Table of contents

Preface xxvii

Acknowledgements xxix

Conference organization xxxi

Introduction xxxv

METHODOLOGY AREAS

Accident and incident investigation and modelling

Aeronautics and aerospace

An incident reporting support system for airline cabin crew 3
K. Furuta, K. Okano, T. Kanno, T. Mori & S. Shimizu

Chemical process industry

The effect of the environment conditions on the prediction of flammable cloud dispersion 11
A.M. Schleder, M.R. Martins, E. Pastor & E. Planas

Scenario identification in oil and gas industry: A case in the Middle East 21
Z. Rezvani, P. Swuste & P. Hudson

Civil engineering

Analysis of roadside safety barrier using numerical model 29
P. Hradil, J. Kala & V. Salajka

Critical infrastructure

Developing a framework for characterising cascading failures in past events to inform emergency response decisions 33
H. Hassel, A. Cedergren, L. Svegrup & J. Johansson

A critical evaluation of risk assessment methodology for natural gas pipeline 43
J. Kraus

An ontology-based approach to vulnerability and interdependency modelling for Critical Infrastructure systems 49
P. Trucco & B. Petrenj

Electrical engineering

Renewable sources impact on power system reliability and nuclear safety 57
A. Volkanovski & B. Gjorgiev

Maritime transportation

Titanic viewed from different perspectives on major accidents 65
H. Kim & S. Haugen

Usability of accident and incident reports for evidence-based risk modeling of ship grounding 75
A. Mazaheri & J. Montewka

Winter navigation at the Baltic Sea: An analysis of accidents occurred during winters 2002–2003 & 2009–2013 83
O.A. Valdez Banda, F. Goerlandt, J. Montewka & P. Kujala

Rail transportation

Structuring contributors to successful operation 93
J. Vatn

Road transportation

Country Safety Performance Function and the factors affecting it 101
K. Jamroz

Method of dynamic identification of hazardous driver behaviour by traffic parameters detection 109
M. Sumiła & M. Siergiejczyk

Waterborne transportation

The method of risk management of accidental oil spills at sea 115
K. Łazuga & L. Gucma

Other reliability and safety areas

The impact of new technologies on the safety level of air traffic in Poland 121
K. Krzykowska & M. Siergiejczyk

Black swan accidents: Predicting and preventing the unpredictable 127
D.J. Winfield

Analytical methods in system safety and reliability

Aeronautics and aerospace

Studies of the jet engine control quality based on its response to the disturbance inflicted on the object, designated from its response to the set point inflicted to the controller 137
K. Golak, P. Lindstedt & R. Grądzki

The mathematical formula of safety of aircrafts 141
J. Lewitowicz, S. Rutkowski, R. Tomaska & A. Żyluk

The reliability analysis of the satellite's driving system based on the IABCBLT method 143
W. Peng, J. Zhang & L.J. Kan

The effectiveness of the FMEA technology in the process of the aerospace product development 151
J. Shuyuan, L. Fuqiu, W. Jinjing & L. Meinan

Reliability modeling method of space mechanism considering dynamical cascading effects 155
C.L. Tan, J.G. Zhang, P. Wang & L.J. Kan

Chemical process industry

Comparative analysis of calculation methods of pressure drops for two-phase flow through pipelines 163
G. Boccardi, R. Trinchieri, R. Bubbico & B. Mazzarotta

Critical infrastructure

Empirical Bayes inference with nonlinear homogenizations and correlated intensity functions: Use in asset degradation modelling 171
G. Blair, J. Quigley & L. Walls

Dependence of the gas supply system criticality indicator(s) on the system elements' reliability 181
B. Jokšas, I. Žutautaitė, J. Augutis & T. Rekašius

Comparing societal consequence measures of outages in electrical distribution systems 189
F. Landegren, J. Johansson & O. Samuelsson

On the resilience analysis of interconnected systems by a set-theoretic approach 197
X. Liu, I. Prodan & E. Zio

A brief note on the ratio of the rectilinear and shortest distance between two arbitrary points on the 3-sphere 207
M.A. Odijk & P.H.A.J.M. van Gelder

A game-theoretical model to allocate security resources in a multi-modal transportation system facing adaptive adversaries 211
L. Talarico, K. Sörensen & G. Reniers

Electronic industry

Assessment of the critical events sequences of systems by means of probabilistic languages 217
D. Ionescu, N. Brînzei & J.F. Pétin

Energy production and distribution

RAM analysis applied to decommissioning phase: Comparison and assessment of different methods to predict future failures 225
E. Calixto & Y. Bot

Reliability indices computation for a flow network with a series-parallel-reducible structure 235
J. Malinowski

Information technology and telecommunication

Minimal cut sets and direct partial logic derivatives in reliability analysis 241
M. Kvassay, E. Zaitseva & V. Levashenko

On the probability of escaping a cell—in wireless networks 249
C. Tanguy

Maritime transportation

Reliability analysis of ship-rope transporter with dependent components 255
A. Blokus-Roszkowska & K. Kołowrocki

Maritime traffic flow simulation in the Intelligent Transportation Systems theme 265
A. Blokus-Roszkowska & L. Smolarek

Modeling of event trees for the rapid scenario development 275
M.K. Gerigk

The influence of screw propellers manufacturing accuracy on conditions of the propulsion system operating 281
E. Skupień

Mechanical engineering

Contribution to oil data assessment for system condition determination 287
D. Vališ & L. Žák

Rail transportation

Dependability and safety analysis of ERTMS level 3 using analytic estimation 293
T. Babczyński & J. Magott

Streamlining architectures for integrated safety analysis using Design Structure Matrices (DSMs) 299
K. Höfig, J.Z. Guo & A. Kazeminia

The Markov reliability and safety model of the railway transportation system 303
F.J. Restel

Reliability analysis of rail teleinformation system 313
M. Siergiejczyk

Road transportation

Premises of evaluation of the technical object suitability with including the quality of its maintenance and operation, and their initial conditions 319
R. Grądzki, P. Lindstedt & K. Golak

Bivariate reliability analysis of driving profiles in automobile fleets 327
T. Köttermann, M. Grabert, S. Kempe & S. Bracke

Attempt to apply the theory of reliability to assessment of signalised lane operation 335
K. Ostrowski

Reliability-exploitation analysis of power supply in transport telematics system 343
A. Rosiński

Reliability-maintenance analysis of highway emergency communication systems 349
M. Siergiejczyk, J. Chmiel & A. Rosiński

Hierarchical random models in road transport safety 355
J. Wachnicka, K. Jamroz & L. Smolarek

Other reliability and safety areas

Overall regional risk analysis of four Norwegian municipalities 361
R. Flage, Ø. Amundrud & H.S. Wiencke

Modeling reliability of complex port transportation system 371
K. Kołowrocki & J. Soszyńska-Budny

Reliability optimization of complex port transportation system 385
K. Kołowrocki & J. Soszyńska-Budny

Involvement of expert judgement in dynamic model 393
R. Krikštolaitis, A.E. Lutynska, S. Pečiulytė & I. Žutautaitė

Anthropo-technical systems reliability 399
D. Laskowski, P. Łubkowski, E. Pawlak & P. Stańczyk

Cost-benefit analysis of surveillance technologies 409
P.-H. Lin & C. van Gulijk

Integrated estimation of pipeline failure probability 417
I. Žutautaitė, G. Dundulis, S. Rimkevičius & R. Janulionis

Reliability and safety management

Aeronautics and aerospace

Reliability engineering interactions in aerospace products 425
E.N. Çetin & A.Ş. Temiz

An influence of the lifetime assessment in aviation technology 433
K. Kustroń & J. Lewitowicz

Chemical process industry

How managers should think about risk—a case study from the oil and gas industry 437
T. Bjerga & T. Aven

Balancing safety and performance through QRA and RAM analyses 445
V. Borges & C. Hickey

Public risk perception towards chemical process industry: Comprehension and response planning 453
D. Botheju & K. Abeysinghe

Risk assessment system for verifying the safety guards system based on the HAZOP analysis information 461
A. Nakai, K. Isshiki & K. Suzuki

Development of the Safety Requirements Specification (SRS) in oil and gas industry 467
E.H. Park, K.P. Chang & S.T. Kim

Civil engineering

Development of functional safety standards for civil engineering 475
E. Nachtigall & V. Shcherbina

Mechanism design for risk allocation and benefit sharing in the development of a Geological Disposal Facility for nuclear radioactive waste 481
O. Nieto-Cerezo, E. Patelli, J. Wenzelburger & M. Beer

Optimization of the drinking water coagulation and filtration system as a result of reliability analysis and Life Cycle Costing 487
J. Szymik-Gralewska & I. Zimoch

Critical infrastructure

Methods of visualizing the risk of lack of water supply 497
I. Piegdoń & B. Tchórzewska-Cieślak

Electrical engineering

Concept for development of safety-related filters 507
O. Krini, J. Krini & J. Börcsök

Energy production and distribution

Heat Supply System reliability management 513
B. Babiarz

Uncertainty in the regulation systems of temporary organizations: A challenge for improving the organizational reliability 521
F. Mazzorana-Kremer, C. Martin & J.L. Wybo

Solutions and safety barriers: The holistic approach to risk-reducing measures 531
A. Sevcik & O.T. Gudmestad

A multi-criteria decision model to mitigate the operational risks of offshore wind infrastructures 539
M. Shafiee & A. Kolios

Manufacturing and supply chain/logistic systems

Evaluation of operational reliability of the supply chain in terms of the control and management of logistics processes 549
I. Jacyna-Gołda

Effectiveness of national transport system according to costs of emission of pollutants 559
M. Jacyna, K. Lewczuk, E. Szczepański, P. Gołębiowski, R. Jachimowski, M. Kłodawski, D. Pyza, O. Sivets, M. Wasiak, J. Żak & I. Jacyna-Gołda

Experiments for PHM: Needs, developments and challenges 569
X.-Y. Li, L. Liu, R. Kang, D. Xu, F. Sun & J. Lee

Maritime transportation

Effects of external audits on safety management systems: A case study of the Norwegian-managed maritime industry 577
J.F. Aae, A.K. Sydnes & C. Heggøy

Review of acceptable risk levels of bridge collapse in respect of ships collisions 585
L. Gucma

A new approach for evaluating the disruption risks of a seaport system 591
A. John, R. Riahi, D. Paraskevadakis, A. Bury, Z. Yang & J. Wang

Methodology for evaluation of barriers for rig move operations 599
E. Okstad, S. Hauge, B.A. Mostue & H. Skår

Natural resources and environment

Performance of skimmers in the Arctic offshore oil spills 607
M. Naseri & J. Barabady

Nuclear engineering

Rethinking nuclear safety management: Injunction as a meta-concept 615
S. Agulhon, D. Pécaud & F. Guarnieri

Using IRIDM & VTA to support the risk management of the research reactor Maria 621
M. Borysiewicz, K. Kowal & S. Potempski

Evaluation of risk impact of equipment ageing and asset management for LWR Gen II and III NPPs in the horizon 2020 627
S. Martorell, I. Martón, S. Carlos & A.I. Sánchez

Rail transportation

Safety of the new control command European System 635
M. Siergiejczyk, M. Pawlik & S. Gago

Software systems

All swept up: An initial classification of NSA surveillance technology 643
M. Cayford, C. van Gulijk & P.H.A.J.M. van Gelder

Study of the security of processes running in computer operating systems 651
I.J. Jóźwiak & A. Szleszyński

Control-in-the-loop Model Based Safety Analysis 655
P.-Y. Piriou, J.-M. Faure & J.-J. Lesage

Developing a shared information surface for offshore work permits 663
S. Sarshar, G. Rindahl, C.S. Olsen, J.M. Røsok, M. Eskerud, O.G. Nedrebø, P.J. Berg & G. Misund

Other reliability and safety areas

Graphical technique for practical dependability management 671
L. Barberá, A. Crespo, K. Kobbacy & P. Viveros

A discussion of the risk-management and the rule-compliance regulation regimes in a security context 677
S.H. Jore & A. Moen

Risk management in anchor-handling operations: The balance between control and autonomy 685
J. Røyrvik, K. Skarholt, G.M. Lamvik & J.R. Jonassen

Safety and environmental control of industrial activities in France: A negotiated relationship 695
V. Sanseverino-Godfrin

Risk assessment methods for improving urban security 701
C. Schoppe, J. Zehetner, J. Finger, D. Baumann, U. Siebold & I. Häring

Abstract representation of power system networks as a function of regularity properties 709
A.B. Svendsen, T. Tollefsen, R.F. Pedersen, K.P. Petursson, D. Patel & O.D. Lampe

Drinking water quality aspect in ensuring the safety of water supply systems 717
I. Zimoch, E. Łobos & T. Żaba

Dynamic reliability

Aeronautics and aerospace

Using dynamic risk modelling in Single European Sky Air Traffic Management Research (SESAR) 729
N. Fota, M.H.C. Everdij, S.H. Stroeve, T. Kråkenes, I. Herrera, J. Quiñones, T. Contarino & A. Manzo

Civil engineering

Modification of response spectra by probabilistic approach 739
V. Salajka, J. Kala, Z. Cada & P. Hradil

Maritime transportation

Dynamic Positioning systems with emphasis on harsh climate conditions 743
T. Li, O.T. Gudmestad & A. Barabadi

Mechanical engineering

Wear time-dependent reliability analysis using Bayesian inference 751
J. Feng, J. Zhang, J. Si & P. Wang

Nuclear Engineering

RAVEN and dynamic probabilistic risk assessment: Software overview 759
A. Alfonsi, C. Rabiti, D. Mandelli, J. Cogliati, R. Kinoshita & A. Naviglio

Integrated Deterministic Probabilistic Safety Analysis (IDPSA) of a fire scenario 767
M. Kloos, J. Peschke & B. Forell

Dynamic reliability models for multiple dependent competing degradation processes 775
Y.H. Lin, Y.F. Li & E. Zio

Expert methods in system safety and reliability

Aeronautics and Aerospace

Development of a new algorithm for optimal multi-level redundancy allocation 785
M.A. Farsi

Aircraft crew escape system assistant 791
N. Grzesik & R. Czapla

A fuzzy system for evaluation of baggage screening devices at an airport 797
J. Skorupski & P. Uchroński

Energy production and distribution

Quantification and modelling of epistemic uncertainties for availability risk of future offshore wind farms using expert judgment 805
A. Zitrou, T. Bedford & L. Walls

Maritime transportation

Expert method and real time simulation in navigational safety analysis 813
T. Abramowicz-Gerigk

Mechanical engineering

Causal modeling in industrial Reliability and Maintenance Management 819
Y. Pang & G. Lodewijks

Other reliability and safety areas

The application of risk and reliability techniques to acquire knowledge in the development of expert system for fault diagnosis 825
E.M.P. Hidalgo & G.F.M. de Souza

Failure identification and degradation processes

Aeronautics and aerospace

Life and reliability evaluation of tuner by Constant-Stress Accelerated Degradation Testing method 837
F. Sun, X. Li & T. Jiang

Estimation of lifetimes of components that operate under ageing-attributable wearing conditions 843
H. Tomaszek, M. Zieja & M. Ważny

A Physics-of-Failure-based approach for failure behavior modeling: With a focus on failure collaborations 849
Z. Zeng, R. Kang & Y. Chen

Electrical engineering

Fault diagnosis method for circuit board based on BP neural networks 857
Y. Peng & J. Shi

Electronic industry

Physics of Failures (POF) version B for MTBF prediction 863
Y. Bot & J.B. Bernstein

An adaptive fault detection threshold hardware circuit design to reduce False Alarms 867
Y. Cui, J. Shi, L. Chen, K. Liu & W. An

Energy production and distribution

MUSTADEPT: A tool for the analysis of industrial equipment degradation 873
M. Compare, L. Legnani & E. Zio

Information technology and telecommunication

Provision of the reliable video surveillance services in heterogeneous networks 883
P. Lubkowski, D. Łaskowski & E. Pawlak

Maritime transportation

Identification of degradation processes of seabed protection in ports 889
T. Abramowicz-Gerigk

Mechanical engineering

The use of Self-Organizing Maps for diagnosing faults in motor bearings 895
S. Al-Dahidi

Selected safety aspects of polymer composites with natural fibres 903
A. Krzyżak & D. Vališ

Application of selected diffusion processes on system state assessment 911
D. Vališ & O. Pokora

Nuclear engineering

A modified Auto Associative Kernel Regression method for robust signal reconstruction in Nuclear Power Plant components 917
P. Baraldi, F. Di Maio, P. Turati & E. Zio

Experimental design for the evaluation of Critical Heat Flux of small-scale pressurized nuclear reactors 923
J.P. Duarte, J.R.C. Piqueira & M.E. Taqueda

Road transportation

The stochastic approach in road network vulnerability analysis 929
M. Bíl & R. Vodák

Analysis of brake testing methods in vehicle safety 933
A. Bojko, A.I. Fedotov, W.P. Khalezov & M. Młyńczak

Hilbert-Huang Transforms for fault detection and degradation assessment in electrical motors 939
M. Rigamonti & S. Rantala

Other reliability and safety areas

Volatility regime switching and jump-diffusion process for prognosis: Case of equity price modeling 945
H. Ghamlouch, M. Fouladirad & A. Grall

Performance evaluation of Emergency Response Plans using a Multi-State System approach 953
C. Girard, E. Piatyszek, P. David & J.-M. Flaus

Human factors and human reliability

Aeronautics and aerospace

The model of a pilot competency as a factor influencing the safety of air traffic 963
J. Skorupski & M. Wiktorowski

Human Dependability Model for space application—the HuDeM project 971
T.M. Stene, S.O. Johnsen & S. Ophof

Towards safer air traffic: Optimizing ATC controller workload by simulation with reduced set of parameters 979
B. Számel & G. Szabó

Human reliability test and identification of HCR model basic parameters for multi-factor "Meta-Operation" 989
Y. Yang, X. Chen, J. Zhang & R. Kang

Chemical process industry

Statistical analysis of past accidents and a methodology (MEDIA) for Human and Organizational Factors assessment in process industries 997
M. Ahmad, M. Pontiggia & M. Demichela

Predictive Human Error Analysis in Permit To Work system in a petrochemical plant 1007
M. Jahangiri, F. Zare Derisi & N. Hobobi

Critical infrastructure

Anticipating impacts of change on individual behaviors within a perspective of safety management 1011
T. Côte, E. Rigaud & E. Garbolino

Modeling and assessment of Performance Shaping Factors in construction 1019
Y. Xenidis & K. Giannaris

Energy production and distribution

The impact of the use of subcontracting on organizational reliability and safety 1027
C. Guers, C. Martin & J.L. Wybo

Human error analysis: Review of past accidents and implications for improving robustness of system design 1037
R. Moura, M. Beer, E. Patelli, J. Lewis & F. Knoll

Operational and organizational barriers as means of enhancing safety and learning 1047
T.J. Steiro, E. Hansson Blix, J. Seljelid, T.S. Johansen, R.J. Bye, H.N. Hansen & A. Doumit

Natural resources and environment

Presumptions of culture: Applications and safety implications 1057
F. Størseth

Nuclear engineering

Coding scheme to measure the operator's workload in advanced Main Control Room 1065
S. Kim, Y. Kim & W. Jung

A survey of Bayesian Belief Network Applications in Human Reliability Analysis 1073
L. Mkrtchyan, L. Podofillini & V.N. Dang

Aggregating expert-elicited error probabilities to build HRA models 1083
L. Podofillini, L. Mkrtchyan & V.N. Dang

Other reliability and safety areas

Organizational factor inclusion in Human Reliability Analysis (HRA) tools 1093
N. Balfe & S. Cromie

Design methods of reducing human error in practice 1101
M. Butlewski, M. Jasiulewicz-Kaczmarek, A. Misztal & M. Sławińska

Maintenance modelling and optimisation

Chemical process industry

A hierarchical framework for the measurement of maintenance efficacy and efficiency using performance indicators 1109
G.M. Galante, R. Inghilleri & C.M. La Fata

Civil engineering

State of the art in Operation and Maintenance planning of offshore wind farms 1119
M. Asgarpour & J.D. Sørensen

Critical infrastructure

Maintenance of power systems considering time-dependent uncertainty 1127
T. Iesmantas & R. Alzbutas

Energy production and distribution

Decision-making support for maintenance optimisation of natural gas compressor stations 1133
J. Blondel, L. Marle, O. Mozar, A. Abdesselam & F. Brissaud

Optimization of maintenance and operational policies of an offshore wind farm subject to stochastic wind conditions 1141
B. Castanier, C. Pehlivan & T.G. Yeung

An age-based preventive maintenance for offshore wind turbines 1147
F.P. Santos, A.P. Teixeira & C. Guedes Soares

Availability modelling and analysis of an offshore wind turbine using Extended Coloured Stochastic Petri Nets 1157
P. Zeiler & B. Bertsche

Manufacturing and supply chain/logistic systems

Maintenance in availability of weapon systems under combat operation—optimization possibilities 1167
T. Smal

Maritime transportation

Optimum CTV fleet selection for offshore wind farm O&M activities 1177
Y. Dalgic, I. Dinwoodie, I. Lazakis, D. McMillan & M. Revie

