarf 1998, Mazzuchi et al. 2007, Ozekici 2006, Thomas 1986, Valdez-Flores and Feldman, 1989)).

The known technical systems maintenance models which base on delay-time concept implementation can be divided into two main groups (Jodejko-Pietruczuk et al. 2013, Wang 2008):

- inspection models for single-unit or complex systems;
- inspection models for multi-unit systems.

The issues on maintenance modelling of single-unit and complex systems were reviewed e.g. in (Jodejko-Pietruczuk et al. 2013). The main problem investigated in this area regard to e.g. replacement decisions (see e.g. (Christer and Waller 1987)), or model parameter estimation issues (see e.g. (Baker and Wang 1992)). Moreover, there can also be found maintenance models for single-component systems under condition based maintenance (see e.g. (Christer and Wang 1992, Okumura 1997, Okumura et al. 1996)), and models dedicated to risk analysis implementation (see e.g. (Wang 2003)) or safety issues investigation (see e.g. (Wang and Christer 1997)).

3 DELAY-TIME MODEL FOR SINGLE-UNIT SYSTEM

In this Section, there is considered a delay-time model for a single-unit system. The performed maintenance policy bases on Block Inspection policy (*BI*) which assumes, that inspections take place at regular time intervals of T, and each requires a constant time. The inspections are assumed to be perfect. Thus, component defect which occurs in the system till the moment of inspection will be identified and replaced within the inspection period.

In the analysed system may be performed one of the two maintenance operations: failure repair or inspection together with replacement of element with defect. Moreover, the performance of the investigated system is also defined by the additional assumptions and notation:

- the system is a three state system where, over its service life, it can be either operating or down for necessary repair or planned maintenance,
- the system is renewed at either a failure repair or at a repair done at an inspection if a defect is identified,
- after either a failure renewal or inspection renewal the inspection process restarts,
- maintenance actions restores maintained components to as good as new condition,
- failures of the system are identified immediately and repairs or replacements are made as soon as possible,
- failure replacement, inspection replacement and inspection replacement require d_f, d_r and d_i time units respectively,
- time of defects occurrence defined by u is a random variable described by its probability distribution functions $g(u)$ and $G(u)$,
- the length of the delay time before element's failure is random and its probability distributions are given by $f_h(h)$ and $F_h(h)$.

Moreover, there is a possibility to define the *c.d.f.* of time to failure, $F(x)$, as the convolution of u and h such that $u + h \leq x$ (Redmond 1997):

$$F(x) = \int_{u=0}^{x} g(u)F_h(x-u)du \tag{1}$$

And the reliability, $R(x) = 1 - F(x)$.

For the presented above assumptions, in accordance with the literature concept of the delay time, known models assume that an inspected element is newly replaced at the beginning of the inspection period, e.g. the previous inspection exposed a defect of the element and caused a maintenance action.

Following this, there can be estimated e.g. the expected cost over each cycle $C(T)$, or expected downtime $E_d(T)$ of an inspection cycle of length T (see e.g. (Christer 1999). The examples of such the model implementation are given e.g. in (Redmond 1997, Wang 2008).

The cost and availability models given in the literature (see e.g. (Jodejko-Pietruczuk et al. 2013)) describes the first inspection cycle results, i.e. when a new element is run to work at the beginning of the cycle. On this base, one can choose the length of the cycle T, and thus—the moment of the first inspection, which yields the minimum expected costs per the cycle. However, not in every situation there is a possibility to define maintenance costs. Sometimes, more important is to optimize maintenance strategy parameters taking into account dependability constraints. Thus, the model for system availability ratio is investigated.

3.1 *Availability model of single unit system with delay time*

The availability results of a system with delay time, which is inspected periodically, depends upon the relations of basic time components, like system up time, time of inspection activities performance, preventive replacements and failure time. To estimate such the relation, one

needs to express the expected values of these time variables.

In the curse of the first inspection cycle the expected lifetime of the system may be expressed:

$$T_M(t_1) = \int_0^{t_1} x \int_0^x g(u) f_h(x-u)\, du dx + t_1 \cdot \int_{u=0}^{t_1} g(u)(1 - F_h(t_1 - u)) du \quad (2)$$

where:
$T_M(t_1)$—the expected lifetime of the system in the first inspection cycle,
t_1—the moment when the first inspection cycle ends.

The first component of the sum in the formulae (2) expresses possible moments of system failures, while the second part of the expression takes into consideration the probability that the system defect is observed in the time of the first inspection performance.

However, if we assume that an element may operate longer than to the first inspection, because the system does not reveal any symptoms of defects, the expected system lifetime should be expressed as follows:

$$T_M(t_{i+1}) = \left[\int_{t_i}^{t_{i+1}} x \int_0^x g(u) f_h(x-u) du dx + t_i \cdot \int_{u=0}^{t_i} g(u)(1 - F_h(t_i - u)) du \right] (1 - G(t_i)) \quad (3)$$

where:
$T_M(t_i)$—the expected lifetime of the system to the end of the i-th inspection cycle,
t_i—the moment when the i-th inspection ends.

The probability of a system failure in the inspection cycle between moments (t_i, t_{i+1}) depends on the fact that the previous inspection have not revealed any defect symptoms. Thus, the expected lifetime length has to be lowered by the probability of this fact $(1 - G(t_i))$.

The total expected length of the system up time in the curse of a single renew cycle (the time elapsing between two consecutive system replacements, independently on the replacement premise) may be estimated as the sum of expected lifetimes resulting from the sequence of inspection periods, when $t_i \to \infty$:

$$T_M(t_i) = T_M(t_1) + \sum_{i=2}^{\infty} T_M(t_i) \quad (4)$$

In practice, when we consider one-component system, the sum from equation (4) converges, when t is three times longer than the expected system lifetime, for the situation when there is no preventive action taken.

When one wants to estimate the expected time of inspection actions performance in a single renew cycle, the formulae (5) may be applied:

$$T_I(t_i) = d_i \cdot \sum_{i=1}^{\infty} (1 - G(t_{i-1}))(1 - F(t_i)) \quad (5)$$

where:
$T_I(t_i)$—the expected time of inspections carried out in the system during a single renew period,
d_i—the time of a single inspection actions.

A next inspection (i-th) may be taken depending on the probability of the two facts: that a previous inspection has not revealed defect occurrence and at the end of $(i-1)$-th inspection period the system is still reliable.

The estimation of the expected time of preventive replacement of the system in the course of a single renew period should base on the probability of defect occurrence at the end of an inspection cycle and lack of this defect at the moment of the previous inspection performance. The time should be calculated separately for every single inspection period and the sum of them expresses the total expected replacement time.

$$T_R(t_{i+1}) = d_r \cdot \sum_{i=1}^{\infty} (1 - G(t_i)) \left[\int_{u=0}^{t_i} g(u)(1 - F_h(t_i - u)) du \right] \quad (6)$$

where:
$T_R(t_i)$—the expected preventive replacement time of the system to the end of the i-th inspection cycle,
d_r—the time of a preventive replacement of the system.

The last time component, which should be estimated to assess the system availability ratio, is the expected failure time in a single renew cycle. The time depends on the failure probability in a given inspection period, assuming that at the moment of a previous inspection performance any defect has not been detected. It lays the foundation to define the following equation:

$$T_F(t_{i+1}) = d_f \cdot \sum_{i=1}^{\infty} \left(1 - G(t_i)\right)\left(F(t_{i+1}) - F(t_i)\right) \quad (7)$$

where:
$T_F(t_i)$—the expected failure replacement time of the system to the end of the i-th inspection cycle,
d_f—the time of a corrective replacement of the system.

The calculated time values of: inspections, preventive and corrective replacement in the curse of a single renew period $(t_i \to \infty)$ allows to estimate

the availability ratio for the cycle, according to the well know formulae:

$$A = \frac{T_{M(t_i)}}{T_{M(t_i)} + T_{I(t_i)} + T_{F(t_i)} + T_{R(t_i)}} \tag{8}$$

where:
A—the availability ratio of the system for a single renew period.

3.2 *Sensitivity analysis of developed availability model for single-unit case*

In this Section, there is presented the short sensitivity analysis of the model developed above. The objective of given analysis was to investigate what is the influence of given model basic time components on the system availability ratio level. To provide the analysis, there have been assumed main model parameters (Table 1).

First, the Figure 1 depicts the expected time components in a single renew cycle for the chosen range of T (length of a single inspection cycle). It presents the relation between expected times and the length of the inspection period T. The mean time to failure of the tested system has been c.a. $MTTF \approx 100$ (units of time), thus the range of T has been set based on this system parameter estimation.

Table 1. The parameters of the tested availability model.

Parameter	Value
d_i	1
d_r	10
d_f	100
$G(u)$	Weibull distribution with $\alpha = 3.5$, $\beta = 65$
$F_h(x)$	Weibull distribution with $\alpha = 3.5$, $\beta = 35$

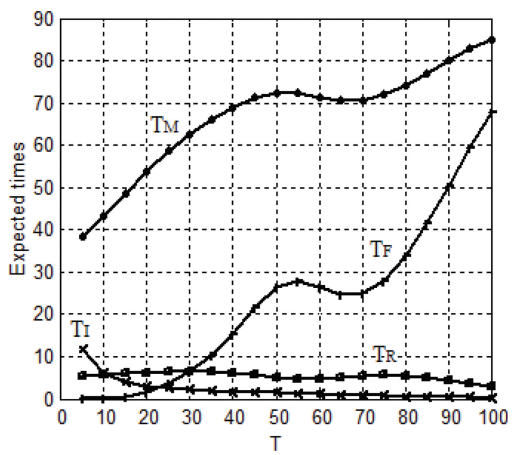

Figure 1. Expected system lifetime and times of inspection, preventive and corrective replacements per a single renew cycle.

During the analysis of results presented in the Figure 1, one might notice that the longer periods between inspections (T), the longer system lifetime (T_M) and failure time (T_F). On the other hand, when the inspection period approaches to the mean time to the defect occurrence (mean time to defect occurrence $MTTD \approx 67$), the expected lifetime as well as the failure time drops for some segment of the tested range of T. This interesting effect results from the fact, that during inspection action performance a defect may be noticed, and the system is preventively replaced. Thus, its lifetime is usually limited to the value of the length of the inspection period and the system is not allowed to start work in a next inspection cycle. The same observable effect in the Figure 1 pertains to the failure time. When the defect is revealed in the time of an inspection, element is preventively replaced, new element starts its lifetime and the probability of a system failure decreases.

On the other hand, when one examines the expected time of preventive replacements, the minimum values are visible at the segment of the tested range of T, lower than $MTTD$ ($T \in (50, 65)$). The same values of T yield the local maximum of the expected failure time T_F. When an inspection action is performed just a moment before a defect will occur, the system is allowed to start a new inspection cycle and the probability of failure occurrence the next inspection cycle increases.

Basing on the presented calculations, the system availability ratio has been estimated and presented in the Figure 2.

The availability ratio reaches its maximum values ($A \approx 0{,}8$) for $T \approx 30$ [units of time]. The location

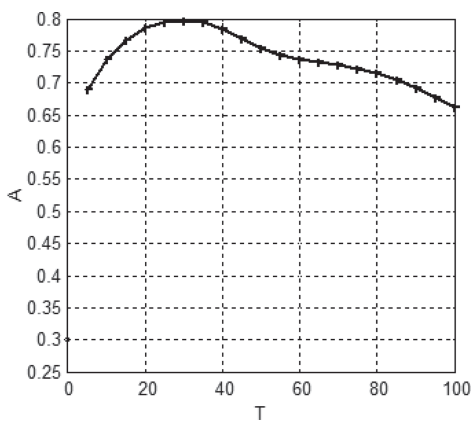

Figure 2. System availability ratio for a single renew cycle.

of the maximum value of the availability ratio may result from the relation of T and $MTTD$ ($MTTD/T \approx 2$) or from the mean time since defect occurs to a failure moment $T \approx (MTTF - MTTD)$. The results obtained for another parameter values of the system are presented in the Figures 3 and 4.

The results, illustrated in the Figure 3, has been obtained for failure replacement times (d_f) extended ten times in comparison to the one, presented in the Table 1. The availability ratio has been reduced for the whole range of the tested values of T and the optimum point has also shifted toward lower values of inspection lengths (T). When failure consequences becomes more severe, one try to reduce the consequence probability. Thus, the system should be inspected more often in order to reveal the defect as soon as it may be visible.

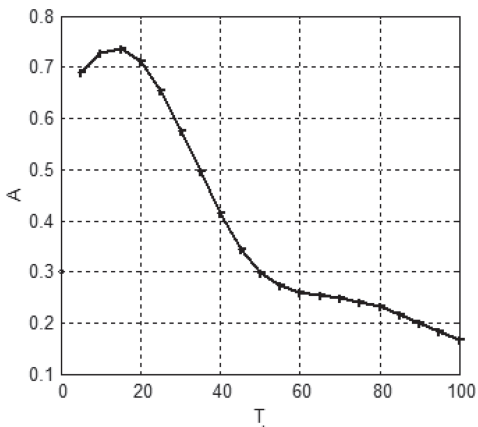

Figure 3. System availability ratio for a single renew cycle and $d_f = 1000$.

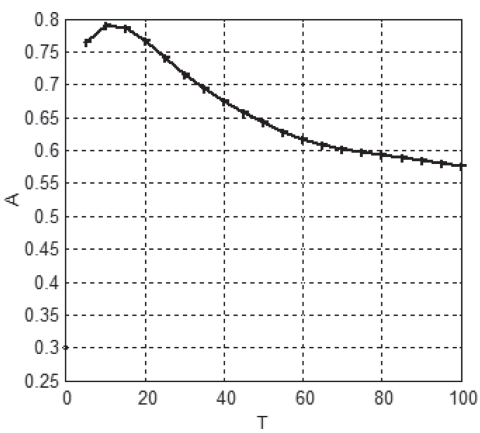

Figure 4. System availability ratio for a single renew cycle and $T \approx MTTF - MTTD \approx 15$.

Figure 4 depicts the availability ratio obtained for the situation, when the mean time of defect occurrence has been reduced ($MTTF - MTTD \approx 15$). It means that the periods of system up time without any defect signals are relatively much longer than the period when the signal may be noticed. Inspections have to be done more frequently in order to complete preventive actions as often as possible. Due to the availability level of the system with delay time, the most profitable solution is to choose the inspection cycle length very closed to the value of $T \approx (MTTF - MTTD)$, the time between the moments of defect and failure occurrence $\approx (MTTF - MTTD)$.

4 CONCLUSIONS

In the area of technical systems maintenance modelling with the use of DT concept, the main task is to optimize the length of time between successive inspection actions performance. In the presented article, this problem is solved by developing an analytical model of the expected availability ratio for single-component case. The authors are continuing their research on the mathematical modeling with the use of DT approach for technical systems presented e.g. in (Jodejko-Pietruczuk and Werbińska-Wojciechowska 2014, Jodejko-Pietruczuk et al. 2013).

Following this, in the next step, authors plan to develop the availability model for the case of multi-element system with delay time. This will complete the research work of authors connected with maintenance analytical modelling for technical systems with time delay.

Condition-based maintenance policies for multi-component systems with Lévy copulas dependence

Heping Li, Laurence Dieulle & Estelle Deloux
Charles Delaunay Institute, University of Technology of Troyes, Troyes, France

ABSTRACT: The maintenance planning of systems has become more and more complex over the last decades due to the fact that systems consist of more components which depend on each other. Stochastic dependencies exist in industry due to a common environment or to the fact that components share the same stress while economic dependencies arise when grouping maintenance activities can save setup cost. Interactions between components make the modeling and optimization of maintenance tricky. However dependencies between components have to be taken into account in order to optimize the maintenance activities but the way of modeling stochastic dependencies remains to explore. Copulas are widely used to model the dependence structure of random variables and they separate dependence structure from marginal properties. Kallsen & Tankov (2006) extended the Sklar's Theorem for Lévy measure and they defined a new copula for Lévy processes so called Lévy copulas. Based on marginal Gamma processes, we use Clayton-Lévy copula to model the dependent stochastic degradation of components. This model of dependence is different from previous literatures as Lévy copula provides a means of modeling stochastic dependence which can be from independence to complete dependence and it is easily simulated. By considering economic dependence, we propose a condition-based maintenance policy with a new decision rule allowing grouping opportunities and we compare the performance with classic maintenance strategies.

1 INTRODUCTION

In order to ensure the productivity, the safety and to save the cost, maintenance policies have been widely studied since the last century. Nevertheless, the nowadays systems contain more and more components resulting in more complex structures. As a result, the research of maintenance policies focusing on the single-unit systems is not suitable any more. For a multi-component system, interactions between components have to be taken into consideration. According to Thomas (1986), generally interactions between components in a multi-component system are classified into three types: economic dependence, stochastic dependence and structural dependence. In this paper, we consider economic and stochastic dependence. Stochastic dependence arises in industry due to the common environment or to the fact that components share the same stress. Hong, Zhou, Zhang, & Ye (2014) shows that maintenance optimization will be affected by dependent degradation. Golmakani & Moakedi (2012) propose a periodic inspection optimization model for a two-component repairable system with failure interactions, Mercier & Pham (2012) model dependence by a bivariate wear subordinator with Gamma marginal distributions. However, these models of dependence can only represent a few range of possible dependence. Moreover, when the system contains a large number of components, it seems that the dependence are hardly to be builded in the system level. In other hands, copulas are widely used to model the dependence structure of random variables as they separate dependence structure from marginal properties. Hong, Zhou, Zhang, & Ye (2014) model the dependence structure of stochastically deteriorating components by the ordinary copula which has several drawbacks when applied to Lévy processes and pointed out by Cont & Tankov (2004). To overcome these drawbacks, they extended the Sklar's Theorem for Lévy measure and they defined a new copula for Lévy processes so called Lévy copulas. Kallsen & Tankov (2006) enrich the properties of Lévy copulas. Based-on marginal Gamma processes, we use Clayton-Lévy copula to model the dependent stochastic degradation of components. This model of dependence is different from previous literatures as Lévy copula provides a means of modeling stochastic dependence which can befrom independence to total dependence and it is easily simulated. Economic dependence offers opportunities to group maintenance actions so as to save set-up cost. Including the economic dependence,

we implement several maintenance policies. The main contribution of this paper is to propose a new adaptive maintenance decision rule considering not just the currently-inspected component, but also the available information about the other components. The paper is arranged as follows. In section 2 we recall some basic information about Lévy copulas and Gamma processes. Section 3 describes our proposal of maintenance decision rule and proposes classic maintenance strategies to implement for the purpose of comparison. In section 4, numerical results are presented. Conclusions and perspectives are given in section 5.

2 STOCHASTIC DEGRADATION MODELS

To simplify the model and the calculations, we firstly consider a system which consists of two components in parallel. The state of the system is characterised by the individual deterioration level of each component. The deterioration level of each component can be represented by a scalar variable X_t^i (i = 1, 2). All of components in the system are new at the beginning. When the deterioration level of component i exceeds its own failure threshold L_i, it is considered as failed.

2.1 *Stochastic degradation modeling of component*

As we assume that the deterioration of the component can be summarized by a scalar variable X_t^i (i = 1, 2), $(X_t^i)_{t\geq 0}$ is supposed to be modeled by a stationary Gamma process with shape parameter α_i and scale parameter β_i ($i = 1,2$) with following properties:

- $X_0^i = 0$
- $(X_t^i)_{t\geq 0}$ has independent increments
- For $t > 0$ and $h > 0$, $X_{t+h}^i - X_h^i$ follows a Gamma distribution with shape parameter $\alpha_i t$ and scale parameter β_i and the probability density function of $(X_{t+h}^i - X_h^i)$ is given by:

$$f(x|\alpha_i t, \beta_i) = \beta_i^{\alpha_i t} x^{\alpha_i t - 1} exp(-\beta_i x)/\Gamma(\alpha_i t) \qquad (1)$$

Such a process means that the mean and variance of X_t^i are $\alpha_i t/\beta_i$ and $\alpha_i t/ \beta_i^2$. Parameters α_i et β_i allow us to model different deterioration behaviours of components in the system. Note that the Gamma process is a positive process with independent increments, hence it is sensible to use this process to describe the deterioration (Noortwijk (2009)). Another interest of the Gamma process is the existence of an explicit probability distribution function, which permits feasible mathematical developments.

2.2 *Stochastic dependence modeling with Lévy copula*

Since the components in the same system share a common stress, it is reasonable to assume that the deterioration of components are dependent. In this paper, we use Lévy copula to model the dependence between components for a wide range of dependence. To introduce Lévy copula, we firstly recall that according to the Sklar's Theorem, for F_1, ..., F_n univariate continuous cumulative distribution function and H a multivariate joint cumulative distribution function there exists a unique function C such that

$$\begin{aligned} H(x_1, x_2, ..., x_n) &= C(F_1(x_1), F_2(x_2), ..., F_n(x_n)) \\ &= C(u_1, u_2, ..., u_n) \end{aligned}$$

This is that $H(x_1, x_2, ..., x_n)$ has the same dependence structure with $C(u_1, u_2, ..., u_n)$ regardless its marginal functions. Hence, copulas allow to separate the univariate margins and the multivariate dependence structure in the continuous multivariate distribution functions. To model the dependence structure for stochastic processes, Cont & Tankov (2004) define the dependence structure of Lévy measure by Lévy copula. Thus Lévy copula retains the dependence information of a Lévy measure. Let $X = (X^1, ..., X^d)$ be a Lévy process. Then there exists a Lévy copula C_L such that the tail integral of X satisfies:

$$U(x_1, ..., x_d) = C_L(U_1(x_1), ..., U_d(x_d)) \qquad (2)$$

with for the joint measure: $U(x_1, \ldots, x_d) = \int_{x_1}^{\infty} ... \int_{x_d}^{\infty} \nu(dx_1 ... dx_d)$ and for the marginal measure: $U_1(x_1) = \int_{x_1}^{\infty} ... \int_0^{\infty} \nu(dx_1 ... dx_d)$. Similar to ordinary copulas, there are also several families of Lévy copulas. For our two-component system with marginal Gamma processes, we choose Clayton-Lévy copula where dependence structure C is defined as follows:

$$C(u,v) = (u^{-\theta} + v^{-\theta})^{-1/\theta} \qquad (3)$$

When $\theta \to 0$, u and v are independent; when $\theta \to \infty$, u and v are completely dependent. What's more, when u and v are independent, $C(u,v) = u1_{v=\infty} + v1_{u=\infty}$.

As a consequence, our model of stochastic dependence is obtained by following steps:

1. For a Gamma process with shape parameter α and scale parameter β, the Lévy measure $\nu(dx) = \{\alpha \exp(-\beta x)/x\}dx$. So we have

$$U(x) = \alpha E_1(\beta x) \qquad (4)$$

where E_1 is exponential integral and the inverse is

$$U^{-1}(x) = E_1^{-1}(x/\alpha)/\beta \tag{5}$$

2. When the dependence Lévy copula is in Clayton family, according to equation (3) the conditional distribution function take a form:

$$C(v,u) = \partial C_\theta(u,v)/\partial u = \left\{1 + (u/v)^\theta\right\}^{-1-1/\theta} \tag{6}$$

and can be easily inverted:

$$v = C^{(-1)}(y \mid u) = u(y^{-\theta(1+\theta)} - 1)^{-1/\theta} \tag{7}$$

where y is a random variable uniformly distributed on [0,1].

3. Since a Gamma process $(X_t)_{t\geq 0}$ can be represented in law by series representations $(\tilde{X}_t)_{t\geq 0}$ where

$$\tilde{X}_t = \sum_{i=1}^{\infty} U^{(-1)}(\Gamma_i)1_{[0,t]}(v_i) \tag{8}$$

with $\{\Gamma_i\}$ a sequence of jumping times of a standard Poisson process and $\{V_i\}$ an independent sequence of independent random variables, uniformly distributed on [0,1] (Rosinski (2001)). Furthermore, a two-dimensional Gamma process (X_t, Y_t) with Lévy copula dependence can be represented as follows (Cont & Tankov (2004)):

$$X_t = \sum_{i=1}^{\infty} U_x^{(-1)}(\Gamma_i)1_{[0,t]}(v_i) \tag{9}$$

$$Y_t = \sum_{i=1}^{\infty} U_y^{(-1)}(C^{(-1)}(w_i \mid \Gamma_i))1_{[0,t]}(v_i) \tag{10}$$

Finally, according to equation (5), equation (7), equation (9) and equation (10), a two-dimensional Gamma process (X_t, Y_t) can be represented by

$$X_t = \sum_{i=1}^{\infty} E_1^{-1}(\Gamma_i/\alpha_1)1_{[0,t]}(v_i)/\beta_1$$

$$Y_t = \sum_{i=1}^{\infty} E_1^{-1}(\Gamma_i(w_i^{-\theta(1+\theta)} - 1)^{-1/\theta}/\alpha_2)1_{[0,t]}(v_i)/\beta_2$$

where $(w_i)_{i\in\mathbb{N}}$ and $(v_i)_{i\in\mathbb{N}}$ are independent random variables which have uniform distribution on [0,1] and $(\Gamma_i)_{i\in\mathbb{N}}$ is an independent sequence of jump times of a standard Poisson process. In next section, we propose an adaptive maintenance decision rule aiming at taking full advantage of the dependence between components by increasing the possibilities of grouping maintenance tasks.

3 MAINTENANCE POLICIES

In this section, we detail our proposal for taking full advantage of grouping opportunities with respect to the current available information. In order to compare the performance of such a decision rule, we propose to implement classical maintenance strategies. For all considered maintenance policies, we make following assumptions:

- In order to avoid failures, a preventive maintenance takes place when X_t^i exceeds corrective threshold M_i (with $0 \leq M_i \leq L, i = 1,2$). Both preventive and corrective replacements are assumed to be perfect and instantaneous.
- The deterioration level of component can be obtained only by inspection. Besides, if the component fails, it remains unavailable until the next inspection and then it is repaired. We assume that each inspection reveals the real state of component perfectly.
- Considering the economic dependence, we assume that the costs of preventive replacement ($c_p^i, i = 1,2$) and of corrective replacement ($c_c^i, i = 1,2$) are composed of two parts: the set-up cost (c_r) and the individual cost. If one component fails but the other one still works, it will have a penalty cost per time unit (c_u); if both of components fail, the system is failed and it will have a down-time unitary cost per time unit (c_d). Of course, we have a inspection cost (c_{insp}) for every inspection.

To evaluate maintenance policies, we use the criterion of expected cost of system per time unit: $\overline{C} = \lim_{t\to\infty} E_0(c(t))/t$. The cumulative cost of system $c(t)$ depends on the number of preventive and corrective replacements ($N_p^i(t)$, $N_c^i(t)$), the number of inspections ($N_i^i(t)$), the cumulative failed time of components ($U_i(t)$) and the cumulative down-time of system ($D(t)$). Therefore $c(t)$ can be represented by

$$c(t) = \sum_{i=1}^{2} (c_p^i N_p^i(t) + c_c^i N_c^i(t) + c_{insp} N_i^i(t) + U_i c_u(t)) + c_d D(t)$$

and the Monte-Carlo simulation method is employed for the computation. In industry, combining the maintenance activities is often cheaper than maintaining the components separately because of the scale effect, the set-up cost or taking full advantage of downtime (Nicolai & Dekker (2008)). In this study, we mainly consider the case of set-up cost (c_r). When the maintenance actions of two component take place at the same time, we save a set-up cost. Therefore, with economic dependence, the expected cost of system per time

unit is modified by the number of group ($N_g(t)$) as follows:

$$c(t) = \sum_{i=1}^{2} (c_p^i N_p^i(t) + c_c^i N_c^i(t) + c_{insp} N_i^i(t) + U_i c_u(t)) + c_d D(t) - c_r N_g(t)$$

3.1 *A new condition-based maintenance policy with grouping opportunities (policy 0)*

The component 1 and 2 are inspected every ΔT_1 and ΔT_2 time unit respectively. Applied at each inspection time, we propose an advanced maintenance decision rule allowing to postpone or to preempt a maintenance task (according to aprobabilistic criterion) in order to take full advantage of the cost saving induced by replacements that are simultaneously performed. Suppose that at time $n\Delta T_1$, the deterioration level of component 1 ($X^1_{n\Delta T_1}$) exceeds the preventive replacement threshold ($M_1 < X^1_{n\Delta T_1} < L_1$) hence the component needs to be preventively replaced. Simultaneous replacement of both components is thus feasible. Two cases are considered according to the available information: postponing or preempting. As component 2 is not observed at time $n\Delta T_1$, the last known deterioration level of component 2 is $X^2_{m\Delta T_2}$ ($m\Delta T_2 < n\Delta T_1 < (m+1)\Delta T_2$) (see Fig. 1) is used as follows:

1. Set $p_a = P(X^2_{n\Delta T_1} > M_2 \mid X^2_{m\Delta T_2})$ be the probability that component 2 would need to be preventively replaced at time $n\Delta T_1$, if $p_a \to 1$, then the component 2 will probably be replaced soon ($(m+1)\Delta T_2$). In this case which is called preempting case, we can preempt the replacement of component 2 in order to save a set-up cost as well as to avoid the failure of component 2 before the next inspection. However such an action may replace the component 2 too early and lead to an increase of preventive maintenance cost. Parameter p_a depends only on the last known deterioration level of component 2 and is computed as follows:

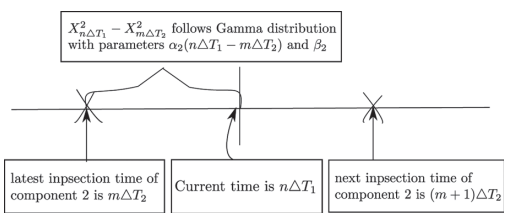

Figure 1. Sketch of inspection time.

$$p_a = P(X^2_{n\Delta T_1} > M_2 \mid X^2_{m\Delta T_2}) = P(X^2_{n\Delta T_1 - m\Delta T_2} > M_2 - X^2_{m\Delta T_2})$$

Since the random variable $X^2_{n\Delta T_1}$ knowing that $X^2_{m\Delta T_2}$ follows Gamma distribution with parameter $(n\Delta T_1 - m\Delta T_2)\alpha_2$ and β_2, therefore $p_a = \overline{F}_{(n\Delta T_1 - m\Delta T_2)\alpha_2, \beta_2}(M_2 - X^2_{m\Delta T_2})$ where $\overline{F}_{(n\Delta T_1 - m\Delta T_2)\alpha_2, \beta_2}(x) = \int_x^{+\infty} f_{(n\Delta T_1 - m\Delta T_2)\alpha_2, \beta_2}(u)du$

2. set $p_p = P(X^1_{(m+1)\Delta T_2} > L \mid X^2_{m\Delta T_2})$ be the probability that component 1 will be failed at the inspection time of component 2, if $p_p \to 0$, then the component 1 will almost impossibly fail before the next inspection time of component 2 ($(m+1)\Delta T_2$). In this case which is called postponing case, the replacement of component 1 can be postponed to the next inspection period of component 2 in order to save a set-up cost also to extend the working hours of component 1. However such an action may take the risk that component 1 fails before it is replaced and furthermore the cost of corrective replacement is more expensive than that of preventive replacement. Similar to case 1,

$$p_p = \overline{F}_{((m+1)\Delta T_2 - n\Delta T_1)\alpha_1, \beta_1}(L - X^1_{n\Delta T_1})$$

For general case,

$$p_a = \overline{F}_{(n\Delta T_i - m\Delta T_j)\alpha_j, \beta_j}(M_j - X^j_{m\Delta T_j}) \quad (11)$$

$$p_p = \overline{F}_{((m+1)\Delta T_j - n\Delta T_i)\alpha_i, \beta_i}(L - X^i_{n\Delta T_i}) \quad (12)$$

where current inspection time is $n\Delta T_i$ and $M_i < X^i_{n\Delta T_i}$.

In order to decide which is more benefit between postponing or preempting, a priority is given to the first condition. Let us note that condition $p_a \to 1$ is checked first because if p_a is small then it would be useless to postpone the replacement of component 1 because component 2 will be hardly replaced at next inspection period. As a result, we give priority to the condition of $p_a \to 1$ and we define our decision rule in Figure 2. Pay attention to that the replacement of component 1 can not be postponed if $X^1_{n\Delta T_1} > L_1$. Condition 1 is met if p_a is greater than an input threshold PA whereas condition 2 is met when p_p is greater than another input threshold PP (see Fig. 2). PA and PP are chosen in order to optimize the cost criterion. When PA is small, condition 1 will be often met leading to many grouped maintenance tasks. When both PA and PP are small then condition 2 is often met and at $n\Delta T_1$, preempting the replacement of component 2 is preferable to postponing replacement of component 1.

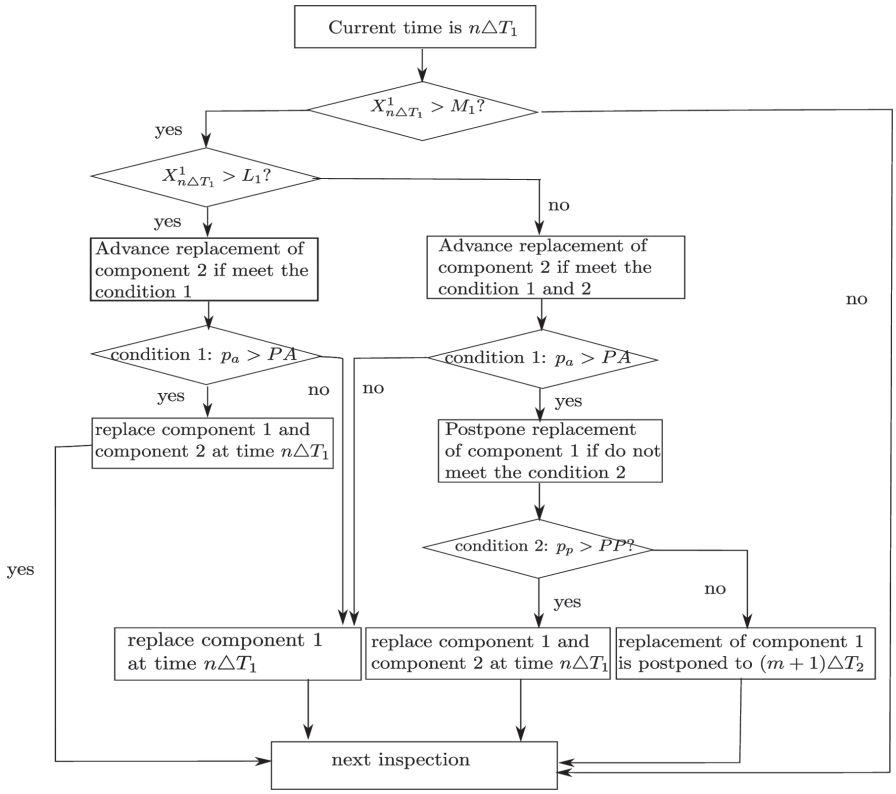

Figure 2. Sketch of decision rule for example of component 1 inspected at time $n\Delta T_1$.

3.2 *Classic maintenance strategies*

3.2.1 *Condition-based maintenance policy not considering the economic dependence (policy 1)*

Firstly we consider a basic condition-based maintenance policy. We inspect the components every ΔT_1 time unit for component 1 and ΔT_2 for component 2. At every inspection time $n\Delta T_i$ $(n \in \mathbb{N}, i = 1,2)$, the deterioration level of component i ($X^i_{n\Delta T_i}$) is revealed. When $X^i_{n\Delta T_i}$ exceeds its own corrective replacement threshold L_i, a corrective replacement takes place; when $X^i_{n\Delta T_i}$ exceeds its preventive replacement threshold M_i, a preventive replacement is carried out; otherwise the inspection to be continued. Obviously, to minimise the expected cost of system per time unit, we have to find the optimal values of ΔT_i and M_i $(i = 1,2)$.

3.2.2 *Condition-based maintenance policy considering the economic dependence (policy 2)*

The maintenance decision rule is the same as the policy 1. The only difference is the account of a set-up cost c_r. As described in the introduction of this section, the set-up cost modifies the expression of $c(t)$ and impacts the optimal values of ΔT_i and M_i $(i = 1,2)$. This maintenance policy is noted Policy 2.

3.2.3 *Condition-based maintenance policy with a unique inspection period and a unique replacement threshold considering the economic dependence (policy 3)*

When the set-up cost accounts a large part, grouping more maintenance activities is more economic. Hence we propose a condition-based maintenance policy where components 1 and 2 share the same inspection period ΔT and the same preventive replacement threshold M. Such a maintenance policy provides more grouping opportunities since maintenance actions take place only at inspection time.

3.2.4 *Block-based maintenance policy considering the economic dependence (policy 4)*

Finally, we propose a block-based maintenance policy. The component i $(i = 1,2)$ is replaced every

ΔTB_i time units, independently of its failure history.

4 NUMERICAL EXAMPLE

Numerical examples are presented and the performance of our new adaptive maintenance decision rule is compared with classic maintenance strategies detailed in section 3.2. Moreover, the sensibility of cost criterion to the set-up cost is studied.

4.1 *Input data*

We consider a two-component parallel system. The degradation parameters of components, as described in detail in section 2, are given in Table 1. Component 2 deteriorates more rapidly in average with the average degradation rate is 9. When the parameter of the Lévy copula θ is set equal to 10, there is a strong dependence between the two components. The characteristic parameters of the various implemented maintenance policies are described in Table 2.

4.2 *Analysis of maintenance policies with different set-up cost*

In order to compare the performance of our maintenance policy with classic strategies, we vary the set-up cost (c_r) from 0 to 5. Optimal inspection periods for Policy 1 are calculated using numerical evaluation of the stationary law as in Dieulle, Bérenguer, Grall, & Roussignol (2003). The simulation results are presented in Table 3, Table 4, Table 5, Table 6, Table 7 and Figure 3 where we note life cycle of component 1 as LC_1 and life cycle of component 2 as LC_2.

From a general point of view, the maintenance policies attempt to balance the life cycle of two components and replace them earlier when set-up cost is higher. When stronger economic dependence exists, the expected global cost of system is more reduced.

Policy 1 (no set-up cost is considered for Policy 1) is always the worst case unless the set-up cost is very small (0 or 1). In this case, Policy 3 (a unique inspection period and preventive threshold for Policy 2) with a unique inspection period cannot take advantage of grouping. Comparing

1	2,7936	18	14	18/14
2	2,7897	18	14	18/14
3	2,7773	18	14	18/14
5	2,6427	15	15	15/15

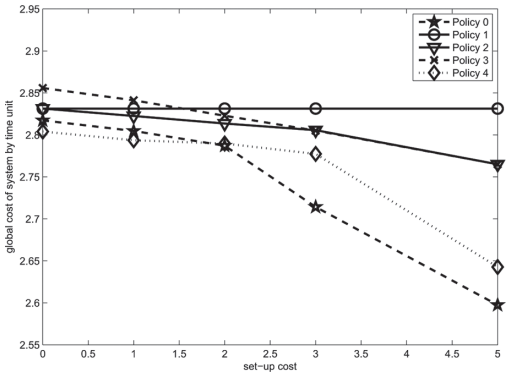

Figure 3. Optimal values of $\bar{C}$ for policy 0, policy 1, policy 2, policy 3 and policy 4 with $c_r = 0$, $c_r = 1$, $c_r = 2$, $c_r = 3$, $c_r = 5$.

Policy 2 (two different inspection periods and preventive thresholds for Policy 2) with Policy 3, Policy 3 is less efficient when the set-up cost is small, because component 1 and component 2 have two different deterioration rate therefore it is better to have various periods and thresholds. However when set-up cost increase to 2, Policy 2 and Policy 3 come up with close optimal values and tends to be equal when set-up cost continue to increase, since the higher set-up cost leads to the same inspection period because the strong economic dependence plays a important role. Furthermore, when the set-up cost passes to 5, Policy 2 and Policy 3 tend to a systematic replacement policy as Policy 4 (block-based maintenance policy). This is because the set-up cost is relatively too high comparing with the preventive replacement cost is 20 and it gains a lot by replacing two components together. However, when set-up cost equals to 5, in spite of the similar optimal values of decision parameters for Policy 2, Policy 3 and Policy 4, the cost of Policy 2 and Policy 3 are greater than that of Policy 4 because of additional monitoring cost. In fact we define a system where components deteriorate so slowly that it is not profitable to apply a condition-based maintenance policy in this case where inspection cost equals to 1. As a result, Policy 4 is always better than Policy 2 et Policy 3. Nevertheless, by applying our new decision rule detailed in section 3.1, Policy 0 (advanced policy with decision rule) can overcome this drawback. The optimal values of PA and PP search the better date for replacing two components together. It is obviousthat PA is smaller with a higher set-up cost and PP can not be too high. In fact, postponing preventive replacement may let the component fail and it would be too expensive. Hence the case of postponing should be strictly controlled. Although Policy 2, Policy 3 and Policy 4 also try to search the better date of grouping, the decision rule offers a broader scope. For example, when $c_r = 5$, in order to have more groups, Policy 2, Policy 3, and Policy 4 only can group at a multiple of ΔT_1 and ΔT_2 (say 15, 30, 45 ...); however, Policy 0 allows the ability to group more often (15, 18, 20, 25, 30, 35, 36 ...) taking advantage of two different inspection periods. The key point of our decision rule is that it includes the available information about all the components at each inspection time so that it achieves to decrease the total cost as well as to increase the life cycle of components.

4.3 *Conclusion and future work*

The objective of this paper was to propose maintenance policies for multi-component system considering the economic and stochastic dependence. As a result, we have shown that our advanced condition-based maintenance policy (Policy 0) can improve results of classic block-based strategy which is known to be well adapted to slowly degrading systems by overcoming the inspection cost drawback by taking full advantage of grouping opportunities.

The decision rule of maintenance is easy to apply and to calculate. It is efficient to find suitable dates of grouping maintenance by including the latest deterioration of components. When we want to extend our model to multi-component system with a largenumber of components, there are not parameter to add in the part of decision rule and we just have PA and PP to optimise. Consequently, our policy will be more efficient for a system which has more components. Nevertheless, for applying our decision rule, it should be convenient to change the maintenance plan.

The investigation of set-up cost shows that grouping maintenance activities is important to reduce the global maintenance cost where it is better to search the opportunities of grouping as possible. As well as the economic dependence, the stochastic dependence has to be taken into consideration for optimising the maintenance schedule. Future work will be on investigating the influence of stochastic dependence which is modeled by Lévy copula on the optimization of maintenance schedule.

Application of standards in reliability prognosis of braking system of moving walks

E. Rogova, G. Lodewijks & Y. Pang
TU Delft, Delft, The Netherlands

ABSTRACT: The reliability of braking systems in people transportation equipment is very important. There are however only a few researchers that developed a maintenance and inspection method for such systems based on accident analysis. These methods are without correspondence to an appropriate Safety Integrity Level (SIL). The international standards IEC 61508 and ISO 22201-2 have special requirements with respect to a SIL. All systems and subsystems of moving walks should correspond to the required level of SIL. In this paper method of reliability prognosis for braking system of moving walks is presented based on the reliability degradation of system components and the requirements of related standards. This method enables the determination of a regular maintenance schedule. It also enables the development of an intelligent system for preventing failures in braking systems of moving walks. This allows keeping the required safety level from the beginning to the end of its technical lifetime.

1 INTRODUCTION

The first task of people transportation equipment is to move people. The second task and equally important is to do this safely. The first and the second task cannot exist separately. Safety is one of the most important property of any device that used by a human. There are many safety standards that regulate norms of construction, exploitation and functional safety of equipment in different engineering fields. These standards have requirements, recommendations, methods and tools for reliability analysis. Although safety and reliability are different properties and a system can be reliable but unsafe and vice versa (Leveson 2011), surely, safety and reliability are closely related. For moving walks it is assumed in this study that unreliable subsystems cannot be safe. That is why the system has to be reliable and to meet requirements of related standards and norms. Reliability is defined as "ability of a functional unit to perform a required function under given conditions for a given time interval". "The term used in IEV 191-02-06 is "reliability performance" and the definition is the same with additional notes" (ISO/IEC 2382-14 1997). Prediction of the reliability value not only for a specified time period, but also for all the exploitation period of a system is called reliability prognosis.

The role of a reliability prognosis cannot be overestimated. Reliability prognosis plays a serious role in maintenance management of a machine. "The ability to forecast machinery failure is vital to reducing maintenance cost, operation downtime or operation risk" (Sun & Jia 2011). Reliability prognosis of the machine consists of several parameters: 1) to predict time of failure of the machine; 2) to estimate money costs for future repair; 3) to conduct appropriate repair or replacement of equipment to reduce the cost of major repairs. Such prognosis allows to reduce probability of accidents and money expenditure for repair of equipment. Reliability prognosis is used in different engineering fields such as nuclear, chemical, aerospace, civil and other fields. This research is focused on implementation of reliability prognosis in mechanical engineering. Reliability prognosis of a braking system of moving walks is considered in this paper.

In most cases reliability prognosis is executed because of reliability degradation of parts of the system. It means that the reliability of a system at the start differs from reliability after some time. In literature four main groups of prognostic approaches for degradation systems are described: experience-based, model-based, knowledge-based and data-driven (Gojian et al. 2009). In practice, reliability prognosis of complex systems doesn't only use one method: sometimes engineers apply even a few approaches. The type of reliability prognosis depends on nature of degradation. For instance, some components such as controllers almost don't have degradation during exploitation period. They have an approximately constant failure rate. But others (mechanical components) have strong degradation of reliability parameters.

Reliability degradation of a braking system of moving walks is caused by wear of mechanical and hydraulic components. Combination of experience-based, SIL-based approach and application of international standards are used in this paper for the reliability prognosis of a braking system of moving walks. This combined method enables not only estimation of the overall reliability of a system, it also creates an intelligent system that will announce not appropriate safety integrity level in advance.

The method described here for the reliability analysis and prognosis is SIL-based which means using the SIL concept—the central concept of functional safety, described in the standard IEC 61508 "Functional safety of electrical/electronic/programmable electronic safety-related systems". The Safety Integrity Level (SIL) is defined as "a discrete level (one out of four) for specifying the safety integrity requirements of the safety instrumented functions to be allocated to the safety instrumented systems" (IEC 61511-1 2004). The standard ISO 22201-2 "Programmable Electronic Systems in Safety Related Applications—Part 2: Escalators and moving walks (PESSRAE)" specifies general requirements of IEC 61508 for escalators and moving walks. These and other standards establish requirements for functional safety of moving walks. However, SIL-based reliability analysis and prognosis of a braking system of moving walks were not considered in research until now. Meanwhile this approach does not only allow meeting all requirements of related standards, it also allows creating a suitable tool for engineers, constructors and audit companies. The target of this paper is demonstration of application of related standards in different stages of reliability prognosis of a braking system of moving walks. The calculations presented in this paper are for illustration purposes only and cannot be considered as direct engineering calculations for any type of braking system.

The focus of this paper is moving walks, an example of transportation equipment. There are two types of brakes recommended by the standard EN 115-1: an operational and an auxiliary (EN 115-1 2010). Auxiliary brakes are optional for the majority of moving walks and required only for inclined moving walks with special conditions. Literature describes two main types of operational brakes: hydraulic and electromagnetic (Al-Sharif 2006). For this paper the estimation of reliability for hydraulic operational braking system of moving walks was chosen, cause hydraulic brakes are more amenable to proportional control, than electromagnetic (Al-Sharif 2006). Statistics of accidents on escalators and moving walks in big malls and metro proves necessity of the present research, because the main part of all deaths on these machines is caused by people falling (Mccann 2006). Possible causes of falling are crowdedness, wrong behavior of elderly people and children, and overspeed. A moving walk has to be stopped immediately in these cases. If brakes are faulty, it can lead to serious injuries or even death.

The structure of the paper is organized as follows. Section 2 describes safety standards applicable for a braking system of moving walks. Section 3 contains risk assessment and SIL requirements for a braking system. Section 4 is about the reliability analysis of a braking system of moving walks in accordance to the SIL requirements. Section 5 describes SIL-based reliability prognosis for a braking system of moving walks. Section 6 is a brief conclusion and discussion of future work.

2 INTERACTION OF STANDARDS

There are several safety standards for consideration of safety questions of moving walks. They can be divided into four groups: 1) standards of functional safety (IEC 61508, IEC 62061, ISO 22201-2, ISO 13849-1); 2) reliability analysis tools (IEC 60300-3-1, IEC 61649, IEC 61078, IEC 61165 etc.); 3) risk assessment (ISO 14798, ISO 12100, ISO/TR 14121-2); 4) mechanical safety standards for the sector application (EN115-1+A1, ISO 18738-2). A diagram of the standards interaction is shown on Figure 1. All four groups of standards are correlated to each other and used for reliability prognosis of moving walks. Moreover, all these standards should be studied in complex reliability analysis of a braking system of moving walks.

Safety standards such as IEC 61508 from the first group of standards are an important source of information for development of safety-critical systems in many engineering fields, including transport engineering. IEC 61508 has become a foundation of international standards for safety-related systems such as airborne systems, railway, nuclear

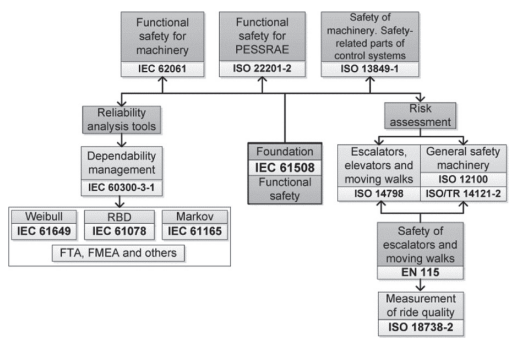

Figure 1. Diagram of standards.

power plants, medical equipment, energy and process systems, machinery, furnaces and automobiles (Azianti 2013). IEC 61508 defines general safety integrity requirements for safety functions allocated to the E/E/PE safety-related systems: SIL1 is the lowest level, SIL4 is the highest. However, IEC 61508 "does not specify the safety integrity levels required for sector applications (which must be based on detailed information and knowledge of the sector application). The technical committees responsible for the specific application sectors shall specify, where appropriate, the safety integrity levels in the application sector standards" (IEC 61508-1 2010). This standard doesn't provide engineers with specific requirements and recommendations for development of transport equipment. That is why three standards of functional safety of machinery were developed: IEC 62061, ISO 22201-2, and ISO 13849-1. IEC 62061 provides a machine sector specific framework for functional safety of machines in general (IEC 62061 2005). ISO 22201-2 has been developed "in order that consistent technical and performance requirements and rational be specified for Programmable Electronic System in Safety-Related Application for Escalators and moving walks (PESSRAE)" (ISO 22201-2 2013). This standard is based on IEC 61508, IEC 62061, and EN 115-1, and is considered as an "application sector standard" (IEC 61508-1 2010). However, ISO 22201-2 defines risk classes by means of the table with correspondence between frequency of accidents and risk consequences. There are no guidelines or rules in this standard how to transfer from risk classes to SILs that makes this a topic of future research. The standard defines the highest (SIL3) and the lowest (SIL1) possible safety integrity levels for moving walks. ISO 13849-1 from the first group of standards provides safety requirements and guidance on the principles for the design and integration of safety-related parts of control systems of machinery (ISO 13849-1 2008).

The second group of standards is used for reliability analysis. The standard IEC 60300-3-1 "describes the usual methodologies, their advantages and disadvantages, data input and other conditions for using various techniques" (IEC 60300-3-1 2003). Standards IEC 61649 (Weibull analysis), IEC 61078 (Analysis techniques for dependability—Reliability block diagram and boolean methods), IEC 61165 (Application of Markov techniques) and others describe in details specific methods and techniques (mentioned in IEC 60300-3-1), that can be applied for reliability analysis and prognosis of a braking system of moving walks, separately.

The third group of standards is divided into two subgroups: general risk assessment for safety machinery and risk assessment for escalators, elevators and moving walks. The standard ISO 14798 "Lifts (elevators), escalators and moving walks—Risk assessment and reduction methodology" describes examples of hazards, consequence of steps of risk assessment for elevators, escalators and moving walks (ISO 14798 2009). The standard ISO 12100 (Safety of machinery—General principles for design—Risk assessment and risk reduction) is basic safety standard "giving basic concepts, principles for design and general aspects that can be applied to machinery" (ISO 12100 2010). This standard describes procedures for identifying hazards and estimating and evaluating risks during relevant phases of the machine life cycle, and for the elimination of hazards or the provision of sufficient risk reduction. "The practical use of a number of methods for each stage of risk assessment is described in ISO/TR 14121-2" (ISO 12100 2010). The technical report ISO/TR 22100-2 describes how ISO 12100 relates to ISO 13849-1 from the first group of standards. "For the correct application of ISO 13849-1, basic input information resulting from the application of the overall risk assessment and risk reduction process for the particular machine design is necessary. Based on this input information, the safety-related parts of the control system can be appropriately designed according to ISO 13849-1. Information resulting from a detailed design of safety-related parts of the control system relevant for its integration into the machine design has then to be considered in the overall risk assessment and risk reduction process according to ISO 12100" (ISO/TR 22100-2 2013).

The standards from the fourth group contain mechanical data for safety limitations. EN 115-1+A1 comprises all types of hazards, allowable distances, speed and load limitations etc. ISO 18738-2 provides readers with information about ride quality of escalators and moving walks, it focused mainly on vibration and noise.

It is important to say that these groups of standards are used in different stages of reliability prognosis, as it will be described in this paper. The standards from the third group can be used mainly in the determination of safety requirements stage. The standards from the second group are used in the stage of reliability analysis in accordance to safety requirements. The fourth group provides information for development additional safety devices, diagnostic systems and redundancy architecture on the stage of reliability improvement. The first group provides general requirements and recommendations for a functional safety concept. Standards from this group are used in all the stages of analysis as a main guideline.

Application of safety standards and using SIL-based methodology, described in these standards, simplifies not only the work of audit companies.

Using an unified method also helps engineer-constructors, project managers at the design and maintenance stages. Safety integrity levels of all the safety functions should be defined in accordance to IEC 61508. Depending on the complexity of a system, there are one, two, three or many subsystems, which execute safety functions. Equipment for these subsystems should correspond to appropriate safety requirements. Knowledge of SIL for a safety function allows to calculate SIL of equipment which performs this safety function. It gives a possibility to find suitable equipment at the design stage of moving walks. It means that a project manager has to buy, for example, 5 devices with SIL2, SIL3, SIL2, SIL3 and SIL2 respectively to provide a safety function of SIL2.

However, the methodology described in standards is general and does not clear up the picture of the process: from risk assessment and determination of the SIL requirements till reliability analysis and reliability improvement. The next sections will show an application of safety standards for different stages of reliability prognosis of braking system of moving walks, using a SIL-based approach.

3 RISK ASSESSMENT AND SIL REQUIREMENTS SPECIFIED FOR MOVING WALKS

The determination of SIL requirements should be started from the determination of accident consequence levels in accordance to standards IEC 61508 and ISO 22201-2. IEC 61508-5 as well as ISO 22201-2 defines four categories of accident consequences: "catastrophic, critical, marginal, negligible" (IEC 61508-5 2010). At the same time ISO 22201-2 also calls accident consequences as "high, medium, low, negligible". Using different terminology inside one standard sometimes creates misunderstanding. The same categorization is suggested by ISO 14798. Unfortunately, these standards do not explain how to define the category of accident consequences. Table 1 suggests correspondence between the consequences of an accident (in injuries and deaths) and the duration of brakes unavailability for determination of an accident consequences category. This table is an interpretation of the table 'Quantitative consequence categories' from the manual for APCS engineers "Risk analysis of technological system in Interlock system for ITER" (Rogova 2012). The table is interpreted and adopted for moving walks in accordance to severity levels description given by ISO 14798 and ISO 22201-2.

Consequences of an accident and brakes unavailability were estimated based on reports, newspaper and scientific papers (Mccann 2006, Scott Tyson 2010). It is important to mention that this table suggests an example of determination accident consequences for moving walks. It is a general idea and it can be varied depending on the transport sector or type of transport equipment.

Table 1. Accident consequences.

	Brakes unavailability				
Consequences of an accident	<1 hour	<1 day	<2 days	<1 week	<1 month
No injuries	Mi	Se	Se	Se	Se
No significant injuries	Se	Se	Se	Ma	Ma
5 severe injuries	Ma	Ma	Ma	Ma	Ca
>5 and <10 severe injuries	Ma	Ma	Ma	Ca	Ca
>=1 death and/or multiple severe injuries	Ca	Ca	Ca	Ca	Ca

where Mi—minor, Ma—major, Se—severe, Ca—catastrophic.

The next significant step in risk assessment procedure is to define occurrence probability. ISO 22201-2 already developed this table for moving walks (Table 2). There are six categories of frequency: frequent, probable, occasional, remote, improbable and negligible. The same categorization is suggested by ISO 14798.

Table 3 demonstrates estimation and evaluation of risk that are described in ISO 14798 and ISO 22201-2. Intersection of "event probability" column and "accident consequences" row gives a risk class: I, II, III, IV (A, B, C, D, E, F).

In this paper for determination of risk mitigation measures it was assumed that consequences of an accident is *No significant injuries* and duration of brakes unavailability is *less than 1 day*. Thereby Table 1 gives a consequences category *Severe*. If an accident happens about 1 time per year, taking into account a mean value for total (2000) population per year, Table 2 gives a frequency category: *Occasional*. Intersection of column *Severe* and row *Occasional* of Table 3 gives risk class *IIIC*, that means "review and determine if any further mitigation is technically practicable" (ISO 22201-2 2013). However further explanation of determination of SIL is absent in ISO 22201-2. IEC 61508-5 provides information on the concepts of risk and the relationship of risk to safety integrity. As one of possible ways, the standard recommends a risk graph method which "has been used extensively within the machinery sector, see ISO 14121-2 and Annex A of ISO 13849-1" (IEC 61508-5 2010). This method was used for determination the safety integrity level

Table 2. Occurrence probability in events per year (ISO 22201-2 2013).

Category	Potential frequency for effect F	Mean value per year per unit moving walk	Mean value for total (2000) population per year
Frequent	$F \geq 0{,}01$	0,01	20
Probable	$0{,}001 \leq F < 0{,}01$	0,005	10
Occasional	$0{,}0001 \leq F < 0{,}001$	0,0005	1
Remote	$0{,}00001 \leq F < 0{,}0001$	0,00005	0,1
Improbable	$0{,}000001 \leq F < 0{,}00001$	0,000005	0,01
Negligible	$F < 0{,}000001$	$4{,}16667 \times 10^{-7}$	0,000833

Table 3. Risk estimation and evaluation (ISO 14798 2009).

Event probability	Accident consequences			
	Catastrophic	Major	Severe	Minor
Frequent	IA	IIA	IIIA	IVA
Probable	IB	IIB	IIIB	IVB
Occasional	IC	IIC	IIIC	IVC
Remote	ID	IID	IIID	IVD
Improbable	IE	IIE	IIIE	IVE
Negligible	IF	IIF	IIIF	IVF

for the safety function *Stop machine* in this paper. By means of application of the risk graph method, SIL was defined as SIL2. Input parameters for the risk graph method were calibrated in accordance to Tables 1–3. Description of the applied method is not the target of this paper and it will not be described here in details. The standards ISO 22201-2 and EN 115-1 confirm the defined SIL for a safety function related to stopping device. ISO 22201-2 defines SIL2 for the safety function "Check Stop switch in inspection controls" (ISO 22201-2 2013). EN 115-1 also defines SIL2 for the safety function "Stopping of an escalator or moving walk …" (EN 115-1 2010). It is important to mention that the brake is a final actuator in case of any type of accident situation. Thus reliability analysis and prognosis will be conducted for a braking system, which performs the safety function *Stop machine*.

4 RELIABILITY ANALYSIS

Equipment of a safety system has to meet the SIL requirements. In the previous section it was estimated that SIL for the safety function *Stop machine* is SIL2. It means that the overall safety integrity level of a braking system, which performs the safety function *Stop machine*, has to correspond to SIL2.

There are many reliability technics described in IEC 61508-6 and IEC 60300-3-1. However, all of them are divided into two main groups: qualitative and quantitative. Qualitative reliability analysis methods are used for analysis the functional system structure, determination "system and component fault modes, failure mechanisms, causes, effects and consequences of failures" (IEC 60300-3-1 2003). But qualitative methods cannot estimate numerical value of reliability. For quantitative analysis there are three most widely used methods: Fault Tree Analysis (FTA), Reliability Block Diagram (RBD) and Markov Analysis (MA). They are used in different situations. All of these methods are recommended by IEC 61508, but the right of choice is on behalf of an engineer.

Markov analysis considers all possible states of a system and this method is mainly used for systems with constant failure rates (IEC 60300-3-1 2003). But braking system contains components with constant and non-constant failure rates. Thus MA is not appropriate for an overall reliability analysis of a braking system of moving walks or can be applied partially to some subsystems. FTA as well as RBD relate to one of the top-down methods. These methods are able to account for effects arising from a combination of faults (IEC 60300-3-1 2003). However, RBD seems to be more suitable for the calculation of the braking system reliability because of its block structure. A braking system of moving walks consists of electrical/electronic parts with constant failure rates and mechanical and hydraulic parts with non-constant failure rate. RBD consists of blocks with known reliability parameters. As IEC 60300-3-1 states, this method is applicable, for systems "where independent blocks can be assumed" (IEC 60300-3-1 2003). It means that this method is good for those systems where reliability for every block of the system is defined or can be estimated at any period of time. In this paper for a braking system whose structure is presented on Figure 2, RBD was chosen as a suitable method for reliability analysis. RBD is not used for repairable systems. However approximation was done in this paper for reliability estimation of a braking system, because time of repair of a braking system is small in percentage ratio as compared with time of exploitation.

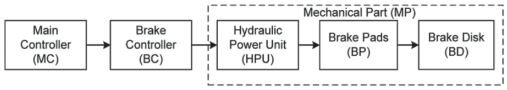

Figure 2. RBD of a braking system.

In this paper a BS (Braking System) is divided into a MC (Main Controller) part, a BC (Brake Controller) part with constant failure rates and a MP (Mechanical Part) with non-constant failure rates. A braking system is considered as high demand (executing in a continuous mode) because an interlock event of the BS is supposed to happen more than once a year. That is why estimation of the reliability for the system is conducted in this section by RBD method using Probability of dangerous Failure per Hour (PFH).

The general equation for the calculation of PFH for the system consisting of serial blocks of RBD is (IEC 61508-6 2010):

$$PFH_S \approx \sum_{i=1}^{N} PFH_i \tag{1}$$

where i is the number of blocks.

The Equation 2 for the reliability of a braking system was obtained by means of Equation 1 and RBD of braking system, demonstrated on Figure 2.

$$PFH_{BS} = PFH_{MC} + PFH_{BC} + PFH_{MP} \tag{2}$$

PFH values of the main and the brake controllers are estimated based on basic configuration of modules. In this paper configuration of main and brake controllers is assumed identical and consists of CPU, digital input/output modules, IM interfaces and Profinet:

$$PFH_{MC} = PFH_{BC} = PFH_{CPU} + PFH_{DI} + PFH_{DO} + PFH_{Profinet} + PFH_{IM} \tag{3}$$

A cumulative distribution function for the estimation of the reliability of a Mechanical Part (MP) with non-constant failure rate is obtained by means of Weibull distribution:

$$F_i^w(t) = 1 - e^{-\left(\frac{t}{\eta_i}\right)^{\beta_i}} \quad \text{(IEC 61649 2008)} \tag{4}$$

where
η is the characteristic life or scale parameter;
β is the shape parameter.

Weibull distribution is experience-based approach as it was mentioned in the Introduction. The standard IEC 61649 considers also other than the Weibull distribution and makes a conclusion that, for example, lognormal distribution is "the second choice for life data analysis" after the Weibull (IEC 61649 2008). Parameters of Weibull distribution characterize nine main mechanical components of a braking system: cylinder, motor DC, solenoid valve, pump, check valve, relief valve, springs, braking disk and pads. Values of the shape parameter and the characteristic life for these components are found in the book "Machinery failure analysis and troubleshooting" (Bloch & Geitner 1994) and free database of Barringer & Associates, Inc. (Weibull Database 2010). It is important to mention that Weibull parameters are not used for specific engineering calculations in this paper. The task of calculations presented here is to reveal a trend and basic regularities for such systems as a braking system of moving walks. Because of current lack of real data for estimation of Weibull parameters authors use data obtained from books and Internet databases presented "for educational purposes" (Weibull Database 2010). Values of the Weibull cumulative distribution function are transferred to PFH values using Equation 4 by replacement of the time value t. Operation time t is the time of use of a braking system in hours per day. In other words, t is time when the brake is used for braking. For example, PFH for motor DC can be obtained in accordance to Equation 4 using Weibull parameters $\beta = 1$, 2 and $\eta = 50000$ hours.

A general time-dependent Equation 5 of PFH calculation for a monosystem (system with 1oo1 architecture) was obtained based on Equations 2–4:

$$PFH_{1oo1}(t) = \sum_{i=1}^{n=9} F_i^w(t) + PFH_{MC} + PFH_{BC} \tag{5}$$

In accordance to Equation 5 PFH values for a monosystem were obtained for seven periods of time (from 1 month till 5 years of exploitation) and demonstrated on Table 4.

The estimation of PFH values of a braking system for 7 periods of time shows degradation of the system in terms of reliability. Comparing with PFH values of SILs given by IEC 61508-1, it is concluded, that after three months SIL of the system is equal 1, while in accordance to SIL requirements, SIL has to be equal to 2. This is not appropriate and means that reliability improvement has to be conducted.

As it was defined by the standard IEC 61508, in case of inadequate level of reliability corrective actions are required. There are a few methods of reliability improvement. The application of redundancy and diagnostics are among of them.

Table 4. PFH values of a braking system.

	Values (for a monosystem)	Values (after applying redundancy)
$PFH_{BS}^{1\,month}$	4,1914e-007	1,1303e-007
$PFH_{BS}^{6\,months}$	2,1421e-006	5,8967e-007
$PFH_{BS}^{1\,year}$	4,3938e-006	1,2702e-006
$PFH_{BS}^{2\,years}$	9,0241e-006	2,8749e-006
$PFH_{BS}^{3\,years}$	1,3805e-005	4,8217e-006
$PFH_{BS}^{4\,years}$	1,8689e-005	7,1146e-006
$PFH_{BS}^{5\,years}$	2,3653e-005	9,7596e-006

IEC 61508-6 considers main types of redundancy architecture. The standard also suggests options of voting logic with and without diagnostics: so-called k-out-of-n (KooN) architecture.

Reliability of a braking system can be improved by means of applying 1oo2D redundancy architecture. The architecture is organized as two identical channels. These channels are supplemented with a diagnostics (based on data from an incremental sensor), and a brake controller. Two brake disks are installed on the same shaft. Data obtained from incremental sensors have to be identical. By means of comparison of data from two sensors these sensors can be verified. Two brakes (main and redundant) have to work in turn that allows verification of their operability permanently. Calculation of the redundant scheme is not the target of this paper and it will not be described here in details. However, all calculations were conducted in accordance to formulas of PFH calculation for 1oo2D architecture (IEC 61508-6 2010). These formulas were converted to time-dependent Equations 6–7:

$$t_{CE}'(t) = \frac{\lambda_{DU}(t)\left(\frac{T_1}{2} + MRT\right) + \left(\lambda_{DD}(t) + \lambda_{SD}(t)\right)MTTR}{\lambda_{DU}(t) + \lambda_{DD}(t) + \lambda_{SD}(t)} \quad (6)$$

$$PFH_{1oo2D}(t) = 2(1-\beta)\lambda_{DU}(t)((1-\beta)\lambda_{DU}(t) + (1-\beta_D)\lambda_{DD}(t) + \lambda_{SD}(t))t_{CE}'(t) + 2(1-K)\lambda_{DD}(t) + \beta\lambda_{DU}(t) \quad (7)$$

Based on Equations 6–7, taking into account $\lambda_{DU}(t) = PFH_{1oo1}(t)$ (Fedorov 2008) and recommendations of ISO 13849-1 for estimation of diagnostic coverage, time-dependent PFH equation for 1oo2D system was obtained. The PFH values for seven periods of time for a system after application of 1oo2D redundancy architecture are shown on Table 4.

5 RELIABILITY PROGNOSIS

After having passed through all the stages of the analysis of a braking system of moving walks (defining of SIL requirements, reliability analysis and reliability improvement) PFH functions required for SIL-based reliability prognosis were obtained. Figure 3 demonstrates two lines of PFH: for a monosystem and for a system with redundancy. These lines present two functions: $PFH_{1oo1}(t)$ and $PFH_{1oo2D}(t)$.

The upper part of the graph shows "SIL zones" for a monosystem, the bottom part shows "SIL zones" for a system with applied redundancy architecture. Division into SIL zones demonstrates the necessity of redundancy of a braking system of moving walks. When divided into SIL zones, the reliability graph can be a prototype of a reliability trend for SCADA systems, which are used for the control of transport systems.

Kuo et al. also consider reliability prognosis. The authors do this for an aircraft engine as an example (Kuo et al. 2001). They developed three criteria for determination the replacement age of a critical item for a maintained system: 1) minimum replacement cost-rate, 2) maximum availability, and 3) lower bound on mission reliability. "Four methods are used to obtain solutions for multiple criteria decision making" (Kuo et al. 2001). However these methods do not take into account SIL requirements, which are mandatory and defined by international standards as mentioned above. The time of replacement of an element is defined by decision-making technic. Suggested in this paper reliability prognosis method allows to

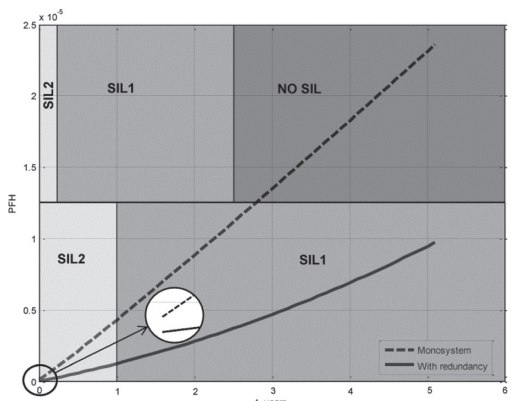

Figure 3. PFH dependence on time.

define the time of replacement or repair of a braking system component by means of an estimation of SIL requirements for a system and degradation of SIL during the exploitation period.

SIL-based approach uses obtained time-dependent PFH functions for a monosystem and for a system with applied redundancy architecture to calculate the corresponded safety integrity level at any period of time. This approach can be implemented in an intelligent system that will periodically recalculate PFH value of a system and related SIL. An intelligent system will notify an operator about a close border between SILs. In addition, based on introduced method, it can be suggested two modes of maintenance for a braking system of moving walks: full and economical. In a full maintenance mode the system has to be completely recovered till the initial value of reliability. In an economical mode SIL will be kept on the required level, but the system will be recovered partially by means of replacement/repair of the elements with the worst reliability characteristics. Time of periodical maintenance t_{per} is different in these two modes. In case of full mode t_{per} is constant. In case of economical mode, this time is reduced every maintenance period.

6 CONCLUSIONS

The described SIL-based method of reliability prognosis is based on a combination and interaction of requirements and recommendations of safety standards. This method meets requirements of related standards required for studying of safety of braking system of moving walks. These standards are compared, classified and divided into several groups.

Time-dependent PFH functions for a monosystem ($PFH_{1oo1}(t)$) and for a system with redundancy ($PFH_{1oo2D}(t)$) were obtained and demonstrated on Figure 3. The area of this graph was divided into several areas with different SIL for the system with and without redundancy. The graph demonstrates reliability improvement after applying redundancy. This approach allowed introducing an intelligent system that will recalculate reliability values during the exploitation period and compare them with appropriate SIL requirements. The intelligent system can predict possible failures by means of detecting close SIL border between two areas which means increase of PFH value (Fig. 3). The decision about replacement or repair of equipment is made by means of a calculation of the system reliability. If this value doesn't meet the SIL requirements, the system notifies an operator about the necessity to plan maintenance.

Maintenance procedure, used now on moving walks, can be simplified by means of this approach. The method also allows creating a suitable tool for engineers, constructors and audit companies to check safety of people transportation equipment in buildings, supermarkets, metro and other objects of civil engineering. The developed method can be applied not only for braking systems of moving walks, but also for other technical systems with degradation of their reliability parameters over time.

The future work relates to the verification, the validation of the described methods, and further development of the intelligent system. The application of this intelligent system will allow correction of Weibull parameters in online mode based on braking time. Subsequent study also will be focused on mathematical justification of the correspondence between risk classes and SILs for elevators, escalators and moving walks, which can be summarize in a table. Such a table of correspondence could be a suitable tool for engineer-constructors, project managers, audit companies, and important supplement to the existing sector application standards.

ABSTRACT: Occupational accidents pose several negative consequences to employees, employers, environment and people surrounding the local where the accident takes place. Thus, this paper proposes a Bayesian population variability analysis-based method for the prediction of work time loss distributions due to occupational accidents. The use of Bayesian analysis aims at investigating future trends regarding occupational accidents in the workplace as well as enabling a better management of the labor force. In fact, the key performance indicators here estimated are the expected unavailability of the labor force and also the expected recovery time from an accident which will be computed by a Markov-based model. Finally, the paper presents a practical example by using available data on occupational accidents from a hydroelectric power company in Brazil to predict the work time losses and their respective distributions.

1 INTRODUCTION

Occupational accidents pose several negative consequences to employees, employers, environment and people surrounding the local where the accident takes place (Marcoulaki et al. 2012). Therefore, it is imperative to develop adequate safety policies and operational procedures that minimize the probability of occurrence of occupational accidents. To do that, it is required to predict measures such as the expected work time loss.

As in failures analysis this process consists of two main steps: (i) inference of reliability quantities that explain the stochastic mechanism that originate the accident/recovery process such as accidents and recovery rates and (ii) characterization of accidental behavior by applying stochastic process analysis methods (e.g. Markov process).

A lot of research has been done on the quantitative analysis of occupational accident data. This includes modeling of occupational accident frequency (Marcoulaki et al. 2012, Marcoulaki et al. 2011, Meel et al. 2007) and work time losses (Marcoulaki et al. 2012, Blanch et al. 2009). Several authors have used descriptive statistics and factor analysis, as Babu & Nayak (2003). From the 90's, Bayesian inference methods have long been used for the analysis of accident databases (Hora & Iman, 1990) to model uncertainties and enable future predictions but very few studies deal with prediction of work time loss (Marcoulaki et al. 2012).

For Meel et al. (2007), the use of advanced Bayesian prediction methods is more suitable due to the scarcity and censorship of accident data. Meel & Seider (2006) and Meel et al. (2007) developed a Bayesian approach for the assessment of accident frequency in petrochemical industries in Europe. Marcoulaki et al. (2012) extended the Meel's model by including analysis on work time loss and unavailable due occupational accidents.

Marcoulaki et al. (2012) assumed that all workers have the same accident and recovery rates. Thus, the authors used data from all workers together and treated them as homogenous in order to formulate the likelihood function of the Bayesian model. However, due to the existence of subjective and individual characteristics it is expected that a same class of employees have a unique accident and recovery rates even though they have similar functions in the workplace or are allocated in the same occupational environment as other employees. Therefore, a population variability assessment over the rates is more appropriate for accidents analysis.

Thus, this paper proposes a Bayesian population variability analysis-based method for this

problem. Bayesian population variability analysis is an estimation procedure for the assessment of the variability of reliability measures among a group of similar systems/employees. Moreover, a Markov-based model is proposed for investigating future trends regarding occupational accidents in the workplace as well as enabling a better management of the labor force from the results of the population variability analysis. In fact, the key performance indicators here estimated by the Bayesian models will be the expected unavailability of the labor force and, consequently, the expected recovery time from an accident which will be computed by a Markov-based model. Thus, the Markov-based model will work as a simulation algorithm to generate the accident and recovery times for the workers. To do that the numerical method proposed by Moura & Droguett (2009) will be used because it is efficient to estimate the expected unavailability curve and associated uncertainty.

The remainder of this paper is organized as follows. Section 2 presents the theoretical background about the Bayesian Population Variability Analysis. Section 3 presents the proposed model, while Section 4 discusses the numerical results using evidence from a real accident database of a hydroelectric power company in Brazil. Finally, section 5 presents concluding remarks.

2 THEORETICAL BACKGROUND

2.1 *Bayesian population variability assessment for accident analysis*

The failure and repair rates of a system are often used to characterize our expectations regarding the system's ability to perform its intended function. Likewise, we can use these measures to represent our prospects about the workers safety making the accident an expression of our personal uncertainty about the workers accidental behavior (Singpurwalla, 1988).

Thus, let ρ be a random variable that defines the accident or recovery rate of an employee and $\varphi(\rho) = (\rho/\theta_1, \ldots, \theta_r)$ denote the parametric variability distribution model. Then, a probability distribution $\pi(\theta_1, \ldots, \theta_r)$ over the parameters $\theta_1, \ldots, \theta_r$ of the model can be used to describe the uncertainty about the population variability distribution. The estimated population variability density is taken as

$$\hat{p}(\rho) = \int \ldots \int_{\theta_1, \ldots, \theta_r} \varphi(\rho \mid \theta_1, \ldots, \theta_r) \cdot \pi(\theta_1, \ldots, \theta_r) \cdot d\theta_1 \ldots d\theta_r \quad (1)$$

Therefore, the estimated density function consists of a weighted mix of distributions of the chosen model. This is opposed to estimation methods as the Maximum Likelihood Estimators which is based in a single 'best' distribution chosen from the set of distributions.

The Bayesian population variability analysis of ρ assumes that the distribution $\pi(\theta_1, \ldots, \theta_r)$ is uncertain and a Bayesian method is applied to infer it. For this, in addition to the collected accident data is necessary to have prior information about the population variability. Let E_0 be prior evidence that provides information about the π distribution, i.e. E_0 is the prior knowledge over π without considering data recorded (e.g. the expert's estimates about the probability distributions of $(\theta_1, \ldots, \theta_r)$. Then, $\pi_0(\theta_1, \ldots, \theta_r) = \pi(\theta_1, \ldots, \theta_r \mid E_0)$ is the prior probability distribution of the population variability distribution parameters $(\theta_1, \ldots, \theta_r)$ and $\hat{p}_0(\rho \mid E_0) = \int \ldots \int \theta_1, \ldots, \theta_r \, \varphi(\rho \mid \theta_1, \ldots, \theta_r) \times \pi_0(\theta_1, \ldots, \theta_r) \cdot d\theta_1 \ldots d\theta_r$ is the prior population variability distribution of ρ.

Let the evidence E_1 include the information about the accidents database i.e. the information obtained from accidents records. Then, the employees' population distribution over ρ, conditional on E_0 and E_1 is given by

$$\hat{p}_1(\rho \mid E_0, E_1) = \frac{P(E_1 \mid \rho, E_0) \cdot \int_{\underline{\theta}} \varphi(\rho \mid \underline{\theta}) \cdot \pi_0(\underline{\theta}) \cdot d\underline{\theta}}{\int_{\rho} P(E_1 \mid \rho, E_0) \cdot d\rho \cdot \int_{\underline{\theta}} \varphi(\rho \mid \underline{\theta}) \cdot \pi_0(\underline{\theta}) \cdot d\underline{\theta}} \quad (2)$$

where $\underline{\theta} = \{\theta_1, \ldots, \theta_r\}$ and $P(E_1 \mid \rho, E_0)$ is the likelihood of the evidence E_1. The posterior distribution of the population variability parameters based on information types E_0 and E_1 is developed by applying the Bayes' theorem:

$$\pi_1(\underline{\theta} \mid E_0, E_1) = \frac{P(E_1 \mid \underline{\theta}, E_0) \cdot \pi_0(\underline{\theta})}{\int_{\underline{\theta}} P(E_1 \mid \underline{\theta}, E_0) \cdot \pi_0(\underline{\theta}) \cdot d\underline{\theta}} \quad (3)$$

Therefore, it's possible to evaluate the posterior population variability distribution of the accident or recovery rate by making $\hat{p}_1(\rho \mid E_0, E_1) = \int_{\underline{\theta}} \varphi(\rho \mid \underline{\theta}) \times \pi_1(\underline{\theta} \mid E_0, E_1) . d\underline{\theta}$ (Kaplan 1983, Deely & Lindley, 1981).

Assuming that the accidents occurring in each employee are independent, the likelihood function of the exposure data becomes

$$P(E_1 \mid \underline{\theta}, E_0) = \prod_{i=1}^{n} P(E_{1i} \mid \underline{\theta}, E_0) \quad (4)$$

where $P(E_{1i} \mid \underline{\theta}, E_0)$ is the probability of observing evidence E_{1i} for the i-th out of n employees. Note that the accident measure for the i-th worker, ρ_i, is not known exactly and therefore $P(E_{1i} \mid \underline{\theta}, E_0)$ is given as a function of ρ_i ($P(E_{1i} \mid \underline{\theta}, E_0, \rho_i)$). We know

that ρ_i is one of possibly many values of variable ρ. Moreover, according to our model, ρ is distributed according to $\varphi(\rho|\underline{\theta})$, and $\underline{\theta}$ is also unknown. Therefore, we calculate the probability of observing the information E_{1i} by allowing the accident measure to assume all possible values i.e. by averaging ($P(E_{1i}|\underline{\theta},E_0,\rho)$ over the distribution of ρ:

$$P(E_{1i}|\underline{\theta},E_0)=\int_{\rho}P(E_{1i}|\underline{\theta},E_0,\rho)\cdot\varphi(\rho|\underline{\theta})\cdot d\rho \quad (5)$$

3 A POPULATION VARIABILITY AND MARKOV-BASED INTEGRATED MODEL

3.1 *The timeline of the worker*

The assessment of the likelihood function (4) is mainly based on the exposure data i.e. the number of accidents or recoveries by the operational time of a worker (runtime data). In general, the employment time is not necessarily the same for all workers. Therefore, only knowing the number of accidents suffered in an observation period is not sufficient. The observation of the timeline for each worker allows obtaining exposure data (Marcoulaki et al. 2012).

Then, consider that any occupational accident is reported and recorded. Typically, the registration and reporting forms of occupational accidents contains the accident date and the duration of the recovery period following the accident. This information, in addition the admission and dismissal dates, sets the timeline for each work as illustrated in Figure 1.

Figure 1 shows the timeline for a workplace with 12 workers during a period of observation starting at time T_S and terminating at T_F, where $T_{Si} \geq T_S$ and $T_{Fi} \leq T_F$ are, respectively, the starting and finishing times of i-th worker. If $T_{Si} > T_S$ then the worker was admitted after the initial observation period and, similarly, if $T_{Fi} < T_F$ then the worker was fired before the final observation period. In the interval $[T_{Si}; T_{Fi}]$ the worker is involved in K_i accidents. The working time of worker n between k_{n-1} and k_n ($k_n = 1, 2, \ldots, K_n$) is denoted by t_{n,K_n}. The respective recovery time is denoted by r_{n,K_n}. The time range between the recovery from the last accident, K_n, and T_{Fn} is denoted by s_n.

The staring times T_{S1}, T_{S2}, T_{S3}, T_{S6}, T_{S7}, T_{S9}, T_{S10} and T_{S11} coincide with T_S; this means these workers were hired before or at T_S. The finishing times T_{F1}, T_{F2}, T_{F3}, T_{F4}, T_{F5}, T_{F7}, T_{F10} and T_{F11} coincide with T_F i.e. the workers 1, 2, 3, 4, 5, 7, 10 and 11 remained working after T_F. Only workers 1, 2, 3, 7, 10 and 11 are employed over the whole exposure time, while the others work only for a fraction of this time. Workers 3, 5, 8 and 11 have no accidents, so $s_3 = T_{F3} - T_{S3}$, $s_5 = T_{F5} - T_{S5}$, $s_8 = T_{F8} - T_{S8}$ and $s_{11} = T_{F11} - T_{S11}$. The contract of worker 9 expires when he recovers from his last accident, thus $s_9 = 0$ (it is noteworthy that some regulations protect workers from this type of situations, giving him a labor warranty for a specified period after the recovery from an accident. However, this example is useful for illustration). Ultimately, the finish time (T_F) occurs before the worker 10 back to work, therefore the recovery time $r_{10,1}$ is said to be censored and there is no s_{10}.

Note that $T_n = \left(\sum_{i=1}^{K_n} t_{n,k_i}\right) + s_n = T_{Fn} - T_{Sn} - R_n$ (where $R_n = \sum_{i=1}^{K_n} r_{n,k_i}$) represents the total time for which the worker n was submitted to the risks of occupational accidents. Thus, we can determine the exposure data of each work by the pair (K_n, T_n). Similarly we can determine the exposure data for the recovery data by the pair (K_{Rn}, R_n), where K_{Rn} is the number of recoveries of the worker n. Thus, it is possible to use the censored data found in the database available. Table 1 illustrates the exposure data extracted from in Figure 1. The information in Table 1 provides a clear view of the E_1 evidence needed for the likelihood function construction in the population variability model ($E_{1\lambda}$ corresponds to E_1 type evidence for the accidents rate analysis and $E_{1\mu}$ corresponds to E_1 type evidence for the recovery rate analysis).

3.2 *The population variability analysis construction*

3.2.1 *Mixed likelihood model*

In order to perform a population variability analysis of accident or recovery rate we need to specify an appropriate probability distribution to describe the underlying variability of the measure of interest, $\varphi(\rho|\underline{\theta})$, as well as construct the likelihood function $P(E_1|\underline{\theta},E_0)$. The specification of the probability distribution describing the variability may be guided by the nature of the accident measure. According to Droguett et al. (2004), the use of the Gamma or Lognormal distribution is suitable for representing the variability in the number of failure of the various systems with different failure rates. Thus, let us consider the population variability of the accident measure is given by a lognormal distribution i.e.

$$\varphi(\rho|v,\tau)=\frac{1}{\sqrt{2\pi}\rho\tau}e^{-\frac{1}{2}\left(\frac{\ln\rho-v}{\tau}\right)^2} \quad (6)$$

where v and τ are the parameters (mean and standard deviation). The Lognormal distribution can be

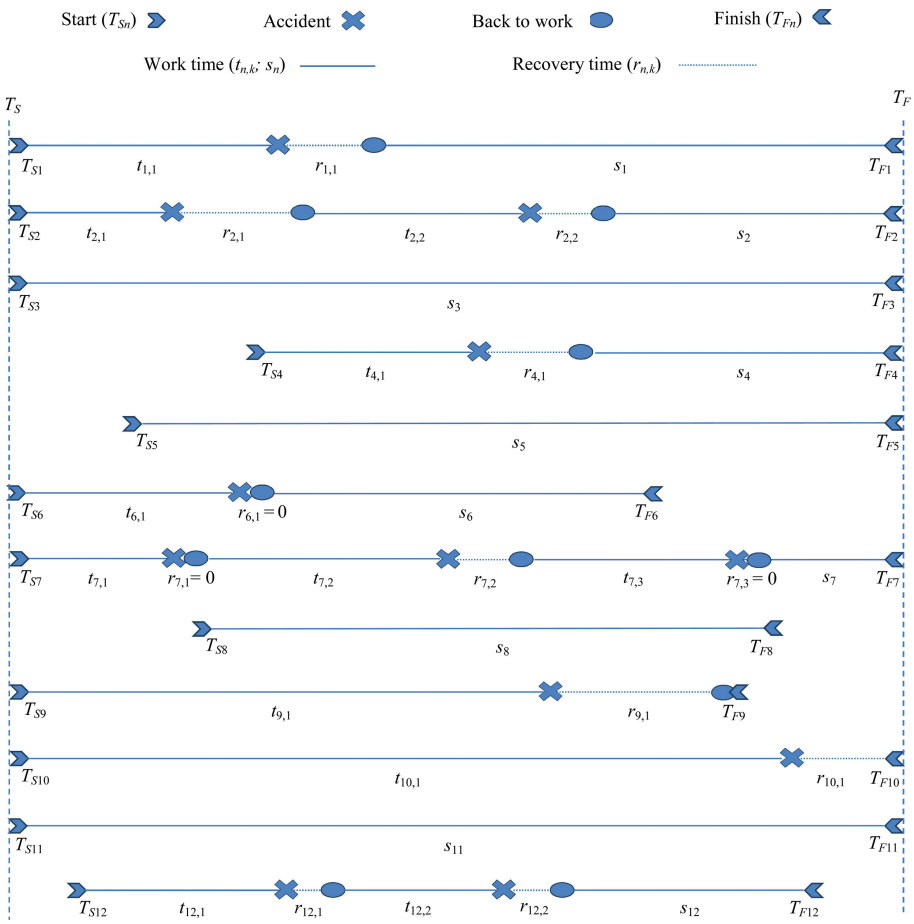

Figure 1. Timelines for a workplace with 12 workers. Source: Adapted from Marcoulaki et al (2012).

Table 1. Exposure data (E_1 evidence) for Figure 1 example.

	$E_{1\lambda}$		$E_{1\mu}$	
Worker (i)	K_i	T_i	K_{Rn}	R_n
1	1	$t_{1,1}+s_1$	1	$r_{1,1}$
2	2	$t_{2,1}+t_{2,2}+s_2$	2	$r_{2,1}+r_{2,2}$
3	0	s_3	–	–
4	1	$t_{4,1}+s_4$	1	$r_{4,1}$
5	0	s_5	–	–
6	1	$t_{6,1}+s_6$	1	$r_{6,1}$
7	3	$t_{7,1}+t_{7,2}+t_{7,3}+s_7$	3	$r_{7,1}+r_{7,2}+r_{7,3}$
8	0	s_8	–	–
9	1	$t_{9,1}$	1	$r_{9,1}$
10	1	$t_{10,1}$	0	$r_{10,1}$
11	0	s_{11}	–	–
12	2	$t_{12,1}+t_{12,2}+s_{12}$	2	$r_{12,1}+r_{12,2}$

written in terms of median (ρ_{50}) and error factor ($EF\rho$) of the distribution by making the following changes: $\rho_{50}=e^{\nu}$ and $EF\rho=e^{1.645\tau}$, as illustrated in Equation

$$\varphi(\rho\,|\,\rho_{50},EF\rho)=\frac{1}{\sqrt{2\pi}\cdot\rho\cdot\dfrac{\ln EF\rho}{1.645}}e^{-\frac{1}{2}\left(\frac{\ln\rho-\ln\rho 50}{\ln EF\rho/1.645}\right)^2} \tag{7}$$

The posterior of the variability distribution parameters in Equation

$$\pi_1(\underline{\theta}\,|\,E_0,E_1)=\frac{P(E_1\,|\,\underline{\theta},E_0)\cdot\pi_0(\underline{\theta})}{\int_{\underline{\theta}}P(E_1\,|\,\underline{\theta},E_0)\cdot\pi_0(\underline{\theta})\cdot d\underline{\theta}} \tag{3}$$

can be written as Equation

$$\pi_1(\rho_{50}, EF_\rho \mid E_0, E_1) = \frac{P(E_1 \mid \rho_{50}, EF_\rho, E_0) \cdot \pi_0(\rho_{50}, EF_\rho)}{\int_{\rho_{50}} \int_{EF_\rho} P(E_1 \mid \rho_{50}, EF_\rho, E_0) \cdot \pi_0(\rho_{50}, EF_\rho) \cdot dEF_\rho \cdot d\rho_{50}} \quad (8)$$

$$\varphi(\rho \mid \rho_{50}, EF\rho) = \frac{1}{\sqrt{2\pi} \cdot \rho \cdot \frac{\ln EF\rho}{1.645}} e^{-\frac{1}{2}\left(\frac{\ln\rho - \ln\rho 50}{\ln EF\rho/1.645}\right)^2} \quad (7)$$

$$\pi_1(\rho_{50}, EF_\rho \mid E_0, E_1) = \frac{P(E_1 \mid \rho_{50}, EF_\rho, E_0) \cdot \pi_0(\rho_{50}, EF_\rho)}{\int_{\rho_{50}} \int_{EF_\rho} P(E_1 \mid \rho_{50}, EF_\rho, E_0) \cdot \pi_0(\rho_{50}, EF_\rho) \cdot dEF_\rho \cdot d\rho_{50}} \quad (8)$$

The likelihood construction is an evidence-driven process i.e. it is dependent on the type of the available evidence E_1. In the analysis of accidents is difficult to obtain expert estimates on the accidents rate of each worker individually. In general, the exposure data (as in Table 1) are the only available evidences. Moreover, due to non-homogeneity among workers (as discussed in Section 2), it is not representative to obtain such estimates directly from the accidents databases.

In this way, the likelihood can be constructed. If we know the accident rate $\lambda_i = \lambda$ or the recovery rate $\mu_i = \mu$ of each employee (ρ represents both rates), we can use the Poisson distribution to estimate the likelihood of observing q_i events (K_i accidents or K_{Ri} recoveries) in the time w_i (T_i or R_i):

$$P(q_i \mid w_i, \rho, E_0) = \frac{(\rho \cdot w_i)^{q_i} \cdot e^{-\rho \cdot w_i}}{\Gamma(q_i + 1)} \quad (9)$$

As we only know that ρ is one of the possible values of the rate represented by its population variability distribution $\varphi(\rho \mid \rho_{50}, EF\rho)$, we average the likelihood given by Equation

$$P(E_{1i} \mid \underline{\theta}, E_0) = \int_\rho P(E_{1i} \mid \underline{\theta}, E_0, \rho) \cdot \varphi(\rho \mid \underline{\theta}) \cdot d\rho \quad (5)$$

over all possible values of ρ in order to calculate the probability of the data unconditional on the unknown value of ρ:

$$P(q_i, w_i \mid \rho_{50}, EF_\rho, E_0) = P_i = \int_\rho P(q_i, w_i \mid \rho, E_0) \cdot \varphi(\rho \mid \rho_{50}, EF_\rho) \cdot d\rho \quad (10)$$

Replacing Equations

$$\varphi(\rho \mid \rho_{50}, EF\rho) = \frac{1}{\sqrt{2\pi} \cdot \rho \cdot \frac{\ln EF\rho}{1.645}} e^{-\frac{1}{2}\left(\frac{\ln\rho - \ln\rho 50}{\ln EF\rho/1.645}\right)^2} \quad (7)$$

and

$$P(q_i \mid w_i, \rho, E_0) = \frac{(\rho \cdot w_i)^{q_i} \cdot e^{-\rho \cdot w_i}}{\Gamma(q_i + 1)} \quad (9)$$

into Equation

$$P(q_i, w_i \mid \rho_{50}, EF_\rho, E_0) = P_i = \int_\rho P(q_i, w_i \mid \rho, E_0) \cdot \varphi(\rho \mid \rho_{50}, EF_\rho) \cdot d\rho \quad (10)$$

$$P_i = \int_\rho \frac{(\rho \cdot w_i)^{q_i} \cdot e^{-\rho \cdot w_i}}{\Gamma(q_{i+1})} \cdot \frac{1}{\sqrt{2\pi} \cdot \rho \cdot \frac{\ln EF\rho}{1.645}} e^{-\frac{1}{2}\left(\frac{\ln\rho - \ln\rho 50}{\ln EF\rho/1.645}\right)^2} d\rho \quad (11)$$

The total likelihood is then obtained by replacing Equation

$$P_i = \int_\rho \frac{(\rho \cdot w_i)^{q_i} \cdot e^{-\rho \cdot w_i}}{\Gamma(q_{i+1})} \cdot \frac{1}{\sqrt{2\pi} \cdot \rho \cdot \frac{\ln EF\rho}{1.645}} e^{-\frac{1}{2}\left(\frac{\ln\rho - \ln\rho 50}{\ln EF\rho/1.645}\right)^2} d\rho \quad (11)$$

into Equation

$$P(E_1 \mid \underline{\theta}, E_0) = \prod_{i=1}^{n} P(E_{1i} \mid \underline{\theta}, E_0) \quad (4)$$

$$P(E_1 \mid \underline{\theta}, E_0) = \prod_{i=1}^{n} \int_\rho \frac{(\rho \cdot w_i) q_i \cdot e^{-\rho \cdot w_i}}{\Gamma(q_{i+1})} \cdot \frac{1}{\sqrt{2\pi} \cdot \rho \cdot \frac{\ln EF\rho}{1.645}} e^{-\frac{1}{2}\left(\frac{\ln\rho - \ln\rho 50}{\ln EF\rho/1.645}\right)^2} d\rho \quad (12)$$

3.2.2 *A prior distribution specification*

Application of population variability analysis requires specifying the prior distribution defined over the parameter space of the chosen variability model, representing the prior belief about the variability distribution before the evidence (accident database) becomes available. Some authors propose that the prior be specified in the form of a

discrete prior distribution (Kaplan 1983, Pickard et al. 1985).

The algorithm here adopted involves the specification of an informed continuous prior over the parameter space of the variability model. The analyst is required to provide initial estimates in terms of a central value (median) and the extent of variability (error factor) in the population variability distribution. As discussed in Droguett et al. (2004), these estimates take the form of Lognormal distributions. If the parameters v and τ of the population variability distribution of ρ are distributed as a Lognormal distribution, then the distributions of $\rho_{50} = e^{v}$ and $EF\rho = e^{1.645\tau}$ take the forms

$$f(\rho_{50}) = \frac{1}{\sqrt{2\pi}\cdot\rho_{50}\cdot\dfrac{\ln\varepsilon_{\rho_{50}}}{1.645}} e^{-\frac{1}{2}\left(\frac{\ln\rho_{50}-\ln\gamma_{\rho_{50}}}{\ln\varepsilon_{\rho_{50}}/1.645}\right)^2} \quad (13)$$

and

$$f(EF_{\rho}) = \frac{1}{\sqrt{2\pi}\cdot EF_{\rho}\cdot\dfrac{\ln\varepsilon_{EF_{\rho}}}{1.645}} e^{-\frac{1}{2}\left(\frac{\ln EF_{\rho}-\ln\gamma_{EF_{\rho}}}{\ln\varepsilon_{EF_{\rho}}/1.645}\right)^2} \quad (14)$$

where γ_x and ε_x are the median and error factor of the distribution of x (where x can represents both the median and error factor of ρ). Considering the independence between v and τ then the prior distribution of variability model is $\pi_0(\rho_{50}, EF\rho) = f(\rho_{50}) \times f(EF\rho)$. The definition of prior distributions consists in to determine the values $\gamma_{\rho 50}$, $\varepsilon_{\rho 50}$, $\gamma_{EF\rho}$ and $\varepsilon_{EF\rho}$ (e.g. by specialist's opinions):

$$\pi_0(\rho_{50}, EF_{\rho}) = f(\rho_{50}\,|\,\gamma_{\rho_{50}}, \varepsilon_{\rho_{50}})\cdot f(EF_{\rho}\,|\,\gamma_{EF_{\rho}}, \varepsilon_{EF_{\rho}}) \quad (15)$$

So the set $\{\gamma_{\lambda 50}, \varepsilon_{\lambda 50}, \gamma_{EF\lambda}, \varepsilon_{EF\lambda}\}$ corresponds to the E_0 evidence for accident rate analysis and the set $\{\gamma_{\mu 50}, \varepsilon_{\mu 50}, \gamma_{EF\mu}, \varepsilon_{EF\mu}\}$ is the E_0 evidence for recovery rate analysis.