Mechanical engineering

Practical aspects of the application of RCM to select optimal maintenance policy of the production line 1187
M. Jasiulewicz-Kaczmarek

Hidden Markov Models for diagnostics and prognostics of systems under multiple deterioration modes 1197
T.T. Le, F. Chatelain & C. Bérenguer

Nuclear engineering

Application of the Maintenance Rule to Nuclear Power Plant systems through Bayesian Networks 1205
D.P. Dionizio, P.L.C. Saldanha & P.F. Frutuoso e Melo

Experience on risk-informed approach to Allowed Outage Time changes due planned maintenance 1211
P.L.C. Saldanha & P.F. Frutuoso e Melo

Rail transportation

Expert system for means of transport maintenance processes performance. A comparative analysis for various types of rail vehicles 1217
T. Nowakowski & S. Werbińska-Wojciechowska

A Colored Petri Net model for railway track maintenance with two-level inspection 1227
H. Shang & C. Bérenguer

Analysis of the process of unloading containers at the inland container terminal 1237
M. Zając & J. Świeboda

Return logistics/waste management

Reliability based model of the cost effective product reusing policy 1243
A. Jodejko-Pietruczuk & M. Plewa

Other reliability and safety areas

Asset maintenance optimization: The case-study of an offshore wind farm 1249
Y. Bot & D. Azoulay

Maintenance planning for drum shearer machine based on its reliability characteristics and economical sensitivity analysis 1257
S.H. Hoseinie, B. Ghodrati & U. Kumar

A guide for Block Inspection Policy implementation 1263
A. Jodejko-Pietruczuk & S. Werbińska-Wojciechowska

Availability model of technical objects—block inspection policy implementation 1275
A. Jodejko-Pietruczuk & S. Werbińska-Wojciechowska

Condition-based maintenance policies for multi-component systems with Lévy copulas dependence 1281
H. Li, L. Dieulle & E. Deloux

Application of standards in reliability prognosis of braking system of moving walks 1289
E. Rogova, G. Lodewijks & Y. Pang

Occupational safety

Electrical engineering

A Bayesian population variability analysis for estimation of the work time loss distributions due to occupational accidents 1301
M.C. Moura, R. Azevedo, E.L. Droguett, L. Rego, W. Jorge & R. Vilela

Manufacturing and supply chain/logistic systems

Continuous monitoring of at-risk behaviours: A risk-based statistical control method 1311
D. Masi & P. Trucco

Enhancing the implementation of Occupational Health and Safety interventions through a design of the socio-technical interaction 1319
D. Masi, E. Cagno, P. Hasle & S. Farnè

Return logistics/waste management

A risk-based approach to manage the Occupational Hazards in the Arctic drilling waste handling practices 1329
Y.Z. Ayele, A. Barabadi & J. Barabady

Other reliability and safety areas

Estimating individual occupational risk using registration data 1335
P.H.G. Berkhout & M. Damen

Quantification of risk rates of occupational accidents 1345
I.A. Papazoglou, O. Aneziris, L.J. Bellamy, M. Damen, B.J.M. Ale, H.J. Manuel & J.I.H. Oh

Quantitative risk assessment

Aeronautics and aerospace

Reliability assessment method for Ion thruster based on competing failure analysis and performance degradation data 1357
Z. Zheng, S. Dong, L. Zhang, D. Xu, H. Tian & T. Zhang

Chemical process industry

Comparison of risk profiles for chemical process plants using PLATYPUS 1363
C. van Gulijk, B.J.M. Ale, D. Ababei & M. Steenhoek

The use of the combination of indexing and semi-quantitative methods in audits for individual risk assessment in the field of fire and explosion protection 1369
A. Leksin, U. Barth, D. Adeulov & R. Mock

Estimation of the impact probability of fragments produced by explosions of vessels: A case study 1377
M.F. Milazzo, R. Lisi, G. Consolo & G. Maschio

Dynamic risk assessment: Development of a basic structure 1385
N. Paltrinieri & P. Hokstad

Joint applicability test of software for laboratory assessment and risk analysis 1393
D.N. Pluess, Th. Meyer, J. Mašin, P. Mikulášek & M. Ferjenčik

Is a QRA-based method suitable to guide Land Use Planning decisions in India? 1401
A. Sengupta, D. Bandyopadhyay, C.J. van Westen & A. van der Veen

Civil engineering

The effect of maintenance on inflation correction in Dutch PPP projects 1411
D.S. Vervoort

Handling dependencies in Probabilistic Risk Assessments using Evidential Networks 1421
D. Wang, Z.J. Cheng, P. Jiang & B. Guo

Critical infrastructure

The use of geoevents in the risk management of Wastewater Treatments 1431
G. Ancione, M.F. Milazzo & G. Maschio

Utilizing knowledge-to-number-processes in smaller and less resource intensive risk assessments 1439
T. Askeland & R. Flage

Risk assessment of ground water sources for emergency supply 1447
F. Bozek, L. Jesonkova, A. Pawelczyk, Z. Malek & J. Dvorak

Study of volcanic Na-Tech risks in primary Waste Water Treatments 1453
M.F. Milazzo, G. Ancione, E. Salzano & G. Maschio

Optimum concept of management and trade-off with risks 1463
D. Prochazkova

Possibilistic risk analysis of failure in water supply network 1473
B. Tchórzewska-Cieślak, K. Boryczko & I. Piegdoń

Electrical engineering

Multidimensional risk to networks of distributed systems 1481
T.V. Garcez & A.T. de Almeida

Mathematics of PRA applied to Distributed Generation curtailment in saturated grids 1489
P.E. Labeau, F. Faghihi, J.C. Maun, V. De Wilde & A. Vergnol

Energy production and distribution

Priorities assignment for actions in a pipeline: A decision model to evaluate multiple objectives 1497
M.H. Alencar, M.F. Marsaro & A.T. de Almeida

Risk assessment in heat supply system 1501
B. Babiarz

Vulnerability of Energy Infrastructure to intentional attacks—the interplay of resource, conflict and security 1507
P. Burgherr, J. Giroux & M. Spada

Solar storm impact on critical infrastructure 1515
O. Sokolova, P. Burgherr & W. Collenberg

Accident risk assessment for deep geothermal energy systems 1523
M. Spada, E. Sutra, S. Wolf & P. Burgherr

Information technology and telecommunication

Enhancement of IT Risk Assessments by UML 1531
R. Mock, B. Truninger, P. Brunner & T. Hruz

Maritime transportation

Quantitative risk assessment of new ship designs in damage conditions 1539
M.K. Gerigk

Review of risk concepts and perspectives in risk assessment of maritime transportation 1547
F. Goerlandt & J. Montewka

Risk based assessment on increased gas safe machinery spaces of liquefied natural gas fuelled ship 1555
X.J. Li & R.P. Zhou

Semi-qualitative method for ship collision risk assessment 1563
W. Zhang, J. Montewka & F. Goerlandt

Mechanical engineering

RAPP method: Failure analysis and risk determination in automobile fleets within the case study electric actuator 1573
S. Bracke & S. Sochacki

Natural resources and environment

Composite methodology for tsunami vulnerability assessment based on the numerical simulation of 1755 Lisbon tsunami—application on two Portuguese coastal areas 1581
J.L. Barros, A. Emídio, A. Santos & A.O. Tavares

Monte Carlo simulation and Bayesian Evidence Synthesis 1589
U. Sahlin & Y. Jiang

Nuclear engineering

Amendments of the existing guidance on PSA application to nuclear power plants in Germany 1599
H.P. Berg, M. Krauß & M. Röwekamp

Focus areas for a Level 2 PSA that supports a site NPP risk analysis 1605
D.M. Helton, M. Zavisca & M. Khatib-Rahbar

A PSA Level-1 method with repairable components: An application to ASTRID Decay Heat Removal systems 1611
R. Kumar, S. Bechta, P. Kudinov, F. Curnier, M. Marquès & F. Bertrand

Effect of human factor in the analysis of changes to Limiting Conditions for Operation (LCO) applied to Residual Heat Removal System 1619
S. Martorell, I. Martón, P. Martorell & M. Saiz

Application of PSA for design optimization of VVER 440/213 1629
P. Picca, F. Pierro, M. Giovannini, J. Cech, P. Baumeister & J. Prochaska

Rail transportation

Deriving a distribution for accident severity from an F-N curve 1635
J. Braband & H. Schäbe

Geospatial modelling of rail safety hazards 1639
D.J.K. Griffin

Comparing the two methods for judging changes in European railways and in European nuclear safety 1649
N. Petrek & H.P. Berg

Road transportation

Combination of technological and economical risk assessment using the Monte-Carlo-Simulation 1655
F. Plinke, D. Althaus, A. Braasch & A. Meyna

The results of a systematic study of the risks associated with the transportation of hazardous substances 1663
D. Prochazkova, J. Prochazka & H. Patakova

Preference risk assessment of hazardous substances road transportation 1671
D. Rehak, A. Bernatik & P. Novotny

Other reliability and safety areas

Quantifying MSD risks through Job Hazard Analysis 1677
L. Dement

Handling epistemic uncertainty in the Fault Tree Analysis using interval-valued expert information 1683
M. Francese, G.M. Galante, C.M. La Fata & G. Passannanti

Expressing and communicating uncertainty and bias in relation to Quantitative Risk Analysis 1691
F. Goerlandt & J. Montewka

Safety analysis and CFD dispersion simulation of cryogenic release in a deep underground large scale cryogenic installation 1701
E.C. Marcoulaki, A.G. Venetsanos, M. Konstandinidou & I.A. Papazoglou

Reliability and safety based system design

Aeronautics and aerospace

European survey on safety methods application in aeronautic systems engineering 1711
A. Berres, H. Schumann & H. Spangenberg

Semi-formal static and dynamic modeling and categorization of airport checkpoints 1721
P. Renger, U. Siebold, R. Kaufmann & I. Häring

Chemical process industry

Achieving safe designs through evaluation of options at the conceptual level of safety system design 1733
E. Alijagic & V.N. Dang

Civil engineering

Conventional correlation factors in the safety analysis of stochastic systems 1741
O. Lukoševičienė & A. Kudzys

Safety-based approach in multifunctional building design 1749
A. Taraszkiewicz & M.K. Gerigk

Electrical engineering

Management of controls of fire protection systems in Switzerland 1755
E. Nachtigall & S. Metzger

Electronic components with time-dependent failure rates—reasons, values and consequences 1761
P. Zeiler, O. Koller & B. Bertsche

Electronic industry

Availability and reliability evaluation of systems periodically maintained 1771
N. Hu, J. Huang, Ch. Yang, Y. Zheng & O. Dong

Maritime transportation

Reliability and safety based design of lifesaving appliances systems 1777
Z. Burciu

Nuclear engineering

Nuclear power plant safety improvement with new system for safety injection 1783
B. Gjorgiev & A. Volkanovski

Rail transportation

A systematic approach for defense against transient failures 1791
H. Schäbe & I. Shubinski

Reliability allocation for a system with complex redundancy 1797
Z. Vintr & T. Vintr

Other reliability and safety areas

Effective searching process used in obtaining Pareto solutions of two-objective network design problem 1801
N. Takahashi, H. Yamamoto, T. Akiba & K. Shingyochi

Reliability and safety data collection and analysis

Aeronautics and aerospace

SYMBAD—Artificial Neural Networks in furtherance of managing aircraft testing 1811
W. Kosiński, J. Wójcik & M. Zieja

Accelerated Life Test method for satellite electronic instrument 1817
D. Shu, Z. Liang, Z. Zhiteng & M. Haibo

Reliability of the airlines operations system 1823
A. Słodownik & J. Żurek

Quantitative evaluation on storage reliability of pyrotechnics based on thermodynamic characteristic of dynamite and performance degradation data 1829
Z. Wan, W. Hang & C. Hai Long

Agriculture and food industry

Telematics used in the campaigns machinery safety management systems 1833
J. Napiórkowski, P. Szczyglak & K. Kołakowski

Chemical process industry

Collection and analysis of failure data for pressure equipment 1841
P.A. Bragatto, S. Ansaldi, C. Delle Site & P. Agnello

Reliability analysis of prototypes based on small and heterogeneous test data volumes. Case study: Organic fibre prototype analysis 1849
A. Lücker, M. Hinz, S. Bracke & G. Knübel

How to present and understand uncertainty of production assurance analyses with respect to data quality 1857
C. Persskog-Lundtofte, S. Isaksen & L.M. Pedersen

Critical infrastructure

Universal method of battery life prediction 1865
Y. Hanyu, T. Yamamoto, T. Ezawa & A. Itakura

Electronic industry

Reliability prediction of electronic boards by analyzing field return data 1871
S.V. Comert, H. Yadavari, M. Altun & E.N. Erturk

Energy production and distribution

A double-loop Monte Carlo approach for Part Life Data Base reconstruction and scheduled maintenance improvement 1877
F. Di Maio, M. Compare, S. Mattafirri & E. Zio

Using field experience in the treatment of Common Cause Failures in reliability assessment 1885
S. Hauge, S. Håbrekke & M.A. Lundteigen

A geometric test for the analysis of contingency tables 1895
J. Quigley & K.J. Wilson

Assessment of a remaining working life of energetic devices using service data 1903
M. Sykora, M. Holicky, J. Marková & K. Presl

Information technology and telecommunication

Model for Information Quality determination of teleinformation systems of transport 1909
M. Stawowy

Manufacturing and supply chain/logistic systems

A framework proposal to analyse the performance of assets under complex system 1915
T. Grubessich, E. Johns, P. Viveros, R. Stegmaier & F. Kristjanpoller

Proven in use in the machine tool industry for demonstrating the quantitative functional safety according to EN ISO 13849-1 1925
B. Günnel, A. Meyna, M. Schlummer, H. Mödden & A. Broos

Mechanical engineering

Probabilities in safety of machinery—Part 1: Risk profiling and farmer matrix 1933
A. Bornemann, Y. Froese, L. Landi & H. Mödden

Probabilities in safety of machinery—Part 2: Theoretical and practical design 1943
A. Bornemann, Y. Froese, L. Landi & H. Mödden

Research on reliability qualification test design by considering inheritance factor 1951
Y. Wang, D. Xu & L. Liu

Optimal design on Accelerated Degradation Testing with Gamma process for reliability demonstration 1957
C. Zhang, X. Lu, X. Chen & Y. Wang

Road transportation

One producer, two brands: A comparison of car operating conditions 1965
M. Jadwinska, T. Siekierka & M. Zając

Waterborne transportation

Ship voyage characteristics in Wuhan Yangtze River Bridge waterway 1969
Y.-P. Zhou, L.-Z. Sang, Z. Mao & Q. Wu

Other reliability and safety areas

Fleet-level reliability estimation of repairable units 1977
A.H.S. Garmabaki, A. Ahmadi & J. Block

Reliability and safety education and training

Nuclear engineering

Learning from failures: The case of Deepwater Horizon disaster 1985
A.W. Labib

The representation of nuclear power in cinema: The contribution of a filmic analysis to understanding the public debate 1993
A. Portelli, C. Martin & F. Guarnieri

Road transportation

On designing educational aids for users' safety in road tunnels 2001
K. Chatzoglou, E. Rokou, I.P. Tatsiopoulos & K. Kirytopoulos

Other reliability and safety areas

Public buildings safety: Addressing a pilot evacuation exercise 2009
A. Santos & M. Queirós

Simulation methods in system safety and reliability

Aeronautics and aerospace

A safety analysis via minimal path sets detection for object-oriented models 2019
C. Schallert

The use of on-board flight recorder in the modeling process of aircraft landing operations 2029
P. Stańczyk & A. Stelmach

Reliability analysis for Runway Overrun using subset simulation 2035
K. Zwirglmaier, L. Drees, F. Holzapfel & D. Straub

Chemical process industry

A meta model framework for risk analysis, diagnosis and simulation 2043
H. Kanj & J.-M. Flaus

Critical infrastructure

Proposing a multi-layer modeling framework for complex infrastructure systems 2051
C. Nan & G. Sansavini

Hybrid modeling and simulation approach selection to the reliability and vulnerability analysis of Critical Infrastructures 2059
G. Sansavini, C. Nan & W. Kröger

Energy production and distribution

Time dependent gas transmission network probabilistic simulator: Focus on storage discharge modeling 2069
V. Kopustinskas & P. Praks

Information technology and telecommunication

Weekly availability changes of web applications implemented in virtualized environment 2077
T. Walkowiak

Manufacturing and supply chain/logistic systems

Dynamic approach to modeling MTBF/MTTR in industrial and logistics systems 2085
P. Hoffa & P. Pawlewski

Maritime transportation

A new Monte Carlo method for environmental contour estimation 2091
A.B. Huseby, E. Vanem & B. Natvig

On multistate technical system operation process influence on its reliability 2099
K. Kołowrocki, E. Kuligowska & J. Soszyńska-Budny

Mechanical engineering

Uncertainty improving in importance sampling: An integrated approach with fuzzy-cluster sampling 2107
M. Nadjafi, M.A. Farsi & A. Najafi

Medicine and health service

Conversion of a based risk model into a simulation model for simulation and analysis 2113
K. Negrichi, J.-M. Flaus & M. Di Mascolo

Nuclear engineering

Common cause failures modelling by means of Coloured Petri Nets for dependability assessment of a control system of nuclear power plant 2121
N. Brînzei, G. Deleuze, N. Villaume & J.F. Pétin

Propagation of aleatory and epistemic uncertainties in quantification of systems failure probabilities or safety margins 2131
M. Marquès

Road transportation

Safe level of redundancy in Discrete Transportation Systems 2141
D. Caban & T. Walkowiak

Using Petri-Net analysis for advanced reliability analysis of polymer electrolyte membrane fuel cells 2147
M. Whiteley, J. Leigh, A. Fly, L.M. Jackson & S.J. Dunnett

Waterborne transportation

Analysis of ship navigation behaviors in the Wuhan Yangtze River Bridge waterway 2155
X. Chen, L.-Z. Sang, Z. Mao & Q. Wu

Other reliability and safety areas

A novel methodology for availability assessment of complex load sharing systems 2161
F. Kristjanpoller, P. Viveros, A. Crespo, R. Mena & R. Stegmaier

Structural reliability and safety

Aeronautics and aerospace

Life distribution and P-S-N curve analysis of TC21 titanium alloy joint with Electron Beam Welding in ultra-high cycle fatigue regime 2169
Z. Zhiteng, D. Shu, Z. Liang & X. Danjun

Civil engineering

Optimal design of ground-mounted solar systems 2175
R. Boccara, D. Diamantidis & M. Sykora

Approximate quantification of the robustness index of concrete beams subjected to deterioration 2183
W. Botte, R. Caspeele & L. Taerwe

A condition-based deterioration model for the crack propagation in a submerged concrete structure 2193

Preface

Within last fifty years the performance requirements for technical objects and systems were supplemented with: customer expectations (quality), abilities to prevent the loss of the object properties in operation time (reliability and maintainability), protection against the effects of undesirable events (safety and security) and the ability to restore performance (resilience). The high regard that firms and researchers are paying to risk, safety and dependability is probably caused by the intensity of catastrophes that seem to have increased on a global scale. To the most publicized disruptions belong: the terrorist attacks on the World Trade Center on September 11, 2001, the SARS epidemic in South-East Asia in 2003, the natural disaster of Hurricane Katrina in 2005 and Fukushima nuclear power plant disaster in 2011. Thus, the need to adapt the operation of complex systems in such an uncertain and volatile environment has caused the need to formulate new and well established achievements associated with modeling, testing and evaluation of the reliability and maintainability, safety and security, vulnerability and resilience. The concept of a complex system applies not only to the technical systems but also the infrastructure of major importance for social life such as transport and logistics infrastructure, buildings, power systems, water distribution systems or health service. The problem applies to the entire lifetime of the system from the design phase through manufacturing, execution, operations, maintenance and renovation until decommissioning decision. We hope the ESREL 2014 conference will provide an valuable platform for presenting and discussing developments and applications related to indicated problems.

ESREL is a series of annual conferences promoted by the European Safety and Reliability Association ESRA, which dates back to 1989 (in La Baule, France), but was not referred to as an ESREL conference before 1992 (in Lyngby, Denmark). The Conference has become well established in the international community, attracting a good mix of academics and industry participants that present and discuss subjects of interest and application across various industries in the fields of Safety and Reliability. This is the 24th edition of its annual conference that takes place in various countries in Europe. Till now it was organized in: ‘13 Nederland, ‘12 Finland, ‘11 France, ‘10 Greece, ‘09 Czech Republic, ‘08 Spain, ‘07 Norway, ‘06 Portugal, ‘05 Poland, ‘04 Germany, ‘03 Netherlands, ‘02 France, ‘01 Italy, ‘00 United Kingdom, ‘99 Germany, ‘98 Norway, ‘97 Portugal, ‘96 Greece, ‘95 United Kingdom, ‘94 France, ‘93 Germany, ‘92 Denmark, ‘ 91 United Kingdom.