3.2.3 *Variability measures*

The likelihood functions and prior distributions have been incorporated in a Bayesian inference procedure in which the posterior density $\pi_1(\underline{\theta}\,|\,E)$ is computed. The Bayesian inference is performed by using a Markov Chain Monte Carlo Method (MCMC), which allows samples to be generated from a continuous unnormalized density (Chiband & Greenberg, 1995). The MCMC method, which is frequently applied to Bayesian Inference problems (Gilks et al. 1996), results in a m-samples set $S = \{\underline{\theta}_1, \ldots, \underline{\theta}_m\}$, representing the posterior density over the parameters of the variability distribution model $\varphi(\rho\,|\,\underline{\theta})$. Given S, the estimated population variability density is computed as

$$\hat{p}(\rho) = \frac{1}{m}\sum_{i=1}^{m}\varphi(\rho\,|\,\underline{\theta}_i) \quad (16)$$

The corresponding mean and variance are computed as

$$\hat{\mu}_{\rho} = \frac{1}{m}\sum_{i=1}^{m}\mu(\underline{\theta}_i) \quad (17)$$

$$\hat{\sigma}_{\rho}^{\,2} = \frac{1}{m}\sum_{i=1}^{m}\sigma^2(\underline{\theta}_i) \quad (18)$$

where $\mu(\underline{\theta})$ and $\sigma^2(\underline{\theta})$ are the mean and variance of $\varphi(\rho\,|\,\underline{\theta})$.

Furthermore, the generated results include uncertainty bounds of the cumulative variability density $P(\rho) = \int_{x=0}^{\rho} p(x)dx$ in the form of zth percentiles $P_z(\rho)$, defined as $\Pr(P(\rho) < P_z) = z/100$. The zth percentiles are determined by finding the value $\hat{P}_Z(\rho)$ for which for a fraction z/100 of the samples $\underline{\theta}_i \in$ S:

$$\int_{x=0}^{\rho}\varphi(x\,|\,\underline{\theta}_i)\cdot dx < \hat{P}_z(\rho) \quad (19)$$

These bounds provide the analyst with a basis to assess the uncertainty associated with the estimated population variability distribution related to accidents or recovery rates.

3.3 *Estimation of the work time loss distributions by Markov-based model*

As discussed in Section 2 it is assumed that each employee has a unique accident rate even that they have functions similar or be allocated in the same occupational environment as the other employees. This assumption is due to the existence of idiosyncrasies that make every worker particular.

The random behavior, which leads to occupational accidents, and the corresponding recovery of the worker, can be represented by a Markov-based stochastic process as shown in Figure 2. Workers who are in the first state are performing their function normally (they are available for work), while those in the second state are recovering from an accident (on medical leave). Random mechanisms, which lead the worker i to an accident, occur with rate λ_i, so that if the worker was available (State 1) he becomes unavailable (state 2). Another random mechanism recovers the victim to the available

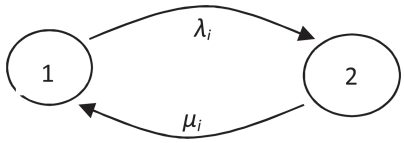

Figure 2. Markov diagram of the stochastic process.

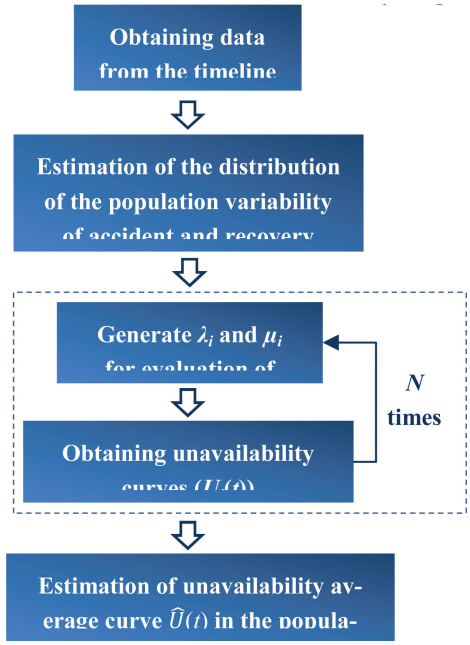

Figure 3. Proposed model.

status with rate μ_i. It is assumed that the two rates, λ_i and μ_i, are independent.

If we know the accident rate λ_i and the recovery rate μ_i we can determine the unavailability curve of the worker by applying some method of solution of the Markov diagram (numerical methods, analytical treatment, simulation, etc.). However, we only know that λ_i and μ_i are one of possibly many values of the variables λ and μ, distributed as $p(\lambda)$ and $p(\mu)$ respectively. $p(\lambda)$ and $p(\mu)$ are estimated by $\hat{p}_1(\lambda|E_{0\lambda},E_{1\lambda})$ and $\hat{p}_1(\mu|E_{0\mu},E_{1\mu})$ from the Bayesian model presented in Section 3.2.

Of course, if workers have different accident and recovery rates, they have different unavailability curves. We can simulate the stochastic process linked to accidental behavior of a worker by generating the values λ_i and μ_i from $\hat{p}_1(\lambda|E_{0\lambda},E_{1\lambda})$ and $\hat{p}_1(\mu|E_{0\mu},E_{1\mu})$. By doing this, we obtain the unavailability curve by solving the Markov process. However, we can't determine the worker for which this result is valid. Repeating this process N times (N must be large enough to ensure the representativeness of the simulation), we obtain an N-samples set where each sample contains one curve of unavailability. Thus, we estimate the average unavailable curve ($\hat{U}(t)$) as

$$\hat{U}(t) = \frac{1}{N}\sum_{i=1}^{N} U_i(t) \tag{20}$$

where $U_i(t)$ corresponds to the curve of the unavailability resulting from the i-th iteration of Markov process.

It is acceptable to assume that $\hat{U}(t)$ represents the fraction of man-hour loss due to occupational accidents. Also, it is possible to define the uncertainty associated with this estimate by the zth percentiles of the set $\{U_1(t), \ldots, U_N(t)\}$.

In this paper, we use the numerical treatment based on transition frequency densities by Moura & Dorguett (2009) to infer unavailability curves. The Population Variability and Markov-based integrated model can then be resumed by Figure 3.

4 EXAMPLE APPLICATION

In this section, we illustrate and discuss the use of the Bayesian Population Variability analysis and Markov-based models by means of an example. We start by supposing that we are interested in assessing the average distribution of work time loss due to occupational accidents for workers of a hydroelectric power company in Brazil. Runtime data were collected from the timeline of operation employees between 01/01/2005 and 09/31/2012 in order to construct the likelihood function.

As discussed in Section 2.1 the Bayesian Population Variability Analysis must be used in a workers population subject to similar risk of accidents. So, in this section, the model is applied to employees with the same job and workplace. The administrators located in the operation sector of the company were analyzed. These workers suffered mainly two types of accidents: (1) accidents in commuting and (2) falls. It is expected that one worker has different accident and recovery rates for each type of accident. Therefore, the model was applied separately for analyzing the work time loss distributions due to accidents in commuting and falls.

4.1.1 *Results*

57 workers were analyzed in a total of 157,784 mendays of work. 27 accidents were recorded in the period, of which 13 are accidents in commuting and 14 are falls. Upon solving the Bayesian population variability and Markov-based integrated

model, the expected unavailability of the population of workers has a 5th and 95th percentiles of 0.00017 and 0.0043 due accidents in commuting an of 0.00025 and 0.008 due falls, respectively, with a mean of 0.0013 for accidents in commuting and of 0.0022 for falls.

If $T_L(t)$, $T_L^{5\%}(t)$ and $T_L^{95\%}(t)$ correspond to the mean and the 5th and 95th percentiles distributions of expected work time lost by one worker of population then the mean and the 5th and 95th percentiles distributions of expected work time lost in the population of workers ($T_P(t)$, $T_P^{5\%}(t)$ and $T_P^{95\%}(t)$) can be obtained by multiplying the $T_L(t)$, $T_L^{5\%}(t)$ and $T_L^{95\%}(t)$ by the number of workers in population. This means that the expected work time loss by workers located in the operation sector in one year is $0.46 \times 57 = 26.35$ men-days due to accidents in commuting and $0.81 \times 57 = 46.33$ men-days due to falls, amounting 72.68 men-days loss per year among the workers located in operation sector of the hydroelectric power company. The corresponding 5th and 95th percentiles are $0.063 \times 57 = 3.60$ and $1.58 \times 57 = 90.10$ for accidents in commuting and $0.09 \times 57 = 5.10$ and $2.9 \times 57 = 165.81$ for falls. Figures 4 and 5 illustrate the expected work time loss curves for accidents in commuting and for falls.

4.1.2 *Validation*

To validate the application of the model we generate the data from the results of the Bayesian population variability model in order to compare them with the actual data. The Bayesian model applied in the real case provides estimations for population variability distributions of accidents and recoveries rates. From these distributions we generate the accidents and recoveries data of workers. It is expected that these data can represent the accident-recovery process of this population of workers.

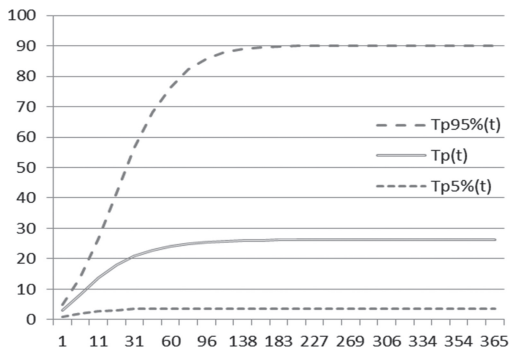

Figure 4. Work time loss distributions for accidents in commuting.

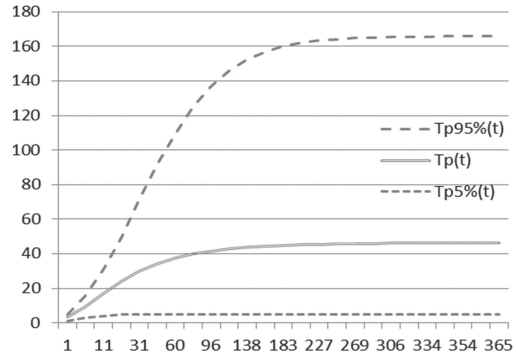

Figure 5. Work time loss distributions for falls.

Table 2. *p*-values of the hypothesis tests.

Test	Accidents in commuting	Falls
Time to accident	0.1871	0.125
Time to recovery	0.2606	0.1755
Unavailable	0.2606	0.1705

These data were compared with the actual data by application of the statistic Kruskal hypothesis test (Kruskal & Wallis, 1952) under the null hypothesis that the data follow the same distribution. Three tests were realized for each type of accident: (i) test on time to accident, (ii) test on time to recovery and (iii) test on unavailability, amounting six (6) hypothesis tests. Table 2 shows the *p*-values of each test.

All *p*-values are greater than 0.1, then we can say that there is no evidence to reject the null hypothesis. Furthermore, we can accept the null hypothesis to be true i.e. the simulated and actual data come from the same distribution since the *p*-values in Table are large. This result validates the proposed model in this paper because it proves the efficiency of the model to represent the real population.

5 CONCLUDING REMARKS

The model presented in this paper represents an extension of the Bayesian population variability assessment method in accidents analysis. A Markov-based model is used for estimation of the expected work time loss distributions due to occupational accidents. The Bayesian population variability assessment method allows the evaluating of population variability of accidents and recovery rates based on exposure data of workers submitted to same occupational risks and the Markov-based model is used to derive the worker unavailability

statistics to predict the amount of time that workers will be recovering from accidents and therefore won't be available to perform the job they are paid for. The use of the population variability analysis allows to assess the uncertainty presented on the results of the Markov-based model.

The models developed here can be informed using available databases of occupational accidents documented in the industries. Sufficient statistics to use the models include only the number of workdays, the workdays loss due to recovering from occupational accidents, and the number of occupational accidents over the period of observation for each worker.

The implementation of the extension used in the examples in Section 4 has shown that the numerical solution of the models is feasible and provides a good estimation for the expected work time loss distribution due to occupational accidents. Also, the comparison of simulated data, from the population variability distributions, with real data showed that the estimated population variability distributions of the accidents and recoveries rates can be used to represent the actual situation.

Continuous monitoring of at-risk behaviours: A risk-based statistical control method

D. Masi & P. Trucco
Politecnico di Milano, Milan, Italy

ABSTRACT: An effective implementation of the behaviour-based safety approach requires a continuous monitoring of the performance of workers. However, this continuous monitoring is challenging for practitioners due to the great demand of time, cost, and professional skills needed for its implementation. This paper proposes a sustainable solution consisting in a method which combines the continuous safety sampling method, a statistical analysis of non-conforming observations, and a consistent experts' judgements elicitation process based on the analytic hierarchy process.

1 INTRODUCTION

Accidents at work continue to be one of the major work environment challenges facing legislators, enterprises, and workers worldwide. According to the Labour Force Survey (LFS), using data from 2007, the 3.2% of the workforce in the EU-27 reported an accident at work in the past 12 months. This corresponds to approximately 6.9 million persons. In line, data from the European Statistics on Accidents at Work (ESAW) showed that 2.9% of the workers had an accident at work with more than three days of sickness absence and 5580 workers died in a fatal accident in 2007 (Eurostat European Commission. 2010). The data clearly show that accidents at work place a considerable burden on individuals, society and enterprises.

Because of the relevance of the problem, several attempts have been made aiming at improving Occupational Safety and Health (OSH) conditions within enterprises. In particular, several studies focused on the causes of accidents, with the purpose of removing these causes by means of different kinds of interventions. In this regard, there is scientific evidence that unsafe behaviours are a major cause of accidents (see e.g. Heinrich, 1950 and Hide et al., 2003); as a consequence, many approaches aiming at modifying human unsafe behaviours have been proposed in the scientific literature.

Among these, the Behaviour-Based Safety (BBS) approach is gaining an increasing attention in the area of OHS. BBS aims at modifying human unsafe behaviours (Scott Geller, E., 2001) by adding antecedents and/or consequences to the situation to alter response probability (DePasquale & Geller, 2000). Examples of interventions creating antecedents and consequences are Goal Setting and Feedback (DePasquale & Geller, 2000; Cameron & Duff, 2007). A goal of compliance level to safety is an antecedent which alters workers' response: the desire to achieve the goal would motivate workers to make efforts in this direction. On the other hand, positive feedback, incentive or reward are consequences which reinforce workers' safe behaviours.

Over the years, BBS has been applied successfully by many researchers in various settings such as clinical medicine (Dickerson et al., 2010), manufacturing (Hermann et al., 2010), mining (Hickman & Geller, 2003) and institution office (Al-Hemoud & Al-Asfoor, 2006). Moreover, BBS was found to be a promising way to further prevent accidents. Many researchers analysed the OSH records of enterprises which implemented BBS and the results revealed a significant decrease in incidents across groups following the BBS implementation (see e.g. Krause et al., 1999).

Despite these successful implementations, BBS approach faces a critical difficulty in achieving persistent effects. Some studies have reported that behavioural safety performance declined (Johnston et al., 1994; Lingard & Rowlinson, 1998) or even went back to the baseline level (Komaki et al., 1978) after intervention was stopped.

Although many factors may affect the final outcomes of BBS approach, this difficulty is largely attributed to the intervention strategy itself. Basically, BBS intervention focuses on external antecedent and consequence for the reinforcement of safe behaviours (Cameron & Duff, 2007), thus creating OHS improvements with a sensitive dependence on external situations. When the external situation changes, the safety performance

is likely to deteriorate (DeJoy, 2005). As a consequence, a continuous monitoring of the external situation and of the performance of the workers is necessary.

However, this activity is challenging due to the great demand of time, cost and professional skills for its implementation. In the light of the relevance of this practitioners' challenge, this paper proposes a solution consisting in a method which combines three different techniques: the Continuous Safety Sampling Method (CCSM) (Quintana and Nair, 1997), a statistical analysis of non-conforming behaviours, and a consistent experts' judgements elicitation process based on the Analytic Hierarchy Process (AHP).

The paper is structured as follows. In paragraph 2, the CCSM is summarised, due to its relevance for the proposed model. In paragraph 3, the Risk-Based Statistical Control Method is presented, by means of its application in an Italian manufacturing enterprise. Finally, in paragraph 4 main conclusions are taken.

2 THE CONTINUOUS SAFETY SAMPLING METHODOLOGY

The CCSM (Quintana and Nair, 1997) represents a method for the continuous monitoring of the external situation and of the performance of the workers. The methodology aims at collecting information on the safety conditions in a statistically verifiable and economically viable manner by using the principles of work sampling and control charts. The hypothesis is that a random sample of a sufficiently large size, as in work sampling, reflects the state of the system being observed. Sampling aims at observing the occurrence of conditions that may become hazardous in a given system, called dendritics. On the other hand, by providing information regarding the tendency of a system, the control charts in CCSM indicate when systems tend to become hazardous, thus facilitating the implementation of corrective steps.

For the creation of CSSM five steps are necessary:

Step 1—Dendritic construction. This step consists in the identification of the core conditions leading to hazards in any given system. This analysis can be performed by means of a Preliminary Hazard Analysis.

Step 2—Random Sampling. The sampling can be performed in conjunction with other routine job functions, without additional allocation of resources.

Step 3—Control chart. A p-chart is constructed by plotting the daily value of $\overline{p}$ against the date. The $\overline{p}$ is the daily weighted average of all the proportion of non-conforming observation. The Upper Control Limit (UCL) and the Lower Control Limit (LCL) are given by formulas reported in Equation (1) and in Equation (2):

$$UCL = \overline{p} + 3 \cdot \sqrt{\frac{\overline{p} \cdot (1 - \overline{p})}{n}} \tag{1}$$

$$LCL = \overline{p} - 3 \cdot \sqrt{\frac{\overline{p} \cdot (1 - \overline{p})}{n}} \tag{2}$$

Step 4—The control chart observations are tested for "out of control conditions".

Step 5—If an out of control condition is detected, appropriate action is taken to eliminate or control these conditions and thus to maintain a desired safe system.

The application of the above stepwise procedure provides a cost effective way of keeping a continuous check on the safety status of the workplace under consideration.

However, CCSM, in the described formulation, is not adequate for the continuous monitoring of the external situation and of the performance of the workers in a Behaviour-Based Safety perspective. The main limitation is that the model does not provide an estimation of the risk related to the non-conforming behaviours. The method distinguishes between conforming and non-conforming behaviours, without any further clarification on the criticality or on the expected consequences of the behaviours themselves. In fact, different at-risk behaviours are characterized by different criticalities.

When the OHS performance of the whole enterprise is monitored, interventions can be introduced only when the risk related to the non-conforming behaviours is not acceptable, while it is not possible to intervene every time that behaviours are simply non-conforming. If interventions implemented without any estimation of the criticality of the related non-conforming behaviours, resources can be easily wasted in correcting behaviours which are not critical for the improvement of the OSH performance of the enterprise.

In the light of the above, modifications and integrations to the CCSM are necessary for the continuous monitoring of the external situation and of the performance of the workers in a Behaviour-Based Safety perspective. This paper proposes a risk-based statistical control method which is grounded on the original CCSM and which overcomes its mentioned limitations by combining CCSM with a statistical analysis of non-conforming behaviours, and with a consistent experts' judgements elicitation process based on the Analytic Hierarchy Process (AHP).

The risk-based statistical control method redefines some parameters proposed by CCSM, thus shifting the method from a simply non-conforming based method into a risk-based method. The method has been tested by means a pilot application in an Italian manufacturing company which produces tractors. The method, together with the results obtained during its empirical application, are presented in the following paragraph.

3 THE RISK-BASED STATISTICAL CONTROL METHOD

Coherently with the steps proposed by CCSM, for the creation of the model five steps are necessary, which consists in (1) Dendritic construction, (2) Random Sampling, (3) Control chart design (4) Test for "out of control conditions, and (5) Action.

Step 1—The dendritic construction consists in the identification of the core conditions leading to hazards in the system. A preliminary hazard analysis has been performed in the monitored enterprise, and a checklist of behaviours leading to hazards has been identified. The dendritics leading to hazards have been classified in different groups. These dendritics are reported in Table 1. Many of the identified dendritics are workers' behaviours; however, some dendritics more related to contextual aspects, such as obstacles not clearly indicated, have been included.

The contemporary assessment of behavioural and contextual conditions potentially determining accidents is one advantage of the model, which allows for an unique analysis of all the aspect that determine the OSH performance of the company. Each of the dendritics is assessed during the inspection, and 1 is used for the indication of non-conformity, while 0 is used to state conformity.

Step 2—The sampling can be performed in conjunction with other routine job functions, without additional allocation of resources. In the analysed enterprise, the sampling has been done by monitoring the safety conditions of the "Transmissions" department, during 19 work-shifts.

Step 3—Control chart. The main modification introduced in the model consists in the way in which the control chart is designed. Instead of the p-chart proposed by CCSM, the model uses a R-chart, which means Risk-chart. A R-chart is constructed by plotting the daily value of $\bar{R}$ against the date. $\bar{R}$ is the daily weighted average of all the proportion of non-conforming Risks. The Upper Control Limit (UCL) and the Lower Control Limit (LCL) are given by the formulas reported in Equation (3) and in Equation (4)

Table 1. Checklist of dendritics.

Machinery and tools

D24 Safety devices are not correctly used
D25 Lack of indications for the shelves

$$UCL = \bar{R} + 3 \cdot \sqrt{\frac{\bar{R} \cdot (1 - \bar{R})}{n}} \tag{3}$$

$$LCL = \bar{R} - 3 \cdot \sqrt{\frac{\bar{R} \cdot (1 - \bar{R})}{n}} \tag{4}$$

Risk is defined as the product between the severity of consequences (D) and the probability of occurrence of the accident (E) and of its related causes C_k, as indicated in Equation (5).

$$R = D \cdot P(E, C_1, C_2, \ldots, C_n) \tag{5}$$

The probability of occurrence of the accident and of its related causes can be calculated by means of Bayesian marginalisation, i.e. the summation of the products between the probability of occurrence of the accident, conditional to the occurrence of the k-cause $P(E/C_k)$, and the prob-

ability of occurrence of the cause $P^*(C_k)$, as indicated in Equation (6).

$$P(E, C_1, C_2, \ldots, C_n) = \sum_{k=1}^{N} P(E/C_k) \cdot P^*(C_k) \quad (6)$$

It is important to underline that the first term $P(E/C_k)$ has to be estimated during the setting of the model, and it is kept constant in further observations, while the second term $P^*(C_k)$ is obtained by the daily observation of non-conforming dendritics.

The probability $P(E/C_k)$ can be easily estimated using the Bayes' theorem, as shown in Equation (7)

$$P(E/C_k) = \frac{P(C_k/E) \cdot P(E)}{P(C_k)} \quad (7)$$

In Equation (7), $P(C_k/E)$ indicates the probability that an accident occurs as the direct consequence of the occurrence of the k-cause; $P(E)$ indicates the probability of occurrence of the accident, and $P(C_k)$ indicates the prior estimation of the probability of occurrence of the k-cause. An estimation of these three terms is necessary.

The probability of occurrence of an accident $P(E)$ has to be estimated during the setting of the model, and kept constant in further observation. The historical value of $P(E)$ during the year t, called $P(E)_t$, can be estimated as ratio between the number of accidents happened during one year and the number of total worked hours. The actual value of $P(E)$ can be estimated by applying exponential smoothing to the historical values. In the analysed case, the historical values of the last three years have been used; these values are reported in Table 2. Exponential smoothing (Equation 8) has been applied to the historical values $P(E)_t$ reported in Table 2.

$$S_t = P(E)_t + (1 - \alpha) \cdot S_{t-1} \quad (8)$$

In Equation (8), the initial value of the S_1 has been calculated as value of the first year, and the parameter alpha has been set to 0,9 in order to give higher importance to the most recent data. Indeed, the interventions progressively implemented improve the OHS conditions of the enterprise, and it is possible to predict that this trend is ongoing. The final estimation, calculated with exponential smoothing, is $P(E) = 0{,}39$.

The initial estimation of the probability of occurrence of the k-cause $P(C_k)$ has been calculated as ratio between non-conforming observations and total observations during five working shifts. Some representative values of $P(C_k)$, with the relative number of non-conforming observation, are reported in Table 3.

$P(C_k/E)$, namely the probability that the k-cause will generate an accident, has been estimated by combining an estimation from historical data $P(C_k/E)_t$ and experts' judgments $P(C_k/E)_{AHP}$.

As for the estimation from historical data $P(C_k/E)_t$, coherently with the technique used for the estimation of $P(E)$, the data of the last three years have been used. $P(C_k/E)_t$ has been estimated as ratio between the occurrences of accidents generated by the k-cause $\#(E/C_k)_t$ of the considered year and the total number of accidents of the considered year $\#\ accidents_t$. This ratio is shown in equation (9).

$$P(C_k/E)_t = \frac{\#(E/C_k)_t}{\#\ accidents_t} \quad (9)$$

On the other hand, experts' judgments $P(C_k/E)_{AHP}$ has been obtained using the Analytic Hierarchy Process (Saaty, 2008). The Analytic Hierarchy Process (AHP) is a theory of measurement through pairwise comparisons and relies on the judgements of experts to derive priority scales. It is these scales that measure intangibles in relative terms. The comparisons are made using a scale of absolute judgements that represents, how much more, one element dominates another with respect to a given attribute. Five experts were interviewed: the production engineer, the technology development engineer, the safety engineer, the safety manager, and the responsible for workshop machining. The experts were asked to pairwise evaluate the k causes by means of the following question: "Which of the two causes has the higher probability of generating an accident?".

Table 2. P(E) calculated for the last three years.

Year	Accidents	$P(E)_t$
1	117	0,53
2	96	0,44
3	84	0,38

Table 3. Examples of values of $P(C_k)$.

Dedritics	Non-conf. obs.	Total obs.	$P(C_k)$
Tools are not correctly used	3	224	0,01
Tools are not adequate or in non-adequate conditions	6	224	0,03

The results consists in a set of weights related to the k-causes of accidents.

The estimation from experts' judgments $P(C_k/E)_{AHP}$ and the estimation from historical data $P(C_k/E)_t$ have been mediated when possible. Indeed, the historical data did not contain any reference to some of the k-causes. For these k-casues, the final estimation $P(C_k/E)$ is equal to the estimation collected through experts' judgments $P(C_k/E)_{AHP}$. Some examples of final estimations are reported in Table 4.

Having estimated all the terms necessary to the estimation of the probability $P(C_k/E)$, the last parameter estimated is the severity of consequences (D). Again, the historical value of D during the year t, called D_t, can be estimated as ratio between the number of work shifts lost because of accidents and the total number of working hours, multiplied by 1000, as reported in equation (10).

$$D_t = \frac{\#\,work\ shifts\ lost}{\#\,working\ hour} \cdot 1000 \tag{10}$$

The actual value of D can be estimated by applying exponential smoothing to the historical values. Also in this case, the simple exponential smoothing has been used with data of the last three years. Alpha has been set to 0,9 since the hypothesis is that OHS interventions implemented in the last years progressively reduce the number of injuries and that this positive trend will continue in the future. The historical values D_t are reported in Table 5.

The application of an exponential smoothing with alpha = 0,9 gives a final value of D equal at 0,97.

Table 4. Examples of estimation of $P(C_k/E)$.

Dedritics	$P(C_k/E)_{AHP}$	$P(C_k/E)_t$	$P(C_k/E)$
Tools are not correctly used	0,08	–	0,08
Tools are not adequate or in non-adequate conditions	0,09	0,07	0,08

Table 5. Data used for the estimation of D by exponential smoothing.

Year	D_t
1	1,03
2	1,06
3	0,96

Having estimated all the terms of Equation (7), it is now possible to calculate the criticality of the k-cause. The criticality is defined by Equation 11.

$$Criticality_k = D \cdot P(E/C_k) \tag{11}$$

The criticality calculated for some of the k-causes is reported in Table (6).

The criticality is used for weighting the estimations of $P^*(C_k)$ obtained by the day-by-day observed non-conforming dendritics.

Having estimated all the terms of Equation (5), it is possible to calculate the total Risk of a production department, unit or single workplace. Some examples of numerical values of Risk are reported in Table 7.

The internal elements of Table (7) are the estimations of $P^*(C_k)$ obtained as ratio between the number of non-conforming observations and the total number of observations at each sampling session. For instance, the value 0,003, obtained in the sampling session of the day 2 for the cause "Heavy objects are not ergonomically stored", has been obtained as ratio between the number of non-conforming observations for "Heavy objects are not ergonomically stored" in the sampling session of the Day 2 (1 non-conforming observation) and the total number of observation in that day 2 (341 total observations).

In order to create the control chart, it is finally necessary to estimate the average R (equation 12), the Upper Control Limit (UCL) (equation 13), and the Lower Control Limit (LCL). In order to simplify the model, the lower control limit has been set to zero.

$$\bar{R} = \sum_t \frac{R_t}{t} \tag{12}$$

$$LCS = \bar{R} + 3 \cdot \sqrt{\frac{\bar{R} \cdot (1 - \bar{R})}{n}} \tag{13}$$

In Equation (13) n is the number of observations at each sampling session whereas in Equation (12) t the number of periods.

Having estimated all the parameters, it is now possible to create the final control chart, as shown in Figure 1.

Step 4. The control chart shows that the risk level has been out of control in one case. An analysis of the out of control case showed that it was created by the synergic combination of different causes. In the analysed enterprise, the sampling has been done by monitoring the safety conditions of the "Transmissions" department, during 19 work-shifts.

Step 5. Interventions have been introduced to remove these causes.

Table 6. Criticality calculated for some of the k-causes.

Dedritics	P(Ck/E)	P(E)	P(Ck)	Criticality
D1 Tools are not correctly used	0,08	0,39	0,013	2,14
D2 Tools are not adequate or in non-adequate conditions	0,09	0,39	0,027	1,31
D3 Heavy objects are not ergonomically stored	0,05	0,39	0,009	1,94
D4 Materials are not ergonomically stored in cart lifts	0,04	0,39	0	0

Table 7. Risk of the department.

	D1	D2	D3	…	D24	
Critic.	2,14	1,31	1,94	…	0,00	Risk
Day 1	0	0	0	…	0	0,01587
Day 2	0	0	0,003	…	0	0,01507
Day 3	0	0	0	…	0	0,01456
Day 4	0	0	0	…	0	0,00482

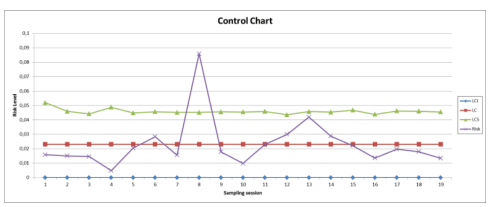

Figure 1. Control chart.

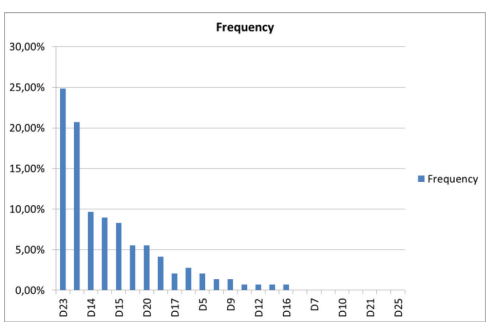

Figure 2. Frequency of occurrence of the k-causes.

Further analyses show that the department does not present particular criticalities. The non-conforming observations are mainly related to a restricted set of causes, with a prevalence of

– Lockout procedures not correctly followed (D23)
– Workers do not use protective glasses necessary for the task (D6)
– Safety belt is not used (D14)

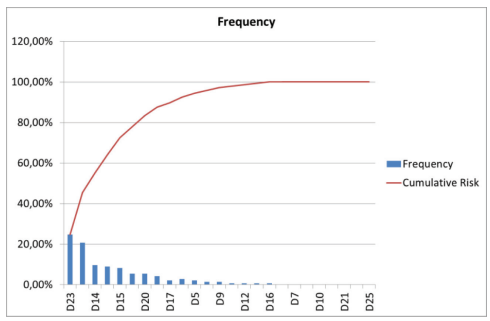

Figure 3. Cumulative risk curve.

– Forklifts stop in forbidden areas (D22)
– Use of music earphones (D15)

The frequency of occurrence of each single cause is reported in Figure 2, while the cumulative risk curve is reported in Figure 3.

4 CONCLUSIONS

The proposed method allows the continuous monitoring of OHS conditions in workplaces associated to workers' safety performance. The combination of a checklist of dendritics and a control chart seems to be an adequate and sustainable approach for this purpose. On the one hand, the checklist, developed by mean of a Preliminary Hazard Analysis, includes all the hazardous conditions of the company and in particular all the at-risk behaviours. On the other hand, the control chart allows identifying all the hazardous conditions that are critical for the employees.

This is a first innovative aspect respect to the simple CCSM method. While CCSM gives the same importance to all the detected non-conforming behaviours, our method introduces a distinction based on the criticality of the specific non-conforming observation. A second innovative aspect of the method is related to the possibility of combining historical data and experts' judgments in the estimation of the criticality. This aspect is of paramount importance, since the external conditions, which influence workers' behaviours, change

dynamically; experts' judgment is essential for a sound assessment of the dynamic evolution of the system.

Summing up, CCSM does not provide an estimation of the severity of the consequences related to the non-conforming behaviours, while traditional risk assessment does not allow continuous monitoring of working conditions and of the performance of the workers. The proposed method overcomes these limitations of CCSM and of risk assessment by combining their advantages. Being risk-based, the method allows for the estimation of the severity of consequences related to the non-conforming behaviours; on the other hand, thanks to statistical analysis of observed non-conformities, the method allows for the continuous monitoring of the external situation and of the performance of the workers, with an affordable demand of time, cost and professional skills for its implementation. Despite the implementation of our method requires an initial investment of resources that is higher than basic CCSM, the effort needed for its daily implementation is comparable. However, the former is substantially covered by the traditional risk assessment process (e.g. by using Job Safety Analysis or Facility Hazard Analysis), which is performed in each company (generally required by law).

The proposed method has some limitations, which open room for future improvements. The main limitation is related to the estimation of the severity factor (D). For the sake of simplicity, a single point severity value has been used for all the at-risk behaviours. However, a more robust estimation should consider different severities for different causes. Again, this estimation could be done by combining historical data, when available, with experts' judgments. A further limitation is related to the effectiveness of the model; it should be tested by means of a long term pilot implementation to check for any positive correlation between safety performance trends and the implementation maturity of the proposed method. This means that after the implementation of the method, a test should verify that the number of non-conforming behaviours as well as the related risk level reduced over time.

Finally, the model has been implemented at shop floor level (i.e. a Transmissions assembly department). Future researches could consider an extension of the method to be applied in other workplaces of a gneric industrial or service company. This requires a more flexible checklist as well as a clear definition of the sampling criteria that must be applied.

Enhancing the implementation of Occupational Health and Safety interventions through a design of the socio-technical interaction

D. Masi & E. Cagno

ABSTRACT: A multitude of Occupational Health and Safety (OHS) interventions have proven to be effective under controlled conditions, but their implementation in practice is often difficult and interventions may therefore not work as expected, especially when referring to Small and Medium sized Enterprises (SMEs). In order to solve this challenge, this paper proposes a model for the systematic design of OHS interventions which takes into account the underlying mechanisms and the contextual factors which can hamper or further the implementation of interventions.

1 INTRODUCTION

A multitude of Occupational Health and Safety (OHS) interventions have been proposed by researchers and practitioners. Even though the interventions as such have proven to be effective—normally under controlled conditions—implementation in practice is often difficult and interventions may therefore not work as expected. Therefore literature points out that the effects of interventions rarely are as strong as expected (see e.g. Kennedy et al., 2010). A number of researchers have tried to solve this problem by suggesting various models for the design of interventions which should secure a stronger implementation. Most of these models understand interventions as projects and they have adapted phase models from the industrial management literature (see e.g. Hare and Cameron, 2012).

However, even assisted by the phase-models, implementation of interventions is not necessarily effective, because the implementation is crucially dependent on the mechanisms promoting the social change and on the contextual factors which enable or disable these mechanisms (Pawson, 2002; Pedersen et al., 2012).

In order to consider the mechanisms and the contextual factors enabling the change process during the implementation of OHS interventions, Pedersen et al. (2012) have proposed a revised realistic evaluation model for the design and evaluation of OHS interventions. It includes factors such as role behaviour, leader and worker motivation, underreporting of injuries, production pressure, unplanned organisational change and accounting. More recently, Nielsen and Abildgaard (2013) presented an evaluation framework based on intervention research and process-oriented organization theory. The framework offers suggestions for which elements to include when evaluating organizational interventions. Within the framework, elements crucial to intervention evaluation are grouped into four overarching categories: the organizational "actors", the mental models of those actors, the context of the intervention, and intervention design and process.

Yet, these models are not fully exploitable by OHS practitioners during the design of OHS interventions because they do not guide practitioners into a systematic and structured fashion in the identification of the mechanisms and the contextual factors relevant for the particular OHS intervention. The models limit themselves to provide a generic definition of mechanisms and contextual factors, assuming that practitioners will be autonomously able to identify specific mechanisms and contextual factors on the basis of their skills and previous experience. The problem is that practitioners could be unable to properly identify specific mechanisms and contextual factors, since the practitioners' decision-making processes can at best be described as governed by bounded ration-

ality, in which heuristics and prior experience play a large role (Hasle and Sorensen, 2011). Moreover, several models assessing context and behavioural mechanisms in accident analysis (see, e.g., Chang and Mosleh, 2007), or human reliability analysis (see, e.g., Kim and Jung, 2003) demonstrate that the analysis of contextual factors and mechanisms is a complex task that needs to be supported by highly structured decision making models.

Practitioners can therefore be expected to face difficulties on the one hand in carrying out a sufficient in-depth analysis of context and mechanism, and on the other hand in keeping it sufficiently simple for utilisation in the practical situation.

This paper aims at providing a solution for this practitioners' challenge by proposing a model for the design of Occupational Safety and Health (OHS) interventions which takes into account the contextual factors and the behavioural mechanisms affecting the implementation of the intervention. The paper is structured as follows. In paragraph 2 (background), the literature related to implementation of interventions is briefly presented, with a focus on the realistic analysis and its limitations, which generated the research work. In paragraph 3, (the model), we present the model. In paragraph 4, the results of the test of the model in 20 Italian manufacturing firms are presented. Finally, in paragraph 5 some conclusions are taken.

2 BACKGROUND

The studies dealing with the implementation of OHS interventions have generally focused on a limited number of factors fostering or hindering the implementation of the interventions.

For instance, Whysall et al. (2006) explored the process of implementing interventions to tackle occupational ill-health, in particular the facilitators and barriers involved in implementing such interventions. The factors cited as key barriers and facilitators include the resistance of workers to changing their behaviour, gaining managerial commitment, and managers' general attitudes towards health and safety. Hale et al. (2010) describe the patterns of interventions distinguishing between successful and not successful projects and discuss the mechanisms lying behind them. They conclude that interventions that bring about constructive dialogue between shop-floor and line management, provide motivation to line managers and strengthen the monitoring and learning loops in the safety management system appeared more successful. There are other examples of studies which however share the same approaches, proposing one or more factors fostering or hindering the implementation of the interventions (see, e.g., Vedung, 2006; Nielsen and Randall, 2013). Thanks to their focus on behavioural characteristics and contextual factors affecting the performance of the workers, these studies help to explain the complex process necessary for the correct implementation of OHS interventions.

However, these studies cannot support practitioners in the design of more effective OHS interventions, because of a limited understanding of the role of the factors within the more general implementation process and of the way in which the factors interact. Existing studies propose factors that can actually play a key role in the implementation of interventions, such as the resistance of workers to change their behaviour or the managerial commitment and attitudes towards OHS. However, it is not clear how to promote the managerial commitment or how to overcome the resistance of workers to change their behaviour. In the same way, it is not clear whether these factors are equally important in different contextual conditions.

In order to effectively plan the implementation of OHS interventions, it is essential to have a clear understanding of the mechanisms promoting or overcoming some of the key factors listed in the literature, and it is essential to understand how these mechanisms and these factors are conditioned by the different contexts arising in different enterprises.

Realist analysis represents a valid theoretical approach for describing the mechanisms promoting or overcoming some key factors in the implementation of intervention and the interplay between those mechanisms and the context in which interventions take place (Pedersen et al., 2012). Realistic analysis was introduced by Pawson and Tilley (1997), and further developed in Pawson's later work (Pawson, 2002; Pawson et al., 2005). It is founded on the ontological position realism, and the key element is to identify what works for whom, under what circumstances, in what respects and how (Pawson and Tilley, 1997). The generative model of causality, which underpins realist enquiry, holds that to infer a causal outcome between two events, one needs to understand the underlying mechanisms that connects the events, and the context in which the relationship occurs (Pawson et al., 2005). The key elements are Context, Mechanism, and Output. Interventions are not presumed to have causal powers in themselves, instead context and mechanisms are seen as the factors which initiate or trigger the causal relationships; for instance motivation from the key actors is a necessary ingredient for the program to work. The actual outcome of the intervention will vary depending on the intervention, the context, the mechanisms, and the interplay between these, and can be categorized as positive or negative, expected

and unexpected. Realist analysis represents a valid alternative for describing the interplay between personal characteristics and contextual factors within safety interventions because it turns the chain of reasoning of workers into a comprehensive theory of the mechanisms through which the desired change should happen. In the same way, the chain of reasoning and reaction is influenced by some technical and organizational features of the company, and realist analysis represents these features of the company in terms of contextual factors affecting the mechanisms through which the interventions may enter the operator's mind.

Summing up, it is essential to have a clear understanding of the mechanisms and the role of the context in the implementation of OHS interventions, and realist analysis represents a valid theoretical approach in order to deal with these issues.

However, practitioners cannot use the realistic analysis yet for improving the implementation of OHS interventions. Indeed, in order to use realistic analysis in the industrial practice, practitioners need procedures which are simple, easy to use, systematic, but at the same time, comprehensive, valid and with a strong theoretical foundation. This aspect has not been adequately considered in the reviewed studies, which show two main limitations. Firstly, existing studies do not organize the analysed factors into a comprehensive model that can be used by practitioners in the design of OHS interventions. Each study focuses on a limited number of factors or on specific aspects, and a comprehensive view is missing. In order to properly design OHS interventions, practitioners dealing with the design of OHS interventions should identify all the relevant behavioural characteristics and contextual factors affecting the change process. Their knowledge as well as the amount of time and resources they can invest in the design of interventions is however limited. As a consequence they should be supported by a comprehensive taxonomy of contextual factors and behavioural characteristics that underlie the change process necessary for the implementation of OHS interventions. Some comprehensive taxonomies of contextual factors and behavioural mechanisms have been proposed in the accident analysis (see, e.g., Chang and Mosleh, 2007), and in the human reliability analysis (see, e.g., Kim and Jung, 2003) literature. Nevertheless, these models cannot be simply extended to OHS interventions, because they focus on specific actions in a short term temporal horizon, while the behaviour of the workers relevant for OHS interventions is made up of several different actions, that take place in a longer temporal horizon, and that are influenced by some intervention specific contextual factors. Secondly, practitioners need procedures which are simple, easy to use, and systematic. As a consequence, even if we have a clear theoretical understanding of the factors triggering the behavioural change of the workers, of the factors describing the context in which this behavioural change is embedded, and of the interplay between them, it is necessary to develop a procedure that drives practitioners in considering these factors during the design of the intervention. However, existing studies are mainly theoretical, and they do not propose any procedure that can be used by practitioners in their industrial practice.

In the light of the above limitations, in this paper we develop a model which supports practitioners in the use of the realistic analysis for an effective plan of the implementation of OHS interventions and which overcomes the abovementioned limitations.

3 THE MODEL

The model includes a taxonomy of mechanisms and contextual factors and a stepwise procedure which allows for a systematic analysis. Before developing the taxonomy, however, it has been necessary to develop a theoretical definition of mechanisms and contextual factors, presented in the following paragraph.

3.1 *Theoretical definition of mechanisms and contextual factors*

In order to produce a definition of mechanisms, we critically reviewed and combined previous definitions. Pedersen et al. (2012) defined mechanisms as "relevant personal characteristics of key actors or interpersonal relations between them". We picked the first part of this definition, and we focused on "relevant characteristics of key actors". In our model the mechanisms represent the thought that is instigated or "triggered" by the intervention and through which the workers' behaviour is changed. As a consequence, we narrowed the definition of Pedersen and his colleagues, and we assumed mechanisms as "mental state of key actors". Astbury and Leeuw (2010) discuss the concept of "mechanism'' and they attempt to elucidate what mechanisms are and what they are not. They conclude that there are three essential clues located in a "realist'' reading of mechanisms. These are that: 1) mechanisms are usually hidden; 2) mechanisms are sensitive to variations in context; and 3) mechanisms generate outcomes. We picked the last two definitions, since we are already assuming that mechanisms are hidden when we define them as mental states of key actors. In our case, the outcomes generated by mechanisms are the modifications in the performance or in the behaviour of the workers. Finally, Pawson and Tilley (1997)

point out how mechanisms are "triggered by a program". We included this aspect in our definition in order to clearly make a distinction between the personal characteristics of actors that are not varying and the ones that vary with the implementation of a particular intervention. For instance, while the motivation of the workers is a personal characteristic that varies on the basis of the particular intervention implemented, the experience of the workers is a cognitive state that cannot be modified by implementing a particular intervention, at least in the short term.

On the basis of the previous arguments, we define mechanism as "mental state of key actors that are triggered by a program, that vary with changes in the context, and that produce a change in the performance or in the behaviour of the workers". It is important to notice that the change in the mechanisms could enable or disable the desired change. The purpose of practitioners is to promote the mechanisms enabling the social change and to eliminate the mechanisms disabling the desired change.

As for contextual factors, we partially modified the definition of Pedersen et al. (2012) and we define contextual factors as "factors that are not directly related to the performance or to the behaviour of the workers, but that are expected to influence the performance or the behaviour substantially". Indeed, according to the proposed realist model, the mechanisms are directly related to the performance or to the behaviour of the workers, while the contextual factors create the conditions enabling or disabling mechanisms.

3.2 *Taxonomy of mechanisms and contextual factors*

Having developed a definition of mechanisms and contextual factors, we defined the criteria for the selection of mechanisms and contextual factors adequate for the purposes of the study. These criteria are listed below.

Criterion 1—Focus on the behaviour of the workers during the implementation of OHS interventions. The amount of factors which could potentially describe the context and the mechanisms influencing OHS interventions is huge. However, it is possible to select a limited number of relevant factors by focusing on the sole factors that are relevant for the behaviour of the workers during the implementation of OHS interventions. The behaviour of the workers during the implementation of OHS interventions indicates a complex set of specific actions, which all together influence the overall implementation of OHS interventions. A specific action is for instance a wrong movement of the operator, that could provoke an accident. Such an action is relevant in a model for accident analysis, but not so relevant in the more general optic of an OHS intervention. The hypothesis done is that an isolated action has not a relevant influence on the overall effectiveness of the intervention, and it's rather necessary to focus on a more general set of actions, and to consider a longer temporal perspective.

Criterion 2—Level of causality adequate for the assessment by SMEs' practitioners. The "level of causality" (Mohaghegh and Mosleh, 2009; Cagno et al., 2014) describes the position of the factors in the cause-to-effect chain. The choice of the level of causality answers questions such as: should the managerial decisions (hiring, training, etc.) be "bottom layer" factors, or should we move further up in the chain of causality, to top managers' strategic decisions, and do we need to include the regulators' impacts on interventions? In our model, we decided to set the level of causality considering the factors internal to the company that are able to affect the whole behaviour of the workers during the implementation of OHS interventions. This modelling choice is justified by the assumption that it is possible to describe the effect of external factors on the performance of the workers during the implementation of OHS interventions by means of some mediating factors that are internal to the company. For instance, the conditions of the financial markets, that are considered by Pedersen et al. (2012) as a relevant contextual factor, could be described by means of the Perception of available resources, the Trust in management and in the enterprise, and the Rewards. This modelling choice offers several advantages. For instance, the factors could be easily assessed by SMEs' practitioners. It is extremely difficult for OHS practitioners to assess the conditions of the financial markets and their influence on OHS interventions, while it is easy to assess the rewards available for the workers within the company.

Criterion 3—Level of detail adequate for the development of hypotheses on the overall intervention. The "level of detail" (Mohaghegh and Mosleh, 2009; Cagno et al., 2014) of factors depends on the importance attached to the different dimensions of the factors in terms of their impacts on the model output. For example, there are two possible approaches to make a cause-to-effect interaction between the "human resource system" and "safety climate". The modeller can consider these two factors as global factors. On the other hand, he/she can establish multiple relations between the "human resource system" and different dimensions of the "safety climate" (e.g., "perception of the reporting system", "perception of training", etc.). The latter is modelled with a higher level of details (Cagno et al., 2014). In our

model, we decided to set a level of detail optimal for the needs of the realist analysis, i.e. a level of detail allowing practitioners to develop hypotheses on the whole behaviour of the workers during the implementation of intervention. In order to understand this level, we reviewed some studies specifically developing hypotheses on the mechanisms underlying the behavioural change and the success during OHS interventions. On the basis of these studies, we identified a preliminary set of mechanisms and factors that has been used as a benchmark for the level of detail to be adopted in the taxonomy.

Criterion 4—Practicality. The factors should be used by ordinary field "safety persons", eventually of a SME, without the need for highly trained experts.

We did not find taxonomies in the literature which covered all the above aspects, neither for the mechanisms nor for the contextual factors. However, we found that some specific factors were able to satisfy all the mentioned criteria and that other factors were potentially suitable after a tailoring process. As a consequence, we performed a conceptualization work and we developed new taxonomies for mechanisms and contextual factors. In some cases, we simply picked factors from existing taxonomies, selecting some factors and excluding others for different reasons. Some factors mentioned in literature are split in different factors. Some were found to be overly broad and as such had to be modelled through other more narrowly defined sets of factors.

We focused on three kinds of studies. First, we reviewed the studies dealing with Human Error Analysis (HEA) or Human Reliability Analysis (HRA) in safety assessment. These studies represent the conditions that influence human performance by means of several 'context factors'. These context factors are referred to by different terms according to method: PSF (performance shaping factors), PIF (performance influencing factors), IF (influencing factors), PAF (performance affecting factors), EPC (error producing conditions), CPC (common performance conditions), and so on. Second, we reviewed the studies dealing with barriers and drivers to OHS interventions; barriers and drivers identify all those factors of context not directly involved in workplace safety intervention, but significantly affecting, respectively hindering and fostering, the outcome of interventions. Third, we reviewed studies dealing with realistic analysis of OHS interventions.

We combined the factors in order to obtain a taxonomy that is as comprehensive as possible. The taxonomy of mechanisms is reported in Table 1, while the taxonomy of contextual factors is reported in Table 2.

Table 1. Taxonomy of mechanisms, classified in classes.

Class	Mechanism
Temporary cognitive states	Memory of previous interventions
	Anticipation
	Autonomous identification of effective behaviours
	Perception of the importance of the intervention
	Perception of the consequences associated with the own behaviour
	Expectations of the workers
	Perception of familiarity with the situation
	Proper interpretation of the own role and responsibilities
	Perception of available resources
	Perception of the complexity of the intervention
	Emulation of behaviours of the working group
Psychological states	Motivation
	Morale
	Confidence in own behaviours
	Confidence in the chosen intervention
	Trust in management and in the enterprise
	Fear of failure
	Stress due to urgent requests
	Stress due to the conflict
	Frustration
	Uncertainty
	Attention

3.3 *Structure of the analysis*

In order to structure the analysis in a systematic and structured fashion we propose a stepwise procedure for the design of working environment programmes. The design procedure therefore adds some supplementary steps to the original procedure proposed by Hasle et al. (2012) and is made up of seven steps:

1. Define the OHS challenges of the target group.
2. Select methods and solutions that can improve the working environment by reducing the exposure and thereby producing the intended OHS outcome; for instance, the solution could consist in the introduction of Personal Protective Equipment (PPE), or in the modification of the tasks of the target group.
3. Define the change in the behaviour or in the performance of the workers necessary to the effectiveness of the OHS intervention; for instance, following the previous examples, the change in the behaviour of the workers consists in the first case in the fact that the workers use the PPE and

Table 2. Taxonomy of contextual factors, classified in classes and sub-classes.

Class	Sub-class	Factor
Operators	Physical factors	Fatigue
		Physical abilities
	Cognitive factors	Skills
		Knowledge
		Experience
		Training
Physical work environment, equipment and tools	Physical work environment	Illumination
		Noise
		Air quality
		Temperature and humidity
		Freedom of movement of workers
		Freedom of communication
		Layout of the plant
		Order and cleanliness
	Equipment and tools	Availability
		Quality
Organization factors	Management and policy	Plant Policy
		Work and task organization
		Level of supervision
		Production pressure
		Rewards
		Punishments
		Safety culture
	Tasks	Task related difficulties
		Other difficulties
	Procedures	Availability
		Quality
Team factors	Features of the team	Cohesiveness
		Coordination
		Composition
	Communication	Availability
		Quality
	Leadership	Leadership

in the second case in the fact that the workers accept and follow the new task.

4. Develop theories about mechanisms which can motivate the target group to initiate change, or which can hinder the change; in order to ensure the comprehensiveness of the analysis, the mechanisms should be selected from the taxonomy proposed in Table 1. For instance, following the previous examples, the mechanisms could be the "Motivation of the workers" and the "Fear of failure".
5. Analyse the influence of the context for each of the selected mechanisms; in this step, for each mechanism practitioners should select one or more contextual factors that "condition" the mechanism itself. For instance, the "Fear of failure" can be conditioned by the "punishments" adopted within the company, while the "Motivation of the workers" can be conditioned by the "rewards". In order to ensure the comprehensiveness of the analysis, the contextual factors should be selected from the taxonomy proposed in Table 2.
6. Assess the adequacy of the contextual factor in relation to the particular mechanism; for instance, practitioners should ask themselves question like: "Are the punishments adopted within my enterprise adequate in order to activate the fear of failure of the workers?" or "Are the rewards adopted within my enterprise adequate in order to activate the motivation of the workers?".
7. Develop design recommendations for the intervention which build on the results of the four preceding steps. For instance, on the basis of the previous assessment, the workers could decide to modify the reward or the punishment system.

4 TEST OF THE MODEL

4.1 *Methodology*

Between September 2013 and March 2014, twenty safety officers were interviewed, with the support of a questionnaire. The questionnaire was divided into three sections. In the first part, some enterprise characteristics (sector, turnover, etc.) were asked. In the second part, the safety officers used the model: the several steps of the procedure, as well as the preliminary steps necessary for the problem setting, were proposed to the practitioners by means of ten structured questions. In the third part, we asked to the practitioners to evaluate the performance of the model taking into account three main criteria: usefulness, completeness, and difficulty of use. The questions used for the evaluation of the performance are reported in Table 3.

The distribution of sample firms by industry sectors, turnover, and number or workers is summarised in Table 4. The Small- and Medium-sized Enterprises (SMEs)—as defined in the 2003/361/EC Recommendation (European Commission, 2003)—mainly belong to the most important manufacturing sectors of the Lombardy Region in Italy in terms of employees and turnover and they have been classified according to the International Standard Industrial Classification of All Economic Activities "ISIC rev.4", as reported in Table 5. As it can be argued from Table 4, the SMEs have been divided into four classes: Micro (MiEs, employees ≤ 10), the Small (SEs, 10 < employees ≤ 49), Medium (MEs, 50 < employees ≤ 99), and Medium-Large Enterprises (MLEs; 100 < employees ≤ 250).

Table 3. Questions used for the assessment of the performance of the model in the third part of the questionnaire.

Criterion	Questions
Usefulness	Was the model useful for the design of the intervention? Why? Did the model help to identify some factors that you did not identify? Did the model help you to better structure what you had in your mind?
	While setting the improvements of the intervention, was it helpful to consider the interaction between mechanisms and contextual factors? Why ? Were you able to identify—thanks to this interaction—some aspects of the contextual factors that you would have neglected without the model?
	Do the improvements introduced thanks to the model compensate the difficulty of use?
	Would you obtain the same results in the same time without the support of the model?
Completeness	Do you think that the list of mechanisms is complete?
	Do you think that the list of contextual factors is complete?
Difficulty of use	Which was the most difficult step performed during the use of the model? Why?

Table 4. Features of the companies in terms of turnover and employees.

Enterprise	Number of employees	Turnover [mln €]	Sector
1	20–49	5,9	C25
2	100–250	32,9	C25
3	20–49	3,67	C25
4	50–99	n.a.	C28
5	50–99	n.a	C10
6	100–250	n.a	Other
7	100–250	n.a	C22
8	100–250	60	C28
9	10–19	8	C22
10	20–49	5	C27
11	20–49	4,5	Other
12	20–49	12	C28
13	20–49	5	Other
14	50–99	10,5	C25
15	20–49	2,5	C25
16	10–19	3	C25
17	20–49	3	C25
18	10–19	3	C17
19	20–49	5	C22
20	50–99	10	C28

4.2 *Results*

All the twenty practitioners were able to correctly compile the second part of the questionnaire, in which they had to use the stepwise procedure and the taxonomies. The third part, in which we asked to the practitioners to evaluate the performance of the model taking into account the usefulness, the completeness, and the difficulty of use of the model was filled in by 19 of the 20 practitioners (excluded the practitioner of company 6).

In all the cases, the interviewees confirmed that the model was useful for the design of the intervention. The reasons reported by the interviewees include a higher effectiveness in the design of the solution, a better focus on the aspects that should be considered, the identification of aspects usually neglected, and a more organic and systematic way of structuring the data.

Table 5. Sectors of the companies.

Metal products, excluding machinery and equipment	C25
Machinery and equipment n.e.c.	C28
Food	C10
Paper and paper products	C17
Rubber and plastic products	C22
Electrical equipment and non-electric domestic appliances	C27

All the interviewees confirmed the usefulness of considering the interaction between mechanisms and contextual factors. The main reason was the identification of specific aspects of the contextual factors highlighted by the comparison with the mechanism. Other interviewees reported how the comparison between mechanisms and contextual factors improves the comprehensiveness of the analysis.

As for the improvements introduced compared to the difficulty of use, the answer to this question varied among the interviewees. In some cases, the interviewees reported that the improvements compensated the difficulty of use (company 1, 3, 5, 7, and 8, and 11–20); in other cases the interviewees reported that the improvements compensated the difficulty of use only partially (company 4, 9, and 10); and in one case the interviewee reported that the improvements did not compensate his difficulty of use (company 2).

As for the possibility of obtaining the same results in the same time without the support of the model, the interviewees provided different answers. In the majority of the cases, the interviewees reported that they would not obtain the same results in the same time without the support of the model (company 3, 5, 7, 8, and 9); in other cases, the interviewees were not able to answer to the question (company 1 and 4), and in other cases (company 2 and 10) the interviewees reported that they would obtain the same results in the same time without the support of the model, coherently with previous answers.

As for the completeness of the model, all the interviewees reported that the list of mechanisms and of contextual factors is complete.

There are three steps that seem to be critical. The first critical step is the selection of the mechanisms (company 3, 4, 7, 9, 11, 12, 13, 19, 20), because it is not easy to make a distinction between mechanisms "enabling" and mechanisms "disabling" a change in the behaviour of the workers (company 4) or because it is not easy to connect mechanisms with corresponding behaviours (company 9). In other cases (company 3 and 7) practitioners were not able to explain specifically the criticality of the step.

The second critical step is the combination between mechanisms and contextual factors (company 2, 10, 15, 16, 17 18), because, according to some interviewees, it requires a perfect knowledge of the context and of the workers involved in the intervention.

The third critical step is the development of the design recommendations (company 2 and 5), because, according to the two interviewees, it is difficult to identify solutions that are effective and, at the same time, realistic and feasible.

5 CONCLUSIONS

The test proved that the procedure and the proposed taxonomies can be easily used by "ordinary" safety practitioners. The practitioners identified several interesting combinations of mechanisms and contextual factors, which introduce novel insights also for the safety literature. For instance, the "Perception of familiarity with the situation" influenced by the "layout of the plant" has been identified as a mechanism disabling the desired performance. According to the authors' knowledge, the layout of the plant has never been related to the Perception of familiarity with the situation in previous safety literature.

The usefulness of the model seems to be clearly proved—although in a small sample—by the answers of the practitioners. The model does support practitioners during the design of the intervention, since it highlights specific aspects of contextual factors and mechanisms and it organizes the data in a more systematic and structured fashion. In the majority of the cases, the improvements introduced by the model compensated the difficulty of use and the model seems to be necessary for the introduction of these improvements.

The model seems to be complete, in sense that all the relevant factors and mechanisms determining the performance of the workers have been included in the taxonomies.

Some improvements could regard the difficulty of use. For instance, two critical steps are the selection of the mechanisms and combination between mechanisms and contextual factors; some practical examples could be helpful in these tasks. Examples can be progressively collected with the use of the model.

This test involved twenty companies and, as a consequence, the results can be considered as a preliminary validation of the model. Further researches will repeat the same test with a broader sample.

It is important to underline how the test analysed the outcome of the design process. After the design, the intervention should be actually imple-

mented and its effectiveness should be assessed. The improvement of the effectiveness of the intervention designed with the help of the model is the main objective of the model itself. This aspect will be investigated in further researches, also using the preliminary results of this test.

A risk-based approach to manage the Occupational Hazards in the Arctic drilling waste handling practices

Y.Z. Ayele, A. Barabadi & J. Barabady
Department of Engineering and Safety, UiT The Arctic University of Norway, Tromsø, Norway

ABSTRACT: The paper proposes a risk-based approach to eliminate and manage occupational hazards, associated with the handling of drilling wastes in the cold and harsh operational condition. The proposed approach can help the user to investigate the occupational hazards, by recognizing, predicting and interpreting information about the potential hazard/risk influencing factors which are caused by the operating environment of the Arctic region. The approach can also help to identify and understand the peculiar occupational hazards, for the range of possible drilling waste handling technologies/solutions in cold Arctic regions. It also offers step-by-step risk reduction measures, by determining actions which are necessary to eliminate or reduce the occupational hazards identified as above acceptance criteria. By employing the proposed approach, an effective occupational hazard management plan—with suitable risk management and reduction measures can be selected and implemented.

1 INTRODUCTION

The oil and gas exploration results in the creation of drilling wastes that consist of a mix of drill-waste solids (cuttings) and non-recoverable drilling muds. These wastes can be contaminated with various chemicals which are added throughout the drilling process and in some cases with the hydrocarbons from the formation. In general, in the conventional waste handling practices, once the drill cuttings have passed through the solids control system, the cuttings collection and handling system takes the waste stream of cuttings with adhering drilling fluid and delivers it to the next stage of the disposal process (IPIECA and OGP, 2009). If discharge into the sea is the selected disposal option, handling requirements will be minimal and the occupational exposures to the waste will also be insignificant (IPIECA and OGP, 2009). However, for non-discharge options, some type of cuttings collection, processing, transport and disposal system will be required (Ayele et al., 2013, Paulsen et al., 2005, Veil, 2002). During those activities the workers involved faces occupational health and safety hazards (Holmér, 1999, Broni-Bediako and Amorin, 2010, Mearns et al., 2003, Robson et al., 2007, IPIECA and OGP, 2009). Moreover, the range of possible drilling waste handling technologies/solutions poses their own peculiar occupational hazards in terms of exposure routes (such as ingestion, inhalation, skin contact and skin absorption), frequency of exposure, and exposure duration.

Humans are "designed" to operate in very narrow temperature range and thus wind, icing and darkness reduce the operational effectiveness considerably and possibility of mistakes or being inaccurate increases (Barabadi and Markeset, 2011, Markeset, 2008, Gudmestad et al., 2007, Kumar et al., 2009). In other words the harsh and the cold operational environments of the Arctic have significant effect on the occupational performance of the workers, and these magnify the hazards associated with the waste handling practices. Thus, all influencing factors that affect the occupational performance must be recognized and quantified throughout the various phases of the waste handling streams properly. These identifications of the influencing factors can help to have an effective drilling waste handling practices with high level of safety in the harsh, remote and cold Arctic region. Moreover, it is also necessary to analyse the severity of each exposure routes from the occupational hazards point of view.

When deciding on the type of drilling waste handling technologies to use for work in cold Arctic environments, the operators need to conduct comprehensive occupational hazard assessments of the drilling waste streams. This is especially due to the negative impact of cold on human health and performance, as well as on work productivity, quality and safety (ISO 15743, 2008). The rigorous hazards assessment can be done by considering the HSE (health, safety, and environment) aspects, and by striking an appropriate balance between their potentially conflicting requirements (IPIECA and OGP, 2009). Moreover, an effective occupational hazards management plan need to comprise the assessment of potential job hazards, risks of

occupational injury, and health risks stemming from exposure to harsh environmental factors, such as cold, icing of work surfaces, ice falling from heights, darkness, etc. (Det Norske Veritas, 2009). Furthermore, identifying occupational hazards and assessing the level of risk associated with those hazards is the most important activity you perform every day, during handling and managing of the drilling wastes in cold regions (Public Services Health and Safety Association, 2011).

In order to investigate the workplace injuries in cold region, a number of occupational health and safety hazards assessment models have been developed (Giedraitytė, 2005, Holmér, 1999, Holmér, 1994, Broni-Bediako and Amorin, 2010, Risikko et al., 2003, Geller, 2005, Lindøe et al., 2006, Robson et al., 2007). ISO 15743:2008, Ergonomics of the thermal environment—Cold workplaces—Risk assessment and management, has been developed to describe the methods and practices for assessing and managing occupational health and performance risks in cold workplaces. In addition, occupational exposure limits for several types of drilling fluids are specified in IPIECA and OGP (2009) occupational health and safety regulations, and exposure should not exceed these levels.

However, the missing point in most of the occupational hazards assessment literature is that the effect of the operating environment of the cold region on the performance of workers during handling of drilling wastes has received less attention. This can have a significant impact during the planning of the waste handling process as well as during the execution of the intended work. As a result, in order to assure the operational performance and high level of safety in the cold Arctic region, occupational exposure assessment associated with the handling of drilling wastes should necessarily be risk-based.

Minimizing the overall hazards and risk profile and increasing safety and performance of the workers is the main objective of risk-based occupational hazard assessment in the drilling waste handling practices in the cold Arctic region. By analysing each drilling waste streams and identifying and quantifying the unique occupational hazards and risks involved, the oil and gas industry operating in the harsh and cold Arctic region, can take appropriate measures to mitigate those risks. Furthermore, taking appropriate mitigation measures can improve operational performance and reduces the consequences of unwanted events during the handling of the wastes. By employing a risk-based approach it is often easier and more effective to eliminate the occupational hazards before they are introduced into a drilling waste handling workplace by incorporating safety features at the design stage (Safe Work Australia, 2011).

Hence, the aim of this paper is to propose a risk-based approach to manage exposures to hazards during the handling of the drilling waste in the cold and harsh operational condition. The rest of the paper is organized as follows: Section 2 examines and summarizes the main occupational hazards associated with the handling drilling wastes in the harsh and the cold Arctic regions. Section 3 presents a risk-based approach. Section 4 proposes risk reduction and/or management measures and Section 5 provides the conclusion.

2 EXAMINATION AND SUMMARY OF THE MAIN OCCUPATIONAL HAZARDS

In general, an occupational hazard can be defined as a thing or situation with the potential to harm a worker (Ontario Ministry of Labour, 2013, Safe Work Australia, 2011). The occupational hazards can be divided into two categories: safety hazards that cause accidents that physically injure workers, and health hazards which result in the development of disease (Ontario Ministry of Labour, 2013). It is important to note that a "hazard" only represents a potential to cause harm. Whether it actually does cause harm will depend on circumstances, such as the toxicity of the drilling waste, exposure duration and amount, as well as the rate of recurrence of the exposure. Hazards can also be rated according to the severity of the harm they cause—a significant hazard being one with the potential to cause a critical injury or death (Ontario Ministry of Labour, 2013). Identifying hazards in the drilling waste handling and treatment workplace involves finding things and situations that could potentially cause harm to waste handling personnel's.

Some of health hazards due to exposure to cold environment during the drilling waste collection, processing, transporting as well as disposing are (Cameron, 2013): decreased blood circulation in the muscle tissue of the extremities (hands and feet) which can result in a reduction in waste handling staff's ability to function adequately; and exposure to the wind and draught can also compound the health issues by increasing ear and eye infections, which in turn can impair hearing and vision which may increase the risk of accidents.

Moreover, long-term exposure to cold environments can lead to a worsening of existing rheumatic conditions and occurrence of Raynaud's Syndrome, a vascular disease in which constricts blood vessels in the extremities such as the hands and feet, causing the blue colouring of the affected areas accompanied by on-going pain and discomfort and cold stress (Cameron, 2013). Furthermore, exposure to cold environments also increases the risk to persons with known asthma or cardiovascular disease.

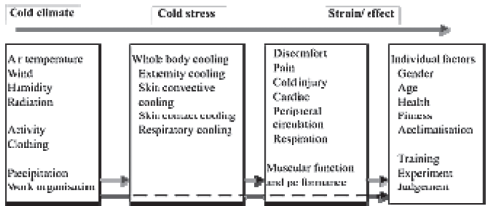

Figure 1. Relation between climate, stress, and strain, adapted from Holmér (1999).

Table 1. Example of common occupational hazards and their potential consequences.

Hazard	Consequences/potential harms
Extreme cold temperature*	: Cold injury such as hypothermia or frostbite.
	: Performance decrements due to cold hands, cold muscles or general cooling or due to hinders caused by protective clothing against cold such as weight, bulk, friction, etc.
Hazardous chemicals/dust inhalation**	: Chemicals (such as acids, hydrocarbons, heavy metals) and dusts (such as asbestos and silica) can cause respiratory illnesses, cancers or dermatitis.
Machinery and equipment*	: Being hit by moving vehicles, or being caught by moving parts of machinery can cause fractures, bruises, lacerations, dislocations, permanent injuries or death.
Gravity*	: Falling objects (such as icicles and falls) can cause fractures, bruises, lacerations, dislocations, concussion, permanent injuries or death.
Wind chill effect	: Extended period of exposure to the cold without adequate protection can lead to frostbite, hypothermia and freezing to death.
Psychological hazards	: The extended period of darkness leads to stress and depression.
Human error	: Lack of concentration, due to harsh and cold environment, during waste container lifting activities can causes fatal accidents.
	: Insufficient visibility due to darkness, heavy fog, rain, and snowfall increases the hazards during the handling of the waste containers.
Other hazards*	: Result from equipment or machine failures and misuse, chemical spills and structural failures may have many different occupational hazards.
	: Less frequently reported health effects are headache, nausea, eye irritation and coughing.

*Safe Work Australia (2011) and Giedraitytė (2005); **Safe Work Australia (2011) and US Department of Health and Human Services (1985).

The other significant contributor that magnifies the occupational hazards, in the cold Arctic region, is the wind chill effect. The wind chill effect can be defined as the perceived decrease in air temperature felt by the body on exposed skin due to the flow of air. The effect of the wind chill will even increase with high wind speed and in the worst case it can be expected to have outdoor working restrictions, for waste handling personnel, for some specified period.

Thus, when assessing occupational hazards in cold Arctic regions, the effect of the operating environment on the performance of the workers needs to be analysed thoroughly. Figure 1 shows the relationship between the various characteristics of the cold climate and its associated effect or strain.

Table 1 is an example of common types of occupational (workplace) hazards during handling wastes in the cold Arctic region. These hazards are for waste handling workers including those who work directly on top of uncovered waste sites, for workers collecting drilling wastes as well as for workers transporting the drilling wastes.

3 THE RISK-BASED APPROACH

Risk can be defined as the possibility that harm (death, injury or illness) might occur when exposed to a hazard (Safe Work Australia, 2011). Figure 2 shows the proposed risk-based approach for eliminating and/or managing the occupational hazards associated with the handling of drilling wastes in the harsh, remote and sensitive Arctic environment. The proposed risk-based approach

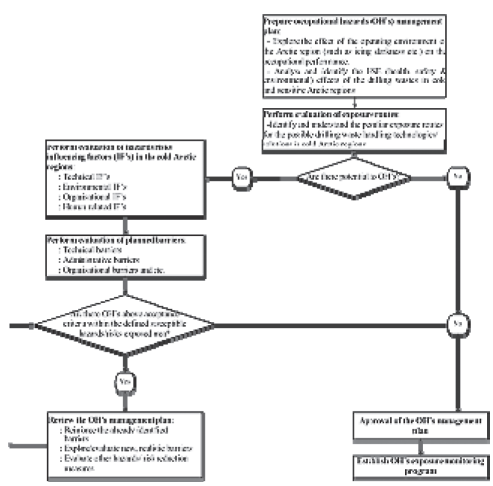

Figure 2. A risk-based approach to eliminate and/or manage the Occupational Hazards (OH's) in drilling waste handling practices in the cold Arctic region.

starts with preparing the Occupational Hazards (OH's) management plan. The plan needs to explore the overall effect of the physical operating environment of the Arctic region on the performance of the workers, the drilling waste handling tasks and how they are performed as well as the type of equipment, materials and drilling substances used.

During preparation of the plan, the HSE effects of the drilling mud and the associated drilling wastes in the cold Arctic regions needs to be identified and recognised. In addition, some types of hazards prevention and/or reduction barriers needs to be planned. A barrier is defined as a measure which is put in to prevent the release of a hazard or to prevent the occurrence of a top event once the hazard is released, and barriers may be physical or non-physical (Veerasingam, 2011). These prevention measures or barriers can be actions aimed at eliminating or minimizing the impact of the hazard or the top event (the incident that occurs when a hazard is realized). Successful prevention of occupational hazards depends upon: knowledge of causation or exposure routes, identification of risk factors, availability of early detection measures, and continuous evaluation of and development of new and timely prevention procedures (Robson et al., 2007).

Subsequently, the evaluation of the main exposure routes (such as ingestion, inhalation, skin contact and absorption) needs to be performed. This evaluation needs to include the understanding as well as identifying of the peculiar exposure routes for the range of possible drilling waste handling technologies/solutions to be deployed in cold and harsh Arctic environment. The analysis of the most commonly observed health effects of drilling wastes, such as skin irritation and contact dermatitis, in waste handling workers, needs to be part of the evaluation. In addition, the physico-chemical properties of the drilling wastes and the inherent properties of drilling mud needs to be evaluated.

In the next stage the assessment of the potential Occupational Hazards (OH's) need to be carried out. At this evaluation stage, it is crucial to identify and recognise all possible OH's related to the handling of drilling wastes in the cold Arctic region. There are several techniques for identifying and analysing occupational hazards associated with handling of drilling wastes, such as checklist analysis, what-if analysis, and Hazard and Operability (HAZOP) analysis. In addition, bow-tie methodology, is one of the simplest and pragmatic hazard identification approach (Hamzah, 2012). Bow-tie technique is a graphical representation used to show hazardous events in such a way to easily show the connections between hazards/threats and their consequences (Hamzah, 2012). In this technique the hazards and the possible consequences are linked to a top event. The evaluation of the hazards can also help to generate information for other purposes, for example to attract attention to a specific hazard or a cumulative of hazards.

The evaluation of the hazard/risk Influencing Factors (IF's) is another part of the assessment. Hazard/risk influencing factors are factors that affect barriers and barrier performance (Aven, 2008). The evaluation process comprises estimation of the various effect of the operational environment of the cold Arctic region on the occupational performance. Environmental conditions such as icing, wind speed, wind direction, temperature, wind chill effect, and polar low must be described and quantified based on the way that they can affect the occupational performance. Some of these environmental conditions can be combined with each other and make new influencing factor. For example, the air temperature combines with wind speed to describe the wind chill factor, which is the effect of these two parameters on exposed skin. The evaluation also needs to include the assessment of technical IF's (such as design, material characteristic and technical condition), organisational IF's as well as human-related IF's (such as competence, workload, and working environment).

Thereafter, the evaluation of the planned barriers, such as technical, administrative, and organisational barriers need to be carried out. During this process the identification of the available/planned barriers that controls or reduces the occupational hazards needs to be performed. Throughout this identification and evaluation process, the results from the assessment of the potential occupational hazards are compared against to the planned goals or objectives. This identification process will also help the user to differentiate the "steel" barriers (effective and reliable barriers) and "paper" barriers (less effective or reliable barriers) (Neogy et al., 1996). Moreover, the evaluation process can provide feedback which may be expected to modify the occupational hazards management plan and lead to redefinition of the main objectives.

After evaluating the planned barriers as well as the influencing factors, then, the assessment of the occupational hazards within the defined susceptible hazards/risks exposed area need to be performed. The susceptible hazards/risks exposed area can be defined as per expert's judgement (opinions) and past experience. For example, a checklist analysis which is an experience based approach, can be used to identify known types of occupational hazards, potential accident situations, or design deficiencies (Neogy et al., 1996). Thereafter, the hazards needs to be classified as well as prioritise based on the standards, regulations and statutory requirements.

In the case of the identified OH's are above the acceptance criteria, the next step will be reviewing the already defined OH's management plan. Acceptance criteria are criteria used as a basis

for decisions about acceptable risk—a risk that is accepted in a given context based on the current standards, regulations and values of the company (Rausand, 2013). The review will include reinforcing the already identified barriers, exploring and/or evaluating new (realistic) barriers as well as evaluating the hazards/ risk reduction measures.

Finally, after assessing and evaluating the hazards the occupational hazards management plan will be approved, when the results suggests that all required acceptance criteria are met. The decision utilises the evaluation, identification as well as analysis results in order to eliminate and manage the occupational hazards related with handling of drilling wastes in cold Arctic region. Thereafter, the approved OH's management plan will be monitored by establishing the OH's exposure monitoring program. This monitoring program helps to detect any changes in the operating environment and its effect on the workers occupational performance.

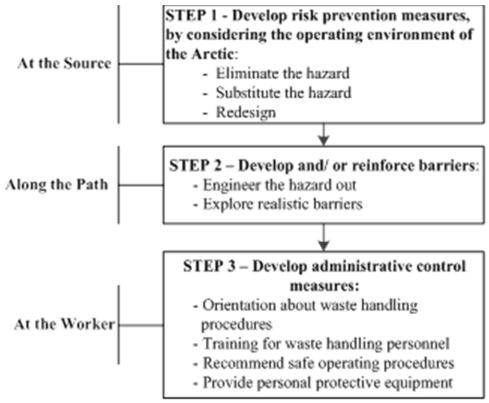

Figure 3. A step-by-step hazards/risks reduction and control measures during the handling of drilling wastes in the cold Arctic region.

4 STEP-BY-STEP OCCUPATIONAL HAZARD/RISK REDUCTION MEASURES

Working in the cold Arctic environments has the potential if not managed properly to cause an increase in incidences and injuries. However, if managed properly through the appropriate controls and at the design stage the hazards/risks can be minimised. Waste handling and disposal workers following safety guidance will reduce their total on-site occupational hazards exposure (US Department of Health and Human Services, 1985). In addition, to guard against the cold and harsh Arctic environment, the worker are recommend (US Department of Health and Human Services, 1985): to wear appropriate clothing; to have warm shelter readily available; to carefully schedule work and rest periods, as well as to monitor workers' physical conditions. In addition, it is important to factor the effect of the cold environment on the workers, in the pre-employment phase to identify any conditions that may be exacerbated by working in a cold environment as well as review the status of the existing staff moving into a cold environment (Cameron, 2013).

To propose measures and address the impacts of cold exposure as well as to mitigate the associated hazards: recognizing, predicting and interpreting information about the potential hazard/risk influencing factors on the performance of the workers, will be very helpful. Figure 3 shows the step-by-step measures that can help to prevent, reduce and/or control the occupational hazards associated with the handling of drilling wastes in the cold Arctic environment. At the first step, risk prevention measures needs to be determined and developed. In this process, the measures or procedures that are essential for eliminating or reducing the identified occupational hazards needs to be established.

According to Public Services Health and Safety Association (2011), hazard/risk prevention or control measures can be implemented at the source level (e.g. elimination of the hazard, substitution, and redesign), along the path (e.g. during processing and transporting of the drilling waste), and at the worker.

For example, careful development of cold weather clothing materials, taking into account the waste handling personnel, the tasks to be performed and the environmental conditions, can guarantee comfortable sensations and good performance during exposure to cold weather (Jussila et al., 2010). Developing a realistic barrier as well as reinforcing the available barriers is the next step. In this step the various types of guard as well as safety devices needs to be provided. Moreover, the engineered control measures need to be evaluated and implemented. For example, engineer the hazard out can be effective means of controlling hazards.

The third step is developing different measures which can help to reduce and control the hazards/ risks, such as: administrative controls, orientation, training and supervision, waste handling work procedures, emergency planning, and cold protective clothing (Public Services Health and Safety Association, 2011).

5 CONCLUSION

Workers involved in drilling waste handling operations may be exposed to various occupational hazards. In addition, it is clear that the performance of the drilling waste handling workers in cold Arctic regions can be greatly influenced by the operational conditions

such as low temperature, snow and ice. Furthermore, the chosen drilling waste handling technology poses its unique occupational hazards. Therefore, in order to minimize and manage the occupational hazards and risk profile during handling of drilling wastes in cold Arctic regions, the principles of risk-based approaches need to be implemented.

The proposed risk-based approach can help the user to examine the occupational hazards, by considering the main influencing factors which are caused by the operating environment of the cold Arctic region. By employing the proposed approach, the effective occupational hazard management plan—with better risk management and reduction measures can be selected and implemented. In addition, the proposed approach can be verified through replication of findings in more case studies.

Estimating individual occupational risk using registration data

P.H.G. Berkhout & M. Damen
RIGO Research Consultants, Amsterdam, The Netherlands

ABSTRACT: In this paper the occupational risk of individual employed workers is assessed using merged registration data. The analysis features a negative binomial count data regression model for statistical inference. In the model the hazard rate is determined by variables characterizing the personal background and working conditions, such as age, sex, tenure, contract type, working hours and sector. The estimation results can be used to assess individual occupational risk and identify high-risk groups and branches of industry. The main contribution of the paper to the literature is the fact that calculations include the entire population at risk and are based solely on registration data on individuals, jobs, firms and accident casualties.

1 INTRODUCTION

Risk assessment is a cornerstone of the European approach to prevent occupational accidents and ill health. European legislation with respect to risk assessment is grounded on the Framework Directive 89/391, which has been transposed into national legislation of member states. The European Agency for Safety and Health at Work (EU-OSHA) suggests a stepwise approach to risk assessment: 1) identifying hazards and those at risk; 2) evaluating and prioritizing risks; 3) deciding on preventive action; 4) taking action and 5) monitoring and reviewing. Clearly, the process of risk assessment builds on identifying hazards and the workers at risk in the initial step. This paper sets out to quantify the occupational risk of all registered employed workers, based on merged registration data and conventional statistical methods.

Usually statistics on occupational accidents are presented on the aggregate level. Risk assessment of individual workers is complicated, since it requires detailed information on outcomes of all workers at risk, not only the accident casualties. Information gathering is usually initiated when occupational accidents occur; the counterfactual—workers who under the same circumstances did not get involved in an accident—is not observed. For instance, Rivas et al. (2011) analyze with the help of data-mining techniques 62 questionnaires to be completed whenever an accident occurred. They conclude that data-mining outperform conventional statistics in terms of the predictive function and the possibility of identifying interactions between variables with a bearing on accidents. However, the question is whether inferences drawn from a sample of accidents only can be extrapolated to the workers who did *not* get involved in an accident. In experimental lingo this is referred to as the external validity, see Shadish, Cook & Campbell (2002). In sample surveys of the population at risk generalization is usually not a problem. But sample surveys are usually too small in relation to the probability of observing enough accident casualties in the survey sample.

In the present paper we will demonstrate that plausible estimations of individual occupational risk can be extracted from detailed registration data representing the entire population at risk. The negative binomial count data model is used to estimate the individual rate of accident occurrence per working day. To this end complete registration data on casualties of serious occupational accidents was merged to individual registration data describing the entire population at risk. In the model occupational risk may vary for individual workers as a result of differences in their human capital (age, gender, flex worker, nativity, tenure, hours worked per week) and the hazardous nature of the work (instrumented by 262 sector fixed-effects covering the entire economy).

Since the available data cover a time span of thirteen years (1999–2011), the analysis is not only focused on cross-sectional explanation of occupational risk. In addition, time trends and business-cycle effects were identified. A declining number of accident casualties in this decade was in fact one of main reasons why this study was initiated. Estimation results show a decline of 27% in the average rate of accident occurrence in time. This raises the question whether occupational safety in The Netherlands has truly improved to such extent. We conjecture that structural changes in labor market supply and demand have contributed significantly to changes in the observed average accident rate. For one, ageing of the worker population

pushes the average rate upward (since occupational risk tends to rise with age for workers older than 30). The size of this ageing effect is considerable, due to an increase in the average age of the worker population from 36.3 in 1999 to 39.5 in 2011. On the other hand, a hazard-biased destruction of jobs over time has changed the composition of the job-pool in favor of the less hazardous jobs. A lower average rate of accident occurrence would be the result. Roughly estimated this composition-effect accounts for one third of the total decline. All in all, a 'true' decline in the accident rate of 19% in 13 years remains, implying a considerable improvement in occupational safety in The Netherlands in the past decade.

The paper is structured as follows. In Section 2 the observed individual occupational risk is considered within the conceptual framework of labor market matching of workers to jobs. Data, definitions and a formal description of the empirical model are presented in sections 3 and 4. In Section 5 estimation results are presented. Section 6 concludes.

2 CONCEPTUAL FRAMEWORK

2.1 *Labor market matching of individual skills to job requirements*

In this paper the rate of occurrence of occupational accidents—the accident frequency—is analyzed within the human capital framework of labor market matching of workers to jobs. On the labor market the skills of individual workers are matched to jobs requiring certain skills. Each worker-job match results in a hazard rate specific to that particular match.

Each existing job represents an objective hazard potential intrinsic to the job. This potential is not affected by the worker selected for the job. The job hazard potential is an unobserved (latent) variable in the framework. One might say that in case an accident occurs, part of the potential's hazardous energy is released and observed. The hazards require skills to handle them. These hazard handling skills are supplied by the workers. Anything contributing to the ability of handling hazards successfully can be considered: vitality, experience, responsiveness, knowledge etc. We refer to the aggregate all of such characteristics as the 'hazard handling skills'. In the framework of matching workers to jobs these skills can be treated as any other requirement for the job.

Workers are heterogeneous in their skills endowment, jobs are heterogeneous in their hazard potential. Since occupational accidents involve costs (and accident prevention reduces these costs), the employer treats the worker's hazard handling skills as any productive skill. Depending on relative prices, there's a trade-off between the cost evading hazard handling skills on the one hand and productive skills incurring revenue on the other hand. Should accidents incur high expected costs employers will emphasize hazard handling skills in the selection of workers. Vice versa, hazard handling skills will have low value to the employer if expected costs of accidents are low. Expected costs are defined by actual costs multiplied by the accident probability. Given a worker-job match, the job's latent hazard potential is transformed into an observed occupational risk. Thus from the worker's perspective his individual occupational risk will vary with the job he is matched to. From the employer's perspective the occupational risk related to his jobs varies with the matched workers.

In the present analysis the individual occupational risk is defined as the rate of accident occurrence per working day. For the sake of brevity we will refer to the rate of accident occurrence as the '*hazard rate*'. This concept is commonly used in survival analysis, defining the rate at which individuals leave a certain state, conditional on having survived up to that point. In the present context we might say workers 'survive' as long as they are not involved in an occupational accident. Note that the term 'hazard' does not refer to the actual occupational hazards (i.e. risks or dangers) the worker is confronted with in his job. Instead, it refers to the risk of 'not surviving', that is of getting involved in an accident. The hazard rate is estimated on the individual level. Hazard handling skills are instrumented by age, sex, nativity, hours worked, tenure and type of contract. On the demand side fixed-effects for 262 sectors of industry are estimated, representing job average hazard potentials.

2.2 *Structural changes in labor supply and demand*

The above matching framework is used to explain changes in the population average over time. That is, developments on the macro level are related to mechanisms operating on the micro level of matching workers to jobs. We will assume matching technology did not change during the thirteen years of observation. With the matching technology given and fixed relative prices of hazard handling skills and productive skills, two different ways to change the average accident frequency on the demand side of the market are identified. First, the safety conditions in existing jobs may be affected by technological progress (e.g. improved gear and materials), investments in the firm's safety culture and regulation by authorities. These factors affect the hazard potential in existing jobs. One might say they are associated with the 'intrinsic' or real occupational safety. Second, on the demand side

there is on-going dynamic process of destruction and creation of jobs. This process in itself may be hazard-biased in a sense that it is selective with respect to hazard potential. When for instance due to technological progress relatively hazardous job are destroyed and relatively safer job are created, the composition of the job-pool changes over time. All else held constant, this will be revealed in a declining average hazard rate. However, such a composition-effect can also contain a spurious improvement of occupational safety. For example, when relatively hazardous jobs are shifted to self-employed individuals the average hazard potential in the entire job population declines, but occupational safety from the national perspective remains unaltered (the hazardous work is still done, but not by employed workers). In this respect one might argue that outsourcing tasks to countries with low labor costs does not change occupational safety in global perspective; it only reallocates hazards geographically. Thus, as long as the destructed jobs are associated with hazardous work that has become redundant, the job-pool composition-effect will represent a real change in occupational safety. If destruction of jobs is associated with a reallocation of hazardous tasks (e.g. from employed workers to self-employed workers), the job-pool composition-effect is in essence no more than a spurious change in occupational safety.

On the supply side of the market the matched worker population is equipped with hazard handling skills determining how much of the hazard potential is transformed into observed accident frequencies. Clearly, the amount of these skills present at any moment in time is subject to changes. One interesting hypothesis in this respect is for instance the effect of an ageing worker population on the accident frequencies. Presumably, as workers get older their hazard handling skills seem to deteriorate. The Dutch data show a steadily with age rising accident frequency for workers older than 30. In theory, this suggests that ageing of the worker population induces a higher accident frequency.

3 DATA

3.1 *Registered population at risk*

The population at risk is defined as all employed workers registered to be living in The Netherlands. Self-employed individuals and foreigners not formally registered are excluded from the analysis. Micro register data on the population at risk was supplied by Statistics Netherlands (CBS). Information of several registrations is combined in the so-called SSB, which is the Dutch abbreviation of 'social statistical micro data'. The SSB is in essence based on the municipal registrations of inhabitants, registrations of social insurances of employed workers and income taxes. The following information was used:

- date of birth; gender; first and second generation foreign descent;
- beginning and end dates of jobs; contract hours; type of contract (flex workers)
- sector of industry (distinguishing 262 sectors).

Individuals are uniquely identified by a personal code derived from the citizen service number (BSN). Sectors of industry are identified using the Dutch Standaard Bedrijfsindeling (SBI 2008) which is based on the activity classification of the European Union (Nomenclature statistique des activités économiques dans la Communauté Européenne, NACE) and on the classification of the United Nations (International Standard Industrial Classification of All Economic Activities, ISIC). In the present paper the first three digits allow differentiating between 262 sectors of industry.

3.2 *Registered accident casualties*

The Dutch labor inspectorate (I-SZW) registers the casualties of serious occupational accidents. These accidents are serious in the sense that they lead to death, permanent injury or hospitalization of the casualty. Traffic accidents on the road, in the air and on sea or waterways are not included in this registration. Furthermore accidents with dangerous substances (e.g. fireworks, asbestos, radioactive materials) and natural resources (gas) are excluded. All these excluded accidents are investigated by other specialized inspectorates. The I-SZW registration however covers the vast majority of serious occupational accidents in The Netherlands. From all registered casualties in 1999–2011 only the employed workers were selected. Self-employed individuals and collateral casualties (e.g. passers-by) were excluded from the analyses.

Although reporting of accidents is mandatory/compulsory, there is suspicion of underreporting. This may occur when a serious accident is erroneously not reported to the inspectorate. The amount of underreporting is estimated to range from 1000 to 1500 accidents per year (Schouten et al. 2008). This amounts to say 30–40% of the yearly average of serious accidents investigated by I-SZW or say 25% of the 'true' number of accidents. However, the estimate by Schouten et al. should be treated with caution, since it is based on a comparison with registered casualties of a small sample of first-aid centers unevenly spread across the country.

Since there is no evidence of a selection bias due to underreporting, we will treat the registered casualties as a representative 75%-sample of the true casualty population.

3.3 *One-to-one merging*

Data was assembled by one-to-one merging of several registers by means of a unique identifier of individuals: the citizen service number (BSN). The BSN-code of the casualties was not registered by I-SZW but derived by CBS on the basis of date of birth, gender and address (zip-code and house number). In 1999–2011 a total of 30,424 casualties were registered in all inspected serious accidents in The Netherlands. The citizen service number of 6,353 (20,9%) of these casualties could not be identified, mostly due to lacking or incorrect personal information. Also casualties who were not formally registered as inhabitants or as tax-paying workers could not be identified. The remaining 24,071 (=30,424 – 6,353) identified casualties compare very well to the total number of casualties counted in the Storybuilder database, in which all serious accidents are bow tie modelled by hand (Bellamy et al. 2006, 2007, 2008). This suggests that the quality of gathering of personal information by I-SZW may fall short when it turns out during the course of the investigation that the incident does not formally qualify as a serious accident. In general, identification failure does not give rise to a selection bias, with the exception of lethal accidents. Since the count of lethal accidents is well-established in Storybuilder we estimate a loss of say 10 out of the expected number of 75 deaths per year. From the 24,071 identified casualties another 2,842 were excluded because they were not identified as members of the population at risk (employed workers). The final sample of occupational accident casualties consists of 21,229 individuals.

4 DEFINITIONS AND EMPIRICAL MODEL

4.1 *Definitions*

The time axis is measured in months, resulting in 156 time periods t in the years 1999–2011. In each t the actual number of workers—on average 7.5 million workers per period—is selected using the dates marking the beginning and ending of a job. The duration of exposure to occupational hazards per month is measured in full time (8 hour) working days according to the contract, denoted as d_{it}. For part time workers the working hours are transformed to full time working day equivalents. For instance, a half-time job of four days per week adds up to two full time working days. Workers with flexible hours are separated from other workers. Exposure is corrected for weekend days, varying length of the calendar months and Christian and national holidays. Sick leave and vacations could not be corrected for. The job hours of workers with two (or more) jobs at the same time are added up. Should these jobs be in separate sectors of industry, the sector of the largest job is assigned to the smaller ones. In each period t an indicator C_t expresses the state of the Dutch business cycle (DNB, 2013). A discrete indicator A_{it} expressing whether member i of the population at risk was registered as an accident casualty in period t was constructed by one-to-one merging the casualties to the population at risk. Indicator A_{it} is defined as:

$$A_{it} = \begin{cases} 1 & \text{member } i \text{ of the population identified} \\ & \text{by data merging as casualty in } t \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

With on average 7.5 million workers per period we observe approximately one billion A_{it} in 1999–2011. In order to bring down this number to manageable size, groups of population members are defined. Each group g contains all population members i in period t who are homogenous with respect to characteristics vector X_i. This vector includes the variables: age, gender, native versus non-native workers, flex versus normal workers, part time workers, new recruits and 262 sectors of industry. This results in on average 90.000 homogeneous groups g in any period t. Note that regression-wise no information is lost since there are no variables left to differentiate within the groups. Within groups g the total number of accidents N_{gt} in period t is defined as:

$$N_{gt} = \Sigma_{i \in g} A_{it} \quad (2)$$

and the group's total amount of exposure to hazards measured in full time working days is calculated as:

$$D_{gt} = \Sigma_{i \in g} d_{it}. \quad (3)$$

Since N_{gt} is a nonnegative integer count it can be regressed on explanatory variables by means of a count data model.

4.2 *Empirical model*

The literature offers a wide variety of count data models to regress a count variable on a set of independent variables (see for example Cameron and Trivedi, 1998). A well-known example is the Poisson model. The applicability of this model however is limited due to the fact that it imposes equi-dispersion, which means that the conditional mean and variance are equal. This is a rather strong assumption. A more flexible count data model is obtained when unobserved heterogeneity is introduced in the Poisson intensity parameter λ. The most commonly used extension to the Poisson model is the negative binomial model (negbin),

which results when λ is mixed with a gamma distribution. The negbin-model imposes over-dispersion, meaning that the conditional variance exceeds the mean. The model contains the Poisson model as a directly testable special case. The negbin-model is written as:

$$\mathrm{P}(N_{gt} = y) = \frac{\Gamma(\rho^{-1} + y)}{\Gamma(\rho^{-1})\Gamma(y!)}\left(\frac{\rho\lambda_{gt}}{1+\rho\lambda_{gt}}\right)^{y}(1+\rho\lambda_{gt})^{-\rho^{-1}} \tag{4}$$

where the non-negative parameter ρ captures the degree of over-dispersion. If ρ converges to zero, the model reduces to the Poisson model. We will use the negbin type I model, which is parameterized such that ρ is scaled by λ_{gt}. This means that λ varies across individuals and that—conditional on covariates—the count variance is a linear function of the count mean. The model is estimated using the nbreg procedure in STATA (version 12).