This book contains the proceedings of the ESREL 2014 Conference, held in Wroclaw, Poland and organized by the Wroclaw University of Technology, the Polish Safety and Reliability Association (PSRA) and the European Safety and Reliability Association (ESRA). Originally, approximately 650 abstracts were submitted and following the review by the Technical Programme Committee about 320 full papers in 17 methodological tracks were accepted and are included in the program. The review process was mainly organised by the Technical Area Coordinators and the process was made by a large number of reviewers, which are gratefully acknowledged for their contributions to the improvement of quality of the papers. The review process is an important aspect of the Conference and contributes to the fact that this series of Conferences has been included for the last several years in the ISI citation index, which—at least to academics—is an important feature. This book contains the extended abstracts and a CD with the full electronic text of the papers presented at the ESREL 2014 Conference.

We wish you an interesting and useful reading.

Tomasz Nowakowski
Conference General Chair

Acknowledgements

The conference is organized jointly by Wroclaw University of Technology, Polish Safety and Reliability Association (PSRA) and European Safety and Reliability Association (ESRA). The Editors would like to thank the many contributors for their active participation, which made the organisation of ESREL 2014 possible.

The joint work of the Technical Area Coordinators, the peers involved in the Technical Programme Committee, the reviewers and the organisers of special sessions have resulted in a number of very interesting meetings. Thanks to all the contributors for the participation and effort in the technical programme setting.

Special thanks are sent to honorary patrons of the Conference: prof. Tadeusz Wieckowski, Ph.D., D.Sc. Rector of Wroclaw University of Technology and Rafał Dutkiewicz, Ph.D. President of Wrocław

We would like to acknowledge specially the conference secretariat, all the administrative and technical support at the Wroclaw University of Technology and the local organising committee. We pass special expressions of gratitude to the website administrators. Their many hours of work are greatly appreciated.

Finally the editors would like to thank the authors, session chairs and conference participants without whom there would not have been any conference.

Introduction

The *ESREL 2014* conference covers a number of topics within safety and reliability, and provides a forum for presentation and discussion of scientific papers covering both methodology and applications to a wide range of industrial and problem areas.

METHODOLOGY AREAS

M1. Accident and Incident Investigation and Modelling
M2. Analytical Methods in System Safety and Reliability
M3. Reliability and Safety Management
M4. Dynamic Reliability
M5. Expert Methods in System Safety and Reliability
M6. Failure Identification and Degradation Processes
M7. Human Factors and Human Reliability
M8. Maintenance Modelling and Optimisation
M9. Occupational Safety
M10. Quantitative Risk Assessment
M11. Reliability and Safety Based System Design
M12. Reliability and Safety Data Collection and Analysis
M13. Reliability and Safety Education and Training
M14. Simulation Methods in System Safety and Reliability
M15. Structural Reliability and Safety
M16. Uncertainty and Sensitivity Analysis
M17. Processes Reliability and Safety Modelling

APPLICATION AREAS

T1. Aeronautics and Aerospace
T2. Agriculture and Food Industry
T3. Chemical Process Industry
T4. Civil Engineering
T5. Critical Infrastructure
T6. Electrical Engineering
T7. Electronic Industry
T8. Energy Production and Distribution
T9. Information Technology and Telecommunication
T10. Manufacturing and Supply Chain/Logistic Systems
T11. Maritime Transportation
T12. Mechanical Engineering
T13. Medicine and Health Service
T14. Natural Resources and Environment
T15. Nuclear Engineering
T16. Rail Transportation
T17. Return Logistics/Waste Management
T18. Road Transportation
T19. Software Systems
T20. Waterborne Transportation
T21. Other Reliability and Safety Areas

An incident reporting support system for airline cabin crew

K. Furuta, K. Okano & T. Kanno
Graduate School of Engineering, The University of Tokyo, Tokyo, Japan

T. Mori & S. Shimizu
ANA Strategic Research Institute Co., Ltd., Tokyo, Japan

ABSTRACT: The objective of this work is to propose a method to provide computer supports to field staff, airline cabin crew as an application domain, in making incident reports. Based on the review of accumulated reports and interview to cabin crew, an ontology of cabin services was constructed, which contains structuralized terms on airplane equipment, cabin and flight crew, cabin crew tasks, causality of unsafe events, and so on. The ontology is used to provide skeletal reporting formats depending on the context of reporting. It has been demonstrated through experimental trials that the reporting support system can contribute to efficiency and ease of reporting, while the improvement of report quality was marginal.

1 INTRODUCTION

Minor human errors and equipment failures that are hidden behind serious accidents are called incidents. Previous works such as (Heinrich 1980) revealed the relation between serious accidents and incidents. Heinrich showed from the statistical records of occupational accidents in US that behind one case of accident, 29 cases of medium-scale accidents with injuries and 300 cases of minor events without any losses occur, which are often called near misses.

Most enterprises and institutions in various industries are enforcing their staff to report and analyze information on background and causal factors of medium-scale accidents and near misses. It is possible to reveal the trends and patterns of incident occurrence and to acquire valuable knowledge for preventing serious accidents by systematically analyzing lots of reports; incident reporting is a key activity for engineering reporting culture, which is a component of a safety culture (Reason 1997).

The most famous incident reporting system in aviation is the Aviation Safety Reporting System (ASRS) of US National Aeronautics and Space Administration (NASA). ASRS is expecting a wide range of reporters including pilots, air traffic controllers, cabin crew, and maintenance staff. It does not seem that ASRS reporting forms have any particular theoretical foundations; it is suited for identifying broad trends of incidents rather than for identifying specific problems (Beaubien & Baker 2002). Accident/Incident Data Reporting Program taxonomy or ADREP 2000 (Cacciabue 2000) is the taxonomy supported by the European Union. The ADREP taxonomy covers an extensive range of incidents, and it focuses on human factors. It was, however, developed to be use by trained analysts rather than pilots.

The Human Factors Analysis and Classification System (HFACS) is a general taxonomy of human errors for identifying causal factors of accidents (Shappell & Wiegmann 2000). It is based on Reason's model of human error (Reason 1990). HFACS was not developed to be used directly by pilots, either. The British Airways Safety Information Systems (BASIS) is a software tool for supporting airlines to collect incident reports from pilots and to manag the data (O'Leary 2002). There is little information available about BASIS, but it does not appear that these is any particular theory behind the BASIS development. The Critical Event Reporting Tool (CERT) was developed for supporting pilots' self-report of relevant information by using a schematic map (Wiegmann & von Thaden, 2003). This work demonstrated that a schematic map is effective for pilots to elicit information about why the incident happened rather than what happened.

A problem in incident reporting is that the quality of reports, which includes both the coverage and the accuracy of reported information, depends on the reporters. If the quality of reports is insufficient, it is impossible to obtain useful outcomes from its analysis. Previous studies, however, primarily focused on the analysis phase by trained analysts but less on how to extract necessary information

from reporters efficiently considering the analysis that follows. The reporting systems usable for field staff rather than analysts were sometimes not powerful enough to extract the causal factors.

The aim of this work is to propose a method to provide computer supports to field staff in making incident reports so that information sufficient for incident analysis can be acquired and the quality of incident reports will be improved. This work adopts incident reporting by airline cabin crew as the application domain. Most previous works are interested in incident reporting from pilots rather than cabin crew. Tasks in a cabin are more influenced by situations than those in a cockpit, because cabin crew have to attend passengers; incident reporting support for cabin crew is particularly focused on in this work.

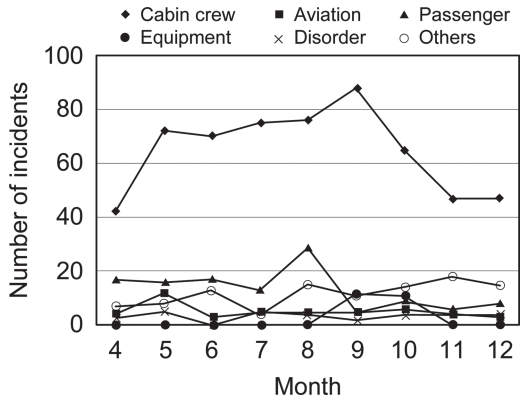

Figure 1. Number of reported incidents for each attribution.

2 ANALYSIS OF APPLICATION DOMAIN

2.1 *Field review*

The role of airline cabin crew as a safety staff is more important than that as a service staff, and the procedures and guidelines as a safety staff are clearly predefined. In order to obtain an overview of cabin services, accumulated incident reports, service manuals, training sessions, briefing about cabin services, and the services during actual flights were reviewed.

An incident that occurred in a cabin is reported following the process below in the target airline company.

1. The crew involved in the incident makes a report using the fixed form after the flight.
2. Another crew who is in charge of checking will supplement the report by interviewing the reporter, if the report submitted is insufficient or ambiguous.
3. The report submitted and checked is proceeded to further analysis.

This work particularly tries to curtail the second step of the above and to make the report quality independent of reporter's skill as much as possible.

The current situation of incident reporting in the field was investigated by reviewing 1,136 cases reported from April to December 2012. The reports are categorized in six classes and the cases that are unrelated to safety issues were omitted from further review here.

Though some reported incidents in cabins are attributable to flight conditions, equipment failures, or passenger behaviors, most of the reviewed cases are related to cabin crew performance, i.e., human errors, regardless of time, crew's experience level, and situation of occurrence. Figure 1 shows the number of reported incidents per month for each attribution.

2.2 *Domain ontology*

Based on the results of field review, an ontology of airline cabin services was constructed. An ontology here means a structured set of concepts and terms that are used by the field staff: cabin crew in this work. The framework of the domain ontology has been chosen so that it matches well incident analysis to be performed using the ontology. The C-mSHELL model, which is obtained from the P-mSHELL model for medical service domains by substituting Customer for the Patient, has been adopted as the framework (Kawano 2002).

The C-mSHELL model consists of six components of Customer, management, Software, Hardware, Environment, and Liveware. In addition to these six components, the tasks allocated to cabin crew and the threats that may disturb cabin services have been added as the top-level nodes of the ontology tree. The ontology will be used for providing various supporting functions to cabin crew in making incident reports.

3 SUPPORTING METHODS

Various methods for incident analysis have been proposed so far, but their basic procedures are similar. The common procedure consists of identification of events that occurred, identification of critical points, analysis of causal factors, proposal of counteractions, and finally assessment of the proposed counteractions.

This work aims to generating high-quality incidents reports uniformly regardless of who made

the reports. The system functions expected from the common procedure of incident analysis are therefore supports for building up event sequences, describing event situations, analyzing causal factors, and proposing counteractions. It is desirable that non-experts of incident analysis can use these functions intuitively, and incident analysis can be applied easily to output data of the system.

Since human errors consist the almost portion of causal factors of incidents in the target domain, the system provides the supports based on the Common Performance Conditions (CPCs), which is the description framework for the context of human performance adopted in the Cognitive Reliability and Error Analysis Method (CREAM) (Hollnagel 1998).

3.1 *Common Performance Condition*

It is assumed in CREAM that human reliability depends heavily on the context of human performance described as a combination of three factors: human, technology, and organization. The original CPC consists of nine items, and each item is scored semi-quantitatively and then the results are aggregated to yield a single score that represents the goodness of context. Since it is recommended in CREAM, CPC has been modified referring to the opinions obtained from field staff of the airline so that it matches the application domain. The modified CPC consists of the following ten items:

1. Effects of cabin environment and team configuration,
2. Parallel tasks performed simultaneously,
3. Available time for executing the task,
4. Availability and familiarity of the manuals,
5. Teamwork of the crew,
6. Usability of the equipment,
7. Role assignment and locus of responsibility,
8. Effects of time of day and time difference,
9. Education and training,
10. Knowledge and experience.

3.2 *4STEP/M*

The counteractions for preventing recurrence of similar incidents are proposed using 4STEP/M, which is a method of enumerating countermeasures against human errors (Miura & Harada 2007). The countermeasures are performed by two phases: prevention of errors and mitigation of negative effects. 4STEP/M provides a framework for enumerating the countermeasures in four steps:

Step1 Minimization of the number of tasks,
Step2 Minimization of error probability,
Step3 Multiple detection of errors,
Step4 Minimization of damage.

Figure 2. Example screen shot of event sequence editing.

4 SYSTEM ARCHITECTURE

4.1 *Input of basic data*

The system architecture is explained following the flow of system use.

If the reporter starts the system, the initiating screen appears prompting the reporter to input basic data of the incident. The basic data include report category, reporter's name and ID, date of reporting, flight number, origin and destination, date and time of incident, aircraft type, reporter's position in the crew, the time interval from reporter's last flight on the same type of aircraft, and the category of incident.

If the reporter has chosen the category of incident, the system provides the standard procedure of the task related to the category referring to the information contained in the domain ontology.

4.2 *Description of event sequence*

A screen as shown in Figure 2 is used for editing event sequences for all the staff involved in the incident. Each row of the boxes in the figure shows the event sequence for a separate member of the related staff. Creation, changing the title, and rearrangement of sequence by drag-and-drop are allowed for each box, which corresponds to a unitary cabin crew task. The reporter enters box titles that represent briefly what happened and arrange them in the order of event occurrence. This operation is repeated to describe all the event sequences.

4.3 *Assessment of CPC*

Having described all the event sequences, assessment of CPC follows. If the reporter clicks on a box, a popup window for CPC assessment for the task unit appears. The reporter will assess ten CPC items in a three-grade scale by choosing one radio button as shown in Figure 4. Descriptions of assessment are different for different CPC items, and they have been determined through consultation with airline cabin crew so that they can easily understand the options. Default options are

Effects of cabin environment and team configuration
- ○ Favorable effects
- ◉ Indifferent/Normal effects
- ○ Unfavorable effects

Parallel tasks performed simultaneously
- ◉ None.
- ○ Some but not so many as makes a problem.
- ○ Too many parallel tasks that exceed capability.

Available time for executing the task
- ◉ Enough time was secured.
- ○ The task was finished but done in a hurry.
- ○ Insufficient time was available for finishing the task.

Description of the procedure in CAM
- ◉ The procedure was clearly described.
- ○ Only necessary items were described.
- ○ No descriptions.

Teamwork of the crew
- ◉ Satisfactory.
- ○ Slightly poor.
- ○ Poor.

Usability of the equipment
- ○ Appropriate / Effective for error prevention.
- ◉ No problems.
- ○ Inappropriate / Likely to cause an error.

Role assignment and locus of responsibility
- ◉ Clearly defined.
- ○ Not necessarily clear.
- ○ Ambiguous.

Effects of time of day and time difference
- ◉ None.
- ○ Some but not so much as make a problem.
- ○ Too many parallel tasks that exceed capability.

Education and training
- ◉ Sufficient.
- ○ Not necessarily sufficient.
- ○ Insufficient.

Knowledge and experience
- ◉ Sufficient.
- ○ Not necessarily sufficient.
- ○ Insufficient.

Figure 3. CPC assessment.

preset and the reporter can skip choosing buttons, if there are no unusual situations with CPC. The assessment result for each item is scored [–1, 0, +1] or [–2, –1, 0] depending on whether the best mark for the item is good (favorable) or normal (no problems).

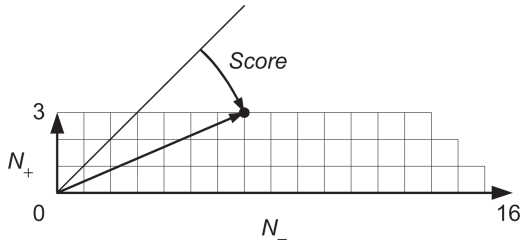

Figure 4. Aggregation scheme of CPC scores.

4.4 *Analysis of causal factors*

After having finished CPC assessment, the system asks the reporter some additional questions for clarifying the context of incident. The system then lists up the candidate factors that may have caused the incident. This judgment is made based on the result of CPC assessment, and the task steps with unfavorable CPC scores are focused on.

CPC scores for different items are aggregated following the work of (Yoshida et al. 2003). Plus scores and minus scores are summed up separately, and then the result is located on the plane as shown in Figure 4, where the horizontal and the vertical axis correspond to the sum of minus scores and that of plus scores respectively. Since the diagonal line represents the neutral situation, the degree of preferable or unpreferable situation is assessed as the deviation from the neutral line, i.e., the arc length normalized by the longest arc. A clockwise deviation corresponds to an unfavorable, and an anticlockwise one to a favorable situation.

The reporter will select some causal factors from the candidates proposed by the system. If the system, however, overlooked any plausible causal factor, the reporter can input an arbitrary causal factor.

4.5 *Proposal of counteractions*

The system asks the reporter some more additional questions, and then it proposes counteractions following the 4STEP/M framework. If the system overlooked any plausible counteraction, the reporter can input an arbitrary counteraction. The system finally prints out the all outcomes of reporting.

5 SYSTEM ASSESSMENT

5.1 *Experimental method*

Two test experiments were conducted, the first experiment for finding out the drawbacks of the original design to improve the system, and the second experiment for assessing usability,

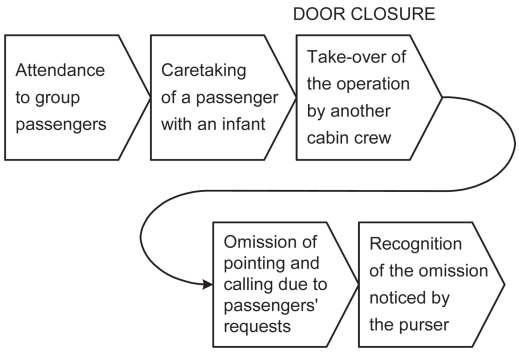

Figure 5. Overview of the test incident scenario.

functionality, effectiveness, and efficiency of the system after modification.

A test incident scenario written in a text was prepared and used in the experiments. The scenario describes a complicated case of omitting a check in door operation that involves more than one cabin crew and passengers. An overview of the scenario is shown in Figure 5. The participants of the experiments read the scenario and then reported the incident in two groups. One group used the support system and then made reports with the current reporting format looking at the outputs of the support system. The other group reported the incident directly without using the support system.

5.2 *Results*

5.2.1 *Usability*

The usability of the system was evaluated by questionnaire to the test users in a five-grade scale, from 1 to five. The average score obtained was 3.2, which means that the participants did not evaluate the system usable. Since the tutorial session for using the system was insufficient, it seems the participants were not accustomed to use the system.

5.2.2 *Functionality*

The radar chart shown in Figure 6 shows the evaluation result of system functionality by questionnaire in a five-grade scale for the following five functions.

1. Describing event sequences in detail,
2. Assessing the context of each step in detail,
3. Proposing the causal factors to be attended,
4. Proposing plausible counteractions,
5. Printing out the results.

The result shows that the participants evaluated the system functionality fairly high except proposing the causal factors to be attended, and printing out the results.

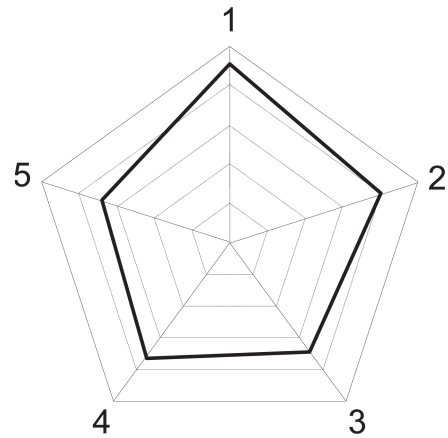

Figure 6. Evaluation result of system functionality.

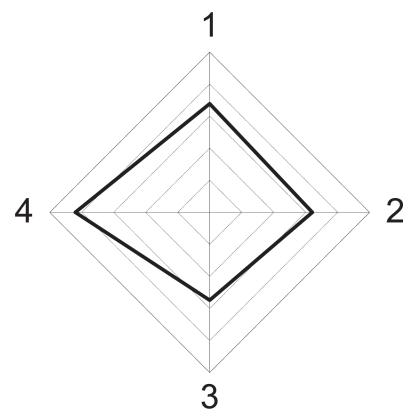

Figure 7. Evaluation result of system effectiveness.

5.2.3 *Effectiveness*

The radar chart shown in Figure 7 shows the evaluation result of system effectiveness by questionnaire in a five-grade scale for the following five aspects.

1. Effectiveness for reporting with ease,
2. Effectiveness for reporting in detail,
3. Effectiveness for reporting in a short time,
4. Effectiveness for clarifying thoughts and analysis.

The participants did not think that the system con tributes to shortening the time of reporting, but they evaluated the system high in terms of clarifying thoughts and analysis.

5.2.4 *Time required for reporting*

The efficiency of the system was assessed by measuring the time required for reporting. Figure 8 compares the time required for reporting between the

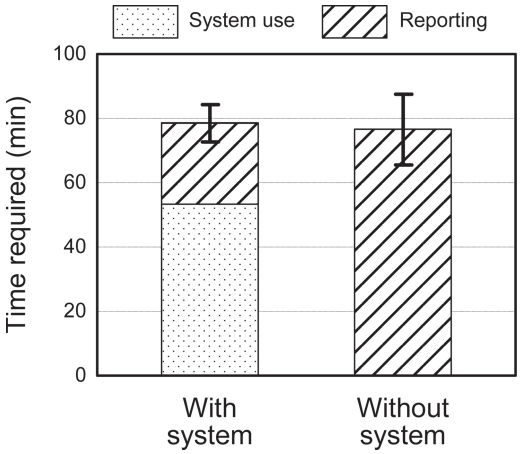

Figure 8. Average time required for reporting.

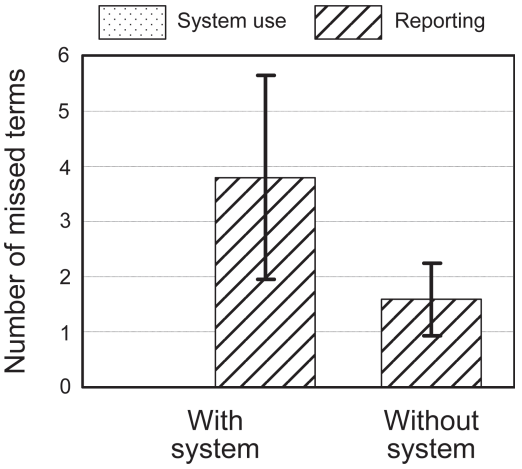

Figure 9. Average number of missed terms.

two groups: with and without using the system. For the group who used the system, the time required for using the system and that for making a report with the fixed format are measured separately.

The average total time for the group with the system was 78.8 ± 5.9 minutes, and it is almost the same as for the group without the system, 76.8 ± 11.1 minutes. If the system can output the results in the fixed reporting format, it is expected that the system will contribute to shortening the time required for reporting considerably.

5.2.5 *Quality of reports*

The quality of the reports that were made with and without using the system was compared. Expert airline staff made an ideal report for the experimental incident scenario and listed up the terms essential for reporting the case. The terms that were missed in the reports generated in the experiment were then counted. For the group who used the system, the count was made both for the system outputs and for the final reports.

Figure 9 shows the result. Those who directly made a report in the fixed format missed some essential terms. Though no missed terms were found in the outputs from the system, those who used the system failed to transcribe some terms into the fixed format of incident reporting. It is expected therefore that such failures can be avoided, if the system can output incident reports in the fixed format directly.

6 DISCUSSION

Extracting relevant information from reporters for incident analysis was achieved by providing guiding frameworks of the information in each step of incident reporting. In particular, since no items for describing context of human performance are given in the present reporting scheme, the analysts have to guess and assess the context from indirect descriptions of the report. The most significant merit of the developed system is that the system can provide a good guiding framework based on CPC for describing and assessing the context.

The time required for using the system alone was cut to one third, though the total time including transcribing the outputs from the system into the present reporting form was almost the same. Direct output in the present reporting form is required for improving thefficiency of reporting with the system. The usability of the system depends highly on users' familiarity to the system and was not necessarily high in the test experiments.

The participants of the experiments made reports reading the written experimental scenario, while they recall their memories in actual reporting. Some of the participants stated that the system will be more useful in the actual than the experimental setting. It is therefore expected that the system can contribute more to improving the efficiency and quality of reporting in actual use.

7 CONCLUSION

A support system of incident reporting for airline cabin crew was developed. The system was assessed by experiments, where the participants read a test incident scenario created from some past cases and made reports with and without using the support system. In addition, the participants answered a questionnaire for subjective assessment. As a

result, it has been demonstrated that the support system can contribute to enhancing the efficiency and ease of reporting, while the improvement of report quality was marginal.

The effect of the environment conditions on the prediction of flammable cloud dispersion

A.M. Schleder & M.R. Martins

E. Pastor & E. Planas
Department of Chemical Engineering, Centre for Technological Risk Studies, Universitat Politècnica de Catalunya—BarcelonaTech, Barcelona, Spain

ABSTRACT: In order to quantify the damage caused by undesired events involving leakages of flammable materials, specific models are used to analyze the spills or jets of gas and liquid, gas dispersion, explosions and fires. The main step of this analysis is to estimate the concentration, in space and time, of the vapor cloud of hazardous substances released into the atmosphere; the purpose is to determine the area where a fire or explosion might occur and the quantity of flammable material in that area. Recently with the computational advances, CFD tools are used to short and medium range gas dispersion scenarios, especially in scenarios where there is a complex geometry. However, the accuracy of the simulations strongly depends on the boundary conditions. Therefore, this study investigates the sensitivity degree of the prediction of cloud dispersion to changes in values of wind speed, ambient temperature, atmospheric pressure and ground roughness. This paper contributes to an appropriate assessment of the effects of these environment conditions to perform an accurate dispersion simulation using CFD tools and therefore contributes to a more effective analysis of the consequences.

1 INTRODUCTION

Specific models are used to evaluate the release and dispersion of flammable substances when an undesired event occurs; the determination of the dispersion features is essential to model the consequences such as fires and explosions. The consequence analysis is used to define the extent and nature of effects caused by such events and thus is of great help when quantifying the damage caused.

Dispersion models estimate the evolution and the features of the cloud, such as concentration, temperature, velocity and dimensions as a function of time and position. In the case of flammable substances, these models facilitate the prediction of an area where a fire or explosion might occur and the quantity of flammable material in that area.

Nowadays, the use of numerical methods associated with different algorithms of Computational Fluid Dynamics (CFD) to determine the concentration of the vapor cloud of hazardous substances released into the atmosphere, in space and time, has grown considerably (Comier 2008, Middha 2009, Dharmavaram, 2005). CFD is found in some commercial software tools such as CFX, FLACS and FLUENT. The CFD tools transform the governing equations of the fundamental physical principles of fluid flow in discretized algebraic forms, which are solved to find the flow field values in time and space (Anderson, 1995).

CFD tools have proven promising to perform analyzes of consequences in environments with complex geometry, as in the comparative study about the use of integral and CFD tools to evaluate cloud dispersion reported by Schleder & Martins (2013). Nevertheless, as reported by Plasmans et al. (2012), previous studies have shown that consequences analysis using CFD are frequently not easily reproduced and, in many occasions, large differences can arise between the simulation results when working with different tools and/or different CFD analysts to assess the same scenario. These problems stem from the fact that the simulation results can be very sensitive to the wide range of computational parameters that must be set by the user; for a typical simulation, the user needs to select the variables of interest, turbulence models, computational domain, computational mesh, methods of discretization, convergence criteria and boundary conditions among others. The boundary conditions, especially the atmospheric conditions, affect directly the dispersion; however, in most

cases, the conditions are not known and approximate values are used to perform the consequences analyses.

In this context, the study presented here intends to investigate the effects of variations on boundary conditions on the simulation of a cloud dispersion. This study is part of a research project that aims to provide key information for decision making about the use of CFD tools on cloud dispersion evaluation for different scenarios of interest, such as those containing barriers to dispersion; and therefore contributing to optimize the accuracy of the results.

In order to perform this analysis, the same scenarios used in a previous study of grid dependence are used (Schleder et al., 2014) in this case to assess the influence of variations on boundary conditions on the predicted values of the cloud features. The variables of interest have been ambient temperature, atmospheric pressure, wind speed and ground roughness. Two scenarios are presented: a former scenario of a jet release of dense gas in open and flat terrain and a similar release with the presence of a fence.

1.1 *Computational Fluid Dynamics (CFD)*

The physical aspects of any fluid flow are governed by three principles: mass is conserved, Newton's second law is fulfilled (also referred as momentum equation) and energy is conserved; these principles are expressed in integral equations or partial differential equations (continuity, momentum and energy equations), being the most common form the Navier-Stokes equations for viscous flows and the Euler equations for inviscid flows.

The CFD tools transform these governing equations of the fundamental physical principles of fluid flow in discretized algebraic forms, which are solved to find the flow field values in time and/or space. Thus, the results obtained by CFD are a set of data which represent the flow field characteristics at discrete points in time and/or space. The application of CFD tools are related with the computational advances, which explains the growing use of CFD in the recent years (Anderson, 1995).

The boundary and initial conditions of the flow dictate the particular solution obtained from the governing equations, and as such the solution of the governing equations must provide a suitable representation of the boundary conditions.

The software FLACS was used to perform this study (GexCon AS, 2013); FLACS incorporates a water-based model for the simulation of pool spreading and vaporization, and the Reynolds Averaged Navier-Stokes (RANS) equations for the simulation of vapor cloud dispersion.

The pool vaporization is evaluated based on heat transfer from the substrate, solar radiation, convective heat transfer from the air, local wind speed, turbulence levels and local vapor pressure. All these variables are calculated at each time step and locally, for each grid cell (Gavelli et al., 2011). The cloud concentration also will be influenced by atmospheric turbulence, atmospheric stability and density changes. FLACS models flow in the atmospheric boundary layer by profiles of wind, temperature and turbulence parameters on the inlet boundaries (GexCon AS, 2013).

As presented by Gavelli et al. (2011), the model available in FLACS solves Reynolds Averaged Navier-Stokes (RANS) equations based on the standard k-ε model of Launder & Spalding (1974). According to HSE (2010), RANS approach is widely accepted and documented; it is based on the concept of separating the fluid velocity components and scalar quantities (pressure, temperature, concentration) into mean and fluctuating components, then transport equations are used to evaluate the model. The standard k-ε model of Launder & Spalding (1974) presents a turbulence model in which the magnitudes of the two turbulence quantities are evaluated: the turbulence kinetic energy k and its dissipation rate ε, which are calculated from transport equations solved simultaneously with those governing the mean flow behavior (Launder & Spalding 1974).

1.2 *The effects of the atmospheric conditions*

As reported by CCPS (1995), to analyze an accidental release it is necessary to define the governing conditions of the discharge scenario and environment. The items that can define these conditions are source term characteristics, environmental conditions, types of releases, possible source scenarios and possible dispersion mechanisms. The release is usually described separating the region analyzed in three sections: first the discharge section, where the release is almost independent of the environmental conditions and as such the features of the source term define this region; next the intermediary section where both source and environmental conditions are significant in the modeling and the last section, where environmental conditions dominate the process of dispersion. In this paper the focus is on the effects of environmental conditions in the whole dispersion process.

If the substance released presents density higher than air, the first stage of the dispersion will occur as dense gas and when the cloud dilutes enough to its density be equal to the air's, the dispersion will occur as passive or neutral dispersion. In the dense gas dispersion phase, the cloud will be making

descent movements until it reaches the ground and then will spread radially under influence of the gravitational forces, hence having the dense cloud the horizontal dimension greater that the vertical dimension. The vertical dimension will be higher in the extremities of the cloud due to the air resistance (TNO, 2005).

After this stage, when the cloud has density equal to the air's, the passive dispersion occurs which is governed by the environmental conditions, mainly by wind and atmospheric stability (TNO, 2005).

The atmospheric instability occurs because of the wind flow and the air displacement between different layers due to the temperature difference between these layers. This turbulence generates eddies with different sizes; eddies smaller than the cloud disperse the cloud and increase the cloud size (there is no effect on position of the cloud), eddies much bigger than the cloud merely move the cloud (there is no effect on form neither on size) and eddies with the same size of the cloud change the cloud form and increase its contour (TNO, 2005).

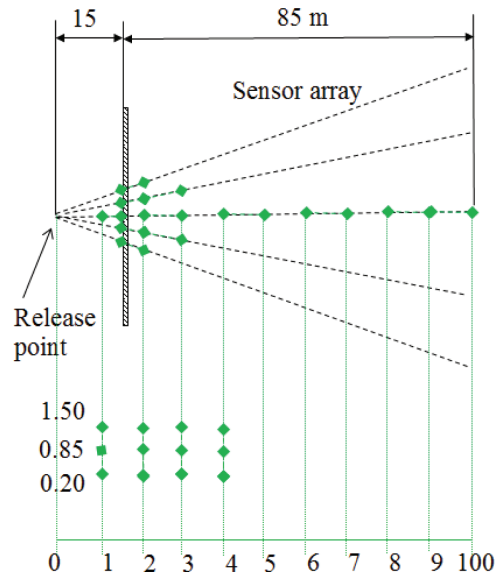

Figure 1. Sensor array.

2 BASELINE SCENARIO

As previously mentioned, the baseline scenario in this study is the same used in a previous study of grid dependence (Schleder et al., 2014) where two trials of the field tests performed by Health and Safety Laboratory (HSL) at the HSL laboratories in Buxton, England (Butler & Royle, 2001) were chosen to perform the sensitivity analysis.

The HSL trials consisted of liquefied propane continuous releases at rates up to 4.9 kg/s, at a height of 1.5 m; during the release a biphasic jet was formed, however there was no pool formation, since the liquid present in the jet evaporated before reaching the ground. The concentration of propane in the resulting vapor cloud was monitored by gas sensors to determine the cloud features at different distances from the release point. The trials set-up involved a liquefied propane storage facility, a release system and a discharge area in which the vapor clouds were produced. The discharge length was aligned with the prevailing wind.

Sensors were placed over a 600 m^2 area (100 m in downwind direction and 6 m in crosswind direction), located within the gas dispersion site; they were located at heights of 0.20, 0.85 or 1.50 m above the ground on the first 40 m of the centerline of the site and at a height of 0.20 m in arcs around the release point, as showed in Figure 1.

In order to investigate the influence of an obstruction, in some of the trials a fence was placed in the cross wind direction in the path of the vapor flow. A 1 m high fence was chosen to be a suitable obstruction; using this height, the top of the fence was approximately in the middle of the gas cloud height, allowing a significant volume of gas to flow unobstructed, whilst at the same time providing an obstruction for the lower part of the cloud. The fence was 20 m long, positioned 15 m from the release nozzle, perpendicular to the centerline of the trials site; it was made by wood and form an impermeable barricade. It was centered so that there was 10 m of fence at either side of the centerline. More details about the field tests are reported in Butler & Royle (2001) and Schleder et al. (2014).

In the previous study (Schleder et al., 2014) trials 8 and 11 of these field tests were selected as baseline scenarios (B1 and B2) to perform the CFD grid dependence analysis. The same trials were selected to perform the sensitivity analysis. The former test (B1 representing test 8) presents an unobstructed scenario while the other (B2 representing test 11) presents the scenario with a fence acting as an obstruction to cloud dispersion. The input parameters used to perform the simulations are presented in Table 1.

The domain and the grid of the baseline scenarios were built according to previous study (Schleder et al., 2014): an orthogonal base X, Y and Z was used, being the X direction horizontal and parallel to wind, the Y direction perpendicular to the wind and horizontal and the Z direction vertical, being the point (0, 0, 1.5) coinciding with the release point.

Table 1. Scenario conditions of baseline scenarios.

Variable	Unit	B1	B2
Ambient temperature	ºC	14.5	17.5
Atmospheric pressure	bar	1	1
Wind speed	m/s	3.0	5.0
Pasquill class	–	D	D
Wind direction	º	195–225	110–225
Relativity humidity	%	63	63
Ground roughness	m	0.03	0.03
Temperature release	ºC	11.96	11.26
Pressure release	bar	7.87	7.58
Discharge rate	kg/s	2.5 ± 0.3	3.4 ± 0.3
Discharge direction	–	Horizontal	Horizontal
Release duration	s	131	141
Discharge height	m	1.5	1.5

The domain was divided in three areas: the first one around the release point (micro grid), formed by the specific and adjacent cells where the leak takes place; the second, the prevailing grid formed by the area where the dispersion is expected (macro grid); and the third, the stretched area in the far field where no relevant concentrations are expected. The transitions among these areas are made gradually in order to obtain stable simulations; the cells are increases gradually from one region to another of the grid such as the maximum ratio between one cell and the next one is two.

The computational domain extended 170 m in the X direction (from 20 m upwind to 150 m downwind from the release point), 30 m in the Y direction (symmetric crosswind plan from the release point) and 10 m in the Z direction; the cells were initially represented by $1\ m \times 1\ m \times 0.5\ m$ cuboids (forming the macro grid).

Concerning the micro grid dimensioning, the guidelines (GexCon AS, 2013) specify that the cross area of the expanded jet must be solved in only one cell and that the area of this cell should be larger than the area of the expanded jet but not larger than twice. Therefore, the jet area expected after the expansion at ambient pressure was estimated and the dimensions of the face cell across the jet defined so that the area fell between these limits. Thus, in B1 scenario, the width and height of the micro grid cells (the release cell and adjacents) were fixed at 0.15 m (as a function of the jet area expected after the expansion at ambient pressure) and, in order to maintain the aspect ratio smaller than 5, the length of the cells was fixed at 0.5 m. In B2 scenario, the width and height of the micro grid cells were fixed at 0.17 m and the length of the cells was fixed at 0.86 m. Once the dimensions of the cells around the leak were defined, cells nearby were smoothly increased to the macro grid resolution: in z direction, the transition zone between the micro grid and the macro grid is from 2 m to 5 m high; in y direction, this region has 12 m in the symmetrical crosswind plan from the release point; and in x direction, the macro grid begins 1 m after the release in downwind direction and 1 m after the release in upwind direction.

Lastly, in both scenarios, the macro grid was stretched in X direction away from the leakage point, (he length of cell growing continuously at a rate of 1.15 to provide a smooth growth with increasing distance from the source. The cells were stretched after 100 m from the leakage point because after this distance significant concentrations of gas are not expected. More details about the grid are reported by Schleder et al. (2014).

Taking into account that the focus of this study is on the dispersion of a cloud the main variable of interest was defined as the concentration of this cloud.

The results of the baseline scenarios are presented in Figures 2 and 3 for scenarios B1 and B2 respectively; the blue lines represent experimental data and the green lines represent the simulated concentrations.

The HSE in the Model Evaluation Protocol (MEP) recommends the use of a factor of 2 range to validation purposes of CFD models, the fraction of predictions should fall within a factor of two of the measurements (Coldrick et al., 2009); in the cases analyzed here, 60% of the simulated values fitted well to this range, the major discrepancies found are related to values of concentration smaller than 2% in scenario B1 that are over simulated by the model. The simulated concentrations concerning to baseline scenarios were reported and discussed in Schleder et al. (2014).

3 SENSITIVITY ANALYSIS

In CFD modeling, the analyst should choose a large number of parameters and these can affect significantly the results. As reported by Pandya et al. (2012), there are three varieties of sensitivity analysis: local, global and screening methods. The local methods evaluate the effects in the outputs given each input varying one factor at a time around a baseline point; the global methods are more sophisticate and aim to evaluate quantitatively the influence of the entire range of inputs values on the outputs uncertainty. Finally, the screening methods that are based on computing for each input a number of incremental ratios, which are then averaged to assess the importance of the input (Pandya et al., 2012).

The global and screening methods are comprehensive methods that assess the sensitivity of the models in more detail; however, these models deal with the variables as functions, therefore are more time consuming and require more complex tools for their development such as the software's used by Pandya et al. (2012) and Gant et al. (2013). Considering that CFD models are computationally expensive and have a large range of possible inputs, the sensitivity analysis performed here will follow the local approach, which is less time consuming and can be executed with no need of specific software.

The objective of the sensitivity analysis is to verify which inputs affect more the results of the simulation, thus the first step is the choice of the variables subjected to sensitivity analysis. Next, these inputs are varied and the effects on the results regarding to concentration of the cloud are analyzed. Finally the degree of sensitivity is estimated.

As seen, the boundary conditions, especially the atmospheric conditions, affect directly the dispersion; however, in most cases the exact values of the parameters that characterized the conditions are not known and approximate values are used to perform the consequences analyses. In this sensitivity analysis the effects of variations in the wind speed, ambient temperature, atmospheric pressure and ground roughness on predicted concentrations are analyzed.

In order to perform the sensitivity analysis the influence of variations of up to ±10% in the ambient temperature, wind speed, ground roughness and atmospheric pressure values was studied. Each variable was changed independently of the others: for example, when the ambient temperature was decreased by 10%, the other variables remained the same as those defined in the baseline scenario (Table 1).

The same approach was used for both baselines scenarios (B1 and B2); nine simulations were performed for each one: the former using the original values presented on Table 1 and one for each variation presented on Table 2, in which the first column describes the variable of interest, the second is the variation applied over the original value of this variable and the last two the final value of each variable after increasing or decreasing by 10% for scenarios B1 and B2 respectively.

The simulated values for concentration of each simulation were compared with the simulated values of the original baseline scenarios. Monitor points measuring concentration every 10 m following X direction were inserted in the simulations at three heights: 0.2, 0.8 and 1.5 m and thus the comparative analysis between the simulated concentrations of the original baseline scenarios and the simulations after the variation of each parameter was made for each distance and height.

Only the results obtained for the monitor points at 0.2 high are presented here due to space constraint, on Tables 3 and 4. In these tables, the first column reports the distances from the monitor point to the release point, and the other columns

Table 2. Variations in each scenario.

Variable	Variation	Unit	B1	B2
Ambient temperature	–10%	ºC	13.05	15.75
Ambient temperature	+10%	ºC	15.95	19.25
Wind speed	–10%	m/s	2.70	4.50
Wind speed	+10%	m/s	3.30	5.50
Ground roughness	–10%	m	0,027	0,027
Ground roughness	+10%	m	0,033	0,033
Atmospheric pressure	–10%	bar	0,90	0,90
Atmospheric pressure	+10%	bar	1,10	1,10

Table 3. Concentration variation on B1.