In the present application of the model the intensity parameter λ is be interpreted as the mean rate of occurrence of serious occupational accidents per 8-hour working day. In short we will refer to λ as the *hazard rate* of getting involved in an occupational accident. Hazard rate λ is modelled to vary with group characteristics X and may vary in time t. Time variation may be due to structural tendencies (as a result from changes in the matching of supply and demand on the labor market), seasonal patterns and the business cycle C_t. In short:

$$\lambda_{gt} = \exp(X_g, f(t), C_t, D_{gt}) \tag{5}$$

with the log of D_{gt} enclosed as an offset to correct for group differences in exposure and $f(t)$ capturing a yearly trend and a seasonal pattern. A seasonal pattern is modelled by dummy variables for the twelve months. However these estimates are likely to be biased by the fact that season-biased sick leave and vacations cannot be corrected for in D_{gt}. For instance, since many workers spend most of their time off during the summer holidays, exposure D_{gt} is probably overestimated in July and August leading to a (spurious) decline in the hazard rate λ in these months. Therefore, any observed seasonal pattern in λ is attributed to unobserved patterns in absence from work due to sickness and vacations.

In the specification of eq. (5) mainly 0/1-indicator variables are included. Initially, indicator variables for all ages ranging from 15 to 64 were estimated, revealing a declining accident frequency only for worker between 20 and 30 years of age. Therefore, in the final model linear effects were estimated for three age intervals: 15–19, 20–29 and 30–64. The effect of job tenure is estimated discretely using an indicator for 'new recruits'. New recruits are defined as workers not registered to have been working in the preceding year. In each age interval a fixed effect for new recruits is estimated. Three job size intervals are specified: part-time workers of 1–49% and 50–89% of a working week and full-timers (90–100%). The model also includes 262 coefficients for sectors of industry, one for male workers, one for flex workers, one for non-native workers and eleven for the months February to December (January was chosen as reference). A linear time trend is included by counting the years as of 1999.

4.3 *Hazard ratio*

We will denote the estimated coefficients by β. Whenever β refers to a 0/1-indicator variable $exp(\beta)$ can be interpreted as a hazard ratio. For instance, let β be estimated coefficient for male workers. Hazard ratio $exp(\beta)$ then expresses the relation between the incidence rate of male and female workers. An estimate of say 0.69 would imply that the incidence rate of occupational accidents among male workers is twice the incidence rate of females since $exp(0.69) = 2$. We will express the hazard ratio with respect to a reference group (within the indicator set) with the mean hazard rate closest to the population average.

5 ESTIMATION RESULTS

In this section the results of the estimated negbin-model are discussed. The estimated model results in 286 coefficients of which 262 are fixed-effects for sectors of industry. We will address these sector effects separately by means of descriptive statistics in subsection 5.3. In subsections 5.1 and 5.2 we will discuss the remaining coefficients reflecting differences in age, gender and nativity and the worker-firm relationship. Subsection 5.4 focusses on the question to what extent the results can be interpreted as an achieved improvement in Dutch occupational safety.

5.1 *Worker heterogeneity*

The average hazard rate of serious occupational accidents in The Netherlands in 1999–2011 per 8-hour working day is estimated at 1.03×10^{-6}. Taking into account a possible underreporting of 30–40 percent the mean hazard rate would be approximately 1.4×10^{-6}. That means 1.4 serious accidents on one million full time working days. The hazard rate varies strongly over the population at risk. The distribution of hazard rates is skewed to the right, showing a relatively large amount of mass beneath the mean. The median is less than half the mean: 0.6×10^{-6}.

The ratio of the hazard rates defining the 1st and 99th percentile of the worker population is approximately 700. This means that the risk determinants incorporated in the model (age, sex, nativity, worker-firm relationship and sector) can account for large risk differentials within the worker population. However, further improvement of the model could be achieved if workers within the sectors are differentiated according to the hazard potential of their jobs, for instance by means of the International Standard Classification of Occupations (ISCO). This information was not available in our data.

The male-female hazard ratio is estimated at 4.2, implying male hazard rates of on average say four times the female hazard rate. It is likely that this large hazard ratio is to some extent due to selection of male workers in jobs with high hazard potential (in for instance construction work and industry). A remarkable hazard-age pattern is observed. An initial specification of the model with separate fixed-effects for all ages revealed that the hazard rate peaks at the age of 19 and subsequently declines with age in the interval 20–29. For workers older than 30 the hazards rate increases steadily as they grow older. On the basis of this observation separate linear effects were estimated for the intervals 15–19, 20–29 and 30–64. Results are displayed in Table 1.

As Table 1 shows, the hazard rate increases at a rate of 9 percent per year for workers younger than 20. The hazard ratio for workers of 15 and 19 years of age equals 1.42, implying a 42 percent higher rate for the 19-year old workers compared to workers 15 years of age. An explanation for this remarkable difference may be found in the fact that young students in low vocation education are formally employed by firms but spend half of their contractual working hours in school. As their education evolves, their actually worked hours converges to full time hours. This suppresses their true exposure to hazards at younger ages, resulting in low estimated hazard rates. Since trainees and their true working hours cannot be identified in our data, this explanation could not be elaborated on in more detail. Presumably, effects of dual vocational education is minimal for young workers older than 20, since most programs end before 20.

Table 1. Estimated age effects.

			Hazard ratio	
	B	Std error	Year-to-year	Interval min to max
Age 15–19	0.088	0.028	1.09	1.42
Age 20–29	–0.023	0.005	0.98	0.81
Age 30–64	0.006	0.001	1.01	1.23

For workers 20–64 year of age the hazard-age pattern is U-shaped. In the first ten years the hazard shows a 19% decline of the hazard from age 20 to 29. Subsequently the hazard gradually rises as workers grow older. From age 30 to 64 an increase of 23 percent is estimated. The estimated effects are significant beyond statistical doubt. The average hazard rate for all age cohorts is depicted in Figure 1.

The hazard ratio of non-native workers in The Netherlands equals 1.3, implying a significantly higher accident rate among workers with at least one parent born in a foreign country. In a preliminary specification of the model (not presented in this paper) an effect was tested for second generation non-natives. For those workers the hazard rate turned out to be approximately equal to the hazard rate of Dutch natives. From this one may conjecture that later generations of non-native workers:

- end up in less hazardous jobs than earlier generations, and/or
- are better equipped with hazard handling skills.

The literature provides little solid empirical evidence supporting relatively high hazard rates of foreign/migrant workers. In Berkhout et al. (2014) an analysis of foreign accident casualties in the Netherlands shows that 15% of all casualties was foreign, whereas their share in the total number of worked days is estimated at 5–10%, depending on how one deals with multiple nationalities. They show that most of the differential can be accounted for by selection of foreigners in high-risk sectors. High accident rates of foreigners prevail in some high-risk sectors, such as the construction industry. In Dressler (2012) it is argued that there is a relation between occupational risk and the extent to which workers are familiar with safety regulations, cultural settings and the dominant language at the workplace. In the present framework migrant workers are in that case

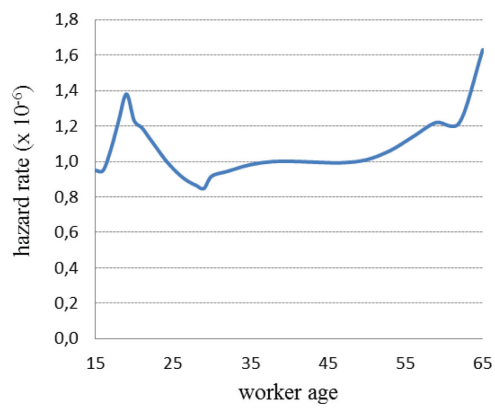

Figure 1. The average hazard rate and worker age.

on average less endowed with hazard handling skills. On the other hand, it is sometimes claimed that cultural differences will force foreign workers to work more safely than their local counterparts, grounded by a sense of responsibility towards the family and their financial needs (Grøn, 2012).

5.2 *Worker-firm relationship*

Whether the worker-firm relationship is associated with hazard rate differentials is tested by three variables: job size (i.e. hours worked per week), flexible hours and tenure. Estimates indicate that ceteris paribus the hazard rate tends to decrease with increasing job size. That is, part time workers have higher hazard rates than full timers. See Figure 2.

The hazard ratio of flex-workers is estimated at 1.3, indicating that workers flexibly affiliated to the firm tend to have higher occupational risk. A job tenure effect was tested by separating new recruits—those entering the labor force for the first time or after an absence of at least one year—from the more experienced workers. Effects in the three age intervals 15–19, 20–29 and 30–64 were estimated, none of which were found significant by conventional standards. This means we find no evidence of higher occupational risk for new recruits in general.

5.3 *Sector hazard ratios*

Sectors of industry were defined using the first three digits of International Standard Industrial Classification of All Economic Activities (ISIC). This results in 262 sectors for all of which a fixed-effect is estimated. For all sectors the hazard ratio with respect to sector Manufacture of Communication Equipment (ISIC-code 26.3) is calculated. This sector is chosen as reference since its average hazard rate is closest to the total weighted population average.

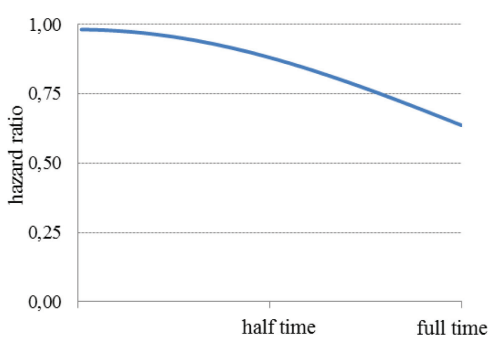

Figure 2. The job size hazard ratio.

By definition the sector hazard ratios express average job hazard potential differentials, controlled for worker selection. However, sector differentials will in fact be larger if male workers are selected into hazardous jobs. That is, if jobs with high hazard potential are mostly done by male workers. If that would be the case, the estimated male-female hazard ratio merely reflects this selection effect rather than a gender difference in hazard handling skills. A high percentage of male workers in a sector then presumably signals the presence of hazardous jobs. Therefore an alternative sector hazard ratio incorporating sector differences in male-female composition is presented. This correction inflates the standard deviation of the sector hazard ratios from 1.4 to 1.7. The maximum hazard ratio increases from 6.5 to 7.9. Descriptive statistics of the 262 gender-corrected sector hazard ratios are displayed in Table 2.

The sectors Manufacture of Weapons & Ammunition (25.4) and Other First Processing of Steel (24.3) show the highest hazard ratio and can be regarded as the most risky sectors to work in. The top 10 high-hazard sectors features three branches of the metals industry, two mining branches and two branches closely related to construction: Demolition & site preparation (43.1) and Manufacture of articles of concrete, cement and plaster (23.6). Various branches in the construction sector show hazard ratios ranging from 4.0 to 5.2.

Table 2. Sector hazard ratios (male-female composition included).

		Percentiles	Hazard ratio
Average	1.5	p(10%)	0.12
Standard deviation	1.7	p(25%)	0.30
Minimum	0.0	p(50%)	0.75
Maximum	7.9	p(75%)	2.20
N (sectors)	262	p(90%)	4.10
10 highest hazard ratios w.r.t. Manufacture of communication equipment (ISIC 26.3)			
Manufacture of weapons and ammunition (25.4)			7.9
Other first processing of steel (24.3)			7.8
Casting of metal (24.5)			6.9
Manufacture of basic precious and other non-ferrous metals (24.4)			6.4
Mining of stone, sand and clay (08.1)			6.2
Demolition and site preparation (43.1)			6.1
Materials recovery (38.3)			6.1
Manufacture of articles of concrete, cement and plaster (23.6)			6.0
Sawmilling and planing of wood (16.1)			6.0
Other mining and quarrying (08.9)			6.0

Occupational accidents are unevenly distributed over the population at risk. This can be shown graphically by means of a Lorentz curve, which is commonly used in economics to analyze inequality in the distribution of wealth and income. Inequality can be measured by the Gini-coefficient, calculated as the ratio of the area enclosed by the curve and diagonal and the total area beneath the diagonal. For the sector distribution of occupational accidents in The Netherlands the Gini-coefficient is estimated at 0.37. In Figure 3 the Lorentz curve of occupational accidents is depicted.

For example, from Figure 3 we have inferred that 36 percent of all serious occupational accidents are registered in just a handful of sectors representing 14 percent of total employment. These sectors (in the upper right corner of Fig. 3) are:

Sector (ISIC-code)	Share in accidents
Temporary employment agencies job pools (78.2)	8.8%
Roofing and other specialized construction (43.9)	4.6%
Construction installation (43.2)	4.0%
Construction of buildings (41.2)	3.6%
Manufacture of structural metal products (25.1)	2.7%
Other specialized wholesale (46.7)	2.6%
Building completion (43.3)	2.5%
Construction of roads, railways, bridges (42.1)	2.4%
Freight transport by road (49.4)	2.4%
Cleaning activities (81.2)	2.2%

Temporary employment agencies are at the top of the list. This implies that temporary workers can be considered a high-risk group of workers that may need special attention in preventive policy measures.

5.4 *Effects of structural changes in labor supply and demand and the business-cycle*

Over the years 1999–2011 a significant decline of the hazard rate of 1.9% per year is estimated. This adds up to a total decline of 27% between 1999 and 2011. The observed population average hazard rate decreased from 1.60×10^{-6} in 1999 to 1.20×10^{-6} in 2011, including structural changes in labor supply and demand. On the supply side ageing of labor supply affects the hazard rate if hazard handling skills of workers gradually deteriorate when they grow older. Between 1999 and 2011 the average age of workers increased from 36.3 to 39.5. The share of workers older than 30 increased from 67.4% to 72.4%. As was mentioned in section 5.1 (see Table 1), the hazard rate of workers older than

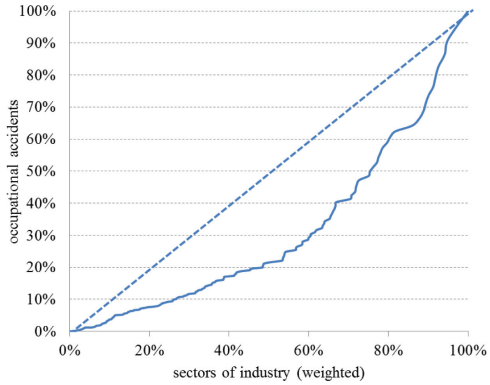

Figure 3. Lorentz curve of occupational accidents in The Netherlands.

30 significantly increases each year by 0.6%. From this we estimate an ageing effect of approximately 2%. Thus, without ageing the average hazard rate in 2011 would have been approximately 1.15×10^{-6} instead of the observed 1.20×10^{-6}. On the other side of the market structural changes in the sector composition of labor demand affect the population average hazard rate. Holding the sector composition of 1999 constant, the hazard rate corrected for ageing is estimated at 1.30×10^{-6} in 2011.

We conclude that in the absence structural changes in labor demand and supply the population average hazard rate would have decreased by 19% in 13 years. This may be interpreted as the achieved improvement of occupational safety in 1999–2011. The observed 27% decline between 1999 and 2011 is obscured by a small ageing bias (+2%) on the one hand and a somewhat larger hazard-biased destruction of jobs on the other hand (–10%). The former pushes total decline downward (towards zero), since older workers are associated with high hazard rates. The latter amplifies the decline, as jobs with high hazard potential are more often subject to job destruction.

A business cycle effect was tested by incorporating a monthly national business cycle indicator in the model. The results show a positive significant effect. That is, in an economic boom the accident frequency is 4–6% higher than in a slump.

6 CONCLUDING REMARKS

This paper sets out to quantify the occupational risk of all registered employed workers, based on merged registration data. By means of a negative binomial count data model cross-sectional differences as well as time trends are analyzed. In cross-sectional perspective the model predicts a hazard

ratio between the 1st and 99th percentile of the worker population of approximately 700 on the basis of age, sex, nativity, worker-firm relationship and sector. A 27% decline in the hazard rate over the years is partly explained by structural changes in labor supply and demand (e.g. ageing and hazard-biased jobs destruction). All in all, a considerable 'unexplained' improvement of occupational safety in The Netherlands remains.

In The Netherlands the use of registration data for statistical purposes has become common practice in the past decade. In this study a registration of casualties of serious occupational accidents was merged to the entire population of employed workers. The analysis combines data from individuals, jobs, firms and casualties. As the paper shows, the registration data can be transformed into accurate policy information when the proper statistical tools are utilized. Accuracy of the results would improve considerably if a job classification could be made available. But all in all, the paper shows that the hazard rate of individual workers can be assessed effectively by combining registration data. We consider this the main contribution of the paper to the literature.

Finally, we have shown that occupational accidents may be analyzed within the standard labor economics framework of matching skills (human capital) to job requirements. The skills needed to handle a job's hazard potential—say the hazard handling skills—may be treated as any productive—revenue generating—skills workers are endowed with. Since it is practically impossible to measure the hazard potential of jobs, we believe the focus of attention should be on the actual hazard rate which results from particular job-worker matches. The paper shows that by using complete registrations we are able to identify the effects of structural changes in labor supply and demand on occupational safety in national perspective.

ABSTRACT: Occupational risk rates per hour of exposure are quantified for 63 occupational hazards for the Dutch working population. Data were obtained from the analysis of more than 9000 accidents that occurred over a period of six years in the Netherlands and resulted in three types of reportable consequences under Dutch law: a) fatal injury, b) permanent injury, c) recoverable injury requiring at least one day hospitalisation. A Bayesian uncertainty assessment on the value of the risk rates has been performed. Annual risks for each of the 63 occupational hazards have been calculated including the variability induced by the variability of the annual exposure of the working population to these hazards. Suitability of three risk measures, individual risk rates, individual annual risk and number of accident occurred is examined and commented upon.

1 INTRODUCTON

Occupational health and safety is a major concern to many countries since occupational accidents represent a major source of risk. In 2010, accidents at work killed 3691 workers in in EU-28, while 2721629 workers were injured, with absence of work more than three days (Health and Safety at Work).

Traditional occupational safety methods are legislation, regulation, standards, safety guidelines, collection of best practices, accident statistics, investigations and inspections, analysis of safety management systems and personal behaviour. The most significant standards used for occupational safety are the British (BSI, 1996, 1999) and the international standard by ILO (ILO, 2001). In addition various analyses of occupational accidents have examined the causes of occupational injuries and fatalities such as those performed for construction, electric power and extractive industry by Carnero & Pedregal (2010) Silva & Jacinto (2012) and Ale et al. (2008).

A number of attempts to a more systematic and consistent approach to quantitative occupational risk assessment have appeared in the literature. A model has been developed to predict the frequency of occupational accidents in offshore oil and gas industry, based on direct, corporate and external factors, as proposed by Attwood et al. (2006). Quantified risk for various occupational groups in Sweden based on the number of accidents and relevant exposure has been calculated by Larsson and Forsblom (2005). A method has been proposed by Ivan et al. (2010) for risk assessment of several trades in the construction industry, based on estimating the overall frequency and severity from historical data of accidents in Hong Kong and their consequences regarding injuries, days lost and compensation cost. Fuzzy methods have been

Table 1. Point risk rate (/hr) and variability characteristics of risk rates (/hr) for fatality accidents for various single hazards.

Hazards	Point risk	5%	90%
1.1.1.1 Fall from height - placement ladder	2.38E-08	1.64E-08	3.52E-08

used for risk assessment of occupational accidents in a steel company by Mure and Demichela (2009), at construction sites by Gurcanli and Mungen (1009), Pinto (2014) and Liu and Tsai (2012), and workplaces by Grassi et al. (2009). Artificial neural networks and a fuzzy inference system have been proposed to assess occupational injury risk indexes and predict number of injuries by Ciarapica & Giacchetta (2009).

The Ministry of Social Affairs and Employment in the Netherlands developed, a large scale project during 2003–2008 to improve the level of safety at workplace, by introducing quantitative occupational risk. This project had four major parts: assembly and analysis of accident and exposure data, generalisation of these data into a logical risk model, deriving improvement measures and their costs and developing an optimizer that supports cost effective risk reduction strategies, as described by Papazoglou et al. (2008), Ale et al. (2008) and Oh & Sol (2008). Results of the Workgroup Occupational Risk Model (WORM) project are presented in RIVM (2008) and its main achievements are: (a) construction of logic models (bowties), which allow for the quantitative assessment of risk of 63 activities of workers, such as fall from ladders, scaffolds, roofs Papazoglou & Ale (2007) and Aneziris et al. (2008a), hit by falling objects Aneziris et al. (2008a), etc., built on the detailed analysis of 12500 accident reports in the Netherlands extracted from the Occupational Accident Database GISAI (Gemeenschappelijk Informatie Systeem Arbeidsinspectie) (GISAI, 2005) and data concerning the exposure of the Dutch population to various hazards, as reported by Kuiper et al. (2008) and (b) the development of the probabilistic occupational risk model (ORCA), which performs risk calculation of workers performing various tasks and exposed to several hazards, as presented in construction and manufacturing case studies Aneziris et al. (2010a, 2010b, 2012).

Occupational accidents can result in health damages of various degrees. Occupational risk from accidents is quantified when the degree of severity of the potential health damage can be measured along with the relative likelihood with which each level of damage is expected to occur. In the WORM model the damage to the worker's health is discretized to three possible values: a) recoverable injury; b) permanent injury; and c) fatality. Every time a worker performs a work-related activity and faces a particular hazard he faces the possibility of an accident that may result in one of the above consequence levels. Such a consequence does not happen with certainty but rather randomly in the work-population and during the lifetime of the workers. The associated risk is quantified when the probability with which each of these possible consequences such as recoverable injury, permanent injury or fatality, can occur during a specific period of time is known. Thus for our purposes the risk is quantified when the three probabilities have been assessed or by the triplet {p1,p2,p3}, where it is understood that p1 is the probability of recoverable injury, p2 is the probability of permanent injury and p3 is the probability of death. These probabilities should always be thought in association with a given period of time during which the accident might happen.

The WORM project identified 36 hazards with the potential of causing an accident during work with detrimental health effects. The 36 hazards were further developed into the sixty three (63) hazards listed in Table 1. Consideration of the particular 63 hazards was mainly dictated by the need to identify hazards simple enough that can be attributed to various jobs and activities without the need to differentiate between industrial sectors or types of jobs.

The purpose of this paper is to present the quantification of the risk rates, that is the probability per unit of time (hour) for each and every of the 63 hazards. The paper is organised as follows: Section 2 outlines the modelling of the arrival of occupational accidents as a Poisson random process and briefly describes the procedure followed for identifying the number of accidents and the exposure of the Dutch working population to the occupational hazards during a given period of time. With these two sets of data point estimates of the risk rates are obtained. Section 3 presents the assessment of the uncertainties associated with this estimation following a Bayesian approach. Finally Section 4 discusses the obtained results.

2 MODEL AND DATA REQUIREMENTS

Occupational accidents occur randomly in time. As "*time-to-accident" (t)* we define the time elapsing between the start of a certain job that involves the exposure to a given hazard and the onset of an accident. This analysis assumes that accidents happen randomly as the worker performs the job and that accidents arrive according to a *Poisson* random process. This means that the times-to-accidents are exponentially distributed with parameter λ or that the probability density function (pdf) of the random variable t is given by

$$f(t) = \lambda e^{-\lambda t} \tag{1}$$

If a worker is exposed to an accident hazard for τ hours during a calendar period (e.g. a year) then the probability that there will be an accident anytime during this period is equal to the probability

that the time of accident arrival will be less than τ or

$$p = F(t \le \tau) = 1 - e^{-\lambda\tau} \tag{2}$$

2.1 *Sampling and likelihood of sample*

The parameter λ is estimated from observations of the random process and recording of the times at which accidents occur.

This is usually done by observing a population of N workers each for a given period of time t_0. During this period some of the workers will actually suffer an accident with given consequences and some will simply work the whole period t_0 without an accident. Let k be the number of workers suffering an accident at times $(t_1, t_2, \ldots, t_k)$. Then N-k is the number of workers without an acciden, that is each of them worked for t_0 without an accident.

Assuming that the occurrence of each accident does not depend statistically to the other occurrences or non-occurrences, and that if a worker has an accident at t_i she is no more exposed to the hazard for up to t_0, it is possible to calculate the probability of such an outcome also called *likelihood.* The likelihood of a sampling outcome like the one described before is given by

$$\begin{aligned} L &= \prod_{i=1}^{k} \lambda e^{-\lambda t_i} \prod_{j=k+1}^{N} e^{-\lambda t_0} \\ &= \lambda^k \exp\left[-\lambda\left(\sum_{i=1}^{k} t_i - \sum_{j=k+1}^{N} t_0\right)\right] = \lambda^k e^{-\lambda T} \end{aligned} \tag{3}$$

where T is the total exposure given by

$$T = \sum_{i=1}^{k} t_i + (N-k)t_0 \tag{4}$$

From equations (3,4) it follows that the likelihood of the sample depends only on the statistics $\{k, T\}$ and not on the individual observed times (t_k). For this reason the statistics $\{k, T\}$ are called *sufficient statistics* of the sampling procedure.

It can be shown that the estimation of the accident rate $\hat{\lambda}$ that maximizes the likelihood L given by Eq. (3) is given by

$$\hat{\lambda} = \frac{k}{T} \tag{5}$$

Equation (5) is widely used to obtain a point estimation of the accident rate λ. It has been used in the calculation of the point estimates of the various hazard rates given in Table 1.

2.2 *Sampling a random process—sufficient statistics*

The general expression for the sufficient statistic T of a sample taken from a Poisson random process is given by Eq. (4). There are, however, some special cases that are amenable to further analysis. The distinction of the various types of sampling schemes has to do with the way the sample is taken and in particular on the way the sampling procedure is terminated.

In the WORM project a fixed period of time (calendar years) has been chosen and the number of accidents that occurred during this period has been determined. This is equivalent to a *Poisson* type of sampling.

In the Poisson type of sampling, the sampling procedure stops when a certain predetermined total exposure has been achieved and the number of accidents that have occurred has been recorded. In this case the number of accidents (k) to be observed is random.

Poisson sampling without replacement

$$T = \sum_{i=1}^{k} t_i + t \tag{6}$$

where $\{t_i,\ i = 1, \ldots, k\}$ are the k times to accident and t the remaining time (can be equal to zero) to complete the fixed time period T.

If there are N workers in the sample to be observed, then the duration of observation of each one is set to t_0. If in addition there is no replacement of a worker having an accident, then

Poisson sampling of size N without replacement

$$T = \sum_{i=1}^{k} t_i + (N-k)t_0 = Nt_0 - \sum_{i=1}^{k} (t_0 - t_i) \tag{7}$$

If there is replacement of a worker in the sample when she have an accident then

Poisson sampling of size N with replacement

$$T = Nt_0 \tag{8}$$

In all these cases the statistic T is predetermined and known and the statistic k is random determined after the sampling ends.

2.3 *Number of accidents*

In the WORM project the constant accident rate for each of the 63 single hazards has been estimated following the analysis of section 2.2 A number of 9387

accidents reported according to the Dutch labour law that occurred in the 1998–2004 period (6.23 years) and contained in the GISAI (Geïntegreerd Informatie Systeem ArbeidsInspectie) data base have been analysed using the STORYBUILDER tool developed by Bellamy et al. (2007). This tool allows the building of scenarios or accident sequences incorporating all the factors that have contributed to the accident and eventually builds a logic model connecting the ultimate consequence (death or injury) to the underlying factors and in general the working environment conditions. The 9387 accidents are distributed across 36 Storybuilds, graphical structures in the software StoryBuilder, each representing a type of occupational accident, characterised and named in each case by the event that characterizes the accident also called "Centre Event". The 36 qualitative models have been subdivided into 63 more specific hazards for which detailed logical models have been developed. A number of reports had unidentified consequences. These accidents have been redistributed to the permanent or recoverable injuries, since it is believed that deaths are reported precisely. The results are given in Table 1.

2.4 *Exposure to hazards*

Exposure is the time that a worker is at risk of having an accident. The exposure for each of 63 hazards has been determined by defining the activities/situations—known as *missions*—that can lead to these accidents and then conducting a nationwide survey in the Netherlands to establish the exposure to each mission (expressed as duration in hours). For example for Hazard #2: Struck by moving vehicle the mission is defined as:

> "Number of hours workers are as a pedestrian at locations with moving vehicles during work. This includes working on industrial premises, in warehouses or at loading/unloading bays, or along the public highway in the role of (for example) road construction worker, garbage collector, roadside vehicle repair mechanic/pick-up service or police officer. Normal traffic activity as a user of the public highway (including commuting and business travel) is not included."

In November 2006 the mission survey was carried out among a random net sample of 30000 from the TNS-NIPO Internet Panel that has approximately 200000 members of which about 50000 constitute a representative sample of the Dutch working population; so in practice the 30000 were drawn from the 50000. For each mission the respondents filled out how many hours they were exposed in the week preceding the survey. To obtain representative exposure data for the Dutch working population, major deviations from the survey sample with known population distributions were corrected for over and under representation by applying a weight factor, as proposed by RIVM (2008) and Hahn & Shapiro (1994). Aspects of the population distribution that were considered in this weighting procedure were: industry sector, job type, type of employment, education level, age and gender. The weighting procedure also took into account the changes in composition of the working population in the period 1998–2004 (the period from which accidents were analysed) and 2006 (the year the exposure was measured). Since the accident population did not include some specified occupational groups, these occupational groups were excluded from the exposure data. The same holds for the self-employed when not working under the authority of others (as they are also excluded from the available accident data).

The weekly exposure was extrapolated to a yearly exposure, effectively based on a 42 working weeks year. The week in November was an average working week; however, the impact of seasonal labour on the total exposure Figures is probably missed. Next the survey sample was extrapolated to the whole of the Dutch working population. Figure 1 demonstrates one example of this exercise.

The average exposure time per year is in this case 506.52 hours. The total number of exposed workers is 1.28×10^6. Hence, total number of exposure hours in this case is 648×10^6 per year. Since the observed number of fatalities in this case corresponded to a period of six years and two months the total exposure used in equation (5) is $\sim 4 \times 10^9$ hours. During the same period the number of reported fatalities from accidents with moving vehicles has been 46. Hence equation (5) calculates the fatality risk for the occupational accident "struck by a moving vehicle" as equal to 1.15×10^{-8}.

It is noteworthy that in this quantification it has been assumed Poisson sampling with replacement (see Eq. 8). This approximation, however, is very

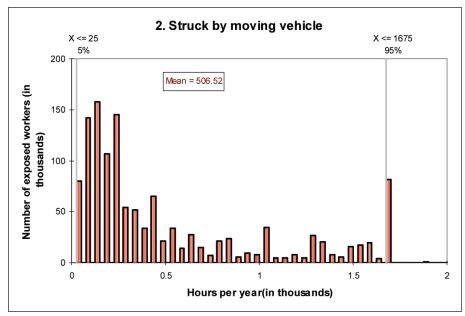

Figure 1. Histogram of frequencies of various yearly exposure times for hazard "struck by moving vehicle". Extrapolated to the total Dutch working population.

good. The term $\sum_{i=1}^{k}(t_0 - t_i)$ in Eq. 7 is less than kt_0 which in this case is $46 \times 506.52 \times 6.12 = 142{,}595$ h ours; a negligible amount when compared to the total of 4×10^9.

3 UNCERTAINTY ASSESSMENT

Uncertainties owning to the limited size of the sample or the equivalent sufficient statistic $\{k, T\}$ can be quantified following the Bayesian approach, proposed by Lindley (1965) and Bedford & Cook (2001).

3.1 *Prior distribution of accident rate* λ

Prior to obtaining the sampling results the state of knowledge is described by assuming that the accident rate (λ) is distributed according to a gamma-1 pdf or

$$f'(\lambda) = f_{\gamma_1}(\lambda|\alpha,\beta) = \frac{e^{-\lambda\beta}(\lambda\beta)^{a-1}}{\Gamma(\alpha)}\beta \quad \alpha > 0, \beta > 0 \tag{9}$$

The gamma-1 distribution has been chosen simply for calculation convenience since the gamma-1 pdf is the natural conjugate distribution to the likelihood of sample from a Poisson random process resulting in a gamma-1 posterior distribution.

Parameters (α, β) are chosen so that the mean and the standard deviation are getting desirable values.

Even though the accident rate λ is the basic parameter of our model the risk measure of interest is the annual probability for an accident. It is more natural then to express the state of knowledge on the probability of an accident during the course of a year. Complete lack of knowledge on the value of this probability would imply a uniform pdf spanning the interval (0,1).

Since the p and λ are connected through equation (2) the parameters (α, β) in the prior of $f'(\lambda)$ can be chosen such that the prior of p is non-informative. This is done as follows.

The pdf of p is uniform over an interval (a,b) hence,

$$f(p) = \frac{1}{b-a} \tag{10}$$

By virtue of equation (2) it follows that

$$\frac{\partial p}{\partial \lambda} = \tau e^{-\lambda\tau}$$

and since the pdf of λ $g(\lambda)$ is given by $g(\lambda) = f[p(\lambda)](\partial p/\partial\lambda)$ it follows that the prior of λ is given by

$$f(\lambda) = \begin{cases} 0 & if \quad \lambda \le \lambda_L = \dfrac{-\ln(1-a)}{\tau} \\ \dfrac{1}{b-a}\tau e^{-\lambda\tau} & if \quad \lambda_L \le \lambda \le \lambda_U \\ 0 & if \quad \lambda \le \lambda_U = \dfrac{-\ln(1-b)}{\tau} \end{cases} \tag{11}$$

If (a,b) is the whole interval (0,1) then the prior of λ is

$$f'(\lambda) = \tau e^{-\lambda\tau} \quad = f_{\gamma_1}(\lambda|1,\tau)$$

That is the prior of λ is a gamma-1 distribution with parameters

$$\alpha = 1 \quad \text{and} \quad \beta = \tau \tag{12}$$

This prior for $\tau = 2000$ hrs is shown in Figure 2. For the variable p and in Figure 3 for the variable λ. It is noteworthy that the 95% percentile is 2.6×10^{-3} while the 5% percentile is 1.5×10^{-5}. This means that the 90% probability interval for the accident rate λ is [2.6×10^{-5}, 1.5×10^{-3}]. Equivalently this means that the 90% probability interval for the yearly risk is [0.05, 0.95].

The value of τ = 2000 hrs has been chosen because it represents an upper limit to the amount of working hours in a calendar year.

The sufficient statistics of a sample generated by a Poisson process is the number of accidents observed (k) and the total exposure of the population (T) as described in 2.1.

3.2 *Posterior distribution of* λ

It can been shown that given the sufficient statistics of the sample (k,T) the posterior distribution

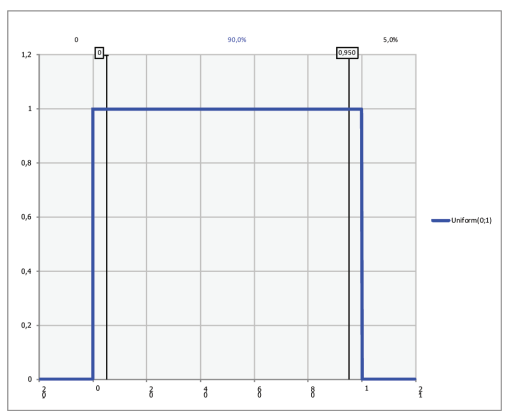

Figure 2. Prior distribution for annual accident probability.

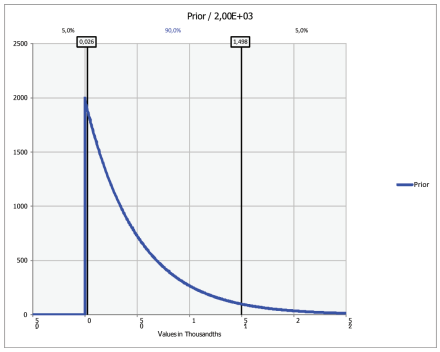

Figure 3. Prior distribution for λ.

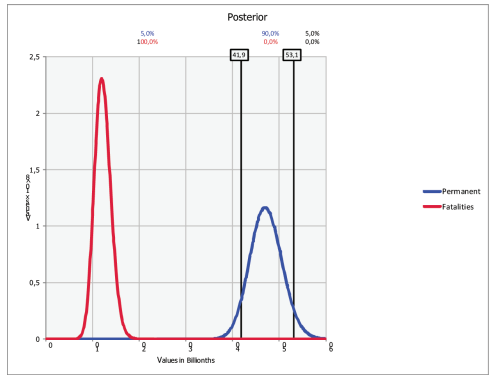

Figure 4. Posterior distributions for risk rates for fatal and permanent injuries for the hazard "Struck by a moving vehicle".

of λ $\{f''(\lambda)\}$ is also gama-1 distribution with parameters

$$\alpha'' = \alpha' + k \quad \text{and} \quad \beta'' = \beta' + T \tag{13}$$

and

$$f''(\lambda) = f_{\gamma_1}(\lambda \mid \alpha' + k, \beta' + T) \tag{14}$$

As a demonstration of this approach the posterior distributions for the accident rates for permanent injuries and fatal injuries for the hazard "Struck by a moving vehicle" are given. As below for the hazard "Struck by moving vehicle" the observed number of incidents and the Total Exposure during the observation period are:

	Number of accidents	Total exposure (hours)
Fatal injuries	46	4.01×10^9
Permanent injuries	189	4.01×10^9

Given these sufficient statistics Equations (13) and (14) provide the posterior distributions given in Figure 4.

It is noteworthy that the uncertainty in the posterior assessment of the risk rates is extremely small given the size of the available evidence (sufficient statistics). Characteristic values of the assessed uncertainty are:

	5% percentile	Mean	95% percentile	Maximum likelihood
Fatal injuries	0.9×10^{-8}	1.17×10^{-8}	1.47×10^{-8}	1.15×10^{-8}
Permanent injuries	4.2×10^{-8}	4.74×10^{-8}	5.3×10^{-8}	4.71×10^{-8}

It follows that the uncertainty owning to the limited amount of experiential evidence is relatively small. Additional evidence would not improve the uncertainty range significantly since the 90% probability interval spans a factor of 1.6 for fatal injuries and only 1.26 for permanent injuries. Similar results are obtained for all 63 single hazards and are given in Table 1 for fatalities.

4 DISCUSSION

Occupational risk rates constitute a quantitative measure for prioritising individual occupational risk. The results given in Table 1 indicate that, even after consideration of the associated uncertainty, the riskier occupations per unit of time is "working on the roof of a building"—a rather intuitively expected result but- also working in a space where loads stuck in piles or shelves are present a rather not expected result. While working on a roof a worker can fall from protected or unprotected edges or through existing holes on the roof. The mean value of the fatality risk rate is 2.32×10^{-7}/hr while the 90% probability interval is extremely narrow [1.77×10^{-7}/hr, 2.92×10^{-7}/hr] with an error factor of 1.65. Working in an area where loads are piled up or set in shelves a worker can be hit by a falling load. The mean value of the fatality risk rate is 1.73×10^{-7}/hr while the 90% probability interval is [1.13×10^{-7}/hr, 2.43×10^{-7}/hr] with an error factor of 2.15.

In general working in heights are among the riskier occupational hazards for causing fatal injuries while handling (lifting) objects, falls on the same level, and moving into sharp objects are the safest.

Probability intervals are narrow for types of accidents that have generated incidents and increase

inversely proportional to number of incidents. The relative position of the interval in the x-axis depends on the size of the exposure. For example, no deaths have been observed for work involving closing vessels containing a hazardous substance (accident #15.3) with a total exposure of 420×10^6 hours. The 90% probability interval is [1.24×10^{-9}/hr, 7.24×10^{-8}/hr] with an error factor of 58. Similarly no deaths have been recorded for hazard "working in an area where one can be buried by a balk mass" with an exposure of 600×10^6 hours. The 90% probability interval is [8.60×10^{-11}/hr, 5.01×10^{-9}/hr] with an error factor of 58. This time the probability interval although having the same size is moved to the left by an order of magnitude.

It should be emphasized that occupational risks rates refer to individual risk per unit of time of exposure. Full comparison among alternative hazards should include the exposure to this hazard. Consequently, working on the roof of a building for one hour (Hazard #7) is less dangerous than working on moveable platform (Hazard #11) for 5 hours. The former has a probability for a fatal injury equal to 2.32×10^{-7} while the latter has a fatality probability equal to 4.2×10^{-7} (~5 hrs $\times$ 8.4×10^{-8}/hr).

Often individual occupational risk is confused with group or collective occupational risk. The latter includes not only the time of exposure to a particular hazard but also the worker population exposed to the hazard. An interesting case is the risk of an accident while working on a mobile ladder versus a mobile scaffold. Over the period examined in the WORM project there were 18 deaths 159 permanent injuries and 628 recoverable injuries from accidents that occurred while working on a mobile ladder. The corresponding numbers for accidents involving work on mobile scaffolds for the same calendar period were (8 deaths, 44 permanent injuries and 193 recoverable injuries). Obviously on a collective basis working on a mobile ladder looks riskier than working on a mobile scaffold. Care must be exercised, however, before rushing to the recommendation that mobile ladders must be replaced my mobile scaffolds. Data analysis (taking into consideration the number of workers and the exposure time involved) indicate that the individual risk rate for working on a mobile ladder is 2.51×10^{-8}/hr for fatal injuries, 2.11×10^{-7}/hr for permanent injuries and 8.30×10^{-7}/hr for recoverable injuries. The corresponding values for working on a mobile scaffold are: 6.34×10^{-8}/hr, 3.20×10^{-7}/hr, 13.6×10^{-7}/hr. Obviously the individual occupational risk per hour while working on a mobile scaffold dominates the risk of working on a mobile ladder. A recommendation to replace a mobile ladder with a mobile scaffold would be meaningful if this replacement reduces the time required to perform a specific task by a factor of 3 or more. In this case the exposure to the hazard of an accident while working on a mobile scaffold will be less than one third of the exposure on a mobile ladder and the probability of an accident will be less for the case of scaffold.

ABSTRACT: In this paper, the method to evaluate the reliability of ion thruster system was discussed on the basis of components and assembly information. Combined with the survey results of domestic and foreign literatures and validation test for ion thruster assembly, the key assembly influencing reliability of ion thruster are accelerator grid and hollow cathode. The main failure modes for accelerator grid are electron-backstreaming due to accelerator grid erosion and structure failure due to ion sputter erosion. As to the two complicated failure modes, the competing failure model was introduced to evaluate the reliability of the accelerator grid system. The main failure mode for cathode is depletion failure of the emitter, so method to analyze the reliability information of the cathode assembly was based on the performance degradation data. Finally, CMSR method combined with system validation test information is adopted and the point estimation and lower confidence limit of reliability for the ion thruster system was calculated meaningfully.

1 INTRODUCTION

Ion thruster is an advanced stand-alone system for space propulsion. Commercial applications of electric propulsion include north-south and east-west station-keeping, attitude controlling, momentum dumping, de-orbit and orbit raising. The low-thrust nature of electric propulsion results in the requirement for very long thruster operating times for deep-space missions. Required operating times of thousands of tens of thousands of hours are typical. Due to small sample size, long service life and diverse failure modes characteristics, having a scientific evaluation on its working life and reliability by the traditional reliability assessment methods is necessarily inadequate. Therefore, in order to provide guidance and technical support for reliability modeling and assessment of long life, high reliability electric propulsion system, systematic assessment method for ion thruster is discussed in this paper.

2 FAILURE MODES ANALYSIS FOR ION THRUSTER

A typical ion thruster is mainly composed of cathode, accelerator grid, neutralizer, gas insulating device and discharge chamber as shown in the reliability block diagram in Figure 1. According to the block diagram, we can know that the ion thruster system is a series model and the system reliability is

$$R_s(t) = \prod_{i=1}^{5} R_i(t) \tag{1}$$

where R_s is the system reliability and R_i is the assembly reliability.

According to the failure mechanism, the failure modes for ion thruster can be divided into accidental failure modes and wear-out failure modes. The occurrence for accidental failure modes is mainly because the devices are subjected to the exceeded voltage, temperature or pressure environment, which can be avoided by adjusting the operating parameters and environment suitable for working correctly. However, wear-out failure modes

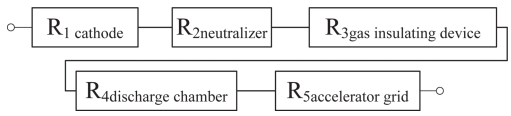

Figure 1. Reliability block diagram for ion thruster.

are associated with the accumulation of continuous operation of the thruster. For example, some key components subjected to ion sputtering environment have performance degradation or failure phenomenon, resulting in end-life of the entire propulsion system. Currently, the main countries for ion thruster research are the USA and Japan. They have conducted substantial ground life tests and durability tests for ion thruster and obtained considerable valuable data. According to the investigation at home and abroad and the life test results of ion thruster system in Lanzhou Institute of physics, the main wear-out failure modes are shown in the following Table 1.

Through the analysis, we select accelerator grid and cathode as the key assembly for ion thruster system assessment and the technological process for systematic assessment is shown in Figure 2. And the details for ion thruster assessment will be discussed in further.

Table 1. Ion thruster wear-out failure modes.

Assembly	Failure modes
Accelerator grid	Accelerator grid groove erosion from neutralizer ion
	Accelerator grid structural failure due to ion sputter erosion
	Accelerator grid electron-backstreaming due to grid erosion
Cathode	Cathode heater failure
	Cathode-to-keeper short
Neutralizer	Performance reduction due to orifice clogging
Gas insulating device	Gas insulator seam failure
	Electrical insulator failure caused by high voltage

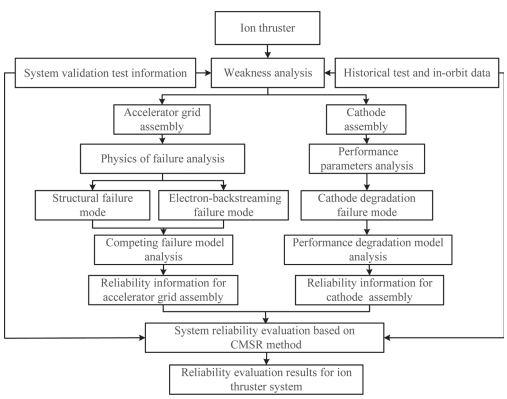

Figure 2. Reliability assessment method for ion thruster.

3 COMPETING FAILURE MODEL ANALYSIS FOR ACCELERATOR GRID ASSEMBLY

3.1 *Failure modes and mechanism for accelerator grid*

The structure of accelerator grid unit is shown in Figure 3(a). Because of the bombardment from Charge Exchange Xenon (CEX), the atoms at accelerator downstream surface are sputtered out. Along with the sputtering process, the eroded orifice brim of accelerator grid gradually becomes thinner. As shown in Figure 3(b), when the hexagon is penetrated completely, the orifice falls off and the grid short happens. What needs to be emphasized is that the structural failure phenomenon usually occurs in the center of the grid due to the maximum central current density.

In operation time, in order to maintain electrically neutral property of the spacecraft, neutralizer will launch electron flow to neutralize the beamlets. And the role of negative voltage on accelerator grid is to prevent the counterflow of the electrons to the discharge chamber. The potential distribution around the accelerator grid is shown in Figure 4. Dotted lines are the potential distributions at different radial positions from beamlet axis and solid line is the potential distribution between beamlets, i.e. the potential distribution on the grid boundary. From Figure 2, we can know that the lowest point (saddle point) of beamlets potential on the axis is higher than the accelerator potential points, which is the potential barrier the electronic refluxes need to overcome when flowing into the discharge chamber. The central orifices of accelerator grid become larger at the effect of ion beamlets, then the potential of grid becomes smaller. As a result, the electrons having enough energy are able to pass the accelerator grid to the discharge chamber and

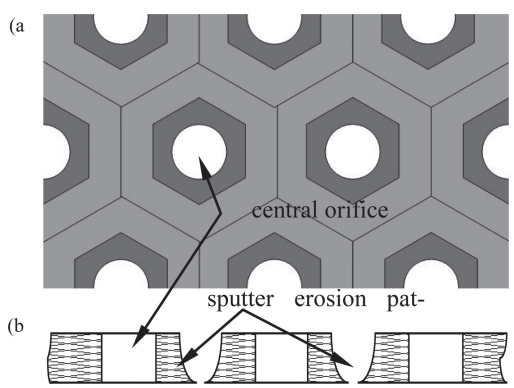

Figure 3. Schematic for accelerator grid (a) accelerator structure unit (b) profile for failure.

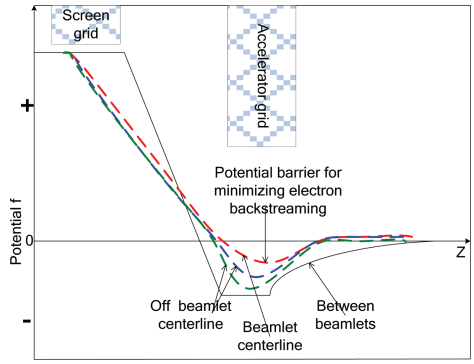

Figure 4. Schematic of potentials distribution at different radial positions around accelerator grid.

electron-backstreaming phenomenon happens. The occurrence of electron-backstreaming will cause unnecessary power consumption, decrease of ion thruster performance and local high temperature, even lead to the end of life.

3.2 *Competing failure model analysis*

As for structural failure mode and electron-backstreaming failure mode, the happening of any one of the two will bring deadly trouble to the propulsion system. However, which failure mode happens firstly is not completely clear yet, so competing failure model is introduced to analyze the life and reliability information of the accelerator grid assembly. According to the failure characteristics and principle of competing failure method, the following assumptions are correct:

1. The distribution of the two failure mode are independent;
2. The kind of earliest occurrence failure mode will lead to accelerator grid failure.

Through abundant investigation home and abroad of failure mechanism, we know that the life for structural and electron-backstreaming failure modes submit Normal and Weibull distribution separately. In order to make the data more abundant, Monte-Carlo simulation method is used to obtain the solution of competing failure model and the procedure is as follows:

1. On the basis of the two kinds of distribution parameters, the created random life sample is

$$\begin{cases} T_{structure} = \{T_{structure1}, T_{structure2}, \ldots, T_{structuren}\} \\ T_{backstreaming} \\ \quad = \{T_{backstreaming1}, T_{backstreaming2}, \ldots, T_{backstreamingn}\} \end{cases} \tag{2}$$

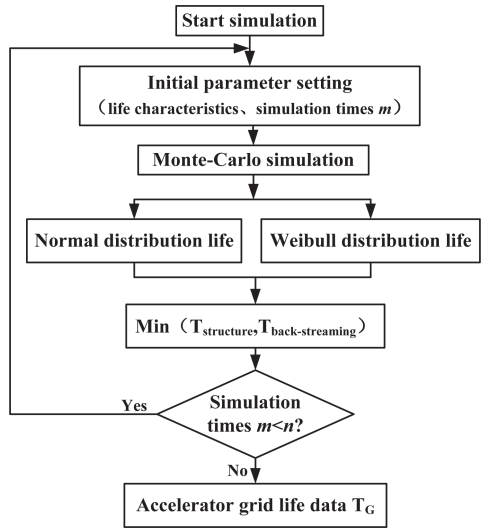

Figure 5. M-C simulating process for competing failure mode.

2. Then the life for accelerator grid assembly system T_G is

$$T_G = \min\{T_{structure}, T_{backstreaming}\} \tag{3}$$

3. Repeat procedure (1) and (2) m times (according to different precision requirements, the simulation times can be increased properly), the M-C simulation process is displayed in Figure 3. Then the simulated life sample for accelerator grid assembly can be obtained

$$\{T_{G1}, T_{G2}, \cdots, T_{Gm}\} \tag{4}$$

And the M-C simulation process is displayed in Figure 5.

Then the lower reliability limit R_{LG} and point estimation R_G of accelerator grid can be obtained by confidence degree γ, simulation times m according to GB/T 4885.

4 PERFORMANCE DEGRADATION DATA ANALYSIS FOR CATHODE ASSEMBLY

4.1 *Failure modes and failure mechanism for cathode*

The key component of cathode assembly is hollow cathode which mainly consists of LaB_6 emitter, heater coils, cathode tube and keeper, which is shown in Figure 6. Among them, the life of emitter is the decisive factor influencing the properties of cathode

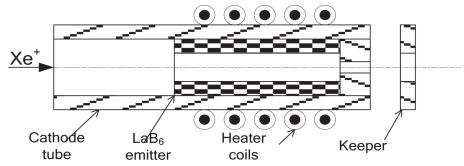

Figure 6. Schematic of the cathode assembly.

assembly. The main failure mode for LaB_6 emitter is depletion failure due to evaporation at high temperature. Because the depletion process is very slow, even subjected to higher accelerated stress, the failure phenomenon can't be observed yet. Therefore, performance degradation data analysis method is adopted to obtain the life and reliability information of cathode assembly, greatly reducing the test time and improving the economic benefits.

4.2 *Performance degradation data analysis*

For ion thruster hollow cathode, degradation model has the following two basic hypotheses:

1. Performance degradation process is irreversible;
2. One degradation model corresponds to only one degradation process or failure mechanism.

Considering the characteristics of cathode, anode voltage or keeper voltage is chosen as the performance degradation parameter generally. According to the variation characteristics of voltage data, the degradation model is as follows:

$$v(t) = b\varphi(t) + a + \varepsilon \tag{5}$$

where $v(t)$ is the variable value of voltage, b is the drift coefficient characterizing the degradation rate, a is unknown parameter and ε is the residual error.

The degradation data analysis processing is as follows:

1. The cathode sample number is n and the number of degradation data for each sample is $m_i (i = 1, 2, \ldots, n)$, according to the detected voltage and the correspondent time, the unknown parameters can be calculated;
2. The data processing procedure adopts least square method, then the estimation value for a and b can be obtained;
3. According to equation (6), the performance data equation for n sample is

$$\begin{cases} v_1(t) = \hat{a}_1 + \hat{b}_1 \cdot \varphi(t) \\ v_2(t) = \hat{a}_2 + \hat{b}_2 \cdot \varphi(t) \\ \vdots \\ v_n(t) = \hat{a}_n + \hat{b}_n \cdot \varphi(t) \end{cases} \tag{6}$$

4. Then the pseudo life T_{ci} *of each cathode* can be calculated by equation (6);

$$\{T_{C1}, T_{C2}, \cdots, T_{Cn}\} \tag{7}$$

5. As for degradation failure mode, the life submits Weibull distribution, and the reliability model is

$$R(t) = \exp\left[-\left(\frac{t}{\eta}\right)^m\right] \quad t > 0 \tag{8}$$

where m is the shape parameter, η is the characteristic life and t is task life.

6. The shape parameter m can be calculated by equation (9);

$$\frac{1}{m} + \frac{\sum_{i=1}^{n} \ln T_{Ci}}{n} - \frac{\sum_{i=1}^{n} {T_{Ci}}^m \ln T_{Ci}}{\sum_{i=1}^{n} {T_{Ci}}^m} = 0 \tag{9}$$

7. Then the point estimation of characteristic life $\hat{\eta}_C$ and the point estimation $\hat{R}_C$ and lower confidence limit R_{LC} of reliability for cathode can be obtained easily by equation (10).

$$\begin{cases} t^* = \sum_{i=1}^{n} {T_{Ci}}^m \\ \hat{\eta}_C = \left(\frac{t^*}{n}\right)^{\frac{1}{m}} \\ \hat{R}_C = \exp\left[-\left(\frac{t}{\hat{\eta}_C}\right)^m\right] \\ R_{LC} = \exp\left[-\frac{t^m}{2t^*}\chi^2_\gamma(2r+2)\right] \end{cases} \tag{10}$$

where t^* is the equivalent total test time and $\hat{\eta}_C$ is the estimation of characteristic life.

5 RELIABILITY ASSESSMENT OF ION THRUSTER SYSTEM BASED ON CMSR METHOD

Because the reliability information of ion thruster consists of assembly information, system validation test data, prior information etc, CMSR (Combined Modified Maximum Likelihood & Sequential Reduction) method combined with system validation test information is used to evaluate the reliability of the ion thruster system.

5.1 *Reliability information conversion for accelerator grid and cathode*

For accelerator grid and cathode assembly, the reliability information is obtained already. Then the equivalent exponential data for each assembly can be calculated separately. By equation (11), the total accumulating test time T_G for accelerator grid and T_C for cathode can be obtained.

$$\begin{cases} R_L = \exp(-\lambda_U t) \\ \lambda_U = \chi^2_\gamma(2r+2)/2T \end{cases} \tag{11}$$

Then the equivalent failure number r_G for accelerator grid and r_C for cathode can be calculated by equation (12):

$$\begin{cases} \hat{R} = \exp(-\hat{\lambda} t) \\ \hat{\lambda} = r/T \end{cases} \tag{12}$$

5.2 *Assembly reliability information calculation*

According to the standard—Assessment methods for spacecraft reliability(Q/W 8B 2007) issued by China Academy of Space Technology, the reliability point estimation $\hat{R}_A$ for accelerator grid and cathode assembly and its variance $D_A(\hat{R})$ are

$$\begin{cases} R_A = R_G \cdot R_C \\ D_A(\hat{R}) = \hat{R}_A^2 \left(\dfrac{r_G t_G^2}{T_G^2} + \dfrac{r_C t_C^2}{T_C^2} \right) \end{cases} \tag{13}$$

where t_G and t_C are the task time for grid and cathode separately.

Then the equivalent task number η_A and the equivalent failure number r_A for accelerator grid and cathode assembly are

$$\begin{cases} \eta_A = -\dfrac{\hat{R}_A^2 \ln \hat{R}_A}{D_A(\hat{R})} \\ r_A = -\eta_A \ln \hat{R}_A \end{cases} \tag{14}$$

5.3 *Ion thruster system reliability calculation*

After the conversion of assembly reliability information, the results for system validation test should also be considered so as to make the system information more abundant and the evaluation result more convincing. And the conversion method for assembly assessment information and system test information is shown in the following equations,

$$\begin{cases} \eta_S = \eta_A + \eta_{SV} \\ r_S = r_A + r_{SV} \end{cases} \tag{15}$$

where η_S and r_S is the the equivalent task number and equivalent failure number for ion thruster system seperately, η_{VS} and r_{SV} is the the equivalent task number and equivalent failure number for system validation test seperately.

After the conversion of equivalent test information, the point estimation $\hat{R}_S$ and lower limit of reliability R_{LS} for ion thruster system are

$$\begin{cases} \hat{R}_S = \exp(-\hat{\lambda} t) = \exp\left(-\dfrac{r_S}{\eta_S} \right) \\ R_{LS} = \exp(-\lambda_U t) = \exp\left(-\dfrac{\chi^2_\gamma(2r_S+2)}{2\eta_S} \right) \end{cases} \tag{16}$$

Above all, the estimation value of system reliability can be calculated meaningfully by sequential information reduction adding the system validation test information.

The reliability assessment method discussed in this paper has got good achievement in a certain type of ion thruster developed by Vacuum & Cryogenic Technology and Physics Laboratory in Lanzhou. For security reasons, public discussion of test data is prohibited here.

6 SUMMARY

The method to evaluate the reliability of ion thruster system was discussed elaborately on the basis of components and assembly information. Accelerator grid and cathode were chosen as the key assembly influencing reliability of ion thruster. And the competing failure model was used to analyze the electron-backstreaming and structure failure mode for accelerator grid and performance degradation data analysis method for depletion failure mode of the cathode emitter. Then CMSR method combining system validation test information was elaborated properly and the point estimation and lower limit of reliability for the system were obtained separately. The method is an investment for the assessment of ion thruster with small sample size, long service life and high reliability properties and also provides guidance and technical support for the reliability research of other complicated aerospace products.

ACKNOWLEDGMENT

The research described in this paper was carried out by the China Academy of Aerospace Standardization and Product Assurance, under a contract with the Science and Technology on Vacuum & Cryogenic Technology and Physics Laboratory.

1 INTRODUCTION

1.1 *General introduction*

Recent disasters in high hazard industries such as Oil and Gas Exploration (The Deepwater Horizon) and Petrochemical production (Texas City) have been found to have causes that range from direct technical failures through organizational shortcomings right up to weak regulation and inappropriate company cultures. Traditionally, risk models for process plants concentrate upon technical failures because there is relatively concrete technical failure data available for risk modeling. Modeling human activities, and their interaction with the process plant is a quite different proposition. Yet it is imperative to incorporate the human. Humans contribute to safety measures in process plants and thereby become integral part of the safety functions in process plants.

The Platypus software integrates both technical and human performance for the prevention of process leaks. That is to say, it models the left-hand-side of the bow-tie. Thus the safety effects of technical failure, human failure, and to some extent organizational failure are directly modeled through the appearance of leaks in process plants.

1.2 *The development of Platypus*

Platypus models the left hand or fault-tree side of a bowtie model for process safety by using a Bayesian Belief Net (BBN). That is to say, it calculates the frequency of occurrence of leaks of arbitrary size in process equipment. A leak or Loss of Containment (LoC) event does not necessarily lead to a catastrophe but in some cases leads a loss of containment can have severe consequences ranging from accidents or catastrophes. Most of the BBN-based method was developed in 2011 and 2012. The background information for the model can be found elsewhere. (Ale et al., 2014; Ale et al., 2011; Hanea et al., 2012; Lin et al., 2012, Sillem et al., 2012; Van Gulijk et al., 2012; Van Gulijk et al., 2013).

The first version of Platypus was made in May 2013. Though the initial program could already be used to calculate an entire site it was not very user friendly. Since then, there was a strong drive to improve the functionality of the program, especially with respect to the improvement of analysis tools. Improvements included: an engine to read equipment lists, an engine to change parameters in subsets of process equipment in a plant and copying subsets of the plants. This combination of features has led to a piece of software that enables left-hand side BBN-based risk analyses of entire chemical—or process plants, something that was never done before.

Note that detailed scientific information is not disseminated in this paper. Rigorous scientific reporting will take place after full testing of the program. Nevertheless, the reader may increase their understanding by reading earlier publications about this project that explain the philosophy and theoretical framework of Platypus.

1.3 *This paper*

This paper is limited to a description of the capabilities of Platypus. It shows the results of case study that was performed with Platypus version 0.7.10. The case study involves test calculations for the reactive section in an ethylene oxidation process that contains 4 reactors.

Since the program is still under development, these results are preliminary. That means that the results in this paper are used to demonstrate how the results that Platypus yields and how they can be used for risk-analyses of process plants. The results should not be interpreted as exact.

A brief description of the structure and some of the software features of Platypus is enclosed in this paper.

2 ABOUT PLATYPUS

2.1 *Structure of Platypus*

Some explanation is necessary to understand how the results presented in this paper came to be. This section explains the relevant elements in the structure of the Platypus software.

2.1.1 *Parameter excursions*

Any part of the chemical process plant is designed to contain hazardous chemicals under operational process conditions with a built-in safety margin. These margins are typically subject to rigid design standards. In this work deviations of the process parameters beyond these margins are called parameter excursions. Parameter excursions are quantifiable entities that have probability of occurrence [year^{-1}].

2.1.2 *Barriers*

Ordinarily, there is at least one safety barrier that controls parameter excursions. Barriers have a probability of failure per activation [activation^{-1}] or [–]. The failure probabilities are the input parameters for a barrier.

2.1.3 *Excursion control path*

For process parameter excursions (like temperature or pressure) there may be up to three or more consecutive, independent barrier systems to prevent loss-of-control. In that respect this work follows the LOPA method (Dowell, 2001). This methodology leads to a chain of barriers that may be activated when a parameter excursion takes place. The parameter excursion, including the initiating parameter excursion and the activation of the chain of barriers is termed an excursion control path. The combination of starting frequencies and the frequency of failure of the barriers leads to an annual frequency of occurrence for LoC's.

2.1.4 *LoC*

A Loss of Containment or LoC of process equipment follows when all barriers fail. The uncontrolled deviations from normal or abnormal process conditions and operations that are so extreme that leaks, cracks, ruptures or failing barriers cause the uncontrolled transport of materials from inside process equipment to the outside. In the current version of Platypus, the LoC's are of arbitrary size. That is to say that Platypus does not predict the size of the leak. The reason for that is the size of the leak is a consequence rather than a cause, which puts it in the right-hand side of the bow-tie.

2.1.5 *Combination of LoC's in equipment*

For a given piece of equipment, a number of excursion controls combine; for instance corrosion, wrong installation, and overpressure combine (amongst others) into a vessel equipment model. It is important to remember that an excursion control path links a single type of a parameter excursion (say, corrosion) to a LoC. The combined LoC's model the LoC frequency of the equipment. Detailed information about the equipment models are proprietary information that cannot be repeated here.

Note that the inputs in Platypus are distributions into the non-parametric BBN's and that the results are distributions from those BBN's. That is why the standard deviation that represents aleatory uncertainty is reported along with the central estimate.

So far, eleven pieces of equipment were modeled. They are:

1.	vessels HC only	V-HC
2.	vessels L-L separator	V-LL
3.	reactors	R-GEN
4.	pipework	PW
5.	centrifugal pump	P-C
6.	reciprocating pump	P-R
7.	furnace	F-GEN
8.	fin-fan coolers	E-FF
9.	tubular heat exchanger	E-TS
10.	centrifugal compressor	C-C
11.	reciprocating compressor	C-R

2.2 *Software features of Platypus*

Platypus can import process equipment lists of a process plant or a site that houses several process plants. The equipment list is translated into a hierarchical model structure to represent the plant and represent individual safety barriers for process control. Currently, the barriers are grouped into 11 individual Equipment LoC template models (EqLoC's) but Platypus can be used to build any barrier-structure in a process plant. The templates provide quick references that contain estimates for global average leak rates for a predetermined set of leak scenario's. These templates function as a first estimate when assessing the leak rate of a site or a plant. Someone that is familiar with the program can make this first estimate within the time span of 15 minutes or less for any given chemical site or process plant.

3 METHOD

3.1 *Process under consideration*

This paper demonstrates seven calculations that were performed by Platypus version 0.7.10. The program runs on a 64 bit Intel i7-2640M CPU at 2.80 GHz with a RAM memory of 4 GB.

The calculation (known as BBN sampling) is a Monte Carlo simulation with 50.000 passes. The calculation takes about 30 seconds.

The process unit that is under consideration is a reaction section in an ethylene oxidation plant. It consists of the following parts:

– 8 HC vessels only
– 4 reactors
– 1 centrifugal pump
– 11 heat exchangers
– 208 pipework sections.

This equipment list draws 5 types of equipment in Platypus out of 11 are standard equipment LoC models.

3.2 *Interventions*

For this paper, a few technical interventions in that reaction section are calculated. The interventions represent alterations in the assembly or operation of the unit. The interventions are presented as changes to the base-case calculation. That is to say the calculation that only incorporates unaltered equipment LoC models. The results for the base-case are presented section 4.1. The interventions are treated in the subsequent sections. Section 4.2 treats changes of the PRVs (Pressure Relief Valves) in the unit. That is to say, SIL 3 PRVs are replaced by SIL 4 PRVs. Section 4.3 treats the complete elimination of hoisting activities in the vicinity of the unit. Section 4.4 treats a redesign of pipework in the sense that less connections with measurement instrumentations are designed. Section 4.5 treats the redesign of pipework in the sense that less pipework is installed. Section 4.6 treats the complete elimination of corrosion as a factor in all equipment. Section 4.7 treats improved maintenance operations for the centrifugal pump.

4 PRELIMINARY RESULTS

4.1 *Baseline calculation*

The baseline calculation for the process unit under consideration yields the results in Table 1. Figure 1 is a graphic representation of the distribution of the leak frequency.

4.2 *SIL4 PRVs*

One possible safety intervention is the replacement of SIL3 PRVs with SIL 4 PRVs. So the existing pressure relief valves, that are usually the last line of defense in overpressure LoC scenario's, are changed to more reliable systems.

Table 1. Platypus results for the case study: Base case.

	LoC frequency/ [year^{-1}]	
Part of unit	Freq.	Stdev.
Base case	6.68	0.674
In which the contribution to the mean equal:		
Reactors (4)	0.056	–
HC vessels (8)	2.35	–
Heat exch. (11)	2.02	–
Centrifugal pump (1)	0.0051	–
Pipework (208 units)	2.25	–

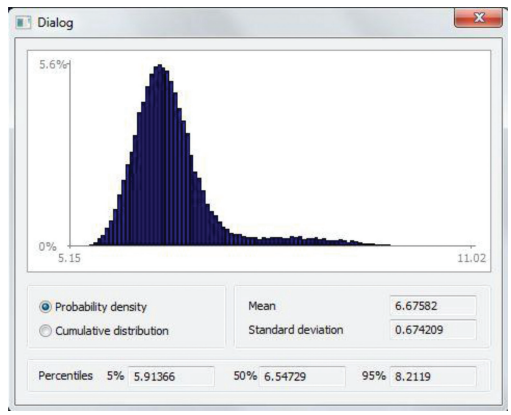

Figure 1. LoC frequency distribution for unit.

Table 2. Platypus results for various cases.

	LoC frequency/ [year^{-1}]	
Analysis case	Freq.	Stdev.
Base case	6.68	0.674
SIL4 PRVs	6.67	0.674
Eliminate hoisting	4.95	0.634
Less connectors in pipes	6.58	0.67
Less number of pipes	5.26	0.642
No corrosion	6.68	0.674
Sup. pump maintenance	6.68	0.677

Table 2 shows the results from Platypus. Note that the change in the overall leak frequency is nearly negligible which demonstrates that the overall contribution of replacing ordinary PRVs by high-quality PRVs does not yield much safety gain in the sense that they do not lower the LoC frequency distribution.

4.3 *Eliminate hoisting activities in the unit*

The second intervention is the complete elimination of hoisting activities of any kind. Table 2 shows the results. The LoC frequency dropped to 11% to 4.95, which is substantial in this case. This large change is mostly due to the fact that all pieces of equipment are prone to this threat. Despite that explanation, current thinking is that this effect may be overestimated in Platypus.

4.4 *Less connectors to a pipe*

Our current information says that a piece of pipework has 26 connectors and flanges associated with it. Each of those is prone to installation errors. If the number of connections is lowered, the probability of having installation errors lowers and the overall LoC frequency should drop. In fact lowering the connectors from 26 to 10 yields 6.58 ± 0.67. This is a relatively small change for the entire unit. That is to say, the influence of installation errors in pipework contribute to the total LoC prediction is relatively small.

4.5 *Less pipework*

Less pipework influences the LoC frequency considerably. When the piping layout is simplified (*viz.* 208 units of pipe are reduced to 80 units of pipe) the frequency lowers to 5.25 ± 0.642; a reduction of over 20% on the overall. This suggests that clever layout of pipework reduces LoC's in a process plant.

4.6 *Corrosion-resistant materials*

In this case the influence of corrosion is completely eliminated from the threat scenario's. The lowering of the frequency for LoC's is negligible. This means that the current corrosion controls are sufficiently effective in preventing LoC's.

4.7 *Improved pump maintenance*

For this case, the maintenance of the centrifugal pump is better in the sense that people make no omissions in the tasks that have to be performed in the maintenance and repair of the pump. In this case, it means that the probability of skipping a safety-sensitive maintenance activity is effectively reduced to zero. The effect on the overall LoC frequency of the centrifugal pump clear; the mean has lowered by 17% from 0.0051 ± 0.00452 to 0.0042 ± 0.00452. However, the contribution on the LoC's of the whole unit is negligible since just one pump is installed in this case.

5 DISCUSSION

It has to be stressed that Platypus is still under development and these results are preliminary. That means that the results in this paper are used to demonstrate how the results that Platypus yields and how they can be used for risk-analyses of process plants. The results should not be interpreted as exact.

5.1 *Distribution of LoC probabilities*

The results from the calculations yield a distribution function for the LoC frequency. Figure 1 shows the results for the base case. The figure should be read as follows. On the x-axis is the frequency of an LoC event of arbitrary size in [year^{-1}]. On the y-axis is the percentage of the frequency distribution histogram where the histogram has 100 equidistant size bins between the minimum LoC frequency (5.15 year^{-1}) and the maximum LoC frequency (11.2 year^{-1}). This means that it is estimated that the LoC frequency is between 5.15 and 11.2. Any leak frequency rate between those limits may be expected in the observation of the unit. There is a 90% probability interval between 5.91 year^{-1} and 8.21 year^{-1}, which narrows the likely occurrence of an observable LoC rate. The mean is 6.68 year^{-1} the standard deviation is 0.674 year^{-1}. The median is 6.55 year^{-1}.

It is tempting to compare the mean or the median to traditionally used point-estimators for failure frequencies but that diminishes the added value of working with a distribution. For instance, with a point estimator, an LoC frequency of 6.68 year^{-1} it would be easy to judge an observed frequency of 11.2 as a serious safety issue but in reality, it is still within possible bounds (even if it is unlikely).

Another reason to consider a distribution is setting safety standards. The distribution shows that it is not very useful to set a safety standard that says that the leak frequency should not be higher than the mean of 6.68 year^{-1} because in nearly 40% of instances this threshold will be exceeded anyway. Alternatively, it would be more useful to set thresholds based on the 95% threshold of 8.2 year^{-1} (for instance exceeding that value in to consecutive years).

5.2 *Comparison of cases*

Several possible safety-interventions were modeled with Platypus. These are examples of interventions that a safety-manager may consider. Three interventions are operational and three from the design of the unit. The replacement with better pressure relief valves, elimination of hoisting, and

improving pump maintenance can be decided by a local safety manager. Changing piping layout and using corrosion resistant materials can be decided in the design phase. Platypus easily shows which of the safety interventions provides the best safety gain in the sense that less leaks are expected. It is this type of sensitivity analysis that will help improve the safety performance of the process plant most.

This case study demonstrates that once a model can be loaded into Platypus, it is relatively easy to test safety interventions in process plants. In that sense, Platypus is a rapid analysis tool that immediately provides insight into the safety gain that a safety intervention might yield in an existing process plant. This rapid analysis also enables relatively straightforward comparison between different options for intervention.

Note that an extensive sensitivity analysis may be developed to optimize a mix of safety interventions to a maximum safety yield. We believe that this will remain a task for safety experts and not for users in the field. In the future, an extensive sensitivity analysis functionality may be added to Platypus but at this time that is not included in the software.

5.3 *Generic and detailed analysis*

The information that was used for this simulation is generic data. That is to say, the information about the process unit is limited to an instrument count and the instruments were modeled with generic equipment models. This is the coarsest application of the Platypus software that we term the 'generic analysis'. A detailed analysis is also possible. In that case, the total length of pipework, the number of connections to a vessel, the SIL level of technical safety barriers may be modeled to represent the unit as closely as possible. Historic failure data of the plant can also be implemented. This is possible because Platypus allows for the adaptation of the generic models on each level of detail of the model. This makes it very flexible but the workload associated with modeling an entire process plant (which may literally consist of thousands of pieces of equipment) may not be very practical. In addition, it may be hard to find relevant data.

5.4 *Data requirements*

Since the calculations are performed with distributions, the data-requirement for input data is more challenging than it already is in QRA calculations for process safety. Now, a central estimate failure rate does not suffice but a whole distribution is required. In this work, we use a triangle to represent distributions that we do not know (*viz.* when only point estimate failure data is available). However, the further implementation of Platypus may require more advanced failure data than are commonly available today.

6 CONCLUSION

Platypus presents unique advantages over any other risk analysis software.

Firstly, the use of a BBN as an advanced method for risk calculations yields new possibilities for risk analysis. Platypus generates risk analyses that yield risk distributions rather than point estimations. These risk distributions automatically address aleatory uncertainties in risk analysis (whose origin lies in randomness) and identifies instances of high risk that are overlooked in setting risk standards. The distribution will also yield new leading risk indicators and new methods and instruments for risk management. When estimates of epistemic uncertainty ranges are available, these can be incorporated in the overall distributions as well.

Secondly, Platypus provides insight into the factors that influence the frequency of LoC events before accidents have taken place, whereas traditionally that information could only be derived from historical data. In Platypus, technical, organizational and human factors elements are integrated which enables an in-depth analysis of causes of LoC and the effectiveness of measures. This paper demonstrates how easy it would be to perform such an analysis.

Thirdly, due to its efficient calculation engine, initial LoC estimates for entire sites can be calculated in a matter of minutes which makes it very easy to minimize the LoC frequencies in process plants in the future.

We believe Platypus is a leap forward in estimating leak frequency rates for process plants. We believe it will change the face of risk analysis in the process industries and beyond that work area.

The use of the combination of indexing and semi-quantitative methods in audits for individual risk assessment in the field of fire and explosion protection

A. Leksin & U. Barth
University of Wuppertal, Wuppertal, Germany

D. Adeulov
Agency PB, GCE Group, Limited Liability Company, Saint Petersburg, Russia

R. Mock
Zurich University of Applied Sciences, Winterthur, Switzerland

ABSTRACT: In the field of fire and explosion protection the assessment of individual risks often bases on heuristics or indexing methods because a full-scale probabilistic approach is infeasible in many cases for en-terprises. On the other hand, this established procedure undermines efforts of Quantitative Risk Assessment (QRA) to assess frequencies of undesired events and their consequences as accurately as possible. The paper outlines an approach to objectify the process of a QRA audit. Based on an online search, the available QRA and indexing tools are characterized. The combination of the indexing method and semi-quantitative approaches allows to carry out an audit, which is based on weighting procedures utilizable for risk rating and benchmarking for individual risk quantification. Regarding this, audits are facilitated and the quality of the outcome increases. The approach is exemplified by a prototype tool (MS EXCEL). The paper concludes with outlining the benefits and constraints of QRA audit tools.

1 INTRODUCTION

Risk analyses are performed to provide data for decision making, e.g., about the necessity of fire prevention actions with regard to compliance. In this case a qualitative risk assessment is carried out as only specified attributes of the prevention systems and hazards are necessary.

On the other hand, risk analyses identify specific hazards and asses their impact on humans, environment and business.

Procedures, goals and levels of detail of specific risk assessment approaches have to be tailored by the auditor considering resources, regulatory requirements, etc.

There exists no universal method for the assessment of fire and explosion risks which would be accepted as obligatory in the standard regulation in the field of fire and explosion safety of industrial buildings and associated facilities indoor. At the same time these regulations allow the application of qualitative and quantitative approaches, including index methods and the full probabilistic approach.

However, the limits of resources usually results in simplistic risk assessment approaches based on heuristics and expert judgment (checklists, FMEA, etc.). Thus, the common QRA approaches are unable to cope with individual risks in a level of detail as preferable.

Taking up the authors' preliminary studies (Leksin et al. 2013, Mock et al. 2012) and linking up the indexing method and semi-quantitative risk assessment approaches result in an enhanced QRA audit methodology. Within the scope of this methodological and operational framework, the paper is structured as follows:

Chapters 2 and 3 outline the context of the tool development, i.e., definitions, methods and tools. Results of an Internet survey show software tools supporting indexing and QRA methods. Chapter 4 covers the general audit principle. Chapter 5 extends the indexing and semi-quantitative approaches and their combination. Chapter 6 sketches the audit application by a prototype tool (MS EXCEL). The concluding chapter 7 discusses pros and cons of QRA audit and of the presented risk audit approach.

2 TERMS AND DEFINITIONS

The synopsis of scientific literature and normative documents shows an inconsistent terminology in

QRA. The paper follows to the definition of (DIN EN ISO 13943 2010):

Fire hazard: physical object or condition with a potential for an undesirable consequence from fire, whereas
Fire risk: probability of a fire combined with a quantified measure of its consequence (it is often calculated as the product of probability and consequence).

Other definitions can be found, e.g., in the British (PAS 79 2011) or in the Russian (GOST 12.1.033–81 1982).

The definitions of explosion hazard and explosion risk are limited even more on account of the specitity of this topic. The paper follows (Dic. Academic 2013):

Explosion hazard: set of the factors causing possibility of formation of the explosive atmosphere in volume, exceeding 5% of room volume, and its ignition. Such factors are: combustible substance, oxidizer and an ignition source (translated from Russian).

A definition of *explosion risk* wasn't found in international standards. For this *explosion risk* is defined by analogy with *fire risk*.

3 RISK ANALYSES IN FIRE AND EXPLOSION PROTECTION

The common Fire and Explosion Protection (FEP) approaches can be differentiated into two categories: hazard and risk analyses.

Hazard analysis focuses on the study of characteristics of a fire and its impact on humans and property at the set scenario, which includes a set of basic data on room geometry, parameters for the center of the fire, conditions of ventilating apertures, a starting position of people in the building, etc. Here, deterministic mathematical (integrated, zonal or differential) or physical (full-scale or reduced in sizes) fire models are used. Research focuses on quantitative data, environment characteristics of fire and explosion scenarios, its striking action and potential property damage.

Risk analysis focuses on the assessment of both consequences and probabilities of occurrence of scenarios.

The central place of these methods is taken by the analysis of accidental factors (e.g., arrangement of a place of fire, quantity of the materials involved, FEP measurements).

The analysis of hazards and consequences of scenarios are included in risk analysis because any of the listed factors have a big impact on the scenarios (Hall & Watts 2008, Hurley & Bukowski 2008).

3.1 *Characterization of methodology*

Fire and explosion risks consider both probability of an undesired event, and severity of its consequences. For risk analysis purposes, the analyst defines the level of detail and system boundary. The common qualitative, quantitative, semi-quantitative risk assessment approaches are supposed to be known to the reader (IEC/FDIS 31010 2009).

Semi-quantitative methods use qualitative as well as quantitative evaluation procedures. Methods of indexing and ranging of risks also belong to this method. From the practical point of view, it is difficult to appraise the value of indexing methods for risk analysis purposes. Unlike qualitative methods it gives a quantitative assessment of a risk level, but differs in straightforwardness demanding for computer recourses. It also uses a small number of parameters to assess the efficacy of the FEP measurements.

3.2 *Literature survey*

The up-dated survey of (Leksin et al. 2013, Mock et al. 2012), considers many computer models for fire and explosion risk assessments, e.g., CRISP and CRISP2 (UK), FiRECAM (Canada), FRAME (USA), AgenaRisk (UK), AssessNET (UK), Synergi Life Risk Management (Norway), SITIS, based on (GOST 12.1.004-91 1992, et al.) (Russia), and TOXI+, based on (RD-03-26-2007 2008) (Russia). These tools seemingly show the current practice in the area of *quantitative risk assessment* audits as all of them name the risk term (Leksin et al. 2013). However, these tools often use a risk terminology in a market-oriented manner whereas their descriptions often remain unclear whether the tools are used for risk estimation or hazard identification.

Where the strict quantitative analysis of risk by probabilistic methods is difficult or impossible, analysts appreciate fast heuristics. Such methods are *fire risk indexing, point schemes, scoring methods* (Hall & Watts 2008, Watts 2002). However, it should be noted that these methods are only practical when carrying out a fast analysis at the level of fire protection equipment, as well as to determine the necessity of additional fire prevention measures.

The literature survey also shows the current practice in the area of indexing point schemes audits:

– *Dow Chemical Method*—developed by The Dow Chemical Company (USA) "… provides a simple method of rating the relative acute health hazard potential to people in neighboring plants or communities from possible chemical release incidents. Absolute measures of risk are very difficult to determine, but the CEI system will

provide a method of ranking one hazard relative to another. It is not intended to define a particular design as safe or unsafe.

The CEI is used:

– For conducting an initial Process Hazard Analysis (PHA).
– As a screening tool for further study
– In Emergency Response Planning

It is a simple method for predicting dispersion of vapors/gases from process leaks, and the Index is used as part of Dow Risk Assessment" (Dow Chemical Method 2013).

– *FRIM (Fire Risk Indexing Method)* for Multistory Apartment Buildings. This method adjusts fire-prevention systems of wooden houses by comparison of an index of fire risk with a similar index for buildings with nonflammable bearing designs. This method is in fact a method of hazard assessment as no likelihoods are considered (Karlsson 2002).
– *FSES (Fire Safety Evaluation System)* evaluates the overall level of a fire safety of buildings. It provides means of comparing the effectiveness of proposed improvements by producing a comparative baseline and shows the relative gain in fire safety for proposed improvements (NFPA 101A).
– *SIA 81 or Gretener method and its modifications* "… is used to evaluate and compare the level of fire risk of alternative concepts by grading the elements of a building and their performance. The grading factors are claimed to be based on expert knowledge, a large statistical survey and tested by a wide practical application. The calculated risk is compared to the accepted risk, where the latter is a function of the number and the mobility of the persons involved and of the location of the relevant fire compartments within the building" (Larsson 2000). Methods like, ERIC—Evaluation du Incendie par le Calcul (Cluzel & Sarrat1979), Fire Risk Assessment Method for Engineering (FRAME) etc. are modifications of SIA 81.

The literature survey testifies that probabilistic and index methods are beneficial tools, which take their own place in the range of approaches to a problem with regard to QRA. However, the application needs a profound expert knowledge about their area of application. Furthermore, these methods are only applicable for fire risks and do not consider explosions risk.

4 RISK AUDIT PRINCIPLE

The paper suggests a technique to assess individual risks for industrial objects in the field of fire and explosion safety. This method rests upon on

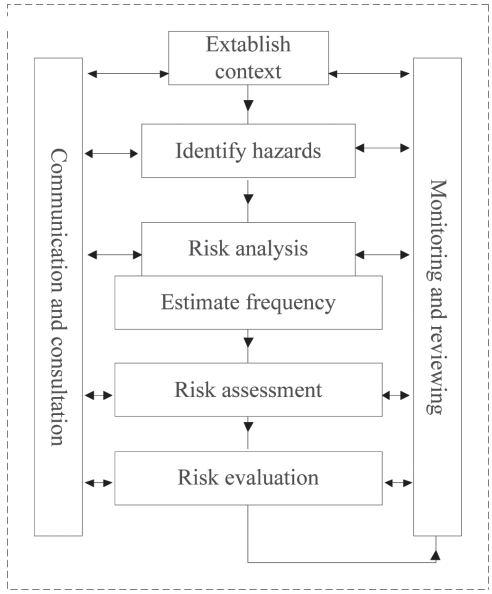

Figure 1. Risk management process.

specified FEP zones at the audited enterprise and then supports threat analysis as well as the overall audit approach.

In order to advance the methodology introduced in (Mock et al. 2012), two major problem areas needs to be addressed:

– an audit approach has to exclude time consuming procedures as well as excessive workload. This problem is addressed by the introduction of the revised indexing method to calculate the individual risk.
– individual risk figures only rely on semi-quantitative or qualitative approaches. The method suggested in this paper introduces reasoned weighting factors (from 0 to 100%).

The following chapters process these steps of the audit development.

This approach follows the risk management process of (Fig. 1) based on e.g., standards as (ISO-GUIDE-73 2009, ISO-31000 2009) and (ISO/TS 16732 2005).

5 EXTENDED AUDIT APPROACH

5.1 *Indexing approach*

The set of hazards and protection measures are considered as factorial indicators which define an indexing equation.

To each factorial indicator of the system, a specified number of points is attributed by rules,

i.e., the assessment of a condition of the system is made from various points of view.

The common indexing methods are developed to assess fire hazards supported by factorial indicators which consider aspects causing fires (fire loading, ignition sources etc.) as well as measures to mitigate fire hazards (availability of fire extinguishing systems, fire resistance of design, existence of an alarm system and evacuation ways, etc.). The calculated index of fire risk expresses a level of fire hazards. The formal goal of the suggested method is to comprise index calculations into QRA.

By combining the risk equation $R = F \cdot C$ (i.e., risk R is a function of frequency F and consequence C of an undesired event; (ISO-Guide-73 2009)) with the indexing model, the resulting equation of individual risk becomes:

$$R_{Ind} = F_F \cdot P_\tau \cdot C_S, \tag{1}$$

where R_{Ind} = individual risk [1/a]; F_F = frequency of a fire at the enterprise [m^2/a]; P_τ = probability of presence of the personnel; C_S = coefficient of safety.

5.1.1 *Influence of the fire frequency*

As mentioned in (Leksin et al. 2013), risk values are industry specific. The probability F_F of a fire at the enterprise is derived from statistical data for the analyzed enterprise. Average values can be obtained from international statistical data and standards like (Purple Book 2005, FZ 1994). Table 1 exemplifies branches and frequencies in use.

Because these values can be different from country to country, an additional factorial indicator, which corrects the suggested frequency of a fire, is considered. The impact of offence in the audited enterprises is determined by this factorial indicator.

5.1.2 *Influence of the personnel presence*

The calculation of individual risk needs to consider the probability of personnel presence at an endangered zone:

$$P_\tau = \tau/24, \tag{2}$$

where τ = working time of a person [h].

Table 1. Fire frequencies of branches (Mock et al. 2013).

Industry	Frequency 10^{-5} [m^2/a]
Power generation	1.20
Storage (chemical production)	1.38
Manufacturing	0.73
…	…
Metal industry	1.78

5.1.3 *Influence of the safety coefficient*

Risk to a single person depends on a number of hazards and safety measures. The set of hazards and protection measures is considered as a variety of factorial indicators which define a function based on the indexing method. These factorial indicators are considered by the calculation of the coefficient of safety:

$$C_S = F_S \cdot F_{Hrisk}, \tag{3}$$

where F_S = factorial indicator of safety, which dependends on the safety measures; F_{Hrisk} = factorial indicator of hazard, which is dependent on the Worst Case path of an Event Tree (relative to indexing factor, which is dependent on the hazard measures).

Because risk considers the frequency F of an event and its consequence C, we have a scale from the Best Case to the Worst Case Scenario which is also considered in ETA (Event Tree Analysis).

In order to consider all scenarios of the event tree and to achieve a more exact calculation of the individual risk, factorial indicators of hazard measures for the worst case and best case scenarios are developed. Figure 2 will show this approach in an extended context in section 5.2. There, the substantiation of factorial indicators of hazard measures is also discussed.

5.1.4 *Influence of the safety factorial indicator*

The influence of the safety factorial indicator F_S is

$$F_S = \overline{M}_{\text{arch}} \cdot \overline{M}_{\text{tech}} \cdot \overline{M}_{\text{org}} = \frac{1}{n}\sum_{i=1}^{n} M_{i,\text{arch}} \cdot \frac{1}{m}\sum_{i=1}^{m} M_{i,\text{tech}} \cdot \frac{1}{k}\sum_{i=1}^{k} M_{i,\text{org}}, \tag{4}$$

where $\overline{M}_{\text{arch}}$ = arithmetic mean of safety architectural measures; $\overline{M}_{\text{tech}}$ = arithmetic mean of safety

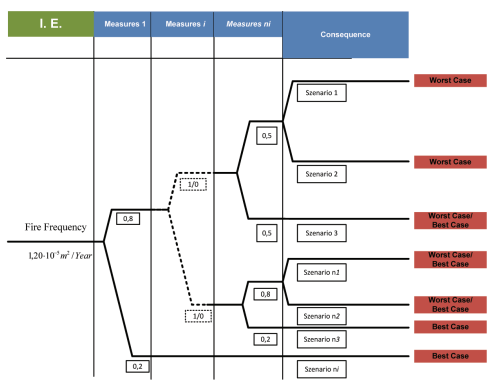

Figure 2. ETA in the audit process (I.E.: initiating event).

technical measures; $\overline{M}_{org}$ = arithmetic mean of safety organizational measures.

5.1.5 *Influence of the hazard factorial indicator*

The influence of the hazard factorial indicator F_{HRisk} is

$$F_{HRisk} = \overline{H}_{fut} \cdot \overline{H}_{f} \cdot \overline{H}_{ex} = \frac{1}{x}\sum_{i=1}^{x} H_{i,fut} \cdot \frac{1}{y}\sum_{i=1}^{y} H_{i,f} \cdot \frac{1}{z}\sum_{i=1}^{z} H_{i,ex}, \quad (5)$$

where $\overline{H}_{fut}$ = arithmetic mean of further hazards (e.g. amount of dangerous substance, room category, technological process etc.); $\overline{H}_{f}$ = arithmetic mean of fire hazards; $\overline{H}_{ex}$ = arithmetic mean of explosion hazards.

As the proposed method bases on the classical risk equation, the risk decreases automatically by simple multiplication of the measure factors. Therefore it is important to use the arithmetic mean of all micro parameters, which form the macro parameter.

5.1.6 *Influence of the safety index*

Parallel to the individual risk estimation the safety index I_S is calculated. Its function is to additionally assess and evaluate the calculated risk adequately:

$$I_S = \frac{F_S}{F_{HInd.}}, \quad (6)$$

where $F_{HInd.}$ = factorial indicator of hazard, which is dependent on the Best Case path of ETA (relative to indexing factor, which is dependent on the hazard measures).

The safety index is based on the classical indexing method—weighting the safety and hazard measure (which is dependent on the Best Case path of Event Tree). As we consider the spent time of the personal in the endangered area, the calculated risk can be acceptable if the probability of the presence of personnel is very small. In the other hand, the frequency of a fire at the enterprise is also small but safety measures can be unacceptable. This gives a signal to the auditor that safety measures have to be raised.

5.2 *Semi-quantitative approach*

In practice, the common QRA approaches are unable to cope with individual risks in a level of detail as needful, e.g., for business and insurance purposes. Taking up authors' preliminary studies (Leksin et al. 2013, Mock et al. 2012), a semi-quantitative approach is used and integrated within a common checklist approach and FMEA-like procedure. As mentioned in the indexing mathematical function of e.q. (1) hazard and safety measures are considered and developed in form of an alternative checklist. This checklist contains indicators of hazard measures, e.g., general hazards, fire hazards, explosion hazards, designated as macro parameters. Every macro parameter has a number of micro parameters, which are evaluated by an auditor. The same applies for the safety measures. This context is outlined in Table 2.

This kind of check list characterizes all scenarios of an Event Tree, which enriches the audit process and takes into account the Worst and Best Case paths of this ETA, as shown in Figure 2. Risk is computed as the sum of all worst case scenarios.

The next step in the semi-quantitative approach is the evaluation of the macro and micro parameters (hazard and safety measures). For this, weighting factors are used.

The weighting factors of Table 3 are used for safety parameters.

For hazard parameters (e.g., common, the amount of dangerous substances), there are weighting factors for both, worst case and best case.

Table 2. Check list of parameters.

Table 4. Weighting factors for best and worst case scenarios.

Compliance	Best case	Worst case
Hazard free	0.95	0.05
Low	0.75	0.25
Average	0.50	0.50
High	0.25	0.75
Maximum	0.05	0.95

The weighting factors represent an important step for an objective evaluation of the calculated risk as the auditors cannot manipulate the factors.

FMEA like procedures, which give information about the risk spectrum of estimates as well as the standard deviation, are taken into account. Due to the complexity of formulas and the dependency among the factorial indicators, the mathematical context is not presented in this chapter. A more visual explication can be found in chapter 6.

In addition to the weighting factors, which are used by the auditor, there are suggested correction factors (e.g., emergency exit—escape route—0.8 and 0.2) to get a more exact statements about the risk.

The dependency of hazard factors and measures is taken into consideration in the same way. By these mathematical combinations between factorial indicators and weighting factors of the evaluated scenario, more exact statement about the calculated risk values are possible.

In this case, the developed checklist actually takes a position about the scenario and thereby about the complete event tree, which can only be visualized in form of a complex graph. Figure 3 shows, how such a graph might look like.

Figure 3 use the following notation: mic/mac = micro and macro parameters of hazard and safety measures; F = fire, e.g., for an I.E.; E = existing violations; t = presence of personnel; i = fire frequency of industry branch; s = substance/material (dust, liquefied gas, etc.); S = area of testing zone; S1-Sn = scenarios; R = risk.

To simplify the application, the approach is rendered in to an MS EXCEL prototype tool, which is present in the following chapter.

6 AUDIT APPLICATION

The combination of methods results in a probabilistic approach, which leads to an audit approach, which bases on weighting procedures. This approach allows to compare input data and

Table 5. Data input mask.

I.C. Minimum value	…	–
II. Technical measures	…	
III. Organization measures	…	

factorial indicators with the auditor's experience. The application has to be easy to handle because of limited resources. Therefore the auditor uses an input mask. First, a parameters check has to be carried out and some audit specific data are entered. The final risk assessment compares the identified frequencies of individual risk with a given tolerance value. The threshold value of the acceptable risk is set for example to 10^{-6} [1/a], which corresponds to European standards (Dijm 2009).

The auditor has also to do the compliance check of hazard parameters, as shown in Table 2.

The compliance check of safety parameters must also be entered.

The resulting risk prioritization and safety index values I_S and their evaluation are given in Table 8 and 9.

If R_{Ind} > value of the acceptable risk, e.g., 10^{-6} [1/a], then the compliance factor for risk is 1.

If $R_{Ind} \leq$ value of the acceptable risk, then the compliance factor for risk is 0.

If $I_S > 1$, then the compliance indicator for index is 1.

If $I_S = 1$, then the compliance indicator for index is 0.5.

If $I_S < 1$, then the compliance indicator for index is 0.

The general class of hazard is the sum of existing violations and the compliance indicators for risk and index.

Table 8. Data output mask of individual risk.

Individual risk (R_{Ind})		Compliance indicator for risk
Maximal individual risk	$8.43 \cdot 10^{-4}$ [1/a]	1
Normal individual risk	$9.90 \cdot 10^{-5}$ [1/a]	1
Minimal individual risk	$2.49 \cdot 10^{-6}$ [1/a]	1

Table 9. Data output mask of safety index.

Safety index (I_S)		Compliance indicator for index
Maximal safety index	13.7765	1
Normal safety index	1	0.5
Minimal safety index	0.04070	0

Table 10. Data output mask of general class of hazard.

Common class of hazard	Increased	5

Table 11. General classes of hazard.

Common classes of hazard	Sum of existing violations and the compliance indicators
Minimal	1
Low	2
Moderate	3
Middle	4
Increased	5
High	6
Maximum	7
Maximum	8
Maximum	9

For the definition of the common class of hazard exists a rating scale is used.

The auditor can draw conclusions about the fire and explosion risk (e.g., that explosion constitutes a bigger danger than a fire) with the help of additional diagrams (not presented in this paper).