Distance [m]	Percentage changes by each parameter on B1			
	Temperature	Wind speed	Ground roughness	Atmospheric pressure
10	–0,7%	–4,4%	0,0%	–2,2%
15	–0,7%	–2,3%	–0,3%	–1,0%
20	–0,4%	+1,8%	–0,4%	+0,7%
30	+0,4%	–0,9%	0,0%	–0,9%
40	–0,5%	–0,5%	–0,5%	–1,1%
50	–0,7%	–0,7%	–0,7%	–2,0%

100	–1,3%	–1,3%	–1,3%	–3,9%

Table 4. Variation in the estimated values on B2.

Distance [m]	Percentage changes by each parameter on B2			
	Temperature	Wind speed	Ground roughness	Atmospheric pressure
10	+0,8%	+6,3%	0,0%	+4,7%
15	+1,0%	+3,7%	+1,3%	+3,0%
20	+0,7%	+0,7%	0,0%	+1,4%
30	+0,7%	+2,2%	0,0%	+0,7%
40	+0,8%	+3,2%	+0,8%	+2,4%
50	–0,9%	–3,6%	0,0%	+3,6%
60	–1,0%	–5,0%	–1,0%	+5,0%
70	0,0%	–5,5%	0,0%	+5,5%
80	+1,2%	+6,1%	+1,2%	+7,3%
100	+1,5%	+7,4%	+1,5%	+8,8%

report the maximum percentage variation between the simulated concentrations using the original values of the baseline scenario and the concentration simulated after the variation on each particular parameter. The symmetry of the results is analyzed posteriorly. For example, varying the ambient temperature of B1 up to 10%, the estimated concentration in the monitor point at 10 m from the release point at 0.2 high varies at most 0.7%.

The same verification of the previous tables was performed for all monitor points at different heights and the sensitivity degree of each parameter was defined according to the maximum percentage changes in the simulated values of concentration. The variables sensitivity was considered "low" if the maximum percentage changes were less or equal to 2%, "medium" if between 2 and 5% and "high" if greater than 5%, this criteria was applied in order to determine which variables are most sensitive to changes.

Table 5 presents the maximum variation caused on concentration for each input and the variables sensitivity degrees for both scenarios. The changes up to 10% in the temperature cause minor effects in the results, since this variation is not enough to represent a change in the atmospheric stability. However, it is important to note that in different scenarios in which the evaporation process may take longer (such in a case of pool formation), the influence of variations in the ambient temperature may increase, since it will directly affect the vaporization rate.

In addition, from Table 5, it is possible to note that changes up to 10% in the ground roughness do not affect the results significantly. However, in both scenarios, the variations of the wind speed and pressure cause more significant changes in the simulated concentration values.

Figure 4 shows the effect on concentration of varying wind speed in scenario B1. Simulated concentrations in each monitor point at height 0.2 m are plotted: the yellow bars represent the simulated values for the baseline scenario B1 using the initial values of Table 1, the green bars represent the simulated values obtained using the wind speed value decreased by 10% and the blue bars represent the results obtained using the wind speed value increased by 10%.

As can be observed, the effects of variations on wind speed are greater in near field and decrease on far field, being the effect anti-symmetric on near field and tending to a symmetric effect on far field; this occurs because near the source term there is more turbulence due to the jet and therefore there are more eddies generated by this turbulence. The wind contributes to the eddies formation and consequently to the cloud dilution. In far field, there is less turbulence; thus, the wind

Table 5. Sensitivity degree.

	Parameter	Maximum variation on results	Sensitivity degree
B1	Ambient temperature	1.3%	Low
	Wind speed	4.4%	Medium
	Ground roughness	1.3%	Low
	Atmospheric pressure	3.9%	Medium
B2	Ambient temperature	1.5%	Low
	Wind speed	7.4%	High
	Ground roughness	1.5%	Low
	Atmospheric pressure	8.8%	High

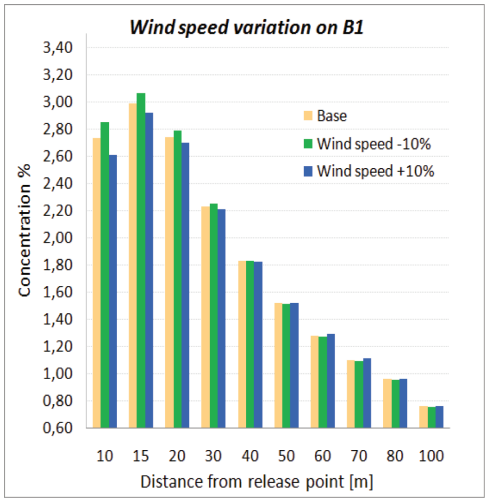

Figure 4. Simulated concentrations varying wind speed on scenario B1.

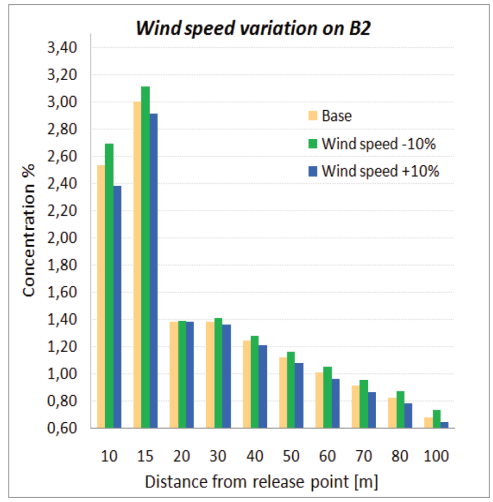

Figure 5. Simulated concentrations varying wind speed on scenario B2.

contributes less to cloud dilution and more to the cloud displacement, moving the entire cloud in the wind direction. This effect would probably be different in a scenario with pool formation; in such a case, there is less turbulence near the source and the wind contributes to cloud displacement and influences the evaporation rate of the pool.

Like Figure 4 for scenario B1, Figure 5 shows the simulated concentrations in each monitor point at height 0.2 m for the baseline scenario B2; it can be observed that the variations in the wind speed cause noticeable effects on the simulated values both on near and far field.

In scenario B2 the variations of wind speed affected the results near the source term, by the same reasons of scenario B1; however, unlike scenario B1, in the far field the results were also significantly affected. In this case, the wind contributes do the cloud dilution in the region near the source, after few meters the turbulence decrease; however, the fence at 15 m blocks partially the cloud and causes turbulence, consequently the results sensitive to variations in wind speed increases. The difference between the results for the baseline scenario and the scenarios with increase and decreased wind speed remains approximately constant from immediately after the fence until the last monitor point.

Concerning to variations in the pressure atmospheric values, Figures 6 and 7 show the simulated concentrations in each monitor point at height 0.2 m for scenarios B1 and B2 respectively: the yellow bars represent the simulated values for the baseline scenario using the initial values of Table 1, the green represents the predict values

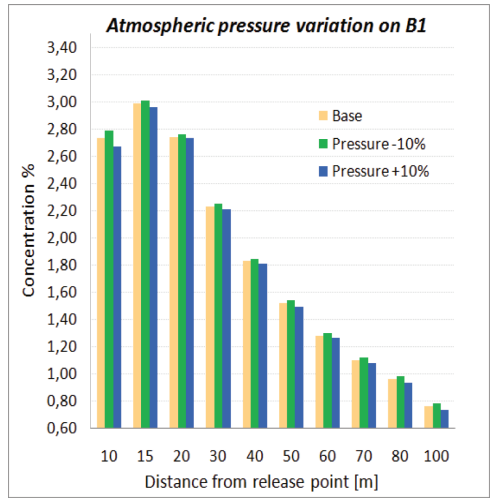

Figure 6. Simulated concentrations varying atmospheric pressure on scenario B1.

obtained using the atmospheric pressure value decreased by 10% and the blue represent the results obtained using the atmospheric pressure value increased by 10%.

When the atmospheric pressure value is increased by 10% the simulated values for concentration for the gas phase decrease and when the atmospheric pressure value is decreased by 10% the simulated values for concentration increase; this probably occurs because with a higher pres-

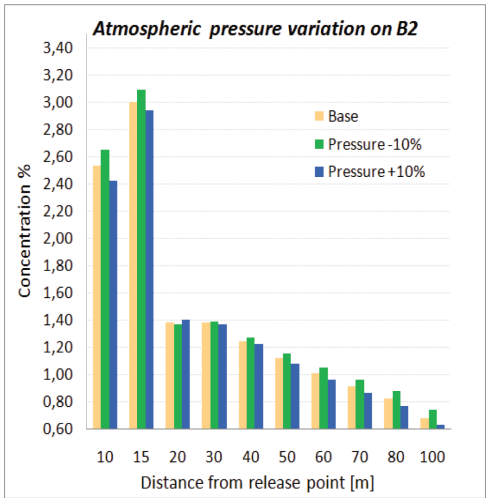

Figure 7. Simulated concentrations varying atmospheric pressure on scenario B2.

sure the liquid fraction into the cloud takes longer to evaporate; from the results of the monitor points at different heights, it is possible to note that the influence of the pressure variations is lowest in the highest part of the cloud, where the liquid fraction is smaller.

4 CONCLUSIONS

This study evaluated the sensitivity analysis of cloud dispersion using a CFD tool; four variables of interest were considered: ambient temperature, wind speed, ground roughness and atmospheric pressure.

In order make the analysis, two trials of the field tests performed by HSL (Butler & Royle, 2001) were chosen; the former presenting an unobstructed scenario and the second with a barrier blocking the spread of the cloud.

In both scenarios the results were more sensitive to changes in the values of the wind speed and atmospheric pressure. The variations on simulated concentrations reach up to 8.8%; however, minor effects on results occurred due to changes in the ambient temperature and ground roughness, in these cases the variations on simulated results reach up to 1.5%.

It is worth noting that the results showed a low sensitivity degree to temperature and roughness variations in the selected scenarios. However, this degree can be higher in other scenarios: for example, in scenarios in which there is pool formation, variations in ambient temperature probably will influence more the results, since this parameter affects the evaporation process.

Moreover, the results were more sensitive to variations in wind speed and atmospheric pressure; it is important to note that the wind variations associated with the presence of the fence affects directly the results, showing that the accuracy of these values is essential to high quality dispersion modeling.

Future research will imply performing a sensitivity analysis of other key parameters on dispersion analysis, especially concerning source term features and other scenarios such as dispersion over water and pool formation. This will allow a better founded decision making process when setting computational parameters in CFD simulations.

Scenario identification in oil and gas industry: A case in the Middle East

Zahra Rezvani, Paul Swuste & Patrick Hudson
Safety Science Group, Delft University of Technology, The Netherlands

ABSTRACT: The first element in safety management is the possession of enough knowledge about what and how accidents happen. Evaluation of the layers of protection is important from both retrospective and predictive points of view. This article focuses on incident scenarios and potential causes of incidents in oil and gas plants, based on literature reviews of accident scenarios in one Middle Eastern case and comparing them with world accident scenarios in this sector. The result shows that accident scenarios in this case are similar to accident scenarios in this sector in the world. We argue that this is because they use similar equipment and facilities. Also, loss of containment and fire are the most popular accident in these industries. Finally, there is a repetitive pattern of accidents world-wide.

1 INTRODUCTION

The definition of accident scenarios lies at the heart of the safety management process and the study of safety related decision-making in which individuals in high-hazard industries are engaged. A scenario is a generalized description of the actors, their goals, sequences of actions and events, and background information (Go & Carroll, 2004)—the dynamics of an accident. First (2010) proposed that an accident scenario forms an unplanned event sequence that can result in unwanted consequences. He argued that one or more conditions, besides the immediate sequence of events, are necessary in an accident oe incident scenario. Fecht et al. (1982) added the notions of initiating and intermediate events into the concept of an accident scenario. An initiating event is the first event in an accident scenario but there are also intermediate events that form enabling events, a "condition which does not directly cause the scenario". For example, loss of containment is an accident scenario for major hazards such as gas or liquids. It can be caused by a direct, initiating, event like a rupture in a vessel or by an indirect, intermediate, event such as the occurrence of a runaway reaction that subsequently results in releases through pressure relief devices or can then cause a rupture. In general, initiating events are typically failures that exceed the boundaries of normal process conditions. They can be classified into control (e.g. automation) failures, mechanical integrity failures (e.g., corrosion or erosion of materials ensuring containment) and human error (e.g., inadvertent opening or closing of valves, setting incorrect control values etc.). The operational conditions themselves should be considered as forming a potential for failure (First, 2010).

From a human error perspective, Guerrero et al. (2008) stated that an incident scenario is a composition of actors, objectives, instruments, action sequences, errors, error causes and error consequences, and context elements.

In summary, a scenario provides an analysis tool for strategic planning in safety management. The typical usage of scenarios in safety involves the description and analysis of the current system, the analysis of the problem domain, provision of a model of the real world, envisioning uncertain feature environments, analysis of user tasks, development of a design rationale and finally provision of a communication tool (Go & Carroll 2004). In fact, based on a review of the literature, there is no firm consensus for scenario definition and its application because the range of topics covered is so wide and the concept does not provide much in the way of theoretical focus. It is as a result of a wide range of influencing factors such as a variety of disciplinary backgrounds and various perspectives (retrospective versus predictive). However, this paper focuses on uncovering the actual common accident scenarios in a Middle Eastern oil and gas company based on historical data about what happened in a specific environment, rather than very general considerations of what might be appropriate scenarios. The question is then posed whether there are any differences between such accident scenarios in this Middle Eastern case and accident scenarios in the world's oil and gas companies? What are the main causes of accidents in these industries and do they differ from a potentially unique isolated environment? And, if they

do, does the scenario approach provide a useful basis for improved understanding?

2 METHOD

A documentary analysis was carried out to investigate accident scenarios from both a retrospective and a predictive point of view. In this study, data from cases, published incident reports from the oil and gas industries, were used to first clarify the concept of an accident scenario and then identify the causes of accidents in this sector. Also, risk analyses which have been conducted by researchers and have been documented in this scope were used to fill out the scenarios.

Oil and gas plants and gas industries use the same basic equipments (pumps, tanks, vessels columns etc.) because the basic physics and chemistry of hydrocarbon and gas processing is the same everywhere. Therefore the scenario types for various types of equipment might be categorized by risk analysis, accident history and operational experience. Accidents in oil and gas plants in one oil and gas operating company which includes six oil fields producing more than one million barrels of crude oil, 500 M ft^3 gas, and 6500 barrels of liquified natural gas per day. Over a time period between 1985 to 2009 were assessed. This company has 7 operation units, 4 distillation plants, 10 gas compressor stations, 3 liquified gas plants, a gas refinery, and one water treatment plant.

The accident data was gathered from a book published by the operator (NISOC, 2011). This may not the complete source of data, since usually incident histories are not published publicly as a result of confidentiality issues and it is evident that this document focused on major events, those that caused loss of life, damage to property or harm to the environment. It is, nevertheless, useful for our purpose, which is the identification of the main accident scenarios in this sector because such major incidents can be treated as representative of the major scenarios that are likely. If some minor scenarios are missed they will appear to be either associated with lesser consequences or be much less frequent. We then compared incidents within this specific area with incidents of the same industry in world-wide over the same period (Sam 2005).

The focus was on process incidents which resulted from plant operation and process activities rather than on personal accidents that were unrelated to the process in the plant. Because personal safety incidents are more common the personal scenarios can otherwise easily swamp the less common process scenarios, while the latter will inevitably have much higher potential for disaster involving more people and larger assets.

3 RESULTS

Overall the use of a scenario approach has several advantages. For example, scenarios help to distinguish which are the important events which should be taken into account. Morover, using a scenario approach can clarify the inter-relationship between different aspects such as individual, psychological, social and political factors. From a predictive point of view, structured techniques such as Process Hazard Analysis (PHA), HAZOP and What-If analyses have been used for identification of scenarios in this area and are used world-wide. These methods can find connections between deviations (process upsets), the possible causes (initiating events) and outcomes (consequences). For instance, the principal goal of PHA is to specify scenarios resulting from failures to manage major hazards.

The paper focuses on a list of common incident scenarios in this industry, identifying and using case histories in a Middle-East case in particular and in the world in general. Although the probability of some scenarios are low, certain initiating events and conditions may still happen and cause catastrophic results. Table 1 shows a list of major accidents, scenario types, and initiating events in a Middle East case. It is based on First's classification (First, 2010) who considered 16 scenario types for incidents for various equipment types.

4 DISCUSSION

As can be seen in Table 1 and Figure 1, these findings are similar to findings of other analyses. The similarities are probably the result of using the same basic equipment (pumps, tanks, vessels columns, etc.) and similar processes. So, fires and explosions, including Vapour Cloud Explosions, are the major accidents with which the oil and gas industry are faced. The most common is fire, however explosion has more potential damage in terms of fatalities and loss of property (Khan & Abbasi, 1999).

The main causes of large fires and explosions in oil industries are release or overflow of flammable liquid or gas, overheating or hot surfaces, fitting or pipe failure, electrical breakdown, and overpressure or pressure vessel failure, explosion in equpment chemical reaction, and inappropriate operation (Khan & Abbasi, 1999).

Explosions form the second most important and common incident scenario in this sector and become the most frequent when different types of explosions are combined. Explosions often cause fatalities, damage to property, shutdown of the plant for some days, often months, and serious negative impact on the reputation of the industry.

Table 1. A list of major accidents in a Middle East oil company between 1983 to 2009 (from NISOC, 2011).

Year	Accident type	Unit	Event	Plant/transport	Chemical	Scenario type	Death (d) injuries (i)	Initiating event
1991	Leakage of wellhead separator	Operation	TOX (H_2S)	Well-head separator	Oil–Gas	Leakage of well-head separator	2 d	Failure in control valve, human error
1983	Fire of oil water separator	Operation	Fire	Oil–water separator	Oil	Fuel accumulation,	1 i	Electrical and mechanical control failure of vertical pump, human error

Figure 1. Comparison of major accidents in Middle Eastern case (blue) with world accidents (red) in the oil and gas industry percentages of different scenarios. (LOCA: Loss of containment; F: Fire; EX: Explosion; BLEVE: boiling liquid expanding vapor explosion; IE: internal explosion; TOX: toxic release; VCE: vapor cloud explosion; VCF: vapor cloud fire; VEEB: vapor escape into, and explosion in, building, B: blowout).

It needs to be noted that the conditions may be different in this case as compared to other countries.

Initiating events or major causes in both cases are plant failure e.g. equipment failure, process problems, material movement problems, control failure (ineffective loss prevention program, inadequate material evaluation). Major contributing factors or intermedidate events in this industry are formed by the human element, faulty design, long replacement times and inadequate explosion relief (Sam, 2005).

It is obvious that incidents like pipeline leakage occur more frequently than has been reported.[1] This report contains accidents with consequences being injuries, fatalities, or damage to property, while accident documentation should also include incidents or near-misses without major consequences. Unlike accidents with significant material or personal damage, near misses and smaller incidents are much harder to discover, even though they may be caused by the same conditions and therefore be represented by exactly the same scenarios. Identifying specific holes in barriers requires more details of input rather than was usually reported here.

Loss of containment is the most frequent scenario type in this case. Pipelines have considerable potential for accident in this industry. The frequency of incidents in this part of utility are the highest (Ghazinoory & Kheirkhah, 2008). There

[1]In the personal experience of one author (PH) in another ME country, the difference between the ME and worldwide frequencies of LOCA and fire and explosion may be due to the availability of considerable space on site, resulting in longer lines for leakage exposure, but less chance of ignition or of achieving the critical stochiometric ratio.

are some reasons. Firstly, these cases have very long pipelines as part of their plant. For example, one such oil and gas plant has almost 5000 km of pipeline. Considering 5 similar plants in this region, the total length of pipeline might be as much as 25000 km. Maintaining and repairing such a wide-spread network of pipelines needs considerable effort by operations, plant management and adequate financing. Defects in any one of those factors have the potential for an incident with catastrophic consequences. Secondly, the crude oil in this plant contains H_2S, and CO_2 either of which cause acidity and thereby increase corrosion. Finally, all pipelines have a limited useful life. They should be in limited service but because of a number of limitations, these pipelines were often not replaced and have had to continue in operation after their useful design life.

Sharing of past major incidents with other oil and gas industries provides useful input data for similar process industries in order to identify the most critical barriers and improve their safety processes. One poignant example highlights this matter. In 1998 there was an accident in the gas compression stage of a Middle East oil and gas plant which caused 7 dead as a result of fuel accumulation and vapor cloud explosion which was very similar to the Texas City Refinery disaster on March 23, 2005 in which a distillation tower was overfilled and an uncontrolled release of hydrocarbons led to a major explosion and fires. Fifteen people were killed and 180 were injured in the worst disaster in the United States in a decade. In both incidents, excess hydrocarbons were diverted into a pressure relief system that included a blowdown stack. In the Iranian case, it was equipped with a flare, but one which the operator didn't ignite; in Texas City the blowdown stack was not equipped with a flare to burn off hydrocarbons as they were released. As a result, the flammable overflow from the tower entered the atmosphere. Ignition of the escaped hydrocarbons was enabled by startup of a nearby vehicle resulted in the explosion and subsequent fires (Hopkins, 2008). This example shows the repetitive patterns of accidents, and root causes of events all over the world in this sector. The lesson of this paper is that accidents in one country, where the scenarios are very similar, can and should serve as lessons to prevent the same scenario being actualized in other countries.