7 CONCLUSIONS

This paper is roughly structured into two parts:

First, it summarises a survey about operative indexing and QRA audit software tools in the field of FEP. Second, the authors continued to formalize their audit approach by the combination of the indexing method and semi-quantitative approaches. By combining the two methods the resulting probabilistic method allows to carry out an audit, which bases on weighting procedures utilizable for risk rating and benchmarking.

The number of commercial indexing and QRA assisting software tools is surprisingly small. Furthermore these tools are only applicable for fire risks and do not consider explosion risks and hazards. Currently, there is no clarity which of the specified tools is more preferable to the quantitative analysis. Often these tools do not asses risk but hazards (i.e. ignoring the frequentistic risk element) or only weight and evaluate the overall levels of fire safety of buildings, which is characteristic for indexing methods.

The probabilistic model of the individual fire and explosion risk discussed in this paper considers the most important aspects in the field of fire and explosion risk protection such as:

- quantitative risk assessment, based on an extended risk equation and
- controls probability of hazard and safety measures, based on a FMEA-like procedure that gives information about the risk spectrum of estimates.

Therefore, the uniqueness of the presented method lies in the robust, easy to understand

approach that combines various systems into a more stringent decision making process. This combining allows to consider a big number of scenarios, which are dependent from aspects causing fires, as well as aspects reducing fire hazard, by the initiating event "fire".

This approach is still depended on expert judgment. However, the auditor is supported with statistical data and reasonable weightings factors.

The audit approach presented as a MS EXCEL prototype tool shows a practice oriented possibility to check quantitative individual risk in the field of fire and explosion protection at enterprises.

The authors feel encouraged to continue their R&D efforts in this area as no tool or method could be found combining QRA methods in the proposed manner.

Estimation of the impact probability of fragments produced by explosions of vessels: A case study

M.F. Milazzo, R. Lisi & G. Consolo
University of Messina, Messina, Italy

G. Maschio
University of Padova, Padua, Italy

ABSTRACT: In order to incorporate domino effect scenarios, deriving from the projection of fragment (so-called missile), within the standard QRA (Quantitative Risk Analysis), a probabilistic model for the estimation of the impact probability of such fragment was developed by applying a Monte-Carlo method to the analytical solution of the set of equations describing the motion of the missile. The objective of this work is to further extend this probabilistic approach, which was previously developed for cylindrical vessels, to make it applicable also to spherical tanks. A case study is presented, it is the accident occurred in the refinery of Feyzin (France); the influence of the size and shape of the fragments on the impact probability is assessed.

1 INTRODUCTION

The term *domino effect* denotes a chain of accidents generated by an initiating accident, which occurs in an industrial unit and causes more severe events in other units (*accident escalation*), either in the same establishment or in neighbouring industries (Delvosalle, 1996). The literature provides some relevant examples, i.e. see the survey performed by Fabiano & Currò (2012), however a complete inventory of domino effects was given by Abdolhamidzadeh et al. (2011). According to Khan & Abbasi (2001), a domino effect may be initiated by several events: (i) fires (pool fire, flash fire, fireball, and jet fire); (ii) explosions (vapour cloud explosions VCE, boiling liquid expanding vapour explosion BLEVE, vented explosion, confined vapour cloud explosion, dust explosion); (iii) toxic release (instantaneous or continuous release of toxic lighter and heavier than air gases, release of toxic liquids and dust), in this latter case aspects of the emergency management are involved.

According to the Council Directive 96/82/EC and subsequent laws, the analysis of domino effects due to explosions and fires is carried out using simplified methods based on damage thresholds. This estimation is based upon technical assessments, which are not probabilistic methods and do not take into account uncertainties (Milazzo & Aven, 2012). Concerning domino effects triggered by fires, the evaluation of the influence of the flame extent and temperature has been amply explored by Palazzi & Fabiano (2012). In this framework the problem of the projection of fragments is not completely faced.

A multi-step approach for the deterministic estimation of the domino effects due to the projection of fragments was proposed by the Centre for Chemical Process Safety (CCPS, 2000). Such method consists in computing: (i) the explosion energy; (ii) the number and size of missiles produced by the vessel fragmentation; (iii) the initial velocity and angle of departure for each fragment; and (iv) the distance of fallout. Afterwards, by analyzing the plant layout, facilities located in the range of potential fallout of missiles are identified; these could be the potential sources of the accident escalation. To include the quantification of such domino effects into the QRA, the consequence and the frequency of the scenario must be estimated, their probabilistic implementation is necessary to extend studies such as those of Baesi et al. (2013) and Milazzo et al. (2010). The frequency of the domino scenario is the product of the frequency of the primary event and the probability of the following sequence of events (given the occurrence of the primary event). This probability is obtained by multiplying the probabilities of the fragmentation, of impact on a target and of damage given the occurrence of the impact (Nguyen et al., 2006). In this frame Holden and Reeves (see Lees 1996) developed models for the estimation of the fragmentation probability. Approaches to the modelling of the impact probability based on the

analysis of the fragment flight are due to Hauptmanns (2001) and Gubinelli et al. (2004). Finally, correlations for the calculation of the probability of damage are reported in Lees (1996).

Lisi et al. (2014a) recently reviewed the analytical solution of the set of ordinary differential equations describing the flight of a fragment proposed by Hauptmanns (2001). Then they validated the reviewed solution by using the accident occurred in the Italian refinery of Milazzo in 1993. The same authors extended the approach, which was previously developed for cylindrical vessels, also to spherical tanks (Lisi et al., 2014b).

This paper aims to investigate the influence of the size and shape of the fragments on the impact probability; to achieve this aim the data of the incident occurred in the refinery of Feyzin (France) in 1966 have been used. The paper presents the methodology in the section 2; in section 3 the incident of Feyzin and the setting up of the parameters for the analysis are described; in section 4 the results of the application of the methodology are shown; finally some conclusions are given.

2 METHODOLOGY

The methodology, presented in this section, has been developed for the estimation of domino effects due to fragments originating from a BLEVE (Boiling Liquid Expanding Vapour Explosion). Thus the proposed procedure accounts for the Baum's model (Baum, 1995) to compute the initial velocity of fragments. The methodology is composed of two steps:

1. Deterministic modelling of the flight of the fragment (i.e. derivation of the trajectory equation for the fragment);
2. Probabilistic modelling of the impact probability of the fragment.

2.1 *Deterministic modelling of the flight of the fragment*

In order to derive the trajectory equation of a fragment, its shape and angle of departure must be known.

Some studies on cylindrical vessels are due to Baum (1998, 1999, 2001); these report about two main types of fragmentation mode:

1. a fragmentation, along the welding, leads to an end-cap fragment, then the crack propagates axially along the shell. In some cases, the end-cap remains linked to a portion of the shell (oblong end-cap). The cylinder usually generates five fragments.
2. a fracture at the middle part of the cylinder is usually due to manufacture defects. The fragmentation unfolds the cylinder, then it propagates towards the edges of the vessel and generates one or two end-caps. Also in this case the end-cap sometimes remains linked to the complete cylinder or part of it.

In case of spherical tanks, the fracture can start anywhere in the vessel. As shown by Baum (1998), it can propagate either in a circular mode, generating a half sphere fragment, or along several directions, generating flat fragments.

If a large number of fragments are produced (in case of the explosion of cylindrical or spherical vessels) the departure angle cannot exactly be defined a priori; anyway each generated fragment has its own vertical and horizontal departure angles, respectively, indicated as θ and φ in Figure 1 (see Mebarki et al., 2009). Obviously, the departure angle is well known in case of a fitting projection (Lees, 1996).

The trajectory of the fragment is described by solving the motion equations in two spatial dimensions (see the axes rotation in Fig. 1), taking into account the air resistance. The lift (F_L) and the drag (F_D) are the components of this force, respectively, perpendicular and parallel to the direction of motion.

The equations of motion in the form of a system of second-order ordinary differential equations are:

$$\begin{cases} \ddot{x} + k\dot{x}^2 = 0 \\ \ddot{y}_A + k_A \dot{y}_A{}^2 + g = 0 \\ \ddot{y}_D - k_D \dot{y}_D{}^2 + g \end{cases} \quad (1)$$

In the system (1), the dot notation stands for the time derivative of the indicated variable; x and y_i ($i = A,D$) are, respectively, the horizontal and vertical components of the trajectory and g is the gravitational constant. The first equation describes the time evolution of the horizontal component of the trajectory, the last ones account, respectively, for the ascending and descending vertical branches.

In (1) the following coefficients are defined as:

$$k = \frac{\rho C_D A_D}{2m_i} \quad (2)$$

$$k_A = \frac{\rho(C_D A_D - C_L A_L)}{2m_i} \quad (3)$$

$$k_D = \frac{\rho(C_D A_D + C_L A_L)}{2m_i} \quad (4)$$

where ρ = air density; m_i = mass of the i-th fragment; C_D = drag coefficient; C_L = lift coefficient; A_D = drag area; A_L = lift area.

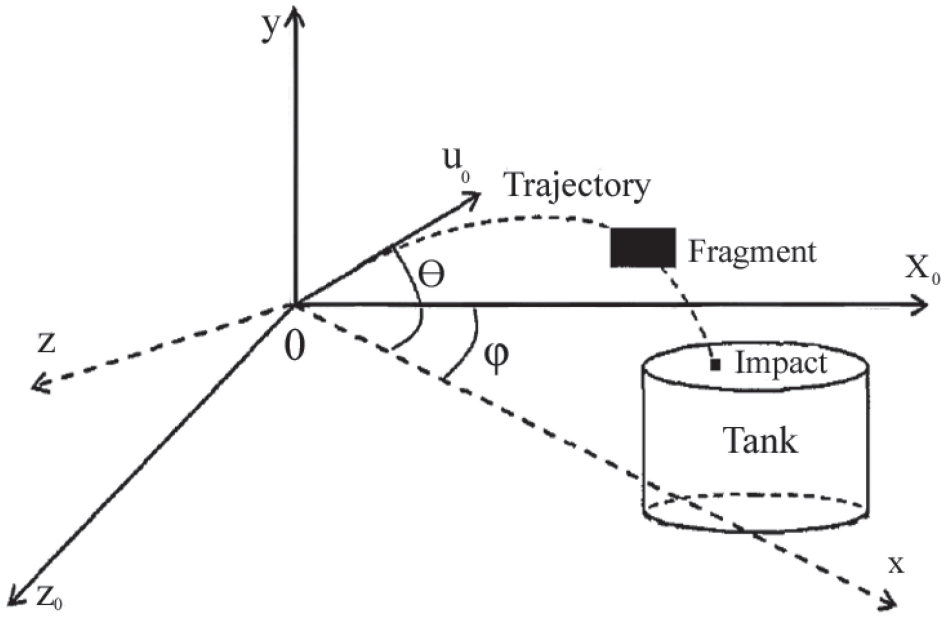

Figure 1. Fragment trajectory and impact on the target (tank).

Lisi et al. (2014a) solved the system (1) by using the initial conditions (5):

$$\begin{cases} x(0) = 0 \\ x(0) = u_o \cos\theta \\ y_A(0) = 0 \\ y_A(0) = u_o \sin\theta \\ y_D(t^*) = \max(y_A(t)) \\ y_D(t^*) = 0 \end{cases} \quad (5)$$

where u_o = initial velocity of the fragment; t^* = time at which the ascending of the trajectory reaches the maximum height.

The lift coefficient rises for asymmetric surface of the fragment (Daugherty et al., 1989), thus in case of cylindrical vessel, it should be considered for the end-cap and the shell. C_L is expressed as:

$$C_L = 0.351 + 0.6723 \cdot \alpha \quad (6)$$

where α = angle of attack.

It is worth noting that C_L is supposed to be equal to zero when the angle of attack ranging outside the interval [0°, 10°].

The drag depends on the several factors, i.e. the geometry, the surface roughness and the fragment orientation with respect to the direction of the initial velocity. An acceptable range values for C_D is [0.8–1.1] for tank end-caps and a range values [1.1–1.8] for the rings (see Baker et al. 1983).

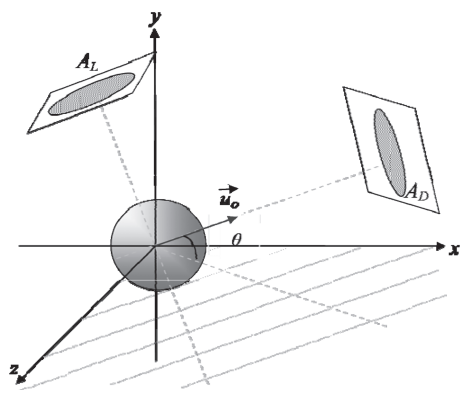

Figure 2. A_D and A_L for a sphere.

To understand the meaning of both the fragment projection on a plane perpendicular to the motion direction (A_D) and on a plane parallel to the motion direction (A_L), Figure 2 shows representation of these areas for a sphere (u_o is the initial velocity and θ is the initial angle with respect to the plane of xz).

2.2 *Probabilistic modelling of the impact probability of the fragment*

To model the impact probability of fragments originated by a BLEVE, a Monte Carlo method has

been applied to the solution of the system (1). The initial velocity and the departure angle are assumed to be stochastic variables. It has been assumed that both the variables obey: (1) a uniform and (2) a Gaussian (normal) probability density functions.

To compare the results obtained by using these probability density functions, the half-amplitude of the interval occurring in the uniform distribution is taken equal to twice the standard deviation of the normal distribution; while the expectation value of the Gaussian distribution is set at the centre of the interval of the uniform distribution.

3 CASE-STUDY

As previously mentioned, the case-study in this work is the incident of Feyzin (France). The effects, due to the fireball and the blast wave of the whole scenario, were investigated by Török et al. (2011). Lisi et al. (2014b) used this case-study to estimate the impact probability of fragments, produced by spherical vessels, by the application of the procedure described in Section 2; their work allowed a further validation of the method.

In this section, an investigation of the influence of the size and shape of the fragments on the impact probability is given. The data of the incident has been extracted from the report produced by the Ministère Chargé de l'Environnement (2006).

3.1 *The incident of Feyzin (France)*

The incident occurred in the refinery of Feyzin in 1966 and caused 18 dead and 81 injured. The refinery, located near to Lyon, was built in the 1964 for the treatment of 1.7 million barrels per year of petroleum. It had a storage area of Liquefied Petroleum Gas (LPG) under pressure of about 13,100 m^3. The LPG storage area, which was located in the Southern of the production units, comprised 10 tanks, 8 spheres and two cigars (Fig. 3), it also includes storage tanks for the heating oil, the gasoline and the premium gasoline.

The incident was caused by the uncontrolled release of propane from a storage sphere (T61 443), due to the misbehaviour of the operators involved in the purge operation. These did not execute the correct instructions for the blockage of the two safety valves (located at the base of the sphere) and caused a leakage of propane.

As reported by Kletz (1985), an operator was draining the water from the sphere T61 443 (the volume of the vessel was ~1,200 m^3) nearly full of propane. To execute the operation, the drain valves A and B of the vessel (see Fig. 4) were opened. When the drainage was completed (this was underlined by traces of oil), the operator shut the valve A. The team of workers intended to close the valves, but the upstream valve did not perfectly close. It seems that the leakage was caused by the freezing of the valve due to the drain work.

It must be pointed that, if the pressure is lowered to atmospheric pressure, the temperature of the propane drops to –40°C. At this temperature, a leak of propane leads to a moisture with frozen air and also forms a solid hydrate. If this occurs either the valve handle can be stuck by the frozen moisture or the valve could not be closed tightly as a result of the hydrate formation. Considering the possibility of ice formation, two drain valves are mounted in series at the bottom of the tanks (Fig. 4). The drainage operation requires (IChemE, 1987): (i) the upstream valve (A) must be fully opened and the inlet side of the downstream valve (B) has to be pressurized, (ii) the downstream valve is gradually

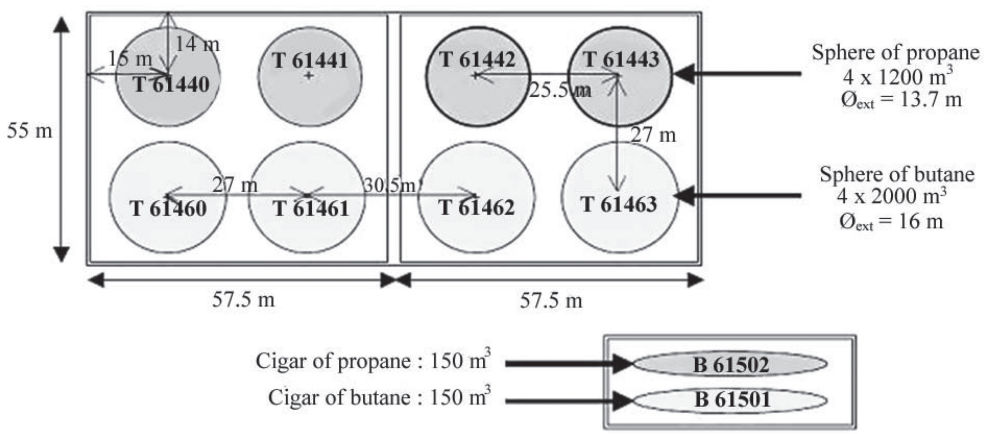

Figure 3. LPG storage area in the Feyzin refinery (source: Ministère Chargé de l'Environnement, 2006).

opened, starting from a slight open and then adjusting it to create the necessary flow rate. If the inlet of the valve B is pressurized, the temperature at the valve A does not drop. The outlet side of the downstream valve is cooled under the operation, and it is also important to ensure a sufficient distance between A and B, so that the upstream valve does not drop to a low temperature.

This accident was believed to be caused by the following causes: the valve A was not opened fully and the pressure at the outlet of this valve was near the atmospheric pressure, thus it was cooled by the pressure difference. It was absolutely forbidden to operate in this condition. Therefore, the cause of the accident was either the operator's human error or a mistake of the plant management in not to explain the proper execution of the operation (website HSE). Moreover another cause was that the operator did not close the downstream valve, this was probably due either to the ice formation or a rapid propane leak so that the operators could not close the valve.

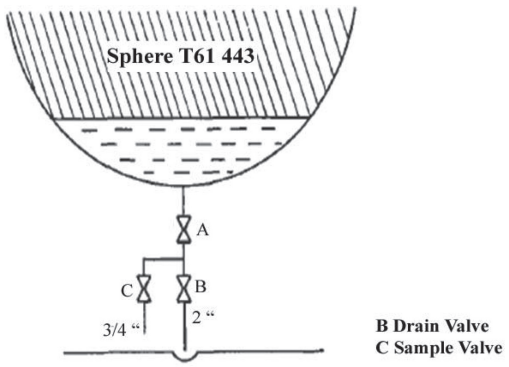

Figure 4. Drain valves' structure of the sphere T61 443.

The cloud of propane vapour spread, until it was ignited by a car that was driving along the local road. The pool of propane caused the storage tank to be engulfed in flames, which produced a BLEVE and, thus, the tank rupture. The released substance resulted in a fireball which killed and injured firemen and spectators. Flying missiles broke the legs of an adjacent sphere (T61 442) causing another BLEVE.

Three further spheres toppled due to the collapse of support legs which were not adequately fire protected. Three other spheres were broken during the accident, without generation of fragments. After the explosions of the spheres T61 442 and T61 443, many fragments were projected within an area having a radius of 800 m (Fig. 5), some of which weighed more than 80 tons. The characteristics of the exploded spheres are given in Table 1, whereas Table 2 shows the sizes, masses and distances of fallout of the main fragments.

3.2 *Deterministic analysis*

The deterministic analysis has been started with the calculation of the initial velocities by using the model proposed by Baum (Van den Bosch and

Table 1. Characteristics of the tanks (source: Ministère Chargé de l'Environnement, 2006).

Tank	Volume [m³]	Dimension [m]	Pressure [bar]	Empty weight [t]
Sphere of propane	1218	13.27 (d*)	18.7÷28.05	220
Sphere of butane	2038	15.74 (d*)	7.97÷11.95	186
Cylinders of propane/ butane	161	3.04 (d*) 20.80 (l**)	28.05	Unknown

*d = diameter; **l = length.

Table 2. Main fragments (source: Ministère Chargé de l'Environnement, 2006).

Item	Description	Weight [t]	Distance [m]	Dimension [m × m]
A1	T61 442	88.2	138	19 × 21.5
A2	T61 442	47.7	325	10.5 × 18.3
A3	T61 442	53.1	222	12.6 × 14.5
B1	T61 443	48	85	10.5 × 15
B2	T61 443	2.8	82	4 × 3
B3	T61 443	18	228	4.2 × 11.5
B4	T61 443	79	248	16.8 × 18.2
B5	T61 443	37	270	10.5 × 17.5

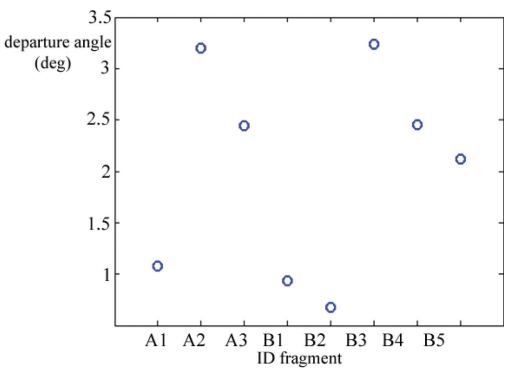

Figure 6. Deterministic estimation of the departure angles (θ).

Weterings, 2005) because it seems the most suitable for BLEVE.

The numerical integration of the equations of motion provided the values of the departure angles (θ) for the fragments, given the knowledge of the fallout distance reported in Table 2. This analysis allowing setting-up the numerical values of the parameters involved in the phenomenon (extracted from the survey after the accident) with the aim to verify whether, once inserted them into the equation of motion, they realistically reproduce the experimental data (the fallout distance have been calculated and compared with real data).

Figure 6 shows the results of the deterministic estimation of the departure angle θ of each fragment. The range of variability is $0° < \theta < 5°$.

4 RESULTS

The impact probability (P) has been evaluated as a function of the spatial position of the target. Results are shown in Figure 7 and lead to the following considerations. All the fragments depart almost parallel to the floor (as underlined in Fig. 6); the impact probability for the fragment produced by the fragmentation of both the spheres, T61 442 (A1, A2 and A3) and T61 443 (B1, B4 and B5), exhibits a monotonically decreasing dependence on the target disstance.

Figures 7(a) and 7(b) show the results obtained by using a uniform probability distribution function for the stochastic variables (P_U vs. target distance), whereas in Figures 7(c) and 7(d) these variables have been assumed to obey to a Gaussian one (P_G vs. target distance).

Appreciable differences cannot be observed by comparing the results obtained from all fragment types. In particular, in all cases, the probability is about 0.4 at 120 m, using a uniform probability distribution function (Figs. 7(a) and 7(b)), and 150 m, in case of a Gaussian one (Figs. 6(c) and 6(d)); then in all cases it smoothly decreases down to 10^{-3} at 450 m. Figure 7(e) and 7(f) show the deviation (given by the difference $P_U - P_G$) vs. target distance, and provide the following information: at distances lower than ~80 m, no appreciable difference can be observed by comparing all fragment types (A and B); the use of the Gaussian probability distribution function makes the estimation more conservative.

Concerning the size and shape of the fragments, it can be stated that according to the data of Table 2, the mass (m_i) of the fragments has the following order: $m_{A1} > m_{A3} > m_{A2}$ and $m_{B4} > m_{B1} > m_{B5}$. This order does not coincide with the trend of the impact probabilities given by the curves of Figure 7.

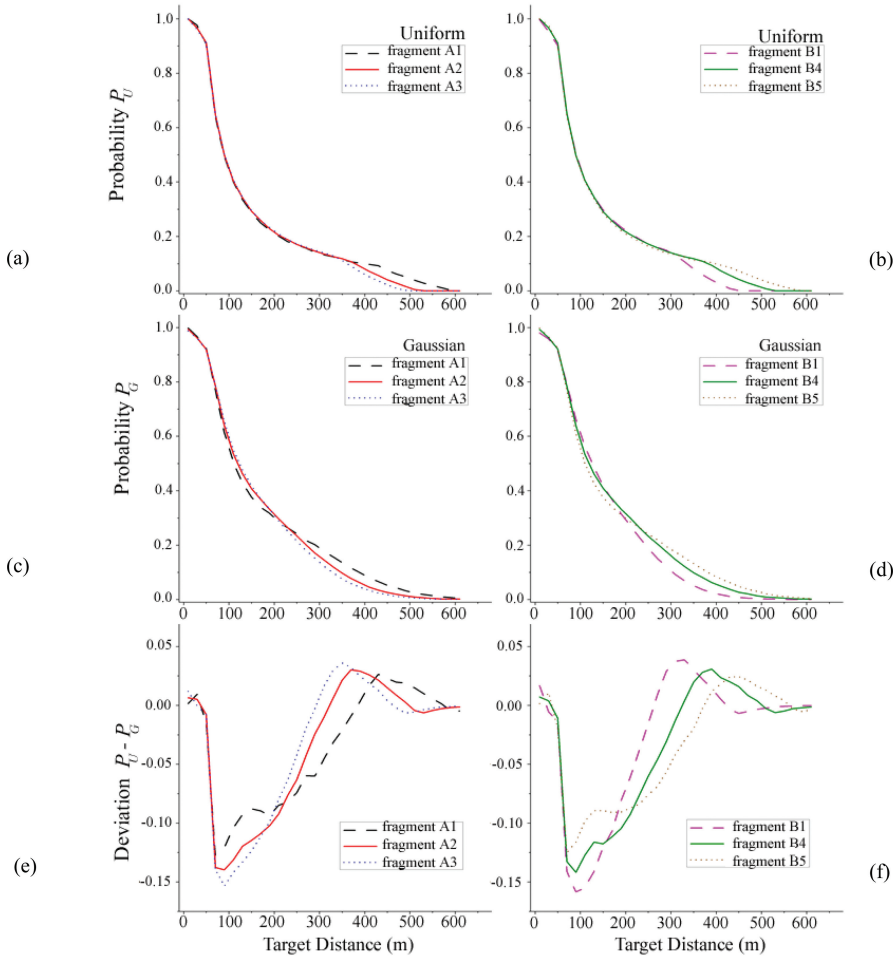

Figure 7. LPG storage area in the Feyzin refinery (source: Ministère Chargé de l'Environnement, 2006).

Table 3. Inputs to the probabilistic model.

Item	Vessel	A_D [m^2]	C_D [--]	A_L [m^2]	C_L [--]
A1	T61 442	408.5	0.351	0.76	1.2
A2	T61 442	192.1	0.351	0.42	1.2
A3	T61 442	182.7	0.351	0.504	1.2
B1	T61 443	157.5	0.351	0.42	1.2
B2	T61 443	12	0.351	0.16	1.2
B3	T61 443	48.3	0.351	0.168	1.2
B4	T61 443	305.8	0.351	0.672	1.2
B5	T61 443	183.7	0.351	0.42	1.2

As all the fragments depart almost parallel to the ground, the most significant contribution to the fallout distances and, thus, to these probabilities is given by the values of A_L. The extent of these areas has the following order: $A_{L,A1} > A_{L,A3} \sim A_{L,A2}$ and $A_{L,B4} > A_{L,B1} = A_{L,B5}$ (Table 3). This last parameter is the one influencing the final probability.

5 CONCLUSIONS

In this paper the methodology, proposed by Lisi et al. (2014), for the estimation of the impact probability of fragments originated by tank explosions (BLEVE), has been validated through its application to spherical tanks. The set-up of the model has been made by using the data of the incident occurred in the refinery of Feyzin. The probabilistic model for the estimation of the impact probability of the fragments has been developed by applying a Monte-Carlo simulation to the analytical solution of the trajectory of fragments, where the departure angle and the velocity are assumed to

be stochastic variables obeying either a uniform or a Gaussian distribution. The trend of the impact probability with respect to the target distance has shown a monotonically decrease.

The proposed approach allows the integration of the domino projection of fragments in the QRA. In fact, once potential domino scenarios have been identified, the proposed framework allows estimating the impact probability of a given fragment on each selected target.

Dynamic risk assessment: Development of a basic structure

N. Paltrinieri & P. Hokstad
Safety Research, SINTEF Technology and Society, Trondheim, Norway

ABSTRACT: The availability of real-time data provided by solutions for Integrated Operations (IO) in the petroleum industry may allow the development of advanced risk assessment techniques previously considered time-consuming and ineffective. For this reason, an approach for monitoring performance of barriers and assessing their influence on the overall risk picture is being developed. This approach aims to support the process of decision making both in the engineering and operational phases. The contribution shows the basic structure of this dynamic risk assessment approach. A case-study on sand erosion issues is taken as representative example. The application of this approach leads, on one hand, to the detailed modelling of safety barriers and their mechanisms and, on the other hand, to the definition of the barriers relative importance at affecting the overall risk picture.

1 INTRODUCTION

The Center for Integrated Operations (IO) in the Petroleum Industry is a research-based innovation centre that aims to develop new methods and tools for the integration of people, organizations, work processes and disciplines through new information and communication technology. For instance, IOs are being developed to improve capture of real-time safety barrier data and to process, visualize and share this information for closer onshore-offshore collaboration and more effective expert support.

One important question that can emerge from the assessment of safety barriers in a plant is how their performance can affect the overall risk picture. A technique capable to assess this and effectively visualize the result would provide an important decision support not only during daily operations but also on the medium term. For example, it would allow defining a maintenance plan by assessing the effect on the overall risk of temporary impairment of specific safety functions.

These are critical questions that industry is trying to answer with various solutions. One example is the Technical Integrity Management Programme (TIMP) by Statoil (Statoil 2013), which focuses on measuring the integrity of the technical barriers, but does not explicitly relate it to the overall risk. Within the IO Center, a tool aiming to continuously monitor risk picture changes and support decision making, named "Risk barometer", has been built (Paltrinieri et al. 2013). This tool is influenced by previous analogous methods, such as the ORIM (Organizational Risk Influence Model) (Øien 2001) and Risk OMT (risk modelling—integration of organisational, human and technical factors) (Vinnem et al. 2012).

As a prerequisite, the Risk Barometer should be based on an existing Quantitative Risk Analysis (QRA), in order to identify the most risk-affecting QRA parameters (e.g. probabilities of failure on demand of safety barriers). Factors describing the condition of barriers, named Risk Influencing Factors (RIF), are then defined for each QRA parameter. A set of risk indicators are finally introduced to measure the status of the various RIFs.

The study this contribution describes initially considers the Risk Barometer approach and adapts it to a specific case-study where no QRA is performed in advance. An alternative and case-specific basic structure is developed by means of expert input and judgment.

The case-study is based on an actual sand erosion issue present in an offshore oil production system. Material degradation due to processes of erosion/corrosion is the main focus. The production system is located subsea and connected to a spread-moored FPSO (Floating Production Storage and Offloading) unit, which is used as a hub, processing the fluids produced from the subsea wells.

In the following sections the case-study and the related scenario are described in detail by means of a bow-tie diagram. A methodology is then proposed for dynamically assessing the risk connected. To conclude, a set of simulation results are shown in order to illustrate the application of the methodology.

2 CASE-STUDY

A bow-tie diagram was used to visualize the case-study (Fig. 1—the terminology follows the one

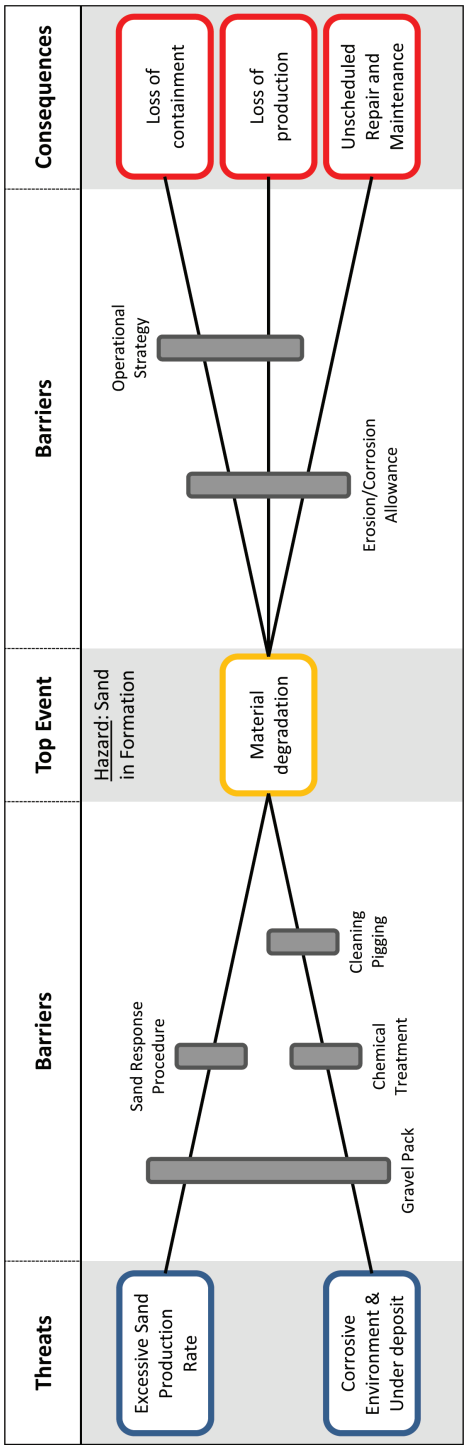

Figure 1. Bow-tie diagram illustrating the case-study (adapted from the result obtained with BowTieXP®).

used by the software BowTieXP®). In fact, the bow-tie technique in its visual form makes an accident scenario easy to understand, and can show what safeguards protect against particular initiating causes (or threats) and loss event consequences (CCPS, 2008).

In this case, the threats are:

- excessive sand production rate;
- corrosive environment & under deposit of sand.

The top event is material degradation due to sand erosion/corrosion. The identified consequences that can derive from sand erosion/corrosion are:

- loss of containment;
- loss of production;
- unscheduled repair and maintenance.

Between threats, top event and consequences, safety barriers are implemented in order to stop the development of the scenario by either preventing or mitigating the events considered. The barriers are described in the following section.

The elements displayed in the diagram do not specifically refer to discrete events, but continuous processes. For instance, the occurrence of material degradation can be better described by a degradation rate than a probability. The definition of a correlation between causes, top-event and consequences is addressed in the following sections.

2.1 *Hazard of sand in formation*

During oil production from a subsea well sand may be produced. In order to control sand formation and retain potential erosion and corrosion of oil production pipelines, several safety barriers are in place.

Material degradation may be caused by sand erosion or corrosion. As shown in Figure 1, two potential threats leading to sand erosion or corrosion are identified. The first threat focuses on excessive sand production rate. This does not only mean that there is an increase in sand production, but also that the velocity of the flow in which sand is carried exceeds a critical threshold. In order to prevent this threat to develop into pipeline material degradation, two safety barriers are in place:

- Gravel pack
- Sand response procedure

A gravel pack is a downhole filter, which is held in place with a properly-sized screen. In case the gravel pack is not enough, and excessive sand production is detected, a specific sand response procedure should be put into action.

Thus sand detectors are considered as a technical measure of the sand response procedure barrier. In this case-study two means for detecting sand production were considered:

1. An Acoustic Sand Detector (ASD) that performs on line monitoring and gives immediate information. It records the noise produced by sand carried in the process flow. The detectors are placed on the outside of the flow line bends and detect the noise made when sand collides with the pipeline wall.
2. An erosion probe, i.e. an metallic surface inserted in the well stream which is physically eroded by sand particles passing. This detector only reports accumulated effects over a longer time period.

The sand response procedure implies that if sand is detected and its rate exceeds a specific threshold, the flow line should be choked back until the sand production rate is acceptable. Generally the acoustic sand detector is used for dynamic monitoring and the erosion probe represents a later confirmation of the result obtained.

As shown by Figure 1, also corrosive environment and sand under deposit can lead to degradation (in this case corrosion) of the pipeline wall. The gravel pack is again indicated as safety barrier because it can prevent sand production and, thus, sand deposit where the flow is slowed down by line bends.

Injection of appropriate chemicals into the fluids in order to inhibit corrosion (chemical treatment) is a safety barrier defined to prevent corrosive environment, which is itself composed by technical and operational measures, such as the equipment used and its management.

"Pigs" are devices that are placed inside the pipe and traverse the pipeline. Thus, pigging is considered as safety barrier because allows cleaning the pipeline from sand deposit.

From a safety point of view, sand production is critical because it is threatening the integrity of the pipeline and to some extent also safety valves. If these threats are not stopped by the safety barriers mentioned, they can lead to material degradation, (shown in the middle of the bow-tie diagram as top event—Fig. 1).

An erosion corrosion allowance is present in the pipeline wall. The thickness is defined also by taking into account these factors. This represents a further safety barrier mitigating material degradation and preventing worse consequences, such as unscheduled repair and maintenance, loss of production or loss of containment.

Operational strategy is also a safety barrier. In fact, change of strategy when a critical situation is acknowledged can be the last option in order to prevent loss of production or loss of containment. For instance, in a condition of highly degraded material, production strategy can be modified and the production rate decreased, in order to reduce the pipeline stress load and avoid the formation of a leak of hydrocarbon into the sea.

3 METHODOLOGY

3.1 *Description of the proposed model*

The bow-tie diagram in Figure 1 was further re-elaborated (Fig. 2) in order to:

- Show the interaction of the threats; excessive sand production rate (T1) is a stand-alone threat, while corrosive environment (T2) and

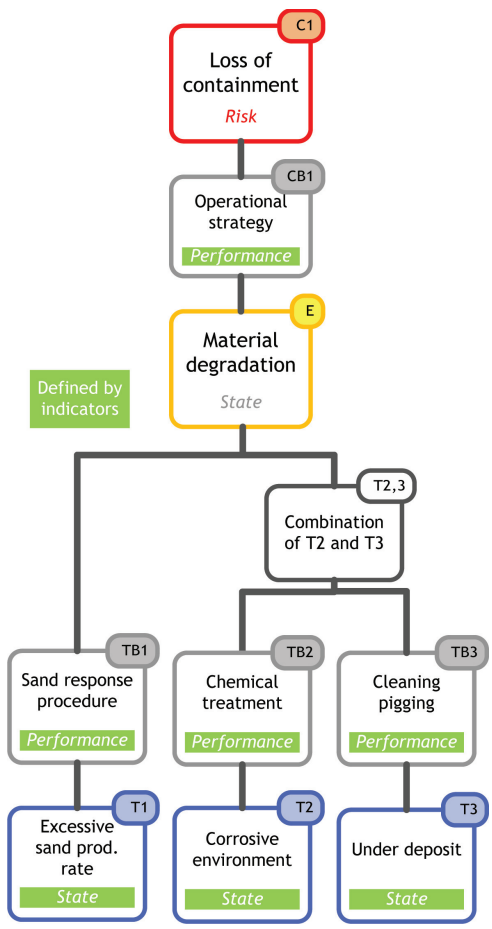

Figure 2. Model structure. The labels indicate both the model elements and their state/performance (Table 1).

sand under deposit (T3) must occur jointly in order to get material degradation.
- Omit the barriers whose performance cannot be controlled (e.g. inherent design issues); gravel pack and erosion/corrosion allowance are passive barriers and for this reason were omitted.

Focus on the worst-case consequence; risk was defined as the risk of loss of containment.

This Figure 2 allowed defining a semi-quantitative model for risk assessment, combining both the assessment of the related threats and the performance of barriers employed. The risk of loss containment is dependent on both the state of the threats and the performance of the barriers (which in turn should stop the threats).

For the development of this model, the Risk Influencing Factor (RIF) approach (Øien 2001a, b) was taken as a reference. For this reason, the main model elements (state of threats and the performance of barriers) are defined by means of indicators, as explained in Table 1 and the following sections.

Once assessed, the state of the threats is expressed on a scale from 1 to 6, where 1 is unlikely and 6 is very likely. This value is then multiplied by a probability of failure of the safety barrier, which is the result of the performance assessment by means of the indicators (Table 1). Thus, if the barrier can completely stop the threat (or the top event if CB1 is considered) the conditional probability will be equal to 0. If the barrier is negligible or impaired, the associated conditional probability will be equal to 1.

While T1 is an independent threat that can lead to material degradation without any other "co-factor", T2 and T3 should occur together in order to result into the top event. Between the two threats there is an "and-gate" and the combination of T2 and T3 is expressed by a weighted sum (Table 1). A weight is assigned to T2 and T3 on the basis of their effect on material degradation. Expert judgment is used for this task.

The state of material degradation is obtained by summing up the two contributions from the two branches (Table 1). This value is then multiplied by the probability of failure of CB1 in order to obtain the risk of loss of containment (Table 1).

Table 1. Definition of model elements.

Model elements	Definition
Threats	The threat state is defined by a set of indicators. The indicators (x_{Ti}) are measured on an arbitrary scale and translated into marks from 1 to 6. $m_{Ti} = \mathrm{M}(x_{Ti})$ A weight (w_{Ti}) is assigned to each indicator and the threat state (T) is obtained by a weighted sum on a scale from 1 to 6. $T = \sum w_{T,i} m_{T,i}$
Barriers	The barrier performance is defined by the performance of the barrier measures, which in turn are defined by indicators. The indicators of each measure ($x_{B,MPi}$) are measured on an arbitrary scale and translated into marks from 1 to 6. $m_{B,MP,i} = \mathrm{M}(x_{B,MP,i})$ A weight ($w_{B,MPi}$) is assigned to each indicator i, and then performance of measure j (MP_j) is obtained by a weighted sum on a scale from 1 to 6. $MP_j = \sum w_{B,MP,i} m_{B,MP,i}$ A weight (w_{Bj}) is assigned to each barrier measure j and the overall barrier performance (B) is obtained by a weighted sum on a scale from 1 to 6. $B = \sum w_{B,j} MP_j$ The barrier performance is translated into a probability of failure (p). $p = \mathrm{P}(B)$
Combination of T2 and T3	A weight (w_T) is assigned to T2 on the basis of its effect on E (material degradation) and the combination of T2 and T3 (state $T_{2,3}$) is obtained by a weighted sum on a scale from 1 to 6. $T_{2,3} = T_2 p_{TB2} W_T + T_3 p_{TB3} (1 - W_T)$
Top event	The state of the top event (E) is obtained by summing up the two contributions from the two branches. $E = T_1 p_{TB1} + T_{2,3}$
Consequence	The consequence risk (C) is obtained by the multiplication of E and p_{CB1}. $C = E p_{CB1}$

3.2 *Assessment of threat state*

Threat state is defined by a set of indicators. These indicators can be chosen among production data, detection results, related barrier demand rate, etc. This type of indicators should be measurable, have some degree of relevance with the threat and indicate the presence of the threat.

However, not all the indicators have the same degree of relevance and reliability. Thus, there may be indicators that are more important than others. For this reason, weights should be assigned to them in order to define the threat state by means of a weighted sum. In this way, the threat state is expressed by a number from 1 to 6 (Table 1).

3.3 *Assessment of barrier performance*

The assessment of barrier performance is based on two activities:

- Definition of the barrier structure (technical and operational barrier measures)
- Identification of suitable indicators

Each barrier is the result of a synergy of various measures. These measures (such as detection or procedure measures) play a part in realizing the task or role of the barrier and their performance is essential for the overall performance of the barrier. The measures of a barrier can be technical or operational and may have a different relative importance in the barrier structure. For this reason, each barrier considered in this contribution was broken down into measures and for each measure a specific weight was assigned.

Indicators should then be defined. This type of indicators focuses on the performance of the barrier measure, i.e. they should be able to show if the measure can deliver the desired outcome or if the measure has failed in delivering it. They should be measurable values and weights should be defined for them, in order to consider also their relative importance at describing the measure performance. In fact, also in this case indicators may have different grades of relevance and reliability.

The indicators are used to assess the barrier measure performance by means of a weighted sum. The performance values of the single measures are finally composed in a new weighted sum in order to define the overall performance of the barrier (Table 1).

3.4 *Weighting*

The assessment of the relative importance of indicators and barrier measures is based on expert judgment. Despite the fact that these elements are organized according to a hierarchical structure (as the Figs. 2–4 show) and their relative importance is defined on the basis of their effect on the governing (upper) element, the experts involved in this phase of the analysis may find it rather challenging and time-consuming. In order to facilitate this process, the technique of

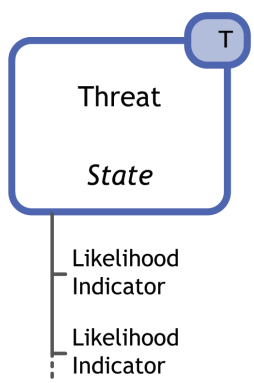

Figure 3. Threat structure.

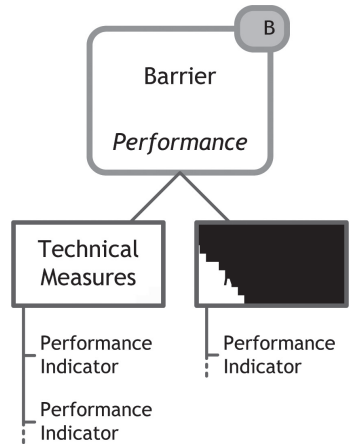

Figure 4. Barrier structure.

Table 2. Scale of relative importance (adapted from Saaty 1983).

Intensity of relative importance	Definition	Explanation
1	Equal importance	Two activities equally affect the governing level above.
3	Moderate importance of one over another	Experience and judgment slightly favor one activity over another.
5	Essential or strong	Experience and judgment strongly favor one activity over another.
7	Very strong importance	An activity is strongly favored and its dominance is demonstrated in practice.
9	Absolute importance	The evidence favoring one activity over another is of the highest possible order of affirmation.
2, 4, 6, 8	Intermediate values between the two adjacent judgments.	When compromise is needed.

If element A dominates over element B, then the whole number integer is entered in row A, column B and the reciprocal (fraction) is entered in row B, column A. If element B dominates element A then the reverse occurs.

Analytical Hierarchy Process (AHP) (Saaty 1983) can be applied.

AHP can help in defining the relative weights of hierarchically organized elements by means of pairwise comparisons among the elements. This produces a square matrix of judgments. The pairwise comparisons are done in terms of which element dominates another. These judgments are then expressed following the judgment values shown in Table 2 (these judgment values can be used also in the combination of T2 and T3). This produces a square matrix of judgments.

Finally, the calculation of the square matrix eigenvector is composed by the relative weights of the elements considered. However, before using the weights, a consistency test should be performed, as indicated by Saaty (1983) and Alonso (2006).

4 RESULTS

A workshop session with personnel from a major oil company allowed the completion of the model structure. A set of indicators was defined for each threat and a structure with specific technical and operational measures were outlined for each barrier of the case-study described. Moreover, weights were assessed on the basis of expert judgment. Table 3 lists all these elements. For the sake of brevity, only some examples of the indicators used are reported in Table 3.

The model was applied in two different conditions (represented by the times t_1 and t_2) with different indicator values. In the first case (t_1), the values of the indicators are completely random and can possibly simulate an average condition of the system. In the second case (t_2), the representative indicators shown in Table 3 describing the threat T1 (excessive sand production rate) and the related barrier TB1 (sand response procedure) were given values between 5 and 6 on purpose, in order to simulate a critical condition of sand production. Moreover, the barrier CB1 was defined as poorly performing. All the other input data, such as weight were assessed on the basis of expert judgment and kept constant.

The state of threats and top event, the performance of the barriers and the risk of loss of containment are visualized by means of a color scale, as it is planned to be performed by the risk barometer graphical interface:

- 1–2 White (W)
- 2–3 Green (G)
- 3–4 Yellow (Y)
- 4–5 Red (R)
- 5–6 Dark Red (DR)

Table 3. Model simulation at the times t_1 and t_2.

Model elements	Indicators	t_1	t_2
T1, Excessive sand production rate		Y	R
	Acoustic sand detection	5.51	5.70
	Erosion probe detection	2.38	5.50
	Daily output of production data	2.34	4.95
T2, Corrosive environment		Y	G
	Corrosion model results	3.03	2.84
T3, Under deposit		Y	Y
	Daily output of production data	4.26	2.49
	Inspection results	3.54	4.32
TB1, Sand response procedure		G	R
Acoustic sand detector	Age of the system	2.07	5.22
Erosion probes	Loss of signal	3.53	4.89
Manual well-flow sampling	Availability of laboratory system	5.43	5.97
Response to sand detection	Formalization and availability of procedure	2.18	5.00
TB2, Chemical treatment		Y	R
Active corrosion inhibition system	Capacity of injection	3.28	1.96
Managing chemical treatment	Competence and training	1.46	6.00
TB3, Cleaning pigging		Y	R
Maintenance	Compliance to schedule	2.69	4.39
Managing pigging/equipment selection	Experience	2.69	3.52
$T_{2,3}$, Combination of T2 and T3		W	G
E, Material degradation		G	DR
CB1, Operational strategy		Y	R
Regular inspection	Overdue inspection	2.60	5.76
Unscheduled inspection	Formalization and availability of procedure	3.17	5.30
Production strategy	Competence and training	5.05	4.77
C1, Loss of containment		W	R

5 DISCUSSION

The results illustrated by Table 3 give two representative examples of how the proposed model can be applied to assess the risk of loss of containment on the basis of the state of the threats and the performance of the barriers.

In the first case (t_1), a random value from 1 to 6 was defined for each indicator. This simulation does not only represent a possible average condition of the system, but shows also how threats with a relatively critical state (all the threats have a yellow state—Table 3) can be mitigated by the safety barriers in place.

In fact, the performance of the barrier TB1 is satisfactory (green performance) and can effectively mitigate the threat of exceeding sand production rate. The performance of the barriers TB2 and TB3 may be improved (yellow performance), but it is enough to mitigate the two threats, which in turn have only a partial weight on $T_{2,3}$. For this reason, this last element has an optimal state (white state).

In t_1 the state of material degradation is acceptable (green state) and this leads to an optimal value of loss of containment risk, described by the white color.

In the second case (t_2), a value between 5 and 6 was given to the representative indicators shown in Table 3 describing the exceeding sand production rate and the related barrier. Thus, T1 and TB1 have respectively a very critical state and performance (red state and performance—the state is not dark red because other indicators with random values were also considered for T1 and TB1). This very critical condition is reflected by the state of material degradation (dark red state because it consider also the contribution of T2 and T3) and the overall risk of loss of containment (red risk because the performance of the barrier CB1 is very critical itself and is not enough to mitigate E).

These two examples demonstrate the importance of threats and barriers. The firsts are a serious issue that should be adequately treated. The seconds are part of the treatment strategy and their performance is essential for the prevention of the overall risk.

5.1 *Future developments*

This study is still ongoing and there are several aspects that need further development and may become interesting topics for future research.

First of all, aggregation of data may lead to several issues. In fact, the indicators defined are collected on different levels of the system and in some cases represent only a part of it. For instance, the acoustic sand detection is performed on the well level, the erosion probes are applied on the flow-line level and the daily output of production data addresses the whole system. It should be investigated what is the best option for the aggregation of indicators. For example, should these indicators on the well/flow-line level aggregated into one indicator or considered singularly?

Moreover, the combination of T_2 and T_3 ($T_{2,3}$) is carried out by means of a weighted sum. This approach is justified by the fact that the model should be kept relatively simple and directly understandable by the operative personnel. In fact, operators would possibly trust more the risk prediction of a model they can understand than a black-box model based on complex data elaboration. However, this choice should be demonstrated by appropriate on-field tests.

Finally, the gravel pack and the erosion/corrosion allowance are not considered in the analysis because there cannot be a direct control on them and their performance cannot be actively improved if needed. Thus, this model makes the assumption that these two barriers performance is constant and does not affect the dynamic assessment of loss of containment risk. However, the ageing of the two systems is an important aspect to be considered. In particular, if the erosion/corrosion allowance is in a critical state, decision-makers will have to take different decisions and properly respond to this serious issue.

For this reason, these two barriers should be re-considered in future research activities, together with an appropriate modelling of their degradation with time. This would produce a more reliable prediction of the risk of loss of containment and improve the dynamic modelling of the system.

6 CONCLUSIONS

A dynamic method is described to follow up on the current risk level of an activity, by utilizing indicators to assess both the current state of the threats and performance of relevant safety barriers to prevent/mitigate the effect of unwanted events/scenarios. This method aims to give the personnel of oil companies a support in critical decisions concerning safety barrier management.

An example is given, considering the threats of erosion/corrosion in the petroleum production. This example shows how the proposed model deals with different operative conditions and how the risk of loss of containment is affected by them. In this way, the importance of both the state of the threats and the performance of the barriers is demonstrated. An effective action of risk prevention should be then focused on both of them by giving priority to the improvement of poor barriers connected to critical threats.

Finally, some related topics for future research activity were identified. In fact, this is an ongoing study and there is still room for improvement. For this reason, future developments of this model are being planned, in order to refine what was outlined in this first phases and further investigate a topical

and challenging field such as real-time assessment of risk.

ABSTRACT: Most of the available risk management methods are not directly applicable to academic research laboratories. One solution to systematically perform risk analyses in this environment is the Laboratory Assessment and Risk Analysis (LARA) method. This method was developed to allow untrained personnel to identify of possible risks and rank them according to their importance. The purpose of this study was to find out, if this method can be used as a holistic risk management technique in different environments, and which are the differences when comparing the results to other, well-established risk analysis techniques. The risk analyses were performed at two European universities and for various procedures. The results show, that the LARA procedure ismore easily performable and giving more adequate results than the other methods. Being applicable by non-experts, this holistic risk analysis method for research laboratories can help to reduce the accident rate in the academic environment.

1 INTRODUCTION

In most sectors of industry, the rate of occupational accidents decreased during the past decades. This fact is due to intensified efforts in occupational safety as well as more strict regulations and laws. Risk management techniques helped to guide those efforts in the desired direction, since they help to allocate the measures according to the relative importance of risks. Most of those methods originate from a specific field of application and are suited for the demands of this field (e.g. Hazard and Operability studies (HAZOP) for the chemical industry (Bluvband et al. 2004)). For academic research laboratories, such a specific technique was never developed; existing methods are often only working for a definite application and cannot be used to perform a risk analysis in different fields (Pluess et al. 2013). Since improving occupational safety gained more importance at universities after various accidents (Marendaz et al. 2013), there is a need for specific risk management technique for research laboratories (American Chemical Society, 2013).

Various solutions were presented in the literature (Kremer et al. 2009, Langerman 2009). However, those methods are still too specialized to serve as a universal risk analysis method for academic research and teaching laboratories (Pluess et al. 2013). A new approach to fulfill the demands of academic research is the Laboratory Assessment and Risk Analysis (LARA) method (Ouedraogo et al. 2011). This method was developed at the Ecole Polytechnique Fédérale de Lausanne (EPFL) to analyze and manage risks even for non-experts and facilitate the risk management process at universities. One of the main features of LARA is taking into account the special setting of this environment (e.g. high personnel turnover, emerging technologies, etc.) and including synergies between different risks (Pluess et al. 2013).

Since the method was developed based on safety regulations of EPFL and originates from its safety culture, the feasibility of LARA to other environments was not demonstrated yet. For the further development and the improvement, the adaption to other universities is a crucial element. The use of LARA at other universities can help to find improvement potential and is able to show if untrained personnel with different occupational safety background can fully benefit of this risk management method. For this reason, joint tests were performed at the Institute of Energetic Materials at the University of Pardubice (Czech Republic) and the Institute of Chemical Sciences and Engineering (ISIC) of EPFL (Switzerland).

The purpose of this study is to answer following question: "can the LARA method be used as a holistic risk management technique in different academic environments and what are the main differences when comparing to the results obtained by industrial risk analysis techniques?" In order to answer these questions, risk analyses of different procedures were performed using LARA, Failure Mode, Effects, and Criticality Analysis (FMECA), and HAZOP. The experiments analyzed are standard operations performed at University of Pardubice and at EPFL. The main differences of the results using the different methods will be pointed out and compared.

2 METHODS

In order to compare the results of LARA with well-established risk management methods, two examples were selected: one from the University of Pardubice and one from EPFL. To have a variety of laboratory tasks, both chemical experiments and routine tasks were considered in the comparison. The first example was analyzed using the LARA method and a HAZOP procedure, whereas the second example was analyzed using the LARA method and the FMECA procedure. Both of these risk analysis procedures are widely acceptedtools to identify and manage risks (Bluvband et al. 2004).

The joint tests described in this article are performed under conditions that simulate the environment for which the method is intended. The risk evaluations were performed and guided by a group of scientists, being familiar with the methods and having experience in performing FMECA and HAZOP procedures. For the LARA method, those scientists had a short introduction, but no information about the principles of the method. This was intended, since non-experts are the designated users of the LARA method. The scientists involved in the experiments provided the analysts with all information necessary, including details about the laboratory environment.

The test results highlight the different aspects of this new method to assess laboratory risks. The results do not only focus on the successfully evaluated risks, but also on the other factors of the evaluation, such as prerequisites and effort to perform the analysis. The tests provides us with answers for questions whether if the LARA method is easily performed, how quick it can be completed and if it is capable to uncover all risks connected with an experiment. In this article we focus on identification and evaluation of the risks; we omit the aspect of applying corrective measures, which is important part of risk analyses, but is not as relevant for this comparison.

2.1 *HAZOP*

The HAZOP technique is as systematic approach to investigate the processes by determining possible deviations from the process intentions and consecutive effects on whole facility. Its strength is in dividing assessed process in the small sections called nodes and thus ensuring examination of each part of the system. The nodes are analyzed by a small multi-disciplinary team, whose members should be able to answer the most questions about given issue on spot. The members have the authority to recommend anyneeded changes in design (Dunjoa et al. 2010).

This scenario-based method relies on using guidewords (e.g. as, no, more, less) in combination of process parameters (such as temperature, pressure, flow). The aim of this combination is to reveal deviations from the process intention (e.g. no flow, more temperature, less pressure). There is a defined list of guidewords, which are applied on each examined node. Once deviations are determined, their possible causes and consequences are discussed by the team of experts. For both cause and consequence safeguards must be identified. The safeguards are corrective measures that could prevent, detect or mitigate the hazardous situation. If there are not feasible safeguards, a change in intended design must be considered (Guidelines for Hazard Evaluation Procedures, 2011).

2.2 *FMECA*

The FMEA systematically analyze a system for potential failures and their consequences on the system. The procedure divides a process or a system into specific components according to their function. Then, the possible failure modes are determined on every component. Failure mode describes how equipment could fail, what will happen if operated improperly and how the failure could cause an accident or contribute to accidents occurrence. Once the failure modes are determined, the systems response to the failure leads to a certain effect. The effects provide a feedback for determining where system changes or improvements should be made (Guidelines for Hazard Evaluation Procedures, 2011). Each individual failure is considered independently without a relation to other failures in the system, except for the subsequent effects it can produce. Results of this procedure are qualitative unless FMEA is extended to FMECA by including the criticality of the failure mode; the priority ranking is based on the failures severity and their probability (R.I. Wagoner 1988). FMECA uses quantitative or semi-quantitative scales to describe the likelihood and impact of a potential incident. After assigning likelihood of occurrence and impact values to each incident, a

matrix is used to prioritize incidents importance (W.E. Jordan 1982).

2.3 *LARA*

During the past several years, various severe accidents (injury and death of scientists, financial losses, and interruptions of the scientific research as consequences) happened at different universities worldwide (Marendaz et al. 2013), emphasizing the need to improve the occupational safety and health in this environment. Differences between research and industrial environment (e.g. equipment and processes at development stage, high turnover of collaborators, scarce statistical data on reliability and accidents) made attempts difficult to implement existing risk analysis methods and are not leading to useful results (Ouedraogo et al. 2011). Solutions for this problem were already presented in the literature, e.g. for biology (Kremer et al. 2009) and chemistry (Langerman 2009). However, most of them focus on a narrow field of scientific research, such as biology. In order to tackle this problem, EPFL's Group for Chemical and Physical Safety (GSCP) is currently developing a holistic risk analysis technique for the academic research setting, called LARA. The goal of this development is to design a risk management method with following properties (Pluess et al. 2013):

- Easily performable by non-experts.
- Less resource-demanding compared to other available methods.
- Semi-quantitative and improved risk estimation.
- Consider the special conditions encountered in academic research laboratories.

First results of risk analyses for different sectors of the academic research environment were already presented by (Ouedraogo et al. 2011). Based on the development, a web application software was developed. The workflow of the LARA method is presented as following:

1. Risk identification: every element (equipment, chemicals and activities) involved in a process is determined. Based on these elements, each hazard present in this process is selected out of a database. This database contains a large number of different hazard categories, based on regulations, past accident data, measurements and expertise. Additionally, the users of the software are able to suggest hazards and expand the database.
2. Risk description: the semi-quantitative risk estimation is a crucial element to reach the goals of the method. In such an estimation method, verbal statements are used to describe the risk factors. According to these verbal statements, a value on a numerical scale is assigned for each hazard. For all the variables a scale of integer numbers between one and five was used. LARA uses four different main factors to describe and estimate the risk related to a hazard: severity, probability, detectability and worsening factors.

   To improve the risk estimation and to take into account the special conditions in academic research laboratories, GSCP introduced the concept of worsening factors (Ouedraogo et al. 2011, Pluess et al. 2013) in addition to the commonly used elements in different risk analysis techniques (severity, probability and detectability). This new concept integrates specificities of research laboratories, which can aggravate the outcome or the probability of an accident. GSCP classified this worsening factors into three groups: general worsening factors are those types of influences which are not directly related to a certain kind of hazard, but which can influence the probability, the severity or the detectability. Hazard-specific worsening factors are directly influencing a certain risk. Synergetic worsening factors are describing synergies between two risks, in particular situations where a risk can be worsened or enabled by the presence of another risk (Pluess et al. 2013).
3. Risk calculation: GSCP developed a new method using Bayesian networks to calculate a risk index called Laboratory Criticality Index (LCI) for each hazard. This improved method is based on Bayesian networks, being used in various applications of risk management (Marhavilas et al. 2011). Bayesian networks are using probability tables (Fenton and Neil 2012) with different states for each node of the network. For LARA, these states represent the different verbal statements for a risk factor. The probability tables used for the factors were created using a ranked node concept described by Fenton et al. (2007). This concept helps to generate the probability tables using truncated Gaussian probability distributions. For better comparison of the differentrisks, the LCI is finally calculated as single crisp number (this calculation is based on a method presented by Yang et al. (2008)). This calculation approach based on Bayesian network is capable of overcoming various disadvantages of other risk estimation methods used in semi-quantitative risk analysis by giving reliable results with a constant variance through the whole spectrum of the results (Pluess et al. 2013).
4. Risk mitigation: Once the LCI value for each hazard is determined, the risk mitigation takes place. The board of the institution sets the limits, which LCI values are not acceptable and which are acceptable. For risks with an acceptable LCI value, no measure is necessary to pro-

ceed with the experiment. The unacceptable risks are treated regardless of the costs and the effort necessary and are re-evaluated. The risks, which are neither acceptable nor unacceptable, should be reduced As Low As Reasonably Practicable (ALARP). Since the academic environment has different demands than the industrial sector, the choice of corrective measures is realized using an allocation matrix. With this matrix, other aspects, such as acceptance and feasibility of the corrective measures are taken into account as well.

3 RESULTS

3.1 *Example 1: Synthesis of methyl nitrate*

Description of process: There is an intention to produce methyl nitrate for testing reasons at the Institute of Energetic Materials of the University of Pardubice. This uncommon, sensitive liquid explosive should be produced regularly in amounts of several kilograms. The synthesis and the product properties are well described in literature (Black 1943). Although the process itself does exhibit difficulties, it requires a certain level of experience. The laboratory intended for the preparation of this explosive does not differ much from standard laboratories equipped for organic synthesis. A couple of tests have been already performed in smaller amounts.

The synthesis is carried out in a beaker. A mixture of nitric and sulfuric acid is poured into a beaker. Methanol is then added dropwise while the reaction mixture is stirred well and cooled in an ice bath. The temperature of the reaction mixture must be kept between 15–20°C. When the whole amount of methanol is added, the reaction mixture is left for five minutes at room temperature. Methyl nitrate is separated from the acid residue, washed with cold water and sodium carbonate solution.

An accident occurred during one of the test synthesis; a sudden decomposition of the product occurred. Later it was discovered that this was caused by the presence of ricin oil in methanol, which was used as a key precursor for methyl nitrate. It is highly probable that if the decomposition would have occurred in larger amounts, it would have caused an explosion.

Safety aspects of the synthesis were discussed with the leader of the project. According to his statement the most important risk is connected with sensitivity of methyl nitrate even a small friction in a part of the equipment used for the synthesis could lead to an explosion. The accident mentioned above emphasizes that only pure chemicals (p.a.) should be used for this synthesis. The acids and toxic materials present during this synthesis may lead to increased risks as well, but can be reduced to minimum by appropriate safety measures.

HAZOP results: The HAZOP analysis was performed according to BS IEC 61882:2001 by the team consisting of organic chemists, explosives and safety engineering experts. The synthesis was divided into six nodes: methanol nitration, stirring, cooling, pouring into separation funnel, separation and washing. Overall eighty-eight deviations were considered. Table 1 shows the six most serious hazards of the methyl nitrate synthesis. However HAZOP does not provide the quantitative risks evaluation and prioritization, therefore the relative importance of risks were chosen according to the experts opinions. The analysis is well performable on a laboratory scale, although is designed mainly for industrial environment. HAZOP gives appropriate results and reflects the experience and predictions of experts. Despite the applicability and realistic results, the procedure is relatively complicated, time and resources consuming and not suited to be performed by non-expert.

LARA results: LARA analysis performed by the same scientists revealed that all 15 identified risks arise from hazardous properties of the involved substances. The relevance of the analysis results is given by risk prioritization, which corresponds to the particular laboratory practice. The procedure determined that methyl nitrate explosives properties have the highest risk priority. Among

Table 1. Most important risks according to HAZOP.

No.	Guideword	Element	Deviation	Possible causes	Consequences
1	More	Methanol	Faster dropping	Funnel valve leaky	Exothermic reaction, explosion
2	As well as	Methanol	Impure methanol	Error at supplier	Exothermic reaction, explosion
3	As well as	Separation funnel	Valve grease washout	Inappropriate grease	Exothermic reaction, explosion
4	No	Stirring	No stirring	Stirrer failure	Local overheating, explosion
5	Other than	Pouring	Reaction mixture poured out	Personnel failure	Irritation and intoxication
6	No	Separation funnel	Valve grease not applied	Personnel failure	Explosion caused by friction

the risks with highest importance belongs methyl nitrate toxicity, corrosive effects of nitric acid and methanol flammability. All these risks are mentioned in laboratory rules and personnel is periodically familiarized with them during safety training. The most important risks according to this analysis are presented in Table 2.

Comparison: Table 1 and Table 2 reveals the most important hazards of this activity based on the results of both analyses. Almost all deviations identified by HAZOP lead to exothermic reaction and/or explosion of methyl nitrate. According to LARA, explosive properties of methyl nitrate have the highest priority. However these results do not reflect the experiences of the experts who performed HAZOP analysis, thus it is not so clear in which particular situation methyl nitrate explosive properties could exert. Remaining risks determined by LARA procedure are connected with the effect of involved substances on the personnel. This is in agreement with the deviation pointing out leakage of the reaction mixture identified by HAZOP.

3.2 *Example 2: Medium scale purification of solvents*

Description of process: the second example, which was chosen to test the LARA method, is the purification of larger quantities of solvents. This process is realized at the laboratory of asymmetric catalysis and synthesis (LCSA) at EPFL. Large amounts of solvents, mainly ethyl acetate and pentane, are used in this laboratory for chromatographic purposes. Since the commonly available solvents are not sufficiently pure enough, a further purification is performed directly in the lab. The task is realized according to a planning, which obligates each member of the group to perform this process periodically. Even thought the task is planned and recurring, there is no Standard Operation Procedure (SOP) available.

Table 2. Most important risks according to LARA.

No.	Risk
1	Explosion caused by methyl nitrate
2	Intoxication (inhalation) caused by methyl nitrate
3	Intoxication (skin) caused by methyl nitrate
4	Irritation (skin) caused by methyl nitrate
5	Intoxication (oral) caused by methyl nitrate

For the purification, a Heidolph LABOROTA 20 medium scale rotary evaporator was used. The purification is realized several times per week with a quantity between 5 L and 10 L of solvent each time. For the ethyl acetate, the device is heated to 50°C and the pressure was set to 25 kPa. For the purification of pentane, the device was heated to 50°C and the pressure was set to 95 kPa. Until now, no accidents have occurred. According to the responsible scientist, the main risk in this process is related to the flammability of the solvents. Other hazards related to the chemical properties of the solvents, such as the hazards for the environment or toxicity, are estimated to be negligible.

FMECA results: a team of scientists performed a systematical risk analysis of the most important components using the FMECA method. In total, 29 potential failures were identified and their relative priorities for applying measures were determined. Seven of these failure modes are only influencing the operability itself and are not relevant form a safety point of view. From the remaining 22 failure modes, 6 are related to mechanical operations and the remaining 16 are indirectly related to the hazardous properties of the solvents. Since those properties are not directly evaluated by the procedure, the relative importance and magnitude of the effects remain unclear after the FMECA analysis.

LARA results: the same team of scientists used the LARA method to perform a risk analysis on this activity. This analysis revealed nine different hazards originating from different sources (chemicals and devices). All of those hazards are relevant from an occupational safety point of view. Four of the hazards are directly related to the hazardous properties of the solvents. The other five hazards present according to the LARA analysis are related to mechanical or physical risk.

Comparison: Table 3 shows the most important hazards of this activity based on the results

Table 3. Comparison of the risk priorities in example 2 using LARA and FMECA method.

Hazard	Risk	Priority in LARA	Priority in FMECA
Blast shield	Injuries due to unintended closing	2	1
Lowering mechanism	Injuries due to pinching	2	5
Toxic substance (solvent)	Intoxication by inhalation	1	2/3/4
Irritating substance (solvent)	Eye irritation	3	2/3/4
Flammable substance (solvent)	Fire	5	2/3/4

of both analyses. The most important hazard determined by the LARA method is the toxic properties (aspiration toxicity) of both solvents. In the FMECA analysis, the toxicity is indirectly related to the failure modes with the relative priority 2, 3 and 4 (all those failure modes are leading to leakage of solvent). Based on the FMECA method, the blast shield of the apparatus is the most hazardous element of this process, which is ranked second in the LARA method. The mechanical hazards do have the same importance according to the LARA method, since both do have similar occurrences and exposures. The FMECA analysis however ranked the similar hazards in a different order, even though the hazards are comparable. The FMECA analysis fails to differentiate between the different hazards originating from the chemical properties of the solvent.

4 DISCUSSION

The results of this study suggest, that the LARA can be used as a holistic risk analysis method in the academic laboratory environment. Even though only two examples were examined, the joint test at two universities showed the advantages compared to established risk analysis techniques.

One of the most important features of a risk management method is the capability to identify risks. Since no method is able to identify all the possible risks, an appropriate method should be capable of discovering the most important risks of a process. On the contrary, the more risks a method can identify, the higher is the probability to identify scenarios, which are either highly improbable or of no importance for occupational safety. In the first example, the HAZOP procedure identifies several scenarios, which are influencing the performance of the process, but are not important to the safety of the involved scientists. Such irrelevant scenarios (in terms of safety) can detract from the safety-related relevant scenarios; additionally, they are extending the analysis itself in terms of complexity. The LARA method is capable of identifying the same relevant scenarios as the HAZOP method. Additionally, the method is able of identifying relations, which the HAZOP procedure is not capable of. The same results were shown in the second example, comparing the results from LARA with the ones of the FMECA procedure.

The effort needed to perform a risk analysis is another important aspect, which influences the feasibility of a method. An ideal risk analysis method for academic research laboratories should not require too demanding resources, since both qualified personnel in safety and time is a rare commodity in this environment. The systematic approach of the HAZOP procedure is not complex itself; however, in order to perform the analysis, an experienced user (the HAZOP moderator) needs to participate to find most of the scenarios. In contrast, the examined example showed that the LARA method is more intuitive when performing the risk analysis. Both methods anyhow need expertise about the process, but LARA needs less experience about the risk management method itself.

However, the comparison has shown some limitations of the LARA method as well. The method relies on a database, and is therefore as accurate as the database is. This drawback can be overcome by systematic use of the software at universities in order to fill the databases with possible hazards and risks.

5 CONCLUSIONS

Since there is no dedicated technique, performing risk analysis in academic research and teaching environment is a challenging task. Nevertheless, being aware of the possible risk is crucial in an environment dealing with emerging technologies and equipment in experimental states. Even though the impact might be less significant compared to accidents in the industry, the accident rate is still unacceptably high. To lower this rate, a specific and holistic risk management method serves as an important tool. The LARA method is such an approach; it was developed specifically for the use at universities and research laboratories. Different experiments and procedures, performed at two European universities were analyzed using the LARA method and compared to well-established risk management techniques. This comparison shows the capability of LARA to be used as a holistic approach, used in various fields of research and for various kinds of tasks. The findings in this article emphasizes that an academic environment could benefit from the introduction of this technique. In order to integrate this method to an environment, it should be embedded into an existing safety framework. Further studies will be comparing more examples and the ease of implementing this technique into such an existing safety framework.

ABSTRACT: In this paper, we have applied a quantitative risk assessment method to map cumulative risk levels arising from a number of hazardous installations located in Haldia, one of the industrial towns of India. The methodology consists of the following steps: frequency and consequences assessment of the select reference accident scearos; estimation of grid-level population distribution using a dasymetric interpolation approach; and finally risk estimation using both individual and societal risk metric. The risk maps were prepared in using common GIS tools and functions, and their sensitivity to various factors ascertained using uncertainty analysis techniques.

Keywords: industrial accidents; population estimation; societal risk estimation; landuse planning; India

1 INTRODUCTION

Over the last few decades, a number of large-scale industrial accidents have occurred world-wide, resulting in damage and loss of life in the surroundings. Among these events, the Bhopal accident in India (1984) is ranked as the world's worst ever industrial catastrophe. In the neighbourhood of the Union Carbide plant, more than 150 people died within a few minutes because of acute exposure to the highly toxic methyl iso-cyanate gas which had leaked and dispersed into the air; within a few days of the accident more than a thousand people died (Lees, 1996). Amongst many other reasons, lack of restrictions in uses of land in the surrounding of highly hazardous industrial site and presence of densely populated residential areas in close proximity, were reported as the key reasons for resulting into high number of fatalities in Bhopal.

However, even several decades after the Bhopal accident, there has been no significant improvement with regard to management of risk originating from hazardous industries in India (NDMA, 2007). At present, the country is densely populated and is home to about 17% of the world's population in roughly 2% of total available land area. With steady economic development, there has been considerable growth in the manufacturing sector during the last two decades, including a large number of hazardous industries. According to the inventory available with central agencies, as of 2008, there were 1949 Major Accident Hazard (MAH) establishments located in 260 districts (MoEF and CPCB, 2008) and since then the numbers have grown further. Many of these establishments co-locate in industrial towns to take advantage of common infrastructural facilities. 170 such towns were identified to have a cluster of more than 5 MAH units, when the inventory was being undertaken. Acting as engines of industrial and economic growth, these towns often witness steady influx of population thus resulting in increasing levels of risk.

Nonetheless such a situation is not typical of India alone—many industrialized western European countries have encountered similar challenges in the past and evolved systematic methods for assessing risk from hazardous industries which then led to the adoption of suitable risk reduction strategies (Pasman and Reniers, 2013). In order to assess cumulative risk arising from a cluster of hazardous industrial establishments and to evaluate options for area level risk mitigation measures, few studies were carried out in countries like Netherlands, UK and Italy during the 1970's. Some examples of these studies include those undertaken in Rijnmond, the Netherlands, Canvey Island in the UK and the Ravenna area in Italy etc. But then, it is only after the accidents in Bhopal

and Mexico (both happened in 1984), importance of restricting the uses of land around hazardous installations became widely accepted throughout the EU Member States as a measure for limiting the adverse effects of such accidents.

Accordingly, the first EU Directive 82/501/EEC—so called Seveso Directive of 1982, focused on the prevention of major accidents, was amended to the Seveso Directive II (96/82/EC). Following the Directive II, EU Member States have laid down different approaches for risk assessment and acceptability or tolerability thresholds in accordance to their political, cultural, technical, legal and societal backgrounds (Christou, Struckel, et al., 2006). These methods range from a consequence-based approach to a risk-based approach based on results of Quantitative Risk Assessment (QRA) as practiced in the Netherlands and the UK (Hauptmanns, 2005). Countries like France and Italy have formulated a hybrid approach as a combination of both approaches (Cozzani, Bandini, et al., 2006; Taveau, 2010).

In India, though certain regulations deal with the safe siting of hazardous industries, but the legal provisions often do not provide any specific criteria which can guide landuse planning decisions. Section 41 A of the Factories Act (MoL, GOI, 1987) requires that the location of hazardous industries has to be evaluated from the safety point of view by a site appraisal committee; however fails to provide a mechanism through which such siting decisions can be linked to landuse planning considerations for an industrial area. Although the EIA Notification (MoEF, GOI, 2006) does provide the scope for assessment of risk originating from new hazardous industries, but in practice these EIA studies seldom evaluate the alternative sites based on risk contribution to the neighbourhood communities or provide recommendations for mitigating offsite consequences from potential accidents. Besides, the Central Pollution Control Board (CPCB) of India prepared the 'Zoning Atlas for Siting of Industries' taking environmental considerations into account, but risk is yet to be factored into criteria for zoning of an industrial area (Punihani, Ravi, et al., 2002). The Zoning Atlas even fails to provide a linkage to the existing landuse planning framework as proposed by the Urban Development Plans Formulation & Implementation (UDPFI) guideline (MoUA&E, GOI, 1996). Later, at the Second India Disaster Management Congress (2009), a consensus was reached on the need for adoption of landuse planning principles as a strategy for risk reduction and mitigation (NIDM, 2009).

However, for the adoption of a systematic approach for risk informed landuse planning in any industrial town, the availability of information on the hazards present in industries and the vulnerability in the surrounding residential areas are vital. In India, an effort to consolidate such information was made through the Risk Management Information System (RMIS) which is capable of storing spatial and related attribute data of industries, including nature of the chemicals that they stored or handled, storage conditions, also information about vulnerabilities in terms of exposed buildings and population at different time periods (Bandyopadhyay, Sengupta, et al., 2011).

The key objective of this research is to apply a methodology based on Quantitative Risk Assessment (QRA), with necessary adaptation, for estimating and spatially representing cumulative risk originating from a cluster of hazardous industries, based on spatial and related attribute information available in the RMIS database. In doing so, we evaluated whether techniques that have been developed and applied in the Netherlands or the UK, could suitably be adapted to an Indian context, using simple GIS tools and techniques. In this study, we have calculated cumulative risk levels, taking into consideration reference accident scenarios from several hazardous units, and spatially overlaying them to arrive at a measure of risk in terms of probable fatalities to resident population. This method can result in the formulation of deterministic risk metrics based on scientific rationale, which can then be used to guide risk informed landuse planning decisions for the area in question.

2 STUDY AREA

The study was carried out in Haldia, near the metropolitan city of Kolkata in West Bengal. The Haldia industrial area, one of the largest industrial areas in the eastern part of India, is supported by a large port complex and other infrastructural facilities (Fig. 1). Presently there are 42 industrial units, of which 17 are identified as MAH industries according to the Manufacture Storage and Import

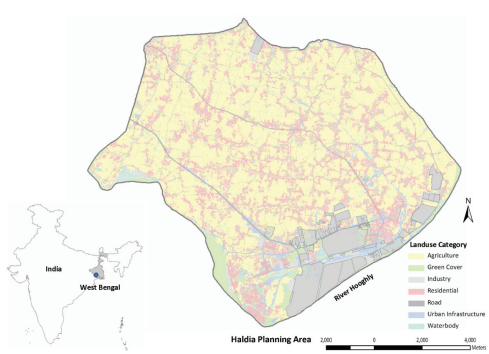

Figure 1. Location of Haldia in India.

of Hazardous Chemicals (MSIHC) Rules 1989 and subsequently amended in 2000 (MoEF, GOI, 2000). Several new industries are also planned in this area. These industrial units are juxtaposed with residential areas with a total population of about 170,000 persons (as per Census 2001), including a large area with informal settlements in close vicinity of these hazardous industries.

3 METHODOLOGY

In this research, we applied a QRA-based approach to estimate the risk originating from hazardous industries for surrounding communities and also to assess the degree of effectiveness of such a risk measure for guiding the landuse planning decisions in the area. In the following sections, the steps are described.

3.1 *Scenario selection*

An accident scenario is one of many specific situations that might evolve at the end of an accident sequence. Here, we have considered eight accident scenarios of Vapour Cloud Explosion (VCE), Boiling Liquid Expanding Vapour Explosion (BLEVE) and toxic release events originating from different hazardous industries located in the study area (Fig. 2). The as 'reference scenarios' were selected with an inherent assumption of having the potential of causing Maximum Credible Loss (MCL) (Khan and Abbasi, 2002) as identified on the basis of facility level risk assessment (Table 1).

For each scenario, possible release types for example pipe rupture, formation of holes in pressurized vessels, major or catastrophic failure etc. were identified which can cause in high loss of life in the surroundings. To ensure that the method remains workable, we propose that a select number of credible accident scenarios per industry, which may lead to potential offsite consequences, be considered.

Figure 2. Location of storages for reference scenarios.

Table 1. Scenario description.

ID	Installation	Containment	Frequency*	Capacity
A	Tank	Motor spirit	$5 \cdot 10^{-6}$ (1)	4200 MT
B	Tank	Ammonia	$4 \cdot 10^{-4}$ (2)	10000 MT
C	Tank	Motor spirit	$2.5 \cdot 10^{-3}$ (1)	24150 MT
D	Tonner	Chlorine	$4 \cdot 10^{-6}$ (3)	1MT
E	Tank	Motor spirit	$1 \cdot 10^{-4}$ (1)	xx
F	Bullet	Propane	$5 \cdot 10^{-6}$ (4)	160 MT
G	Sphere	Butane	$9 \cdot 10^{-7}$ (5)	915 MT
H	Bullet	Butane	$1 \cdot 10^{-5}$ (4)	30 MT

*Numbers in the brackets are corresponding references listed at the footnote.

3.2 *Assigning frequency and probability*

Once the possible scenarios are selected, the next step in QRA requires the estimation of their frequencies. However a review of several industry-specific risk assessment reports of MAH establishments in Haldia point to an absence of any definitive estimate of failures that could result in a major accident with potential offsite consequences. Even at a broader level, no such failure frequency statistics is also known to exist in India. As an alternative, we have used generic failure-frequency databases, such as the TNO's Purple Book, the HSE's Failure Rate and Event Database (FRED) etc. The assigned frequency for the above mentioned scenarios from the available HSE's Failure Rate and Event Database is presented in Table1.

Additionally, in contemporary QRA methodology, the potential incidents for which data is available from failure-frequency databases are further analyzed to obtain the conditional probabilities of a range of possible accident sequences. However, in the present research, the probability of an accident sequence was considered to be equal to the probability of the initiating event (i.e., no mitigation measures were considered) due to the lack of information.

3.3 *Consequence assessment*

The consequence assessment involves determining the impact of an event in terms of its physical extent

[1]Derived from historical data by Glossop (HSE internal report: RAS/01/06); pp. 9.
[2]Documented in a HSE internal report (RAS/00/10) by J. Gould; pp.14.
[3]Reported in the Major Hazard Assessment Unit Handbook; pp. 23.
[4]Documented in a HSE internal report (RAS/06/04) by Keeley and Prinja; pp. 33.
[5]Proposed by M. Selway, 1988; pp. 26.

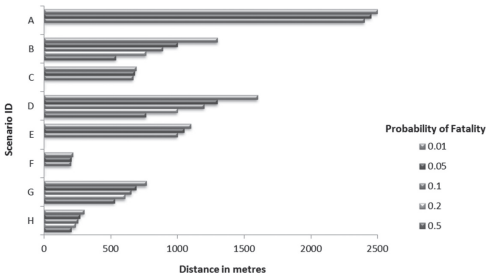

Figure 3. Effect-distances of the reference scenarios.

and severity (Lees, 1996). The physical extent of an accident scenario usually involves the calculation of the effect-distance (i.e. maximum distance with certain intensity) from the source within which people might get affected. The severity of an event is expressed as the level of harm to people such as injury or fatality. Existing QRA approaches generally apply two sets of models for estimating the consequences of an accident scenario: a mathematical model to predict the physical effect (i.e. thermal radiation, overpressure and toxic dose) of an accident and vulnerability model to estimate the impact of an accident on humans (Fabbri and Contini, 2009).

In this research, physical effects of the reference scenarios were calculated using ALOHA[6], one of the widely accepted atmospheric dispersion model used for evaluating releases of hazardous chemical vapors, including toxic gas clouds, fires, and explosions. For calculation purpose, we used data about the hazardous facilities, as obtained from the RMIS database and the most frequently occurring atmospheric condition with an average wind speed of 3.0 m/s, 35°C temperature and stability class of D as input parameters.

The severity of the accident scenarios was estimated in terms of fatalities that may because due to effects of thermal radiation, overpressure wave or concentration of toxic substances. The damage potential in terms of death of a non-protected person from such phenomena was estimated based on threshold values used have been derived from Probit functions as represented in the following equations:

Thermal Radiation:

$$Pr = -14.9 + 2.56 \ln (Q4/3 \cdot t_1) \quad (1)$$

Overpressure:

$$Pr = 1.47 + 1.37 \ln (p) \quad (2)$$

[6]Areal Location of Hazardous Atmospheres

Table 2. Threshold values used.

	Radiation[8]	Overpressure[9]	Toxic release[10]	
PF[7]	Butane	Propane, MS	Chlorine	Ammonia
1	65.00	120.00	8000	18000
0.5	26.50	13.10	870	4000
0.2	20.78	7.15	470	2525
0.1	18.25	5.20	340	2030
0.05	16.42	3.95	260	1680
0.01	13.42	2.40	160	1200

Toxic release:

$$Pr = a + b \cdot \ln (Cn \cdot t_2) \quad (3)$$

where,
Pr = Probit corresponding to the probability of death;
Q = Heat radiation (kW/m^2);
t_1 = Exposure time (sec);
p = Peak overpressure (psig);
Cn = Concentration (mg/m^3);
t_2 = Exposure time (minutes); and
a, b, n = Constants describing the toxicity of a substance.

The calculated threshold values for each reference scenario for different levels of fatality mentioned above are shown in Table 2. Accordingly, the effect-distances calculated for 1, 5, 10, 20 and 50 percent fatality were then overlaid on the map of the area concerned using GIS technique, to visualize the spatial spread of the scenario impact in terms of fatality. The effect-distances were mapped with respect to the storage associated with the identified accident scenario as the point of origin.

3.4 *Risk estimation*

Finally, risk was estimated by combining frequency (section 3.2) with their consequences (section 3.3). As risk to the people concerned, two indices were used: individual risk and societal risk.

3.4.1 *Individual risk*

Individual Risk (IR) is the probability at which an individual may be expected to sustain a given level of harm from the realization of specified hazards (ICheM, 1985). In simple terms it measures the distribution of risk over an area in order to adopt

[7]Measured in mg/m^3.
[8]Probability of Fatality (%).
[9]Measured in kW/m^2.
[10]Measured in psi.

measures that reduce risk to an acceptable level. Generally, the IR estimation takes into account an annual frequency of occurrence of a reference damage (e.g. fatalities) in any area for a person present 24 hours/day and 365 days/year without protection and possibility of being sheltered or evacuated.

Graphically IR can be represented as a set of risk contours around a hazardous installation. In order to generate individual-risk contours, it first requires to estimating the effect of all individual scenarios at each location. Accordingly, risk resulting from each reference scenario was estimated combining frequency of the initiating event (i.e. incident), conditional probability of the scenario (i.e. sequence) and the corresponding probability of fatality (i.e. Probit). In particular, the following expression was used to estimate IR at a given location for a particular accident scenario.

$$IR_{(x,y,i)} = [f_i \cdot PF_i] = [(f_{\text{incident i}} \cdot P_{sequence\ i}) \cdot PF_i] \quad (4)$$

where: $IR_{(x,y,i)}$ is the individual risk at the geographical location (x, y) for a particular reference scenario I, f_i is the frequency of occurrence of the accident scenario i (y^{-1}), PF_i is the probability of fatality that the accident scenario i will result at location (x, y).

The resulting overall IR at that particular location (x, y) was then calculated as the sum of the individual IR's corresponding to each reference scenario.

$$IR_{(x,\ y)} = \sum \text{IR}_{(x,\ y,\ i)} \quad (5)$$

where: $IR_{(x,y)}$ is the overall IR at the geographical location (x, y) for all reference scenarios.

Important to mention that all events were considered to have radial effects, except for the scenarios involving toxic release which were considered as a directional footprint with its spread distributed in a sector of 22.5 degrees.

3.4.2 *Societal risk*

Societal Risk (SR) another risk measure of QRA is the relationship between frequency and the number of people suffering from a specified level of harm in a given population from the realization of specified hazards (ICheM, 1985). Therefore, if no people are present around the hazardous activity, SR is zero whereas IR may be quite high (Bottelberghs, 2000).

A number of measures can be found in the literature to estimate or express the societal risk (Laheji, Post, et al., 2000). Among them, we have chosen the PLL measure as it allows spatial display of the risk to society by combining the damage potential with population density estimates. It is expected that the result would be helpful for the planners and other decision makers to understand the severity of existing risk level and accordingly identify the areas where risk stabilization measures should be adopted, or where to focus for adopting risk reduction strategies either in the form of rehabilitation or restrictions for no further residential area development. It is important to mention here that the societal risk estimation is conservative since it considers all people to be unsheltered and always present at their residences. Here, we have estimated SR in terms of Potential Loss of Life (PLL) using the following expression as adapted from the literature (Jonkman, v. Gelder, et al., 2003).

$$PLL_{(x,\ y)} = [IR_{(x,\ y)} \cdot NP_{(x,\ y)}] \quad (6)$$

where: $PLL_{(x,\ y)}$ is the Potential Loss of Life at a geographical location (x, y); $IR_{(x,\ y)}$ is the individual risk at location (x, y); and $NP_{(x,\ y)}$ is the number of people at a geographical location (x, y).

To be able to estimate PLL across a spatial grid, it is necessary to have a high-resolution spatial population database for the area. This is not readily available for the Haldia area. In order to do so, the area was divided into a series of grid cells measuring 100 m × 100 m's. The number of people per grid cell was estimated by interpolating the census population data (available per administrative unit) to the spatial spread of residential areas using a dasymetric approach (Bhaduri, Bright, et al., 2007).

4 RESULTS

4.1 *Cumulative risk maps of Haldia*

The methodology presented in section 3, was applied in a subset area of about 100 sq. km of the larger Haldia Planning Area to estimate the cumulative risk to the people in the vicinity of the hazardous industries. Figure 4 shows iso-risk contours depicting the probability of an unprotected individual being killed in the vicinity of such industries per year. Finally, the societal risk in terms of the number of probable fatalities that may be caused in an area has been estimated using a PLL function by combining the IR with the number of persons residing in each cell of the grid. The societal risk (unit being no. of people in each grid who can suffer fatalities/year) is presented in Figure 5.

4.1.1 *Uncertainty analysis*

The methodology was designed based on a traditional QRA approach. However, for applying this method in an Indian situation, several assumptions had to be made. These included the frequency of initiation events, the probability of sequence

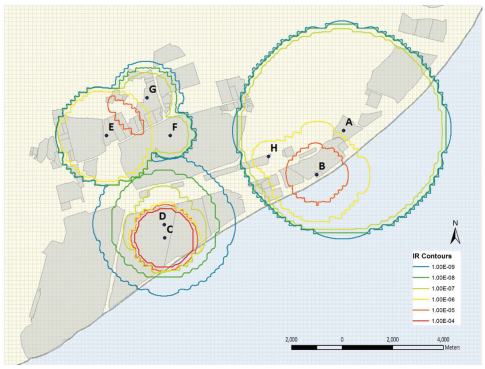

Figure 4. Individual risk. Iso-risk contours of all reference scenarios.

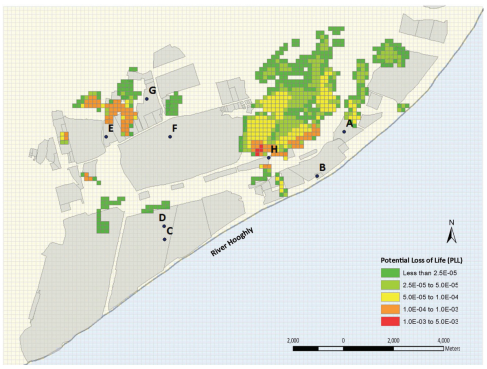

Figure 5. Societal risk. Expected PLL of each grid from all reference scenarios.

leading to the accident scenario, the selection of a limited number of scenarios based on a pre-set criteria and Probit coefficient. Therefore, the reliability of the results presented in the above section, are dependent on these assumptions. To evaluate the validity of these assumptions, an uncertainty analysis was carried out for the key variables on which the sensitivity of the results may vary (Amendola, Contini, et al., 1992). Hence, a discussion can stimulate between risk assessment professionals and planners may intend to apply this methodology.

4.1.1.1 Scenario frequency

To perform a consistent QRA, it is essential to determine frequency of an event as realistic as possible. Alternatively, over or under-estimation of the value can lead to an error of more than one order of magnitude in risk calculation. In general, the estimation of failure frequency for QRA is done based on data obtained either from different research projects, historical analysis of accidents or by the expert's judgment, which are documented in the generic failure-frequency databases. Accordingly, frequency of each scenario was estimated based on an international generic failure database. However, whether these levels of failure frequency are viable for Indian MAH installations has to be discussed and agreed upon, since frequency might vary due to many factors like enforcement of the regulations on maintenance, replacement, safety management etc. Hence, the alteration of risk contribution from different scenarios was studied, based on the variation of scenario frequencies. A comparison between estimated frequencies based on HSE's database and as a common frequency, an indicative of tolerable risk and assumed to be 1×10^{-4} for all scenarios, is presented in Table 3. From Table 3, it is evident that further research needs to be carried out to establish frequency of the initiating event and probabilities of the possible sequences which may result.

4.1.1.2 Weather condition

The results of consequence predictions can vary to a significant extent based on input weather factors like wind speed, direction, stability class etc. (Marx and Cornwell, 2009). The variability in individual risk levels, when using actual wind direction data recorded at a weather station compared to an assumed equal probability wind direction averaged across eight wind directions, is shown in Figure 6.

Table 3. Scenario contribution to PLL estimation (%).

Scenario ID	Estimated Fre^n (as per HSE)	Assumed common Fre^n (1×10^{-4})
A	39.72	75.08
B	9.17	0.22
C	0.00	0.00
D	0.25	0.59
E	28.52	2.70
F	0.00	0.00
G	0.43	4.58
H	21.90	16.83

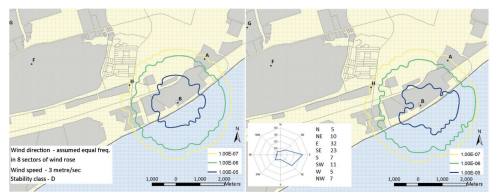

Figure 6. Variation in IR levels accounting for wind direction probability—based on assumed weather data (left); and from wind rose (right).

Table 4. Comparison of area affected in both approaches.

Iso-risk contour value	Risk-based		Consequence-based	
	Area (km^2)	(%)	Area (km^2)	(%)
Within 10^{-4}	1.67	5.92	0.00	0.00
10^{-4} to 10^{-5}	1.84	6.53	0.00	0.00
10^{-5} to 10^{-6}	5.48	19.44	20.60	72.51
10^{-6} to 10^{-7}	12.70	45.05	5.66	19.92
10^{-7} to 10^{-8}	3.58	12.70	1.83	6.44
10^{-8} to 10^{-9}	2.92	10.36	0.32	1.13

5 DISCUSSION AND CONCLUSION

The research presented here shows that a simplified methodology based on the contemporary QRA approach can be applied for estimating the spatial extent of risk originating from a number of hazardous facilities using select reference scenarios. On one side, the outcomes of this research can lead to backward linkage with harmonization of industrial risk assessment method based on standards and criteria as acceptable to the risk management actors. At the other, there is a scope for using the outcomes in the exploration of forward linkage with the adoption of risk-informed landuse planning strategies based on agreed levels of acceptable risk at the societal level. However, testing the proposed methodology in an Indian context revealed several important concerns requiring further research and discussion.

The implication of the accident scenario in risk-informed landuse planning decisions is two-fold. First is the selection of the scenario with an off-site-impact. The experts of the European Working Group on Land-use Planning (EWGLUP) indicated that for the purpose of risk-based landuse planning, accident scenarios have to be selected based on their frequency of occurrence and the severity of their consequences. On contrary, in India risk analysis presently undertaken by the MAH industries are based on the MCL scenarios representing the probable scenario that can cause maximum offsite consequences only. However, no clear criteria or limit is yet formulated for identifying such scenarios at the national level (NDMA, 2007). The choice of MCL scenario is dependent on the methodology adopted for facility level risk assessment, based on a number of assumptions made during the exercise and then presented through a safety report, which will bring in inherent uncertainties in QRA studies involving multiple facilities. Hence, there is a need for arriving at a commonly acceptable method for risk assessment which would enable a cumulative risk assessment study otherwise the results may be faulty and thus convey a wrong picture.

Second is the accuracy or trustworthiness of the scenario and the resulting risk estimation. It has been noted that alteration of any modeling assumptions or variables may exhibit substantial variations in the size of the impact area and thereby the consequences from similar scenarios (see section 4.1.2). Therefore to arrive at a harmonized result, recommended parameters and other input variable (like threshold values for effect-distance calculation, Probit equations etc.) to estimate the consequence of an accident scenario, need to be done in order to generate consistent risk scenarios prevailing in an industrial area.

The next important issue is the number of scenarios that have to be accounted for in order to arrive at a decision. In this research we have only used eight 'reference scenarios'. However, in reality there could be an N-number of such scenarios in an industrial area like Haldia which could have major consequences for the residential areas located in between. In such cases, criteria need to be formulated for selection of the reference scenarios to assess the existing level of risk. The selection of the number of scenarios is also critical as the total individual risk is calculated by adding up the values of the individual scenarios. Ideally all possible scenarios should be taken to arrive at a correct IR value; but that may mean considering thousands of scenarios. So for practical purposes, the scenarios to be considered have to be restricted using certain limiting criteria. In this study, we have estimated individual risk taking eight scenarios, which may lead to an underestimation of the existing risk levels. Nevertheless, the results can be used to analyze areas where the risk level, considering the eight scenarios only, already surpasses international risk acceptability levels.

In India, a specific risk acceptability criterion is not yet defined; hence we made an attempt to compare the results with the Dutch and UK criteria used for landuse planning decision. It has been observed that the application of these criteria might be difficult in India as it would result in too much unacceptable area for landuse planning decisions. Thus further research is required for

establishing risk acceptability criteria for India in accordance with its societal background and existing regulatory framework.

Regarding risk-informed landuse planning decisions, as mentioned earlier, many European countries have formulated different risk assessment approaches. From a methodological point of view two main approaches can be distinguished viz. consequence-based and risk-based approach. The first one is based on consequences of the reference scenarios only considering the probability of the accident intrinsically, while the second one considers both probabilities and consequences. Therefore, for a given hazardous installation, consequence-based approach shows the consequence area for lethal effects and serious injuries resulting from the reference scenarios assessed, whereas risk-based approach shows an area within which there is a given probability of a specified level of harm resulting from the large number of possible accident scenarios. Resultantly in proposing a risk-based approach, in comparison to a consequence-based approach, the proposed methodology assigns due weight to the issue of optimal use of scarce land resources for planning purposes in India. For this purpose, both approaches were tested in the study area (Fig. 7) and percentages of total area affected as well percentage of affected area under different landuse category were compared in the Table 4 respectively. It is evident that a risk-based approach results in stricter landuse planning.

A host of analytical approaches have been formulated and used by risk analysts to predict potential damage, in terms of injury or fatality, from an accident involving a toxic release, fire or explosion in a hazardous installation. Regulatory authorities have varying opinions on the outcome of consequence modeling. Some agencies like Environment Protection Agency in the US, stress the use of simple consequence modeling equations for prediction of worst case damage distances to specific end-points whereas other agencies, like RIVM in the Netherlands or the HSE in the UK, prescribe the use of specific tools like SAFETI and RISKAT respectively, to be applied based on certain requirements and boundary conditions (Ale, 2005; Pasman, 2011). Several independent evaluations undertaken in this regard, however, point to the need for adhering to agree upon benchmarks and prescribed calculation methods for undertaking such risk analysis. Therefore adapting such methods would lead to a reliable and standardized estimate of risk or for judging the severity of consequences which could subsequently be summed up to arriving at a measure of cumulative risk.

Another key aspect of the methodology presented for estimation of risk measures in a spatial context is that no complex or proprietary software tool has been used in realizing the method. The proposed approach takes advantage of using simple GIS functions and the ALOHA model, one of the known and accepted effect models by the regulatory and industrial communities. Therefore, the methodology aligns with the accepted framework set by many countries, should not be a preserve of risk analysts, but a decision maker or planner should be able to apply the same after receiving a basic training. For fast growing industrial areas, landuse planners can thus easily consider various risk scenarios and spatially overlay them on the present landuse in order to allocate future land for future industrial and residential development.

In addition, the present approach also applies a novel method to estimate PLL based on a grid-basis population data derived from the Census data using dasymetric interpolation technique. Generally, for risk estimation purpose, ward-level population as extracted from the Census database is used without considering the exact location of population. However, often this leads to the wrong picture; hence we have interpolated the Census population into a 100 m $\times$ 100 m grid using the cadastral-level landuse map in order to get a fair estimation of number of people who might be affected. Nevertheless, it is important to mention here that grid-wise population data used is just cumulative of all people including the sensitive people as well reside in that grid.

The effect of maintenance on inflation correction in Dutch PPP projects

D.S. Vervoort
Oxand Netherlands, Iter Fidelis B.V., Utrecht, The Netherlands
Delft University of Technology, Delft, The Netherlands

ABSTRACT: In Dutch large scale and long-term infrastructure projects, the risk of uncertain prices caused by inflation is transferred from the contractor to the public authority. In these projects, an index formula is used to correct for the escalating effect of inflation on a contractor's maintenance expenses. This formula is a rough approximation of the actual price level development and it does not perfectly match actual inflation cost. The difference between the approximation calculated with the formula and the actual cost of inflation is called the "indexation mismatch". The mismatch is influenced by the shape and uncertainty of a project's cash flow, which is in turn influenced by choices made in maintenance regime. This research studies the effect of a chosen maintenance strategy on the performance of the index formula. The study concludes that the performance on indexation of different maintenance strategies is indeed relevant and that, in the case of asphalt resurfacing, the use of rejuvenating measures in the maintenance regime performs best with regard to inflation correction.

Keywords: Public Private Partnership; inflation; indexation; DBFM; ARIMA; Monte Carlo; maintenance

1 DUTCH PPP

1.1 *Introduction*

This paper is the result of a Master's thesis at Delft University of Technology. It was performed at Iter Fidelis, a consulting company in the Netherlands. Iter Fidelis noticed that the interface of technology and finance in Dutch Public Private Partnership (PPP) projects is underdeveloped, especially when it comes to inflation correction. This has been the starting point of this research.

1.2 *Inflation*

Inflation is a worldwide phenomenon that influences cash flows over time. Inflation is the rising of price levels (Mishkin, 2001), or in other words, the devaluation of money (Schöndorff, 2000). Nobody knows how inflation will develop, and thus price levels in the future a uncertain.

In long-term projects with incomes or expenses in the future, it is important to take price level development into account. At the beginning of the project an investor wants to know the size of his expenses and revenues in the future to be able to estimate the profitability of an investment. Inflation rates over the short term, one to two years, can be estimated with low uncertainty, but over the long term, estimates introduce a big risk. Too low estimates of price rise result in higher expenses than expected, causing financially unsuccessful projects. Too high estimates result in an estimate that is not competitive. Therefore, it is important to be able to grasp and mitigate the effects of inflation on cash flows in long term projects such as construction projects. The outline of long term construction projects in the Netherlands will be explained hereafter.

1.3 *DBFM*

Traditionally, the government is responsible for the provision of a country's infrastructure. One of the reasons is that infrastructure construction requires high initial investments and only have a return on the long-term (Yescombe, 2007). This traditional government role changed, in accordance with the zeitgeist of the 1980's called 'New Public Management'. This line of thought prescribes a roll-back of state, and the outsourcing of public services.

The tendency towards a small government has resulted in the involvement of private parties in public responsibilities and with that, the rise of Public Private Partnership throughout the world.

Most governments use a public road authority to manage the country's infrastructure, in The Netherlands this role is fulfilled by Rijkswaterstaat. She is responsible for the main road- and waterway network in The Netherlands. Rijkswaterstaat is increasingly realizing the country's infrastructure demands through integrated Public Private Partnership (PPP) contract types, especially "Design, Build, Finance & Maintain"-contracts (DBFM).

In DBFM contracts with Rijkswaterstaat as principal, the private party is responsible for the design, construction, financing and twenty to thirty years of maintenance of an infrastructure asset. The private party, often three or four contractors organised in a consortium, is subsequently paid with instalments for the infrastructure's availability during its exploitation period. For private parties in these contracts, it is key to be able to estimate both the expenses of construction and maintenance. This estimation is then used to forge an offer including all Design, Build, Finance and Maintenance components. Rijkswaterstaat makes a call for tenders and compares the offers of private parties.

1.4 *Indexation*

Construction projects often take several years, which means they are, to some extent, influenced by inflation. Especially projects that include a maintenance period are subject to inflation. For example, a contractor has to estimate the cost of the construction and outfitting of an office building for its client. This estimation should then include the price rise of the carpet installed three years after the client and the contractor have agreed on a price. The contractor has to estimate the nominal price at the time the carpet is bought. Typically, cost estimates are formed in nominal prices at the start of a project, and escalated with an inflation estimation.

Indexation is a method of escalating cash flows based on independent measurements of price level development over time. Costs or income estimates for a future period are corrected for inflation over that specific period.

An eight-year contract between a client and a contractor for instance, can use indexation. The contractor has to pay the energy bill every year which has an uncertain price level. In such a case the contractor estimates the annual cost in euros at year 0 (in this example €100). Subsequently in the following years, the price of the energy bill rises due to inflation, the difference between the estimate in year 0 and the price rise due to inflation is paid by the client. This is called indexation. This correction is either an addition or reduction of the estimated amount see Figure 1 (Vervoort, 2014).

Indexation is the most commonly used term to describe this inflation correction or cost escalation. The word 'indexation' comes from the method used to define the height of the escalation. The amount of escalation is calculated by the change in price level between two points in time. This is laid down in the price level index which is published periodically by independent organisations like the Central Bureau of Statistics (CBS).

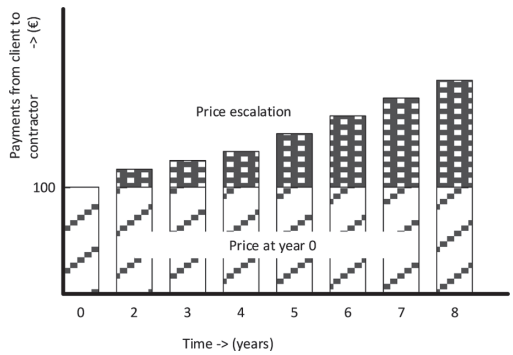

Figure 1. Principle of indexation: escalation of cash flows over time.

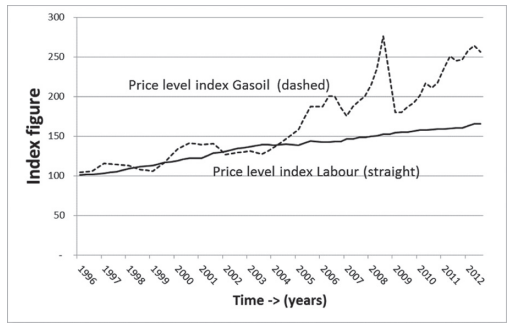

Figure 2. Difference in development of two price level indices; gasoil and labour (CROW, 2012).

The price level index is a series of numbers describing the difference in price at two different moments. Different commodities have different price level developments and have their own price level index. Labour for instance, has a very stable development with an almost constant annual growth of 2–3%. The price of gasoil, on the other hand, is very volatile as it follows geopolitical changes, supply and demand and estimations of reserves. These two different indexes are given in Figure 2. When an index is volatile it is hard to predict future price level thus indexation is more important.

1.5 *Indexation in DBFM contracts*

The contract period of DBFM projects generally ranges between 20 to 30 years, and therefore, introduces inflation risk. Inflation risk is the risk of higher price rise than expected, resulting in higher cost with a negative effect on a project's budget (the risk can also work the other way, causing a positive effect on a project's budget). In accordance with

the PPP-principle, where the party best able to carry a risk, is taking it, the Dutch DBFM agreement includes an indexation clause to transfer the consequences of inflation risk from the contractor to the government.

The goal of this (indexation) mechanism is to escalate the income of the private party in accordance with the increase in expenses resulting from inflation. The starting point of the indexation mechanism is therefore the income of the private party; the periodical instalments called Availability Payments (AP). The AP is paid each quarter in the maintenance phase by Rijkswaterstaat and is the leading parameter on which projects are awarded. The sum of these payments should cover all cost of the private party incurred in the Designing, Building, Financing and Maintaining the infrastructure. Formula 1 shows the index formula used in the standard DBFM agreement (Rijkswaterstaat, 2010).

$$BBV_{t,p} = BBV * Indexnumber_{t,p}$$
$$Indexnumber_{t,p} = 1 + \sum_{n=1}^{6} (a_{n,p} * m_{n.t}) \quad (1)$$

$Indexnumber_{t,p}$ = *Indexnumber for year t in period p;*
index n = available index (*e.g. labour*)
period p = 5-year period
$a_{n,p}$ = *weight factor for index n in period p, laid down at contract close;*
$m_{n.t}$ = *mutation of index n with;*

$$m_{n.t} = \frac{i_{n,t}}{i_{n.ref}} - 1$$

$i_{n.t}$ = *indexfigure of index n in year t;*
$i_{n.ref}$ = *indexfigure of index n in reference year*

The AP is escalated by a multiplication with the indexnumber. The indexnumber is a weighted average of the change of 6 indexes. The weight factor $a_{n,p}$ is fixed by the contractor for each 5-year period. The weight factor resembles the share of expenses of an index as part of the AP. Labour often has a bigger share than gasoil as the largest part of maintenance cost is spent on manpower.

This first section has described the phenomenon, contract and mechanisms at work in this research' field. The following paragraph will elaborate on the problem at hand.

2 PROBLEM STATEMENT

2.1 *Imperfection of indexation method*

The Dutch indexation method uses a formula that tries to model reality (formula 1). Inherent to being a model, it is a simplified version of reality. In order to make the model workable it includes assumptions. This results in residual risk that is not transferred to the public authority. A 'gap' exists between the formula and reality. Two properties of the formula causing this gap are that the price level development is levelled-out over a five-year period and that the moment at which costly replacement maintenance is executed is fixed twenty years in advance. The consequence of this gap is that the actual cost change caused by volatile inflation is not perfectly followed by the inflation correction calculated with the index formula. This mismatch leaves residual risk at the private party and may lead to a negative financial outcome of a project.

2.2 *Influential parameters on inflation correction mismatch*

There are three main parameters that influence the inflation correction mismatch. Firstly, the uncertainty in the maintenance planning. For example, the resurfacing of pavement, it covers the largest part of the maintenance budget in motorway projects. It is planned in a specific year in the exploitation period but there is no accurate information on deterioration over time and therefore it has a wide bandwidth in the maintenance planning. The index formula lacks the ability to cope with this uncertainty, which is one of the reasons for the index-gap.

Secondly, the shape of the cash flow influences the inflation correction mismatch. At what moment and at what cost the maintenance is executed is input for the calculation of the Availability Payment and other parameters in de index formula. The index formula assumes a homogenous spread of cash flow over each 5-year period. However, the spread of cash flow can take many shapes and forms. For the maintenance of pavement, there are different options for the maintenance plan which all have a different cash flow. Normally, there is at least one peak in maintenance cost due to resurfacing of the pavement in a maintenance period of 20 years. But different strategies are possible. For example; rejuvenating measures can be chosen to extend the lifetime of the pavement, in this way the resurfacing peak is delayed a few years. This could result in a maintenance planning with only one resurfacing activity necessary in the exploitation phase, which results in lower maintenance cost and higher availability. This is an area of choice which is currently heavily debated in DBFM projects (Moenielal, 2013) (Spaargaren, 2013).

The third factor that influences the inflation mismatch is the volatility of the price level index within the index formula's resolution of five years. This third factor is also relevant in large asphalt maintenance; resurfacing of asphalt pavements uses products with highly unpredictable price

levels; bituminous products, mostly due to the link with the global oil price.

The three influential parameters on the indexation mismatch described above are all relevant in large asphalt maintenance. The large impact on the cost, uncertainty in planning and volatile price levels make large asphalt maintenance very influential to the inflation correction mismatch. This portion of the cash flow of a DBFM project is therefore chosen as the subject of this research.

2.3 *Problem statement*

There is a lack of knowledge on the mismatch between a DBFM project's inflation cost and its inflation correction payments. Furthermore, the effect of different maintenance plans on this mismatch is unknown as well. The most influential issue on a maintenance budget is the large asphalt maintenance because of its financial weight, numerous maintenance strategies, planning uncertainty and unstable product prices. It would be valuable to know how different resurfacing strategies perform on inflation correction in different scenario's. This is important because correction for inflation influences the tender bid as well as the profitability for the private party. When the parties in DBFM projects are more aware of the inflation correction mismatch and how it can be influenced, the projects will result in a higher value for money for the government and a lower risk profile for the private party. To conclude, the problem is therefore the lack of knowledge of the size and dynamics behind the residual risk of price level development. A better understanding of the impact from different maintenance strategies allows for private parties to improve their tender bid.

2.4 *Research question*

Having defined the problem, the research question is composed to find the knowledge necessary to solve the problem. The research question is formulated as follows:

> *Which resurfacing strategy minimizes the net present value mismatch between inflation correction and actual inflation cost in DBFM road projects in The Netherlands?*

3 RESEARCH METHOD

3.1 *Strategy comparison model*

The three variables that influence the mismatch have been identified as the price level development and the cash flow of the maintenance activities with its uncertainty in planning. To be able to answer the research question without a range of projects to compare, the variables are simulated for four different resurfacing strategies. With such a Monte Carlo simulation, a large number of different future paths is created for one single project. For each future path, a different price level development and timing of maintenance is simulated, resulting in a unique set of performance indicators as output. Doing this for all four resurfacing strategies makes it possible to compare the performance and answer the research question on how to deal with the index gap. An advantage of this artificial method over a real-life case comparison is that the scope, duration and payment mechanism of the project remain the same, resulting in more clear results than a comparison of actual projects with differences in lay-out. An important drawback is that the simulation is based on historical inflation data, which are not necessarily indicators for future inflation development.

3.2 *Model inputs: Case study: A15 motorway*

To make the comparison as close to reality as possible, the simulations are based on an actual case in the Netherlands; the capacity enlargement of the A15 motorway. The road connects the port of Rotterdam, Europe's largest port, with the hinterland while simultaneously facilitating the commuters to and from the area's industry. The road is also the main access to important residential and recreational areas in the Southwest of The Netherlands. With the completion of the recent port expansion and the growth in traffic expected to follow from that, Rijkswaterstaat initiated the project as a DBFM contract.

Key input parameters like pavement area as well as important milestones and payment mechanisms are retrieved from the scope document and DBFM agreement as a basis for this research.

Through interviews with asphalt experts from both the public and private party together with literature on asphalt maintenance, four resurfacing strategies have been identified

Strategy A: Traditional resurfacing
Strategy B: Lifetime extension through Rejuvenation
Strategy C: Replace with innovative asphalt
Strategy D: Start and replace with innovative Asphalt

These strategies all have different cash flows and uncertainties. Heavily loaded lanes are distinguished from lightly loaded lanes, because the deterioration of pavement is highly influenced by the amount of trucks using it. The strategies will be described in more detail in the following sections.

3.2.1 *Strategy A: Traditional resurfacing*

In a traditional resurfacing regime of Double Layer Porous Asphalt (DLPA), the top layer of the pavement is resurfaced when the quality of the road nears its failure condition. In strategy A, the resurfacing of the top layer of the heavily loaded lane is executed at 8 years after construction. 4 years later, the total DLPA package is replaced, both the top and secondary layer on both the heavily and lightly loaded lanes. This is conform the current standard in asphalt maintenance.

3.2.2 *Strategy B: Lifetime extension through rejuvenation*

This second strategy improves the first maintenance regime by extending the lifetime with rejuvenating measures. The embrittlement of the bitumen in the asphalt can be countered by spraying a new bitumious mixture in the porous asphalt. This technique is called 'sealing'. Sealing the pavement twice during its lifetime will extend its total lifetime by two years on average. Besides the lifetime extension, it also reduces the spread of the planning uncertainty.

3.2.3 *Strategy C: Replacement with innovative asphalt*

A more opportunistic strategy is to aim for technological advances in asphalt technology. In this strategy the budget is built on the assumption that at the time of the first traditional resurfacing in year 8, a more durable asphalt type has been developed. The durability of this new asphalt is such that it at least outlasts the contract period. With this strategy only one resurfacing activity is necessary resulting in a much lower tender bid. This risky opportunistic behavior is reality in the current Dutch market in which work is scarce.

3.2.4 *Strategy D: Start and replace with innovative asphalt*

The last strategy that is used in DBFM contracts also aims for only one resurfacing activity during the contract period. But instead of choosing a new asphalt type after using traditional pavement in the first phase of the contract period, this strategy starts with innovative asphalt right away. The exact details are commercially sensitive and therefore confidential but it is a different pavement type than traditional double layer porous asphalt. This strategy is currently being used at the A15 project by *A-lanes A15*, the concession contractor. A major disadvantage is that, when introducing a new asphalt type in the Rijkswaterstaat network, the introducer is obliged to prove the quality of the pavement. Meeting this obligation takes time and money.

Based on experience abroad, the expected lifetime of this innovate asphalt is 12 years for both the heavily and lightly loaded lanes (Moenielal, 2013). Furthermore, there is no need to distinguish between heavily- and lightly loaded lanes; the entire pavement is resurfaced in one go.

These four strategies are compared by running them in the strategy comparison model. The innovative aspect of this model is the way inflation is modelled.

3.3 *Inflation modelling: Autoregressive Integrated Moving Average*

Inflation modelling for probabilistic analysis has to deal with the properties of inflation datasets. These datasets follow an exponential trendline, with a heteroskedastic deviation. Furthermore, the dataset has positive serial autocorrelation and some indexes, like gasoil and bitumen, are strongly positively correlated. These properties are included with a modelling technique used in the field of econometrics, named: ARIMA-modelling.

ARIMA is a sophisticated univariate modeling technique. ARIMA is the abbreviation of *Autoregressive integrated moving average* (also known as the Box-Jenkins model). It was developed in 1970 for forecasting purposes and relies solely on the past behavior of the variable being forecasted. The model creates the value of Y_t with input from previous values of the same dataset. This input includes a factor of previous values Y_{t-p} as well as the elasticity of the previous values ε_{t-q}. In a formula it looks like:

$$Y_t = \Phi_1 Y_{t-1} + \Phi_2 Y_{t-2} + \cdots + \Phi_p Y_{t-p} + \varepsilon_t + \theta_1 \varepsilon_{t-1} + \theta_2 \varepsilon_{t-2} + \cdots + \theta_q \varepsilon_{t-q} \quad (2)$$

With Φ and θ as unknown parameters to be found in a variant study. The ε's are independent and identically distributed normal errors with zero mean. This stochastic error term is called the *innovation* or *white noise*. The number of historical values used to generate value t is p, and is called the number of lags. The number of innovations incorporated in value t is expressed by q.

The ARIMA method uses historical values to set the parameters described above. These datasets can only be used when they have specific properties like homoscedasticity and uniformity. The datasets of inflation do not have these properties, therefore some deformations on the dataset need to be performed. The number of deformations needed is described by the letter d. The theory speaks of ARIMA (p,d,q) models to describe the lag structure. In this research, different ARIMA lag structures are used to model the different indexes. The choices of the p d and q are based on the Akaike Information Criterion (AIC). The modelling is executed with Palisade's @RISK software as plug-in in Microsoft Excel.

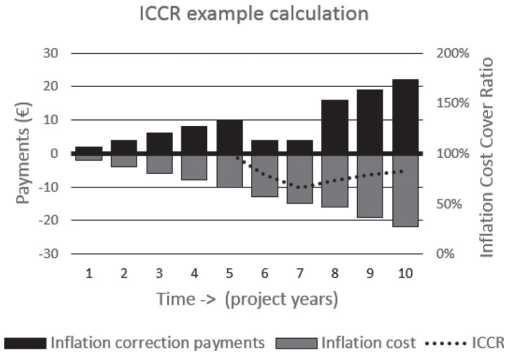

Figure 3. Mechanism of Inflation Cost Cover Ratio performance indicator.

3.3.1 *Inflation Cost Cover Ratio*

In order to answer the research question on the mismatch between inflation cost and inflation correction, a special performance indicator is designed to compare strategies and reveal the mismatch. The indicator is called the *Inflation Cost Cover Ratio* (ICCR) and describes the percentage of extra cost due to inflation, that is compensated by the inflation correction. Because the time value of money is relevant in the comparison of the four strategies, the percentage is calculated with the present values of the inflation cost and inflation correction. The discount rate is 6,25% as used by Rijkswaterstaat to compare tender bids. Figure 3 shows an example of an ICCR calculation of a cash flow. The formula below shows how the ICCR is calculated.

$$ICCR = \frac{PV\ Inflation\ correction}{PV\ Inflation\ cost} * 100\% \qquad (3)$$

In an ideal situation, where all cost for inflation are perfectly compensated by payments from the public authority, the ICCR would be 100% in every quarter. With an ICCR of 100%, there is no mismatch between inflation cost and compensation.

The ICCR is compared to the base case. In this base case, neither volatile price levels nor uncertainty in planning are taken into account. This comparison gives insight in the behaviour of the index formula under uncertainty. The closer the ICCR is to the base case, the better the predictability.

4 RESULTS

Figure 4 shows the probability density function of the ICCR for the four strategies. Here, strategy A has the most positive output; the mean ICCR calculated by the model is 3,1% higher than expected in the base case (the peak is 0,03 right of the y-axis). The high value is in this case caused by conservative budgeting, which anticipates higher costs than probable. Without these extra cost items in the last two years however, the deviation from the ICCR in the base case becomes much lower, as displayed by the line of strategy C.

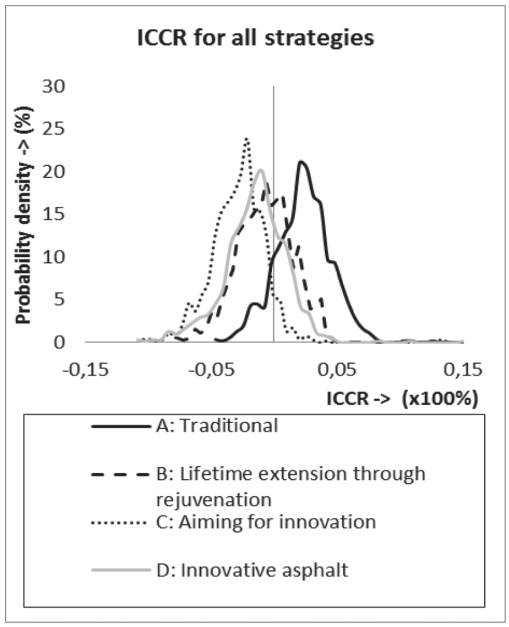

Figure 4. Output ICCR of 4 maintenance strategies. (Vervoort, 2014).

The other two ICCR outputs deviate less from their expected value, with a mean of –0,5 and –1,2% for strategy B and D respectively.

5 CONCLUSION

The answer to the research question is the following: Because strategy B deviates least from the expected outcome of the ICCR, the strategy of *Lifetime extension through rejuvenation* is considered to be the best resurfacing strategy when it comes to the net present value of the mismatch between the inflation correction and inflation cost in Dutch DBFM projects.

As seen in the output figure, the traditional resurfacing regime, Strategy A, performs best for the budget of the private party. With a positive mean ICCR, the inflation correction paid by Rijkswaterstaat, minus the inflation cost, is more than expected in the base case. This is good for the project balance but this strategy outper-

forms the expectations which makes the tender bid commercially not very competitive. This is due to the safe budgeting in this strategy which assumes an unlikely peak in maintenance cost in the final two years of the project. The strategy's cash flow is constructed based on maintenance theory, degradation data and engineering practice. However, in a competitive market, the bid resulting from this strategy is very safe. It is so safe, that the actual cash flow never occurs exactly as budgeted in the simulation. This causes the inflation cost to be much lower than expected, which benefits the ICCR. The safe maintenance strategy is reflected in the high reference bid, making this strategy the losing one in the tender.

Strategy B: *Lifetime extension through rejuvenation* performs almost exactly as expected. The mean of the ICCR outputs is very close to zero and besides that, the spread of the 95th percentile is much smaller than the other two strategies C and D.

Conversely, strategy C: *Replace with innovative asphalt* and strategy D: *Start and replace with innovative Asphalt* on average perform worse than expected (ICCR < 100%). In most simulations, the inflation correction is insufficient to cover the cost of inflation, which causes negative financial outcomes for the private party at the end of the project.

Because strategy B deviates the least from the expected outcome of the ICCR, the strategy of Lifetime extension through rejuvenation is the best resurfacing strategy when it comes to the net present value of the mismatch between the inflation correction and inflation cost in Dutch DBFM projects. This is the answer to the research question.

6 RELEVANCE

To prove the relevance of the inflation correction a hypothetical statement is formulated as follows:

> *It is expected that a choice between two maintenance strategies has a relevant effect on a project's budget, the choice results in a difference in the inflation correction mismatch of over €530.000 in Present Value.*

The value is based on current profits of Dutch construction companies (2–3%). If the difference is larger than a typical profit, it is worth taking into account. Figure 4 shows the different outcomes of ICCR for the four different maintenance regimes. The difference of the outcomes confirms the first part of the hypothesis; the maintenance strategies perform differently on inflation correction. The largest difference in inflation correction is between the *traditional* strategy A and the *Aiming for innovation* strategy B. The difference between their mean ICCR is 5,3%, which comes down to € 2,6 million in terms of present value.

In other words, the choice in maintenance strategy changes the expenses on resurfacing maintenance more than 2% in present value cost. Therefore, the hypothesis is accepted.

This research shows that inflation correction should be taken into account in a variant study of maintenance strategy, because it has a relevant impact on the budget. This means that if contractors take the mismatch of the indexation formula into account, they can present offers that entail better mitigation of risk resulting in better value for money for Rijkswaterstaat in DBFM projects.

In several meetings after publication of this thesis, clients of Iter Fidelis, the host company, affirmed their interest for using this method in upcoming tenders.

7 OTHER FINDINGS AND RECOMMENDATIONS

Besides the answer to the research question and the relevance test, several other findings can be noted. This paragraph describes these other findings.

7.1 *Two kinds of mismatches*

The research shows that there are two kind of mismatches in inflation correction. The first mismatch is caused by imperfections of the index formula even when the cash flow behaves exactly as expected in a deterministic budget. At the moment, this mismatch is taken into account in DBFM projects. The second mismatch occurs when the cash flow deviates from its expected path. This deviation may occur in the price development or the timing or amount of expenditures. This second mismatch is not taken into account in the current DBFM projects. The research suggests the private party should take this into account in the tender bid, because it causes variations in the cash flow of a maintenance plan.

7.2 *Evaluation of index formula*

First of all, the private party should be thankful for the existence of the index formula. The formula is a helping hand for the private party that takes away a lot of uncertainty. A strong property of the formula is that there is little room for strategic behaviour, this benefits equal assessment of the competing parties in a tender. The index formula is constructed in such a way that when commercial parties try to use it for strategic behaviour, it either leads to more risk or a higher offer.

This research shows the index formula is somewhat unrefined in its calculations, resulting in a mismatch. The rough level of detail is chosen for the ease of calculation, changes can be made to the formula in order to reduce the mismatch, but this would introduce discussion as explained hereafter.

7.2.1 *Mismatch 1*

'Inequality between inflation correction spread over 5 years and maintenance expenses peaks' can be removed as follows. The spread-out of the inflation correction over a five year period could be refined to a correction calculated annually or even quarterly in order to reduce the mismatch. In this way, the inflation correction and inflation cost profiles are mirrored better which strongly reduces the mismatch. However, due to the uncertainty of the timing at which the peak expenses are made, fixed weight factors for each year could result in even larger mismatches than with a spread-out over 5 years. If a peak expenditure is made earlier than budgeted, the fixed inflation correction does not match the expenses because the weight factors are based on the budgeted timing of expenses. Thus, the current method in which the weight factors are spread over a 5-year period is a protection against the mismatch cause by flexibility.

To make use of this build-in protection, the peaks must be budgeted in middle year of the five-year period in order to have the biggest chance that the peak expenses remain inside the period.

7.2.2 *Mismatch 2*

'Inflexibility of index formula regarding uncertainty of maintenance activities' timing can also be reduced. An improvement of the formula could be done by introducing flexibility; giving private parties the possibility to change the weight factors as their maintenance activities change from what was budgeted. The drawbacks of this is that it will give room for discussion and strategic behaviour. In the current index formula everything is fixed and undebatable. If weight factors can be changed after the tender offer is made, the client and private party will be debating constantly whether or not the change is reasonable. And with the current state of heavy debates in DBFM projects, an additional point of debate is not welcome.

7.2.3 *Mismatch 3*

'Use of outdated index figure*s in inflation correction*' can be reduced by using quarterly indices in the calculation of the index figure. In the current state of affairs, the formula uses the indices from January, also to calculate the inflation correction for the third, second and fourth quarter. It is possible to use the indices publicized in each respective quarter, but because there is a big delay between the moment of measurement and the moment of publicizing, calculations delay inflation correction payments. Figures of January are publicized two to three months later, making it only possible to calculate the inflation correction in a later stage. With the time value of money in mind, a delay in inflation correction payments is unwanted.

Concluding, the index formula can be improved to reduce the mismatch. However, this introduces debates and slows down the process of inflation correction payments. The current index formula has a good balance between workability and precision, therefore the research recommends Rijkswaterstaat to keep the current indexation method untouched.

7.3 *Use more likely budget for weight factor calculation*

One reason for the mismatch between inflation correction and inflation cost is the fact that the weight factors in the calculations are based on a budget designed with a 85% certainty interval. A recommendation is to use two budgets, a safe one, and a more probable one to be used to define the weight factors.

The second one will have the maintenance peaks planned at a 50% certainty interval, making the match between the out- and inflowing cash flow more probable. This improvement has been tested on Strategy C; aiming for innovation with an improvement of the ICCR from 95,1% to 95,7% (€ 304.000 present value benefit).

In this method, a large part of the weight factor set of are shifted to a more probable period. Because it is also more likely that the expenses will occur in this period, the set of weight factors is more likely to be more accurate. The result is an improvement of the Inflation Cost Cover Ratio.

This improvement has been tested for strategy C, where it results in a better performance from a private party point of view. It is recommended that the private party runs simulations like these to test whether the weight factor calculation can be improved.

7.4 *Limits to conclusions*

It is important and necessary to note that the conclusions are based on assumptions. Especially the assumption on the future development of inflation is debatable. The price level development is based on an extrapolation of historical behaviour of data, but there is no certainty at all that the future will resemble history. Major shifts in geopolitical relations or technological advances may change price level drastically. Also, events like hyperinflation, which occurred not that long ago in Latin

America in the 90's, are not taken into account. Therefore, the conclusions remain confined to a specific assumption on the future.

Furthermore, the assumptions on the lifetime of the pavement is based on historical behaviour of double layer porous asphalt. But a series of very cold and wet winters or a new law allowing heavier trucks would change the degradation of the pavement insofar, that it would fall outside the probability density function expected of the maintenance interval. Therefore, the conclusion must be used with care by taking the assumptions into account.

The incorporation of these two uncertainties oblige the reader to be careful with the interpretation of the results. Especially the quantitative values must not be seen as exact truth, because they are all forecast of the future based on assumptions.

Handling dependencies in Probabilistic Risk Assessments using Evidential Networks

D. Wang, Z.J. Cheng, P. Jiang & B. Guo
College of Information System and Management, National University of Defense Technology, Changsha, Hunan, P.R. China

ABSTRACT: Dependencies or failure dependencies in probabilistic risk assessments may lead to significant errors if not properly analyzed. In order to overcome the limitations of traditional methods, a modified Bayesian Network (BN), which is called Evidential Network (EN), was proposed with evidence theory to handle dependencies in Probabilistic Risk Assessment (PRA). Fault Trees (FTs) and Event Trees (ETs) were transformed into an EN which constructs a uniform framework to represent accident scenarios. Dependencies can be processed through the corresponding evidential networks where uncertainties are characterized by basic belief mass. A case study was discussed to demonstrate the proposed approach. Frequencies of end states were obtained and expressed by belief and plausibility measures. The proposed approach can be easily applied to probabilistic risk assessments that involve dependencies while addresses the uncertainties in experts' knowledge.

1 INTRODUCTION

Probabilistic risk assessment is an effective analysis approach that systematically estimates the occurrence frequency of an accident sequence. It has been used in nuclear industry since 1970's (Keller & Modarres 2005) and also widely adopted in space industry (Stamatelatos 2002) and civil engineering (Nývlt et al. 2011).

ETA and FTA are two distinct methods used in PRA. ETA is a technique used to display sequences of system (or human) failures or successes that can lead to specific end states and estimate the likelihoods (frequency) of each end state. FTA is often used to analyze the probability of failure or success of pivotal events in an event tree. A pivotal event is treated as top event and proceeded down to basic events using logic gates in each fault tree. Despite the fact that the two methods are widely adopted, some limitations as the lack of ability of modeling dependencies are suffered (Khakzad et al. 2011).

Failures arising from dependencies are often difficult to identify and, if neglected in modeling and quantifications, may result in an underestimation of risk (Stamatelatos 2002). However, till now, researchers from different industries haven't reached an agreement on the definition of dependency or failure dependency. In a broad sense, dependency implies relationship between failures. Since reliability and safety analysis focus on failures, dependency and failure dependency have the same meaning in this article.

For a proper treatment, dependencies are categorized into intrinsic dependencies and extrinsic dependencies in the report of United States Nuclear Regulatory Commission (USNRC 1998b). In (IAEA 2000) dependencies are divided into 4 types (functional dependencies, physical dependencies, human interaction dependencies and component failure dependencies). Despite the differences in categorization, every kind of dependency should be proper treated in a PRA. For example, the graphic structure of a fault tree is used to handle some of the dependencies among failures (e.g. dependencies of system failures on support electric power failures are included in FTs by including failure of power system components as basic events). For those with logical relationships that cannot be expressed explicitly in FTs or ETs, Common Cause Failure (CCF) analyses are then conducted.

While efforts are made to treat different kind of dependencies properly, dependency across event trees is not often discussed and not much explored. These dependencies may be caused by shared utilities, shared components, or general CCFs underline an event tree. A common method is utilizing a uniform framework to combine FTs and ETs together so that components or events that depend on each other can be connected and processed in a single structure. FTs/ETs can be transformed into an integrated FT which acts as a uniform framework. However, the calculations for a giant FT are cumbersome. Existing scientific

papers related to this issue also tried binary decision diagrams (Andrews & Dunnett 2000) and Petri nets (Nývlt & Rausand 2012) to form the uniform framework. Recently, Bayesian networks are increasingly used for the constructions of system reliability models, risk management, and safety analysis based on probabilistic and uncertain knowledge (Weber et al. 2012). The advantage of using BNs in safety analysis is that a BN combines all factors related to system safety together. These factors range from human errors, environment influences to organization methods. Naturally, BN becomes an alternative for uniform frameworks that combine FTs and ETs (Hosseini & Takahashi 2007). Meanwhile, CCF factors such as β factors are widely used in CCF analyses to measure degree of dependencies. They can bring additional sources of uncertainties to analyses. Together with other uncertain inputs, they bring another challenge to the existing methods.

In this work, a modified Bayesian Network (BN), which is called Evidence Network (EN), is proposed to handle dependencies in PRA. The equivalent EN structures of ETs and FTs are discussed. Specifically, this paper is believed to be the first study dedicated to the transformation of ETs into ENs. Dependencies can then be tackled through the corresponding evidential network where uncertainties are characterized by basic belief mass.

The remainder of the article is organized as follows: In Section 2, the β factor model, which is a typical CCF factor model, is briefly introduced. Uncertainties brought by β factors are discussed and serve as an inspiration of using modified models to deal with dependencies in PRA. The D-S evidence theory and evidential networks are briefly introduced in Section 3. The EN based approach is then discussed in detail in Section 4. In Section 5, a part of a practical probabilistic risk assessment is analyzed using the proposed approach. The conclusion is expressed in the end.

2 FAILURE DEPENDENCY UNCERTAINTY

The dependencies one needs to take into further consideration are those that haven't been explicitly represented in the original FTs. Dependent failures that are not explicitly modeled in FTs are known as Common Cause Failure (CCF). A formal definition follows:

A common cause failure is defined as the failure (or unavailable state) of more than one component due to a shared cause during the system mission (Stamatelatos 2002).

Usually, the dependencies caused by CCFs are depicted using factor modeling such as the α factor model, the Multiple Greek letters (MGL) model and the β factor model. Details about these models can be found in many publications (Barros et al. 2009, Humphreys 1987, USNRC 1998a). Basically, all the mentioned models use a CCF factor to represent the proportions of different type of failures. In this paper, the β factor model is preferred due to its reasonable complexity. Take the β factor model for example, it can be noticed that the factor modeling can bring additional dependency uncertainties.

2.1 *β factor model*

The β factor model initially proposed by Fleming (Fleming 1974) uses a β factor to represent the failure probability due to a common cause given the occurrence of a failure. The expression of β is given by

$$\beta = \frac{P_{(\mathrm{CCF})}}{P_{(\mathrm{T})}} = \frac{P_{(\mathrm{CCF})}}{P_{(\mathrm{I})} + P_{(\mathrm{CCF})}} \tag{1}$$

where $P_{(\mathrm{CCF})}$ is the failure probability due to common cause failures, $P_{(\mathrm{I})}$ is the failure probability due to independent failure and $P_{(\mathrm{T})}$ is the total failure probability.

2.2 *Uncertainties in β factor*

Usually β factors are regarded as crisp values which are evaluated in two approaches. The first approach uses statistic data gathered from systems in operation to obtain β factors. This method is frequently used in nuclear industry (USNRC 1998a, USNRC 1998b). In recent years, researchers in space industry also started to collect data to evaluate β factors. For example, Rutledge evaluated the β factor of redundant electric hardware to be 0.11 after analyzing 473 abnormal flight data provided by NASA (Rutledge & Mosleh 1994). Nevertheless, such data analyses may have not been conducted in other industries yet. Moreover, even the β factors in nuclear industry, which obtained from statistic data of a specific type of reactor, are not applicable for all the plants (Song 2007).

The second approach uses judgment standards to evaluate β factors. For example, the β factor is increased if two generators are placed in the same room or maintained by the same worker. A relatively complete set of standards was proposed by Humphreys (Humphreys 1987) and adopted by Atomic Energy Authority (AEA) (Brand 1996). Generally this approach provides ranges of β values, but the final choice is subjectively done by analyzers.

Summarizing above, both approaches can just get a possible realistic value of β in the context of

a particular analysis. Normally, the actual β factor value agreed by experts is between 0.005 to 0.11 for hardware failure and 0.05 to 0.6 for software failure. However, the exact value is hard to get due to limited data, incomplete or imprecise information. It's reasonable to doubt that a point-valued β factor ignoring uncertainties can lead to a false decision-making. Thus, this paper proposes the using of intervals to represent the value of β factors, allowing experts to express the uncertainty about the grade of dependency.

3 A BRIEF INTRODUCTION TO D-S EVIDENCE THEORY AND EVIDENTIAL NETWORKS

Uncertainties brought by β factors are labeled as epistemic uncertainty (Hoffman & Hammonds 1994). While BN is an effective uniform framework to represent dependencies, it lacks of the ability to handle epistemic uncertainties brought by them.

While few researches on the use of BNs in system reliability and safety analysis take epistemic uncertainty or uncertainty propagation into account, one exception is an interesting work by Simon et al. (Simon et al. 2008) which concerns how a BN can be modified to a so called evidential network to handle epistemic uncertainties. Evidential network is a combination of evidence theory and BN. In this section the basic concepts of D-S evidence theory and evidential network are introduced.

3.1 *Basics of D-S evidence theory*

The D-S evidence theory, is developed by Dempster (Dempster 1967) in the 1960'. Shafer developed the original theory by introducing the concept of belief function. Some basics of D-S evidence theory are given as follows.

3.1.1 *Frame of Discernment (FD)*

The frame of discernment is a finite nonempty exhaustive set of mutually exclusive possibilities denoted by $\boldsymbol{\Theta}$ which includes all the possible propositions. The propositions are called "focal elements". If $\boldsymbol{\Theta} = \{H_1, H_2, \ldots, H_i, \ldots, H_n\}$ then there are n hypotheses in the frame. H_i represents "hypothesis H_i appears".

3.1.2 *Basic Belief Assignment (BBA)*

The sources of information can distribute masses on every subset A_i of the frame of discernment. A_i is expressed by:

$$A_i \in 2^{\boldsymbol{\Theta}},\ 2^{\boldsymbol{\Theta}} = \{\emptyset, \{H_1\}, \ldots, \{H_n\}, \{H_1, H_2\}, \{H_1, H_3\}, \ldots, \{H_{n-1}, H_n\}, \{H_1, H_2, H_3\}, \ldots, \{H_1, H_2, \ldots, H_n\}\}.$$

This process is called basic mass assignment which is represented by a function m defined by:

$$m: 2^{\boldsymbol{\Theta}} \to [0,1] \text{ with } m(\emptyset) = 0,\ \sum_{X \subseteq 2^{\Theta}} m(X) = 1.$$

3.1.3 *Belief function and plausibility function*

The analysis results are demonstrated by an interval which describes the degree of support for a hypothesis. The lower bound is called belief function, denoted by

$$Ble(A) = \sum_{B|B \subseteq A} m(B) \tag{2}$$

The upper bound is called plausibility function, denoted by

$$Pl(A) = \sum_{B|B \cap A \neq \emptyset} m(B) \tag{3}$$

3.1.4 *Combination rules*

Combination rules are used to combine evidence from different sources. The D-S combination rule can be expressed by the following relation:

$$m(C) = m_i(X) \oplus m_j(Y) = \begin{cases} 0 & C = \emptyset \\ \dfrac{\sum_{X \cap Y = C, \forall X, Y \subseteq \boldsymbol{\Theta}} m_i(X) \times m_j(Y)}{1 - \sum_{X \cap Y = \emptyset, \forall X, Y \subseteq \boldsymbol{\Theta}} m_i(X) \times m_j(Y)} & C \neq \emptyset \end{cases} \tag{4}$$

Many other combination rules have also been presented (Smets 1990). The original DS combination rule is used in this study.

3.2 *Evidential network*

An Evidential network can be represented as $G^* = ((N^*, A^*), D^*)$, where (N^*, A^*) represents the graph in which "N^*" is a set of nodes, "A^*" is a set of arcs and "D^*" represents the set of belief distributions that are associated with each node in the graph (Simon et al. 2008). The basic belief assignments are set for some of the nodes (basically leaf nodes) as priori probabilities. A belief propagation is then performed through the so called "Conditional Belief Mass Table (CBMT)" which is equivalent to Conditional Probability Table (CPT) in BN. The belief propagation or evidence propagation in ENs can be done by traditional algorithms developed for inference in BN.

Details about EN can be found in a series articles of Simon et al. (Simon & Weber 2006, Simon & Weber 2009, Simon et al. 2008) So far, applications of EN can be found on the reliability evaluation of power distribution and aircraft servo-actuation

systems (Zhao 2010, Yang et al. 2011). It has also been used to help the safety analysis of aerospace systems (Jiang et al. 2011).

4 EVIDENTIAL NETWORK MODELING

4.1 *FT and equivalent EN structure*

Simon (Simon & Weber 2009) suggested converting a fault tree into an equivalent EN and presented the CBMT of "AND" and "OR" gate in a table form. EN models for other logic gates (e.g. "NOR" gate) that often used in FTA can also be expressed by EN models easily. The transformation of logic gates to EN structures are shown in Figure 1.

Though the equivalent EN structures look the same for the two logic gates in Figure 1, the Conditional Belief Mass Tables (CBMTs) are different. The CBMTs for AND and OR logic gates are defined and shown respectively in Tables 1 and 2 in which "N" means normal, "F" means failure and "$\{N, F\}$" means that the system is exclusively in one of the two conditions without distinguishing exactly which. This allows us to express uncertainties on the states of events in FTs.

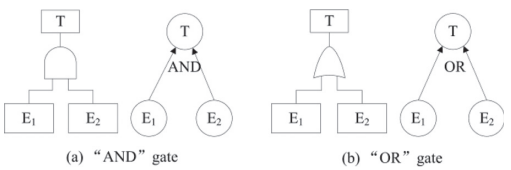

Figure 1. Logic gates and equivalent EN structures.

Table 1. CBMT for AND gate.

	E_1	N			F			$\{N, F\}$		
	E_2	N	F	$\{N, F\}$	N	F	$\{N, F\}$	N	F	$\{N, F\}$
T	N	1	1	1	1	0	0	1	0	0
	F	0	0	0	0	1	0	0	0	0
	$\{N, F\}$	0	0	0	0	0	1	0	1	1

Table 2. CBMT for OR gate.

	E_1	N			F			$\{N, F\}$		
	E_2	N	F	$\{N, F\}$	N	F	$\{N, F\}$	N	F	$\{N, F\}$
T	N	1	0	0	0	0	0	0	0	0
	F	0	1	0	1	1	1	0	1	0
	$\{N, F\}$	0	0	1	0	0	0	1	0	1

Unfortunately, the size of a CBMT increases exponentially with the number of input events. For a logic gate with three inputs, the size of the corresponding CBMT will be 81. This problem can be relieved by converting the logic gate to an equivalent form and add a "dummy" node in the corresponding EN. The process is shown in Figure 2. The sizes of the related two CBMTs in the modified equivalent EN are both 27 which make the total size 54 instead of 81. This greatly alleviates the computational labor when dealing with complex FTs.

4.2 *ET and equivalent EN structure*

Event trees are used to display sequences of events that can lead to specific end states. The headings of an ET are the Initiating Events (IE), the Pivotal Events (PEs), and the End States (ESs). An illustration of an ET is shown in Figure 3(a).

If end states are treated as a single node in ENs, the corresponding frame of discernment would include all the possible outcomes. The corresponding FD for the end states in Figure 3 can be defined by $\Theta = \{\{ES_1\}, \{ES_2\}, \{ES_3\}\}$. Then the power set of the ES node is then defined by $2^\Theta = \{\emptyset, \{ES_1\}, \{ES_2\}, \{ES_3\}, \{ES_1, ES_2\}, \{ES_1, ES_3\}, \{ES_2, ES_3\}, \{ES_1, ES_2, ES_3\}\}$.

We call the elements in the power set of an ES node General End States (GESs) and use them as the states of ES nodes in ENs. For end states of an ET are influenced by all the pivotal events, the graphic representation of ETs in a network form is clear. The graphic representation of the ET in Figure 3(a) is shown in Figure 3(b).

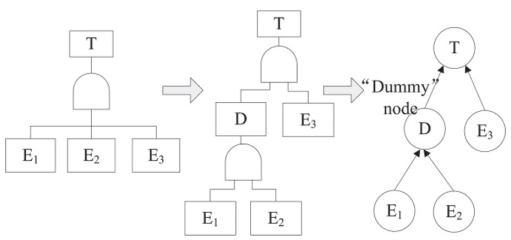

Figure 2. Transformation of logic gates with three inputs.

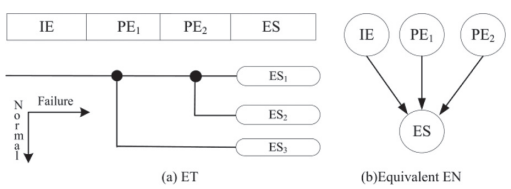

Figure 3. ET and equivalent EN.

In a PRA process, the PEs in an ET are analyzed as top events using FTA techniques. As stated in Section 5.1, the state of each PE is presented by $\{N, F, \{N, F\}\}$. For each combination of states of PEs, the outcome can be found in the state power set of the ES node. The combination of every PE states in Figure 3 and its corresponding (generalized) end states are shown in Table 3.

As shown in Figure 3, when PE_1 is in normal state "N", the end state would be "ES_3" regardless of PE_2. When PE_1 fails, end state would be ES_1 or ES_2 depending on the state of PE_2. We cannot be sure which one will the end state be if the state of PE_2 is characterized by $\{N, F\}$. Then the generalized end state $\{ES_1, ES_2\}$ is adopted. If the states of all the PEs in ET are characterized by $\{N, F\}$ which means the ignorance of which branch will the event sequence take after each PE, the end state is then characterized by $\{ES_1, ES_2, ES_3\}$.

Table 4 shows the CBMT for the EN in Figure 3, which is equivalent to Table 3. The information contained in an ET can be completely transferred into an EN structure with the corresponding CBMT.

Noticing from the CBMT in Table 4, the size of a CBMT also faces the problem of state explosion. With n end states and m pivotal events the size of the ET's CBMT is $3^m \times (2^n - 1)$.

Table 3. PE states and corresponding GESs.

PE_1	PE_2	GES
N	N	ES_3
	F	ES_3
	$\{N, F\}$	ES_3
F	N	ES_2
	F	ES_1
	$\{N, F\}$	$\{ES_1, ES_2\}$
$\{N, F\}$	N	$\{ES_2, ES_3\}$
	F	$\{ES_1, ES_3\}$
	$\{N, F\}$	$\{ES_1, ES_2, ES_3\}$

Fortunately, we don't have to add ES nodes to ENs clumsily. The end states we are interested in must be included in the GESs. By computing the joint probabilities of the combinations of PEs' states corresponding to those GESs, the information of the interested end states can be obtained. Take Table 3 for example, if we want to get the information about ES_1, only general end states $\{ES_1\}$, $\{ES_1, ES_2\}$, $\{ES_1, ES_3\}$, $\{ES_1, ES_2, ES_3\}$ should be considered. Thus, the joint probabilities of corresponding combinations of PEs' states $\{F, N\}$, $\{F, \{N, F\}\}$, $\{\{N, F\}, N\}$, $\{\{N, F\}, \{N, F\}\}$ carries the information of ES_1.

4.3 *Basic belief assignment for basic events*

Leaf nodes in ENs represent basic events. The belief masses must be assigned in order to make the EN inference process work. Expert knowledge is used to define the probability of occurrence. Generally, there are two ways of expressing uncertainties to get the belief masses.

1. Experts give values of $m(N)$, $m(F)$ and $m(N, F)$ of a leaf node directly.
2. Experts give values of the lower and upper bound of $m(F)$ (i.e. $Ble(F)$ and $Pl(F)$) or $m(N)$. From plausibility and belief measures, the basic mass assignment is computed by the Möbius transform. Here we have

$$\begin{cases} m(F) = Bel(F) \\ m(N) = 1 - Pl(F) \\ m(N,F) = Pl(F) - Bel(F) \end{cases} \tag{5}$$

For CCFs, the value of a β factor is given by the interval $[\beta_1, \beta_2]$ $(0 < \beta_1 < \beta_2 < 1)$.

1. If the total failure probability is given as a crisp value $P_{(T)}$, then the failure probability due to CCFs can be obtained as $[\beta_1 P_{(T)}, \beta_2 P_{(T)}]$, the failure probability due to independent failure $P_{(I)}$ can be obtained as $[(1 - \beta_2)P_{(T)}, (1 - \beta_1)P_{(T)}]$.

Table 4. CBMT for EN in Figure 3.

	PE_1	N			F			$\{N, F\}$		
	PE_2	N	F	$\{N, F\}$	N	F	$\{N, F\}$	N	F	$\{N, F\}$
GES	ES_1	0	0	0	1	0	0	0	0	0
	ES_2	0	0	0	0	1	0	0	0	0
	ES_3	1	1	1	0	0	0	0	0	0
	$\{ES_1, ES_2\}$	0	0	0	0	0	1	0	0	0
	$\{ES_1, ES_3\}$	0	0	0	0	0	0	1	0	0
	$\{ES_2, ES_3\}$	0	0	0	0	0	0	0	1	0
	$\{ES_1, ES_2, ES_3\}$	0	0	0	0	0	0	0	0	1

Basic belief assignment of the CCF events can then be calculated using Equation (5).

2. If the total failure probability is given as values of the lower and upper bound of $m(F)$ (i.e. $Ble(F)$ and $Pl(F)$), the failure probability due to CCFs can be obtained as $[\beta_1 Ble(F), \beta_2 Pl(F)]$, the failure probability due to independent failure can be obtained as $[(1-\beta_2)Ble(F), (1-\beta_1)Pl(F)]$. Basic belief assignment of the CCF event can then be calculated using Equation (5).

The belief masses assigned to leaf nodes from different experts are then combined together by the DS combination rule (e.g. Eq. (4)). Combined belief masses are then used in ENs.

5 CASE STUDY

The approach described above has been applied to an ET/FT analysis that described in (Nývlt & Rausand 2012). It's a part of a probabilistic risk assessment of the Strahov highway tunnel in Prague, Czech Republic.

5.1 *Event tree and associated fault trees for the case study*

The event tree is shown in Figure 4. It consists of one initiating event, three pivotal events and five end states. The initiating event is fire in one of the two tunnel tubes.

The pivotal events are listed as follows:

1. Fire and Smoke Detection (FSD). The related FT is shown in Figure 5.
2. Fire and smoke control in the tube where the fire occurred (FSCA). The related FT is shown in Figure 6.
3. Smoke Control in the Escape Tube (SCET). The related FT is shown in Figure 7.

End state "$ICFE_1$" to "$ICFE_4$" means different degrees of insufficient conditions for evacuation. End state "OK" means the system works as planed and safety is secured when fire in one of the two tunnel tubes occurs.

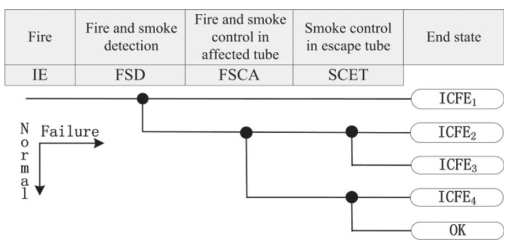

Figure 4. Event tree with initiating event "fire".

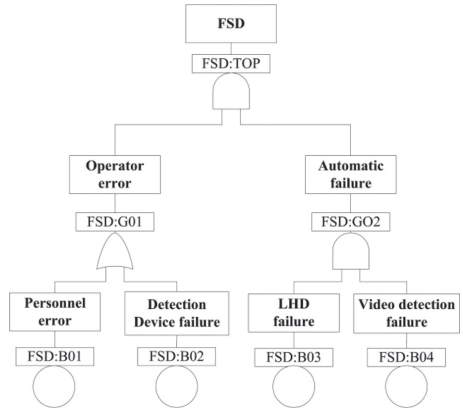

Figure 5. Fault tree for top event FSD.

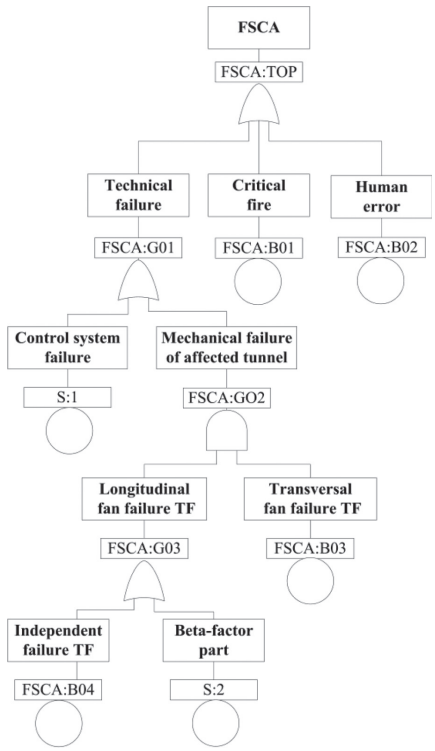

Figure 6. Fault tree for the top event FSCA.

The exact definitions of various events in the fault trees can be found in (Nývlt & Rausand 2012). Codes in the FTs starting with a letter "B" implies basic events, "S" implies shared events. It is evident that the FSCA and SCET fault trees are dependent. Traditional methods reach

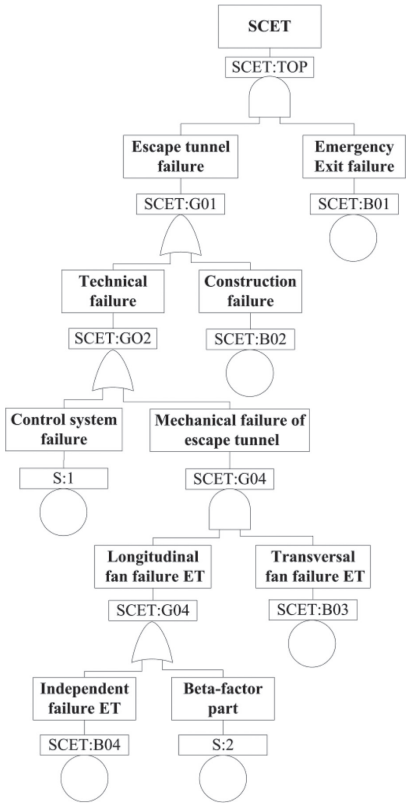

Figure 7. Fault tree for the top event SCET.

their limits, when uncertainties brought by CCF factor models are considered.

5.2 *FT/ET transformed to an EN*

The event tree and associated fault trees for the case study were converted to an EN according the approach described in section 4. The network obtained with the software MSBNX is presented in Figure 8.

5.3 *Basic belief assignment for basic events*

Basic belief masses were given by two unbiased and independent experts. The β factor were given

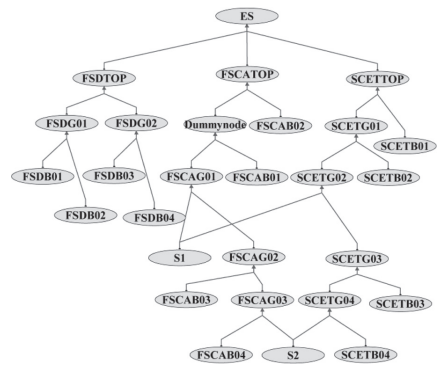

Figure 8. EN corresponding to ET/FTs in Figures 4–7.

Table 5. BBAs for basic events in Figure 7.

Table 7. Frequency of the end states.

ES	Bel	Pl
$ICFE_1$	2.280E-8	6.120E-8
$ICFE_2$	7.200E-8	2.232E-7
$ICFE_3$	9.137E-6	1.555E-5
$ICFE_4$	3.492E-7	6.588E-7
OK	1.037E-4	1.104E-4

as [0.05, 0.1] by the first expert and [0.08, 0.12] by the second expert. Basic belief assignment for basic events in Figure 8 is shown in Table 5. The aggregation is performed using Equation (4). The presented expert estimates are idealized to illustrate the application of the proposed approach. We emphasize that they do not reflect the real failure behavior.

5.4 *Frequencies of end states*

Using the EN structure in Figure 8 and the combined basic belief masses listed in Table 5, the result was derived by BN inference using MSBNX and shown in Table 6.

"–" means the probability of the corresponding general end state is too small ($<10^{-5}$) that we simply ignore it. The initiating event frequency is given by $\lambda = 1.2 \times 10^{-4}$/yr. The frequencies of the end states were obtained using the belief function (e.g. Eq. (2)) and plausibility function (e.g. Eq. (3)). The final results are presented in Table 7.

6 CONCLUSION

The issue of failure dependency is crucial in PRA. Different tools have been used as uniform frameworks, which represent accident scenarios, to solve this problem. Traditional approaches for dependencies handling in PRA can be cumbersome and ignore the uncertainties brought by dependency modeling, which may lead to a false decision-making.

A different method is proposed in this paper. ETs and FTs are transformed into a single evidential network. Expert knowledge containing uncertainty information is combined using evidence theory. Uncertainties in basic events, including dependent events, are propagated through the new uniform structure. The frequency of each end state of interest is obtained. The proposed approach is applicable to handle dependencies in PRA in the following ways:

1. The proposed approach can be applied to dependencies across events in an ET.
2. Uncertainties in dependency measurements and basic events can easily be propagated through ENs with mature BN software.
3. The proposed approach addresses the uncertainties in experts' knowledge and uses knowledge from different sources to reach the final conclusion.

The failure dependency together with other uncertainty source will not be satisfying handled by only a probabilistic way due to limited data,

incomplete or imprecise information. Alternative epistemic uncertainty representation structures are more reasonable. However, many analyzers are still more comfortable with traditional probability distributions. Few would doubt that a probability distribution is an excellent way to depict uncertainties when enough data has been acquired. Thus, the inputs would often in the form of probability distribution, basic belief assignment. The framework for propagating uncertainties in different forms is needed. The construction of a hybrid framework that combines uncertainties in different forms may offer additional future improvement to the approach developed here.

The use of geoevents in the risk management of Wastewater Treatments

G. Ancione & M.F. Milazzo
University of Messina, Messina, Italy

G. Maschio
University of Padova, Padua, Italy

ABSTRACT: Volcanic eruptions can endanger human health and threat structures, critical infrastructures and lifelines (such as wastewater treatments, electricity networks, etc.), even relatively moderate events often can cause severe damages and economic losses. Among different volcanic phenomena, this paper focuses on the study of the damage triggered by explosive volcanic eruptions (i.e. those causing volcanic ash emissions), due to the large impact area of the particles dispersion. In particular the focus is on the implementation of a procedure for the management of wastewater treatment equipment by using a GIS (Geographic Information System). To achieve this aim, the volcanic ash dispersion in the atmosphere has been considered a *geoevent* because of the possible description of its evolution by means of its geographical coordinates. The evolution representation for the cloud allows the management of the potential impacts on wastewater treatments.

1 INTRODUCTION

In the last decades, worldwide attention has been focused on the definition of procedures for the risk analysis to support the management of various types of emergency. It must be underlined that several European countries have to face various natural hazards, but appropriate management plans based on the definition of the hazards associated with technological accidents triggered by a natural event (so-called Na-Tech) are not designed (Cruz et al. 2004). In this context, Fabiano & Currò (2012) showed nearly 6.4% of the accidents, occurred in the oil industry, are due to natural phenomena. Furthermore after some important international meetings, various relevant research topics related to the process safety have been emerged, amongst these the Na-Tech category is significant (De Rademaeker et al., 2014). Amongst many natural phenomena (such as earthquake, flooding, tsunami, hurricanes, etc.) a growing attention recently has been paid to Na-Techs caused by volcanic eruptions.

The study of volcanic Na-Techs is relatively recent, some examples relate to the investigation of the effects of volcanic ash fallout on structures: Baxter et al. (1982) analysed the reduction of functionality of water treatment systems and the hazards related to the transportation of hazardous materials due to slippery road conditions; Spence et al. (2004) evaluated the vulnerability of buildings; Rasà et al. (2007) qualitatively described the effects of the ash fallout on building, electric motors and other systems; Milazzo and co-authors analysed the fragilities of atmospheric storage tanks (Milazzo et al. 2013a) and filtering systems (Milazzo et al. 2013b). Some of these studies have been used to manage the risk associated to volcanic Na-Techs trigged by the emission of volcanic ash; an example is given in the work of Milazzo et al. (2013c), which describes a GIS-based tool for the vulnerability mapping of industrial facilities under the impact of volcanic Na-Techs. A recent survey of Ancione et al. (2014) has provided a preliminary study of Na-Techs in a generic wastewater treatment plant. Ancione and co-workers highlighted the most relevant investigations given by the literature; moreover, the causes of failure, associated with the fallout of volcanic ash, have been identified for the main equipment included in such system.

The support of a GIS could be useful for the management of technological hazard triggered by the ash fallout; in this context, the volcanic ash emission in the atmosphere could be considered as a *geoevent*, this term identifies a graphical representation of the evolution of the scenario (in this case the plume and the associated fallout) by means of its geographical coordinates. A *geoevent* can be considered as a dynamic event, in some cases, its graphical representation can provide a valid support to risk managers. It is worth noting that the risk management activities could be difficult if the territory is characterized by the presence of a great urbanization, of numerous chemical industries and of a complex network of lifelines.

In the literature there are few methods and tools, developed for the risk management by using dynamic events; the available methods are applied to the management of the transport of hazardous materials (Giglio et al. 2004) and the terrorist actions accomplished by the use of dangerous substances (Milazzo et al. 2009). Other papers relate the management of industrial scenarios triggered by natural events such as the previous mentioned work of Milazzo et al. (2013c), in which a GIS tool is used to obtain vulnerability equipment to a natural phenomenon. Girgin & Krausmann (2013) provides an on-line, integrated Na-Tech risk assessment and mapping framework; whereas Demichela et al. (2013) use a GIS-based application to make an assessment of the vulnerability for human targets due to volcanic ash fallout.

This paper focuses on the management of Na-Tech hazards in wastewater treatments, triggered by the occurrence of explosive volcanic eruptions with strong ash emission. The use of a GIS provides an integrated management tool, due to the support of advanced systems for the data management, analysis and visualization.

The first part of the paper briefly describes the characteristics of a generic wastewater treatment plant; in the second part, the procedure and the implementation of the GIS-based tool is presented. Finally, in the third part, some results related to a case-study are also given, with a brief discussion.

2 WASTEWATER TREATMENT PLANTS

Water is a very valuable commodity, for this reason water supplies must be preserved and protected, but after its use, it must be purified and reused. The water purification is made through a wastewater treatment plant, which is composed by the combination of some processes' units. These units are briefly described in the following.

The primary mission of the wastewater treatment plant is to treat the wastewater stream, coming from the sewage, to an acceptable level of purity, by reducing or removing organic matter, solids, nutrients, disease-causing organisms and other pollutants; then the stream return to the environment by discharging into a water body or by an immediate reuse (i.e. irrigation, etc.).

A wastewater treatment is divided into three phases, these are as shown in Figure 1: (1) physical or primary treatments, (2) biological or secondary treatments and (3) chemical or tertiary treatments.

In the first stage, primary large solids and grit are removed by means of screenings; then the sewage stands in a tank in order to cause the sinking of suspended solids to the bottom and the rise of oil and grease to the surface. The solids are scraped off

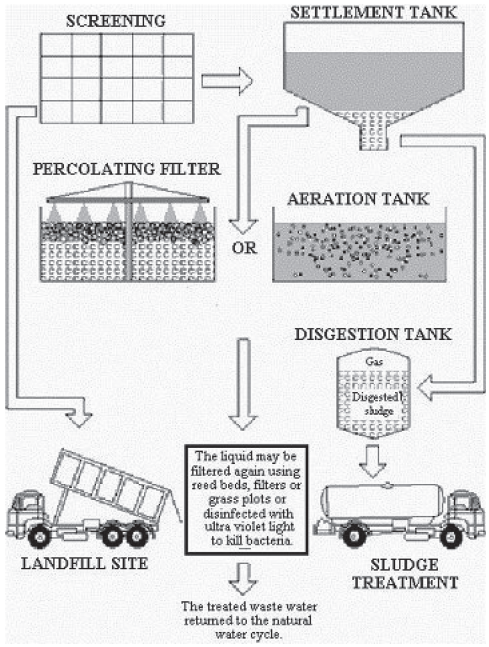

Figure 1. Wastewater treatment (website of The University of Waterloo).

from the bottom and the scum is washed off with water jets. The removed materials form sludge.

In the second stage, the liquid undergoes to a biological treatment; bacteria breakdown the solubilised organic matter. Then the stream is sent to oxidation ponds where heterotrophic bacteria continue the breakdown of the organic matter. Sludge is formed into the whole process; it is treated in large heated tanks, where its decomposition is catalyzed by anaerobic microorganisms (Website of the New Zealand Institute of Chemistry).

In the third phase, the processes aim at the removal of the additional suspended and dissolved solids, the refractory organics, the heavy metals, nitrogen and phosphorus. The equipment used depends on the specific contaminants which have to be removed. Sometimes this phase is not necessary.

3 METHODOLOGY

As mentioned above, the approach described in this paper needs to be supported by a Geographical Information System, or simply GIS. Figure 2 shows a simply scheme of the proposed methodology for the management of Na-Techs.

Firstly two databases must be constructed: the first database collects the volcanic eruptive scenarios and second one stores data about the

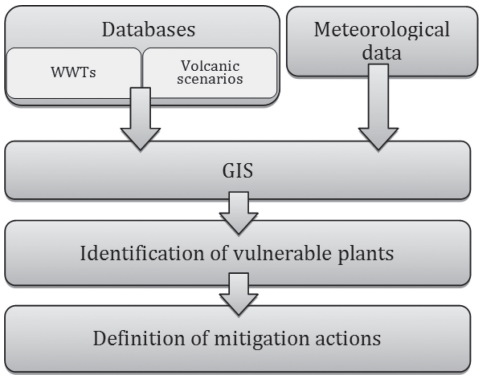

Figure 2. Methodology.

wastewater treatments located on the territory. Furthermore the GIS could be used to include other information related to the distribution of urban centres, the use of the territory, the electric network, the water supply network, etc.

In order to identify the impact areas for each eruptive scenario, a threshold value of thickness for the ash deposit must be defined. To achieve this scope, the data of different works have been examined: Day & Fisher (1980) discussed that serious problems occur with deposit >10 mm (although these are rare events); Blong (2003) reported about the eruption of Mt. Spurr in Alaska, where 3 mm of volcanic ash (~5000 g/m^2) fell on Anchorage in 1992 and caused many pipe blockages; in 2002, during the eruption of Mt. Etna (Italy), small amounts of ash caused the blockages of the rainwater drainage systems in the city of Catania (Barnard 2004), due mainly to the formation of not easily pumped material. To make this analysis conservative, a threshold limit of deposit of 1000 g/m^2 has been considered.

The use of real-time meteorological information (i.e. wind direction and velocity) and the characteristics of the eruption (emission rate) allows the selection of the scenario and its incorporation into the GIS. The impact of the *geoevent* on the territory is then easily evidenced because a map quickly identifies the impact area and the potential WWTs, which are involved at different time from the starting of the eruption. Their identification allows focusing on the mitigation actions for the plants.

The last step of the approach regards the definition of the measures that could be implemented to protect some parts of the wastewater treatment. These can be:

- the timely cleaning of roads;
- putting in place all protective measures for each equipment (i.e. the coverage of settling tanks);
- the extraordinary maintenance of the WWT.

The use of the available resources must be rational, especially when this requires the use of public funding.

4 A CASE STUDY

To show how the approach, implemented within the GIS, works, an application to the surrounding of Mt. Etna (Italy) has been carried out.

4.1 *Databases*

A census of wastewater treatments has been made; Figure 3 shows the graphical inventory, where also a legend of colour highlights the inhabitants for each area identified in the region. The collected data has been extracted by ARPA-Sicilia (2012); it can be observed that the WWTs are distributed in the whole region (Sicily) and several of them serve small urban areas. The number of wastewater treatments per provinces in Sicily is given in Table 1; the total operating plants are 225.http://www.arpa.sicilia.it/UploadDocs/6286_acque_reflue_report_2012.PDF.

Mt. Etna is a volcano located in the Southern Italy; Figure 4 shows the location (Sicily). Its surrounding is characterised by the presence of the city of Catania, many small urban centres and agricultural and industrial areas. The volcano has recently changed its eruptive style, giving more frequent explosive eruptions with strong emission of ash in the atmosphere (Branca & Del Carlo 2013). A number of eruptive scenarios have been collected from the literature and the related iso-deposit maps at different time have been stored in the GIS-database. The effects of the territorial morphology are taken into account during the execution the simulation of the scenarios. The simulations would be executed by considering a number of classes of potential wind direction and velocity and of volcanic ash emission rate.

4.2 *Meteorological data*

The use of the developed GIS-tool allows the representation of the evolution of the deposit by means of the meteorological data. The wind direction is needed to conservatively drawn the deposit formation, which will be selected according to the classes mentioned above for the wind and the emission rate.

4.3 *Identification of vulnerable plants*

The GIS allows discerning those facilities which will be potentially exposed to the ash fallout and

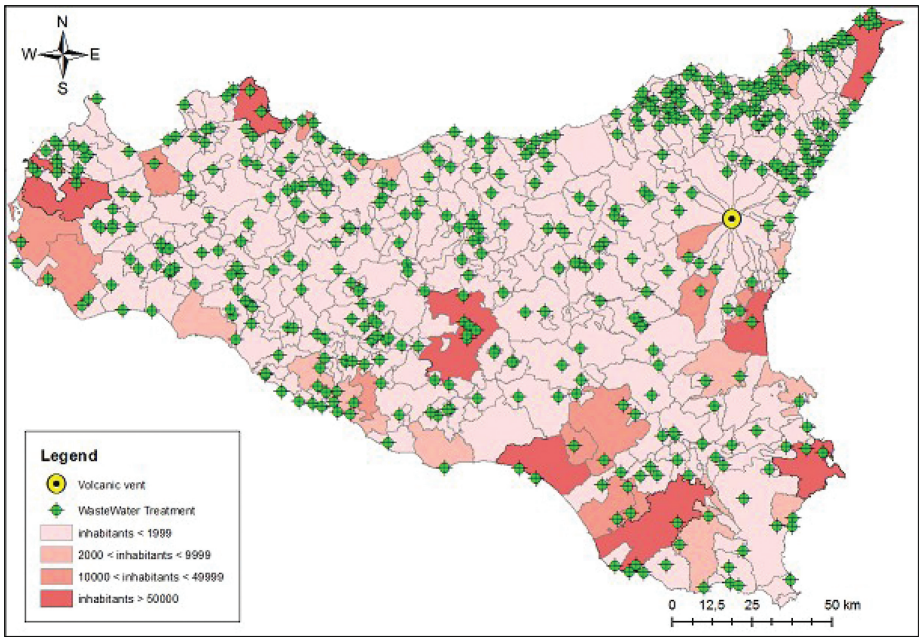

Figure 3. Census of wastewater treatments in Sicily (Italy).

Table 1. Reference samples for the study (ARPA-Sicilia 2012).

City	Plants	Operating plants
Agrigento	50	28
Caltanissetta	28	24

Enna	25	13
Messina	114	100
Palermo	70	68
Ragusa	22	21
Siracusa	12	12
Trapani	29	26

the time when the impact will occur. This means that the *geoevent* permits to gain time in activating the rights mitigation actions on WWTs and, thus, minimizing economic losses and human resources.

4.3.1 *Effect of the rainwater on ash deposit (experimental test)*

According to Milazzo et al. (2014), the effect of the water on ash deposit is significant due to the formation of aggregates of particles.

An experimental test has been executed in the laboratory to achieve a qualitative estimate of the amount of ash which will be dragged away by the rainwater. Figure 5 schematizes the simple apparatus used for the experimental test. A valve regulates the water flow rate into a drainage channel where, to simulate the eruptive scenario, a certain thickness of ash was uniformly

Figure 7. Ash aggregates in the drainage channel (compacted layer).

distributed; finally a tank (beaker) collects the water flowing through the channel. It must be underlined that during the experimental test, the water flowed very slowly, simulating a light rain (for 90 min).

To execute the experimental test, 20 g of ash (with particles having an average diameter of 0.5 mm) have been deposited in a drainage channel (length = 20 cm, width = 1 cm). A constant flow-rate of water (~0.0023 L/s) has been set (Fig. 6). To verify the reproducibility of the experiment, it has been performed several times. Each test has shown that about 50% of ash is dragged away, the remaining part forms a compacted layer and the water flows on it (Fig. 7).

5 RESULTS

Ash deposits, related to the case-study, are represented using iso-deposit curves on cartography. Figure 8 refers to the explosive eruption of Mt. Etna occurred on the 11th November 2013. A legend of colours has been defined, where each colour is associated with a class of thickness of ash on the ground. The same figure shows the wastewater treatments which could be impacted if a similar scenario occurs. The GIS quickly provides the information that the risk managers needs to put in effect mitigation measures.

To demonstrate the GIS-tool support in planning the actions to protect WWTs, an example of its use is shown relatively to the case of the occurrence of an event similar to the worst-case scenario of Mt. Etna. The worst case scenario refers to the event occurred in the period 27th October–30th December 2002; its mass flow rates was about 10^5 kg/s. Assuming that the weather condition guide the ash plume as shown in Figures 9 and 10, where the iso-deposit curve related to the previous fixed threshold limit (1000 g/m^2) is shown, it is possible to identify the wastewater treatments involved at different time from the beginning of the explosive eruption.

Figure 9 shows the scenario after 12 hours, the GIS-tool evidences 4 plants are involved. Figure 10 is related to the same scenario after 24 hours, at that time 7 plants are impacted.

The procedure permits to choose the actions to be taken to protect the facilities. The risk manager is able to define their priority and the available resources in real-time. Obviously, actions to mitigate the impact of ash fallout on facilities should be previously stored into the GIS. Thus when the event occurs, the software gives back the adapted information; as an example it is possible: to underline the presence/absence of covers for sedimentation tanks; to highlight which roads need to be swept and their priority, in order to avoid the clogging of drainage systems; to quickly identify the location of the closest disposal sites.

6 CONCLUSIONS

In this work a procedure for the risk management in wastewater treatments has been defined by means of the representation of *geoevent*.

The objective has been to provide to risk managers and planners useful tools for the emergency planning associated with volcanic Na-Tech scenarios.

The proposed approach is applicable to different case-studies. It requires the knowledge of volcanic scenarios, territorial and meteorological data. It allows the optimum use of resources to manage several wastewater treatment plants. Its use can also be applied to other kind of facility vulnerable to this natural phenomenon.

Utilizing knowledge-to-number-processes in smaller and less resource intensive risk assessments

T. Askeland & R. Flage
University of Stavanger, Norway

ABSTRACT: Turning knowledge and lack of knowledge into numbers (probabilities) is common practice in risk assessments, and several formal procedures exist today for expert elicitation of probabilities. However, these processes are often quite rigorous and extensive, while many smaller risk assessments have constraints in both cost and time, resulting in limited resources available for such processes, even though the need for numbers based on expert knowledge is essential. Thus, there is a need for less resource intensive knowledge-to-number processes, for use in the increasing number of smaller risk assessments being performed in today's society.

The aim of this paper is to review current literature within formal expert eliciting to identify if there are vital activities that can be applied also in smaller risk assessments with limited time and budgets, and to suggest a simplified process for turning knowledge into number in these assessments.

We start by discussing the fundamental issue of turning knowledge into numbers, before summarizing activities that are commonly recommended in formal expert eliciting processes. We then discuss how these activities can be utilized in smaller risk assessments, pointing out minimum activities relevant to ensure confidence in the result. Including a qualitative strength-of-knowledge assessment step to the suggested process is a main contribution of the present paper.

1 INTRODUCTION

Risk characterization is commonly based on using probability as a tool for describing epistemic uncertainty. Often there is little or no relevant data to base these probabilities on, resulting in significant reliance on expert statements. Expert eliciting processes as described by e.g. Meyer & Booker (1991), Cooke (1991) and O'Hagan et al. (2006) are processes for transforming knowledge and lack of knowledge into numbers (probabilities) through rather extensive processes. Moreover, the increasing use of risk assessments across most sectors in today's society has also led to an increased use of less extensive and less resource intensive risk assessments. Quantifying annual losses due to operational risk events in the bank sector, planning new road or rail tunnels, and documenting acceptable risk when using other than pre-accepted solutions in building design, are all examples of application areas where less extensive risk assessments are ubiquitous. These risk assessments are carried out within a relatively short time-frame and usually do not involve modelling and uncertainty aggregation resulting in overall risk indices, but are rather based on assignment of a single probability and expected consequence for hazards/threats individually. Formal expert elicitation processes involve activities that can then be too time consuming and resource intensive in this context.

Lack of data is a common challenge also for smaller risk assessments, meaning that expert knowledge remains an essential input, but inevitably, without use of the same rigorous framework for identification and training of experts, elicitation of numbers and post-processing that is common in comprehensive Quantitative/Probabilistic Risk Assessments (QRAs/PRAs).

There is hence a need for less resource intensive process for transforming knowledge to numbers for use in smaller risk assessments.

The aim of the present paper is to suggest a common platform and process for the utilization of a knowledge-to-number process in smaller risk assessments. This is done as follows: In Section 2 we first discuss the fundamental issue of turning knowledge into numbers, before reviewing activities that are commonly recommended in knowledge-to-number-processes. In Section 3 we discuss how these processes can be adapted and utilized in smaller risk assessments, resulting in a set of minimum activities necessary to ensure confidence in the result. A qualitative strength-of-knowledge assessment step in the suggested process is a main contribution of the present paper. Section 4 concludes.

2 DEFINITIONS AND FUNDAMENTAL ISSUES IN TURNING KNOWLEDGE TO NUMBERS IN RISK ASSESSMENTS

2.1 *The need for expert knowledge*

Risk assessments commonly use frequencies of observed events (i.e. historical data) as a major part of the basis for the risk assessment. To decide whether some available historical data is relevant for the future situation may be challenging. When in lack of data, or when we believe the past is not relevant for assessing the future, we turn to experts who possess knowledge that we consider relevant and want to apply in the assessments. We ask the experts to provide their opinion, and quantify degrees of belief using subjective probabilities.

2.2 *What is an expert?*

Meyer & Booker (1991 p. 85) define an expert as "… anyone especially knowledgeable in the field of detail being elicited—the individual should not be considered an expert unless he or she is knowledgeable at the level of detail being elicited." O'Hagan et al. (2006 p. 26) use a somewhat broader definition: "An expert may, in principle, just mean a person whose judgments are to be elicited."

Cooke & Goossens (2004) describe that the selection of experts may take place through a formal procedure, where the selection criteria are:

- Reputation in the field of interest
- Experimental experience in the field of interest
- Number and quality of publications in the field of interest
- Familiarity with uncertainty concepts
- Diversity in background
- Awards
- Balance of views
- Interest in the project
- Availability for the project

While Cooke & Goossens (2004) emphasize formal background to be defined as an expert, neither Meyer & Booker (1991) nor O'Hagan et al. necessarily define the expert as an academic person. In a risk assessment, also operational experience for example related to a particular piece of process equipment, or to local conditions in a land area, may be useful information. The knowledge of such details may make a person an expert, even without publications or awards, but through operational experience. A pump mechanic may be the best available expert on the pumps in the plant where he or she works. Requiring an expert to be used to work with probabilities in order to participate in a knowledge-to-number process reduces the availability of experts for smaller risk assessments. In this case, more guidance from the risk analyst may be appropriate, underlining the importance of the analyst's facilitation skills and competence.

2.3 *What is knowledge?*

Knowledge is defined in a wide variety of ways. One definition is that knowledge is "*information, gathered from experience and reasoning, that has been interpreted and can be used*" (Oxford dictionary of Environment and Conservation, 2013). By using this definition, we allow the pump mechanic to be an expert, because he or she through experience with daily use and maintenance of the pumps should be expected to have gathered knowledge about level of functionality, possible failures, etc.

2.4 *Activities in knowledge to number processes*

Several different approaches or processes for expert elicitation can be found in the literature. These are often tailored specifically to certain types of risks and sources of risk (Melnick et al. 2008). Some commonly referred processes are those described by Merkhofer (1987), Meyer & Booker (1991), Cooke & Goossens (2004) and O'Hagan et al. (2006).

Despite some variation in where the processes start and finish, and in the number and order of the steps, some common core elements can be distilled:

- Identification of need for expert knowledge
- Design of elicitation process
- Identification, selection, motivation and training of experts
- Elicitation
- Post elicitation work (aggregation and documentation)

A review of each of these steps is given in the following.

2.4.1 *Identification of need for expert knowledge*

The identification of need is as a trigger of the entire process. It is necessary to clarify why expert knowledge is required in the risk analysis process in the end, to ensure that the result from the process matches the need in the risk analysis. Expert judgment is especially suitable in the following settings (Meyer & Booker, 1991):

- To provide estimates on new, rare, complex, or otherwise poorly understood phenomena
- To forecast future events
- To integrate or interpret existing data
- To determine what is currently known, and what is not known.

2.4.2 *Designing elicitation process*

The references in Section 2.4 all include a design activity related to structuring the questions we want to ask the experts, even though they use some different expressions. Cooke (1991) defines some recognized principles to follow when designing an expert elicitation process:

- Reproducibility—it must be possible for scientific peers to review and to reproduce all calculations.
- Accountability—the source of expert subjective probabilities must be identified.
- Empirical control—expert probability assessments must in principle be susceptible to empirical control.
- Neutrality—the method for combining/evaluating expert opinion should encourage experts to state their true opinions.
- Fairness—all experts are treated equally, prior to processing the results of observations.

Cooke & Goossens (2004) focus on the identification of variables (target variables, query variables and performance variables), so do Merkhofer (1987), while Meyer & Booker (2009) focus on questions (question areas and particular questions). Of course, the identification of variables in the next step has to materialize into some questions before the experts enter the process, and many of the points made in these references are the same.

First, the variables to be considered need to be identified, and a procedure for doing so has to be designed; which may be more or less demanding. Furthermore, the variables may have to be decomposed. There are several reasons for this: First, decomposition gives a better understanding of causes and underlying factors. Secondly, even experts may not have a well-developed comprehension of very small probabilities (Aven, 2012). Decomposition is recommended by Merkhofer (1987), Meyer & Booker (1991) and O'Hagan (2006) as one of the major preparation step to an elicitation or as a part of the work for the experts, e.g. when doing a cause analysis. The use of decomposing improves the quality of the elicitation of subjective probability assessments (Kleinmuntz, 1996). The decomposing also reduces the difficulties experts may have in assessing very small probabilities.

Cooke (1991) argues that the design step should include a testing activity, where experts are tested before the elicitation by giving them questions from within their field of knowledge where the answer is known, although not to the experts. Such testing should be followed by a calibrating session, helping the expert to assess the "right" probability. Aven (2012, p 73) argues that calibration in general is not very useful to evaluate the goodness of the probability assignments in risk analysis, as the probabilities then needs to be evaluated before the observations. He rather sees calibration as a tool for training experts to provide input to the risk analysis, giving increased credibility to the expert.

Practical issues such as budget, time schedule, means of communication, remuneration etc. is a part of this design activity.

2.4.3 *Identify, select, motivate and train experts*

The identification, selection, motivation and training of experts is perhaps the step with the greatest variation between the procedures described in the literature. While Merkhofer (1987) starts the process by motivating the experts (thus presupposing that the expert is already identified and selected), Cooke & Goossens (2004) emphasize that all experts within the given area should be carefully identified according to a set of selection criteria. As many experts as possible should be selected, they argue, and as a minimum four experts.

Meyer & Booker (1991) warn of using too many experts together in an elicitation process, due to potential conflicts that may arise from group dynamics, such as "follow the leader" effect.

O'Hagan et al. (2006) present a similar but shorter list of selection criteria compared to Cooke & Goossens (2004), pointing out that the selection of experts has to be an open process when there is public interest or controversies attached to the process.

Cooke & Goossens (2004) suggest an expert training session, since most experts are not necessarily familiar with stating their degree of belief related to uncertain quantities. In the training session, the expert should be informed about the purpose of the upcoming elicitation process, as well as given practical information related to the process. The importance of giving the experts a good understanding of subjective probability is emphasized.

O'Hagan et al. (2006) propose a three-step training process, and point out that the training must be adapted to the assigned expert, i.e. there needs to be differentiated training depending on the expert's understanding of probabilities. The training should include:

- Probability and probability distributions.
- Information about the most common heuristics and biases, including advice about how to overcome them.
- Practice elicitation, particularly using examples where the true answer is known, but unlikely to be known by any of the experts.

Meyer & Booker (1991) emphasize training not only for the experts, but also for the team managing the process. Organizing a large elicitation process

with many experts and a tight schedule, the team management must be well prepared to avoid mistakes or misunderstandings, both methodically and logistically. However, this is not always relevant for smaller risk assessments, due to a small staff, even though it is a point always being well prepared, also when just eliciting one or a few expert.

Turning knowledge to numbers, through eliciting probabilities from experts, is a heavy mental process. According to Meyer & Booker (1991), the expert will perform four cognitive tasks during elicitation:

- Understanding the question
- Remembering the relevant information
- Making judgments
- Formulating and reporting an answer.

This process is often exposed to heuristics. Many sources concerning heuristics and biases within expert elicitation points at the work of Kahneman, et al. (1982), and in some degree Hogarth (1975). Kahneman et al. (1982) describe how we perform judgments, but are inclined to do so using heuristics—mental shortcuts used when processing information and analysis in human mind, leading to biases in the answers. Both Meyer & Booker (1991) and O'Hagan et al. (2006) emphasizes that giving the expert sufficient knowledge of these biases, as a part of their training is crucial.

2.4.4 *Elicitation*

The elicitation activity in a formal elicitation process is where knowledge actual becomes numbers. The activity may include one or more experts, face-to-face interviews, group sessions, or other types of communication. Garthwaite et al (2005) present an iterative process for this activity:

- Elicit specific summaries of the expert's distribution
- Fit a probability distribution to those summaries
- Assess adequacy: If adequate, then stop; otherwise repeat the process, asking the expert to make adjustments.

Meyer & Booker (1991) describe how different methodologies than face-to-face interviews can be used in a group elicitation, such as the Delphi technique, not to be further commented in this paper.

Even though focus is on turning knowledge to numbers, it must be emphasized that the expert knowledge can be utilized also to increase the understanding of phenomena when necessary. This can be done through a stand-alone activity, often followed by the elicitation of numbers. For example, when building an event tree it is necessary to understand the phenomena in order to establishing the tree, followed by the elicitation of numbers to fill into the tree.

2.4.5 *Post elicitation work*

When eliciting probabilities or distributions from several experts, the experience may be that the experts disagree to some extent. This disagreement can be followed up further, exploring the underlying assumptions, but at some point, we may have to use one number or distribution to represent the experts' input. O'Hagan et al. (2006) describe two ways of aggregating or combining the experts' responses:

- Mathematical aggregation (also called mechanical aggregation)
- Behavioral aggregation

Clemen & Winkler (1999 p. 188) define mathematical aggregation as "processes or analytical models that operate on the individual probability distributions to produce single combined probability distributions", and behavioral aggregation as an "attempt to generate agreement among the experts by having them interact in some way". Mathematical aggregation methods range from more sophisticated methods using axiomatic approaches or modeling of the aggregation process, taking care of dependence between the experts' opinions, to more simple measures, such as the arithmetic mean (Equation 1) or geometric mean (Equation 2).

$$\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{1}$$

$$\left(\prod_{i=1}^{n} x_i\right)^{1/n} = \sqrt[n]{(x_1 x_2 \ldots x_n)} \tag{2}$$

where n is number of probabilities/observations, and x_i the i'th probability/observation value.

Behaviour aggregation is the process where a group reaches consensus, by "*bring[ing] experts together in a group and eliciting their beliefs as if they were a single expert"* (O'Hagan et al., 2006 p. 186). Challenges with behavioural aggregation is more psychological than mathematical of nature (O'Hagan et al., 2006 p. 187), as the process is subject to several group dynamic biases. Behavioural aggregation may be very time consuming (Meyer & Booker, 1991 p. 118), but it can also increase the understanding of differences between the experts, clarifying the background knowledge available for each expert's view, being a valuable contribution to further analysis.

An interesting point made by Clemen & Winkler (1999) is that both more advanced mathematical approaches and behavioral aggregation often is outperformed by simple mathematical approaches. Furthermore, Meyer & Booker (1991 p. 317) show how little weighting of experts (proposed as a method when having more trust in one expert than

Table 1. Roles in a formal expert eliciting process.

Roles	C&G	Merk.	O'Hagan	M&B
Expert(s)	x	x	x	x
Analyst(s)	x	x	x	x
Statistician (s)	(x)	–	(x)	(x)
Adm. pers.	–	–	(x)	x
Decis. maker	x	–	x	x

in another) affect the mean. Extreme values affect much more, which can be handled by relying on the geometric mean rather than the arithmetic mean.

Kahneman, et al. (1982) argues for using the median rather than the mean in knowledge-to-number processes. They found that when experts were forecasting the mean value in a distribution, in reality they used a value that was more like the median. Kahneman, et al. (1982) found that the shape always had a skew-ness, resulting in an arithmetic mean different from the median. From this, Meyer & Booker (1991 p. 316) argue to use an expert judgment of the arithmetic mean value as median value, or to use the geometric mean.

2.5 *Roles and resources*

The scope and extent of the process will affect the resources needed. Cooke & Goossens (2004) point out that past studies have used between 4 and 20 experts, which probably would require several analysts and administrative personnel to run the process.

O'Hagan et al. (2006) point out that the process can be performed by only two persons if necessary, one expert and one analyst. Often there is also a decision maker included; however, as O'Hagan (2006) says, the expert and decision maker may be one and the same, and if the analyst also is capable within statistics, the process can be performed by only two persons. However, both O'Hagan et al. (2006) and Meyer & Bookers (1991) include more roles to the process. These are often necessary in larger formal expert eliciting processes. Table 1 gives a summary of actual roles described in the processes of the referred literature.

3 UTILIZATION OF KNOWLEDGE TO NUMBER PROCESS IN SMALLER RISK ASSESSMENTS

3.1 *Challenges in smaller risk assessments*

The wide range of situations were risk assessments are required has led to an increased number of risk assessment being performed. Many of these risk assessments are characterized by fewer resources available than what is the case in extensive Quantitative/Probabilistic Risk Assessments (QRAs/PRAs) in for example the oil & gas sector or the nuclear sector. Another typical aspect with these risk assessments is that the need for expert knowledge is huge, as they often are related to new events and/or new surroundings, resulting in lack of data, and perhaps poorly understood causes. The budget of a typical small risk assessment may be between 40 and 200 hours, inevitably giving a weaker foundation for decision than a QRA/PRA (unless given a narrowed scope).

A small amount of available hours gives limitations on how the process can be carried out, and how many experts that can be involved. Cooke & Goossens (2004) say that the amount of expert time required for making the assessments depends on the subject and may vary between a few hours and a week, per expert.

A challenge for most risk assessments, not only the small ones, is that the numbers used do not properly reflect the strength of the knowledge it is based upon. To be aware of the actual knowledge level, we need to identify what we know, but also what we do not know. The strength of knowledge is not visible in a single probability; thus, we may have to assess the knowledge, in some way demonstrate the strength of the available knowledge. This weakness of should also be addressed in the knowledge to number process, identifying the degree of expert knowledge utilized.

3.2 *Recommended activities within knowledge to number in smaller risk assessments*

3.2.1 *Identification of need for expert knowledge*

The need for expert knowledge in smaller and less resource intensive risk assessment may be huge, and the use of expert knowledge is probably the only way to ensure a useful and trustworthy result. However, there will not be much resources available for identifying and evaluating experts, reducing the identification and selection of experts to a limited activity.

The identification of a need for expert knowledge is rather an input to, more than an activity in the process. A need is not an activity by itself, but comes as a result from another activity. This leaves the design activity, including selection of experts, as the first step in the process, with the identification of need for expert elicitation as the trigger.

3.2.2 *Designing elicitation process*

The design of the elicitation process in less resource intensive risk assessments should, as any other elicitation processes, ensure compliance with the main principles mentioned in section 2.4.2 (reproducibility, accountability, empirical control, neutrality, fairness). However, in smaller and less resource

intensive risk assessments the design phase does not have to be very complicated and resource demanding. We believe a restructured process, shortened and simplified, and supported by an assessment to identify the strength of knowledge, will increase the quality of the process. Instead of five major activities (see section 2.4), we propose three as follows:

- Design phase (preparations, designing elicitation process, identification and selection of experts)
- Data collection (elicitation)
- Data analysis (verification, aggregation and documentation)

The word data is here used in the sense of both hard data and expert judgments; Aven (2012).