5 CONCLUSION

In summary, the existence of scenarios is an aid to the reduction of uncertainty. They provide a way of dealing with different aspects of a problem simultaneously; unlike specifically technical failure analyses, such as FMEA, scenarios allow for a combination of the heterogeneous factors that experience shows actually describe how accidents happen. By using scenarios, the analyst might be able to explore systematically and managers and stakeholders encouraged to think about new possibilities (Wack, 1985).

Oil and gas plants form a major strategic industry all over the world. Every country has confidentiality about public reporting about or even reporting the occurrence of accidents and this is one contributing factor for repeating accidents with the same root or contributing causes in other plants. As Hopkins (2008) mentioned, failure to learn occurs even though there is a "depressing sameness" in the scenarios. It is more unfortunate that this failure continues to happen, even in developed industries which documented and published their earlier failures (Hopkins, 2008). It is better to start to think about accidents in another perspective. Blaming people and considering the technical casues of accidents in isolation is a blind alley for the prevention of accidents. It is necessary to consider the role of other important factors such as culture, organization decision making and management in different level of company. All of these are factors that can be captured in the scenarios that do not necessarily contain specific individuals or machinery, but rather emphasize the overall structure of causal conditions and sequences that lead to incidents or even catastrophes As an example of how to improve matters such as information sharing it is noted that the oil and gas companies has started to have a complete incident database or at least incident investigation reports with more precise and complete information (NISOC, 2011).

Analysis of roadside safety barrier using numerical model

P. Hradil, J. Kala & V. Salajka
Faculty of Civil Engineering, Brno University of Technology, Brno, Czech Republic

ABSTRACT: This paper describes the process by which numeric simulation was recently used to carry out conceptual development of a new temporary protective barrier. An extensive use was made of the non-linear explicit dynamic finite element simulation code LS-DYNA to identify and correct design flaws early in the concept development stage. After arriving at what was considered to be a viable system design, full scale physical crash testing will be carried out to verify the successful performance of the system.

1 INTRODUCTION

Over the past decade, the roadside hardware design process has changed substantially as non-linear dynamic Finite Element Analysis (FEA) has found increasing application. A substantial portion of conceptual design can now be performed using computational simulation rather than experimental testing. The presented paper deals with the analysis of dynamic responses of a noise damping wall to actions of wind as well as to the impact of a vehicle (Hradil et al. 2009). The response to the vehicle impact has been analyzed using a specially elaborated complex computational model, comprising both the nonlinear model of the damping wall and the detailed model of the vehicle (in accordance with EN-1317).

In the past, the development of new roadside safety hardware systems such as railings, barriers, and energy absorbing crash cushions typically required iterative cycles of conceptual design and full scale vehicle crash testing. Much of the conceptual design process was based on sound understanding of engineering and mechanics principles, previous development experience, and intuition. However, with only these tools available, several cycles of concept development and crash testing were usually required to arrive at a successful design. Given the setup time and costs involved in full scale crash testing, and the matrix of testing conditions that must be examined for system approval, this process can be quite costly as well as time consuming. Over the past decade, the roadside hardware design process has changed substantially as non-linear dynamic Finite Element Analysis (FEA) has found increasing application. A substantial portion of conceptual design can now be performed using computational simulation rather than experimental testing (Farnama et al. 2010). Such use of simulation can result in more rapid system development, improved system performance, and reduced development costs. Ultimately, such systems must still be subjected to full scale crash testing to validate and certify their integrity (Consolazio et al. 2003). However, far fewer cycles of development and testing are required if simulation results can be relied upon to identify design flaws that degrade system performance (Adhikary et al. 2012). This paper describes the process by which numeric simulation was recently used to carry out conceptual development of a new temporary protective barrier. An extensive use was made of the non-linear explicit dynamic finite element simulation code LS-DYNA to identify and correct design flaws early in the concept development stage (Kala et al. 2012, Kochavi et al. 2008, Markovich et al. 2011). After arriving at what was considered to be a viable system design, full scale physical crash testing will be carried out to verify the successful performance of the system.

2 DESCRIPTION OF THE DESIGNED MOBILE ANTI-NOISE WALL

The designed mobile antinoise wall system with a length of 36 m involves reinforced concrete anchoring blocks, steel columns with HE 160B cross-sections and antinoise panels of the type SILENT. The anchoring blocks of the designed MAW system have a length of 4 m, see Figure 1.

Both their shape and their in-line arrangement resemble the reinforced concrete crash barrier system. Anchoring blocks are mutually constrained through steel locking pieces, see Figure 3. In the upper part, the anchoring block is provided with a steel clamping piece anchored in the concrete by four shaped steel members, shown in Figure 2.

The clamping piece is designed to fix the steel column HE 160B which (together with the neighboring column) is bearing the antinoise panel. Four bolts are designed to fix the column. The ana-

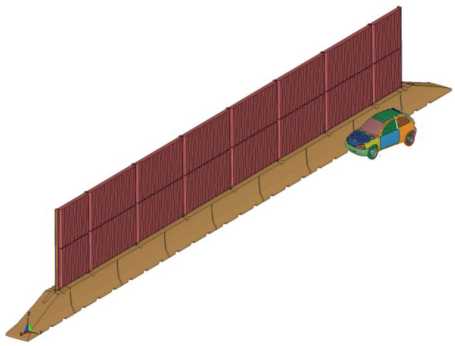

Figure 1. Computation model of the mobile antinoise wall and a vehicle.

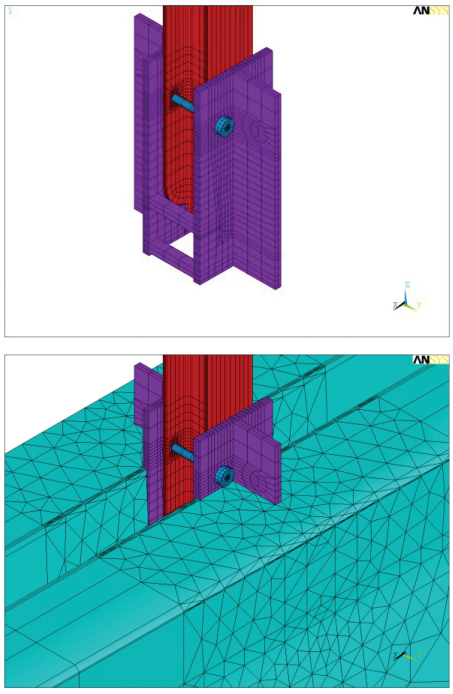

Figure 2. Detail view on designed joint.

lyzed system consists of two terminal anchoring blocks and seven intermediate blocks.

3 CONTINUOUS SURFACE CAP MODEL

The concrete model was primarily developed to simulate the deformation and failure of concrete in roadside safety structures impacted by vehicles. Examples are bridge rails and safety barriers.

The concrete model is commonly referred to as a smooth or continuous surface cap model.

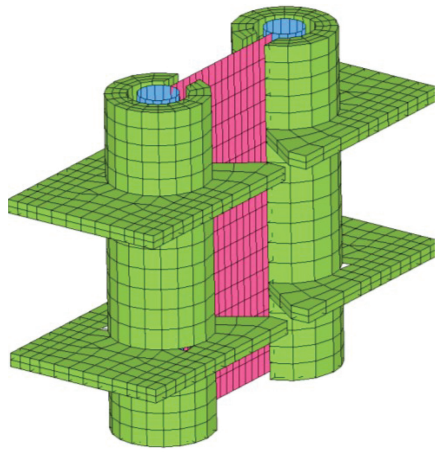

Figure 3. Detail of the block locking piece.

Hence, the 159 model is used for a Continuous Surface Cap Model (Murray 2004, Schwer & Murray 2002). A smooth and continuous intersection is formulated between the failure surface and the hardening cap.

Concrete structures typically contain steel reinforcement. Steel reinforcement exhibits rate effects and yields in a ductile manner until it breaks at an ultimate strain greater than approximately 20 percent. The reinforcement model plays an important role in modeling reinforced concrete behavior (Holomek & Bajer 2012, Jiang et al. 2012). Our approach is to explicitly model the reinforcement (beam elements) separately from the concrete (hex elements) using an elasto-plastic material model with yielding, hardening, rate effects, and plastic strain-based failure.

4 COMPUTATION MODEL OF THE MOBILE ANTINOISE WALL—VEHICLE SYSTEM

The dynamic analysis of the designed mobile antinoise wall has been carried out applying an advanced computation model based on the Finite Element Method. The model has been developed as a spatial non-linear model respecting all substantial structural details of the MAW system. However, various imperfections and gaps due to both manufacturing and assembling process have been neglected. The computation model assumes that anchoring blocks of the MAW system are freely supported on a horizontal plane. Horizontal displacements of blocks are modeled assuming contacts with friction. Non-linear material properties have been considered. Deformation behavior of steel has been described assuming

bilinear kinematic hardening. This concerns structural elements such as block locking pieces, clamping pieces of columns and reinforcing steel bars in blocks. The deformation properties of the concrete of anchoring blocks have been described using a special model developed for the analysis of reinforced concrete crash barriers (Murray 2004). The computation model of the vehicle used in the crash test simulation has been selected from the vehicle database. A light motorcar with the mass of 900 kg has been selected (Sharma et al. 2012).

5 RESULTS OF COMPUTATIONS

The impact of the vehicle on the mobile antinoise wall at the speed of 80 km·h^{-1} under the angle of 15 deg has been analyzed by computer simulation. At the instant of impact, the vehicle contacted the middle of the third anchoring block. The fields of displacements, deformations and stresses of the modeled structures have been computed at discrete time instants. A detailed analysis has been carried out with respect to lateral displacements of anchoring blocks and antinoise panels. The effect of the influence of parameters on the results can be studied by methods of sensitivity analysis (Kala & Kala 2013). Also, a detailed stress analysis of structural elements of joints has been performed.

The analysis has shown that the designed mobile antinoise wall remains stable during and after the vehicle crash.

The maximum stresses appear in the block locking piece elements. Another exposed piece is the connection between steel elements of columns and steel elements anchored in concrete. The stress field in the observed structural elements is displayed in Figure 9. The equivalent stresses attain the level of mean yield stresses, however, the maxima of plastic deformations are well below the allowable limits.

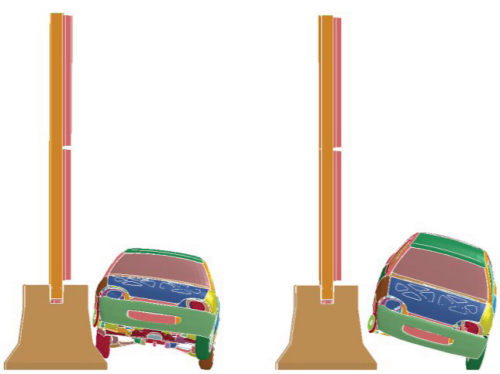

Figure 4. Positions of the vehicle with respect to the mobile antinoise wall (time 0.35 s and 0.60 s).

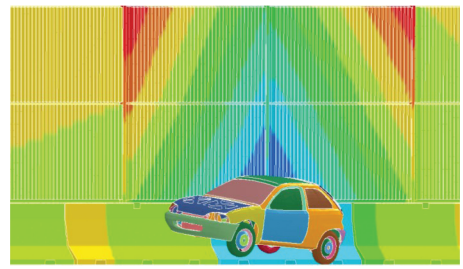

Figure 5. Lateral displacement of the wall, time 0.37 s.

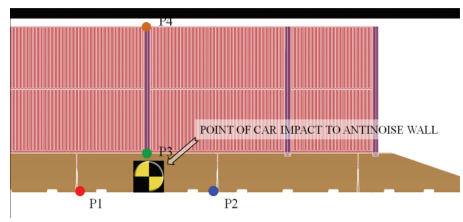

Figure 6. The scheme of simulation configuration.

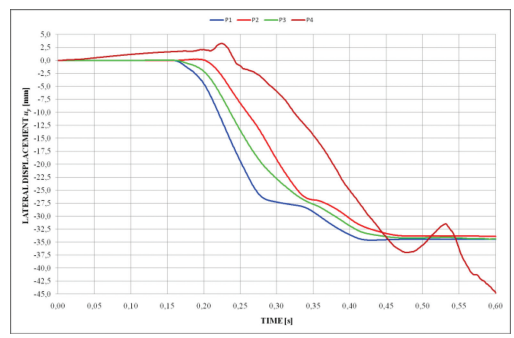

Figure 7. Time history of lateral displacements of points shown in Figure 6.

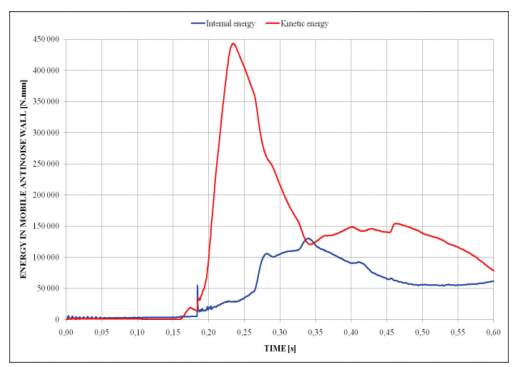

Figure 8. Time history of progression of internal (blue) and kinetic (red line) energy in the mobile antinoise wall.

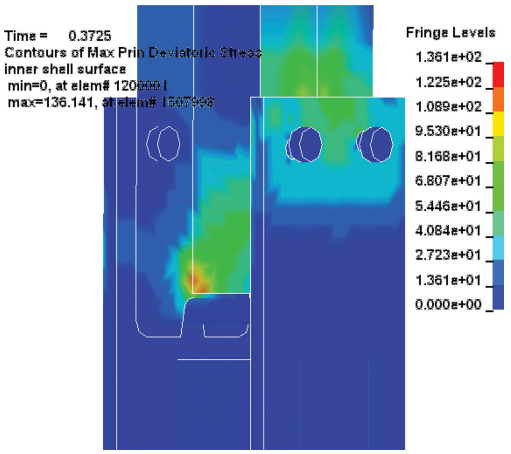

Figure 9. Equivalent stress at the mobile antinoise wall.

Now, the progression of kinetic and internal energy of the vehicle and antinoise wall in time can be determined. The time history of progression of internal and kinetic energy in the antinoise wall is illustrated in the graph in Figure 8. The time of the vehicle impact and the rapid energy change occur in the time of 0.19 s.

6 CONCLUSIONS

An advanced detailed non-linear computation model of the mobile antinoise wall has been used. The computation model of the motorcar has been selected from the database of test vehicle models. The analysis has been carried out using a specially developed procedure. Fulfilling certain specified criteria, the computer analysis substitutes the actual impact test of the vehicle crashing into the restraint system. Following the results of computations, the construction details of the mobile noise damping wall structure have been properly modified. Advanced is a method of global sensitivity analysis that allows us to analyze the higher order interaction effects.

ACKNOWLEDGMENT

This outcome has been achieved with the financial support of the project of GACR 14-25320S “Aspects of the use of complex nonlinear material models”.

ABSTRACT: Increasing interdependencies between critical infrastructures have made these systems more effective, but also more susceptible to cascading failures. In order to reduce the likelihood and consequences of cascading failures, it is essential to develop tools that support incident commander decisions so that an initial failure does not spread to other infrastructures. Here, a framework for generating knowledge from previous events that can feed in to such a tool is outlined. Design science is used to this end which provides a transparent and systematic approach. Moreover, the paper presents an analysis of existing empirical approaches focusing on identifying methodological aspects that can influence the framework. Although further work is needed, the work presented in this paper shows a promising first step to accomplish such a framework.

1 INTRODUCTION

Critical infrastructures and critical societal functions, such as energy supply, water distribution, and communication services play a key role in forming resilient[1] communities, regions and nations (O'Rourke 2007). By ensuring that infrastructures and societal functions can absorb and withstand hazardous events (including natural, mad-made or intentional) and recover quickly from emergencies and disasters, the societal impacts on communities and regions can be drastically reduced. In several past events damages to critical infrastructure and societal functions have significantly contributed to the negative consequences of those events, such as the WTC attacks in 2001 (Mendonca & Wallace 2006) Hurricane Katrina (Boin & McConnell 2007; Leavitt & Kiefer 2006) and the Canadian ice storm in 1998 (Chang et al. 2007).

Over the last decade there has been a growing realisation of the role played by interdependencies between infrastructures (Aven & Renn 2010; OECD 2003). Interdependencies between infrastructures are currently growing, much due to the technological development that allows for more systems to be interconnected. This generally gives rise to more effective and efficient infrastructures and societies but also opens for more widespread and cascading failures to arise in case of infrastructure breakdowns (Rinaldi et al. 2001; Zimmerman 2001).

Research in the field of infrastructure interdependencies and cascading failures, where a cascading failure is seen as a failure in one infrastructure/societal function[2] that gives rise to a failure in another infrastructure/societal function, is currently growing.[3] A large part of this research is devoted to developing new methods

[1]There are different accounts on what constitute resilience but at the least it constitutes the robustness, i.e. the ability to absorb and withstand shocks, and recovery or rapidity, i.e. the ability to quickly restore any disruptions in the functions and services that a system provide (McDaniels et al. 2008).

[2]Although the concept of critical infrastructure often is broadly defined to include both physical networks, e.g. transportation, and more social/societal functions, e.g. emergency services and governmental services, the term to is more commonly associated to physical assets or systems in practice. Therefore, this paper also uses the term critical societal functions to emphasize that the interest here is not only on the more physically-related systems.

[3]A search, dated 2014-02-17, on the online database Scopus (www.scopus.com) on the keywords "infrastructure*" AND "interdependenc*" gives 965 hits. From 1997–2002 the hit rate is about 10–15 per year whereas since then it has gradually increased to around 100–120 hits per year.

and approaches for analysing infrastructure interdependencies in order to better understand cascading failures and their effects, and to increase the ability to estimate societal impacts. The reviews presented by Ouyang (2013), Satumtira & Duenas-Osorio (2010), Griot (2010), Pederson et al. (2006) and Johansson et al. (2013) show that there are several different types of approaches available in the literature. Most of the approaches are forward-looking in the sense that hypothetical scenarios are modelled using e.g. economic (Rose & Liao 2005; Haimes et al. 2005), system dynamics (Stapleberg 2008; Min et al. 2007), agent-based (North 2001; Dudenhoeffer et al. 2006.), expert-based (Chang et al. 2013) or hybrid models (MaKenzie et al. 2012; Johansson et al. 2013).

Another group of approaches is the empirical ones where the focus is to analyse past events in order to identify and characterise interdependencies. These approaches are either those where methodological frameworks for analysing past events are presented (e.g. McDaniels et al. 2007) or those that are restricted to analysis of a single or a few past events (Chang 2000; Bigger et al. 2009).

Surprisingly, analyses of past events to find out the frequency and characteristics of cascading failures are scarce, as pointed out by van Eeten et al. (2011). However, insights about past events can lay a foundation for a better understanding of infrastructure interdependencies and likely future cascading failures. This kind of knowledge has many benefits. First, it is crucial in a proactive perspective in order to design-in or increase the resilience of a community or a region. Without accounting for possible cascading failures any resources devoted to increasing resilience, e.g. by increasing the resilience of a specific infrastructure, would be sub-optimal. Second, knowledge about likely cascading failures is very useful in the emergency response phase or a disaster, since this knowledge can be used to inform emergency response decisions of how to effectively mitigate the consequences of an ongoing event. Such decisions could for example concern which, of many, infrastructure services to protect; with the purpose of stopping downstream effects of service disruptions. The decisions made by the emergency responder are likely to have a greater chance of success, in terms of stopping or limiting the cascading failures and/or their societal effects, if they are well informed.

The research presented in this paper addresses the latter perspective, i.e. informing decisions in the response phase. More specifically, this paper aims to develop a framework that can be used to study past events with the purpose of identifying and characterising cascading failures as well as the effects of contextual factors on such failures. Such knowledge should then for example be possible to use in an incident decision support tool[4] in order to inform and therefore hopefully improve the decisions taken by emergency responders so that the risks of cascading failures are reduced.

2 A DESIGN SCIENCE APPROACH

Development of a framework for characterising cascading failures constitutes a design science activity. Hevner et al. (2004) argue that design science is composed of two consecutive activities: Construct and Evaluate. Construct refers the development of an artefact (such as a framework) and Evaluate refers to finding out, preferably through practical applications, whether the constructed artefact has the intended effect (i.e. fulfils its purpose). Typically, the Construct and Evaluate activities are performed in several loops in order to refine the artefact. This paper will mainly be limited to the Construct step and leave the full scale practical applications and systematic evaluations for future research.

The Construct step will be performed by adopting the design hierarchy proposed by Rasmussen (1985) and applied in e.g. Cedergren & Tehler (in press) Palmqvist & Tehler (2014), Abrahamsson & Tehler (2013). This design hierarchy describes artefacts on three levels of abstraction, which in the next sections will be used as a point of departure for constructing the framework. On the first level the *Purpose* of the framework will be described which is a statement of *why it exists/is needed*. This also includes what the framework should be used for and as such any user requirement or constraints should also be specified. On the second level the *Functions* of the framework should be specified which are statements of *what it should be able to do* in order to fulfil the purpose. Finally, the third level constitutes the *Form* of the framework which is simply *how it is actually designed*.

Typically, developing a concrete form of an artefact is facilitated by good knowledge of existing similar artefacts as the one to be developed (Tehler & Brehmer 2013). Therefore, this paper will also make a systematic analysis of the existing empirical methods and frameworks for characterising and analysing cascading failures. This will be done by first analysing whether the existing methods contain or address the functions specified for the framework; and in case they do, consideration

[4]Note that the framework developed here is part of an EU research project called CascEff, which has as an overall aim to develop an Incident Evolution tool that can be used proactively for increasing emergency preparedness and during emergency response as a decision support tool.

of whether these methodological features can be used or influence the design of the framework.

By making sure there is a logical chain from purpose to function to form the likelihood of successfully developing a framework is likely to increase. However, at the same time, it is important that the framework is systematically evaluated though practical applications so that it is ensured that it actually fulfils its purpose (has the intended effect). But, as mentioned previously, the full scale application and evaluation will be addressed in research to come.

3 PURPOSE OF THE FRAMEWORK

The overall purpose of the framework proposed in this paper is that it should generate generalised knowledge about cascading failures that can be used to inform decisions made in the response phase of an emergency. Such knowledge would enable the emergency responders to take actions that account for likely cascading failures and their effects, and hence, increase their potential to interrupt or alleviate them and thus mitigating the societal consequences.

The knowledge about cascading failures should be generated based on past events. However, since each emergency is unique it must be possible to extrapolate the findings concerning a cascading failure from one context, i.e. the one defined by the context of the past event, to another context, i.e. the one defined by an ongoing or hypothetical future event. Finally, the framework should be general, in terms of being applicable independent on the event type, and practical in terms of being able to generate knowledge with limited time and resources.

4 FUNCTIONS OF THE FRAMEWORK

Based on the purpose and constraints described above the following functions can be defined which specifies that the framework *should be able to support* the:

1. *Selection of initiating event*[5] *types to consider*—this is important since what types of events to consider will affect the types of cascading failures and contexts that will be covered, which in turn will affect which decision contexts the generated knowledge can be used in.
2. *Selection of initiating events that includes cascading failures*—this is important since the specific initiating events of interest here are those where cascading failures played a major role.
3. *Identification of cascading failures to include*—this is important since a prerequisite for learning from a cascading failure is to identify and find necessary information about them. Also some cascading failures may not be relevant to include e.g. due to their insignificance, or that they are irrelevant to emergency response decisions.
4. *Characterisation of cascading failures*—this is important since information about characteristics of cascading failures, e.g. severity of societal impacts, rapidity of effects, are necessary to provide a sensible decision support, e.g. to enable ranking of decision alternatives.
5. *Characterisation of contextual factors*—this is important since information about context is necessary to enable extrapolation of the findings from one context to another, i.e. whether a particular observed cascading failure would occur in another context.
6. *Inferences about the significance of the cascading failures*—this is important since in order provide sensible decision support in emergency response, collected data must be analysed so that inferences regarding the significance or criticality of cascading failures and/or infrastructures/societal functions can be made.
7. *Inferences about the effect of contextual factors on cascading failures*—this is important since being able to extrapolate from one context to another requires an understanding of how changing contexts are likely to affect the characteristics of cascading failures.

5 ANALYSIS OF EMPIRICAL APPROACHES

In this section, existing empirical approaches will be analyses from the perspective of identifying whether they address the functions described in the previous section; and if that is the case, a brief description of how this function is designed (the form) will be made. This will then be used as input when discussing the form of the framework developed in this paper (see section 6).

In Table 1 the analysis of existing approaches is presented. The empirical approaches addressed here are the following:

1. The framework for characterising Infrastructure Failure Interdependencies, IFI, suggested by a research group at the University of British Columbia (McDaniels et al. 2007; Chang et al. 2007; Chang et al. 2009). The intention of this

[5]An initiating event is seen as the starting point for possible downstream cascading failures, either an external events, such as ice storms, tsunamis, and earthquakes, or internal events, such as electric power blackout or rupture of a water main.

Table 1. Analysis of whether and how the seven functions have been addressed in existing empirical approaches.

	Function						
Approach	1. Selection of initiating event types to consider	2. Selection of events that include cascades	3. Identification of cascading failures	4. Characterisation of cascading effects	5. Characterisation of contextual factors	6. Inferences about significance of cascades	7. Inferences about the effect of context
McDaniels et al., 2007; Chang et al., 2007; Chang et al. 2009	No explicit guidance, but primarily restricted to large-scale power outages	No explicit guidance, limited number of events have been analysed—chosen based on their large-scale consequences.	Keyword search in media accounts, within three months, inclusion/exclusion criteria in manual reading.	Impacted system, type of interdependency, type of failure, order, Societal consequences: e.g. severity, spatial extent, no. of people affected.	Primary power outage: date, description of event, initiating event type, spatial extent, duration, weather conditions, and temperature.	Aggregation over events: e.g. 1) differences in societal impacts in different events. 2) Relative freq. of cascades between sectors	Comparative studies where differences in cascades and societal impacts are compared to differences in context—qualitative arguments.
Rahman et al. (2009)	No explicit guidance. Wide range of computer related failure reports were used, but not sorted on the basis of initiating events.	347 of 10 000 cases selected, where failure originated from, or affected, Communication and Information Infrastructure (CITI)	See 2. Failures originated from, or affected, Communication and Information sector were chosen.	Scale and degree of impact, fault intent, duration, financial impact, public safety, affected sites, description, source/affected infrastr.,	Date and country	Percentages e.g.: per fault type, intention, impact distribution, failure leading to CITI failures infrastructures affected by CITI failures.	Statistical analysis (see 6)
Zimmerman, Restreop et al. (2006)	No explicit guidance, but electric power outages are in focus.	No explicit guidance. Uses a database with no reference on how the events were selected.	Initiators and targets of failures counted as pairwise infrastructure coupling.	Metrics for characterisation of 1) Coupling 2) Cascades as sequence of failures over time	No explicit guidance	Ratios of caused vs. affected infrastr. and durations of outages for initiated/affected infrastr.	No explicit guidance
Van Eeten et al. (2009)	No explicit guidance	No explicit guidance	Google news search and official governmental or sector reports. Number of people affected more than 10 000.	Events that initiate cascades. Events that are result of a cascade. Independent events. An indication of the consequences and impact.	Several factors, e.g.: Affected CI, sector, and organisation init. event, start/end time, spatial extent, duration/progress of recovery.	Number of events, percentage of cascade initiating, cascade resulting, and independent for each sector. Directionality of cascades.	No explicit guidance

Mendonca et al. (2004)	No explicit guidance	No explicit guidance	No explicit guidance	From media reports: Type of interdependency. Number of cascades in different time phases.	No explicit guidance	Number and the percentage of infrastructure disruptions in the time phases. Number of interdep. disruptions.	No explicit guidance
Tsuruta et al. (2008)	No explicit guidance, earthquakes are addressed but approach is general	No explicit guidance, two events chosen based on their large-scale consequences	Based on literature, hearings and visits, but no details are given	Classification of terminal and origin infrastructures; in three time phases: immediate, response, restoration	No description	Number of cases where failures has cascaded between different sectors, also for different time phases	No explicit guidance
Bigger et al. (2009)	No explicit guidance, hurricanes hitting Florida during 2004 selected.	No explicit guidance, Selection of events was made beforehand.	All intra-dependencies within a CI, and interdependencies between and among CIs. Based on interviews with utilities.	First to higher-order dependencies, hurricane impact, event sequences, upstream/down-stream dependencies, recovery and restoration.	Operations during emergency, priorities for service restoration. General information about each of the studied hurricanes.	"Sample matrices", e.g. some analyses of closed-loop interdependencies presented.	Factors influ-encing recovery: 1) limited knowledge about dependence on suppliers 2) analysis of equipment pre-position-ing sites.
Dueñas-Osorio and Kwasinski (2012)	No explicit guidance. Case study of 2010 Chile earthquake.	No explicit guidance.	No guidance. Based on data availability from TCLEE: power, potable water, telecommunication.	Time lag analysis of restoration processes (autocorrelations and cross-correlations of restoration curves)	Claims anecdotal data should be considered. Contextual factor described. No guidance regarding their effect.	No, only one case study.	No explicit guidance.

framework is to enable the identification of empirical patterns of infrastructure interdependencies primarily related to electric power-related failures.
2. The framework for studying interdependencies in the communication and information infrastructures domain suggested by Rahman et al. (2009).
3. The approach suggested by Zimmerman and colleagues where quantitative metrics are suggested to characterise interdependencies (Zimmerman & Restrepo 2006; Restrepo et al. 2006).
4. The approach suggested Van Eeten et al. (2009) in their systematic review of cascading failures, primarily focusing on the Netherlands.
5. The approach used by Mendonca et al. (2004) where the focus was on the assessment of infrastructure disruptions following the WTC attack.
6. The approach used by Tsuruta et al. (2008) where the focus was on the Kobe and the Mid Niigata earthquakes in Japan.
7. The approach used by Bigger et al. (2009) who studied the effect of interdependencies in a number of U.S. Hurricanes.
8. The approach used by Dueñas-Osorio & Kwasinski (2012) who conducted a case study on an earthquake in Chile using a statistical approach.

In summary, the approaches vary in their focus and how they treat the different functions. Few approaches support the choice of type and specific events to address, rather this is typically chosen ad hoc with no "higher goal" in mind (such as generalisability). All approaches identify cascading failures, often based on media accounts, but the characterisation varies greatly from description of a large range of factors to just logging originating and affected infrastructure/function. A few approaches consider contextual factors, but without any explicit account of the reason for choosing a particular set of factors. All approaches do something to draw conclusions regarding significance but this varies from accounting for societal impacts to counting number of times an infrastructure/societal function has been involved in a cascading failure. Finally, none of the approaches perform any systematic assessment concerning how the context affects the characteristics of cascading failures.

6 DISCUSSION ON THE FORM OF THE FRAMEWORK

In this section we discuss and reflect on different ways of designing the form of the seven functions specified for the framework. Whenever possible, this discussion draws on the ways these functions have been addressed in the empirical approaches analysed in the previous section.

6.1 *Selection of initiating event types to consider*

Typically the existing approaches do not provide any support for this function. Rather, the initiating events to consider are either given on beforehand, where only one or a few initiating events are assessed (such as in e.g. Mendonca et al. (2004) or Bigger et al. (2009)) or the initiating events are not distinguished (such as in e.g. Van Eeten (2009)).

In the present framework a number of criteria can be defined that can be used as a point of departure for selection of initial event types to consider. These include the following:

1. All events included must have occurred fairly recently so that the information can be seen as valid for contemporary conditions.
2. Information of the event must be easily retrievable, preferably written in English, to enable a feasible data collection process.
3. The full set of initiating events included must have a large diversity, in order to support decision in a broad range of emergencies.
4. The events must include an active role of emergency responders, since the decision support should enable choices between different action alternatives.

6.2 *Selection of initiating events that include cascading failures*

Based on the selection of initiating event types outlined in previous section, a selection of specific events should be made. With few exceptions, the existing frameworks do not address this function in great detail. In the present framework the following criteria are suggested for the selection of events:

1. The societal consequences should be significant in the event.
2. The events where cascading failures have significantly contributed to the societal consequences are selected. Those where this is not the case are logged so that e.g. inferences about probabilities of cascading failures can be made (in function 6).

These criteria will be evaluated based on reading overall accounts of the events. The overall accounts are judged to be enough to read at this stage since if it is not clear that the criteria are fulfilled based on them it is not likely the event will be relevant. Also, the set of selected events should collectively cover cascading failures occurring in all

critical infrastructures/societal sectors. These critical infrastructures/societal sectors can either be the originating or the affected infrastructure/sector.

6.3 *Identification of cascading failures to include*

This function is something all the existing approaches, as described in Section 5, deal with. Several of the approaches use media accounts to identify information about cascading failures due to the easy access of information. That of course enables a broader range of failures to be included, than if primary data would have been used, but it is somewhat unclear to what extent media provide accurate accounts. In the present framework any written material (media accounts, official investigations, previous research, etc.) will be used to find information about cascading failures. All cascading failures that are described will be selected, except those which do not *directly* give rise to significant societal impacts, and at the same time do not *indirectly* give rise to significant societal impact through a sequence of cascading failures. The following steps will be conducted:

1. First, automatic database searches will be conducted to find written accounts that are relevant for the particular event.
2. Each account will be manually read, focusing on title and abstract/summaries to identify those that potentially include information about cascading failures, which e.g. are those that primarily focus on consequences rather than causes of the events.
3. Detailed manual review of chosen accounts with the purpose of identifying cascading failures.
4. If a large number of accounts is still included after step 2, a stop criteria will be used which essentially states that when no or very few additional cascading failures are identified, then no additional accounts will be read.

6.4 *Characterisation of cascading failures*

The characterisations performed in the empirical approaches (described in Section 5) varies; some simply only describe the originating system and the affected system, some also describe in which time phase the cascading failure occurs, whereas some provide a fuller account of the cascading failure, including societal impacts (using various dimensions), type of interdependency and order of the dependency.

In the present framework the following characteristics of the cascading failures are suggested, which are chosen keeping in mind that the characterisation should be relevant for an emergency responder in the response phase:

1. Originating system
2. Affected system
3. Interdependency type
4. Time lag—i.e. time difference between failure in originating system and failure in affected system or time for restoration in originating system and affected system
5. Spatial lag—i.e. geographical distance between failure in originating system and failure in affected system
6. Duration—duration of failure in originating system, duration of failure in affected system
7. Service reductions—severity of service reduction in originating system, severity of service reduction in affected system
8. Societal effects—type and severity of societal effects due to service reduction in affected system.

These characteristics are chosen based on them being particularly relevant for decisions in the emergency response phase, e.g. when it comes to prioritisations.

6.5 *Characterisation of contextual factors*

Few of the empirical approaches (see Section 5) describe the contextual factors surrounding the initiating event or particular cascading failure. When this is done the focus is on describing the initiating event characteristics, weather conditions, etc. In the present framework, those characteristics that are possible for emergency responders to attain information about during the actual response phase should be described. A tentative list of what characteristics that are included in the present framework include, but is not limited to:

1. Weather conditions
2. Time of the year
3. Country
4. Urban/rural area
5. Available resources for response and restoration.

These contextual factors should be seen as a first suggestion that need to be further addressed. They are chosen based on them being relevant for and possible to characterise in the response phase of an accident.

6.6 *Inferences of about the significance of different cascading failures*

In the existing empirical approaches there is a large variation in the way that inferences have been drawn about cascading failures, but several of these have influenced the suggestion of how to design the present framework. More specifically,

the following types of analyses and result presentations will be made:

1. Relative frequency of an infrastructure/societal function being affected by another one (van Eeten 2011).
2. Relative frequency of an infrastructure/societal function affecting another one (van Eeten 2011).
3. Analysis/Aggregation of several cascading failures into chains and feedback loops (Bigger et al. 2009).
4. Probability of a particular cascading failure (also information about initiating events where cascading failures have not occurred, see 6.2).

6.7 *Inferences about the effect of contextual factors on cascading failures*

None of the existing frameworks do a systematic attempt to find out how the context will affect the characteristics of the cascading failure. Here two possible approaches will be considered and possibly adopted in a complementary way: a statistical approach and an expert-based approach.

In the statistical approach one would look at a rather large number of events to see whether it is possible to find statistically significant correlations between contextual factors and some cascading failure characteristics.

In the expert-based approach contrafactual reasoning is used to identify contextual factors of importance. Contrafactual reasoning has been employed in e.g. accident investigations (Snook 2002), in investigations of emergency response (Abrahamsson et al. 2010) and restoration (Wilhelmsson & Johansson 2009) and is about asking hypothetical questions such as "what if a the event occurred in the summer rather than the winter—how would that affect the characteristics of the cascading failures?". Obviously, this requires good knowledge about the systems of interest, why it is called an expert-based approach.

7 CONCLUDING REMARKS

In order to reduce the likelihood and consequences of cascading failures, it is essential to develop decision support for emergency responders to enable them to make informed decisions. The framework outlined in this paper will serve the purpose of identifying and analysing previous cascading failures that can feed in to such a decision support. In the development of this framework, significant inspiration has been drawn from design science. In particular, the concepts of Purpose, Function, and Form have been used to provide a structured approach to the process of setting up desired requirements and designing the framework. At this stage, the framework is still in its early stage of development, and further work is thus necessary. As a first step, the form of the framework needs further specification, e.g. by operationalising the different selection criteria suggested in the paper. This would for example include how to measure the significance of a cascading failure and the threshold for including a cascading failure in the analysis. In the next step, the framework will be tested on a smaller sample of events, which subsequently will be evaluated in relation to the way the purpose is fulfilled.

A challenge that is foreseen when applying the framework relates to handling situations where complete information about the characteristics of the cascading failure and the context is not available. In such situations other data sources may become necessary, e.g. conducting complementary interviews. Another challenge relates to using or developing a consistent terminology throughout the data extraction and classification process. As a starting point, though, it would be reasonable to adopt the terminology from the European Programme for Critical Infrastructure Protection (EPCIP).

Despite these remaining steps and challenges, the combination of the structured approach offered by design science and the valuable contributions from previous empirical research initiatives addressing cascading failures, the framework outlined in this paper points at a promising route towards generation of new generalised knowledge of cascading failures. This knowledge has a great potential for improving emergency responders' ability to manage emergencies that include the potential for cascading failures if they occur.

ACKNOWLEDGEMENT

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007–2013) under grant agreement n° 607665.

ABSTRACT: A new methodology for the quantitative risk assessment in the vicinity of high pressure natural gas pipelines has been recently adopted in the Czech Republic. A major objective of this methodology is to determine the minimum distances between gas pipelines and buildings and it can be used during a process of planning the route of new pipelines as well as for a risk assessment in individual cases when it is not possible to keep the minimum distance. Since the outputs of proposed methodology are used for a land planning, it is appropriate to examine the quality of methodology. This is done by identification and evaluation of uncertainties in individual steps of risk assessment. The purpose of the evaluation is to get the information on uncertainties of risk assessment and limits of usability of the methodology.

1 INTRODUCTION

A Quantitative Risk Assessment (QRA) is always performed on one or more models of a real world, a system or an event. The model never contains all information on modeled system and this state of deficiency of information related to understanding or knowledge of a system or an event is called uncertainty. The necessity of identifying and expressing the uncertainty is widely recognized (Helton & Burmaster, 1996) and this need is even more important when there is an intention to use the QRA as a tool in more cases. As the outputs of the QRA methodology for gas pipelines (CGA, 2013a) are currently used in valid codes of practice of Czech gas industry (CGA, 2013b), the need of uncertainty evaluation is clear.

There are a lot of different uncertainty categories and no generally accepted uncertainty taxonomy exists (Nøkland & Aven, 2009). The similar statement can be made about ways in which the uncertainty is expressed. For a purpose of evaluation of the QRA methodology for gas pipelines a semi-quantitative method of expressing uncertainty originally presented by Aven (2008) is applied. Following degrees of uncertainty are defined and used for evaluation.

1.1 *Minor uncertainty*

All of the following conditions are met:

- The phenomena involved are well understood; the models used are known to give predictions with the required accuracy.
- The assumptions made are seen as very reasonable.
- Much reliable data are available.
- There is broad agreement among experts.

1.2 *Major uncertainty*

One or more of the following conditions are met:

- The phenomena involved are not well understood; models are non-existent or known to give poor predictions.
- The assumptions made represent strong simplifications.
- Data are not available, or are unreliable.
- There is lack of agreement among experts.

1.3 *Moderate uncertainty*

Conditions are between those characterising minor and major uncertainty.

2 QRA METHODOLOGY FOR GAS PIPELINES

A detailed description of evaluated QRA methodology is given in CGA (2013a). Due to the fact that so far the methodology is available in Czech only, it is appropriate to outline the process of QRA here. The process of QRA involves steps listed below with defined inputs, outputs and activities within every single step.

2.1 *Scenarios selection*

The process of risk assessment begins with a selection of events representing disruption of gas pipeline and a natural gas leak. A set of scenarios of possible gas pipeline damages and following physical effects

has been selected by a group of experts from gas industry. Every scenario is given by nominal pipe size, pressure of natural gas, extent of damage and physical effect following the gas leak. Only two extents of damage are included in scenarios—hole in the pipeline and rupture of the pipeline. The hole is defined as damage with the diameter of the hole larger than 2 cm and smaller than or equal to the diameter of the pipe, while rupture is damage with the diameter of the hole larger than the pipeline diameter. Pipe sizes include those used in the Czech Republic with nominal diameters from 100 mm to 1000 mm for transportation of natural gas with nominal pressure from 4 MPa to 10 MPa. Physical effects cover the gas leak and fire of released gas. Three possible types of fire (fire ball, jet fire, flash fire) are considered in the QRA.