The design phase starts when the need for expert judgment is identified. The expert(s) are going to use their knowledge of some specific phenomena, e.g. to quantify lack of knowledge about the variables of interest using probabilities. These variables should be identified, and if possible, the need for decomposing should be identified and carried out by analysts if possible. Alternatively, if the analyst has a poor understanding of the knowledge area, the use of expert should include time also to perform the decomposition as one of the activities for the experts. The data may have different formats dependent on the risk assessments methodology used. They can be single numbers (probabilities) or distributions as input to a quantitative model, or they can be probability classes (intervals) or consequence classes if using risk matrixes. Eventually, the data can be knowledge helping the analyst to establish either an event tree or a fault tree, helping the analyst to understand the phenomena, and how it can affect other parts in a given system.

The design should also give input to how many experts are needed. Lack of resources gives limitations; however, within these limitations, referenced literature advice to have as many as possible. Clemen & Winkler (1999) shows that a group of experts tends to outperform the average expert, but that the best expert outperforms the group as a whole. The benefit of using several experts are then obvious, but if in lack of resources or experts, one is better than none, otherwise forcing the analyst to do his/ her own assessments, which often is the alternative. This means that number of experts must adapted to available resources. However, O'Hagan et al. (2006) point out that one man can do the job, if we are confident that we are able to have one excellent expert. We believe always struggling for four or more, as Cooke & Goossens says, are unrealistic within these limitations of resources. As a follow up of this, and to ensure that the decision-maker is made aware of what knowledge is being used, we propose a "*strength-of-knowledge assessment*" to evaluate the expert knowledge available (see 3.3).

The data analysis procedure must be planned. If we use several experts, and if there is a need for aggregated data, referenced literature shows that simple calculations, using the geometric mean, is often to prefer. Then there is no need to spend more time or effort than necessary, but plan to report the data and the geometric mean. However, depending on the scope, further analysis may be appropriate, and this has to be considered in the design phase, but also during the elicitation. Some resources to continuously follow up the data, safeguarding quality, must be secured.

As a part of the design, when we know the expert's knowledge better, elicitation training should be planned. Even though we plan to do the whole process as fast as possible, referenced literature shows that giving experts information and training in front of the elicitation makes sense, especially regarding heuristics and bias. We see no reason to change the 3-step training procedure proposed by O'Hagan et al. (2006). Small assessments usually have at least one one-day workshop. It is possible to plan for both the training and the elicitation during this day, if the amount of elicitation rounds are limited, as expected in smaller and less resource intensive risk assessments.

Information to the expert should include all practical information, and all background information relevant for the scope of the assessment. The information should be sent in advance to the experts, encouraging them to prepare for the day.

3.2.3 *Identify, select, motivate and train experts*

The identification of a need for expert knowledge is a result of a lack of knowledge in a risk assessment. The analyst, or other in charge of the risk assessment, has to identify the field of knowledge needed, and find persons with the demanded knowledge. Is it good enough to have general phenomenological knowledge? Are there any people at all with activity-/system-specific expert knowledge? If in need of e.g. an expert to evaluate landslide risks, the probability that any geologist has knowledge to the current area up front is low, but being a geologist is by definition being an expert in geology, being able to understand and analyze a current situation related to land slide risks. Likewise, if searching for experts regarding a company's internal culture, relevant experts are probably working within the company, probably having sufficient expert knowledge, reducing the search activities to be acceptable also in a less resource intensive risk assessment.

The decision maker must have confidence in the results, leaving him the choice of increasing the resources, if that is the issue, or having less confidence in a result made of the analyst, without expert knowledge.

The activity called "identify, select, motivate and train experts" could be seen as both a part of the preparations in design phase, and the training and motivation is really a activity taking place together with the elicitation, and should be placed there.

3.2.4 *Elicitation*

The elicitation activity, the data collection, is not different in smaller and less resource intensive risk analysis than in other elicitation processes, maybe except for a less comprehensive scope, with fewer runs.

The goal of the elicitation activity is to elicit numbers from the expert, handling heuristics in a way reducing bias. If only one expert is used, group heuristics are reduced, such as anchoring, follow the leader, etc. unless the analyst make some pitfalls.

When the elicitation starts, the expert has participated in the training, giving him/her a basic understanding of probabilities and relevant probability distributions. Further, the expert has knowledge about heuristics, and how to overcome them.

To ease the elicitation activity, the analyst may use software for expert elicitation to run the elicitation smooth and fast.

3.2.5 *Post elicitation work (aggregation and documentation)*

In this step the data analysis activities, data are checked, verified, and if necessary aggregated, prepared to use in a risk model or other tool. Cooke & Goossens (2004) propose weighting of the experts judgments if there is reasons to differentiate the influence each expert should have. However, Meyer & Booker (1991) shows that the weighting must be disproportionately uneven to really affect the result, compared to how variations in the judgment affects the arithmetic mean. With reference to section 2.4.5, the geometric mean could be used instead of arithmetic mean, reducing the need for weighting. Compliance with Cooke's recognized principles (see section 2.4.2) should be documented.

3.3 *Strength-of-knowledge assessment*

As mentioned in section 3.1, a weakness of many risk assessment is the lack of documentation of strength of knowledge. It is common to see the risk assessment as a process where the analyst identifies and documents some defined expert's knowledge in the field studied. Aven & Guikema (2011) say; "*The produced probability assessments are founded on the knowledge of subject matter experts but are heavily filtered through and, in some cases heavily influenced by the expert knowledge of the risk analysts*". The risk assessment should systemize knowledge, but also lack of knowledge, using the probabilities as measures of the related uncertainty. From this follows two points. Firstly, the analyst does apply knowledge to the risk assessment, and the analyst's knowledge should then be seen as a part of the total knowledge available. Secondly, it is crucial, given a phenomenon, to identify what is known, and what is unknown. Doing a risk assessment of a poorly understood phenomenon is often necessary, even though we know there is a lack of knowledge, because societies need decisions. Identifying both knowledge, and lack of knowledge, is crucial when making decision support.

We suggest a "strength-of-knowledge assessment", which is expected to increase the awareness related to both expert's and the analyst's knowledge level, and may support a decision maker, making her/him aware of the level of knowledge used. The following criteria may serve as a guideline.

3.3.1 *Strong knowledge*

All of the following conditions fulfilled:

- Several experts are used, with insignificantly diverging statements.
- All experts are experts both in terms of general phenomenological knowledge as well as in terms of specific system/activity knowledge.
- All experts have both formal competence in probability/statistics as well as practical experience with probability elicitation.
- All the principles of rational consensus (Cooke, 1991) are followed.

3.3.2 *Weak knowledge*

At least one of the following conditions fulfilled:

- Several experts with significantly diverging statements.
- Expert(s) without specific knowledge about the system/activity considered.
- Several of the rational consensus principles are not followed.

3.3.3 *Moderate knowledge*

Conditions between strong and weak, e.g.:

- Several experts with some diverging statements.
- Some experts are only experts in terms of either general phenomenological knowledge or in terms of specific system/activity knowledge.
- Only one expert, but expert both in terms of general phenomenological knowledge as well as in terms of specific system/activity knowledge.
- A few of the rational consensus principles are not followed.

3.4 *Summary of suggested procedure*

Table 2 summarizes the suggested activities for a knowledge-to-number process, in smaller risk assessments, highlighting differences compared to formal expert eliciting processes. It shows the

Table 2. Proposed changes in elicitation process.

Activity	Differences
Identification of need:	Identification of need:
Design:	Simplified elicitation process. – Design – Data collection – Data analysis Simplified plan for data analysis.
Identify/select/ train expert:	Activities allocated in design and elicitation (data collection) Only1–3 experts, better with one real expert than several fair. Focus is to find real expert. Expert does not have to be an academic record, but his/hers knowledge useful in the risk assessment
Elicitation: (Data collection)	Not different, just less Comprehensive, reflecting the nature of smaller risk assessments. Training and elicitation in one day.
After elicitation work: (Data analysis)	Mainly mathematical aggregation, with use of geometric mean. No weighting of expert judgment. Strength-of-knowledge assessment

activities from a formal elicitation process (left), describing the differences in an alternative, scaled-down proposed process (right). The change from the more formal process to this shorter process makes it easier to follow a structured approach for expert eliciting, and transforming knowledge to numbers, as it can be carried out with fewer resources than a formal eliciting process as described by e.g. Cooke & Goossens (2004) and Meyer & Booker (1991).

4 CONCLUSION

The purpose of this paper has been to point out how we can improve smaller risk assessments by improving the use of expert knowledge. Today's utilization of expert knowledge in smaller risk assessments often do not follow proposed formal expert eliciting process activities. Despite limited resources in smaller risk assessments, we believe a simple, yet more structured process will increase the quality and contribute to more valuable decision support, increasing the decision maker's confidence in the result.

This structured process should include a design phase, a data collection phase and a data analysis phase. Just to be aware and plan (design) how to use expert knowledge, is an advance compared to how small risk assessment often are done today. A simple mechanical aggregation, if relevant, without behavioral aggregation or weighting, will simplify the analysis phase.

The strength-of knowledge assessment is a new activity in risk assessments. We believe that a strength-of-knowledge assessment as suggested will increase the analyst's awareness when using experts, forcing analysts to identify and document the level of own and expert knowledge, adding value to the risk assessment as decision support by giving the decision-maker insight into the knowledge base of the analysis.

ABSTRACT: The paper deals with the procedure of semi-quantitative risk analysis of ground water source earmarked for emergency supply of population with regard to a selected set of natural and anthropogenic hazards. The risk analysis proved that the source is sufficiently resistant to identified hazards and may be included into the regional crisis plan. The proposed method may become a guideline for the risk assessment of ground water sources as one of the significant classification criteria of these important alternative sources of emergency supply with drinking water within the crisis planning system.

1 INTRODUCTION

It is highly topical and important to pay attention to the security aspects of infrastructure supplying population and industry with drinking water. It reflects the development and understanding of global security threats from the EU standpoint (European Council 2003), as well as from the standpoint of the Czech Republic (The Government of the Czech Republic 2011), and close dependence and interrelation of individual branches, elements and services of critical infrastructure. At first, emphasis was not put on water supply in the process of assessment and protection of critical infrastructure. However, in the last decade this branch of critical infrastructure has gained an adequate significance in relation to the assessment of economic, social, health and ecological risks. Generally speaking, there is an increasing risk that either natural impact or anthropogenic intervention on a sensitive spot of water supply system within public network will cause a large-scale and avalanche-like spread of damage (Hubackova et al. 2014).

During crisis and emergency events the supply of drinking water is often interrupted, which results in the paralysis of life of population, the production processes demanding drinking water, the operation of medical facilities, the fire protection of built-up areas and industrial areas (Hubackova et al. 2014). The exploitation of ground water sources may significantly contribute to a state when a situation is managed and a crisis overcome (Bozek et al. 2013). The condition of an effective exploitation of such sources and an easier decision-making process in a crisis is to include the sources into crisis plans on the basis of selection carried out with the help of risk analysis and the assessment of other indicators (Bozek at al. 2012).

2 THE ANALYSIS OF CURRENT STATE

The emergency water supply of population by drinking water during crisis situations or emergency events is not addressed by Community Law in the EU as a whole. The solution of this matter is solely the responsibility of the EU member states.

Most countries transfer responsibility for managing emergency situations from a public sphere to citizens. Fast and effective decision-making is thus individual and has to reflect the awareness of a particular situation and local conditions (National Institute of Public Health 2007). It is usually assumed that the households will supply themselves with water in the amount depending on the number of persons and domestic animals. Some authors even recommend the people afflicted by the interruption of drinking water supply to treat raw water on their own (Lantagne & Classen 2012) and provide them with guidelines how to

do it (Lantagne 2008). The US EPA also presents detailed guidelines on its websites informing the population about what to do in a crisis in case there is not enough bottled water and it cannot be disinfected by boiling (US EPA 2014).

The public sphere solves primarily the situations when water has to be supplied to hospitals, medical facilities (American Water Works Association and Centers for Disease Control and Prevention 2014) and other public institutions, reception camps and centres in which it is necessary to accommodate more people during the crisis (Amar 2010). The US EPA report is not focused only on the practical aspects of local planning in relation to the emergency supply of drinking water, but also on the roles and responsibilities of various levels of state administration. It also includes technical planning elements and presents recommendations how to respond better to post-crisis situations (US EPA 2011). Daniel and Morley also deal with the issue of water supply immediately after the crisis situation is over (Daniel & Morley 2011).

The emergency water supply in the Czech Republic is provided by crisis management authorities through the Emergency Water Supply Service. Depending on the level of disturbance of drinking water public supply systems the population may be supplied in the following ways (Ministry of Agriculture of the Czech Republic 2011):

a. Undisturbed water supply systems or their parts;
b. Undisturbed independent intake structures, mainly wells;
c. Drinking water supplied in tanks;
d. Mobile water treatment plants and other technological facilities;
e. Supply of bottled drinking water as an additional way of supply.

During emergency supply the priority is given to the water supply system capability of supplying drinking water even at lower quality. It is also preferred to exploit primarily the alternative sources of ground waters, especially vertical intake structures, built and equipped for collecting the ground waters of deeper circulation, and possibly also horizontal and combined intake structures (Ministry of the Agriculture of the Czech Republic 2011). The accumulation of surface waters in water reservoirs and watercourses cannot be recommended for the emergency supply due to its high level of vulnerability and often lower water quality. The above mentioned sources should be used only exceptionally and in well justified cases. Even not all hydrogeological structures are suitable, because they are exposed to different hazards and have different levels of vulnerability (Bozek et al. 2011).

At present the alternative sources of ground water for emergency supply of population are classified in the following three categories in the Czech Republic (Bozek et al. 2013–2013):

a. The sources of extra significance, such as ground water intake structures of increased resistance capable of supplying the required amount of drinking water;
b. The sources capable of resisting a small scale damage to the drinking water supply system;
c. The other intake structures not included into the sources of the above mentioned categories, which are used for mass supply of population with drinking water from public water supply systems.

The current classification of water sources is imperfect as it does not stem from the analysis of risks, which may damage or destroy the alternative sources. Therefore the University of Defence participates, together with the GEOtest plc., in the project of security research No. VG20102013066 into "Methodology of Assessing the Emergency Water Supply on the Basis of Risk Analysis" (Bozek et al. 2013–2013), which is financed by the Ministry of Interior of the Czech Republic. The aim of the project is to develop the classification of ground water sources based on the analysis of risks resulting from natural and anthropogenic hazards, health hazards related to water quality, the assessment of traffic accessibility, availability, and richness of the source and the costs of putting the water source into operation. Such an analysis will improve the selection of water sources to be incorporated into crisis plans and will help to manage crises more effectively with accent on the emergency survival of population, important production processes and the functions of public administration.

The implementation of our methodology of assessing the selected natural and anthropogenic risks to ground water sources (Bozek et al. 2012) is presented in the paper on a particular source Drnovice, drill-1, which has been earmarked for the emergency supply of drinking water. The considered hazards include primarily natural hazards, breakdowns, ordinary activities and environmental burdens.

3 APPLIED METHODS

The assessment of risk that a selected ground water source is threatened by natural and anthropogenic hazards stemmed from the index point values of identified hazard/sensitivity pairs assigned to individual elements of hydrogeological structure and technological equipment of water source. Brainstorming was used for indexing the levels of hazards and vulnerabilities (Osborn 1963). The indexation was made at three meetings of seven experts and one laic.

The same brainstorming became the basis also for setting the hazard/sensitivity pairs of individual water source elements. The indexation of the level of j-hazard $f_j(\tau) \in (0; 5\rangle$ was in a set of positive real numbers Re^+ depending on the hazard source activation frequency and considering the historical data. Similarly, the sensitivity index point values $S_{j,i}(\tau) \in (0; 4\rangle$ were determined in the set of Re^+ as the function of damage to i-element of water source caused by the activation of j-hazard source.

The quantification of risk index $R_{j,i}(\tau)$ representing the level of contamination, damage, or destruction of i-element of the assessed ground water source caused by j-hazard in given time τ has been calculated according to relation (1):

$$R_{j,i}(\tau) = const'_i(\tau) \times f_j(\tau) \times S_{j,i}(\tau) \quad (1)$$

Thus risk index $R_{j,i}(\tau)$ represents the product of invariable $const'_i(\tau)$, frequency value $f_j(\tau)$, and sensitivity value $S_{j,i}(\tau)$ expressed in point indexes. The invariable $const'_i(\tau) \in \langle 1; 3\rangle \wedge const'_i(\tau) \in Re^+$ is the reflection of criticality $C_i(\tau)$ of the assessed i-element of water source in given time τ.

Brainstorming has also been applied for determining the values of $const'_i(\tau)$ for i-element of ground water source. During this process it was respected the importance of each element for fulfilling its function as a water source for emergency water supply, as well as the possibility of its substitution or repair, as in case of water intake structures and water treatment plant being substituted by a mobile water treatment facility. The values of invariable $const'_i(\tau)$ are reported in Table 1. They have been acquired as a median from the values suggested by the members of brainstorming team.

Furthermore, the risk acceptability of each i-element of ground water source has been determined in relation to j-hazard by comparing the calculated value of risk $R_{j,i}(\tau)$ with the characteristic of particular interval of risk point values. The characteristic of risk point intervals has been acquired through a complete Delphi method with one iteration (Dalkey & Helmer 1963).

Table 1. The invariable of criticality $const'_i(\tau)$ for the i-elements of monitored water source.

4 FINDINGS AND DISCUSSION

The values of activation frequency point indexes $f_j(\tau)$ for the identified j-hazard sources are presented in Table 2 together with the values of sensitivity point indexes $S_{j,i}(\tau)$ for i-elements threatened by j-hazard of the assessed water source.

Based on the known values of invariable $const'_i(\tau)$, values of frequency point indexes $f_j(\tau)$ and sensitivity point indexes $S_{j,i}(\tau)$ the calculation of risk point indexes $R_{j,i}(\tau)$ has been made for each i-element of the assessed ground water source in relation to each j-hazard source. The acquired outcomes are clearly shown in Table 3.

Furthermore, individual intervals of risk point indexes have been defined for assessing the acceptability of risk in relation to each j-hazard source and i-element of water source. The outcomes are in a well arranged way shown in Table 4. It is obvious from equation (1) and the definitions of frequency $f_j(\tau)$, sensitivity $S_{j,i}(\tau)$ and invariable $const'_i(\tau)$, that the values of risk point indexes $R_{i,j}(\tau) \in (0; 60\rangle \wedge R_{i,j}(\tau) \in Re^+$.

By comparing the data from Table 3 with the characteristics of intervals of risk index point values in Table 4 it may be discovered that all the identified risks resulting from the selected set of natural and anthropogenic hazard sources threatening the assessed ground water source are either negligible or acceptable.

The risk point index $R_{i,j}(\tau)$ of the increased radioactive background accompanied with the leak of radon is near the tolerable limit. This is caused by the origin of sedimentary material of rocks with the higher content of potassium and a number of mineral deposits of radioactive materials, which are still mined. While the radioactive background is almost constant in the area of infiltration and the source vicinity and its intensity decreases in time only due to the fission of radionuclides, the leakages of radon in the atmosphere fluctuate in dependence on the atmospheric pressure. The increased radioactive background accompanied by the leak of radon may deteriorate working conditions in non-ventilated water treatment facilities. The occurrence of radon in water does not represent risk in case of oral exposure. However, it represents not negligible carcinogenic risk due to the respiration exposure to radon volatilized from water in non-ventilated environment.

North of the assessed drill in the former stone quarry there is an illegal dump of solid household waste. The composition of waste dump as well as the migration of possible contamination are not known and more detailed information is not available. However, the extended analysis of water in the drill did not detect the leak of contaminants from the illegal dump into the hydrogeological col-

Table 4. Characteristics of risks $R_{i,j}(\tau)$ for individual intervals of risk point indexes.

Interval of risk point indexes $R_{j,i}(\tau)$	Characteristics of risks
(0; 5⟩	Negligible. Water source may be immediately exploited without implementation of countermeasures.
(5; 18⟩	Acceptable. Water source can be immediately exploited with implementation of countermeasures, if need be, on the basis of a statement and decision made by top-management of source operator. The benefit of measure should be higher than costs.
(18; 30⟩	Tolerable. The exploitation of water source is heavily limited. If water source is to be used for the emergency supply of population, it is necessary to implement countermeasures in order to reduce the risk on the acceptable level. The costs of reducing the risk have to be adequate for the value of protected source element and the social benefit. In this case it is recommended to apply the Cost-Benefit Analysis method, possibly a multi-criteria assessment, which will enable us to assess the effectiveness of particular countermeasures being taken.
(30; 60⟩	Unacceptable. It is not recommended to exploit the water source for emergency supply.

lector. It may be caused by the fact that the waste is inert, the filtration coefficient of water source covering rocks is so low, or, in other words, the covering layers are so thick, that the contamination has not occurred. The latent risk may soon become acute, though.

The risk point index of agricultural production $R_{i,j}(\tau)$ is higher as well. Synthetic and natural fertilizers, mordants, seeds for sowing and pesticides are used in the field near the water source infiltration area and their leak into the hydrogeological collector may negatively affect the quality of water source. The covering layer of loess with good sorption capacity prevents larger contamination of ground water, though.

It should be added that the risk analysis considered also previous exploitation of the infiltration area and the source vicinity, which could signal a type of environmental burden. The area in the source vicinity was exploited solely for agricultural production, a part of the infiltration area was exploited also for forest production. Therefore agrochemicals were the only environmental burden expected in the area of interest. Due to the good bedrock the migration of contaminants into the saturated zone of water source has not been monitored though, which has been proved by an extended water analysis.

Therefore it may be stated that the assessed drill is sufficiently resistant to the identified natural and anthropogenic hazards, has a good water quality and is utilizable for emergency supply. It was necessary to assess also its availability, accessibility and richness in order to include it to the regional crisis plan. The findings of the assessment proved that the drill belongs to the category of water sources of regional importance capable of supplying 5×10^4 people during a crisis, i.e. almost the whole region. As the drill has been included into the system of group water supply it was not necessary to consider the costs connected with the process of putting it into operation.

At the same time the following measures have been proposed to increase the resistance of water source and operator's health safety, in case of which the cost-benefit efficiency is expected to be higher:

a. To analyze the composition of waste at the illegal waste dump and verify the migration of potential contamination. If there is an acute risk that the drill hydrogeological aquifer may be contaminated, the waste dump has to be immediately remediated;
b. To ensure that the building and the reinforced chamber are ventilated and the caught ground water is aerated.
c. To harmonize the exploitation of areas near the drill infiltration area according to area plans and in compliance with the drill water supply exploitation;
d. To carry out correct and sustainable activities in agriculture and forestry on the territory near the source infiltration area;
e. To control the technical condition of machinery in agriculture and forestry, including regular drivers' training.

5 CONCLUSION

The semi-quantitative risk analysis of ground water source earmarked for the emergency supply of population has been carried out. The analysis of water source hazards caused by natural events, breakdowns and ordinary anthropogenic activities proved that the risk is either negligible or acceptable with regard to all the identified hazard/sensitivity pairs and all the incorporated criticality elements

of the source hydrogeological structure and technical equipment. The source may be included into the regional crisis plan as it is resistant to the identified hazards, with good accessibility, availability and richness. It is assumed that the presented case study will become a guideline for risk assessment as a basis for the classification of ground water sources within the crisis planning system.

ACKNOWLEDGEMENT

The outcomes presented in this paper were acquired within the framework of the security research project of the Czech Republic on the Methodology of Assessing the Emergency Water Supply on the Basis of Risk Analysis, abridged as EWSSA. This project has been granted by the Ministry of Interior of the Czech Republic under No. VG20102013066.

ABSTRACT: Recently scientists focused their attention on Na-Tech risks (technological risks triggered by natural events). Among different Na-Tech risks, this paper aims at the study of those triggered by explosive volcanic eruptions, i.e. those caused by the fallout of volcanic ash. These events can directly endanger human health due to the inhalation of solid particles or indirectly compromise the safety of people due to damages on critical structures, infrastructures, chemical plants and lifelines. The main goal of this paper is to analyse volcanic Na-Tech risks in Waste Water Treatments (WWTs), with the respect to the phenomenon of volcanic ash emission. A preliminary research of the same authors highlighted the main modes of failure of the vulnerable components included in a WWT. By using the results of this survey, this work aims at the definition of the conditions leading to failures in the primary treatment (or mechanical treatment). The estimation of the threshold amounts of ash causing the equipment's damage has been made for a case study by using literature data.

1 INTRODUCTION

Due to some recent significant natural events (i.e. earthquakes, floods, tsunamis, landslides, volcanic eruptions, etc.), which caused several damages to industrial facilities (6.4% occurred in the oil industry in according to Fabiano and Currò (2012)) and lifelines (electrical power grids, water distribution systems, gas and oil pipelines), many scientists started to focus their research on the study of Na-Tech risks (technological risks triggered by natural events).

The last decades gave tangible evidence that natural disasters, together with technological disasters, may pose tremendous scenarios; this is not only due to the phenomena's simultaneity, but it is also determined by the lack of preparation in coping to such risks. Recently, De Rademaeker et al. (2014) have indicated some prioritised research topics according to process safety relevance, the category "Natural hazard triggering technological disasters" is amongst the emerging issues. In Europe there are many vulnerable installations located in areas subject to natural hazards, thus potentially prone to their impacts; it is also worth noting that the disruption of lifelines can affect whole cities or even entire countries (Cruz et al., 2004). In this framework, the need of specific tools quantifying the vulnerability of critical structures to Na-Tech risks, has emerged mainly to support risk managers in managing such events.

The literature shows some approaches estimating the failure probability of industrial facilities caused by many types of natural events, such as lightning, earthquake, flooding, etc. (Antonioni et al., 2007), but only few works investigate the effects of volcanic eruptions on industrial structures and infrastructures. Significant contributions are those due to the following authors: Spence et al. (2004) evaluated the vulnerability of buildings to pyroclastic flows; Baxter et al. (1982) analysed the reduction of functionality of water treatment systems (either industrial or civil installation); Milazzo and co-authors analysed the fragilities of atmospheric storage tanks (Milazzo et al., 2013a) and filtering systems (Milazzo et al., 2013b) to volcanic ash fallout, then, they also developed procedures for the vulnerability mapping (Milazzo et al., 2013c).

This paper focuses on the study of the Na-Tech events triggered by volcanic ash emissions. The main reason of such a study is that, after the recent eruption of the Eyjafjallajökull volcano (Iceland), the attention to the potential impacts of volcanic ash fallout, is growing. In particular this work deals with the analysis of the potential

damage on lifelines, more specifically, on Waste-Water Treatments (WWTs). Following an explosive volcanic eruption, thus causing ash fallout, the water quality of natural and man-made ponds in the surrounding the volcano can change. This is mainly correlated to the amount of ash, which enters both into the drainage system and wastewater treatments.

This paper is the prosecution of the study started by Ancione et al. (2014); the authors gave a survey of Na-Tech events in WWTs due to ash fallout. They identified the vulnerable equipment of a typical wastewater treatment; in that preliminary study, the causes of damage and the potential effects were also defined. The present work represents a further progress, since it contributes to the definition of the conditions leading to damages in primary treatments (or mechanical treatments). The focus in particular is on screenings.

This paper is structured as follows: in the first part, the characteristics of the natural phenomenon are described and a brief section has been devoted to the description of a typical wastewater treatment; in the second part a methodology for the quantification of the critical thicknesses of volcanic ash accumulated on the screens is proposed; finally the application to a case-study, which is the area surrounding Mt. Etna is shown.

2 VOLCANIC ASH EMISSION

Among several volcanic phenomena (e.g. lava flows, pyroclastic flows, etc.) which can potentially affect inhabitants and buildings, the volcanic ash emission is the most significant, due to its large impact area.

Volcanic ash is made up of tiny fragments of jagged rock, minerals and volcanic glass generated during volcanic eruptions. The size (diameter) of ash particles is equal or less than 2 mm. The quantities and the average grain-size of the volcanic ash emitted from the crater greatly vary for each eruption, but also during a single short explosive phenomenon (few hours or days).

Particles can travel downwind from about tens to thousands kilometres, depending on the following parameters: the wind speed, the volume of erupted ash, the height of the eruption column and the size of particles. The size of ash, falling to the ground, generally decreases exponentially with the distance from the crater (see Fig. 1, volcanoes.usgs.gov).

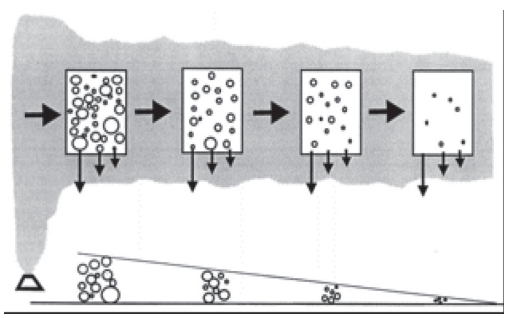

Figure 1. Trend of the size of the particles of ash with the distance from the vent.

3 WASTEWATER TREATMENT PLANT

The general principle in wastewater treatment is to remove pollutants from the water by getting them either to settle or float. Then this material must be removed. Some pollutants are easily removable, whereas others must be converted to settleable materials. The process of wastewater treatment is composed of subsequent steps, each one either removes particles from the sewage or changes dissolved and suspended material to a removable form. A wastewater treatment plant usually includes main phases. A schematic flow-chart of the process is given in Figure 2.

The first step is the primary treatment which provides a mechanical separation of most of the suspended and floating solids from the liquid stream (wastewater). In this phase, raw sewage passes through raked bar screens to remove large debris (such as rags, plastics, sticks and cans). Smaller inorganic material is removed by fine screens and grit removal tanks. Lighter organic solids remain suspended in the water and flow into large tanks, called primary clarifiers. Here, the heavier organic solids settle by gravity; the settled solids (named primary sludge) are removed and pumped to

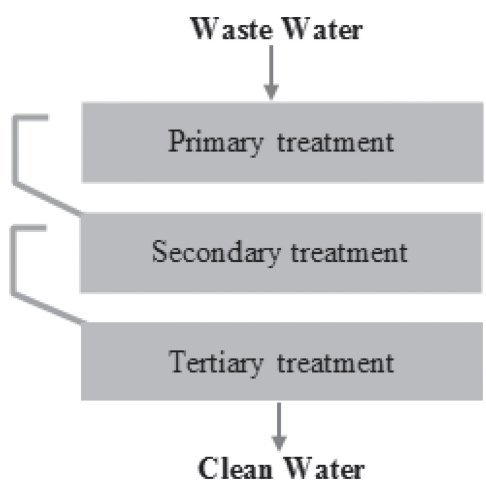

Figure 2. Flow-chart of a generic wastewater treatment.

anaerobic digesters for further treatment. Even if this phase is called mechanical treatment, a few chemicals are sometimes used to accelerate the sedimentation process.

Next step is the secondary treatment, also named biological treatment. It aims to remove the dissolved organic substance, escaped from previous treatments. The removal is achieved by bacteria, which consume the organic matter for their sustenance and convert it in carbon dioxide, water and energy for their own growth and reproduction. The biological process is then followed by additional settling tanks (secondary sedimentation). Secondary treatment technologies include basic activated sludge processes, the variants of pond and constructed wetland systems, trickling filters and other forms of treatment which use biological activity to break down organic matter.

The final step is the tertiary treatment. It is used for specific contaminants which cannot be removed by the secondary treatment. This phase is not always present in a WWT, it depends on the origin of the sewage and the final use of the water output. Individual treatment processes sometimes are necessary to remove nitrogen, phosphorus, additional suspended solids, refractory organics, heavy metals and dissolved solids. The technologies to be used depend on the contaminants which must be removed, i.e. filters and separation membranes, systems for dechlorination and disinfection, reverse osmosis systems, ion exchangers, activated carbon adsorption systems and physical-chemical treatments.

4 POTENTIAL FAILURES IN WASTEWATER TREATMENTS

A previous literature review allowed the identification of the main causes of damage in wastewater treatment plants associated with the volcanic ash fallout (Ancione et al., 2014).

Table 1 shows the modes of damage of some facilities and also points at the physical parameters causing the damage. It is possible to underline that the volcanic ash mainly causes mechanical screenings clogging (due to the overload of the lines because of the reduction of the flow-section caused by the particles), blockages and erosion of pumps and pH changes in biological and chemical treatment tanks. In the same table the potential effects associated with each failure are given.

This paper aims at the identification of the conditions leading to failures of screenings. Screens are included in the first step of the wastewater treatments. Next section analyses the events which could occur, after an explosive eruption, and defines how to correlate the damage to the amount of ash accumulated on the system.

4.1 *Screening*

Screens are the first equipment in a wastewater treatment plant. They are used to protect the following facilities by removing solids. Materials to be removed could be of different size and, therefore, screens can be composed by different mesh. There are usually coarse screens and fine screens.

Coarse screens remove large solids from sewage, and typically have openings ≥ of 6 mm. Coarse screens include mechanically and manually cleaned bar screens. Fine screens are typically used to remove material that could cause problems during the operations and the maintenance. Typical opening sizes for fine screens are in the range 1.5–6 mm, whereas very fine screens have openings from 0.2 to 1.5 mm; these sometimes are placed after coarse or fine screens to reduce suspended solids at levels close to those achieved by the primary clarification. Under normal operation, the velocity of water through the screen should be sufficient to avoid the sedimentation of particles, but not so high to produce an excessive pressure drop or a complete clogging of the equipment.

The degree of clogging depends both on the water quality and the system used to recover the waste from the screen. Taking into account the context outlines in the introduction, the potential clogging depends also on the characteristics of the volcanic ash, such as its size distribution.

The potential damage of screens, caused by volcanic ash fallout, is associated with the amount of particles accumulated on the grid. The main causes of failure are: (1) the partial or total blockage of the system and (2) the incomplete removal of the solid in waste stream. Malfunctions can also cause economic losses, mainly related to the energy consumption.

5 METHODOLOGY

In this section a methodology for the estimation of the threshold deposit of ash on a fine screen, which can cause certain damage, is described. The ash deposit can be considered as a granular bed and the sewage represents the fluid passing through it. The thickness of the accumulation can be estimated by means of the Darcy's equation for a streamline flow, or by the Carman's equation, if a transition or a turbulent flow occurs.

5.1 *Streamline flow regimes*

In 1856, Darcy gave a general relation to describe the flow rate of water through beds of sand of various thicknesses. He showed that the average velocity is directly proportional to the driving

Table 1. Main causes of damage in wastewater treatment and consequent effects.

Equipment	Cause of damage	Physical parameter	Effects	Reference
Pump	Blockage wear	Mass of the ash Ash concentration	Fluid is not pumped Unstable operating conditions (variability of flow-rate, water infiltration)	Day and Fisher, 1980; Blong, 1984
Primary sedimentation tank	Dispersion of particles	Ash concentration	Uncompleted separation	White et al. 2011.
Biological treatment tank	Dispersion of particles	pH of the ash	Bacteria death due to acidification followed by absence of organic matter removal	White et al. 1980
Grit removal, screen	Vibrations clogging	Mass of the ash Mass of the ash	Unstable operating conditions (variability of flow-rate, water infiltration) Flow rate reduction, flow absence	Blong 1984
Gearbox	Vibrations	Mass of the ash	Unstable operating conditions (variability of flow-rate, water infiltration)	White et al. 1980
Biofilters	Dispersion of particles	Ash concentration	Bacteria death due to acidification and asphyxiation followed by absence of organic matter removal	White et al. 1980
Metallic structures	Wear	Ash concentration	Damages depend on the equipment	Johnston 1997
Drainage system, stormwater system and pipe	Clogging/ blockage	Mass of the ash Mass of the ash	Flow absence	Blong, 1984; Blong, 2003; Barnard, 2004; Stewart et al., 2006
Electric system	Ash infiltration	Ash concentration	Power outage	Smithsonian-Institution 2000
Terminal disinfection tank (chlorination)	Dispersion of particles	Ash concentration	Higher turbidity levels which causes the protection of micro-organisms by the effects of disinfection	Stewart et al. 2009

pressure and inversely proportional to the thickness of the bed (Coulson et al., 2002), as follows:

$$Q = \frac{K}{\rho \cdot g} \cdot A_{tot} \cdot \frac{\Delta P}{l} \quad (1)$$

where: Q = volumetric flow rate of water [m^3/s]; A_{tot} = cross-sectional area [m^2]; ΔP = pressure drop [kg/m·s^2]; l = thickness of the porous medium [m]; g = acceleration of gravity [m/s^2]; K = constant, it depends on the characteristics of the porous medium (intrinsic permeability, B) and the fluid (viscosity and density) [m/s].

$$B = \frac{K \cdot \mu}{\rho \cdot g} \quad (2)$$

where: ρ = fluid density [kg/m^3]; μ = fluid viscosity [kg/m·s].

The equation (1) allows estimating the ash thickness l, which can cause certain damages. It is worth noting that this relation is not verified for transition and turbulent flows of the fluid. In these latter cases, the threshold of thickness must be estimated through another approach (see section 5.2).

5.2 *Transition and turbulent flow regimes*

If the flow is not streamline, the Carman's equation must be applied to estimate quantify the thickness of ash (Coulson et al., 2002):

$$\frac{R'}{\rho u_1^2} = \frac{e^3}{S \cdot (1-e)} \cdot \frac{(-\Delta P)}{l} \cdot \frac{1}{\rho \cdot u^2} \quad (3)$$

where: R' = component of the drag force per unit area of particle surface in the direction of motion; e = voidage or porosity, it represents the fraction of the volume of the bed which is not occupied by solid material [dimensionless]; S = specific surface area of the particles, it is the surface area of the particles divided by their volume [m^{-1}]; u_l = average velocity through the pore channels [m/s]; u = average velocity of the fluid [m/s].

Carman found that when the friction coefficient ($R'/\rho u_l^2$) is plotted against the Reynolds's number (Re), by using logarithmic coordinates, his data for the flow through randomly packed beds of solid particles could be correlated approximately by a single curve (curve A, Fig. 3).

The general equation of curve A is:

$$\frac{R'}{\rho u_1^2} = 5\,\mathrm{Re}^{-1} + 0,4\,\mathrm{Re}^{-0,1} \tag{4}$$

In equation (4):

$$\mathrm{Re} = \frac{Deq \cdot \rho \cdot u_l}{\mu} \tag{5}$$

where: D_{eq} = equivalent diameter of the pore space [m].

The equivalent diameter D_{eq} depends on the characteristics of granular bed, i.e. the specific surface area and the voidage:

$$Deq = \frac{e}{S \cdot (1-e)} \tag{6}$$

The average velocity through the pore channels is correlated to the average velocity of the flow:

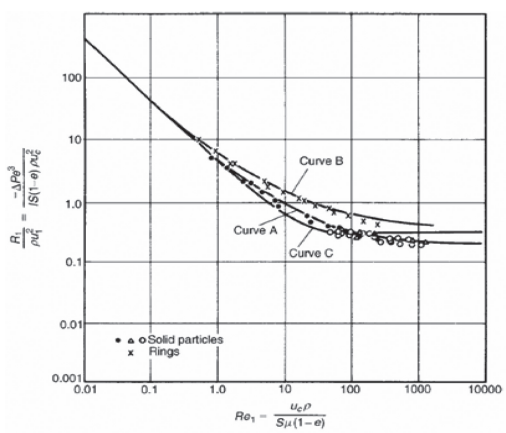

Figure 3. Carman's graph of $R'/\rho u_l^2$ against Re (Coulson et al., 2002).

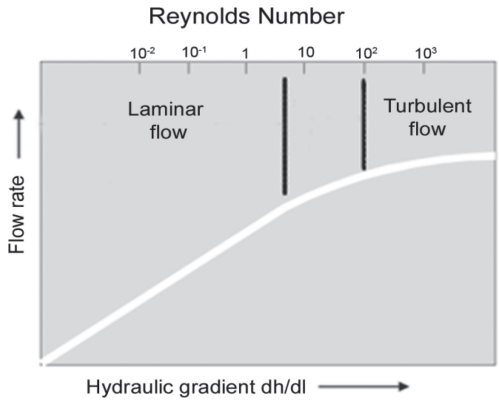

Figure 4. Flow regimes in granular beds.

$$u_l = \frac{u}{e} \tag{7}$$

Finally:

$$\mathrm{Re} = \frac{u \cdot \rho}{S \cdot \mu \cdot (1-e)} \tag{8}$$

5.3 *Determination of the regime of flow*

To choose the equation which better fit to the case under analysis, it is necessary the knowledge of the characteristics of the flow. In the fluid dynamic, the parameter, which permits to determine the flow's type for the fluid, is the Reynolds number (equation (5)). It is a dimensionless quantity. Figure 4 shows the ranges of number of Reynolds, where the various regimes occur. It refers to flow in granular beds.

The laminar (or streamline) flow occurs at low Re (<10), when viscous forces are dominant and is characterized by smooth, constant fluid motion; turbulent flow occurs at high Re (>2000) and is dominated by inertial forces, which tend to produce chaotic eddies, vortices and other flow instabilities (Coulson et al., 1999).

6 A CASE STUDY

The approach described above has been applied to a case study. A fine screen, which is included in a wastewater treatment plant, has been assumed. The WWT is located in the surrounding Mt. Etna (South Italy). The area close to the volcano is characterized by the presence of the city of Catania (300 thousand inhabitants), by many small urban centres and agricultural and industrial areas. Mt. Etna has recently changed its eruptive style

giving more frequent explosive eruptions with ash emissions (Palumbo 1988).

The first step of the methodology, given above, is the calculation of the Reynolds number for the wastewater stream, which flows in the granular bed (ash deposit). The value e and S for the volcanic ash are needed. In this preliminary analysis this data has been extrapolated from the literature as described in the following.

A sample of ash produced by an eruptions of Etna was taken in Giarre (coordinates: lat. 15°10′9″E, long. 37°44′5″N; distance 15.5 km). The average diameter of the particles has been calculated by means of an analysis of the size distribution. Then, by comparing the geometrical characteristics of the ash with those of different beds of particles, given by Coulson et al. (2002), some representative values of e and S have been assumed for the ash.

6.1 *Analysis of the size distribution*

The sieving has been used to determine the size distribution of the volcanic particles (Milazzo et al., 2014). The experimental determination makes use of special sieves arranged in a column; each of them retains the fraction of granules having larger dimensions compared with those of the holes of the sieve. The sieves must be stacked in such a way that the top has the larger mesh and the others have a gradually smaller mesh going down to the bottom. At the base of the column, there is a plate which is used to collect the granules with smaller diameters than the holes of the sieve with the lower mesh. The column is placed on a mechanical shaker for 20 min and, after the shaking, the solid fractions retained by each sieve is weighted. The weight of each solid fraction is then compared to the weight of the total solid to obtain the percentage of solid retained by each sieve.

The results (Fig. 5) are presented in a logarithmic graph of the retained percentage of solid versus the Krumbein parameter ϕ (Krumbein, 1934). Afterwards the weighted average diameter (d) of the particles has been calculated: $d = 5.3 \cdot 10^{-4}$ m.

6.2 *Properties of the granular bed*

Coulson et al. (2002) gave the properties of different granular beds. The particles are classified according to their geometric characteristics (dimension and shape) as shown in Table 2.

The following step has been to compare the geometrical characteristics of the ash with those of the particles of Table 2. The chosen values for e and S are those associated with the particles having similar dimensions. Table 3 gives the list of the samples considered in this study.

6.3 *Flow regime*

In order to choose the right approach to estimate the thickness of volcanic ash deposit on a fine screen, the Reynolds number of the wastewater through the granular bed has been calculated.

Re has been calculated by using equation (8); the values for e and S of the particles are shown in the previous section (Table 2). To take into account the variability of the characteristics of volcanic ash, several calculations have been made by referring to all the types of particles reported in the table.

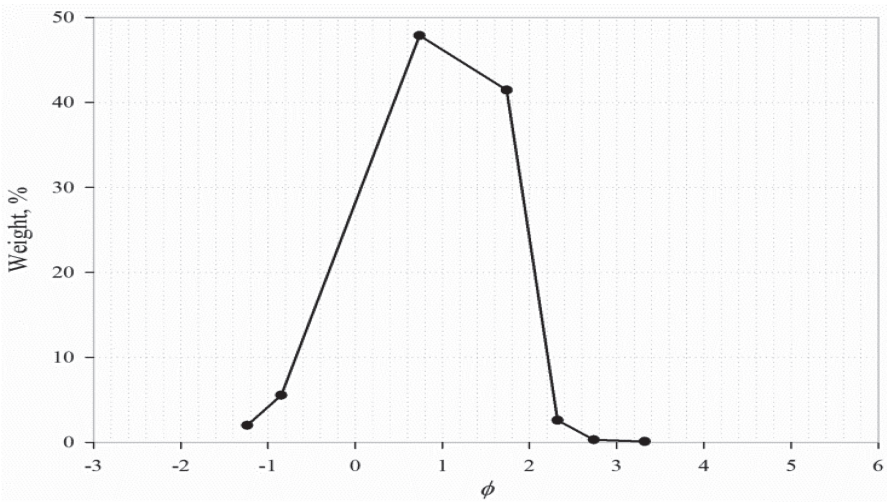

Figure 5. Size distribution for the sample of volcanic ash.

Table 2. Properties of beds of some regular-shaped materials (Coulson et al., 2002).

Table 4 shows the value of the Re for the various cases. It can be noted that the flow is never streamline; this means that the thickness of the deposits must be quantified with the Carman equation.

7 RESULTS

As mentioned above, in this study a fine screen included in a wastewater treatment has been considered. Its characteristics are the following:

- $q = 0.8$ m^3/s
- u = 0.7 m/s
- $A_{tot} = 1.14$ m^2

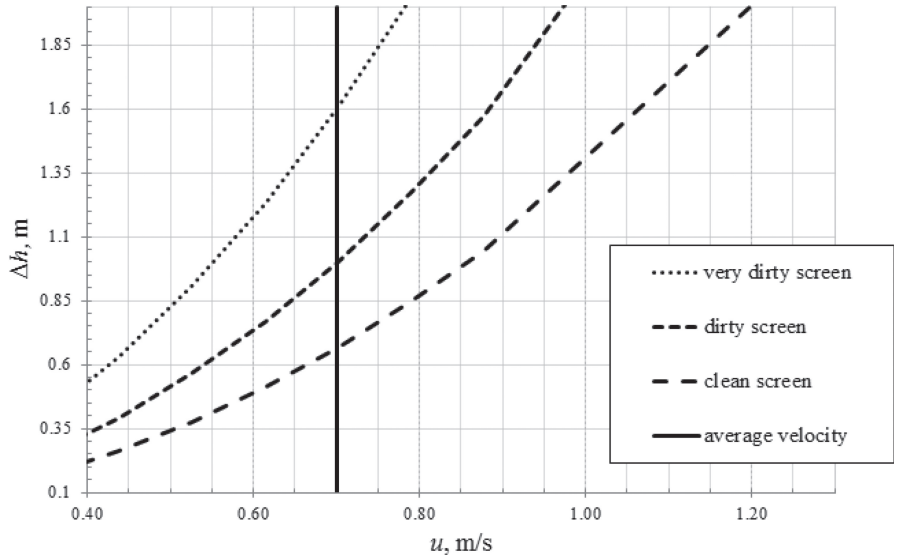

Figure 6. Head losses for fine screens vs. stream velocity.

– bar spacing = $0.5 \cdot 10^{-3}$ m
– bar thickness = $0.5 \cdot 10^{-3}$ m

The potential modes of failure, identified by Ancione et al. (2014) and investigated in this paper, are the partial clogging due to a dirty and a very dirty screen. The events, respectively, occurs when the following values of head loss are measured:

– $\Delta h_1 = 0{,}38$ m (for dirty screen),
– $\Delta h_2 = 0{,}8$ m (for very dirty screen).

These conditions lead to malfunctions and reductions of the stream flow rate. The extreme event is the total clogging; this condition has not been considered in this work, since we assumed that the cleaning operations are executed before the occurrence of a total blockage.

The previous values of head loss have been calculated by using the following equation, specific for fine screen (Metcalf et al., 2004):

$$\Delta h = \frac{1}{2 \cdot g \cdot C} \cdot \left(\frac{Q}{A} \right)^2 \tag{9}$$

where: Δh = hydraulic gradient (or head loss) [m]; C = coefficient of discharge for the fine screen (typically this value for clean screens is 0.60, for dirty screens is 0.4 and for very dirty screens is 0.25); A = effective open area of submerged screen [m^2].

Equation (9) has been plotted in a Cartesian axes system (Fig. 6), where the head loss is a function of the velocity of the upstream flow.

Table 5. Thicknesses of the volcanic ash deposit causing the values Δh_1 and Δh_2 of head loss.

Sample	Re	$R'/\rho u_1^2$	l_1 [mm]	l_2 [mm]
Spheres 1	151.7	0.27	0.3	0.8
Spheres 2	313.0	0.24	0.7	2.0
Hexagonal prisms 10	860.0	0.21	1.6	4.2
Triangular pyramids12	454.5	0.22	0.8	2.1
Volcanic ash (Mt.Etna)	151.7	0.30	0.3	0.8
“	153.5	0.30	0.3	0.8
“	184.2	0.28	0.7	2.0
“	230.3	0.27	1.7	4.5
“	307.0	0.25	3.7	10.0
“	460.5	0.24	8.9	23.7
“	921.1	0.21	27.8	74.0

Then, by using the Carman equation (4), the thicknesses of the ash deposit on the screen have been calculated. Results are shown in Table 5 (l_1 and l_2, respectively, are the thicknesses of the ash deposit causing the values Δh_1 and Δh_2 of head loss).

The results show that the increase of the index of the voidage for the granular bed determines an increase of the deposit thickness causing the values Δh_1 and Δh_2 of head loss. It must be noted that a minimum quantity of ash is enough to clog the screen.

8 CONCLUSION

In this paper the conditions leading to failures or malfunctions of screens, with the respect to the phenomenon of volcanic ash emission, have been determined. The estimation of the threshold amounts of ash causing the screens' damage has been made for a case-study (surrounding Mt. Etna) by using literature data. The results show that the increase of the voidage of the particles increases also the accumulation thickness, which causes a given head loss.

The study has provided the base for the construction of the vulnerability maps related to these facilities located in the area affected by the fallout of volcanic ash, according to the methodology presented by Milazzo et al. (2013c).

Optimum concept of management and trade-off with risks

D. Prochazkova
Faculty of Transportation Sciences, Czech Technical University in Prague, Czech Republic

ABSTRACT: The paper gives the results of expert's judgement of five basic procedures of management and trade-off with risks that are used in managerial and engineering disciplines in a present practice. The judgement is based on evaluation of procedures with regard to the public interest, i.e. according to their capability to ensure the security for humans through ensuring the safe buildings, safe infrastructures, safe territories and safe human communities considered as systems. The assessment respects that human system: is a system of systems having several incommensurable assets, which have sometimes different goals. Among assets there are interdependences of a different nature, which are sources of different conflicts. It is used: the multicriterial approach based on 14 criteria and quantity "criticality rate". Data for determination of criticality rates are obtained from experts from domains: public protection, territory protection, environment protection, public administration responsible for strategic development, protection of technological systems, and Integrated Rescue System. The optimum concept is determined by application of the theory of marginal assessment.

1 INTRODUCTION

For ensuring the live of humans in a safe space there is necessary to manage and trade-off with risks properly, i.e. measures and activities targeted to the existence, security and development of human system. In 1994 the UN (UN 1994) formulated the human society target as the human system safety and the EU (EU 2004) formulated it as the safe community in 2004. The basic tools of human society for achievement of these objectives are the human society governance and the correct application of knowledge and experiences connected with trade-off with risks respecting the public interests. In this respect the great role plays the management and engineering disciplines, the aim of which is to arrange the human security and sustainable development.

Present cognition shows that it means to take care on public assets: human lives, health and security; property and welfare; environment; critical technologies and infrastructures, Figure 1 (Prochazkova 2011a). The tool that is aimed to mentioned targets is an integral (complex) safety (Prochazkova 2011a). To reach above mentioned targets the problems on several levels: technical, functional (organisational, operative), tactical, strategic and political (Fig. 2) have been solved (Prochazkova 2011b) by a way that solutions on all levels have been interconnected.

Robustness and capacity on technical level are aspects that the under critical conditions guarantee the safety of objects and that are the important for

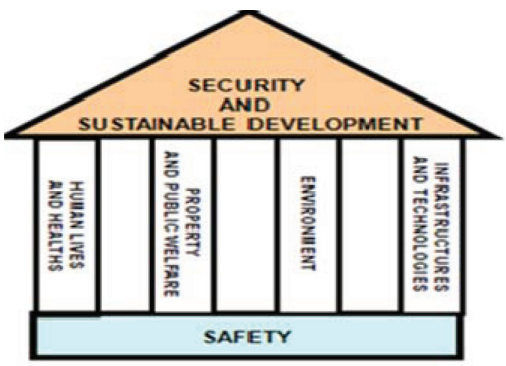

Figure 1. Human system public assets.

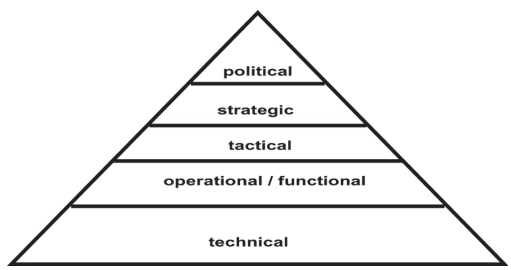

Figure 2. Levels on which security problems should be addressed.

ensuring the protection and survive of inhabitants (Prochazkova 2012).

2 STATE-OF-ART AND TERMS USED IN MANAGEMENT AND TRADE-OFF WITH RISKS

State of art of problems´ solution according to knowledge summarizes in works (Prochazkova 2011b, 2012) is:

– each object under consideration is a system, i.e. it is characterized by elements, linkages and flows,
– the system vulnerabilities are also caused by linkages and mainly by flows of energy, information, material, finances etc. among the system elements that cause couplings; mentioned couplings create often interdependences that are often the causes of failures and often by a cascade failure of several partial systems at occurrence of extreme (beyond design, severe) disasters, Figure 3 (Prochazkova 2011a, b, 2012, 2013). The nature of interdependences is physical, cyber, organisational and territorial (Prochazkova 2012).

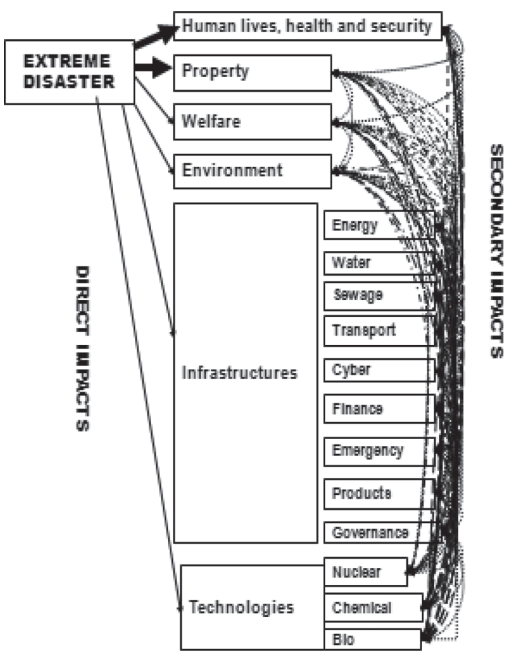

Figure 3. Impacts in the human system at extreme disaster; anthropogenic measures and activities ensure the protection of public assets only for disasters with size smaller than design disaster; only at defined nuclear facilities there are carried out measures and activities against selected beyond design disasters (Prochazkova 2011a).

The recent cognition shows that the present world and its objects are represented by a model denoted as a system of systems i.e. several overlapping systems that are open and fulfil certain functions (Prochazkova 2011a, b, 2012). They are interconnected by linkages and flows which create mutual interdependences that cause specific vulnerabilities (Prochazkova 2012).

A system according to its core means more than only a sum of parts (Prochazkova 2011b), and therefore, the stress is put on:

– a study of the interactions and associations,
– non-linear thinking,
– interactions,
– inductions;
– feedbacks,
– experiments or realistic simulations.

E.g. feedbacks cause non-linearity in the system behaviour and cause that the behaviour is not predictable, and therefore, it is not possible to use the common prognostic methods for the identification of the possible states of a system. The consequence is an occasional occurrence of unexpected situations that threaten the humans, and it is difficult to get over them.

The complexity of systems with which we work in practice is different. According to work (Prochazkova 2013) four types of system configurations are used; they are:

– simply organized units,
– composite systems,
– complex systems,
– set of overlapping systems.

Behaviour of simply organized units is clearly given by structure and properties of units and it is described by analytic functions. The composite systems are understood as a representation of elements that are organized and connected in a certain way and because of a proper structure they fulfil certain functions. Their behaviour is described by results of statistical solutions based on analytic functions, the parameters of which are variable in a certain interval, which are a reflection of various possible states/variants of the system behaviour. The complex systems have many components (often systems too) that interact together and are organized in several levels (Prochazkova 2013), which causes that we observe: suddenly emerged behaviour features that is not possible to obtain from the knowledge of components' behaviour, it is the so-called emergence; hierarchy; self-organization; and various management structures, which all together seems as a chaos, and therefore,

in their description there are random and epistemic uncertainties. Their behaviour is described by results of simulations taking note of existence of epistemic uncertainties. The System of Systems (SoS), i.e. a set of several overlapping systems (often complex systems), is very complicated, and therefore, its behaviour can be only obtained if a multidimensional and inter-dimensional approach is applied and it is based on simulation of variants by multi-criteria procedures.

Since the solution of many problems in practice means to consider the complex systems and the SoS, the system thinking is the fundamental principle of research if we deal with safety. The system thinking means: to see both, the whole and the details at the same time; ***to focus on the dynamics of processes;*** to pay attention to relations, associations and interactions; ***to take into account the roles of a feedback;*** to consider the relativity of possible situations; and to think in a long-term way (Prochazkova 2011b, 2012).

At management and engineering solution of complex systems and systems of systems it is then *necessary to use the multi-criteria approach and in a case of system of systems it is also* necessary to consider the cross-sectional risks that are the causes of emergent interdependences originating at certain conditions, and therefore, to their detection the attention of engineering disciplines is concentrated at system design. At their problems' solution the tools are based on: the theory of chaos; theory of fuzzy sets; complexity theory; and theory of possibilities—set of references to their derivation is in books (Prochazkova 2012, 2013). In case of management of SoS we must also respect basic requirements, i.e. co-existence of overlapping systems (Bossel 2004). For human goals fulfilment it is necessary to arrange the co-existence of important systems, minimally social, environmental and technological systems that create the human system.

Regarding to present view of the UN, EU and public interest (EU 2004, Prochazkova 2011a, UN 1994) the ground for human being is a conservation of existence, security and potential for development for humans. In this context in practice the following terms are used.

Security is the state of system at which the occurrence of harm or loss on system assets (protected public interests) has an acceptable probability (it is almost sure that harm and loss do not arise). It means that it ensures a certain stability of a system in time and space, i.e. a sustainable development which means that the system is well protected against internal and external disasters of all kinds.

Safety is a set of human measures and activities for ensuring the existence, security and sustainable development of system and its assets. Its measure is the effectiveness of appropriate measures and activities at ensuring the system assets security and sustainable development.

Secured system is the system that it and its assets are not threaten by disasters, the origin of which are inside and outside of system, including the human factor.

Safe system is the system that it and its assets are not threaten by disasters, the origin of which are inside and outside of system, including the human factor, and the system itself does not threaten its vicinity at its normal, abnormal and critical conditions.

Human system safety management is the management of human system directed to human system safety, the product of which is the security and sustainable development of all public assets.

The engineering is a set of disciplines that realise the tasks determined by management procedure into practice. The risk is for engineering practice expressed as probable size of losses, damages and harms on followed assets that are caused by a given disaster with specified size (size of normative hazard) and that are rescheduled for a certain time unit (usually 1 year) and a certain object or a certain site. The risk engineering was the 20th century phenomenon and on its base there was set up in developed countries the groundwork for human development that is quite resistant against to traditional disasters, namely natural ones; human, animal and plant diseases; technology failures; and social disasters.

According to definitions used by the UN, Swiss Re, World Bank etc. (summarized in Prochazkova 2011b) the risk engineering:

- is the systematic use of engineering knowledge and experiences for the optimization of the protection of human lives, environment, property and economic assets, i.e. for the optimum reach of security and sustainable development of human system,
- has a main purpose to reduce all types of harms and losses by the means of aimed and qualified trade-off with risk.

It is necessary to note that at present practice the risk engineering has not yet been interpreted by an explicit way and different concepts are not often distinguished.

It is necessary to consider that risk engineering is not a static discipline because it has been developed in time. ***The problem of present specialists, mainly oriented to calculations***, is that they do not distinguish different concepts, and in some cases such ignorance is a cause of incorrect solutions (e.g. if they used standards and norms for secured system and the correct solution of problem requires standards and norms for the safe system because the failure of system has a great potential

to damaged assets being in system vicinity); see lessons learned from recent important accidents (AIChE 1994, Prochazkova 2013).

3 PROCESS MODEL OF WORK WITH RISKS

According to present standards the risk expresses the probable size of undesirable and unacceptable impacts (losses, harms and detriment) of disasters with the size equal to a normative hazards on system assets or subsystems in a given time interval (e.g. 1 year) and a given site, i.e. it is always site specific (Prochazkova 2011b).

The typical risk properties are random and epistemic uncertainties (epistemic uncertainties = vagueness). If we want to manage risk, we must identify, analyse, assess it and after this to decide what we can do, in dependence on our possibilities—knowledge, staff, technical means and finance sources. For this, we must use a lot of different methods, tools and techniques and also principles of good practice (good engineering practice).

Work with risk is expressed by model shown in Figure 3 (Prochazkova 2013). It starts with definition of concept of work with risk (system characteristics, determination of assets, specification of aims), on the basis of which risks are identified, analysed, assessed, judged, managed, traded-off and monitored. Feedbacks denoted in this Figure 4 are used if risk level is not on required level (Prochazkova 2013).

For human safety and for human system safety (i.e. territory, organisation, plant) we must manage the integral risk including the human factor, i.e. to find the way of cross-section risks management and to concentrate the investigation on interdependences and on critical spots with a potential to start the system cascade failures, domino effects,

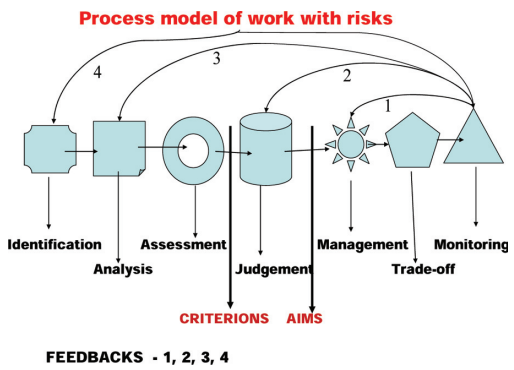

Figure 4. Process model of work with risks, numbers 1, 2, 3 and 4 denote feedbacks.

strange behaviour etc., and on the basis of such site knowledge to prepare measures and activities ensuring the continuity of limited infrastructure operation and of the human survival.

Evaluation of present knowledge shows that one of number of causes are interdependences inducing the cascade failures in the human system or in its part are the human errors (intentional or involuntary) in management and in deciding. Therefore, we must do all measures in managerial and engineering activities to avert human failures, namely at decision-making. Because consequences of errors originating at decision are often huge, the great attention is concentrated to work with risks at present (Prochazkova 2013, AIChE 1994).

The often used characteristic of engineering's work with the risks is:

- it considers multi-fields and cross-sectional disciplines that use both, the general and the specific methods, tools and techniques (specific ones are either simple or complex, complex ones represent well-ordered use of several general or simple methods, tools and techniques),
- it uses methods, tools and techniques logic, technological, financial, managerial and deciding because their integral part is a decision on technological problems, costs and time planning,
- it deals with tasks that connect the trade-off with risks for human system safety ensuring and the requirement of non-trivial solution of problems by use of multi-criteria methods, tools and techniques.

In all procedures it must be respected that assets and causes of risks have different natures that cause incommensurability of criterions and reasons, which only allows application of multi-criteria methods, tools and techniques that are suitable, i.e. correct and valid for a given problem target.

From the methodical viewpoint at selection of methods, tools and techniques they must be respected: data quality; structure of problem that is solved and requirements on quality of results; which means specially to test both, the data quality (accuracy, completeness, homogeneity, bearing witness to a given problem (Prochazkova 2011b)), and the qualification of experts if they are used (IAEA, OECD, World Bank etc. have strict criteria for judgement of expert qualification) (Prochazkova 2013).

4 PRESENT CONCEPTS OF MANAGEMENT AND TRADE-OFF WITH RISKS

The ground of human effort is to cope with (to tame) the risks. The term "*risk*" has the origin in

the middle Ages and our present knowledge on trade-off with risk has been collected since 30s of last century. Obtained knowledge and experiences have been influenced the management of risks and its measures and activities have been introduced step by step into practice by engineering disciplines (Prochazkova 2012).

At present work with risk, the risk is understood as the potential that a chosen action or activity (including the choice of inaction) will lead to a loss (an undesirable outcome). Now in practice there are used five types of risk management/engineering of systems, i.e.

– classical risk management and risk engineering,
– classical risk management and risk engineering including the human factor,
– security management and security engineering,
– safety management and safety engineering, i.e. risk governance/trade-off for security and sustainable development of system,
– safety management and safety engineering determined for System of Systems (SoS) (Prochazkova 2011b, 2012),

See Figure 5 and the detail description in the annex.

It is evident that each more advanced type keeps the higher demands on knowledge, tools, times, finance, personnel qualification etc. For each management and each engineering concept there has been developed a certain set of standards and norms for its use in practice (Prochazkova 2012).

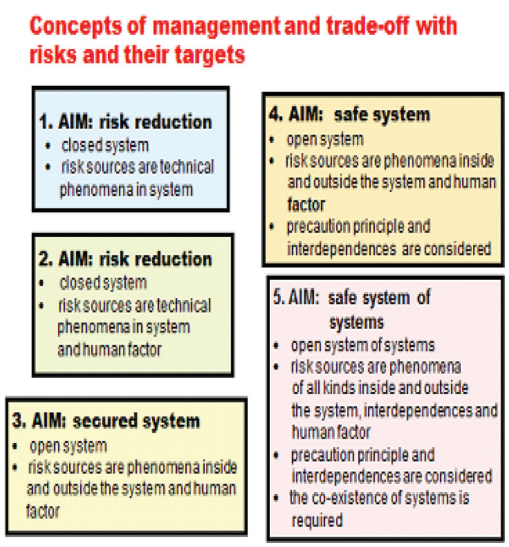

Figure 5. Concepts of management and trade-off with risks and their targets arranged chronologically according to introduction in practice.

For different assumptions of concepts the results of their applications in practice have not been the same. From these reasons in next paragraphs we compare mentioned concepts, especially in engineering disciplines and judge the validity of their use with regard to their capability to ensure human system safety, i.e. human security, existence and sustainable development.

5 DATA AND METHODS FOR DETERMINATION OF CRITICALITY RATES OF PROCEDURES FOR WORK WITH RISK

Object of our interest in which we test procedures for work with risks is the human system that is composed of assets: human health, property, welfare, environment, infrastructures and technologies that are incommensurable and some of their aims are conflicting (e.g. environment vs. technologies—exploitation of natural resources, contamination of air, water and rock); and linkages and flows among the assets. Therefore, for searching the best way of human work with risk the special tool must be used. As is given above we use five different concepts at present.

For comparison of concepts used in practice for system risk management and for trade-off with system risk from the viewpoint of their capability to ensure the human system security we use the quantity "criticality" and the procedure based on the Multiatribute Utility Theory (MUT) (Keeny & Raiffa 1976) with the statement "the higher, the worse". The criticality is given by level of integral risk in which the main role is played by level of cross-sectional risks (Prochazkova 2011b).

The assessment respects that human system: is a system of systems; and has several incommensurable assets, which have sometimes different goals and among them there are interdependences of a different nature, which are sources of different conflicts. Therefore, there are used: the multicriterial approach; 14 criteria directed to the public protection; quantity the criticality rate; and defined value scale.

The set of criterions used for judgement of capability of followed procedures is the following:

1. rate of capability of protection of human lives, health and security inside the system
2. rate of capability of protection of human lives, health and security outside the system
3. rate of capability of protection of property inside the system
4. rate of capability of protection of property outside of system
5. rate of capability of protection of welfare inside the system

6. rate of capability of protection of welfare outside of system
7. rate of capability of protection of environment inside the system
8. rate of capability of protection of environment outside the system
9. rate of capability of protection of live-giving infrastructures and technologies inside the system
10. rate of capability of protection of live-giving infrastructures and technologies outside the system
11. rate of capability of protection of human lives and health against disaster impacts caused by interdependences
12. rate of capability of protection of environment against disaster impacts caused by interdependences
13. rate of capability of protection of human society against disaster impacts caused by interdependences
14. rate of capability of protection of live-giving infrastructures and technologies against disaster impacts caused by interdependences

The used value scale that is used in many norms and standards for risk assessment (Prochazkova 2013) and in norms used by FEMA, Swiss Re etc. is the following:

0 point—criterion ensures extremely high capability of protection (expected damages are lower than 5%, concept application means no significant risk for assets, i.e. negligible concept criticality),
1 point—criterion ensures very high capability of protection (expected damages are in interval 5–25%, concept application means low risk for assets, i.e. low concept criticality),
2 points—criterion ensures high capability of protection (expected damages are in interval 25–45%, concept application means median risk for assets, i.e. median concept criticality),
3 points—criterion ensures median capability of protection (expected damages are in interval 45–70%, concept application means high risk for assets, i.e. high concept criticality),
4 points—criterion ensures low capability of protection (expected damages are in interval 70–95%, concept application means very high risk for assets, i.e. very high concept criticality),
5 points—criterion ensures negligible capability of protection (expected damages are higher than 95%, concept application means extremely high risk for assets, i.e. extremely high concept criticality).

Data for determination of criticality rates were obtained from experts from domains: public protection, territory protection, environment protection, public administration responsible for strategic development, protection of technological systems, and Integrated Rescue System. These experts fulfilled the criteria for expert competence used in the EU (Prochazkova 2013) and they evaluated 14 factors given above according to their knowledge and experience.

Table 1. Scale of values for determination of rate of criticality of concepts for work with risk.

Rate of concept criticality	Values in %	Number of points for factor
Extremely high	More than 95%	More than 66.5
Very high	70–95%	49–66.5
High	45–70%	31.5–49
Median	25–45%	17.5–31.5
Low	5–25%	3.5–17.5
Negligible	Less than 5%	Less than 3.5

The resultant value for each factor is determined as the median from data obtained from experts. Resultant assessment of capability of protection for all factors with assumption that all factors have the same weight can take on values from 0 to 70. If we again apply approach used in (Prochazkova 2013) we obtain values given in Table 1.

6 RESULTANT CRITICALITY RATES AND OPTIMUM CONCEPT OF WORK WITH RISKS

In work (Prochazkova 2014) there are described in detail results of evaluation obtained on the data from 6 experts who performed evaluation according to 14 criteria given above and directed to judgement of capability of followed concepts of risk management and engineering procedures for trade-off with risks to implement targets of humans that are existence, security and development of humans, i.e. it goes on public protection in the broadest context.

The author remarks that at other evaluation targets or at different assets' specification the different criteria and another threshold values must be used, which substantially affect the results. The results of evaluation under account are given in Table 2.

From Table 2 it follows that the criticality is:

– extremely high for the classical system risk management/engineering,
– very high for the classical system risk management/engineering considering the human factor,

Table 2. Rate of criticality of followed concepts of risk management/engineering.

Criterion	Classical system risk management and risk engineering	Classical system risk management and risk engineering considering the human factor	System security management and security engineering	System safety management and safety engineering	System of systems safety management and safety engineering
1	4	3	1	1	1
2	5	5	5	1	1
3	4	3	1	1	1
4	5	5	5	1	1
5	5	3	1	1	1
6	5	5	5	2	1
7	4	3	1	1	1
8	5	5	5	1	1
9	4	3	1	1	1
10	5	5	5	1	1
11	5	5	4	5	1
12	5	5	4	5	1
13	5	5	4	5	1
14	5	5	4	5	1
Total	66	60	41	31	14

– high for system security management/ engineering,
– median for system safety management/ engineering,
– low for system of systems safety management/ engineering.

It means that the system of systems safety management/engineering is the most effective concept of work with risk with regard to our present knowledge and experience directed to human system safety from the viewpoint of ensuring the human security and sustainable development. Taking into account the reality that the use of various concepts are differ by requirements on knowledge, data, personal qualification, material, finance and technical solutions, it is evident that the most effective concept is the most challenging. Therefore, it is necessary and important for strategic level of problems' solution. For tactical and functional levels of problems' solution is sufficient the concept ensuring the system safety management/engineering. The concept called as system security management/engineering is only suitable for technical level of problems' solution, i.e. in cases in which high damage on system vicinity are not probable.

It is also evident that at emergency management or at crisis management we have not time to determine the most suitable strategic solution, i.e. at emergency at simple case the risk management/engineering principles are sufficient, but at most of real cases the security management/engineering principles are applied if we *only* protect object under account and not its vicinity, ***otherwise*** the safety management/engineering principles or SoS management/engineering principles must be applied.

Because the system safety is complementary quantity to system criticality, i.e. safety + criticality = 1, we obtain from Table 2 the following values for safety rate: 0, 1, 2, 3, 4; and for safety rate the statement "the higher, the better".

To obtain the optimum concept for our aim we use the way used in the engineering disciplines, i.e. the theory of margin assessment (Sage & Rouse 2011, Savin 2010) which is often used in the engineering disciplines. By this way we obtain for safety rate the values: median $\mu = 2$ and standard deviation $\sigma = 0.63$; $\mu + \sigma = 2.63$; $\mu + 2\sigma = 3.26$; and $\mu + 3\sigma = 4.89$. From this it follows that ***the concept for system of systems safety management/engineering is the optimal for ensuring the EU security.***

The output also shows that at all fundamental decisions that have strategic significance and long-term consequence the work with risks must respect minimally a concept of work with risk for ensuring the safe system. Only by this way humankind might preserve a chance for long-term existence, security and development.

7 CONCLUSION

Five types of the risk management and risk engineering are used in a present practice. For each risk management and risk engineering type based on negotiation with risks there are standards and norms. Because the demands of various concepts are different, the standards and norms are

different, the results are different and requirements on data, knowledge, material, technology, finances etc. are different.

Owing to provident handle with sources, forces and means it is necessary in real cases to decide which concept is sufficient for a given problem solution. At deciding the role plays the risk size and the level of problem solution.

The results given above show that at:

- strategic level of problem solution it is necessary to use the system of systems safety management and system of systems safety engineering that fulfils demands of social engineers, technical engineers and environmental engineers,
- tactical and functional levels it is necessary to respect strategic concept recommendations and at site specific immediate problems' solution it is possible to use the system safety management and system safety engineering because character of solved problems is not so fundamental from the long term viewpoint,
- technical level it is necessary to respect recommendations of all higher concepts, i.e. strategic, tactical and functional ones and for site specific immediate problems' solution it is possible to use the system security management and security engineering if character of solved problems is not so fundamental from the time viewpoint,
- political problems solutions it might be respected strategic solutions if they want to respect public interests.

At solution of emergency situation there is lack of time, information and knowledge, and therefore, it is justified the reaction using the concept of management and engineering trade-off with risk directed to secured system and at critical cases only concept of management and engineering trade-off with risk directed to risk reduction considering the human factor.

Annex—description of types of risk management and risk engineering.

Type	Concepts of work with risks—characteristics, targets and procedures
Classical risk management/ engineering	Object is a closed system. Risk sources are internal technological phenomena in system. The target is to reduce the technological risks of a system to a certain level, given by standards and norms. It originated in 30s of last century. The risk is determined after the design of the system, and therefore, there is no possibility to reduce risks connected with an inappropriate solution for a given site and system. The reduction of risks connected with an inappropriate solution for a given site and system may be removed only by organisational measures, the effectiveness of which is lower than effectiveness of technical ones.
Classical risk management/ engineering considering the human factor	Object is a closed system. Risk sources are internal technological phenomena and human factor in system. The target is to reduce: the technological risks of a system to a certain level given by standards and norms; and risks connected with a human factor by safety instructions for danger works. It originated at the end of 70s of last century. The risk is determined after the design of the system, and therefore, for reduction of risks connected with an inappropriate solution for a given site and system may be removed only by organisational measures, the effectiveness of which is lower than effectiveness of technical ones.
System security management/ engineering	Object is an open system. Risk sources are external and internal phenomena including the human factor. The target is to reduce risks for a system: from external and internal phenomena, a human factor, and also failures of decision-makings at risk management/ engineering were to a certain level given by standards and norms; i.e. to ensure the security of a system and its assets. No interest on system vicinity. IT originated at the first half of 80s of last century. The protection of system vicinity is not solved. Unacceptable impacts on vicinity can be only mitigated by special off-site emergency plans, i.e. by organisational measures and activities if state enforces such legislation.
System safety management/ engineering	Object is an open system. Risk sources are given by all hazards approach. The target is to ensure the security of a system and its assets and the security of system vicinity. The advanced safety engineering uses at risk determination the following principles: risk is determined during the given system whole life cycle, i.e. at sitting, designing, building, operation and putting out of operation, and eventually at territory bringing in original condition; the risk determination is directed to user's demands and to the level of provided services; risk is determined according to the criticality of impacts on processes, provided services and on assets that are determined by public interest; and unacceptable risks are mitigated by tool for risk management, i.e. according to technical and organisational proposals, by standardisation of operating procedures or by automatable check-up. It originated at the second half of 80s of last century. The target is the safety, i.e. it is also necessary to trade-off with risks having low occurrence frequency if their impacts are unacceptable, and i.e. precaution principle is applied. The set of standards and norms exist especially for nuclear and chemical domain. To prepare groundwork, it is necessary to combine analytical methods with expert judgement by which we remove vagueness (epistemic uncertainties) in data. Except of technical measures respecting the precaution principle, special technical problems solution there are continuity plans containing the procedures for overcoming the critical conditions in system and system vicinity, emergency plans and crisis plans. The risk management viewpoint by these characters: sitting—designing—construction—project with risk reduction; operation with the integration of early warning systems and of procedures for the management of the acceptable level of risks; and defeating the abnormal, emergency and critical conditions at the operation and at putting out of the operation.
System of systems safety management/ engineering	Object is an open system of systems. The target is to ensure: the security of both, the system of systems including its assets and the system of systems vicinity; and the co-existence of individual systems creating the system of systems. Risk sources are given by all hazards approach and by interdependences among the partial systems and by those with vicinity. Formation at the beginning of third millennium. The set of standards and norms are under discussion and preparation.

Possibilistic risk analysis of failure in water supply network

B. Tchórzewska-Cieślak, K. Boryczko & I. Piegdoń
Department of Water Supply and Sewage Systems, Rzeszow University of Technology, Rzeszow, Poland

ABSTRACT: The paper proposes an alternative approach to the failure risk analysis of water supply network which includes random emergency events inaccuracy, diversity and a small amount of data. The presented method is based on the so-called theory of facts (Shafer) based on the concept of inaccurate probabilities and possibilities (Zadech), which combines the so-called distribution capabilities of the belonging function of fuzzy set. The main aim of this paper is to present the concept of failure risk analysis of water supply network. The proposed model was used for failure risk analysis of water supply system serving 63 thousand people in the east of Poland.

1 INTRODUCTION

The Collective Water Supply System (CWSS) as a complex technical system consisting of functionally interrelated objects, whose task is to provide safe drinking water for residents. It is one of the priority technical systems included in the basic infrastructure of urban agglomerations. Its importance to the public is unquestionable because water is a prerequisite for human existence. The World Health Organization (WHO) warns about the so-called global water crisis which is not only associated with a changing climate but also resulting from of the aquatic environment pollution, constantly increasing population (especially in poor regions) or armed conflicts.

The main element of this system is the water supply network, which supplies buildings with water. Reliability of water supply is to ensure stable conditions, enabling current and future water demand in accordance with the WHO and local standard. The water transported by the water network should be safe and should be provided in the required quantities and at the required pressure. The unreliability of the water supply system resulting mainly from various types of failures or the appearance of biofilm in the network. Those events can cause interruptions in water supply or polluted water provision. It is assumed that the measure of the loss of CWSS safety is risk related to system reliability. In terms of risk management in water supply systems spaces the European standard EN 15975-1-2011 Security of drinking water supply—guidelines for risk and crisis management—Part 1: crisis management. In Poland, they are respectively the PN-EN 15 975-2:2013-12 E and PN-EN 15975-1-2011.

It was assumed that the risk of failure of the water supply system is a function of the probability of failures occurrence, the consequences but also the degree of vulnerability to the hazard. Research conducted in this area by (Apostolakis & Kaplan 1981, Aven 2010, Christodoulous et al. 2008, Craun & Calderon 2001, Ezell et al. 2000, Haimes 1998, Zio 2007) cover a wide range of failure events cause and effect analyses related to the functioning and operation of water supply network. These studies demonstrate a significant effect of the material, the age of pipe, network pressure, the foundation but also chemical and biological stability of water (Christodoulous et al. 2003, Faber & Steward 2003, Grey-Gardner 2009, Hokstad et al. 2009, Hrudey & Hrudey 2004, Hubbard 2009 Very often hydraulic models are used (simulations using EPANET software) and various databases (e.g. GIS), which allow not only to evaluate the technical state of pipes, but also to forecast failure events (Boryczko et al. 2014, Maqsood et al. 2005). Such studies require appropriate methodology but also a detailed and structured database. It determines the correct statistical analysis of the data and the appropriate cause-effect model, e.g. event tree or fault tree, in terms of the analysis of various emergency scenarios that may cause the loss of water consumer safety (Ezell et al. 2000, Kołowrocki 2004, Rak 2003, Zio 2009, McGill et al. 2005).

The problem in the analysis occurs when the database is incomplete or uncertain. There is a need to rely on the knowledge and the experience of experts. In the literature it can be found a new issue of so-called risk analysis in uncertainty conditions. There are two approaches related to this issue. The first approach assumes that the risk is a kind of uncertainty. Taking into account the uncertainty data in risk analysis it is possible to make an analyse using the theory of subjective probability and neural Bayesian networks (Dempster 1967, Hahn et al. 2002, Haimes

et al. 2006, Kleiner & Rajani 2000). The second approach is based on fuzzy logic, neuro-fuzzy networks and genetic algorithms (Christodoulous & Deligianni 2010, Kleiner et al. 2004, Markowski & Mannan 2008, Sadiq & Tesfamariam 2009, Shang-Lien & Ruei-Shan 2002). This approach is used in a variety experts systems and in technical infrastructure management processes. In fuzzy models it is possible to use experts knowledge as a linguistic variables, which facilitates the analysis, primarily in the area with small data sets in which designated the combination of the probability distribution is significantly more difficult. In the absence of sufficient static database the parallel methods based on the so-called soft models including Bayes network, fuzzy modelling, were developed. The aim of this paper is to propose an alternative model of water supply system including failure risk analysis which uses a Dempster Shafer theory and fuzzy models for very unlikely events, but which may have serious consequences. The main applications of the model are analysis and risk assessment based on expert knowledge.

2 ASPECTS OF FAILURE RISK ANALYSIS OF WATER SUPPLY NETWORK

Failure risk analysis of water supply network is connected with (Ezell et al. 2000, Tchórzewska-Cieślak 2007, Souza & Chagas 2001, Mays 2005):

- failures of water pipes and fittings,
- secondary water pollution in the water supply system.

The consequences of these events are:

- lack of water supply to consumers or interruption of the supply,
- health risks of water consumers as a result of the consumption of poor quality water,
- waterworks company financial losses incurred as a result of failure removal, rinsing the network, the lack of water sales and compensating water consumers,
- water consumers financial losses related to the need to purchase bottled water, treatment costs, costs arising from difficulties with hygiene and sanitation.

The priority is to provide consumers with water of the right quality, at the appropriate pressure, at any time (Hrudey 2001, Johanson 2008). Water supply system failures are a major problem in the process of system operation (Hubbard 2009).

Failures of this type includes: the body of the pipe, joints or expansion joints, valves hydrants, vents, drains, etc. They may occur as a result of one-time random events or human intervention, or are the result of the combined action of time, excessive stresses and (or) local negative environmental conditions (Rak 2003). The causes of water supply network failures could also be a wrong concept of water supply network structure, wrong hydraulic operation (too high pressure, lack of protect valves against water hammer), the corrosiveness of the soil, temperature changes, etc. (Christodoulous et al. 2008, Craun & Calderon 2001, Sadiq et al. 2007).

T. Aven defines risk as a combination of three parameters: the probability of adverse events, their consequences and the uncertainty will those events will occur and what will be the consequences (Aven 1992, Haimes 2009, Rak & Tchórzewska-Cieślak 2006, Ezell et al. 2000, Zio 2007):

$$r = \{S, P, C\}$$

where:
S—failure events scenario,
P—probability of failure events scenario,
C—consequences (losses, effects) of scenario failure events occurrence.

In (Kaplan 1997) risk is described as a set of probabilities and consequences. Grouping them in terms of low probability, i.e. a vector of risk can be determined in the form of an equation that illustrates the so-called risk curve (Fig. 1) (Ezell et al. 2000, Haimes 2009, Hastak & Baim 2001, Kaplan 1997, Zio 2009):

The definition of water supply system failure risk should take into account both the possibility of the loss of water consumer safety as a result of lack of water or interruptions in water supply and consumption of poor quality water. Using the matrix method for Quantitative Risk Analysis (QRA), the following formula for determining the water supply system failure risk was proposed (Michaud & Apostolakis 2006, Tchórzewska-Cieślak & Rak 2006, Johanson 2008):

$$r = P \cdot C \cdot N \tag{1}$$

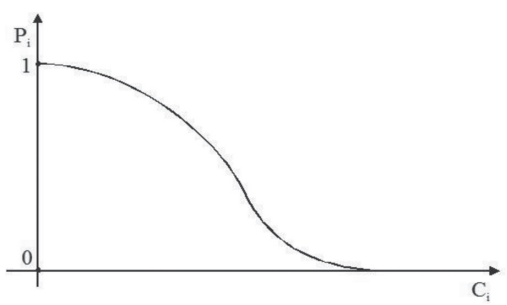

Figure 1. Risk curve.

where:
P—point weight related to the probability of failure event occurrence,
C—point scale related to the size of losses,
N—point weight associated with population at risk.

The process of risk analysis for water consumer safety occurs in the following phases of reconnaissance:

- determination of the number of residents using the CWSS,
- identification of the representative failure events and determination of scenarios to estimate losses,
- determination of the probability (frequency) of failure event occurrence.

Scales for point weights are as follow:

- a scale for the probability (frequency) of failure (*P*):
  - low—unlikely—once every 10÷50 years; $P = 1$,
  - average—quite likely—once for 1÷10 years; $P = 2$,
  - high—likely—1÷10 times a year, or more often; $P = 3$,
- a scale for the number of residents (N):
  - low—number of residents at risk up to 5 000, $N = 1$,
  - average—number of residents at risk from 5001 to 50 000, $N = 2$,
  - high—number of residents at risk more than 50 000, $N = 3$,
- consequences category (*C*):
  - small—noticeable organoleptic changes of water, individual consumer complaints, financial losses up to 5×103 EUR, $C = 1$,
  - average—a significant nuisance organoleptic (odour, colour change and turbidity), health indisposition of consumers, numerous complaints, the information in the regional public media, financial loss up to EUR 105, $C = 2$,
  - high—required hospital treatment, the results of indicator organisms revealed high levels of toxic substances, the information in the national media, financial loss above 105 EUR, $C = 3$.

Thus, the risk parameters: $P = \{1, 2, 3\}$, $C = \{1, 2, 3\}$, $N = \{1, 2, 3\}$. According to the formula (1) risk values are in the range [1–27]. The risk matrix has the form:

$$R_{PCN} = \begin{vmatrix} 111 & 121 & 131 & 112 & 122 & 132 & 113 & 123 & 133 \\ 211 & 221 & 231 & 212 & 222 & 232 & 213 & 223 & 233 \\ 311 & 321 & 331 & 312 & 322 & 332 & 313 & 323 & 333 \end{vmatrix} \quad (2)$$

The set of possible values for risk: $R = \{1, 2, 3, 4, 6, 8, 9, 12, 18, 27\}$.

Risk assessment is the comparison of this value with criteria values:

- tolerable risk (rT) (1÷6>,
- controlled risk (rK) (6÷8>,
- unacceptable risk (rN) (8÷27>.

It should be noted that this assessment does not take into account the weights of the parameters, i.e. each parameter *P*, *C*, *N* is equally important in the risk assessment because the assessment is subject only to final risk value. For example, the risk may be equal 4 to the results of $P = 2$, $C = 2$, $N = 1$ or $P = 2$, $C = 1$, $N = 2$ or $P = 1$, $C = 2$, $N = 2$. Thus, such an analysis may be subject to some kind of uncertainty. The consideration of the possible weights for the respective risk parameters requires deeper analysis and expert knowledge.

3 POSSIBILISTIC RISK ANALYSIS

3.1 *Principles of the method*

The risk is very often equated with a kind of uncertainty. In this case, the risk is determined as a combination of the probability of failure events occurrence and consequences of these events, and uncertainties, whether those events will occur and what will be the consequences. Traditionally, failure risk modelling in CWSS is applied to the calculus of probability. It requires a statistically representative data set of faults. Often, in practice, this condition can't be met. Very often the data are derived from the experts whose knowledge is incomplete or uncertain. In this case, the use of arbitrary probability and its distributions leads to unreliable results (Tchórzewska-Cieślak 2010).

Probability can also be reported as a fuzzy, especially when it is estimated. In contrast to the classical set the boundary of fuzzy set is not precisely defined. This smooth transition is determined by the so-called membership function μA, where A denotes the set of fuzzy numbers. Fuzzy sets can be used to describe different linguistic terms associated with risk analysis (small, medium, large, very large). A linguistic variable is a variable that characterizes fuzzy, imprecise terms, expressed in words, for example: about number 1, high risk, low risk value. Before starting the process of fuzzification, the domain of discourse should be strictly defined, the so called X universe, which is an ordinary not fuzzy set. A fuzzy set is determined if all the membership functions for each element of the universe are given. The membership function (matching degree, compliance) assigns to each element x of the domain of discourse (space) a value within the range [0, 1], μ_A: X μ[0, 1], which means that every element x of the space X belongs to a fuzzy set A with certain degree of membership.

A fuzzy set A is defined as: $A = \{\mu_A (x), x\}$. The values of the membership function μ_A are real numbers in the interval [0, 1] (Braglia et al. 2003, Dubois & Prade 1980, Kleiner et al. 2006, Lee 1996, Sadiq et al. 2007, Tchórzewska-Cieślak 2010, Tchórzewska-Cieślak 2011, Zadeh 1965).

A possibilistic approach based on fuzzy set theory can be found in the so-called theory of possibility. The foundation of the theory of possibility is possibility distribution, which can be used to describe the data belonging to a particular fuzzy set. The distribution of possibility is equal to a defined membership function of fuzzy set (Johanson 2008, Klir & Folger 1988, Kluska 2009).

A special case is the so-called theory of possibility the Dempster-Shafer Theory (DST) called a mathematical theory of records (Alim 1988, Kacprzyk & Fedrizzi 1994, Shafer 1976). The Dempster-Shafer theory gives the possibility to combine different hypotheses (provided by experts) to determine the baseline probability. Different hypotheses assigns probabilities using the so-called Basic Probability Assignment (BPA) or mass function (the mass m (X) of X) function of belief m (Kacprzyk & Fedrizzi 1994).

The lower and upper boundary of the function of belief degree (m) of the truth of a hypothesis H with regard to X (or its components) define the measure (Kacprzyk & Fedrizzi 1994, Shafer 1976, Yager 1987, Luo & Caselton 1997):

belief degree: bel (X),
plausibility: pl(X),

belief ≤ *plausibility*

The belief degree has the following properties: $m(X_i) \rightarrow [0,1]$;

$$m(\varnothing) = 0 \tag{3}$$

$$\sum_{X_i \subseteq X} m(X_i) = 1. \tag{4}$$

where:
$m(X_i)$—belief degree,
$i = 1, 2, 3, ..., n$,
n—number of hypotheses concerning the set X,
$n = 2^j$; j—the number of elements of the set X,

The value of the function $m(X)$ refers only to the set X, and does not give any information about the subsets of X, for which individual belief functions are defined:

$$bel(X) \le P(X) \le pl(X) \tag{5}$$

$$bel(X_i) = \sum_{X_k \subseteq X_i} m(X_k) \tag{6}$$

$$bel(\varnothing) = 0,\ bel(X) = 1 \tag{7}$$

$$pl(X_i) = \sum_{X_k \cap X_i \neq \phi} m(X_k) \tag{8}$$

$$pl(\varnothing) = 0,\ pl(X) = 1 \tag{9}$$

$$pl(X_i) = 1 - bel(X_i) \tag{10}$$

where:
$bel(X)$—measure of belief (faith),
$pl(X)$—measure presumption (plausibility).

Combining rules (Dempster-Shafer Rule of Combination—DSRC). The result is a new distribution: $m(X) = (m1 \oplus m2 \oplus \cdots \oplus mi)(X)$

For two experts is as follows:

$$m_{1-2}(\varnothing) = 0 \tag{11}$$

$$m_{1-2}(X_i) = \frac{\sum_{X_a \cap X_b = X_i} m_1(X_a) \cdot m_2(X_b)}{1 - \sum_{X_a \cap X_b = \varnothing} m_1(X_a) \cdot m_2(X_b)} \tag{12}$$

In case of information conflict, i.e. the product of belief functions is an empty set, the conflict indicator K_f, is defined:

$$K_f = \sum_{X_a \cap X_b = \varnothing} m_1(X_a) \cdot m_2(X_b) \tag{13}$$

K_f is often interpreted as a measure of conflict between the different sources. The larger K is the more the sources are conflicting and the less sense has their combination. The factor K indicates the amount of evidential conflict. If $K = 0$, it shows complete compatibility, and if $0 < K < 1$, it shows partial compatibility. Finally, the orthogonal sum does not exist when $K = 1$ (Zadeh 1984).

To exclude information conflict the normalizing factor K_N is introduced:

$$K_N = (1 - K_f) \tag{14}$$

3.2 *The application case*

The water supply network in southeastern Polish city was analysed. The risk of failure of one of the major water mains, for the designated number of residents exposed to the lack of water supply due to failure was analysed (area A in Fig. 2).

The vast majority of the WDS works in the general supply pumping system without the expansion tanks. Most of the city is covered by a peripheral network. Only a small part of the network works as a branched network. Most of the WDS is built of steel and PVC. More than 40% of water supply pipeline is more than 20 years old. The second stage pumping station operates at a constant pressure at discharge (40 kPa). At present, urban water supply system serves about 63 thousand residents.

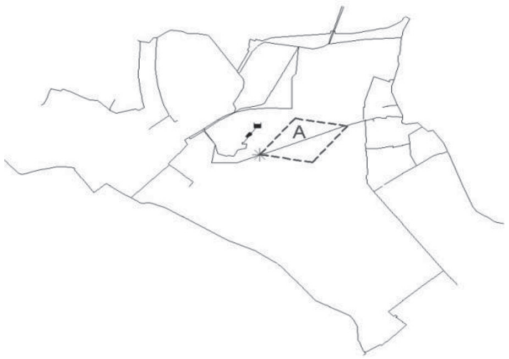

Figure 2. Diagram of the analyzed water supply system.

The state of metering of drinking water consumers is high, because it is 100% for the mass recipients and 98% for individual customers.

For risk the set of the possible risk levels were as follows: $R = \{rT, rK, rN\}$,

where:

– rT—tolerable risk,
– rK—controlled risk,
– rN—unacceptable risk.

The number of possible hypotheses Hn:

$n_j = 2^3 = 8, j = 1, 2, 3, 4, 5, 6, 7, 8.$

The characteristics of all possible hypotheses regarding the interpretation of risk values are presented in the form of a matrix. The matrix hypothesis is as follows:

$$M_{j,r} = \begin{vmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{vmatrix}$$

The evaluation is made by two experts E1 and E2. Each expert assesses the risk analysis result in a fuzzy way. It was assumed that the adopted Fuzzy Risk Model (FRM) the membership functions take the form:

$$\mu_{(rT)} = \begin{cases} 1 \; dla \; x \le 6 \\ \dfrac{8-x}{2} \quad dla \; 6 < x < 8 \\ 0 \; dla \; x \ge 8 \end{cases} \tag{15}$$

$$\mu_{(rK)} = \begin{cases} 0 \; dla \; x \le 6 \\ \dfrac{x-6}{7{,}5} \quad dla \; 6 < x < 13{,}5 \\ \dfrac{18-x}{4{,}5} \quad dla \; 13{,}5 < x \le 18 \\ 0 \; dla \; x \ge 18 \end{cases} \tag{16}$$

$$\mu_{(rN)} = \begin{cases} 0 \; dla \; x \le 13{,}5 \\ \dfrac{x-13{,}5}{5} \quad dla \; 13{,}5 < x < 8 \\ 1 \; dla \; x \ge 18 \end{cases} \tag{17}$$

For determined risk value $r(x) = 7{,}2$

Risk assessment by experts is to estimate belonging to a specific set $r = \{rT, rK, rN\}$:

E1:

– the risk is certainly not unacceptable,
– the risk can be considered as tolerated to a higher degree (with weight) than the controlled,
– utilizing fuzzy membership functions the value of belief functions were estimated.

E2:

– the risk is certainly not unacceptable,
– the risk is tolerable with weight two times greater than the controlled risk,

$$M_{m(EiHj)} = \begin{vmatrix} 0 & 0{,}4 & 0{,}16 & 0 & 0{,}4 & 0{,}01 & 0{,}01 & 0{,}02 \\ 0 & 0{,}4 & 0{,}16 & 0 & 0 & 0{,}4 & 0{,}02 & 0{,}02 \end{vmatrix}$$

– utilizing fuzzy membership functions the value of belief functions were estimated.

The matrix of experts is as follows:

The next step is to make the process of combining the rules according to formulas (4) ÷ (11). For the opinion of two experts (E1, E2) the matrix is as follows:

$$M \prod_{i=1,j=1}^{i=2,j=8} m(EiHj)m(EiHj)$$

$$= \begin{vmatrix} 0{,}12 & \overline{0{,}048} & 0 & 0{,}12 & 0{,}003 & \overline{0{,}003} & 0{,}006 \\ \overline{0{,}104} & 0{,}0416 & 0 & 0{,}104 & \overline{0{,}0026} & 0{,}0026 & 0{,}0052 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0{,}16 & \overline{0{,}064} & 0 & 0{,}16 & 0{,}004 & 0{,}004 & 0{,}008 \\ \overline{0{,}008} & 0{,}0032 & 0 & 0{,}008 & 0{,}0002 & 0{,}0002 & 0{,}0004 \\ 0{,}008 & 0{,}0032 & 0 & 0{,}008 & 0{,}0002 & 0{,}0002 & 0{,}0004 \end{vmatrix}$$

The overline values represent a conflict of information, i.e. it is not possible to assess the risk of

Table 1. The result values mE(1-2)(rn): belE(1-2)(rn), plE(1-2)(rn).

H_n	Description	$m_{E(1-2)}(r_n)$	$bel_{E(1-2)}(r_n)$	$pl_{E(1-2)}(r_n)$	AF
H_1	∅	0	0	0	0
H_2	rT	0,75	0,75	0,77	0,02
H_3	rK	0,23	0,23	0,232	0,02
H_4	rN	0,006	0,006	0,023	0,017
H_5	rT∨rK	0	1,0	1,0	0
H_6	rT∨rN	0,015	0,771	0,773	0,002
H_7	rK∨rN	0,001	0,237	0,253	0,016
H_8	rT∨rK∨rNA	0,001	1	1	0

failure in a defined scale. The degree of conflict was calculated using the formula (1):

The normalizing factor was determined by (13):

$$K_N = 0{,}7704.$$

Table 1 shows the main characteristics of the functions of belief m using the formulas (4) ÷ (11).

The highest values of the resulting belief function mE(1–2)(rn), the combination of two experts hypotheses indicates the level of failure risk analysis of water supply network. Measures of beliefs belE(1–2)(rn) and the presumption plE(1–2)(rn) characterized by the so-called interval of uncertainty as to the hypotheses interpretation. The uncertainty factor AF is the difference between belief and presumption in the case of hypothesis.

For the studied network (according to Fig. 2) the experts determined risk as tolerated with the uncertainty factor AF equal to 0.02, which proves the conformity of experts about hypotheses.

4 CONCLUSIONS AND DISCUSSION

If it is not possible to obtain accurate and complete statistical data which are required in the analysis and assessment of the risk of failure of the water supply network the necessary information can be obtained from experts. On the basis of their knowledge, experience and literature data they estimate the individual risk parameters.

Data obtained in this way are the basis of subjective evaluations, which are the basis for the fuzzy risk modelling. The theory of fuzzy sets allows to perform a risk analysis in natural language (e.g. low loss, risk tolerated) based on the experience of experts. It allows to model non-linearities, where the analytical, statistical or probabilistic description is difficult or impossible.

The model of fuzzy risk analysis can be combined with the Dempster-Shafer's model in the risk management process, particularly at the stage of obtaining, verification and grouping data and hypotheses posed by different experts. This allows the modelling of fuzzy evaluations of individual experts. The advantage of presented method is the ability to take into account the experts knowledge in case where there is no statistical database about adverse events in water supply system. Contrary to other experts methods which use Bayesian networks, Dempster-Shafer theory and fuzzy modeling does not require knowledge about probability distribution for every emergency events. The main limitation of presented method is uncertainty resulting from expert knowledge. Various experts opinions are eliminated through the use of normalization (so-called conflict information). There is why some informations might be not included in the final result. Application example demonstrates the usefulness of this method especially for events with incidental character (small statistical database) but which may have serious consequences. In the example a failure of one of the main pipeline in the city and its results in a lack of water supply was shown. That is why many times experts knowledge is the only method to determine the risk of failure on the main pipeline.

The proposed possibilistic model of failure risk analysis and assessment of water supply network is an alternative to the classical methods and models and should be used when possessed knowledge of risk factors is uncertain or incomplete.

Multidimensional risk to networks of distributed systems

T.V. Garcez & A.T. de Almeida
Federal University of Pernambuco, Recife, Brazil

ABSTRACT: Managing risk in networks of distributed systems requires the analysis of large numbers of alternatives, hazard scenarios, consequences and uncertainties regarding the occurrence of an accident, mainly due to the wide diversity of characteristics in the areas surrounding the system. Therefore, the decision making process needs to be analyzed in a more complex way. If decisions are to be taken more rationally, the uncertainties inherent in the context of risk itself must be addressed as must how best to aggregate the decision maker's preferences, related to the possible consequences resulting from hazards. Decision theory jointly with a multidimensional view of risk (using Multi-Criteria Decision Making methodologies—MCDM) enables these issues to be dealt with. Hence, this paper puts forward the use of an additional assessment of risk in underground electrical distribution networks with a multidimensional view of risk that may be used as a decision aid tool in risk management.

1 INTRODUCTION

The system of underground cabling in the urban environment is an important part of the infrastructure of electricity which is the lifeblood of urban growth and therefore governments attach great importance to it. Societies are highly reliant on power systems for their energy needs (Castillo, 2014).

The infrastructure of such systems is critical because it is an asset that is essential so that society and the economy can function well. It shares a mutual dependence on numerous other critical infrastructures, including but not limited to the infrastructure that supports the supply of gas, water, and telecommunications, the financial services industry, public safety services, public health, agriculture, and transportation systems.

Any disruptions to these systems, from accidents, result in direct and indirect losses. The effects of power outages can include economic, social, physical and psychological impacts; such consequences on providers and customers include premature death, injury, and indirect and direct economic losses (Castillo, 2014).

In the case specific case of blackouts, widespread economic and non-economic losses on a large scale are not well-understood. This is compounded by the fact that private and public companies do not account for the hidden costs incurred as a result of the loss of reliability in their systems that might generate both other non-economic losses, such as premature human death and human injury, and indirect economic and social impacts (Castillo, 2014). Also, there is a concern about the possibility of terrorist attacks seeking to exploit the vulnerability of power components and the overall system and thereby seriously damaging them.

An aggravating factor in the analysis of the consequences and probabilities of failure is due to the great diversity of other forms of urban infrastructure that interact and interconnect with or are in the vicinity of the underground power grid. Interference from these may cause undesirable events such as accidents and disruptions. There are several factors that interfere with the safety and reliability of these systems amongst which are environmental conditions, technical matters, human errors, third-parties' actions, sabotage, terrorism, etc.

One of the main causes of incidents in underground networks is interference from a third party, which people may provoke by their direct or indirect actions. Examples of direct interference are excavation, cable ducts being crushed on building sites and during and road construction. The probabilities of these incidents occurring are aggravated by the lack of accurate mapping of power underground urban systems.

In technical conditions, errors that stand out include mistakes in design and specifying standards and in selecting inappropriate materials and forms of ventilation. Furthermore, there can be serious operational and maintenance errors that can cause major failures and consequently undesired events.

Among more important environmental conditions there may be the presence of groundwater, excessive humidity, damage caused by rain, sewage, seawater, salts (to thaw snow), excessively warm environments, and so forth. Such factors may lead to the accelerated corrosion of wires and

insulating materials, and therefore cause serious system failures. Furthermore, there are major natural adverse phenomena such as lightning, floods and earthquakes which can lead to serious levels of system failure.

These undesirable events can have various consequences, such as, fatalities and injuries to people, fires in nearby locations, disruptions in local vehicle traffic, loss of company image, financial loss, the local population being afraid (on account of the uncertainty of when and where an underground vault will explode), loss of reliability and safety and other consequences which cannot be measured financially (Garcez & Almeida, 2014; Garcez & Almeida, 2013).

What make risk management even more complex and uncertain are the facts of there being: a large number (hundreds or thousands) of underground vaults of different characteristics within a distributed system; the lack of historical data on failure modes; the rarity of the occurrence of some faults; the magnitude of their consequences and the involvement of a complex environment surrounding the hazard zone besides the need to evaluate different hazard scenarios (which represent different causes of accidents—i.e. failure modes) (Garcez & Almeida, 2014).

Moreover, if one consider the effects of the network, such analysis can become even more complex, and the use of appropriate computational tools and methodologies is necessary. There are instances of dependencies in the electricity network. These include: one node (subsystem) becomes overloaded due to the malfunction of adjacent nodes, and temporary blackouts which take place due to a malfunction in the path in the grid between the power plant and the subsystem (underground vault) (Garcez & Szufel, 2014).

According to Garcez & Almeida (2014), under a management approach to keep the system adequately safe, the Decision Maker (DM) needs to answer some questions: What underground vault is considered to have the highest risk? What is the intensity level of consequences that really is important to the DM? What underground vaults or set of vaults should be considered when allocating hazard prevention resources or scheduling mitigation actions?

Given that the power distribution system in operation meets all the minimum safety requirements required by regulatory and inspection safety agencies, in various situations DMs are faced with problems that are about needing to allocate or assign additional (financial, safety, time, staff, technology, etc.) resources of electric power companies to a given set of alternatives, when these resources are scarce and limited and may not have been distributed equitably. Hence, the DM faces a problem of choosing or prioritizing alternatives to determine which alternative will be chosen (prioritized) from the perspectives of the company's needs (Garcez & Almeida, 2014).

Therefore, a multidimensional approach to risk analysis is required to evaluate the consequences in different aspects. Another important point, which is rarely exploited in traditional models, is related to incorporating the preferences and values of the DM who manages the system. Therefore, aggregating the DM's preferences in modeling, by Multiple-Criteria Decision-Making (MCDM) methods is very important and the results are more complete, comprehensive and in particular consider the DM's desires (Garcez & Almeida, 2013).

Some applications of multidimensional risk and incorporating a DM's preferences can be verified in several papers on creating models for analyzing risk in gas transport and distribution in pipelines (natural gas and hydrogen) such as in studies by Brito & Almeida (2009); Alencar & Almeida (2010); Brito et al. (2010), and Lins & Almeida (2012).

This paper puts forward a multidimensional (multiattribute) assessment of the risk from vaults in underground electricity distribution systems, by generating a decision tool, which ranks risk values in a risk hierarchy.

2 HOW THE MODEL DIFFERS FROM TRADITIONAL RISK ANALYSIS

In traditional risk analysis, the risk is normally assessed under the dimension of human or financial loss. As to human loss of life, certainly the number of people close to an underground vault is directly linked to the possible human loss of life, but there may also be vaults in which there is a high probability of a hazard scenario occurring, but near which the presence of people (pedestrians) is low, and yet, they too must be considered. Which situation should be regarded as more dangerous and therefore treated as a priority? Are there vaults which have a lower probability of a hazard scenario occurring and yet, should an accident occur, a greater number of people than expected may be exposed to the consequences, or should any consideration be given to the possibility of some vaults having a high probability of a hazard scenario occurring and yet, a smaller than expected number of people being exposed to it? (Garcez & Almeida, 2014).

Thus, it is important to consider the DM's preference structure in order to make more rational decisions on allocating additional resources, on a priority basis, to underground vaults. By contrast, the approaches of traditional risk analysis do not

consider this issue. In other words, prioritization, under the approach we suggest, will depend on the DM's preference structure since this is considered to generate a better result in the expected value and to decrease the amount of risk when prevention or mitigation measures are implemented (Garcez & Almeida, 2014; 2013).

As Garcez & Almeida (2014) state, this proposed methodology does not obviate the need for a structured approach to traditional risk analysis to be carried out, whether this be done in a qualitative or quantitative way. In this context there are several approaches of qualitative and quantitative risk analysis widely that can be chosen which are accepted by academic and technical circles.

Hence, the methodology of risk analysis that we propose is complementary to other traditional forms of risk analysis, and thereby offers one more tool that will help the DM to determine which underground vaults should be prioritized.

3 MULTIDIMENSIONAL RISK MODEL

The decision making process is understood as an effort to try to solve problems of conflicting goals that require a "best compromise" between goals list for the best solution, see Keeney & Raiffa (1976). They further note that decision making is of several types e.g., it may be simple or complex, which may have specific or strategic consequences, local or comprehensive impacts, and immediate, short, middle or long term consequences, or any combination of these.

In order to allocate additional investments to manage risk effectively, consideration needs to be given to different issues, such as safety; the financial, operational and external characteristics of the system; the requirements of regulatory agencies; the stance of competitors; and the demands from society (Garcez & Almeida, 2013).

Therefore, it is necessary to ensure that the decisions taken are consistent with the goals of the company in different criteria, and that the DM's preferences are incorporated into it. Multi-Criteria Decision Analysis (MCDA) methodologies are well suited for such situations (Keeney & Raiffa, 1976).

Nowadays, the need to incorporate considerations related to financial, environmental and social matters into planning is associated with studies about sources of energy which makes experts use the multicriteria approach more frequently (Afgan et al., 2008).

Bishop et al. (2009) state that decisions are usually complex. Many criteria need to be satisfied. The consequences of the options to be evaluated present various spatial and temporal distributions, affecting different population and generation groups. Decisions are also made in a social context where perceptions can be as significant as facts. In this complex environment, a survey of the decision making area shows two aspects: commitment and serving the decision-making process.

MCDA is a set of models for operational research that deals with decision problems in the presence of (usually conflicting) multiple objectives, the main purpose of which is to make the problem clearer for the DM (Belton & Stewart, 2002; Vincke, 1992).

Among various issues, the problem of ranking emerges from the need for the DM to build a list of the most important alternatives in order of relevance (prioritization) which, in this particular case, is a risk hierarchy, such that the alternatives (the underground vaults of the system) most likely to be the source of a manhole accident are dealt with first of all by using the available additional resources and only thereafter other sections of the system by order of their ranking if resources are still available. Multiattribute Utility Theory (MAUT) achieves this ranking (Garcez & Almeida, 2013).

MAUT is used to aggregate preferences and consequence values amongst multiple dimensions taking into account the DM's preferences and his/her behavior considering cases with uncertainty in a clear measure of risk.

Specialists in this area consider methods belong to one of three large families: American school methods, outranking methods and interactive methods. Vincke (1992) affirms that MAUT, which started in North America, consists of combining different points of view in the same function that needs to be optimized. Studies linked to this family verify the mathematical conditions of aggregation, the shape of the particular aggregation function, and construction methods. The second family, inspired by the French school, first seeks aid by constructing a known relationship called outranking, which represents DMs' strong preferences. The third family is the newest, and presents methods which alternate calculations (thus producing successive commitment solutions) and dialogues (the source of extra information on decision preferences) (Alencar et al., 2009).

MAUT allows DMs to structure complex problems in a simple hierarchy, and to evaluate, in a subjective way, a large number of quantitative and qualitative factors where there are uncertainties. Utility is a measure of desirability or satisfaction, which makes it easier to use a uniform scale in order to combine and/or compare quantitative and/or qualitative factors. The utility function is an artifice that quantifies DMs' preferences through variations displayed in an index of the extent to which criteria have been satisfied (Belton & Stewart, 2002).

Even though these models are very useful, especially to improve the efficiency of the process of risk control by assigning the most appropriate risk-mitigating activities to be applied to underground vaults, the use of the model by Garcez & Almeida (2013, 2014) can improve the process of assigning such actions by providing a ranking of underground vaults that will be taken into account when defining the process of sorting priorities in order to mitigate risks to a system.

To define a hierarchy, under a risk context, a model of the consequences is needed. According to Aven (2012), the most appropriate definition of risk involves defining the consequences and uncertainties. The uncertainties come from different sources in the model. In this context, under Decision Theory, the uncertainties considered are those (Garcez & Almeida, 2014): (*i*) arising from the occurrence of a hazard scenario (because it is not known what hazard scenario actually will occur), (*ii*) arising from the consequence of a hazard scenario that has occurred (because there are probabilistic mechanisms that interfere in the magnitude of the consequences).

The first uncertainty can be dealt with by using a probability distribution that represents the expert's *a priori* knowledge and/or data gathered from accidents that have occurred. The second uncertainty is modeled by a probability distribution that defines the range of possible consequences that may result from an accident.

By Decision Theory, the loss (consequence) function can be defined as the negative of the utility function of the expected consequence ($L(c) = -u(c)$) (Berger, 1985). These consequences are the outcomes of the impact of an accident in a given dimension, and can be represented by a probability distribution function ($P(c|q, \theta)$), given knowledge of the hazard scenario (θ) (the final outcome of an accident), and the underground vault analyzed (q).

There are several causes of manhole events. The most important include: the aging process, use of inadequate facilities, inappropriate maintenance actions, thermo-mechanical stress of the cable and connections, thermal decomposition of the insulation, overloading the power grid, shared use of the underground space with other public and private utilities, the flooding of underground vaults, or drains and manhole covers being clogged or blocked (for further details see Garcez & Almeida (2014); Garcez & Almeida (2013); Koch and Carpentier (1992); Snodgrass & Black, (2005), and Walsh & Black (2002, 2005)).

These failures can cause internal and external explosions, fire, smoke, displacement of the manhole cover, intense light and noise, flash fires and shock and heat waves (Garcez & Almeida, 2013; 2014).

3.1 *Consequences*

Multidimensional risk has some advantages such as its providing a broader analysis, which makes it more realistic and complete, and it also deals with conflicting objectives, the different parties involved, and uncertainties. Some dimensions addressed are human safety, finance, the environment, property, the impact of stakeholders and the impact on a distribution company's external public image.

This study evaluates the consequences (c) from four dimensions: human impacts, financial impacts, operational impacts and disruptions to vehicular traffic. The human dimension (c_h) deals with the possibility of injuries caused by projection of manhole covers and where they crash land, and burns of at least the second degree due to exposure to incident energy from an arc flash. The financial dimension (c_f) is about any kind of monetary compensation related to an accident occurring. The operational dimension (c_o) corresponds to the impact on the supply operation of the electricity distribution company (downtime). Finally, the dimension of disruption to traffic (c_t) is evaluated by the process of how traffic jams form on the streets around the accident area. The consequence models are described in details in Garcez & Almeida (2013, 2014).

3.2 *Multidimensional decision model*

Multi-attribute utility theory, which lies within the concepts of MCDA, enables the values of the DM's preferences to be aggregated (through the utility function) from multiple attributes, together with the uncertainty inherent in their consequences $P(c|\theta, q)$ and hazard scenarios $\pi(\theta)$, in a unique synthesis criterion function.

As the loss function is defined as the negative of the utility function of the expected consequence, so the utility function is calculated by:

$$u(\theta,q) = \int_c u(c)P(c \mid \theta,q)dc \tag{1}$$

thus,

$$L(\theta,q) = -\int_c u(c)P(c \mid \theta,q)dc \tag{2}$$

The measurement of risk $r(q)$ in an underground vault is the expected value of loss function $L(\theta, q)$. This can be represented by:

$$\begin{aligned} r(q) &= \sum\nolimits_\theta \pi(\theta)L(\theta,q) \\ &= -\sum\nolimits_\theta \pi(\theta)\int_c u(c)P(c \mid \theta,q)dc + (-1)\pi(\theta_N) \end{aligned} \tag{3}$$

where $\pi(\theta)$ is the probability distribution over the states of nature (hazard scenarios); and, the state

of nature θ_N represents the scenario of the normality, in which there is no occurrence of an accident scenario and, consequently, no negative consequences in the system i.e., $\int_c u(c)P(c \mid \theta,q)dc = -1$ (the system is operating normally). The range of risk values is [–1, 0], where the value –1 is related to the "lowest risk" and the value 0 to the "highest risk".

With respect to the DM's preferences, he/ she may have different basic attitudes (behavior), such as: risk aversion, risk neutral or risk prone. If the DM is risk averse, then the expected utility value is greater than the value of the certainty equivalent ($u[E(\tilde{x})] > E[u(\tilde{x})]$). If the DM is risk-neutral, the expected utility value is equal to the certainty equivalent ($u[E(\tilde{x})] = E[u(\tilde{x})]$). Should the DM be risk prone, the expected utility value is less than the certainty equivalent ($u[E(\tilde{x})] < E[u(\tilde{x})]$).

By using MAUT concepts in the risk measure and by taking the probability independence of the consequences into account, the risk measure is expressed by (Garcez & Almeida, 2013):

$$r(q) = \sum_i \sum_\theta \pi(\theta)\left(-\int_c u(c)P(c \mid \theta,q)dc\right) + (-1)\pi(\theta_N) \quad (4)$$

where i represents the several dimensions of the analysis, i.e., the dimensions of the consequence (C_h, C_f, C_o, C_t), when a determined hazard scenario (θ) occurs. These risk measures form a top-down hierarchy of the risk from the underground vaults evaluated. Consequently, they serve as a support tool for decision making and risk management.

4 APPLICATION

This paper uses a numerical application based on the study by Garcez & Almeida (2013), in which a multicriteria decision model was presented, with a view to assessing and ranking the risks from underground vaults. That was a hypothetical study, albeit of a realistic situation, that was based on an underground system of an electricity distribution company.

The company's senior manager for safety and operations was considered the DM. Seven underground vaults were analyzed (q_1, q_2, …, q_7), which represent a wide range of possible scenarios typically found in electricity distribution companies. The main features of these vaults are summarized in Table 1 (for more details see Garcez & Almeida (2013).

Four main dimensions of consequence were considered: those of human impacts, financial impacts, operational impacts and traffic disruptions. Conservatively, only one hazard scenario was considered: an internal explosion caused by an arc flash, which is considered the greatest impact, and causes the manhole cover to be blown off and projected.

To estimate the projection (distance) of the manhole cover, the elicitation method, called Equiprobable Intervals, was used. Estimating the risk measures is made from the perspective of Decision Theory. At the same time, a multiattribute utility function $U(c_h, c_f, c_o, c_t)$ is elicited from the DM. As it is supposed that the DM's preference structure is additive independent between the criteria, the utility functions from the perspective of a one-dimensional utility ($U(C_h)$, $U(C_f)$, $U(C_o)$, $U(C_t)$) can be elicited separately. To do so, the procedures described in Keeney and Raiffa (1976) were followed. It was considered that the DM is risk averse in the human dimension and risk prone in the remaining dimensions. The values of the scale constants obtained were: $k_{c_h} = 0.3386$; $k_{c_t} = 0.1247$; $k_{c_o} = 0.0944$; and, $k_{c_f} = 0.4423$.

The multiattribute utility functions, by Eq. (4) are combined with the probability density function. Hence, the multidimensional risk measure is calculated. Results of the ranking of the multidimensional risk assessment are shown in Table 2.

Notice that the values of risks ($r(q)$) are close to –1. This is due to the greatest contribution being from the scenario of normal operation (θ_N), since the occurrence of manhole events is rare, the prob-

Table 1. Characteristics of the undergrounds vaults analyzed (Garcez & Almeida, 2013).

q	Description of the external vicinity	Location of the manhole cover	Dist. from the manhole cover center on sidewalk to street (m)	Dist. from the manhole cover center on street to sidewalk (m)	Diameter of the manhole cover (m)
q_1	Commercial area 2	Street	–	4.25	1.5
q_2	Commercial area 3	Sidewalk	2.25	–	1.5
q_3	Residential area 1	Sidewalk	2.50	–	1.0
q_4	Residential area 2	Street	–	3.5	1.0
q_5	Residential area 3	Sidewalk	3.25	–	1.5
q_6	Commercial area 4	Street	–	8.5	1.0
q_7	Commercial area 5	Street	–	8.5	1.0

Table 2. Results of ranking the risk.

Rank	q	Risk value $r(q)$	Risk difference $r_i(q) - r_{i+1}(q)$	Risk range $(r_i(q) - r_{i+1}(q)/ r_{first}(q) - r_{last}(q))$
1st	q_2	–0.99493	–8.86682E-05	3.268%
2nd	q_5	–0.99484	–2.9489E-05	1.087%
3rd	q_3	–0.99481	–0.000555485	20.474%
4th	q_4	–0.99426	–0.001284774	47.353%
5th	q_7	–0.99297	–0.000614308	22.642%
6th	q_1	–0.99236	–0.000140443	
7th	q_6	–0.99222		

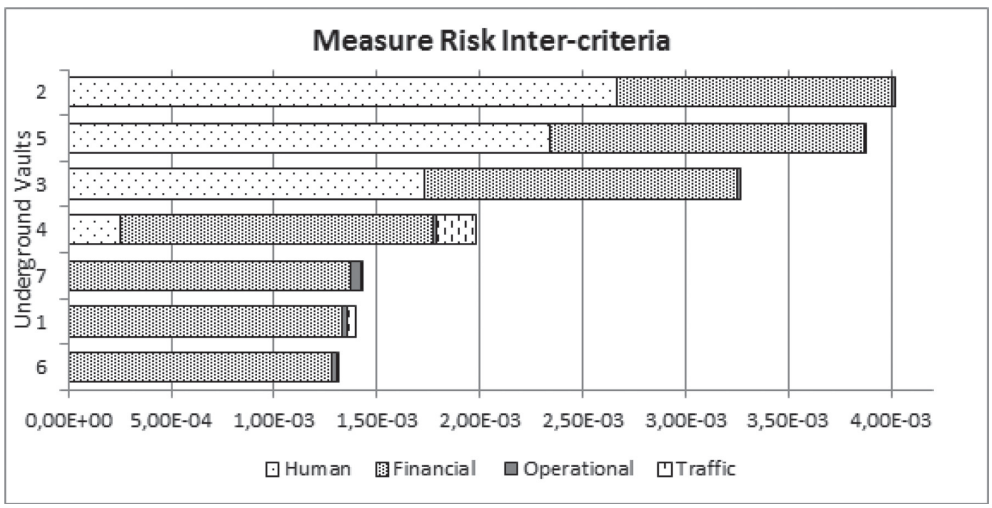

Figure 1. Analysis of the measures of inter-criteria risk.

ability of the scenario of normal operation $\pi(\theta_N)$ is close to 1, and its loss function is –1. The conclusion should be drawn that underground vault q_2 is at the top of the ranking; consequently, it should receive the greatest attention when additional resources are available for allocation to safety measures and system improvements.

By analyzing the differences between the risks and total risk range, the conclusion may be drawn that the difference between the risk values of vaults q_3 and q_4 corresponds to about 47% of the total range of risk $(r(q_3) - r(q_4)/ r(q_2) - r(q_6) \approx 47\%)$, which indicates a large increase in the risk between these vaults.

On analyzing the risk values under an inter-criteria approach graphically (Fig. 1), we conclude that: the first alternatives of the risk ranking show the human impact is major, while in the last-placed alternatives the human impact is nonexistent. The only major value of the impact of these last-placed alternatives is on the operational dimension.

Another source of strategic information comes from comparing the inter-criteria of the increments in risk (Garcez & Almeida, 2012). This analysis enables the criterion (dimension) that contributes the greatest difference in risk between alternatives to be identified. For example, on comparing the alternatives pair-to-pair under the inter-criterion approach, and on evaluating the alternatives q_2 and q_5 (see Fig. 2), these alternatives can be differentiated; there are major influences between the consequences of the financial and operational impacts and human loss (in descending order). Therefore, one can conclude that some preventive and mitigating actions that act on loss, for example, in disturbances to traffic, do not generate any change in the values of the difference in risk between these two alternatives. However, focusing on preventive and mitigating actions in the operational dimension of alternative q_2, would result in reducing the amount of risk compared to alternative q_5. Thus,

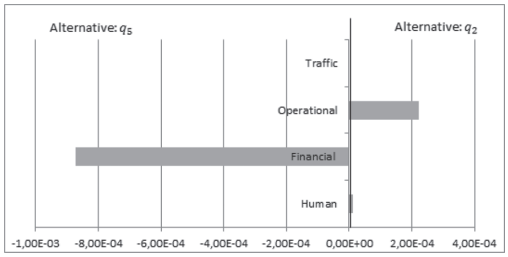

Figure 2. Analysis of the intra-criteria of the risk differences of alternatives q_2 and q_5.

resources can be redirected to manage risk more effectively.

5 CONCLUSIONS

Despite the underground system of electricity supply being safer than the overhead type, several accidents have occurred in these systems, and these have generated repercussions and consequences, not only for power distribution companies, but also for third-parties and society at large.

Thus, this study conducted a study of multidimensional risks in underground vaults in a power distribution system, taking into account several aspects of consequences, such as, the impacts on humans, financial impacts, operational impacts and impacts on the flow of local vehicular traffic.

The model supports a DM to prioritize alternatives in order to manage resources for risk management, plan maintenance for or to improve (upgrade) the system, first by allocating more resources to those that are the most critical among a large universe of alternatives. Furthermore, by analyzing the differences of risk inter-criteria, a better indication can be made of to what dimensions of the impact (loss) must preventive and mitigating actions be applied so as to guide how risk management can be undertaken more efficiently.

Mathematics of PRA applied to Distributed Generation curtailment in saturated grids

Elia System Operator, Brussels, Belgium

ABSTRACT: The share of distributed generation is steadily increasing in the field of electrical energy production. However, consequently to this shift, in rural areas mainly, grid operators are expecting more frequent line congestions and voltage problems. Active management of the distributed generation units is one of the possible solutions to keep the grid secure, while accepting more connections of this type of units to the existing grid infrastructure: (almost) real-time curtailment is applied to some generators in order to suppress congestion(s) on the grid. However, in the planning phase of the grid, the impact of active management, in terms of e.g. expected curtailed power per year, should be assessed before any possible new connection is allowed. This paper proposes a probabilistic risk assessment to estimate related risk indices, provides the mathematical formulation of the corresponding methodology and gives preliminary results on a simple test-case.

1 INTRODUCTION

The use of renewable energy for power generation has been steadily increasing these last years, as one of the candidate answers to the global warming issue. In addition, other types of Distributed Generation (DG), like e.g. CHP (Combined Heat and Power) units, are taking a significant share in the liberalized electricity market.

At the same time, the distribution grid infrastructure is still designed based on centralized production, i.e. for 'one-way flows' of electricity from large generation units and the transmission grid to local loads. Yet the increasing connection of DG units, mainly to the distribution grid, leads to 'two-way flows'. As a consequence, grid operators (both Transmission System Operators (TSOs) and Distribution System Operators (DSOs)) are expecting more frequent line congestions and voltage problems in many rural areas. To solve this problem, the network should be reinforced; nevertheless it is an expensive and time-consuming task, which cannot be seen as a short-term solution. Alternatively, Active Network Management (ANM) is introduced. An ANM scheme controls the injection of energy produced by DG units to the grid in (almost) real-time in case of congestion(s) on the grid (Davidson et al. 2010, Sansawatt et al. 2012). By this approach, the grid is retained secure.

The objective of an ANM scheme consists in connecting to the existing network infrastructure more DG units than what would be feasible based on their installed power and the strict application of the N-1 criterion. This allows also accepting to connect these DG units before envisioning any grid reinforcement, which is a costly process that spreads over several years. In this way, more energy is likely to be exported from these DG units to the transmission grid. However, the impact of ANM must be assessed before any possible new connection to the grid is allowed. Indeed, a possible investor in a new generation facility requests to obtain guarantees on the possible curtailment his/her unit could undergo. And the performance of the ANM scheme could determine contractual features with the system operator. Moreover, installing a new DG unit can affect the energy curtailment of the already connected DG units. In addition to this, the risk of congestion on the elements of the grid should also be analyzed.

Proper risk indices have therefore to be defined in order to characterize the ANM scheme performance. They also have to be estimated in a limited amount of time, as any request for a new DG unit connection must be answered in a limited amount of time. Deterministic methods (based on the N-1 criterion) used for network calculations in system planning are however not suitable to assess these indices, as DG units display an intermittent

production, contrarily to conventional generation facilities. This intermittency, combined with the variability of consumptions, corresponds to the sources of uncertainty affecting the system in this emerging context.

Analyzing a system whose inputs are stochastic variables, in the search for possible congestions and subsequent curtailment to eliminate them, calls for a probabilistic treatment. However, due to the large number of input variables (generations and loads) to be considered, and to the non-linearity of the electrical system, properly covering the state space of these stochastic variables turns out to be intractable. Moreover, for each variant, i.e. each possible combination of generations and loads, the N situation but also all N-1 situations should be analyzed, in the 3 seasonal regimes (winter, summer and inter-season) corresponding to different line ratings. Therefore, the number of network states to be treated dramatically increases.

In the literature, mainly two types of methods are proposed to deal with this problem, i.e. Monte Carlo Sampling (MCS) and the Multi-State Approach (MSA).

MCS consists in sampling variants from the joint probability density function (pdf) of the uncertain parameters (generations and loads, including correlations). Each sample serves as input data for an Optimal Power Flow (OPF) module to calculate the possible re-dispatching or curtailment of DG units. Based on the results of a large number of runs, MCS can provide an estimation of various quantities of interest, like e.g. the distribution of power flow on each grid element, the distribution of curtailed power for each DG unit, the annual energy produced by each DG unit (from which its utilization factor is straightforwardly derived) … However, it should be noted that the uncertainties of the high-dimensional variants are therefore propagated in a highly non-linear, multi-output model, in order to estimate non-point-wise indicators associated to rare events. Well-known acceleration techniques, like schemes based on a.o. importance sampling (e.g. Lux & Koblinger. 1991), splitting (e.g. L'Écuyer et al. 2009) or surrogate models (e.g. Li & Xiu. 2010), turn out to be irrelevant. A systematic coverage of the variant space is requested, and the resulting sample size is extremely large, even with a moderate accuracy in the estimation of the indicators.

In order to manage the number of variants to be analyzed, the MSA (Siano et al. 2010) rests on a discretization of the stochastic variables in significantly different combinations of discretized loads-generations, with respect to their likelihood to cause congestions. In order to keep the number of variants under control, some simplifications are made. For instance, correlation coefficients between all wind generations are taken equal to 1. The same assumption is made for the loads. These assumptions are likely to oversimplify the problem.

Given the limitations mentioned here above, this paper proposes a pragmatic methodology to handle the high dimensionality of the problem and estimate the impact of connecting a new DG unit. The latter is characterized by several relevant risk indices to be computed. A systematic, yet efficient, search of the variant space allows identifying all plausible congestion zones in a first stage, while an on-target sampling in these zones drives the computational effort towards the direction of interest, in a second stage. This combined approach allows managing the computation time.

This paper is organized as follows. First the steps of the proposed methodology are explained. Then the mathematical formulation of the methodology is exposed. Next, typical results obtained on a test case are presented. The final section is dedicated to the conclusions.

2 METHODOLOGY

The flowchart of the methodology is shown in Figure 1 (Faghihi et al. 2013).

As highlighted in this flowchart, the methodology rests on an attempt at decoupling as much as possible the electrical problem (congestion identification and curtailment analysis) from the probabilistic assessment (modeling of uncertain input variables and likelihood of the challenging situations). The main steps of the methodology are further presented in the next subsections.

2.1 *Modelling uncertainties*

Modeling the stochastic behavior of the generations of all DG units and the loads at all substations of the grid under study rests on eliciting the joint pdf of all these inputs this is based on inference from collected field data and on some assumptions.

Among the latter, correlations between random variables have to be considered:

- Loads at the different nodes are correlated due to either similar weather conditions or same daytime;
- Powers generated by wind farms are also correlated due to dependency on the wind speed in the area;
- Other possible correlations are neglected at this stage of the methodology development.

The joint pdf for each group of correlated variables is built by resorting to a Copula (Sklar 1959, Nelsen 2006).

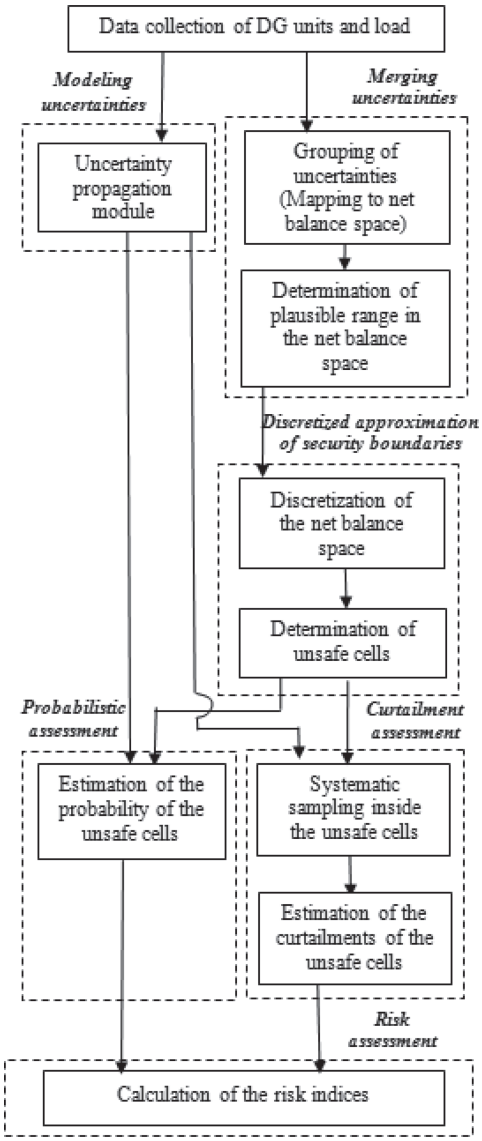

Figure 1. Flowchart of the methodology.

2.2 *Merging uncertainties*

As mentioned in the introduction, the proposed methodology should overcome the shortcomings of both MCS and MSA. The description of the input data, as summarized in the previous subsection, avoids the simplifications introduced in MSA. Now, in order to reduce the dimensions of the problem that affects strongly the efficiency of MCS, the uncertainties are first grouped in *net balances*, i.e. the algebraic sum of all productions minus the total load in each substation. Indeed, from the perspective of causing congestion on the grid elements, multiple variants corresponding to the same set of net balances will have the same effect. Identifying regions of the net balance space (i.e. a much less dimensional space than the variant space) where congestions are possible allows focusing the curtailment analysis on those full variants of interest that correspond to these regions, while avoiding a very large number of analyses of variants not contributing to the curtailment indicators.

In order to achieve this goal, a plausible domain of interest for the study is first determined in the net balance space, by considering on which range generations and load vary at each node. This domain naturally splits into a *safe* and an *unsafe* region, in terms of combinations of net balances making congestion on the grid.

As shown in Figure 2, a security boundary divides the net balance space into these two regions. A huge part of the net balance space belongs to the safe region, for current unsaturated grids in which a new DG unit could be connected. This safe region can therefore be skipped in further analysis. On the contrary, the sampling of variants should be forced into the unsafe region where curtailment is required.

It should be noted that for the N and each N-1 situation, security boundaries are different, due to different possibilities of congestion in each topology. The same remark can be made for different seasonal conditions, for which the line ratings take different values.

The next section deals with how these security boundaries can be approached.

2.3 *Discretized approximation of safety boundaries*

The unsafe region boundaries cannot be easily obtained. This region can take unpredictable

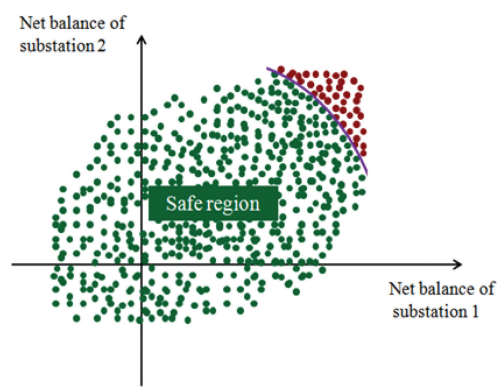

Figure 2. Safe and unsafe regions in the net balance state space.

shapes, mainly in already quite saturated grids, due to the non-linearity of the electrical system behavior. Sampling points in the net balance space, despite the lower dimensionality of the latter, would turn out to be time consuming. Therefore, a mesh is defined in this space (Fig. 3). Cells are labelled as safe or unsafe according to the following criterion: a Load Flow (LF) calculation is applied on the variants located at the corners of the cells; if all the corners of a cell are safe (i.e. cause no congestion), then the cell is considered as safe, otherwise it is assumed to be unsafe (Fig. 4).

This discrimination between safe and unsafe cells is repeated for each topology and each seasonal regime. In each case, only unsafe cells will have to be considered in the sequel of the analysis.

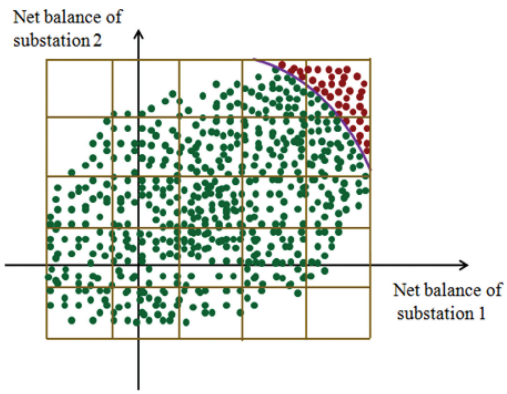

Figure 3. Discretization of the net balance state space.

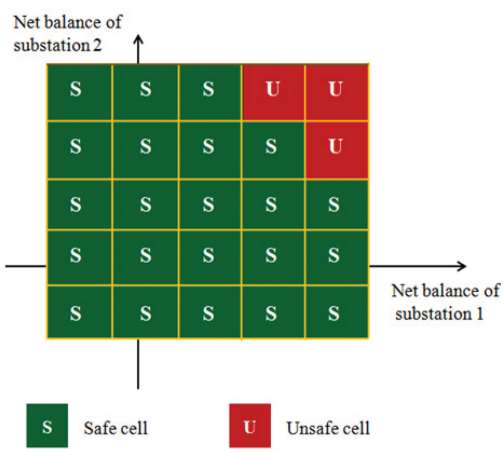

Figure 4. Approximation of the safe and unsafe regions by safe and unsafe cells.

2.4 *Curtailment assessment*

Variants likely to cause congestion on grid elements are thus only those corresponding to combinations of net balances lying inside unsafe cells, for given topology and season. MCS is therefore applied, by systematically sampling inside the unsafe cells. This allows

- Focusing the computational effort on those variants likely to lead to curtailment;
- Assessing conditional risk indicators, given each unsafe cell, before assessing the corresponding global indicators (see next subsections);
- Applying a cut-off criterion for too low-probable unsafe cells, having a negligible contribution to the total risk indices.

Different costs of curtailment can be assigned to the different (types of) DG units via the objective function of an OPF tool. The curtailments of all DG units, for each sampled variant, are calculated by such a tool, while accounting for the Principle of Access (PoA) of each DG unit. PoA defines the priority of curtailment of the different DG units contributing to the same congestion: some can export the power they produce at any time, others are guaranteed to do so only in the N situation, while others are likely to be curtailed in any topology, depending on the contractual characteristics of their connection.

Different PoA's can be defined depending on the location of the congestion, i.e. whether it appears on the HV grid and/or at the HV/MV substation. For instance, a technical optimum can be chosen to handle the overloads on the HV grid and a LIFO (Last in First Out) scheme could be applied at the substation level, in order to distribute the amount of required curtailment (due to overloads on HV grid on one hand and to HV/MV transformers on the other hand).

2.5 *Probabilistic assessment*

In order to calculate the global risk indices of the problem, the probability of the unsafe cells in the net balance space has to be estimated. However, this operation is not straightforward, as the joint pdf of all variants is complex and is not easily integrated on a volume in the net balance space. Therefore, a pragmatic approach is followed. First, a large number of samples are generated by MCS from the joint pdf of the correlated uncertainties (i.e. variants). Those correlated samples correspond to the power produced by the wind farms as well as to the loads at the different substations. However, the possible number of states obtained by combining the production of DG units and the loads may lead to a non-manageable

sample size due to combinatorial explosion. Therefore, a MSA-related technique is applied: the space of each group of correlated variables is discretized on a mesh in order to create a limited (but appropriate) number of states. The center of each cell in the mesh represents all the samples inside this cell, and the ratio of the number of samples inside the cell over the total number of samples determines the cell probability estimation. This is done for the different groups of correlated uncertainties, before combining the corresponding discretized states by a simple rule of product and converting them to the corresponding net balance value. Finally, the probability of each unsafe cell in the net balance space is calculated, considering the sampled variants that can be mapped to this cell and the probabilities of the discretized states associated to each group of correlated uncertainties.

2.6 *Risk assessment*

In the previous subsections, the unsafe cells were identified, the expected curtailments given each unsafe cell were assessed, and the probabilities of the cells were estimated. Having all these ingredients, the total risk of curtailment for each DG unit is obtained by summing on the unsafe cells, the expected curtailment associated to each cell weighed by the corresponding probability. This has to be summed up on all possible topologies and seasonal regimes considered, by considering the probability of each combination 'topology-season'.

Based on the risk of curtailment for each DG unit, its Utilization Factor (UF) can be calculated. The UF of a DG unit is the ratio of the actual energy produced in one year over the corresponding theoretical maximum, based on its installed power. The UF of a DG unit is an economic characteristic of the relevance of the investment for a producer. This UF can also be compared to its Capacity Factor (CF), i.e. the ratio of the energy that could have been produced in a year, without any curtailment, over the maximum energy produced on the basis of the installed power.

In addition to these indices that characterize the expected curtailment in a year, the curtailment distribution can also be provided. The distribution of the congestion on each element of the grid can also be estimated.

3 MATHEMATICAL FORMULATION

The present section aims to express in mathematical terms the methodology summarized in Figure 1 and presented in details in Section 2.

3.1 *General definition of the risk indices*

Consider the risk assessment of an ANM scheme under the following assumptions. The grid under study displays n nodes. To each node i, a load L_i is connected as well as DG units having a production P_{ij}, $j = 1 \ldots n_j$, respectively.

The grid is studied in all configurations N and N-1, with a probability p_k to lie in configuration k, $k = 1 \ldots n_c$, and in the various seasons defined (summer, winter, inter-season), with a probability q_l to be in season l, $l = 1 \ldots n_s$.

Let us define:

- $\overline{L} \equiv \{L_1 \ldots L_n\}$, vector of the loads;
- $\overline{P} \equiv \{P_{11} .. P_{1n}, P_{21} .. P_{2n}, \ldots P_{n1} .. P_{nn}\}$, vector of the productions;
- $\varphi_{kl}(\overline{L}, \overline{P})$, joint pdf of the variants $(\overline{L}, \overline{P})$ in configuration k and season l;
- $f_{kl}(\overline{L}, \overline{P})$, performance function associated to a given risk index RI in configuration k and season l.

This performance function could be for instance an indicator function (equal to 1 when there is a congestion, and 0 else—the result of a Load Flow calculation) for the congestion probability, or the curtailment at a given DG unit if the corresponding expected curtailment is the measure of interest (the result of an Optimal Power Flow calculation).

The risk index RI can then be expressed as:

$$RI = \sum_{k=1}^{n_c} \sum_{l=1}^{n_s} \int\int f_{kl}(\overline{L}, \overline{P}) \varphi_{kl}(\overline{L}, \overline{P}) d\overline{L} d\overline{P} \quad (1)$$

where the integrals on the loads are limited to the ranges (minimum load, maximum load) for all nodes, and those on the productions extend from 0 to the installed power of each DG unit.

As the double summation does not bring any additional complexity in the calculation, we will assume in the following $n_c = n_s = 1$. Therefore:

$$RI = \int\int f(\overline{L}, \overline{P}) \varphi(\overline{L}, \overline{P}) d\overline{L} d\overline{P} \quad (2)$$

3.2 *Mapping to the net balance space*

Let

$$NB_i = \sum_{j=1}^{n_i} P_{ij} - L_i \quad (3)$$

be the net balance seen by the grid at node i, $i = 1 \ldots n$. The Jacobian of the corresponding change of variables being equal to 1, we can rewrite eq. (2) as follows:

$$RI = \int\int f(\overline{L}(\overline{NB}, \overline{P}), \overline{P}) \varphi(\overline{L}(\overline{NB}, \overline{P}), \overline{P}) d\,\overline{NB} d\overline{P} \quad (4)$$

where the integrals on the net balances are to be calculated on a domain (called *search space*) resulting from the possible values of the loads and productions mentioned above.

The performance function can only take non-zero values for variants causing congestion on the grid. Since the latter situation corresponds only to given net balance variants $\overline{NB}$, we can multiply the performance function f by an indicator function $\theta(\overline{NB})$ such that

$$\theta(\overline{NB}) = \begin{cases} 1 & \text{if } \overline{NB} \text{ causes a congestion on the grid} \\ 0 & \text{else} \end{cases} \tag{5}$$

All net balance variants $\overline{NB}$ belonging to the search space and for which $\theta = 1$ compose the so-called unsafe region UR of the search space. Consequently,

$$\begin{aligned} RI &= \int\int f(\bar{L}(\overline{NB},\bar{P}),\bar{P})\theta(\overline{NB})\varphi(\bar{L}(\overline{NB},\bar{P}),\bar{P})d\overline{NB}d\bar{P} \\ &= \int_{UR} d\overline{NB}\int f(\bar{L}(\overline{NB},\bar{P}),\bar{P})\varphi(\bar{L}(\overline{NB},\bar{P}),\bar{P})d\bar{P} \end{aligned} \tag{6a,b}$$

3.3 *Discretization of the search space*

Let us now discretize the search space in n_{cel} cells. Then we have:

$$\int d\overline{NB} = \sum_{c=1}^{n_{cel}} \int_{cell\,c} d\overline{NB} \tag{7}$$

In addition to this, each cell c on which $\theta(\overline{NB}) = 0$ everywhere is called *safe* and the integral over it is 0. Therefore

$$RI = \sum_{\substack{unsafe \\ cells\,c}} \int_{cell\,c} d\overline{NB}\int f(\bar{L}(\overline{NB},\bar{P}),\bar{P})\varphi(\bar{L}(\overline{NB},\bar{P}),\bar{P})d\bar{P} \tag{8}$$

Let

$$\alpha_c \equiv \int_{cell\,c} d\overline{NB}\int d\bar{P}\varphi(\bar{L}(\overline{NB},\bar{P}),\bar{P}) \tag{9}$$

be the probability to be in cell c, and

$$\varphi_c(\bar{L}(\overline{NB},\bar{P}),\bar{P}) \equiv \begin{cases} \dfrac{\varphi(\bar{L}(\overline{NB},\bar{P}),\bar{P})}{\alpha_c} & \text{if } \overline{NB} \in cell\,c \\ 0 & \text{else} \end{cases} \tag{10}$$

be the truncated pdf of the variants belonging to cell c. Then, we obtain:

$$RI = \sum_{\substack{unsafe \\ cells\,c}} \alpha_c \int_{cell\,c} d\overline{NB}\int f(\bar{L}(\overline{NB},\bar{P}),\bar{P})\varphi_c(\bar{L}(\overline{NB},\bar{P}),\bar{P})d\bar{P} \tag{11}$$

We can finally remap this result to the original variant space by writing:

$$RI = \sum_{\substack{unsafe \\ cells\,c}} \alpha_c \int_{\substack{\Sigma\bar{P}-\bar{L} \\ \in cell\,c}} d\bar{L}\int f(\bar{L},\bar{P})\varphi_c(\bar{L},\bar{P})d\bar{P} \tag{12}$$

Each integral in eq. (12) is estimated in our methodology by a MCS approach restricted to each unsafe cell (see Subsection 2.4), while α_c is assessed by the MSA-like technique explained in Subsection 2.5.

4 RESULTS

Our methodology has been applied, for the sake of illustration, on a test case (Faghihi et al. 2014) displaying 3 substations, 5 wind farms (for a total installed capacity of 52 MW), 3 CHP units (total capacity: 35 MW) and one load in each substation (Fig. 5).

For the purpose of our test case, all DG units are assumed to be connected to the MV side. However,

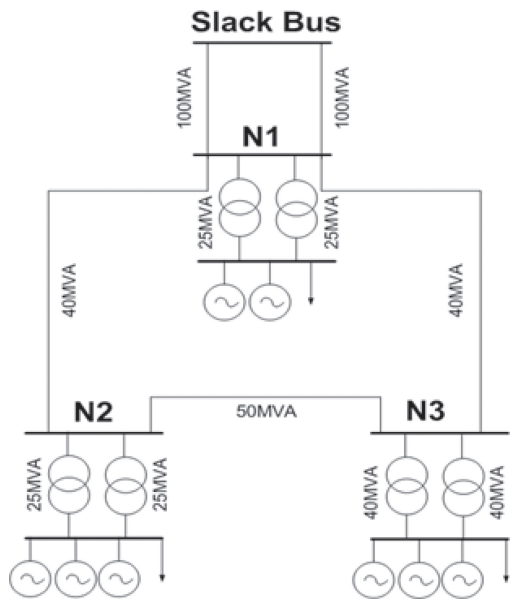

Figure 5. Test grid.

the methodology can be adapted to a mix of connections on both HV and MV sides. Although the network is simply made of 3 lines and 3 substations, the load and production profiles are chosen plausible, since they are inspired from a real case. Risk indices are estimated for the N and all N-1 situations (i.e. outages of HV/MV transformer in substation no. 2 and each HV line), as well as for the 3 seasons considered in a year and characterized by different line ratings. The probabilities to be in summer, inter-season and winter are 0.25, 0.5 and 0.25, respectively. A probability of outage of each line and each HV/MV transformer is assumed as well.

The distributions of the curtailment in one of the wind farms due to outage on the HV grid and in a HV/MV transformer are shown in Figures 6 and 7, respectively. A separate analysis of the distribution of the curtailment of each DG unit in N and each N-1 situation in each season can also be provided. As an example, the distribution of the congestion on a line in a N-1 situation on the HV grid in summer is displayed in Figure 8. Such a detailed analysis can be obtained for each asset in N and all N-1 situations in each season.

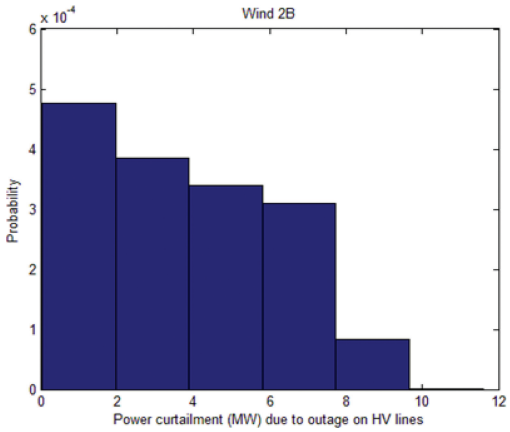

Figure 6. Distribution of the curtailed power in a wind farm due to outage on HV lines.

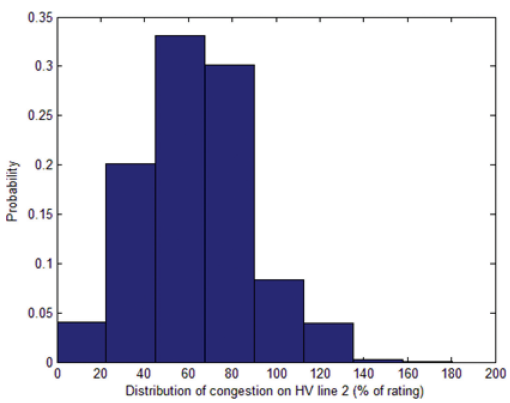

Figure 7. Distribution of the curtailed power in a wind farm due to outage on a HV/MV transformer.

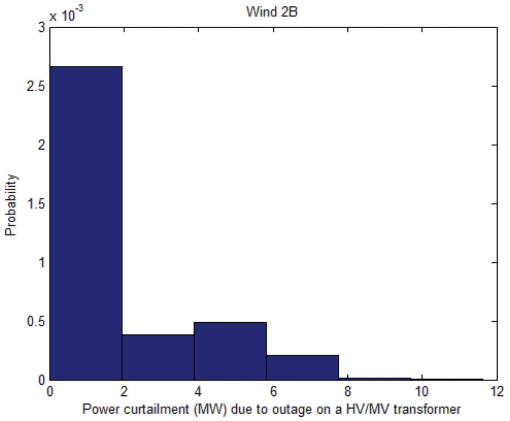

Figure 8. Distribution of the congestion on a line in a N-1 situation on the HV grid in summer.

5 CONCLUSIONS

The share of DG in electricity generation is increasing, at a rate faster than that of possible grid reinforcements, which in addition are very expensive. Both TSOs and DSOs are likely to face more congestion and voltage problems, due to 'two-way flows' at the distribution level. Modern grids should evolve to handle these challenges, before reinforcing their current infrastructure. ANM, in the context of smart grids, allows controlling the injection of energy produced by DG units in case of security problem on the network, and is therefore a possible solution to this challenge.

However, in the planning phase, the performance of an ANM scheme should be assessed when considering the impact of any possible new connection to the grid. Indeed, any new DG unit is likely to modify the current expected curtailment of the other DG units installed in the area. Therefore, proper risk measures related to the curtailment of each producer (in N and N-1 situations) have to be assessed.

Considering the intermittent production of DG units, as well as the variability of the load, probabilistic approaches are developed to handle the problem. However, even for medium-size grids, the

number of random input variables of an OPF tool estimating the curtailment level, soon becomes important. Due to the non-linearity of the electrical system, classical techniques to improve the efficient of a MCS approach turn out to be irrelevant.

This paper proposed a pragmatic methodology to assess risk indices characterizing the performance of an ANM scheme in a systematic way. The method rests on the grouping of uncertainties, based on their similarity in making congestion on the grid. A new, much less dimensional state space, i.e. the net balance space, is then introduced. The unsafe region in this space is identified, and MCS is then limited to variants corresponding to this unsafe domain.

The main advantage of this approach is to drive the sampling towards regions of interest in the search space, while skipping numerous variant analyses that do not contribute to the risk indicators of interest. The results are categorized into two main groups, i.e. risks related to the curtailment of DG units and the risk associated with congestions on grid elements.

Priorities assignment for actions in a pipeline: A decision model to evaluate multiple objectives

M.H. Alencar, M.F. Marsaro & A.T. de Almeida
Universidade Federal de Pernambuco, Recife, Pernambuco, Brazil

ABSTRACT: Pipelines are considered one of the safest means of transport of natural gas. However, when an accident occurs, can generate catastrophic consequences in terms of human, environmental and financial aspects. In this context, this paper presents a quantitative analysis, based on the application of a multicriteria decision model for risk assessment in natural gas pipelines, prioritizing pipeline sections according to the risk value obtained.

1 INTRODUCTION

Shahriar et al. (2012) state that Oil and Gas (O & G) are the major fuel sources consumed in the world. Many of these fuels are transported from origin to destination through pipelines. Jo and Crowl (2008) point out that these distances cover hundreds or even thousands of miles. Long pipelines pass through distinct locations, each with different characteristics e.g. industrial, agricultural or residential areas, commercial districts, preserved environmental sites, etc).

The integrity of pipelines is very important to companies, government agencies, consumers, and other stakeholders, due to the potential adverse consequences related to public health, safety, the environment and financial expenditure on correcting whatever type of system failure may occur. However, a pipeline is subject to deterioration due to age, aggressive environmental factors, inadequate design and improper maintenance and protection. In this context it is observed that some accidents have occurred over the years, which have often generated critical consequences.

Han and Weng (2011) consider that accidents caused by gas pipelines rupturing bring about major threats to public safety. Due to the physical and chemical characteristics of natural gas and the complexity of the topology of pipeline networks, the occurrence of accidents in pipelines are completely different from any other kind of industrial accident.

Marhavilas et al. (2011) describes that different studies on risk in the natural gas pipeline environment have been conducted using different methods of evaluation which have included qualitative and quantitative approaches. More specifically, given these aspects, this paper presents quantitative analyses, based on the application of a multiple criteria decision model for risk assessment of a natural gas pipeline, prioritizing pipeline sections according to the risk value obtained. Multi-Attribute Utility Theory (MAUT) is applied to incorporate the decision maker's risk behavior. MAUT takes into account the probabilistic context in which pipeline risk analysis is inserted, presenting a very well defined axiomatic structure, based on the axioms of utility theory.

The paper presents the following sections: Section 2 presents some aspects associated with the decision context; Section 3 sets out the decision model; Section 4 describes an application of the model; and the last section draws some conclusions.

2 DECISION CONTEXT

According to Alencar and Almeida (2010), segments of pipelines that have homogeneous characteristics can be divided into sections. Age of piping, soil type, pressure and pipeline diameter are some of the homogeneous characteristics that can be considered.

Each section from Figure 1 presents different characteristics, which cover residential areas, industrial areas, commercial areas and a tourist complex. The layout of these sections is shown in Figure 1.

To evaluate the gas pipeline sections, it is interesting to evaluate the decision maker's objectives. Keeney (1992) proposed important steps which point out that values are the basis of interest for any decision, and these become clear after the objectives have been identified. In the same way, consequences are descriptions of alternative impacts described in terms of the degree to which objectives were achieved. Thus, in this multicriteria

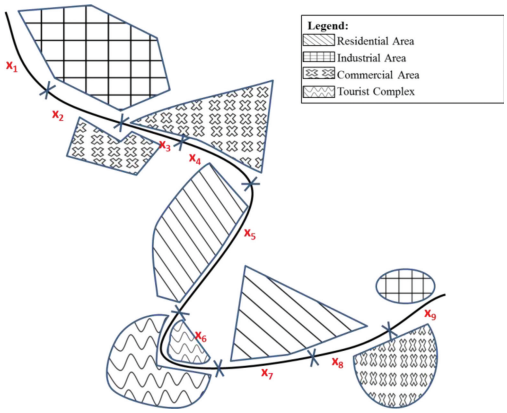

Figure 1. Layout of the arrangement of the sections considered.

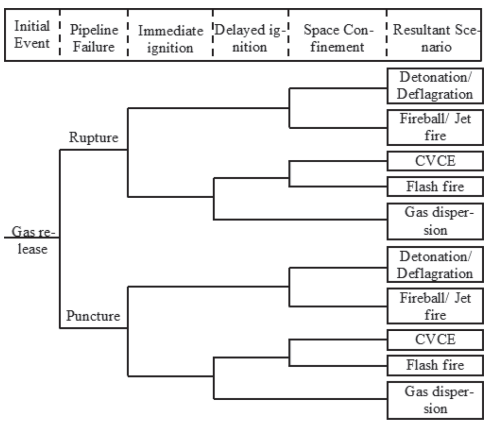

Figure 2. Event tree for a natural gas pipeline (adapted from Brito et al. (2010)).

decision, the consequences of the human (h), environmental (v) and financial (m) dimensions are what the model considers.

While considering that the complexity of operational decision situations can lead to accidents occurring, Crowl and Jo (2007) point out that incidents may also provoke accidents. Many incidents are followed by a series of events that result in an accident. This may include explosions, leaks and fire. In this paper, hazard scenarios are defined for natural gas pipelines based on Brito et al. (2010), as presented (Fig. 2).

3 MULTICRITERIA DECISION MODEL

According Vincke (1992), Multiple Criteria Decision Making (MCDM) is a set of methods and techniques developed to support individuals and organizations in resolving decision problems.

The multi-attribute decision model considered (see Fig. 3) in this paper uses a multiple risk dimension based evaluation for each section of a pipeline network, providing an idea of the risk hierarchy between each pipeline section by comparing these sections.

This information can be used as input for managerial purposes with regard to maintenance and operational decisions, especially to priorities for allocating resources amongst gas pipeline sections, taking human, environmental and financial risks into consideration. This model uses only one decision maker.

As used in Brito et al. (2010), "A" is defined as the set of all possible outcomes from a given accident in a dimension amongst the set of dimensions considered. As described in Brito et al. (2010), states of nature "θ" related to potential accidents in natural gas pipelines express the uncertainty associated to this problem.

To deal with uncertainties in "A", a probabilistic approach is applied by using a probability distribution over consequences and by elicitating utility functions for these consequences. Considering descriptions by Berger (1985), "$\pi_i(\theta)$" sets the probability of each state of nature or accidental scenario.

Each pipe section is denoted by "x_i". The utility when the scenario is "θ" and the section "x_i" is established by "$U(\theta,x_i)$". "q" represents the consequences. The utility is obtained through the combination of the probabilities of deterministic

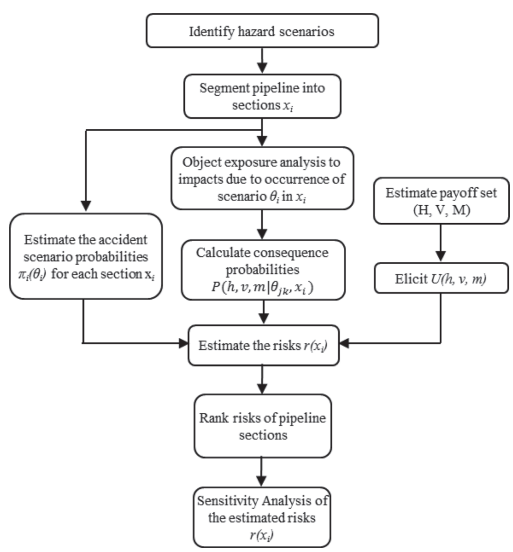

Figure 3. Model structure (adapted from Brito and Almeida (2009)).

consequences "q" in "A" (consequence function, "$P(q|\theta, x_i)$"). Additionally, it is considered that consequence functions are represented by the probability density function "$f(q|\theta, x_i)$".

According to Keeney and Raiffa (1976), the values of the utility function are defined in interval scales between the extremes [0,1], where "0" is associated with "least preferable" and "1" with "most preferable". The utility function of these consequences (represented by "$U(q)$", where "q" Є "A") is defined by the following equation:

$$U(\theta, x_i) = \int_q P(q|\theta, x_i)U(q)dq \quad (1)$$

According to Berger (1985), the loss function is calculated through the negative of the utility function "$L(\theta, x_i) = -U(\theta, x_i)$". The loss is estimated for sections of the pipelines and for the accident scenarios in question as shown below:

$$L(\theta, x_i) = -\int_H \int_V \int_M f(h,v,m|\theta, x_i)U(h,v,m)dhdvdm \quad (2)$$

Brito et al. (2010) argue that the expected value of loss, defined as the risk, should be established for each pipeline section and for each criterion, and enables the decision maker's attitude in relation to risk to be incorporated by eliciting the utility function. In this context, the interval scale for "$L(\theta, x_i)$" and "$r(x_i)$" is defined as [–1,0], where "–1" is associated with "lowest risk" and "0" with the highest risk.

For each criterion related to a pipeline section and for each accident scenario, the risk is defined as the expected value of losses, as per the definitions found in Berger (1985) and Keeney and Raiffa (1976). In this statement, the risk is considered to be the result of summing the losses associated with each specific scenario "θ" and each section "x_i" for the three consequence dimensions considered, multiplied by the probabilities of accident scenarios "$\pi_i(\theta)$" added to the losses indexed to the scenario "θ_N". In this context, "θ_N" represents the scenario of normality of the system, "$r(\theta_N)$" assumes the value of (–1) which multiplies "$\pi_i(\theta_N)$", the loss associated with the scenario "θ_N" without the occurrence of any damage. Thus, the risk is established by the following equation:

$$r(x) = \left\{ \Sigma_j \Sigma_k \left\{ - \left[\begin{array}{l} +k_h \int_h f(h \mid \theta_{jk}, x)u(h)dh \\ +k_v \int_v f(v \mid \theta_{jk}, x)u(v)dv \\ +k_m \int_m f(m \mid \theta_{jk}, x)u(m)dm \end{array} \right] \right\} \cdot \pi_i(\theta_{jk}) \right\} + (-1) \cdot \pi_i(\theta_N) \quad (3)$$

4 APPLICATION

A numerical application is presented. The objective is to illustrate the proposed model for assessing risk in a natural gas pipeline using the multiple criteria decision model developed.

The hazard scenarios were defined from the event tree presented in Figure 2. Simulations were developed for analyzing accident scenarios "θ" and sections throughout the considered pipeline by using computational tools. The probability density functions $f(h|\theta, x_i)$, $f(v|\theta, x_i)$ and $f(m|\theta, x_i)$ are used to estimate probabilities.

Using the structured elicitation protocol described in Keeney and Raiffa (1976), the multi-attribute utility function $U(h,v,m)$ is achieved by choosing from among consequences associated with accidents in pipelines.

Another step of the model includes estimating the risks and ranking them as presented in Table 1. To estimate the risk assigned to each section of the pipeline, the multi-attribute utility function is associated with the probability density function of the consequences.

Further analysis, in addition to ranking, is to compare the increments of risk in relation to pipeline sections. According to Keeney and Raiffa (1976), this is possible due to the interval scale of utility functions.

A descending ranking of values is used for risk assessment. From this result some considerations can be made.

One of these considerations is that an Absolute Difference Index (ADI) for each section should be defined from the ratio "$r(y_i) - r(y_i + 1)$" where "y_i" and "$y_i + 1$" represent the positions in the ranking of given sections of the pipe. Another index for the risk analysis is the Difference Ratio Index (DRI), expressed by Equation (4):

$$DRI = \frac{r_y(x_i) - r_{y+1}(x_j)}{r_{y+1}(x_j) - r_{y+2}(x_j)} \quad (4)$$

Table 1. Result of ranking the risks to sections of the pipeline.

Ranking position (y)	Section (x_i)	ADI	DRI
1	x_8	0.6681	0.2062
2	x_4	3.2395	0.9881
3	x_5	3.2782	6.0895
4	x_9	0.5383	0.3724
5	x_6	1.4455	0.3781
6	x_3	3.8225	1.9350
7	x_2	1.9754	11.6310
8	x_1	0.1698	–
9	x_7	–	–

In this way, is possible to verify in Table 1 that section 8 presents the highest value of risk among the sections that were analyzed, when all three risk dimensions are considered: human, financial and environmental. The highest losses related to the likely consequences of accidents are expected for the section 8. Additionally, it is verified that the increment in the risk values from section 5 to section 9 is 6 times greater than that from section 9 to section 6. In the same way the increment in the risk values from section 2 to section 1 is almost 12 times greater than that from section 1 to section 7.

This evaluation of risk increment allows the decision-makers make better decisions about resource allocation, especially when it comes to scarce resources for the maintenance and management of pipelines designed to risk mitigation. Well as identifies the sections more prone to severe consequences when an accident occurs, the decision maker can identify those most vulnerable sections and requiring more resources.

According to Alencar and Almeida (2010), the last stage refers to verify the consistency of results, from the variation of some parameters. Due the uncertainty related with model parameters, this phase can identify the impact of the results by using a sensitivity analysis.

5 CONCLUSION

The use of a multiple criteria approach to evaluate risk from a natural gas pipeline allows a multidimensional risk analysis to be conducted, as presented in this paper. More specifically, the use of MAUT (Multi-attribute Utility Theory) adds important aspects to this problem such as: taking into consideration the decision makers' preferences; the decision makers' behavior in relation to risk; and using the interval scale for assessing the risk increment through increment ratios.

Obtaining a ranking of risk values allows managers to visualize the existing context better, which should lead the company to consider these aspects of mitigating risks and to adopt preventive actions related to risk mitigation. For future studies, the involvement of stakeholders may be an interesting point to include in the decision making process of risk analysis in natural gas pipelines, and would add the context of group decision making to this approach.

Risk assessment in heat supply system

B. Babiarz
Rzeszow University of Technology, Rzeszow, Poland

ABSTRACT: The task of a heat supply system is to provide the consumer with the required quantity of the energy in the form of the "usable energy"- heat. Both risk and uncertainty are connected with the functioning of communal systems involving heat supply systems. The issue of risk assessment in heat supply systems requires considering their specific character. Heat supply systems characterize changeable heat load during the year. The delivery of heat to consumers depends on changeable external conditions.

These conditions affect energy security, security of energy supply and safety of people as users or operators of system. The paper presents an approach to risk assessment in the heat supply system, as a system consisting of three sub-systems, taking into account the location of the risk, identification, hazard classification, estimation of risk and risk responses. The proposed approach to risk analysis has been summarized with the requirements of the current legislation concerning heat engineering.

Method of risk assessment using an event tree method, possible to application in heat supply system considering changeable atmospheric conditions have been presented in this work.

1 INTRODUCTION

The task of a Heat Supply System (HSS) under the relevant legislation is a current, continuous and reliable heat supply to the needs of local communities through the provision of services, which are commonly available. Ensuring continuity and reliability of HSS must meet the requirements to ensure:

- energy security—as a condition of the economy which enables full coverage of the customers' ongoing and prospective demand for fuels and energy in a technically and economically justified manner, with the observance of the environment protection requirements;
- security of energy supply, forming an ability of the system to ensure the security of the operating network and balancing energy supply with demanding for this energy;
- safety of people, as users or operators of a system.

The measure of the loss of security is the risk, resulting from the likely sequence of events affecting the level or from the possible consequences of the decisions taken. Risk is characterized by the quality of the fulfillment of the system task. Taking into consideration, that risk is inherent in the businesses of heating, and the quality of services provided is a measure of competitiveness, we can conclude, that these companies should strive to eliminate or minimize the hazards, which may affect the level of risk.

It is possible to achieve through improving operating process of the subsystems, objects or elements that are components of the entire heat supply system by introducing into traditional management system methods aimed at identifying hazards, eliminating or reducing their potential effects in order to estimate the risk and to take action with the aim of responding to risk. The results of the risk assessment process should serve as an important basis to determine the strategy of actions to meet the safety requirements in the area of economically reasonable as well as draft a plan for responding to risk.

2 THE TERM AND KINDS OF RISK

Risk is the basic category of security issues. It is derived from the theory of reliability and safety of systems. This is connected with situations of slight, uncertain or problematic effect of exposing to danger, loss or harm—with the likelihood that something will bring negative results. In this perspective, the risk is identified with the loss of safety (Babiarz & Rak 2001).

The risk is at least two-dimensional, complex concept involving the possibility of an adverse outcome or uncertainty about disadvantageous events, which are the occurring time, kind of event, its duration, the size of an adverse outcome. In addition to the term risk is used term hazard, which is more than the risk associated with a sense of danger. The concept of risk, in turn, is more associated with the estimate of uncertainty and possible losses related to this.

Risk characteristics are uncertainty, probability, the dispersion of results (adverse effects). There are two ways to define risk. The first of these combines the risk with possible distribution of results—the risk is a possible variance of the expected results. In this perspective, risk is a function of the variability of possible outcomes. A second look at risk refers to the probability of losses and their sizes. The more probable that an event causing losses occur, the greater risk is. According to this definition, the size of the risk can be defined as the frequency of obtaining undesirable results. Then you can bind the level of the risk with the sizes of possible losses. In this perspective, the greater the loss suffered may be the greater risk occurs. There is also a definition of risk as the product of the probability of occurrence of an adverse event and the size of the losses caused by event.

From the mathematical point of view the basic definition is obligatory:

$$r = P \cdot C \tag{1}$$

where:
P—a measure of the system functioning unreliability, corresponding to the category of probability—frequency;
C—a measure of the consequences, corresponding to the category of effects—damage, expressed in units of financial resources.

3 THE APPROACH TO RISK ANALYSIS IN HSS

Risk and safety analysis in HSS is the basis for the proper conduction of the process of exploitation and prevention the occurrence of serious failures that can lead to economic, social and environmental losses. Heat supply systems characterize changeable heat load in the year (Babiarz 2006). The delivery of heat to consumers depends on changeable external conditions.

Risk analysis in HSS requires taking action on its:

- location (determining the place of occurrence, the type of subsystem, coverage, risk groups);
- identification (identifying the types of risks, factors of uncertainties, kinds of hazards);
- designation (estimation of risk measures, using appropriate quantitative or qualitative methods);
- respond to risk and management of it (controlling and exploration of activities aiming to reduce it).

Identification of risk requires the identification of hazards as factors, that may cause dangerous situations to the users of object, the object itself or its environment.

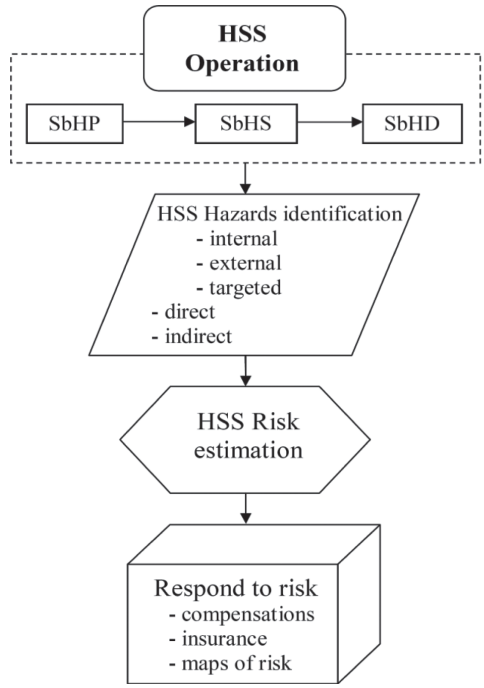

Figure 1. The approach to HSS risk assessment.

From the point of view of the source of danger in HSS, hazards can be distinguished as: internal, external and intentional (targeted).

Internal hazards arise from the nature of the system, its specific character and they are based on the kind of technological processes, which are, depending on the degree of system decomposition, production, supply and distribution of heat to the public via the heating medium with appropriate parameters. In particular, these are:

- deviations from the established parameters, required in given operating conditions: temperature, pressure, flow, thermal power;
- failures of the heat production subsystem components: boilers, pumps, control and measurement devices, etc.;
- failure of heat supply subsystem components: district heating pipes, fittings, alarm devices, etc.;
- failure of the heat distribution subsystem elements: heat distribution pipes in heating stations, fittings, internal system components, etc.;
- error of human—as an operator or conservator of system—maintenance and inspection mistakes;
- unreliability of the system supplying the media needed to execute the HSS tasks, in particular: electricity, water, steam, air, oil, etc.

External hazards are mainly determined by unfavorable weather conditions, or they may be caused by the proximity of communication tractions, and other objects having influence on the state of the object and the consequences of limitations, or the lack of heat supply to consumers. These can be distinguished as:

- natural, extreme climatic events such as floods, earthquakes, landslides, strong winds, lightning;
- serious failures in electric power systems, causing interruptions in the power supply, which can cause even blackout failure;
- other installations or technical facilities located in the vicinity, which could adversely affect the elements of HSS;
- transport routes located nearby, which are the source of stray currents that may cause damage to the network elements.

Intentional (targeted) hazards are those connected with the operation of unauthorized persons, terrorist attacks. Moreover, the political situation has also the impact on the security of fuel supplies needed for energy production.

Considering the impact of adverse events, hazards can be divided into: direct, arising as a result of failures (the direct impact factor of high temperature and pressure) and indirect hazards, which are results of HSS component failures. Direct hazards in the above sense is any factor's impact on the surrounding environment, people, equipment and buildings. Steam and hot water under high pressure are particularly dangerous in the event of damage in the heating network located in street lane or in its close proximity.

Direct hazards are:

- failure posing a threat to human life and health: the possibility of burns as a result of the impact of hot water and steam, scouring the streets, foundations of buildings, caused by leaching of soil by flowing a heating medium;
- failures causing property damage: damage in material objects (buildings, cars, etc.) caused by leaching the soil, damage to existing utilities (sewerage system, water supply and electricity network).

Indirect hazards are caused by HSS element failures and, consequently, by the lack or limitation of heat supply to consumers. Depending on the design of buildings, sealing of windows and doors can cause a significant decrease in temperature in rooms inside buildings. Force of the wind and temperature outside, which prevails at the time of damage are measures of an indirect hazard degree. These threads can be distinguished as:

- lowering indoor room temperatures, which in consequence leads to closure of nurseries, schools, kindergartens, offices, security or evacuation of hospitals, which do not have an emergency heat sources;
- the necessity to drain the internal installations of the water—lack of these activities might result in the possibility of damages in the installation elements, caused by freezing water in it;
- the necessity to stop production and the possibility of occurring serious losses as a result of failure to meet the technological parameters in industrial companies, greenhouses, etc. (Babiarz & Rak 2002).

Failures occurring in the HSS cause lowering of qualitative parameters of generated heat. This usually makes a thermal power balance not sustainable. The balance of thermal power in the heat supply system $\Delta\Phi$ may be expressed by a difference between the thermal power supplied to the system Φ_s and thermal power required (ordered) by the system Φ_o. In the case of optimal cooperation between the heat source and the entire system, the balance is sustainable and it can be described as follows:

$$\Delta\Phi = \Phi_s - \Phi_o = 0 \tag{2}$$

In case of irregularities, the balance equation can take two forms:

$$\Delta\Phi = \Phi_s - \Phi_o < 0 \tag{3}$$

or

$$\Delta\Phi = \Phi_s - \Phi_o > 0 \tag{4}$$

The case defined by the relation (3) occurs, when the thermal power output by the source to the district heating network is less, than the demand of consumers. Then the thermal power deficit occurs. On the other hand, a case described by formula (4) takes place when the network parameters control is not correct and returning water from the district heating network has a higher temperature than it should be according to the thermal power control charts (Babiarz B. 2014). This involves an indirect threat, which, in the case of simultaneous occurrence of several factors having influence on the heat load, can cause significant social and economic losses.

Identification and analysis of hazards give an overview to the characteristics and operating conditions of the system. They are useful in the estimation of risk.

Specialized techniques known as risk assessment are created as part of the developing science of safety. They are based on the qualitative, quantitative, semi-quantitative and simulation methods, using control and data acquisition as well as computer databases, operating system based on GIS.

Risk assessment may be qualitative, quantitative or semi-quantitative. Qualitative risk assessment is

applicable when the risk is small and well known. Simple description of the types of major accidents, their consequences and their likelihood and review of compliance with standards are sufficient. Quantified risk assessment is only appropriate where it is both reasonable and practicable in term of the availability of information and data (Arunraj & Maiti 2007).

Among the qualitative risk assessment methods there should be distinguished:

- CHL—Check Lists;
- FMEA—Failure Mode & Effects Analysis;
- HAZOP—Hazard & Operability Studies;
- PHA—Preliminary Hazard Analysis;
- PSA—Process Safety Analysis;
- Relative Ranking;
- What-If Analysis.

Quantitative methods of risk assessment are:

- ETA—Event Tree Analysis;
- FTA—Fault Tree Analysis;
- CCA—Cause & Consequence Analysis;
- HRA—Human Reliability Analysis;
- Monte Carlo Methods;
- Markov Methods;
- Matrix Methods.

Semi-quantitative risk assessment methods are:

- Domino effect analysis;
- LOPA—Layers of protection analysis.

The choice of the method depends mainly on the complexity of the system, the type of hazard and the probability of their occurrence. In addition, there should be considered: specific character of system, the type and scope of functions, the kinds of hazards and the likelihood of their occurrence, technology and types of databases, etc.

Examples of the application of risk assessment methods are presented in many publications (Werbińska, 2006, Zio 2009, Vališ & Zając 2010, Młyńczak et al. 2011, Aven 2012).

The next step in the risk analysis is responding to the risk. Result of the risk assessment process is used to make a decision on acceptance, minimization, avoidance or reducing risk. On this basis cost and benefits analyzes and strategies as well as responding to the risk plans are created.

According to current law regulations, heating companies should create action procedures, when hazards occur.

Restrictions in the heat supply can be introduced in the case of occurrence:

- a threat to the energy security of the country consisting in a long term lack of balance on the fuel and energy market;
- a threat to the safety of people;
- a threat of significant material loss.

Restrictions consist in a reduction or an interruption of the heat supply.

Supplier of heat introduces restrictions on the provision of heat by:

- reduction of the quality and/or quantitative parameters of heating medium to a level enabling maintenance of temperature 10 degrees Celsius in dwellings and 5 degrees Celsius in other facilities heated;
- the adjustment of parameters in customers' systems by changing the controller settings on particular thermal nodes.

Supplier can reduce the supply of heat to the limit, which guarantees only maintaining the circulation of the heating medium in the district heating network, which prevent it from freezing in the case of restrictions on sale of coal and electricity consumption.

Under the current provisions, in case of default by heating company established customer service quality standards, the recipient is entitled to a decrease of costs. These issues have been regulated in the Ordinance of the Minister of Economy of 17 September 2010 concerning the detailed principles of the establishment and calculation of tariffs and billing principles for heat supply (Journal of Laws No. 194, item. 1291). Recipients are entitled to a decrease of heat costs in case of default by the energy company terms and conditions of sale of heat in terms of start and end dates of heat supply for heating and planned interruptions in the supply of heat in the summer. In accordance with § 40 of the Ordinance, the amount of discounts, referred to above, shall be determined as follows (if the sales contract does not provide differently):

- if the start or end of the heat supply for heating were delayed in relation to established quality standards of customers' service, discount is 1/30 of the monthly fee for the ordered thermal power for plants in which there was a delay—per each day of delay;
- if the planned interruption in the supply of heat in the summer was longer than the established quality standards of customers' service, discount is 1/30 of the monthly fee for the ordered thermal power for plants, in which there was an extension of a break in the heat supply—per each day extension of the break.

Furthermore, in accordance with § 44 of the tariff regulation, when due to breach by the energy company quality standards of customers' service, thermal power has been reduced (if the sales contract does not provide differently), the recipient

is entitled to a discount, the amount of which is calculated as follows:

- if the thermal power limit is up to 40%, the discount is calculated by the formulas:

$$S_{u40} = S_{um40} + S_{uc40} \quad (5)$$

$$S_{um40} = 0,25 \cdot (\Phi_t - \Phi_r) \cdot 3,6 \cdot 24 \cdot C_n \cdot h_p : 365 \quad (6)$$

$$S_{uc40} = 0,4 \cdot (\Phi_t - \Phi_r) \cdot 3,6 \cdot 24 \cdot h_p \cdot C_c \quad (7)$$

- if the thermal power limit is above 40%, the discount is calculated by the formulas:

$$S_{u40u} = S_{um40u} + S_{uc40u} \quad (8)$$

$$S_{um40u} = 0,5 \cdot (\Phi_t - \Phi_r) \cdot C_n \cdot h_p : 365 \quad (9)$$

$$S_{uc40u} = 0,8 \cdot (\Phi_t - \Phi_r) \cdot 3,6 \cdot 24 \cdot h_p \cdot C_c \quad (10)$$

where:

S_u—the total discount for restrictions in heat providing,
S_{um}—crediting (decrease of cost) for limiting of thermal power,
S_{uc}—crediting for undelivered heat,
Φ_t—thermal power determined on the basis of calculating flow rate and heat carrier parameters specified in regulatory table [MW],
Φ_r—the actual thermal power, determined on the basis of the flow rate and actual parameters of the heat carrier [MW],
24—multiplier, meaning 24 hours a day [h],
h_p—the number of days in which there were lrestriction in the supply of heat, due to breach by the energy company service quality recipients' standards,
C_n—the price for the ordered thermal power for the tariff group [PLN/MW],
C_c—the price of heat for a given tariff group [PLN/GJ].

4 AN EXAMPLE OF DETERMINING THE RISK USING EVENT TREE METHOD

The purpose of the risk, hazards and level of safety assessment in HSS is to create a database of relevant, criterial information, necessary in decision-making, optimization of processes, exploitation and control of systems, as well as in taking protective measures to prevent the occurrence of adverse effects of events. There are many methods of determining the risk. Event tree method is often used in analyzes of technical systems. The concept of the event tree method is to consider the consequences of adverse effect as the result of adverse events during or erroneous evaluations and decisions (Babiarz & Rak, 2002). Then all possible sequences of events, being a consequence of

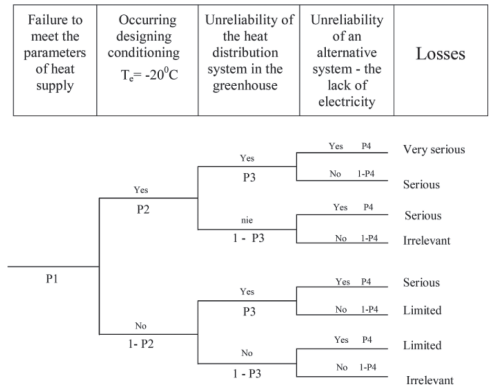

Figure 2. Illustration of event scenario providing greenhouse with heat using event tree.

adverse events in the scenario and their effects are defined. The essence of the method is illustrated in the following example.

A greenhouse is a recipient of technological heat to maintain the proper temperature of the vegetables production process. Alternative heat source is the possibility to use electric power to the provisional, localized heating of the greenhouse capacity. The only security of certainty of heat supply to the greenhouse is reservation of the heating network, supplying heat to heat the greenhouse. The heating medium is supplied to the object by three-wired heating network. One of these three wires is a reserve in the case of failure of any of the two others. Estimation of the risk of incurring identified losses by the owner of the greenhouse is presented is the following example.

Figure 2 presents example of event tree representing a risk for greenhouse facilities, to estimate the loss of the owner. Initiating event is a failure to meet the parameters of heat supply or non-delivery of heat. Then the sequence of possible adverse events is considered in case of occurrence or absence of the computational, design conditions. The one, shown in Figure 2, allows calculating the risk of very serious losses r_{vs}, according to the formula:

$$r_{vs} = P1 \cdot P2 \cdot P3 \cdot P4 \quad (11)$$

In turn, the risk of serious loss r_s is:

$$r_s = P1 \cdot P2 \cdot P3 \cdot (1 - P4) + P1 \cdot P2 \cdot (1 - P3) \cdot P4 + P1 \cdot (1 - P2) \cdot P3 \cdot P4 \quad (12)$$

5 SUMMARY

Risk assessment in HSS is connected with the energy security of the country. Current law

legislations define issues related to energy security, determining the necessity to develop procedures of limitations restrictions in the heat supply by the company in case of emergency. Existing regulations, shaping the issues of decrease of costs, require energy companies to give a discount in the case of occurring certain events failure to meet the quality standards in heat supply service to customers. Very important things in the heat supply management are to assess the risks, inform others of its sizes and initiate actions that must be taken in the face of risk occurring.

The approach to risk assessment, presented in the paper, takes into account the decomposition of HSS system in the analysis of the degree of fulfillment of tasks in the exploitation process. The comprehensive approach to risk assessment in HSS requires its location, identification and classification of hazards, estimation of risk and response to risk, including setting priorities for risk management by comparing the level of risk with pre-established targeted levels of risk. Moreover, monitoring of risk and checking of compliance with established procedures are also necessary. The final product of identification, assessment and measurement of risk in HSS may be risk maps, which are a useful tool in the effective management of centralized heat supply to consumers.

Assessment of risk using the event tree can be useful in countering threats resulting from damage to system components, taking into account the variability of weather conditions affecting the thermal load. It may be an additional element in the conduction of preventive activities, related to prevention of damage, standardization of repairs, as well as in the development of emergency scenarios.

The subject of risk in HSS requires further in-depth analysis, based on the available tools and methods, and particularly determining the required level of risk.

ABSTRACT: Attacks against critical energy infrastructures have recently become an increasingly important factor in energy security discussions. Studies examining such threats often focus on particular aspects like terrorist threats or resource conflicts. Therefore, the recently established Energy Infrastructure Attack Database (EIAD) has a much broader scope by considering attacks towards energy infrastructures that are carried out by a broad range of Violent Non-State Actors (VNSAs). The current study analyzed energy infrastructure attacks with regard to their spatial and temporal clustering patterns to identify and describe differences between countries as well as temporal shifts within a specific country. In this way the observed patterns could be conceptualized as a type of tactical contagion.

This paper presents an analysis of EIAD, which contains about 8600 entries of intentional attacks worldwide for the period 1980–2011. In this study we found that "linear infrastructures" such as transmission lines and pipelines are predominantly targeted because they often run through rather remote areas and are thus difficult to protect compared to "point" sources (e.g. refineries, power plants). Geo-referencing of EIAD data allowed for identifying distinct country/region hotspots, which we conceptualize as attack clusters. Furthermore, the temporal patterns and underlying mechanisms (e.g. tactical contagion) creating these clusters were analyzed. In summary, EIAD offers a comprehensive basis for the quantitative evaluation of energy infrastructure attacks by VNSAs, and provides decision and policy makers with objective facts and recommendations, which are an essential component for contemporary debates on energy security.

1 INTRODUCTION

In an age of increasing complexity and uncertainty risk management has become a default component and practice of many different organizations, assets, processes, etc. Consequently a variety of theoretical concepts, approaches and methodologies have been developed (Aven and Zio, 2012). However, in general, risks are often analyzed in the context of their potential impacts on human health and the environment as well as economic losses (Jonkman et al., 2003), and assessments are used as tool to provide an objective and transparent evaluation that enables informed decision-making. For this purpose, the choice of adequate and understandable risk metrics is indispensable (Johansen and Rausand, 2014). In general, three basic risk management strategies, or risk-based approaches, can be distinguished, including: threshold levels, risk reduction activities using the precautionary principle, and standards derived from discursive processes (Klinke and Renn, 2002, Stirling, 1999). Furthermore, risk and sustainable assessment are partially linked and complementary concepts because in practice they are both often measured by means of indicators, and are concerned about the future. (Gray and Wiedemann, 1999).

The need for a comprehensive risk assessment framework in the energy sector has been expressed by different authors since the 1980s (Fritzsche, 1989, Inhaber, 2004, Rasmussen, 1981). In the 1990s, the Paul Scherrer Institut (PSI) laid the foundations for a methodological approach that allows a transparent and objective quantification of accident risks and their comparison across different energy technologies (Hirschberg et al., 1998). The Energy-related Severe Accident Database (ENSAD) constitutes its core component, and since its initial release it has been regularly updated and extended (e.g., Burgherr et al., 2014). Therefore, the risks of technological accidents in the energy sector and their potentially disastrous consequences are

nowadays included in a comprehensive assessment of sustainability and energy security concerns (Burgherr and Hirschberg, 2014, Burgherr et al., 2013).

In contrast, intentional attacks against critical energy infrastructures have only recently emerged as an increasingly important factor in energy security discussions. This is primarily due to the growing dependence on oil and gas imports from regions considered less reliable and stable, but also large-scale imports of new renewables could lead to increased energy security vulnerabilities (Lacher and Kumetat, 2011, Lilliestam, 2014). Despite growing interest, intentional attacks against energy infrastructures have yet to receive the same analytical treatment as accident risks. Studies examining such threats often focus on particular aspects like terrorist threats (Luft and Korin, 2003, Toft et al., 2010), maritime piracy (Pristrom et al., 2013) or resource conflicts (Rodgers and O'Neill, 2012), and thus do not address the entire picture nor complexity of the topic and hence miss a big part of the risk picture, which in turn impacts assessments. To fill this gap, the present study aims to provide a much broader perspective by considering attacks towards energy infrastructures that are carried out by Violent Non-State Actors (VNSAs), spanning the full motivational and tactical spectrum. For this purpose, the Energy Infrastructure Attack Database (EIAD) was developed, ensuring a consistent data basis.

The main objectives of this article are threefold, namely (1) to introduce and describe this new dataset, (2) to present an initial analysis of the data between 1980–2011, and (3) to discuss potential future research directions.

2 METHODS

2.1 *EIAD database*

The EIAD database is a joint effort of the Center of Security Studies (CSS) of the Swiss Federal Institute of Technology (ETH) and the Technology Assessment (TA) group at the PSI. It has been initiated in 2010, and by now it can be considered a fully matured and comprehensive information source on Energy Infrastructure (EI) attacks that are executed by Violent Non-State Actors (VNSA). Although EIAD is not completely different from other databases, it has some unique features. Databases such as the Global Terrorism Database (GTD) (LaFree and Dugan, 2007) or the Worldwide Incidents Tracking System (WITS) (Wigle, 2010) are focused on the terrorist threat only, but include attacks from all types of sectors and activities. In contrast, EIAD considers all kinds of criminal and politically motivated attacks that are targeted at energy infrastructures. Other outstanding characteristics of EIAD are that it contains successful, failed and foiled attacks, and that it does not code for motivation that is often difficult to accurately determine, but rather for attack type (e.g. bombing, assault, hijacking, etc.).

EIAD has a modularized and standardized data record structure that comprises the following elements:

- EIAD ID: uniquely identifies each database record
- Incident Date
- Incident Location: country, location description (e.g. city name), latitude and longitude coordinates
- Incident information: event type, multiple attack (Y/N), free text summary
- Attack information: primary attack type, secondary attack type (if applicable), instruments used (e.g. explosive, firearms, arson, etc.), combination attack (Y/N)
- Target information: energy sector (e.g. petroleum, gas, etc.), energy infrastructure (e.g. pipeline, refinery, etc.), specific target (free text), second target (if applicable)
- Perpetrator information: group/actor, claim responsibility (Y/N), motive (free text)
- Incident consequences: fatalities, casualties, reported downtime, infrastructure impact (ordinal scale), hostage situation (Y/N), number of hostages, ransom paid (amount)
- Additional information; further event details (free text)
- Source information (up to three primary data sources)

For a more extensive description of EIAD see Giroux et al. (2013).

2.2 *Characterization of data set*

EIAD covers the period 1980–2011, which formed the basis for the analyses performed in this study. It should be noted that in the past months the contents of EIAD has been completely reviewed, and where necessary modified and updated. Therefore, the current analysis can partially differ from previous ones (e.g., Giroux et al., 2013), reflecting the continuous improvements of the database. Data for years 2012 and 2013 were not included because the validation and verification has not yet been fully completed.

First, a general overview and basic characterization of the EIAD data set was performed. This included an evaluation of temporal trends in the annual attack numbers, using the non-parametric Mann–Kendall test (Mann, 1945). A positive (negative) value of the Z-statistic identifies

an upward (downward) trend at the chosen significance level $\alpha = 0.05$.

Calculations were performed with the MS Excel application MAKESENS (Salmi et al., 2002).

2.3 *Frequency distributions of attacks*

In a second step, different distributions were fitted to the data (full data set and individual countries that contribute at least 2.5% to all attacks) to determine the model that best describe the attack frequencies.