2.2 *Determining the frequency of gas leaks*

The basic information on frequency of gas pipeline incidents is taken from EGIG (2011). This database covers a period of 1970 to 2010 and contains data from fifteen European countries on more than 135,000 km of pipelines. Based on these data the frequencies of two considered pipeline damages (hole and rupture) are determined for different pipe sizes. Then the reduction factors are introduced to reflect current technologies used in construction and operation of gas pipelines and their influence to possible causes of gas pipeline damages. These reduction factors are determined using expert judgements on all measures applied against manufacturing defects, construction defects and negative influence of third parties as well as measures for ensuring the appropriate preventive maintenance of gas pipeline. Reduced frequencies of pipeline damages are used for calculations of the individual risk. Table 1 shows reduced frequencies for different pipe sizes and both considered damages of pipeline.

2.3 *Fire ball modelling*

Algorithms for the calculation of the mass of released gas, mass of gas within flammability limits, dimensions of the fire ball and heat flux from the fire ball have been taken from CPR (2005). The meteorological conditions are not taken into account for this type of fire. From computed heat flux and exposure time the thermal dose is determined. Then the probability of death is assigned to the thermal dose. Finally the individual risk for fire ball is computed as a product of the probability of death, the probability of fire ball and the frequency of disruption of gas pipeline.

Table 1. Reduced frequencies of pipeline damages.

Pipeline diameter (m)	Frequency of damage ($km^{-1} \times year^{-1}$)		
	Hole	Rupture	Total
80	5.94×10^{-5}	2.36×10^{-5}	8.30×10^{-5}
100	5.37×10^{-5}	2.20×10^{-5}	7.57×10^{-5}
300	1.99×10^{-5}	1.09×10^{-5}	3.08×10^{-5}
500	7.30×10^{-6}	5.40×10^{-6}	1.27×10^{-5}
700	2.70×10^{-6}	2.70×10^{-6}	5.40×10^{-6}
1000	6.00×10^{-7}	9.00×10^{-7}	1.50×10^{-6}

2.4 *Jet fire modelling*

A simplified Chamberlain model is used for modelling the jet fire. Contrary to the fire ball modelling, the meteorological conditions are considered in this case and the computation of flame shape and heat flux is done for different directions and speeds of wind. Determination of the thermal dose takes into account the exposure time which limited by duration of gas leak (upper limit) and the time necessary to escape from the area affected by the jet fire (lower limit). The individual risk is computed for weighted combination of different meteorological conditions.

2.5 *Flash fire modelling*

The flash fire can occur as a result of delayed ignition of a cloud of gas. In this case a time-limited steady release of gas is simulated as series of puffs, each of which is considered as a separate release described by Pasquill-Gifford model. Both atmosphere stability and direction and speed of wind are taken into account, as the gas dispersion depends on these factors. The computation of individual risk for flash fire reflects the fact that the heat flux, the probability of ignition of dispersed gas and exposure time vary in time and space.

2.6 *Calculation of individual risk*

The QRA methodology covers only risk to human health and lives. Other possible categories of risk such as environmental damage or economic losses are not addressed. The individual risk coming from a single gas leak is computed as a weighted combination of a risk for every type of fire. The weights are given by probabilities of occurrence of different types of fire. Then the individual risk in particular location is determined by integration of risk from individual segments of gas pipeline. Total individual risk is obtained by combining the individual risk from two different extents of gas pipeline damage (hole and rupture). This individual risk is determined for an unprotected person permanently present in a given position. Because these conditions (no protection and permanent presence of a person) do not reflect reality, two reduction factors are introduced and used to obtain reduced total individual risk.

Table 2. Reduced individual risk—pipeline DN 700, type B2.

Distance (m)	Class of building			
	1	2	3	4
20	4.52×10^{-8}	4.05×10^{-8}	3.40×10^{-8}	2.47×10^{-8}
40	4.26×10^{-8}	3.82×10^{-8}	3.19×10^{-8}	2.32×10^{-8}
60	3.69×10^{-8}	3.32×10^{-8}	2.76×10^{-8}	2.01×10^{-8}
80	2.85×10^{-8}	2.56×10^{-8}	2.12×10^{-8}	1.54×10^{-8}
100	1.90×10^{-8}	1.71×10^{-8}	1.40×10^{-8}	1.01×10^{-8}
120	1.06×10^{-8}	9.50×10^{-9}	7.64×10^{-9}	5.38×10^{-9}
140	5.07×10^{-9}	4.53×10^{-9}	3.54×10^{-9}	2.47×10^{-9}
160	1.58×10^{-9}	1.43×10^{-9}	1.09×10^{-9}	7.99×10^{-10}

The degree of protection is specified individually for every type of fire and for four different classes of buildings defined as follows: Class 1—buildings where more than 500 people but less than 1000 people can gather, Class 2—buildings where less than 500 people can gather, Class 3—residential buildings for more than 50 people, Class 4—individual buildings for living and recreation occupied by 50 people or less. The presence of a person in the affected area is reflected by a specified fraction of time the person spent here. Both reduction factors are set according to recommendations published in Bumba et al. (2005) and CPR (1999). Example of calculated reduced individual risk in different distances from the pipeline of construction type B2 with nominal diameter of 700 mm is in Table 2.

2.7 *Calculation of societal risk*

The societal risk is given by the product of reduced individual risk and number of affected people. The QRA methodology allows calculating the societal risk for three different tasks:

- Determining the risk for a group of people inside individual objects.
- Determining the risk for a people on the roads.
- Determining the risk alongside the section of gas pipeline.

The map of individual risk in given area is created for the purpose of determining the societal risk for people inside buildings. Based on this map and number of people inside individual buildings it is possible to compute the societal risk. When determining the risk for a people on the roads, the exposure times and degree of protection are different from those used for people inside buildings. The number of affected people on the road depends on the traffic load and length of road segment affected by the fire. Once these input parameters are determined (or estimated), the societal risk is computed. In case of determining the risk alongside the section of gas pipeline the societal risk is computed as a sum of risk for all affected objects.

Table 3. Minimum distances between gas pipelines of construction type B2 and buildings.

Pipeline diameter (mm)	Class of building			
	1	2	3	4
Up to 100 incl.	–	–	–	–
100 to 300 incl.	–	–	–	–
300 to 500 incl.	70	–	–	–
500 to 700 incl.	110	90	70	–
Over 700	160	140	100	–

2.8 *Acceptability of risk*

Currently no binding limit of acceptable risk is defined here in the Czech Republic, but according to existing recommendations for the risk assessment, the individual risk higher than 10^{-5} is unacceptable while the individual risk lower than 10^{-6} is acceptable. This implies that the individual risk within these limits is considered tolerable. Similar limits for the societal risk are 10^{-3} for unacceptable risk, 10^{-5} for acceptable risk and the interval between 10^{-3} and 10^{-5} for tolerable risk. The authors of the methodology have chosen the middle of this interval, i.e. 10^{-4} as a limit value for acceptable societal risk. Based on calculated societal risk and limit of acceptable risk the minimum distances between gas pipelines and buildings are specified for every construction type of high pressure gas pipelines and four previously defined classes of buildings. As example of minimum distances the results for gas pipelines of type B2 are in Table 3. Missing values mean that for given combination of pipeline diameter and class of building no minimum distance between the pipeline and buildings is necessary to ensure acceptable level of risk.

3 EVALUATION OF QRA METHODOLOGY

The evaluation of QRA methodology for gas pipelines begins with the identification of uncertainty in every of the QRA steps. Identified uncertainties cover uncertainty in models used in individual QRA steps, uncertainty in input data and parameters and their variability, disagreement among experts and completeness of the QRA process. Once the identification of uncertainties is finished, degree of uncertainty is assigned to every identified uncertainty. During the evaluation of QRA methodology, following uncertainties were identified.

3.1 *Uncertainty in scenarios selection*

Scenarios included in evaluated QRA methodology cover only the risk from fire following the gas leaks. Other possible consequences of gas pipeline disruption (e.g. blast) are not mentioned nor discussed and neither the risk from effects other than fire and its share in total level of risk is determined. This restriction of events further examined was identified as a main source of uncertainty in the QRA process.

3.2 *Uncertainty in frequency of gas leaks*

Determination of frequency of gas pipeline incidents is based on data published in EGIG (2011). Authors of the QRA methodology argue that these data do not fully reflect technological improvements applied on construction and operation of gas pipelines in recent years and for this reason the correction coefficients are implemented. A group of 28 experts from gas industry was formed with the task to assess the influence of individual technological measures to frequency of gas pipeline incidents. Disagreement in expert judgements constitutes an uncertainty in estimation of the frequency of gas leaks.

3.3 *Uncertainty in fire modelling*

Various models are used for computing the heat flux of individual types of fire. In general, every model contains calculation of following quantities: mass flow, duration of the gas release, shape of the gas cloud, heat generated due to combustion, heat flux. Meteorological conditions are taken into account in limited extent in models of jet fire and flash fire. Uncertainty in calculation of heat flux, selection of particular meteorological conditions and their influence on distribution of heat flux in time and space are main uncertainties of this part of the QRA.

3.4 *Uncertainty in calculation of individual risk*

Calculation of individual risk from a fire adopts a lot of assumptions regarding exposure time,

Table 4. Summary of uncertainties identified in the QRA methodology.

		Degree of uncertainty		
Step of QRA	Uncertainty	Minor	Moderate	Major
Scenarios selection	Completeness of scenarios		X	
Frequency of gas leaks	Historical data on incidents	X		
	Correction coefficients			X
Fire modelling—fire ball	Mass flow		X	
	Duration of the gas leak		X	
	Heat flux		X	
	Meteorological conditions	X		
Fire modelling—jet fire	Mass flow		X	
	Duration of the gas leak		X	
	Heat flux	X		
	Meteorological conditions		X	
Fire modelling—flash fire	Mass flow		X	
	Duration of the gas leak		X	
	Heat flux			X
	Meteorological conditions		X	
Calculation of individual risk	Exposure time		X	
	Thermal dose		X	
	Probability of death	X		
	Probability of fire occurrence		X	
	Personal protection			X
	Time spent in affected area		X	
	Influence of terrain			X
Calculation of societal risk	Number of affected people		X	
	Personal protection			X

thermal dose, probability of death, probability of ignition and probability of occurrence of individual types of fire. Obtained individual risk is corrected with respect to degree of personal protection and to the time spent in affected area. Mentioned assumptions and correction coefficients present the main uncertainty in calculation of individual risk. Another uncertainty is introduced by fact than land relief and terrain obstacles are not taken into account in any of used models.

3.5 *Uncertainty in calculation of societal risk*

The main uncertainty in determining the societal risk is limited knowledge regarding the number of people affected by events following disruption of the gas pipeline. Also the estimated degree of protection of people inside the buildings and vehicles is uncertain. These factors become even more important when the calculated societal risk is close to the limit of acceptable risk.

Identified uncertainties in individual steps of QRA are summarized in Table 4. A degree of uncertainty is assigned to every uncertainty using the semi-quantitative method presented in Introduction. This way of mapping the uncertainty allows highlighting those uncertainties which deserves further examination and helps to establish a risk picture covering not only the level of risk but also the uncertainty inevitably associated with the risk.

3.6 *Verification*

According to authors of the QRA methodology, historical data on gas pipeline accidents were used for verification of the methodology in terms of scenarios selection and physical effects following the gas leak. One of accidents used for verification was a gas release and subsequent fire which happened in Tresana, Italy in January 2012. The incident happened on the pipeline with diameter of 762 mm (30 inches) and operating pressure of 5.9 MPa. The release and ignition of gas led to a jet fire with flames about 200 high and creation of a crater 20 meters wide and 7 meters deep. Ten people were injured and one of them died after a month due to severe burns. Although the authors of the QRA methodology state there is a good compliance between results of physical effects modelling and historical data, no details are given.

4 CONCLUSIONS

A semi-quantitative approach of expressing the uncertainties has been used to evaluate the quality of QRA methodology for gas pipeline. The evaluation shows a number of uncertainties in the methodology and although assigning the degree of uncertainty is partly subjective, it provides general information on quality of evaluated methodology and can be used as a base for further examination of uncertainties and their importance for results of risk assessment. If the methodology should be used as a tool in a process of land planning, it is necessary to know its weak points and limitations. Uncertainty identification and evaluation helps to get a better picture of a risk and to realize that the methodology can provide only estimation of the level of existing risk. The evaluation also showed that the semi-quantitative method of classification and expressing of uncertainties can be used in the first round of evaluation of the QRA methodology. However for further examination of identified uncertainties it is necessary to use methods other than simple semi-quantitative expression of uncertainties. Identification and semi-quantitative expression of uncertainties in the QRA methodology for gas pipeline together with verification of practical applicability of semi-quantitative approach of expressing the uncertainties are the main findings of this research.

An ontology-based approach to vulnerability and interdependency modelling for Critical Infrastructure systems

P. Trucco & B. Petrenj
Department of Management, Economics and Industrial Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: The systematic and complete identification of meaningful accident scenarios for Critical Infrastructure is still one of the major challenges to achieve higher resilience performance. THREVI2 project has been designed to answer this need by developing a comprehensive and multi-dimensional all-hazards catalogue for CI. Specific objectives are: to develop and elaborate three coordinated ontologies (Hazards & Threats, CIs topologies, CIs Interdependencies); to merge them by existing vulnerability models; and to develop a dedicated software tool for scenarios generation to support different end-users (e.g. authorities and operators). THREVI2 ontologies have been developed by a joint implementation of different methodologies: literature review, experts' review, basic ontology development methodology, and a final pilot testing of the tool. The main results achieved are generalised and standardised: i) specification framework for CIs and services; ii) all-hazards catalogue for CI. The developed SW tool offers an improved scenario generation process to support CI risk assessment.

1 INTRODUCTION

Critical Infrastructures (CIs) are exposed to a wide spectrum of hazards and threats which vary in nature (natural, technological, human-intentional or non-intentional) and, that can be internal (e.g. technical failure, sabotage, human error) or external to the infrastructure (e.g. flood, chemical explosion, terrorist attack). As such, hazard and threat assessment is a key element within CIP strategies and CI risk assessment. However, it is difficult for Authorities or Operators to get comprehensive information of all potential disruption scenarios relevant for CIP, since:

– hazard, threat and vulnerability assessments are often very specific in nature and related to different disciplinary fields;
– existing information most often focuses only on one type of hazard or on the vulnerability of one type of target (a single infrastructure or asset).

This is why the systematic and complete identification of meaningful accident scenarios for Critical Infrastructure is still one of the major challenges to achieve higher resilience performance. At European/National level it is a part of the CI identification process, since the EC Directive 2008/114/EC requires to develop "worst case scenarios", to simulate the failure of a potential ECI, in order to assess the transboundary impacts on other Member States. At infrastructure level, vulnerability and risk assessment needs to be applied to define appropriate protection and resilience measures (e.g. European CI operators have to include in the Operator Security Plan "a risk analysis based on major threat scenarios, vulnerability of each asset, and potential impacts").

THREVI2 project has been designed to answer to the Authorities' and Operators' need to get comprehensive information of all potential disruption scenarios relevant for CIP/R by developing a comprehensive and multi-dimensional all-hazards catalogue for critical infrastructures. Specific objectives are:

– to elaborate three coordinated ontologies (Hazards and Threats, CI topologies, CI Interdependencies);
– to merge them by existing vulnerability models;
– to develop a dedicated software tool for scenarios generation to support different end-users in specifying the overall "system of systems" and generating a set of relevant disruption scenarios.

To this end, an ontology-based approach has been implemented and two interconnected ontologies have been developed:

– an ontology of physical and functional topologies of Critical Infrastructure systems;
– an ontology of Hazard & Threat (H&T) affecting CIs

They have been then merged through specific vulnerability and dependency entities.

In a preceding paper (Trucco et al., 2014) the ontology development process adopted in the project and the main features of the final integrated set of ontologies was presented. In this paper we briefly recall on the main results regarding CI and H&T ontologies and build upon the previous work. The advancements include modelling of vulnerabilities and interdependencies and progress in the development of the supporting software tool (PATHFINDER).

2 ONTOLOGICAL APPROACH TO SCENARIO GENERATION

An ontology can be defined as '*a formal description of entities and their properties, relationships, constraints, behaviours*' (Grüninger and Fox, 1995), or simpler as '*a specification of a conceptualization*' (Gruber, 1993).

Ontology deals with questions concerning what entities exist or can be said to exist, and how such entities can be grouped, related within a hierarchy, and subdivided according to similarities and differences. It is used to describe the concepts and relationships that are important in a particular domain, providing a vocabulary for that domain as well as a computerized specification of the meaning of terms used in the vocabulary. Ontologies are used to capture and share knowledge about some domain of interest, organising elements within the domain by using *classes*, *properties* and *instances*. Ontologies range from taxonomies and classifications, database schemas, to fully axiomatized theories. An ontology together with a set of individual *instances* of classes constitutes a *knowledge base* (Noy & McGuinness, 2001).

In recent years, ontologies have been adopted in many business and scientific communities as a way to share, reuse and process domain knowledge. Ontologies are now central to many applications such as scientific knowledge portals, information management and integration systems, electronic commerce, and semantic web services. From the perspective of Lacy & Gerber (2004) ontologies are beneficial in simulation and modelling through the formalization of semantics, the ability to query and inference, and the sharing and reuse of developed models.

2.1 *Overview of ontologies for CI and emergency management*

Liu et al. (2013) conducted a thorough review of the ontologies for the field of Crisis Management (CM). They have identified a set of critical subject areas that cover the information concepts dealt with in CM. Among the ontologies designed originally for these areas of CM, very few are formally represented and publicly accessible (Liu et al., 2013). Regarding the CI area, existing ontologies represent:

- the domain simulators (used for observing and analysing the behaviours of a system), such as PSCAD—for conceptualising power system simulators and EPANET for representing water distribution simulators (Grolinger et al., 2011):
- geographic information in infrastructure systems, such as OTN (Lorenz et al., 2005)—a formal description of the Geographic Data Files (GDF) ontology (GDF is an ISO standard for specifying how to store geographic information for intelligent transport systems).

Other contributions include:

- ENISA's ontologies of resilience and threats in cyber domain (Vlacheas et al., 2011);
- DISASTER (2014) project—developed an integrative and modular ontology for establishing a common knowledge structure between all the first responders involved in an emergency;
- Emergency Information Sharing Protocols among the operators of CIs and first responders—e.g. *Emergency Information Interoperability Frameworks (EIIF)* for emergency management, through which critical requirements and candidate ontology components are introduced (W3C, 2009), or *Tactical Situation Object (TSO)*—a message structure to record a view of a situation as seen by a particular observer at a particular time (OASIS, 2009);
- HLA (High Level Architecture) standard (by IEEE) and MSI (Multi-Simulator Interface) program (Rubin et al., 2006) focused on modelling of system interdependencies to enable federated simulations. However, environments based on these approaches are not suitable to simulating CIs (Tofani et al., 2012; Masucci et al., 2009);
- The DIESIS project (Design of an Interoperable European federated Simulation network for Critical Infrastructures) aims to establish a basis for the modelling and simulation of CI based upon open standards (Rome et al., 2009). Still, domain ontologies express concepts in a highly specialized manner and are often very detailed, making it difficult to merge ontologies into a general representation (Masucci et al., 2009);
- The Infrastructure Interdependency Simulator (I2Sim) uses a cell-channel model to represent the physical elements of CI and their interdependencies (Rahman et al., 2008). It enables the modelling of interdependencies without modelling the details of involved entities;
- The Meta-Knowledge Infrastructure Ontology (MKIONT) defines a general template for expressing the basic concepts and relationships of CIs and their interconnections. In short, the MKIONT provides: (i) a CI template that

captures basic concepts and relationships pertaining to a CI; and (ii) an interconnection template that represents CI interconnections and their relative semantics (Masucci et al., 2009);
– Tofani et al. (2010) use the ontology framework to model the interdependencies among CIs. Their proposed framework consists of three ontologies: WONT (World ONTology) contains concepts and relations that are common across CI domains; IONT (Infrastructure ONTology) extends WONT to represent the knowledge of specific CIs and FONT (Federation ONTology) enables modeling relations among different infrastructures;
– GenOM (Generic Object Model), represents and organizes the knowledge about CI interdependencies through a three-leveled hierarchy of object classes (Lee & Yavagal, 2004);

A standardized and comprehensive ontology regarding infrastructure's assets, functions and interdependencies is not documented in the extant literature.

2.2 *Study methodology*

We use taxonomies to describe how different classes are related by organising them into groups and/or hierarchies (according to level of detail). Adopting a standardised description is also important for systematic connection between the taxonomies to the other parts of the ontology.

In the first place we have to organise knowledge in specific domain using scattered data and various sources. For the two main domains (Critical