2.3.1 *Fitting the frequency distribution*

A Maximum Likelihood Estimation (MLE) method was used to fit models on the frequency dataset. MLE is a common statistical technique for es-timating model parameters (e.g., Cousineau et al., 2004). The MLE proceeds to maximize a likelihood function, which in turn maximizes the agreement be-tween the model and the data. In this study the MLE algorithm proposed by Rigby and Stasinopoulos (1996) was applied. This algorithm is converging to the model and it stops once the change in the likelihood is sufficiently small, that is the Global Deviance (GD) reaches the minimum.

When fitting models, the MLE is used to find the optimal fit to the dataset. However, maximizing the log likelihood often results in fitting noise and parameter estimates that are unstable, particularly when the data set is relatively small. This is because MLE trusts too much the observed trends in the, often limited, data (Moons et al., 2004). In order to avoid possible over-fitting, the Bayesian Information Criterion (BIC) was utilized (Schwarz, 1978). BIC is a criterion for model selection, and includes a penalty term for the number of parameters in the model. The BIC is given by the following equation:

$$BIC = -2 * \text{loglikelihood} + d * \log(N)$$

where N is the sample size of the training set and d is the total number of parameters. Thus, similar to the Generalized Akaike Information Criterion (GAIC) (Akaike, 1983), the BIC score gives an estimate of the goodness of fit of the model performance to the dataset. A lower BIC score indicates a better model fit. The BIC was used, since it penalizes complexity more than GAIC (Hastie et al., 2009).

2.4 *Distribution family*

A set of discrete distributions described by a maximum two parameters was chosen to avoid overfitting due to high number of parameters used in the model. The following probability distributions were fitted to the EIAD data:

- Negative Binomial distribution (NBI)
- Geometric distribution (GEO); a special case of the NBI
- Poisson distribution (POI)
- Zero-inflated Poisson model (ZIP); allows for frequent zero-valued observations
- Zero-adjusted Poisson model (ZAP); useful when count data with too few or too many zeroes are encountered

2.5 *Spatial distribution of EIAD data*

Geo-referenced EI attacks were imported into ArcGIS (ESRI, 2006) to produce a world map that visualizes and explores specific aspects of the data. Additionally, Kernel density estimation was used to calculate the density of features (e.g. points) in a neighborhood around those features, i.e. a smoothly curved surface is fitted over each point (Silverman, 1986). Lastly, spatial statistics were used to determine if energy infrastructure attacks were clustered or dispersed (randomly distribution) in space. The Average Nearest Neighbor Distance measures the distance between each point (EI attack) and its nearest neighbor's centroid location. All these nearest neighbor distances are then averaged, and if the average distance is less than the average for a hypothetical random distribution, the distribution is considered clustered (Ebdon, 1985). Moran's I calculates spatial autocorrelation (feature similarity), based not only on feature locations (EI attacks) or attribute values (e.g. decade, attack type, perpetrator group, etc.) alone, but on both feature locations and attribute values simultaneously. Given a set of features and an associated attribute, it evaluates whether the pattern expressed is clustered, dispersed, or random (Moran, 1948).

2.6 *Energy infrastructure attack hotspots*

Temporal peaks or hotspots were evaluated using data of individual countries that at least contributed 2.5% to the total of all (see chapter 2.3) to ensure that sufficient data was available. Three peak levels were defined, i.e. a high peak is a year with 200 or more attacks, a medium peak is between 100 and 199 attacks, and a low peak is between 50 and 99 attacks.

3 SELECTED RESULTS

3.1 *Overview and contents of EIAD*

In total, EIAD contains 9432 energy infrastructure attacks, covering the period 1980–2011.

Figure 1 shows the number of attacks per year (blue bars), the cumulated attacks over the observation period (red line), and averages per decade (black line). In the 1980s and 1990s the average number of attacks per year increased only slightly from 184 to 197, whereas in the 2000s it more than doubled (471). The two years available for the 2010s (526) indicate that a further increase could be expected if no drastic changes in the overall situation and/or boundary conditions will occur in the next few years. The apparent overall upward trend in EI attacks was also statistically confirmed by a non-parametric Man-Kendall test ($n = 32$, $Z = 3.84$, $p = 0.001$).

It is worthwhile to note that the year 1993 seems to be a substantial outlier to this trend with only 15 attacks; however it does not affect the prevailing pattern. This can be illustrated by replacing the 1993 value by the average of 1992 and 1994, which increases the decade average by a modest 8%, and which is reported above and shown in Figure 1. The very low 1993 value can be explained by the fact that the Global Terrorism Database (GTD) is one of the major primary information sources used for EIAD. The data for 1993 were unfortunately lost prior to the compilation of the GTD from various data collection efforts, and several attempts to recover the data did not succeed (GTD, 2012). However, cumulated country level statistics in the same GTD document suggest that GTD should contain almost 5000 incidents for 1993. Although a dedicated effort within the EIAD framework was carried out, it was not possible to obtain a better coverage of individual EI attacks for 1993, which is why EIAD currently has the same data gap for 1993 like GTD.

The vast majority of attacks was classified as successful (95.3%), distantly followed by failed (3.7%) and foiled (0.8%) attacks. The remaining 0.2% are plots, threats or unknown. A rather large amount of 43.7% was considered multiple attacks.

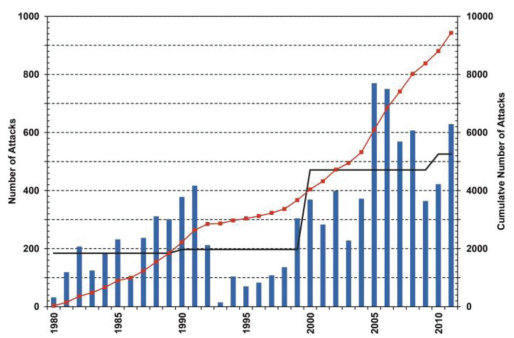

Figure 1. Annual number of EI attacks (blue bars), cumulated attacks (red line), and decadal averages (black line) over the period 1980–2011.

Bombings (82.3) are the dominant attack type, followed by several other attack types that cumulatively amount to 13.6%, of which assault, hostage taking/kidnapping, sabotage, hijacking, assassination and looting/theft were between 1% and 5%. The remaining categories were practically negligible with a share of 0.5%. Finally, 3.6% of all attacks could not be assigned to a specific category because of incomplete information in the available incident summary, and thus were classified as unknown.

The electricity and petroleum sectors account for 54.4% and 36.6%, respectively. The natural gas sector makes up only 7.4%, and all other sectors are almost negligible. A possible reason for this pattern could be that attacks predominantly target "linear" energy infrastructures (e.g. pipelines and transmission lines) that are difficult to protect, and also often pass through remote areas. In contrast, "point sources" such as power plants or refineries can be more easily controlled and secured.

3.2 *Frequency distributions of attacks*

Table 1 shows the BIC scores for the five probability distributions that were fitted to all attacks, and to those countries that have a share of at least 2.5% of all attacks. The Negative Binominal distribution (NBI) fits clearly better than the Poisson distribution, as indicated by the substantially lower BIC scores. The Geometric distribution (GEO), which is a special case of the NBI, performs practically the same. Similarly, the Zero-Inflated (ZIP) and Zero-Adjusted (ZAP) Poisson models are only marginally different from the POI. The NBI has the following advantages compared to the POI:

– The NBI has two parameters unlike the POI with one parameter, which allows adjustment of the variance independently of the mean value.

Table 1. BIC scores of the five probability distributions fitted to the entire EIAD dataset (1980–2011) and the eight countries in which at least 2.5% of all attacks occurred. # Att = number of attacks; see chapter 2.4 for abbreviations of distributions.

Country	# Att.	**NBI**	GEO	POI	ZIP	ZAP
All countries	9432	**418**	429	2584	2587	2587
Colombia	2490	**410**	421	2378	2382	2382
Iraq	1188	**350**	353	1501	1505	1505
Pakistan	1070	**344**	346	1353	1357	1357
El Salvador	840	**401**	400	3422	3425	3425
Peru	532	**316**	323	909	912	912
Nigeria	307	**350**	353	1501	1505	1505
Afghanistan	262	**418**	429	2584	2587	2587
India	240	**374**	375	2395	2399	2399
Chile	234	**414**	424	2481	2484	2484

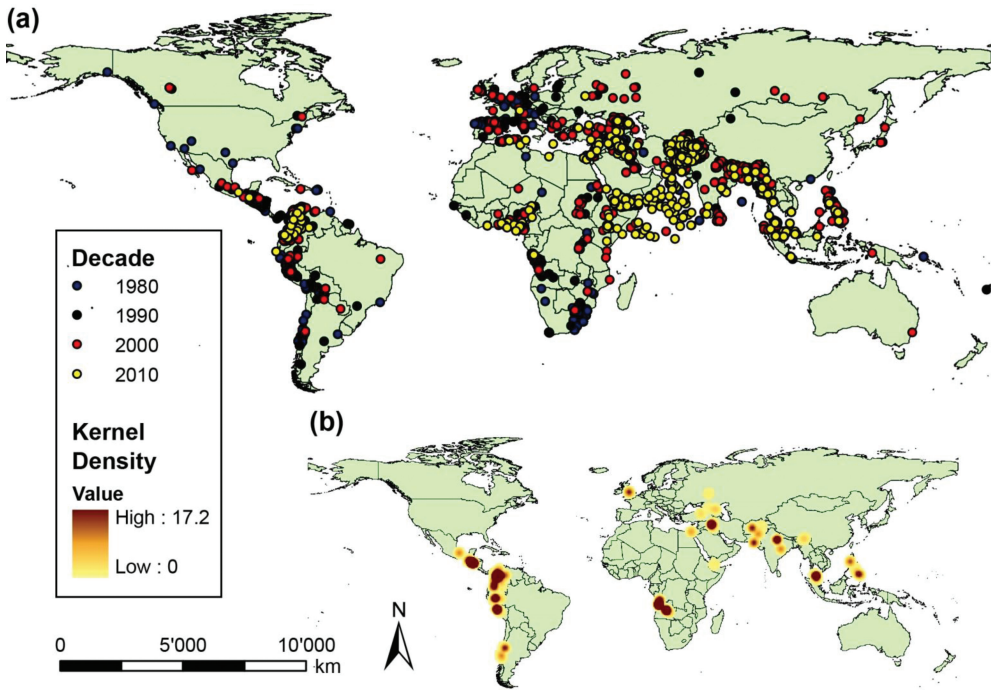

Figure 2. Spatial distribution of EI attacks in the period 1980–2011 (n = 8549). The upper panel (a) shows attacks by decade, and the lower panel (b) displays hotspots areas based on point Kernel density estimation.

Table 2. Results of average nearest neighbor and Moran's I.

	All	Petroleum	Electricity
Average Nearest Neighbor	Clustered Z = –158.72 p < 0.01	Clustered Z = –18.37 p < 0.01	Clustered Z = –50.78 p < 0.01
Morans's I (attribute: Decade)	Clustered I = 0.36 Z = 14.75 p < 0.01	Random I = 0.03 Z = 0.99 p > 0.1	Clustered I = 0.41 Z = 16.13 p < 0.01

– The NBI is especially useful for discrete data with a finite number of confounded positive values whose sample variance exceeds the sample mean.
– Therefore, values of the NBI are more dispersed compared to values of POI.

3.3 *Spatial distribution of EIAD data*

The spatial distribution of EI attacks by country for the years 1980–2011 is given in Figure 2. Only events that could be accurately geo-referenced were considered, which is why only 8549 out of all 9432 EI attacks were included.

The color coding scheme in Figure 2a distinguishes attacks by decades. Already a quick visual inspection suggests that data are clustered. A Kernel density estimation was used to produce a smoother distribution of values to better designate potential hotspot areas (Fig. 2b). Results of spatial statistics are summarized in Table 2. Average nearest neighbor analysis confirmed a clustered pattern for all EI attacks as well as for the dominant petroleum and electricity sectors. Spatial autocorrelation (Moran's I) with decade as the attribute value, indicated clustering for all EI attacks and electricity, whereas for petroleum a random pattern was found.

3.4 *Energy infrastructure attack hotspots*

Figure 3 shows attack patterns for individual countries that at least contributed 2.5% to the total number of attacks in the period 1980–2011. High peaks (≥200 attacks) were only found in the top three countries (Fig. 3a), and medium peaks (≥100) were also quite common. For countries ranked positions four to nine only few medium peaks occurred, but low peaks (50–99 attacks) were more common. In the following individual patterns for the top three countries are briefly described.

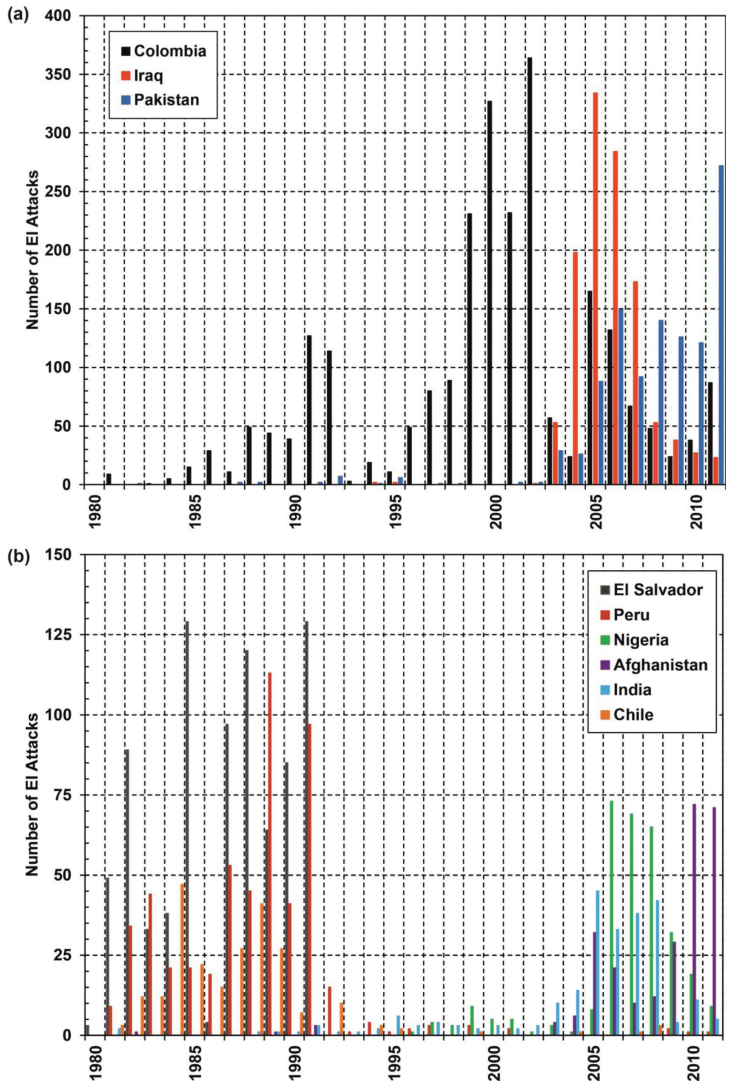

Figure 3. Annual numbers of EI attacks for (a) the top three countries, and (b) the countries ranked fourth to ninth (all contributing at least 2.5% to the total of EI attacks in the period 1980–2011).

For Colombia, three distinct peaks of EI attacks can be observed, i.e. 1991–1992 (medium peak), 1999–2002 (medium to high), and 2005–2007 (low-medium). It is worthwhile to note that annual attacks after the third peak generally remained at higher levels than before the first peak, indicating that the situation is still fragile. The first peak is predominantly attributable to the petroleum sector and attacks on the Cano Limon pipeline. The second peak phase was targeted towards transmission lines in the energy sector, and to a lesser extent this was also the case for the third peak. In Iraq, the medium-high peak from 2004–2007 was mostly due to attacks on oil pipelines. In Pakistan a shift from attacks on transmission lines (2004–2005) to natural gas pipelines (2006–2009), and most recently oil transport by road tanker (2010–2011) was observed.

4 CONCLUSIONS

Overall, EIAD provides a comprehensive foundation for the analysis of energy infrastructure

attacks by VNSAs. Framed within the risk analysis, it was found that while technological accidents in the energy sector are normally rare and independent events, EI attacks are often multiple events and concentrated both in time and space, resulting in distinct hotspots.

The current study evaluated the spatial and temporal clustering patterns of EI attacks in the context of affected energy sectors and infrastructure types. In this way differences between countries as well as temporal shifts within a specific country were identified, and thus the observed patterns could be conceptualized as a type of tactical contagion.

The majority of attacks targeted "linear" energy infrastructures (e.g. pipelines and transmission lines) which are difficult to protect and often pass through remote areas. Therefore, consequences in terms of fatalities and casualties were mostly minor, although when attacks occur frequently (in terms of multiple and connected events), they can result in substantial business and supply disruptions.

The analysis of EIAD data at a macro level has already led to interesting and useful insights and conclusions. However, detailed case studies at the community or micro-level as well as predictive modeling to forecast likely future hotspots could support adapting existing or developing new strategies and policies to contain or mitigate emerging conflict situations.

Solar storm impact on critical infrastructure

O. Sokolova

ABSTRACT: Natural hazards can trigger disasters resulting in large numbers of fatalities and billions of economic losses. In the last decades, critical infrastructures were developed in the way to ensure their stability against natural hazards. Consequently, long, divaricated, interconnected systems were constructed. Hence, such diversification increases systems vulnerability against solar storm. Hydro-Quebec blackout in 1989 was the tipping point for space weather research, shifting status from curiosity to necessity. Despite dedicated research, the widespread outages and economic losses resulting from the relatively strong Halloween blackout in 2003 could not be prevented. The analysis of solar storm impact on critical infrastructure consists of two main parts: the geoelectric field determination associated with geomagnetic storm variations; and the determination of the network vulnerability with known topology. The quantitative assessment of possible solar storm impact on the Scandinavian power system and comparison of geographical areas will be given in the paper.

1 INTRODUCTION

Solar storms are known to affect critical infrastructure, especially power systems by causing voltage blackouts and equipment outage. The first registered impact on galvanic systems is Carrington Event in 1859. The solar storm lasted for six days: 28th August—2nd September 1859, and interrupted normal telegraph operation on large geographical area (UK, France, USA, and Canada). Mr. Wood, superintendent of Canadian Telegraph lines, described the event as follows: so completely were the lines under the influence of aurora borealis, that it was found impossible to communicate between the telegraph stations, and the line was closed for the night. It is still the strongest ever registered solar storm. The event of such strength is called nowadays "Super solar storm".

An extensive research of solar storm phenomena concurred with space exploration era after the launch of first satellite in 1957. Even though the principle of solar storm coupling with Earth magnetic field is evident, the variety of heliophysics questions are in nowhere. The questions are following: what drives the solar wind and where does the coronal magnetic field originate from? how do solar transients drive heliospheric variability? how do solar eruptions produce energetic particle radiation that fills the heliosphere? and others.

Geomagnetically Induced Currents (GIC) which are studied in this paper are so-called echo of solar storm on Earth. The varying Earth's magnetic field associated with geoelectric field induces currents due to Faraday's law. In accordance to Ohm's law, currents lead to transmit over the system of conductors with the lowest resistivity. Power grid can be considered as the sample of such a system. The source of GIC in power grid is the grounding points of power system equipment. By entering the power grid, GIC are distributed over the transmission lines, which might cause equipment outage. A power grid performs like an antenna in the presence of GIC by amplifying the negative impact. The majority of power system equipment is no barriers for GIC distribution.

Not all solar storms affect the power grids. The National Oceanic and Atmospheric Administration (NOAA, USA), European Incoherent Scatter Scientific Association and other agencies provide storm forecasting products in an index-style severity classification. The most familiar one is the K-index, a logarithmic scale from 0 to 9 that classifies the severity of solar storms in a similar way to the Richter scale. All "super solar storms" correlate with K equal to 9. Nevertheless, weaker

solar activity may also interrupt normal power system operation.

The structure of this paper is as follows. First in Section 2, we describe the principles of GIC determination and the studied model. In Section 3, the impact of GIC on power system equipment and on the network as a whole is discussed. Finally in Sections 4 and 5, we discuss possible mitigation actions and do the comparison of power grid vulnerability in different geographical areas.

2 MODELLING TECHNIQUE

2.1 *Calculation scheme*

In general, the following set of factors determines solar storm impact on power systems (Marusek 2007):

- geomagnetic latitude;
- ground conductivity;
- power grid topology and characteristics;
- installed power equipment characteristics.

Scandinavian power grid is located in the northern geomagnetic latitude (aurora region), which makes it liable to space weather impact. In the past years, disturbances of normal power system operation as the result of solar storms were registered in Scandinavian grid. The most famous one is Halloween blackout in 2003. Also one of the highest ever determined GIC (200 A in power transformer neutral) was registered in Finish power grid a part of Scandinavian grid. Thereby, equivalent High Voltage (HV) Scandinavian power grid is studied.

Detailed power system characteristics are not available in the open source because of security reasons. The interconnected ENTSOE network model was used. The final model has a realistic number of nodes and lines and emulates the real processes. The total number of nodes is 150. The simplified calculation scheme is represented on Figure 1.

In (Viljanen et al. 1999) was shown that the reasonable understanding of GIC flow can be achieved

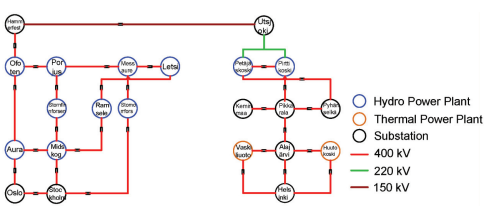

Figure 1. Simplified equivalent Scandinavian power grid model.

even with incomplete data. The final model is described by the following set of characteristics:

- Not all network elements are included.
- The nodes locations are given with varying accuracy up to 20 km.
- All transmission lines are assumed to be straight if no detailed information was found.
- All nodes are far enough from each other to prevent them from bearing each other (Pirjola 2008).

The resistivity of 400 kV lines is taken equal to 0.008 Ω per km (Viljanen et al. 2012). Thereafter the resistivity values of 220 and 110 kV lines were taken as 0.012 Ω per km and 0.016 Ω per km in accordance with the physical dependences between the voltage level and conductor resistivity.

The calculation model was represented as the direct current scheme because the GIC are considered to be the quasi Direct Currents (DC) since their frequency is much lower than the nominal operational frequency (50 or 60 Hz). In the same manner, transmission lines with installed series compensators were neglected, since they perform as barrier to GIC.

2.2 *Geomagnetically induced currents determination*

The analysis of geomagnetic storm impact on power systems consists of two parts:

- Location determination. The geoelectric field determination associated with geomagnetic disturbances.
- Technical arrangement. The GIC determination in the known conductor system due to the geoelectric field variation.

The determination of quantitative dependences between GIC and the electro physical characteristics of structural elements of the Earth's crust is one of the most important and complicated tasks of modern geophysics. The geophysical part does not depend on network configurations and parameters. The input data consists of knowledge concerning ground conductivity and geomagnetic variations at the Earths surface. The used geometrical model for geoelectrical field calculation is shown on Figure 2.

Reflected magnetic field B_x is directed in east-west direction since it is the preliminary direction for geomagnetic field distribution (Marusek 2007). Magnetic permeability is equal to the one in vacuum $4\pi 10^{-7}$ H per m. Ground conductivity is constant. Exact value was taken from the results of European Resistivity Ohm Model (EUROHOM) project. On the basis of Maxwell equations, the analytical dependence between the geolectirc field

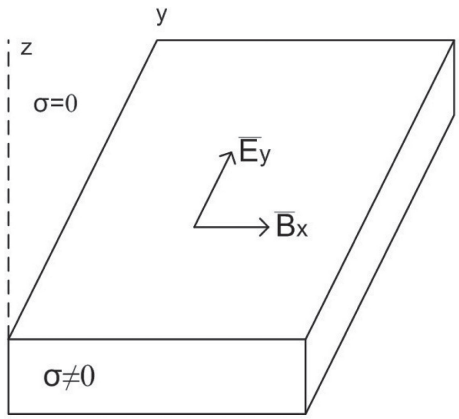

Figure 2. Geometrical model for geoelectric field calculation.

on Earths surface and measured geomagnetic field variation is following:

$$E_y = \frac{(1+j)B_x}{\mu_0 \sigma \delta_e}, \tag{1}$$

where μ_o = magnetic permeability in vacuum; σ = ground conductivity; and δ_e = penetration depth.

Geoelctic field variations are calculated for five geomagnetic severities (from minor to extreme) and six frequencies (10–5–1 Hz). The voltage difference over the branch is calculated by integrating the projected electric field across the path. Since all the HV equipment is grounded, the voltage node difference method is used for GIC determination.

$$GU = J, \tag{2}$$

where G = node conductivity matrix; U = voltage node vector; and J = current source vector.

Obtained results showed that GIC distribution significantly depends on grids topology and characteristics. This dependence is more expressed than the dependence on geomagnetic latitudes in the regions with constant ground conductivity e.g. Scandinavia. This allows us to postulate that mid latitude power systems may also experience negative solar storm impact if they were designed without considering space weather impact.

3 POWER SYSTEM OPERATION RISK ASSESSMENT

3.1 *Power transformer performance*

Power transformer is the key element of reliable power system operation. The power transformers differ from other types of power system equipment as their design, production and operation involve high cost and long time period. In terms of solar storm, the power transformer replacement period is longer than for any other types. Power transformers are designed for normal operation under sinusoidal Alternative Current (AC). The principle of transformers operation is based on the Faradays law, which states that the electromotive force is proportional to the rate of change of the magnetic flux. GIC as the DC component can cause power transformers saturation. Only few amperes and seconds can disrupt normal operation. For example, the interval between the time when electromagnetic impulse interrupted Earths magnetic field and Hydro Quebec blackout was only 92 seconds.

The features of power transformers saturation process depend on construction type. Two common power transformer types exist: shell and core type. Generally, transformers of both types can be constructed for any nominal power or voltage level and from any magnetic material. Nevertheless, the construction type does not influence the functional principle, electromagnetic processes or the ability to ensure required outputs. The set of following characteristics determines the transformers saturation capability: DC flux path, moment of GIC appearance and insulation characteristics.

3.1.1 *Direct current flux path*

Power transformers magnetic characteristics are determined by following parameters: steel type, mark-to space ratio, magnetic conductivity, coil dimensions, specific power losses at the nominal frequency and dependence between power losses and frequency. These parameters specify winding turn leakage inductance L_S, which in turn determines the length of DC flux path. Winding turn leakage inductance is described by equation (3).

$$L_S = \frac{\mu_0 c_t L_t w^2}{3h_t}, \tag{3}$$

where μ_o = magnetic permeability in vacuum; c_t = winding turn thickness; L_t = winding turn length; h_t = winding turn height; and w = winding number.

In other words, wider is the section for reversal magnetic power flow, higher is the transformers vulnerability. The relative comparison of transformers vulnerability is represented in Table 1.

In three-phase three-limb transformer, DC fluxes compensate each other in the main limbs and connecting yokes. Thereby, this transformer type has the highest resiliency. Test results showed that even in case of impact of GIC equal to 50 nominal magnetization current ($\approx 50A$), the transformer current

Table 1. Relative susceptibility of power transformers.

Transformer type	Relative susceptibility
Single phase	1.0
Three phase seven limb	0.67
Three phase five limb	0.33
Three phase three limb	0.05

will be increased less than two times. Single phase trans-former is the most prone type. The magnetic flux inducted by GIC is closed in the power transformers core on the way of the main magnetic flux (inducted by nominal sinusoidal current). The simulation showed that the impact of GIC equal to nominal magnetization current (1 A in studied case) significantly increases transformer current. The current was increased up to 76 A in condition of base-load current equal to 0.8 A. The comparison of magnetization currents for singlephase and three-phase three-limb power transformers is shown on Figure 3. Since power transformers have complex three-dimensional geometry and consist of linear and non-linear components, the assumption of phase symmetry was accepted for the detailed analysis (Mousavi et al. 2013).

Hence, the passport parameter, which determines power transformers susceptibility to saturation, is no-load current. Higher is the value, higher is the saturation risk under GIC impact.

3.1.2 *Moment of GIC appearance*

The second parameter specifying severity of GIC impact is the current phase at the moment of GIC appearance. The power system steady state is described by the following equation set (4) in case of sinusoidal AC. The sinusoidal phase voltages are:

$$\begin{aligned} e_a &= E_m cos(\omega_n t + \psi) \\ e_b &= E_m cos(\omega_n t + \psi - \rho) \\ e_c &= E_m cos(\omega_n t + \psi + \rho), \end{aligned} \tag{4}$$

where E_m = voltage level; ω_n = nominal grid frequency; ψ = initial phase; and ρ = phase angle.

By knowing the phase voltage, the phase current can be found. Due to phase symmetry, one phase model can be analyzed. Thereby, the steady state phase current is:

$$i_a = I_{nmo} cos(\omega_n t + \psi - \phi), \tag{5}$$

where I_{nmo} = current level in steady state; and ϕ = angle between voltage and current of the same phase.

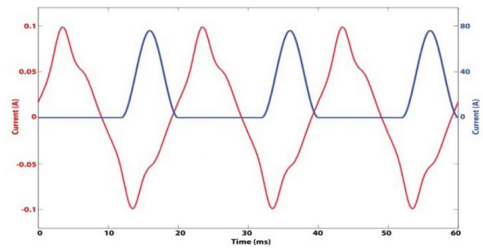

Figure 3. Magnetization current of single phase transformer with GIC equal to nominal magnetization current (red curve) and three-phase thee-limb power transformer with GIC equal to 50 nominal magnetization currents (blue curve).

The phase current under the GIC impact is the solution of following differential equation:

$$e_a = L\frac{di_a}{dt} + ri_a, \tag{6}$$

where L and R = power grid parameters.

Thereby, analyzed current is:

$$\begin{aligned} i_a &= i_{ap} + i_{au} \\ &= I_{nm} cos(\omega_n t + \psi - \phi) - Ae^{\frac{-t}{T_a}}, \end{aligned} \tag{7}$$

where i_{ap} = forced component; $i_a u$ = free component; A = integration constant; and T_a = time constant.

Integration constant can be found as:

$$A = I_{ao} - I_{nm} cos(\psi - \phi), \tag{8}$$

Thereby, criteria for maximum GIC impact are:

1. $\psi = \pi/2$
2. $\omega_n t = \pi$. This corresponds to a moment equal to 0.01 s. in case of power system frequency of 50 Hz.
3. $i_{ao} = 0$ i.e. pre-fault conditions correspond to no-load mode.

3.1.3 *Insulation characteristics*

Inspections of the failed power transformers revealed heat failure, mostly because of paper insulation degradation. GIC can cause immediate or delayed power transformer outage. In the second case, power transformer outage is the result of several solar storms impacts. The diagnostics mechanism with the means of Duval triangle is described in (Gaunt, Charles Trevor 2014).

3.2 *Direct current substations*

Direct current transmissions have several advantages contrary to AC systems. Firstly, the maximum

transmitted power is limited only by equipment characteristics and not limited by voltage stability angle. Secondly, the decomposition of power grid with DC nodes allows reducing the short-circuit injection current. Thirdly, DC transmissions are characterized by higher than AC transmissions controllability. In terms of transmission construction and design, DC transmissions of the length less than 500–700 km are cheaper. The combined factors make the idea of wide DC transmissions usage attractive. Nevertheless, in terms of GIC, DC transmissions have no benefits over AC systems.

The operation principle of DC systems is based on 2–3 rule, meaning that the valves of two phases are burning in normal state and valves of three phases are burning in transient state. This brings the asymmetry to the power system state which leads to decrease its robustness against solar storm.

3.3 *Voltage collapse*

Power transformers under half-cycle saturation pose threat to power system stability. Power transformers saturation intends cores magnetic permeability to lead to the one in vacuum $4\pi 10^{-7}$ H per m. This causes the growth of reactive power consumption as the result of reactance drop and magnetization current growth. Common cause of voltage avalanches is the reactive power deficit especially for networks constructed from long HV transmission lines. The voltage avalanche risk is higher during space weather events, since the power systems are rarely designed for operation under these circumstances.

The disturbance conditions for the network have to be summarized as a whole. The N power system states have to be analyzed. Under saturation, power transformers reactive power consumption Q is described by the equation (9).

$$Q = U(I_{exc} + KI_{GIC}), \tag{9}$$

where U = voltage level; I_{exc} = excitation current; K= empirical coefficient. Experiment results showed out that K is equal to 2.8 for single phase power transformers and 0.4 for three-phase three-limb power transformers.

The system impact depends not only on the power transformer type but also on the exposed node location. The transmission grid can be represented as the generation-transmission-distribution chain (Fig. 4).

Two cases were studied: saturation of step-up power transformer (Fig. 5) and saturation of grid transformer (Fig. 6). In both of the cases, impact of saturated single phase power transformer was analyzed.

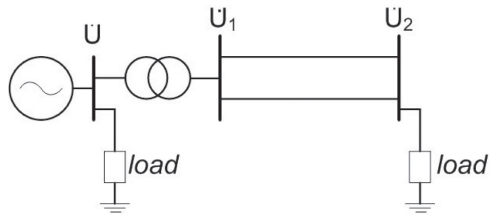

Figure 4. Generation—transmission—distribution chain.

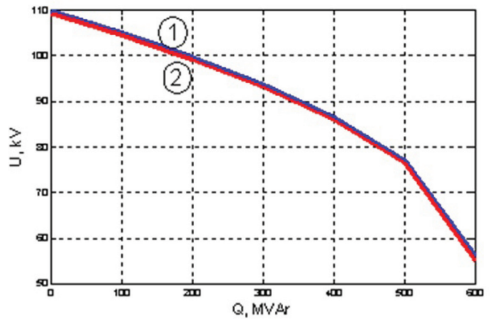

Figure 5. Voltage level as a function of reactive power deficit in case of step-up transformer saturation: 1—voltage at the beginning of transmission line U_1; 2—load voltage U_2.

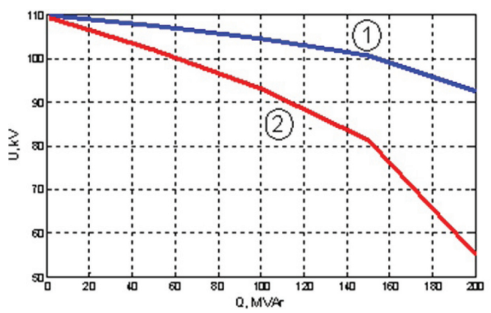

Figure 6. Voltage level as a function of reactive power deficit in case of grid transformer saturation: 1—voltage at the beginning of transmission line U_1; 2—load voltage U_2.

The comparison showed out that grids transformer saturation weakens the grid mode more. The reason of the higher resilience of step-up power transformer is the support of generator excitation system.

Another threat exposed by power transformers saturation is harmonics spectrum change. Thereby, the total reactive power consumption Q_Σ has to be calculated (10).

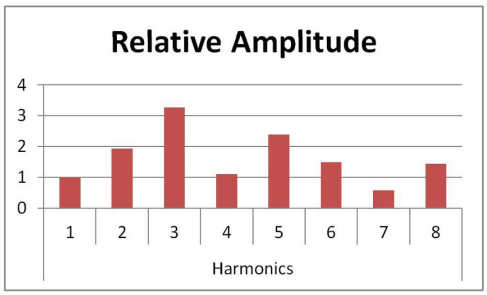

Figure 7. High harmonics spectrum under GIC impact.

$$Q_{\Sigma} = U\left(\sum_{i=1}^{n} I_i^2\right)^{\frac{1}{2}}, \tag{10}$$

where I_i = current level of i-harmonic.

For harmonics spectrum determination, data from measurement instruments installed on 330 kV substation Louhi, Russia (Efimov and Selivanov 2013) is used. The Fourier analysis turned out that high harmonics significantly exceed admissible values (Fig. 7).

The Standard EN50160 puts the limits on maximum harmonics amplitude. For example, the third harmonic has to be not bigger than 5% of the main one. As it is seen on Figure 7, under GIC impact third harmonic is about 3 times bigger than the main one. Such distribution makes challenging the relay protection system operation. Thereby, emergency control system for power system stability ensuring designed for operation under normal harmonic spectrum is ineffective. The power system response time is too short for implementing any meaningful actions. This poses one more threat to reliable and quality power energy supply.

4 MITIGATION ACTIONS

The mitigation actions can be implemented both on network element and system level. On network element level, following actions are possible:

- power transformer change by more resilient types;
- implementation of power transformers with special compensation windings;
- implementation of power transformer with clearance gap in the core;

The lengthwise compensated transmission lines prevent GIC distribution in power grid. The grid redesign with implementation of lengthwise compensated transmission lines was performed in Hydro Quebec system after the blackout in 1989. The project was finalized in 1996. Despite of high effectivenesss in terms of GIC, this mitigation action has to be implemented only after detailed analysis of N normal power system states and N' emergency states. The mitigation actions against GIC impact cannot weaker ordinary power system operation. The same aspect has to be considered while relay protection algorithms change. Technological mitigation measures need to be combined with organizational ones. Operational manuals need to be revised and corrected. Possible list of operational actions is following:

- Decreasing power flows over the transmission lines both AC and DC;
- Switching on neutral blocking devices;
- Switching on series compensators;
- Switching off shunt reactors;
- Switching off vulnerable power transformers;

5 VULNERABILITY COMPARISON

5.1 *Scandinavian power grid*

In 2008, Swedish transmission system operator, Svenska Kraftnat, accepted the project for gradually change of HV power transformers to three-phase three-limb type (Kraftnat 2008). As it is shown in Table 1, this is the most resilient to GIC power transformer type. Currently, 60% of power transformers fulfill the requirements, the rest are either single-phase or three-phase five limb power transformers. The distribution principle is following: single phase transformers are normally used as step-up ones; three-phase five-limb as grid installations. Even though, the impact on grid stability is bigger from saturation of grid transformer, their robustness to GIC is higher, because they are normally three phase five limb or three phase three limb types. The most likely scenario for Scandinavian grid is the voltage avalanche without power equipment loss. Voltage avalanche might happen in case of solar storm impact with severity higher than following: $K = 8$ and $f = 10^{-3}$.

5.2 *US power grid*

The full-scale analysis of installed power transformers is done in (Kappenmann 2010). US power grid is characterized with the presence of the higher voltage levels than in Scandinavian grid. The network consists of three voltage classes: 765 kV, 500 kV and 345 kV. The most common one is 345 kV, which makes up 64% of the transmission network. Nevertheless, the wider usage of single phase equipment is presented in US power grid, because of ultra high voltage networks (Fig. 8).

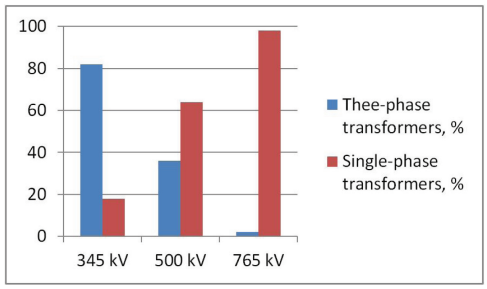

Figure 8. Demographic estimates of power transformers as a function of voltage level (kV rating).

The accumulated power transformer outage in Carrington like event (magnetic field variation equal to 4800 nT) is 368 units (Kappenmann 2010). In other words, 20% of 345 kV, 28,4% of 500 kV and 31,8% of 765 kV power transformers might be damaged.

6 CONCLUSIONS

Solar storms can develop simultaneously over large areas, potentially causing cascade outage of critical infrastructure systems. Power system reliable and high quality operation as the key element of critical infrastructure is of highest importance. Historical examples showed that power system operation algorithms have to include actions not only from known threats ("N-1" principle), but also from solar storm impact in the form of GIC. By entering power system, GIC might cause:

- Voltage avalanche due to reactive power deficit and relay protection system missoperation with equipment outage.
- Voltage avalanche due to reactive power deficit and relay protection system missoperation without equipment outage.
- Power equipment outage without widespread voltage blackout.

Impact on power transformers as the principle elements of power system were analyzed in this paper. The analysis showed that the impact level depends on DC flux path, moment of GIC appearance and equipment isolation. Power transformers vulnerability depends, primarily, on the size of core's section admissible for reversal magnetic flow. The most vulnerable type is the set of single phase transformers. Contrary, the most resilient ones are three-phase three-limb power transformers, in which DC fluxes compensate each other in the main limbs and connecting yokes. The analysis was done on equivalent scheme of Scandinavian power system. The results were compared with the solar storm impact on US power grid. The main conclusion is following: solar storm impact severity is determined mainly by power system technological parameters. For instance, power grid of US might experience higher impact than Scandinavian grid even though it is located in more southern geomagnetic latitude.

Accident risk assessment for deep geothermal energy systems

M. Spada, E. Sutra, S. Wolf & P. Burgherr
Laboratory for Energy Systems Analysis, Paul Scherrer Institute, Villigen PSI, Switzerland

ABSTRACT: Deep geothermal energy systems are, like all energy technologies, not fully risk free. The primary risk identified in the domain of deep geothermal is induced seismicity. However, a comprehensive risk assessment needs to take into account additional aspects such as potential borehole blowout. In this study the different technological risks associated with deep geothermal energy systems are identified, characterized and quantitatively analyzed. First, a literature review is performed to compile a set of risk indicators that has either the potential to affect human health or impact the environment. In a second step, damage rates are calculated for different consequence types (e.g., fatalities, injured persons) for accident risks related to blowouts in the drilling phase and the use of hazardous substances in both drilling and operational phases. Finally, a comparison between identified risks is carried out showing that one of the main sources of accident risk is related to blowout.

1 INTRODUCTION

Geothermal energy is an abundant, clean (low greenhouse gas emissions) and reliable natural resource. The main part of the heat (~80–85%) is generated by the natural decay over millions of years of radiogenic elements from the continental crust and the earth's mantle, such as uranium, thorium and potassium (e.g., Tester et al., 2006).

Geothermal resources nowadays are mainly utilized for electricity generation, although direct-use applications are also significant. Globally, geothermal energy use is projected to more than double over the outlook period to 2035 according to the IEA's New Policies Scenario (e.g., IEA, 2012).

Until recently, geothermal energy was considered to have significant economic potential only in areas with hydrothermal systems, such as active volcanoes (e.g., WEC, 2013). However, in the last few years, new technologies, such as Enhanced Geothermal Systems (EGS) (e.g., Tester et al., 2006), have permitted to use geothermal resources in deeper geological layers and at lower temperatures.

Deep geothermal systems can be subdivided in two main families, hydrothermal and petrothermal systems, (e.g., Goldstein et al., 2011). The former is similar to the common geothermal system, where the warm water in the underground is used to produce electricity and/or heat. In petrothermal systems, on the other hand, the reservoir is created by hydraulic stimulation and the water is pumped in the underground and afterwards circulates in a closed circle. Therefore, considering the latter, all countries have theoretically a clean and abundant energy source in the underground, which could be used for district heating as well as electricity generation (e.g., Breede et al., 2013).

In this context, stakeholder interest has increased for deep geothermal energy systems. However, the exploitation of underground energy resources is, like all energy technologies, not risk free. Studies on deep geothermal risks often primarily focus on induced seismicity, since it has been shown to be one of the biggest issues for deep geothermal energy (e.g., Tester et al., 2006). Furthermore, few studies addressed other possible issues, such as groundwater contamination (e.g., Aksoy et al., 2009), or including an overview of possible associated hazards (e.g., Tester et al., 2006). Therefore, a comprehensive risk assessment is needed in order to take into account additional aspects with respect to induced seismicity, such as borehole blowout and use of hazardous substances, among others. Furthermore, it is important to consider both the drilling and operational phases of a deep geothermal system in order to analyze the two main phases separately.

In this study, different technological risks, with focus on human health effects and environmental impacts, associated with deep geothermal energy systems are identified, characterized and, possibly, quantitatively analyzed. In order to assess the accident risk for deep geothermal systems the current study is divided into two main parts. At first, a summary of possible sources of accident risks is provided. Afterwards, risk indicators relevant for deep geothermal systems with regard to accidents causing damage to human health and the environment are defined for two of the major sources of possible consequences, which are blowouts in the

drilling phase and the use of hazardous substances in both drilling and operational phases. Finally, the risk indicators are quantified and compared for the aforementioned sources of risk.

2 OVERVIEW OF THE POTENTIAL RISKS OF DEEP GEOTHERMAL SYSTEMS

In order to assess the accident risks in deep geothermal systems, a comprehensive literature research is carried out. Different types of potential risks are identified and described for both drilling and operational phases. These are related, for example, to the use of hazardous substances, although most of them in relatively small quantity. In the following, an overview of the different risks is given.

2.1 *Kicks*

A kick is a well control problem in which the pressure found within the drilled rock is higher than the mud hydrostatic pressure acting on the borehole or rock face. When this occurs, the greater formation pressure has a tendency to force formation fluids into the wellbore. This forced fluid flow is called a kick. If the flow is successfully controlled, the kick is considered killed. An uncontrolled kick that increases in severity may result in what is known as a "blowout."

Kicks can be labeled in different ways depending on the material entering the borehole (oil, sand, carbon dioxide, etc.). The accident that happened in 2013 at the deep geothermal site in St. Gallen (Switzerland) is an example of gas kick (Sonderegger, 2014). Furthermore, the kick can be dangerous if it is caused by flammable natural gas or poisonous hydrogen sulphide gas.

Three main parameters play a role in a kick development. Two are related to the type of rocks in which drilling is performed: permeability and porosity. The third parameter is the difference between the formation fluid pressure and the mud hydrostatic pressure. If the formation pressure is much greater than the hydrostatic pressure, a large negative differential pressure exists.

2.2 *Blowouts*

Geothermal drilling relies on the same kind of technology used in the oil and natural gas industry, modified for high temperature applications and larger well diameters (e.g., Finger and Blankenship, 2010). Deep geothermal systems and oil/natural gas also differ in temperature (higher in deep geothermal systems), production pressure (lower in deep geothermal systems), and production rates (higher for deep geothermal systems) on the drilling phase (e.g., Tester et al., 2006).

Therefore, we assume that the blowout risk in the drilling phase for deep geothermal systems can be roughly approximated from the corresponding risks in the natural gas and oil chains.

2.3 *Drilling mud*

In geothermal systems in general, during the drilling phase, the used mud is a composition of water and some additives, such as barite. The additives are added to the fresh water in order to increase the viscosity, the weight and to control the pH, and must be adapted to the geology of the site.

The addition of active solids, clays (bentonite) and polymers to water allows producing a colloidal suspension and are known as viscosifiers. Inert solids are those added to the mud either by drilling (formation particles) or by using barite as a weighting material without significantly affecting the global viscosity (e.g., Chemwotei, 2011).

The alkalinity of the fluid is also essential for corrosion control, rheological properties in bentonite mud, and for its reaction with some formation constituents. Water-based drilling mud (Spud Mud) commonly consists of bentonite clay (gel) accounting for around 10% of the mixture, with additives such as barium sulphate (barite), calcium carbonate (chalk) or hematite (e.g., HSL, 2000). In some cases (Natural Bentonite Mud), caustic soda (ca. 1% of the mud mass) is added to water and bentonite (ca. 9% of the mud mass) to stabilize the pH. The pH usually ranges between 9.5 and 10.5, but higher values are not uncommon (e.g., Finger and Blankenship, 2010).

In general most of the chemical additives are not dangerous for the environment and human health. However, for example, the caustic soda is an extremely corrosive substance for metals, even more for the humans and could cause fatalities primarily in case of ingestion (e.g., ATSDR, 2002).

2.4 *Hydraulic stimulation*

To improve the well productivity, the main stimulation technique generally used in Enhanced Geothermal Systems (EGS) activities is the "hydraulic stimulation" largely associated with the "chemical stimulation" (Aqui and Zarrouk, 2011). Developed and mainly employed in the oil/gas industry, recent studies highlight the use of chemical substances in numerous deep geothermal systems stimulation (Clark et al., 2013). Even if the use of gel and proppant in geothermal wells is not expected, their usage are reported from different sites, e.g., Fjallbacka (Sweden) (e.g., INL, 2006).

In general, during chemical stimulations, the process of acidification implies solutions of HCl, HF, KCl, or NH4Cl, with concentrations around

0.1% to 15%, injected in three main steps (Clark et al., 2013). These acid treatments seem also to be also supplemented with some additives as corrosion inhibitor and inhibitor intensifier, as well as chelating agents in order to minimize iron precipitation (Schulte et al., 2010).

2.5 *Working fluids used in the power plants*

The binary cycle power plant type appears as the more efficient system for deep geothermal energy (e.g., Gerber and Maréchal, 2012). In the binary process, geothermal water is used to heat another liquid, such as benzene, which boils at a lower temperature than water. The two liquids are kept completely separate through the use of a heat exchanger, which transfers the heat energy from the geothermal water to a secondary fluid (also known as the "working fluid"). The secondary fluid vaporizes into gaseous vapor and the force of the expanding vapor turns the turbines that power the generators. Finally, the fluid is air cooled or condensed with water. In the meantime, the geothermal fluid is re-injected into the borehole (e.g., Goldstein et al., 2011).

Within this system, two power plant types exist: a) Kalina cycle, and b) Organic Rankine Cycles (ORC). These types of power plants are commonly used in low-temperature environments (≤ 120ºC).

In the Kalina cycle, the working fluid is a composition of water and ammonia (NH3). Although in wide use (e.g., as a fertilizer), ammonia is toxic and corrosive for humans and in general dangerous for the environment (e.g., Roy et al., 2011). In the ORC cycle, the most common organic fluids used are n-pentane, iso-butane, iso-pentane, benzene, toluene, n-butane and R134a. Most of these fluids are highly inflammable, toxic and dangerous for the environment as well as for human health.

In this context, the transportation of these substances and their use in the power plant pose the main accident risk.

2.6 *Dry and wet cooling systems*

In a geothermal power plant cooling is necessary to condense the vapor feeding the turbine, lower the heat rejection temperature, raise power output and increase heat to power conversion efficiency (e.g., Mendrinos et al., 2006). The process of cooling can be assessed using air (dry cooling) or water (wet cooling). The dry cooling is the most adopted option in geothermal energy systems, ca. 80% (e.g., Mishra et al., 2011). In a binary cycle power plant the cooling of the working fluid is achieved by using a second heat exchanger (e.g., Kutscher and Costenaro, 2002). Thus, the fluids never make contact with the atmosphere (air-cooling) or the water (dry-cooling). However, for example, a failure of the pipe that transports the working fluid into the second heat exchanger could produce a contact between the water/air and the former. As a consequence, based on the working fluids commonly used (see section 2.5), the environment and the human health could be severely affected.

2.7 *Geofluids*

In both drilling and operational phases a potential risk is connected to the chemical composition of the geofluids (or brine). The brine, a highly saline solution mixed with various chemicals and gases, could cause operational limitations due to their severe scaling and corrosion effects that can occur in wells, lines and equipment.

If not handled responsibly, geofluids are a potential source of water and soil contamination due to presence of toxic minerals, such as arsenic, barium, antimony, and elevated dissolved solid elements, such as sodium chloride, bicarbonate, sulphate, silica, calcium and potassium (e.g., Clark et al., 2011). Arsenic is highly toxic for the environment and human health; thus it could be seriously dangerous in case of geofluids release (e.g., due to pipeline leakage), into the environment.

Among all these elements (e.g., Parmaksiz, 2013), radionuclides also appear to occur commonly in geothermal fluids samples (e.g., 238U, 232Th, 40 K and 226Ra). The accumulation of radionuclides in the inner parts of the drilling equipment, in pipes, valves, tanks, or in cooling systems, can represent, at first, a risk for the workers at a deep geothermal system site. However, studies carried out in USA (e.g., EPA, 2013) and Germany (Köhler and Degering, 2010) show that the total expected quantity of radioactive material at geothermal power plants is not harmful for human health, unless water samples are used as drinking water. Actually, the radioactive exposure level is expected to satisfy the limit of 1 mSv/yr valid for the population (e.g., Köhler and Degering, 2010), while the limit for workers is higher, 20 mSv/yr, with which the results of these studies seem to comply.

2.8 *Induced landslides*

In the past, landslides have occurred at not deep geothermal systems, but the cause is often unclear (e.g., Tester et al., 2006). Many geothermal fields are in rugged terrain that is prone to natural landslides, and some fields actually have been developed atop ancient landslides.

The worst disaster attributable to induced landslide, due to the presence of a geothermal field, is still under debate (e.g., DiPippo, 2012). The accident happened at the Zunil geothermal field

(Guatemala) in 1991, where at least 23 people were killed.

2.9 *Induced seismicity*

Induced seismicity is currently the most discussed risk aspect of deep geothermal systems. Drilling through and pumping fluids under high-pressure into an underground formation layer under shear stress conditions can potentially induce seismicity by releasing the stress (e.g., DiPippo, 2012).

In case of deep geothermal systems, seismicity could be induced in two ways. During the hydraulic fracking step, fluids at higher pressure than in the operational phase are injected into the underground to expand existing fractures in the formation. This high pressure could increase the stress in the formation and create induced seismic events. The second possible cause of induced seismicity is related to the reinjection of the geofluids (see section 2.7), which requires high pressure (e.g., DiPippo, 2012).

In the short history of deep geothermal systems, induced seismicity affected the decision to continue or stop a project in several instances. For example in Basel (Switzerland), a petrothermal project was aborted due to an induced seismic event with a magnitude of 3.3 (e.g., Bachmann et al., 2011). Finally, at the ongoing test plant in Soultz (France) a maximum magnitude of 2.9 was registered without consequences for the project (e.g., Genter et al., 2010). Therefore, no clear magnitude limit can be identified, at which a project should be stopped. Furthermore, preventive measures and mitigation plans to reduce the impacts of induced seismicity have been proposed and developed (e.g., DiPippo, 2012).

3 DATA

In this study, historical accidents related to the use of hazardous substances and to blowouts, causing at least one consequence (e.g., 1 fatality, 1 injury, etc.), are collected for the time period 1990–2012 for countries belonging to the OECD (Organization for Economic Co-operation and Development). The latter choice is done in order to assess the accident risk based on data from countries with similar management, regulatory and safety frameworks. Furthermore, the time period is chosen since deep geothermal energy is a new technology. We believe that 1990 as starting year better reflects the historical information relevant for our purpose, since starting from more recent years, for example in 2000, would result in a weaker statistical basis. In this study, different industrial accidents databases are surveyed to find information about accidents related to both the use of hazardous substances and blowouts. Finally, the collected data are homogenized prior to analysis, in order to avoid possible double counts. The examined databases are the following: The Emergency Response Notification System (ERNS) is a database of incidents reported to the National Response Center (NRC) of the USA.

- The Major Hazard Incident Data Service (MHIDAS) developed on behalf of the Major Hazards Assessment Unit of United Kingdom Health and Safety Executive.
- The Analysis, Research and Information on Accidents (ARIA) database is operated by the French Ministry of Ecology and Sustainable Development.
- The UK Health and Safety Executive (HSE) Information Services create HSELINE. Since 1977, HSELINE collects references to documents relevant to health and safety at work.
- The MHAID (Major Hazards Accidents and Incidents) database contains information on worldwide accidents or incidents involving hazardous materials.
- The Failure and Accidents Technical information System (FACTS) is an accident database, which contains information on more than 25200 (industrial) accidents (incidents) involving hazardous materials or dangerous goods that have happened all over the world during the past 90 years.

In addition to the aforementioned, two extra databases are considered to collect data on the risk of blowout accidents:

- PSI's ENergy-related Severe Accidents Database (ENSAD), comprehensively covers energy related severe accidents worldwide (e.g., Burgherr et al., 2013).
- Alberta Oil Spill open data compiled by the Alberta Energy Resources Conservation Board (ERCB).

3.1 *Hazardous substances*

In the drilling phase, the mud is based mainly on water with low percentage of chemical additives. Among the additives considered as "environment and human friendly", acids, such as caustic soda, could be used in order to preserve the pH. Caustic soda is a highly caustic metallic base and alkali salt and is extremely corrosive for humans (as well as metals). Therefore, the risk related to the use of caustic soda as additive in the drilling phase is assessed in this study. Furthermore, in order to assess the risk, only accidents that can be associated to deep geothermal procedures are collected. These are the accidents happened in storage, transportation sectors and in the well drilling phase (Table 1).

In the operational phase, we consider the ORC binary cycle only since it is commonly more suitable than Kalina binary cycle due to the high complexity of the latter (e.g., Köhler and Saadat, 2003). The most common substances used in ORC cycle are n-pentane, isobutane, isopentane, benzene, toluene, n-butane and R134a. These chemicals are highly toxic and inflammable, meaning dangerous for human health and the environment. Among all the substances listed above, the risk related to the use of benzene and toluene is taken into account in this study due to the lack of accident data for the other aforementioned chemicals. Considering only events associated to deep geothermal procedures, for benzene and toluene only accidents related to the storage, the transportation and such that can be associated to ORC binary cycle systems (e.g., pump failure) are collected (Table 1).

3.2 *Blowouts*

Blowout accidents for deep geothermal systems are not present in the examined databases due to the novelty of this technology. Therefore, in order to assess the risk for blowout accidents, onshore data from oil and gas industries are collected. In fact, although, the deep geothermal and oil/natural gas differ in temperature (higher in deep geothermal), production pressure (lower in deep geothermal), and production rates (higher for deep geothermal) in the drilling phase (e.g., Tester et al., 2006), the risk of onshore blowout as estimated for oil/natural gas can be generally considered a sufficiently accurate starting point. Furthermore, only accidents that happened in onshore well areas are considered, since wells for deep geothermal systems are drilled onshore only.

Due to limited historical data on onshore blowout accidents, this study analyzed two specific regions, the province of Alberta (Canada) and the entire onshore USA. The data collected for these two countries are shown in Table 2.

Table 1. Summary of accidents related to the use of hazardous substances with at least 1 consequence (e.g., 1 fatality) in the time range 1990–2012 for OECD countries.

Hazardous substance	Immediate fatalities	Immediate injuries	Evacuees
	Acc/Fat	Acc/Inj	Acc/Eva
Caustic soda	17/39	177/1386	38/15263
Benzene	14/45	54/1273	91/96513
Toluene	31/37	110/1291	61/7826

Table 2. Summary of blowout accidents with at least 1 consequence (e.g., 1 fatality) in the time range 1990–2012 happened in USA and Alberta (Canada).

Country	Industry	Fatalities	Injuries	Evacuees
		Acc/Fat	Acc/Inj	Acc/Eva
USA	Natural gas	4/4	8/16	21/3819
	Oil	1/1	5/8	3/3041
Alberta	Natural gas	9/9	22/33	4/7
	Oil	0/0	35/44	11/50

4 METHOD

4.1 *Overview*

Risk can be decomposed into the product of the frequency and severity (e.g., Haimes, 2009). The number of accidents per year gives the frequency, while severity measures the extent of the consequences of each accident. The frequency distribution is influenced by temporal trends, while the severity distribution is influenced by a number of parameters such as the material involved in the accident or the different products and the amount of material present, or the number of people in the vicinity of an accident. To assess the risk, the standard method of aggregated indicators is applied (e.g., Burgherr et al., 2013). The latter provides a direct comparison of accident consequences (e.g., fatalities) per unit of electricity produced (e.g., GWeyr) between, for example, hazardous substances.

4.2 *Normalization*

In order to derive a comparable measure of accident risk for both the use of hazardous substances and blowouts, the indicators are normalized by the energy production in terms of GWeyr. The Gigawatt-electric-year (GWeyr) is chosen because large individual plants have capacities in the neighborhood of 1 GW of electrical output (GWe). This makes the GWeyr a natural unit to use when presenting normalized indicators generated within technology assessment (e.g., Burgherr et al., 2013).

4.2.1 *Hazardous substances*

In order to assess the normalization factor in GWeyr for each hazardous substance analyzed in this study, the share of the total production of them used in deep geothermal energy systems has to be estimated. In order to do this, the OECD total production for each substance in the time period 1990–2012 is collected (Table 3). Afterwards, a base case 7MW power plant with a capacity factor of 95% and a lifetime of 30 years is considered, which

Table 3. Normalization Factor (NF) for risk indicators in the use of hazardous substances. NF is calculated as the ratio between the total amount of substance used at the power plan and the product of the OECD's total production in the time period 1990–2012 of the substance and the power plant total production in GWeyr over its entire lifetime (30 years).

Hazardous substance	OECD's total production (kg)	Total used over power plant lifetime (kg)	Normalization factor
			GWeyr
Caustic soda	1.03E+12	3E+4	6.78E+06
Benzene	3.74E+11	7.486E+3	9.89E+06
Toluene	2.24E+11	7.417E+3	5.99E+06

results in a total production of 1.98E-1 GWeyr for its entire lifetime.

The use of caustic soda as additive in drilling mud is not constant over the entire drilling phase. Caustic soda is added for short time mainly to stabilize the pH in the underground between 9.5 and 10.5 (e.g., Tester et al., 2006). However, due to the lack of information on the effective quantity of caustic soda handled per well drilled, as a first approximation the use of this substance is considered constant for the entire drilling phase. According to (e.g., Kaiser and Fäs, 2004), 1 kg of caustic soda is used for 1 meter of drilling. Therefore, in this study, where 6 wells of 5000 m are considered to be drilled in the 30 years lifetime for the 7MW power plant, the total amount of caustic soda used in the geothermal drilling phase would be 30000 kg (Table 3).

On the other hand, the use of working fluids is based on the sum of the initial input, that is fixed to 436 kg and 432 kg for benzene and toluene, respectively, and the quantity of substance that has to be used in order to fill up the initial value due to a loss per year set to 8% (e.g., Rogge, 2004).

Finally, by considering the aforementioned data and that the 7 MW power plant is modeled with 5.05 units, the Normalization Factor (NF) in terms of GWeyr, see Table 3, for each hazardous substance over the entire lifetime (30 years) is then estimated as following:

NF = (GWeyr*total kg production (1990–2012))
/kg used over the power plant lifetime

where, GWeyr = 1.98E-1.

4.2.2 *Blowouts*

To assess the blowout risk for geothermal energy systems, accidents from onshore blowouts in oil and natural gas industries in USA and Alberta (Canada) are merged in order to avoid possible issues related to the lack of data. This operation is valid on a first approximation since oil and natural gas extractions are similar in engineering, e.g., use of the same drilling equipment, and physical, e.g., similar pressures involved, terms (e.g., UNEP and E&PForum, 1997).

Table 4. Normalization factor for risk indicators in the onshore blowout case.

Country	Industry	Onshore production
		GWeyr
USA	Natural gas	5480
	Oil	18435
Alberta	Natural gas	1493
	Oil	686

In order to merge the natural gas and oil datasets the accident's frequency for blowout has to be comparable. Therefore, the risk indicators for each industry are normalized by the amount of total production in the time period 1990–2012 in GWeyr. The total amount of oil and natural gas onshore production are collected from the U.S. Energy Information Administration (e.g., EIA, 2014) and from the Canadian Association of Petroleum Producers (e.g., CAPP, 2014) for USA and Alberta, respectively (Table 4).

5 RESULTS

In this section, the risk assessment results for three hazardous materials possibly used in deep geothermal systems and onshore blowouts are presented. The substances are caustic soda used as additive in the drilling phase, benzene and toluene used as working fluids in ORC binary cycle. Results are shown in terms of aggregated indicators for fatalities, injuries, and evacuees. Furthermore, in case of hazardous substances, fatalities and injuries refer to immediate ones, since no exposure and toxicity in this assessment are taken into account.

5.1 *Fatalities*

Figure 1 shows the fatality rate for each hazardous substance and onshore blowouts analyzed in this study. The fatality rate is estimated using all the accidents causing at least 1 fatality. Results clearly show a higher relative risk of onshore blowouts compared to the use of hazardous substances in both drilling and operational phases. Among the latter, all the considered substances show similar results, with a slightly higher risk for caustic soda.

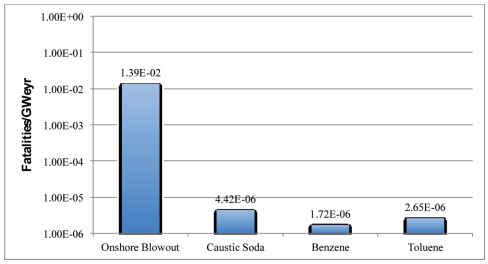

Figure 1. Fatality rate indicator for onshore blowouts and hazardous substances in deep geothermal systems.

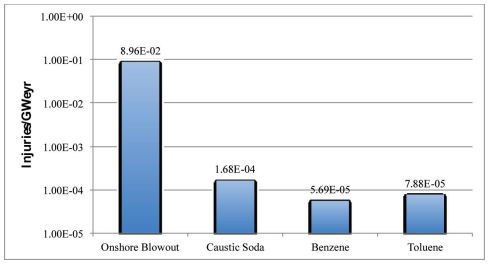

Figure 2. Injury rate indicator for onshore blowout and hazardous substances in deep geothermal systems.

Therefore, the drilling phase exhibits a higher fatality risk than the operational phase, mainly due to the high risk related to blowout accidents.

5.2 *Injuries*

Figure 2 shows the injury rate for the accident risks analyzed in this study. The injury rate is estimated using all the accidents causing at least 1 injury. Similar to fatalities, onshore blowouts show a substantially higher relative risk in comparison to the use of hazardous substances. Among the latter, caustic soda shows a higher risk than benzene and toluene. Therefore, as for fatalities, the drilling phase results to be more risk prone in terms of injuries compared to the operational phase.

5.3 *Evacuees*

Figure 3 shows the evacuee rate for the accident risks analyzed in this study. The evacuee rate is estimated using all the accidents causing at least 1 evacuee. The rate shows a distinctly higher relative risk for onshore blowouts compared to hazardous substances. Among them, benzene shows a higher risk than caustic soda, while toluene appears to be less risky. Therefore, as in the previous indicators, the drilling phase comprises a higher risk in terms of evacuees than the operational phase, mainly due to the high risk related to blowout accidents.

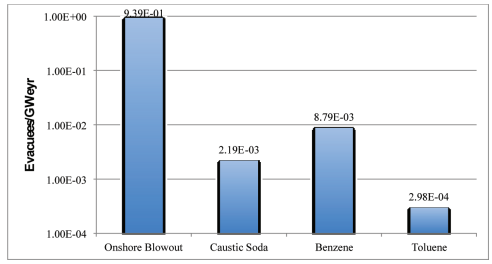

Figure 3. Evacuee rate indicator for onshore blowout and hazardous substances in deep geothermal systems.

6 CONCLUSION

In this study possible accident risks of deep geothermal systems are evaluated. Risks are quantified for blowout accidents and accidents related to the use of hazardous substances in both drilling and operational phases, which represent the main accident risks besides induced seismicity. The analysis showed that the accident risk of blowouts is significantly higher than the risk related to the use of hazardous substances. This is the case for all the considered risk indicators, i.e. fatality, injury and evacuee rates. Therefore, blowouts can be considered one of the main accident risks besides induced seismicity. In addition, based on these results, the drilling phase in deep geothermal systems exhibits higher risks compared to the operational phase.

This study provides a preliminary overview of possible accident risks for deep geothermal systems. Future research should analyze other sources of accident risks, e.g., the chemical composition of the geofluids in the operational phase. Furthermore, exposure and toxicity analyses need to be carried out for hazardous substances in order to correctly assess the risk of chemicals.

Enhancement of IT Risk Assessments by UML

R. Mock, B. Truninger & P. Brunner
Institute of Applied Information Technology, Zurich University of Applied Sciences, Winterthur, Switzerland

T. Hruz
milliPay Systems AG, Zürich, Switzerland

ABSTRACT: Unified Modeling Language diagrams (UML) are considered as an underestimated knowledge source for Risk Assessment (RA) approaches. For this, a combination of Class and Sequence Diagrams is used to get relevant information for further risk analysis. In an IT enterprise, existing business processes source code can be used to automatically generate a full process Class Diagram. The paper suggests a way to significantly reduce the size of the Class Diagram. To do this, the most relevant business case of the audited enterprise is selected and used to generate a Sequence Diagram. Tools simplify this approach. The resulting Sequence Diagram only consists of classes and operations relevant to the chosen business case. They can then be matched to the initial full system Class Diagram. Elements in the Class Diagram that do not have a match in the Sequence Diagram can be removed, resulting in a reduced Class Diagram. The reduced Class Diagram is the base for RA heuristics, e.g., many incoming associations of a class suggest that other classes often depend on this class. Therefore, a failure of this class points to an increased impact value.

1 INTRODUCTION

The keyword "Industry 4.0" outlines the current shift of technical systems from well identifiable structures to indistinct infrastructural entities which depend on Information Technology (IT) to a large extent. This change also has impacts on how to do Risk Assessments (RA): It prompts questions about IT security, shifts assessment goals from hazard evaluation to vulnerability analysis and has to deal with highly dynamic and networked systems. The established tools of engineering RA have reached their methodological and practical limits to characterise this kind of technology (cf. (Mock et al. 2014)). The R&D project Micropayment at Zurich University of Applied Sciences ZHAW targets to merge the areas of engineering RA and IT security approaches in close cooperation with an industry partner in order to draw a profit in fault detection, IT system optimisation and methodological enhancements.

There are only a few methodologies combining both areas in a practice-oriented manner. They mainly base on check list-like procedures (audit, compliance check) or on a semi-formal notation. Some of the latter approaches base on close to business system graphs, e.g., Unified Modeling Language Diagrams (UML), Business Process Modelling (BPM) and Event-driven Process Chains (EPC). The paper substantiates the usage of specified UML diagrams for RA purposes as they are commonly known in enterprises as well as in Informatics. With this, the authors consider UML an unexploited resource for IT risk analyses. In doing so, the paper is structured as follows: Chapter 2 clarifies framework and terms in IT RA. Chapter 3 outlines UML diagrams as well as their current use in IT RA. It also positions them in the framework of engineering RA. In chapter 4, an approach is presented on how to utilise automatically generated UML of a business process in the framework of engineering RA. Open questions and further work are addressed. Conclusions in chapter 5 outline assets and drawbacks of the methodology.

2 IT RISK ASSESSMENT

The common procedures and tools offered for RA of IT depending infrastructural systems are unable to manage the fast modification rates. They have become laboured and too resource-intensive in order to meet the constraints of a fast moving and IT driven business community. Everyday measurements, as the installation of, e.g., a new router, may lever out existing reliability models (cf. (Milanovic et al. 2008)). Nevertheless, a methodology is needed to assess risks in practically relevant procedures. The proposed methodology will finally come to integrate engineering and IT RA approaches:

Definition 1. (Engineering Risk Assessment) *Established RA methodology and approaches as common in non-IT areas.*

The term engineering RA is mainly introduced to highlight differences to the IT RA concept. The framework is well defined in the (outdated) (ISO/IECGuide73 2002). The basic approaches and concepts as, e.g., FMEA, Fault Tree Analysis and Probabilistic Safety Analysis, are supposed to be known to the reader. Major goals are hazard identification and its impact on environment. Typical fields of application are chemical industry and nuclear power generation.

Definition 2. (IT Risk Assessment) *RA methodology and approaches to evaluate IT systems as common in computer sciences.*

The framework of IT RA is mainly influenced by IT security analyses dealing with Confidentiality, Integrity, and Availability (CIA) of data or assets. Major goals are the identification of external threats on and weak points of an IT infrastructure network. In fact, IT RA is a vulnerability analysis concordant with (ISO/IECGuide73b 2009) and (NIST 2012). It also comprises control analyses similarly to Bow Tie Diagrams. Following the definition of the NIST Guide, risk is:

Definition 3. (Risk) *A measure of the extent to which an entity is threatened by a potential circumstance or event, and typically a function of: (i) the adverse impacts that would arise if the circumstance or event occurs; and (ii) the likelihood of occurrence.*

Following the NIST Guide again, the IT RA process comprises four primary working steps:

1. *Prepare for risk assessment* (Derived from organisational risk frame)
2. *Conduct assessment*: identify threat sources and events; identify vulnerabilities and predisposing conditions; determine likelihood of occurrence; determine magnitude of impact; determine risk. (For the close connections of risk, vulnerability and resilience analysis see, e.g., (Pasman et al. 2013)).
3. *Communicate results*
4. *Maintain assessment*

MEHARI 2010 (Method for Harmonized Analysis of Risk) (MEHARI 2010) is a (rare) IT RA check list based approach following these steps, basing on (Stoneburner et al. 2002), and the Code of Practice in IT security (ISO/IEC-27002 2005).

3 UNIFIED MODELING LANGUAGE DIAGRAMS

3.1 *Framework and terms*

UML originally supports software development for business process modelling:

Definition 4. (UML) *The UML serves to "specify, visualize, and document models of software systems, including their structure and design …" (OMG 2013).*

In the meantime, "… just about any type of application, running on any type and combination of hardware, operating system, programming language, and network …" can be displayed in UML (OMG 2013). The UML is "… independent from […] subject and realisation area. It provides notation elements equally for static and dynamic models of analysis, design and architecture and especially supports object-oriented approaches" (Rupp and Queins 2012). This reference also states that UML notation and related diagrams are supported by various industrial branches which has made standardisation possible. The engineering RA community rarely uses UML. According to the authors' opinion, the UML proximity to business, IT and domain flexibility makes them an underestimated resource for RA of IT systems. However, UML does not provide risk assessment, meaning that extensions and adaptations to risk are necessary to develop as already be on hand for IT security analyses.

The OMG Website (OMG 2013) defines three major categories of UML 2.0 diagrams and overall thirteen different types:

1. **Structure Diagrams**: Class Diagram, Object Diagram, Component Diagram, Composite Structure Diagram, Package Diagram, Deployment Diagram
2. **Behaviour Diagrams**: Use Case Diagram, Activity Diagram, State Machine Diagram
3. **Interaction Diagrams** (all derived from the more general Behaviour Diagrams): Sequence Diagram, Communication Diagram, Timing Diagram, Interaction Overview Diagram

The methodical affinity between UML system diagrams and common system representations in engineering RA is obvious as both make extended use of graphs. However, the UML semantics are tailored to IT needs, but nevertheless there are already efforts to fit UML into the engineering RA framework e.g., (Viehmann 2012).

Two types of UMLs are most relevant for the paper. A *Class Diagram* pictures the *classes* and their relations (*associations*) in the system as well as how those classes are built and what *operations* they can execute. As Class Diagrams are Structure Diagrams, they cannot show any time-dependent behaviour. This can be done by *Sequence Diagrams*. They show the order and timing of processes and messages between parts of the system. A Sequence Diagram contains *classes* or *objects* that are connected by an *action* or *operation*.

3.2 *Actual use of UML in IT risk analysis*

Not all of the UML types listed in chapter 3.1 are common, practicable and convenient for IT RA purposes. (Petre 2013) analyses the propagation of UMLs for software engineering in industry. According to this study, UMLs in use are (decreasing number): Class Diagram, Sequence Diagram, Activity Diagram, State Machine, Use Case Diagrams. The same study notes, that professional practitioners consider UML as "primilarly an academic thing" whereby it "… has achieved penetration in software engineering education". For this, the named UMLs are known but neither widespread nor popular among software engineers.

(Neubauer and Heurix 2008) discuss approaches of IT system analysis with regard to IT security and IT risk following a non-frequentistic definition. They state a lack of IT security considerations within business processes because the basic Business Process Modelling (BPM) approaches do not support a semantic of security. UML and ARIS (Architecture of Integrated Information Systems) are named as most popular modelling languages for BPM whereas non of them include methods of "security-related entities". As a consequence, supplementary security (and risk) levels are needed.

With regard to IT security issues, UMLsec (Jürjens 2004) is most prominent in literature. Methodology and tool use a sophisticated UML notation, semantic and formalism to characterise IT security demands as well as to analyse the diagrams byan "automated first-order logic theorem prover."

CORAS is also a frequently named tool and "platform for risk analysis of security critical systems" (CORAS 2014). The CORAS procedure can be split into eight steps (CORAS 2013) following the common RA working steps as presented, e.g., in chapter 3. The methodology is designed around a graphical modelling language based on UML (Stølen 2013), i.e., on adapted Use Case Diagrams (c.f., (Lund et al. 2011)). These UMLs can be supplemented by a syntax for risk graphs(c.f., (Braber et al. 2006)). In four diagram types, the audit team can visualise the relations among assets, how actors threaten those assets, what risks have been discovered and how these specified risks can be treated. The diagrams are gradually built during brainstorming sessions or workshops between the audit team and representatives of the audited enterprise. The diagrams of the CORAS tool offer designated fields for *likelihood* and *consequence* value inputs. However, those fields do not enforce a formal input format. Therefore, the tool cannot be used to automatically calculate any risk values.

In the end, the UMLsec approach needs an extended training period at least. As a consequence, UMLsec is resource-intensive and a bit on the complex side for SME or everyday IT security checks. On the other hand, CORAS is mainly a tool to support brainstorming. Both approaches basically cover the area of IT security and therefore, they are no designated RA tools.

3.3 *Taxonomy for IT risk assessment purposes*

(Paintsil 2012) suggests a taxonomy for information system security RA approaches which clarifies the position and framework of UMLs as well as the proposed RA approach as presented in the following chapter. This taxonomy bisects RA approaches in bottom-up/IT-centric and top-down/information-centric. The (traditional) IT security RA approaches are bottom-up and asset oriented. "They assess risk by identifying an asset and its value, and the likelihood of an unwanted incident and its consequence for the asset". Checklist based or compliance audit approaches, UML-based CORAS approach, and Fault Tree Analysis belong to this category. "The top-down approach is requirement-oriented. It focuses on the security needs of a system or an organization. These security needs are based on requirements for CIA as well as risk to infrastructure, legal, and regulatory or statutory requirements". Non-traditional ("contemporary") approaches are, e.g., Colored Petri Nets (bottom-up) and UMLsec (top-down). According to this taxonomy, the proposed approach in chapter 4 is bottom-up/IT-centric.

4 METHODOLOGICAL ENHANCEMENTS

The proposed approach of this paper uses Class and Sequence Diagrams to analyse specific business processes for risks. For this, the UMLs are automatically generated based on the source code of the business process. However, a practical problem emerged as these diagrams show the complete business process which makes them quickly unclear for analysts. Moreover, these UMLs often encompass many details irrelevant for RA purposes. Therefore, the proposed RA approach includes a procedure to reduce the Class Diagrams which are then the base for further RA working steps. The RA approach is exemplified by a business process at milliPay Systems AG. The company develops and offers a micropayment system, which facilitates very small transactions (micro transactions) between users and vendors, ranging from 0.0001 to 3 Swiss Francs. The examples presented are greatly simplified for easier reading and understanding.

4.1 *Reducing the Class Diagram*

4.1.1 *Full System Diagram*

The starting point is the generation of UMLs from source code by a software tool. The authors use (Architexa 2013), because the tool offers Class and Sequence Diagram generation and is seamlessly integrable into *Eclipse*, milliPay's development environment. The tool does not modify the source code and Sequence Diagrams can be built step by step so that the user may leave out irrelevant information like library code or private methods. Further tools that offer similar support are, e.g., (Visual Paradigm 2014), Astah (Change Vision 2014), and eUML (Soyatec 2013). Figure 1 shows the automatically generated Class Diagram of milliPay's payment module.

In Figure 1 **`PaymentService`** *class* provides *operations* like `identifyUser(…)`, `transfer(…)` money and getting the product with `getProduct(…)`. Other *classes* are connected (*associated*) to **`PaymentService`** that symbolises the process structure. **`CryptoEngine`**, e.g., is used to secure the payment process.

4.1.2 *Sequence diagram of a specified process*

In the next step, the audit team decides which business process should be evaluated, e.g., **`PaymentService`** and `transfer(…)`. Then, a Sequence Diagram is generated showing each *operation* of the process. Again, *Architexa* supports the generation of this diagram. Figure 2 shows the resulting Sequence Diagram.

The Sequence Diagram shows the orders of *classes* and the execution of the *operations*. In Figure 2 **`PaymentService`** encompasses the main steps of the process by executing `transfer(…)`.

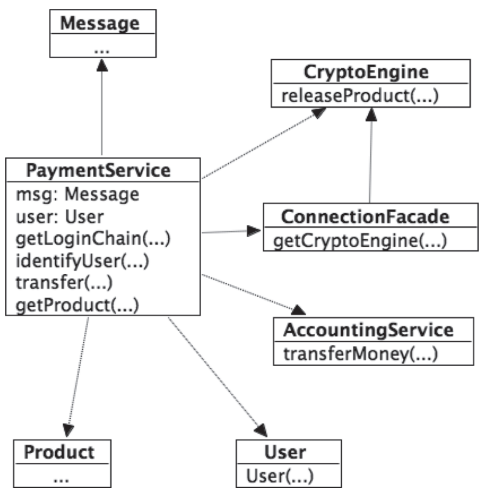

Figure 1. Full system Class Diagram (excerpt).

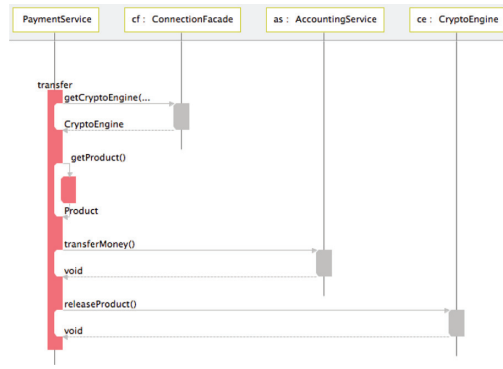

Figure 2. Sequence Diagram of specified business case.

4.1.3 *Reduced Class Diagram*

As mentioned before, the full Class Diagram also contains information that is not relevant to the chosen business process. For instance, there is no need to identify the user in the Class Diagram in Figure 1 for the specified process. (If she had not aready been identified, she would not be able to start a purchase). Thus, **`User`** and `identifyUser(…)` are removed from the Class Diagram. The easiest way to proceed is to go through the Sequence Diagram step by step, from left to right, as this diagram shows which *classes* and *operations* are needed for a process. Each step considers:

1. the starting *class*
2. the target *class*
3. the *operation* from the starting to target *class*.

Each of these three elements is labelled in the full scope Class Diagram. Labelling means that a specified *class* or *operation* is relevant and should not be removed. In this example, labelled classes are **`PaymentService`**, **`CryptoEngine`**, **`ConnectionFacade`**, **`AccountingService`** and **`Product`**, since these *classes* are used for *operations* in this Sequence Diagram. In the end, **`PaymentService`** contains two labelled *operations*, because **`transfer(…)`** also calls `getProduct(…)`. Other *operations* in other classes are labelled as well since they connect the marked objects.

Figure 3 depicts the resulting reduced Class Diagram.

4.2 *Utilisation of UML for RA purposes*

Figure 4 summarises the process by using automatically generated Class and Sequence Diagrams of a specified business process source code as raw material for IT RA purposes.

These UMLs do not contain any information about impacts, likelihoods and resulting risks.

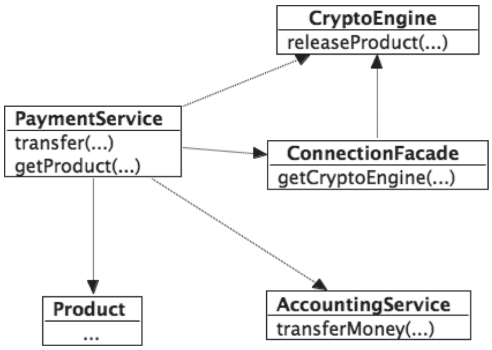

Figure 3. Reduced Class Diagram.

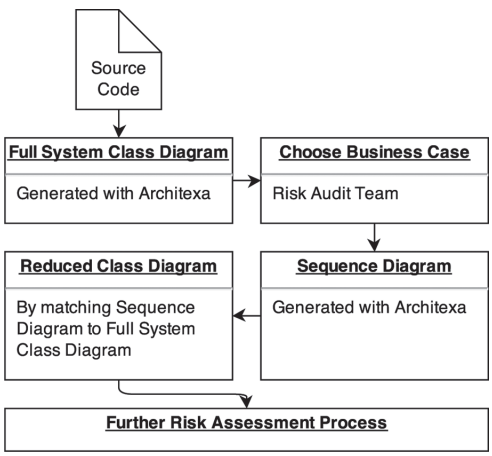

Figure 4. RA process.

However, they structure an FMEA-like RA approach and offer some heuristics to value the orders of magnitudes, e.g., on scales of 1 to 10 (1: rare/negligible to 10: frequent/disastrous). For this, the following working steps are suggested:

Step 0: Preparational Work: Selection of an *operation* to be analysed and generate Class and Sequence Diagrams.

Step 1: Analysis of Classes: The generated UMLs base on the same source code and as a result, the same business process is considered from different angles. In order to structure the IT RA process, *classes* and *operations* are disassociated.

– Many outgoing *associations* (edges) of a *class* in a Class Diagram indicate that it uses many other classes. The corresponding Sequence Diagram also shows many connected *classes*. This dependency exposes the *class* to an increased likelihood of malfunction and may also indicate a major impact. However, the latter needs business specific assessments (or depends on the analysis framework).
– Many incoming *associations* (edges) of a *class* indicate that it is used by many other *classes*. A malfunction points to an increased impact value.

Step 2: Analysis of Operations: Classes encompass *operations* showing further details of the specified business process. The malfunction of an *operation* is considered as a failure mode in the context of an FMEA approach. The Sequence Diagram shows its position within the business process chain. An initial position of an *operation* roughly indicates a more serious impact on the overall business process than a rear light one.

Following the milliPay example, `getProduct(…)` (e.g., an offered journal article) of `PaymentService` is in the beginning of the business process along `transfer(…)` as shown in the Sequence Diagram of Figure 2. A malfunction of this *operation* might result in the wrong amount of transferred money and to a wrongly released product, i.e., a serious impact on business. Note, this operation is indicated as a continuous red-shaded (dark grey in a black & white copy) area in the Sequence Diagram. Hence, any statements are associated with a closed sequence chain.

Step 3: Risk assessment: Following the common FMEA approach, the Risk Prioritisation Value (RPV) is used to identify most important risks, i.e., classes and operations as well as associated sub-business processes, underlying hardware and software, persons responsible to maintain the processes, etc.

The procedure of practical UML utilisation needs supplementary notes:

– *Comprehension*: As *classes* and *operations* in Class and Sequence Diagrams are extracted from the source code, they can easily be found in this code which gives the analyst detailed information about a process. For instance, the code shows the linkage of `getProduct(…)` with a vendor.
– *Impact assessment*: Impact evaluation within RA needs specifications of analysis goals: If the analysis considers, e.g., a single money transfer only, the malfunction of **`PaymentService`** is negligible according to the micropayment business model. If looking on money transfer in general, a malfunction fully touches the business model and consequences would be high.
– *Tools:* For the MICROPAYMENT project, Architexa is used to get UMLs from a Java source code because of practicability. The tool only generates low level (or simplistic) UMLs as shown in this paper, whereas the tool is also able to handle loops, iterations, and conditional statements.

4.3 *Further work*

Within the R&D project MICROPAYMENT, the utilisation process of UMLs for IT RA purposes is in its beginnings. Although the suggested RA procedure looks promising (and practical) for all project partners, the authors have already addressed further work and methodological enhancements. These evolutionary steps are outlined below, as they show the potential of the overall concept.

The original UMLs as provided by the Object Management Group (cf. (OMG 2013)) offer a multitude of notation elements enabling the analyst to depict nearly any system in detail. So, full scope of Class and Sequence Diagram semantics may indicate further information for RA purposes. Examples are (cf. OMG website):

- *associations* (edges) for linking *classes* in Class Diagrams: The basic notation is a non-directed and unlabelled edge between *classes*. Extended notation encompasses roles (indicating the purpose of the linked classes), multiplicity (various rules about the number of objects in each linked class, e.g., 1 to many (1… *)), navigability (unidirectional, bi-directional), aggregation (whole-part relation), composition (as aggregation but the whole-part relation means a physical unit), n-ary (more than two classes are linked), and generalisation (different levels of class abstraction).
- *messages* in Sequence Diagrams: conditional, repetitive, to self.
- The remaining eleven UML types as listened in chapter 3.1 offer further notations, semantics and types of *associations*.

The heuristic to value the risk parameters by Class and Sequence Diagrams is still straightforward. However, the Sequence Diagram makes patterns visible to the analyst. In Figure 5 the specified *operation* highlighted in red (dark grey in a black & white copy) calls-up sequences of *operations* and associated *classes*. Likelihood of malfunction of the specified *class* is expected to be high. The impacts depend on the *classes* involved and tends to be high (sum of impacts).

Figure 6 shows the reverse to Figure 5. The *operations* in red belong to a single *class* which needs the call-up of other *classes*. This may indicate a high likelihood of malfunction of the specified *class*. Impact is given by its malfunction (single class).

In Figure 7, the sequence of *operations* in red also belongs to a single *class*. However, its first *operation* needs a single other *class* and the second triggers the two *operations* of another class. This is an example of a combined sequence, which might be split up into the basic structures of Figures 5 and 6.

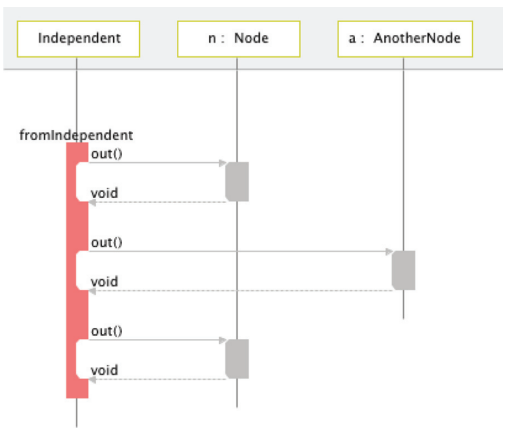

Figure 5. Sequence Diagram plain sequences.

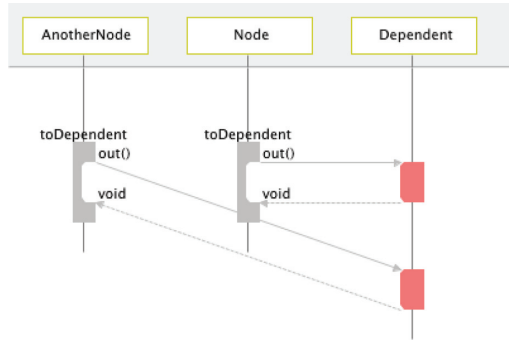

Figure 6. Sequence Diagram: Single class is needed by other classes.

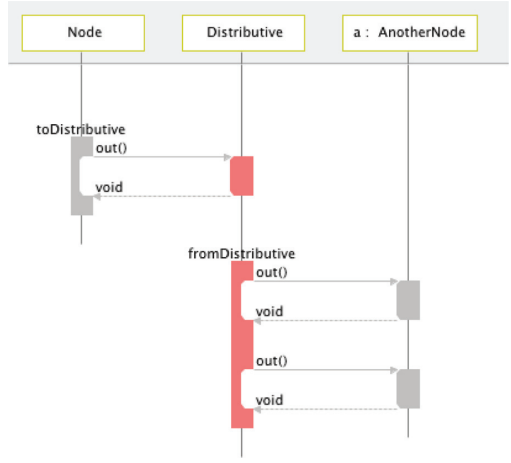

Figure 7. Sequence Diagram one incoming and two outgoing edges.

These basic configurations in Sequence Diagrams show similarities with State Flow Graphs (as, e.g., defined in (Rakowski 2012)). However, as MICROPAYMENT is a typical interdisciplinary R&D project, the possibility of an extended interpretation is still a matter of discussion among the participating engineering risk analysts and computer scientists. State Flow Graph would provide a different and formalised access to risks in the area of IT RA.

5 CONCLUSIONS

The usage of UML diagrams looks promising as it represents a rarely used access to a knowledge base for IT RA. For this, nearly every system or process can be modelled at least by hand. However, the automated generation of UML diagrams from source code highly increases the efficiency of RA. To make this work, a interdisciplinary team of risk analysts and computer scientists is a prerequisite.

The paper outlines basic principles of a UML-based methodology of IT RA. It offers heuristics in order to support the further development of a quick IT RA audit or risk prioritisation tool. As the detailed modelling or simulation of infrastructural IT systems is out of scope at most enterprises, this is considered as a practical approach.

Quantitative risk assessment of new ship designs in damage conditions

M.K. Gerigk
Gdańsk University of Technology, Gdańsk, Poland

ABSTRACT: The paper is devoted to safety of ships in damage conditions. The novel contribution of the paper is connected with a new Multi-Task ship (MT-ship) design at the preliminary stage of design. There are a few problems at the preliminary stage that should be considered. One problem is connected with if the quantitative risk-based method is a reliable and formal method for safety assessment of such the new design (MT-ship) in damage conditions. The current method of safety assessment of commercial ships in damage conditions is based on the requirements included in the SOLAS 2009 regulations. The methods of safety assessment of navy ships in damage conditions belong to the different classification societies and navies. Further development of the SSADC method is connected with its application for safety assessment of a few novel designs.

1 INTRODUCTION

The novel contribution of the paper is connected with a new Multi-Task ship (MT-ship) design at the preliminary stage of design which does not belong to either the passenger, cargo or navy ships.

There are a few problems at the preliminary stage of such the design which have to be taken into account. One problem is connected with if the quantitative risk-based method is a reliable and formal method for safety assessment of such the new design (a new MT-ship) in damage conditions. Another issue is associated with an approach to safety assessment. It may still be considered to use a prescriptive or risk-based oriented approach included in the existing regulations depending on if the MT-ship is a special task ship for either a commercial or navy use. In such the situation the proposed method may still be treated as an alternative method for safety assessment of ships in damage conditions.

The current method of safety assessment of commercial ships in damage conditions is based on the requirements included in the SOLAS 2009 regulations. This method is of prescriptive character and based mainly on the experience in design and operation. It is reliable and harmonized. It is easy to apply for the commercial ships, passenger and cargo ships. It is more devoted to the design stage and is difficult to apply in operation. The measure of safety of a ship in damage conditions is the probability of surviving a collision known as the subdivision index A (IMO 2005, SOLAS 2005, Gerigk 2010, IMO 2014).

Those methods are prescriptive in their character and based on the probabilistic approach to safety. In some cases the semi-probabilistic components are incorporated in those regulations. The main disadvantage of those methods is that they do take into account the fixed set of scenarios of an accident. It means the safety assessment of ships in abnormal/damage conditions concerns considering the flooding of single compartments, groups consisting of two watertight compartments, groups consisting of three watertight compartments, etc. The next disadvantage associated with application of those methods regards the problem that using those methods in case of certain types of ships e.g. car-carriers, ro-ro vessels or passenger ships may lead to insufficient level of safety or provide unnecessary design or operational restrictions.

The basic criteria of the prescriptive method included in the SOLAS 2009 regulations is the condition as follows, (IMO 2005a, IMO 2005b, IMO 2008):

$$A > R \tag{1}$$

where A = attained subdivision index calculated for the draughts d_s, d_p and d_1 defined in regulation 2, according to the formula, IMO (2005):

$$A = \sum p_i s_i \tag{2}$$

where p_i = probability that only the compartment or group of compartments under consideration may be flooded, as defined in regulation 7-1; s_i = probability of survival after flooding the compartment or group of compartments under consideration, as defined in regulation 7-2; R = required subdivision index.

The probabilities p_i and s_i are calculated according to the well known formulae accepted by IMO,

(IMO 2005a, IMO 2005b, IMO 2007). The typical process of assessment of safety of ships in abnormal/damaged conditions at the design stage or when the survivability of existing ships is considered is directed to satisfy the criteria (1).

The methods of safety assessment of navy ships in damage conditions belong to the different classification societies and navies. For example the current quasi-static damage stability criteria method used by the UK MoD is largely based on the Sarchin and Goldberg work published in 1962 (Peters A.J. et al. 2009, Smith D. et al. 2009).

The method presented in the paper called as the SSADC (Ship Safety Assessment in Damage Conditions) method is a risk-based method. It is based on assessment of the ship performance and risk assessment. It enables to quantify the risk and use it a measure of a ship safety. The method is of non-prescriptive character. It may be treated as a prescriptive method form the formal point of view if the structure of requirements in the form of any known regulations are used.

Although some elements of the SSADC method have been published it is important to underline that further development of the SSADC method is connected with its application for safety assessment of novel ship designs and ocean engineering objects in damage conditions.

2 THE SSADC METHOD OF SAFETY ASSESSMENT OF SHIPS IN DAMAGE CONDITIONS

In the following chapter the basic information on the SSADC (Ship Safety Assessment in Damage Conditions) method is introduced. The methodology where the risk-based design and a formalized design methodology were integrated together the first time was introduced by Vassalos and the others, (Skjong et al. 2006, SSRC 2009, Vassalos 2006).

The SSADC method is a kind of performance-oriented risk-based method which enables to assess the safety of ships in damage conditions at the design stage, in operation and during the ship salvage using the same procedure, Gerigk (2010). Within the SSADC method the holistic approach to safety assessment is applied. The method is based on implementation of the system approach to safety. In general, the method takes into account the influence of design and operational factors on safety including the safety management related factors as well.

For the ship performance evaluation the statistics, investigations using the physical models and numerical simulation techniques may be applied. The ship performance estimation enables take into account the influence of the intermediate events, additional events (releases) and consequences on the ship behavior. This may be done for the data sequence of events for an accident under consideration.

The risk assessment is based on application of the matrix type risk model which is prepared in such a way that it enables to consider almost all the scenarios of events regarding the considered accident.

The criteria within the method is to achieve an adequate level of risk using the risk acceptance criteria, risk matrix or ALARP concept, Gerigk (2010).

Providing a sufficient level of safety based on the risk assessment is the main objective. It is either the design, operational or organizational objective. Safety is the design objective between the other objectives. The measure of safety of a ship in damaged conditions is the risk (level of risk).

The SSADC method may be used at any ship's life circle, including safety assessment of a ship during a catastrophe. Some elements of the method can be used for safety assessment of different means and systems of maritime transportation.

The SSADC is still being developed taking into account the latest developments regarding the safety of ships in damage conditions, (Vanem E. et al. 2009, Jasionowski A. 2011, Papanikolaou A. et al. 2013, Montewka J. et al. 2014).

The SSADC method is based on the following main steps:

- setting the requirements, criteria, limitations, safety objectives;
- defining the ship and environment;
- identifying the hazards and identifying the sequences of accident (scenarios development);
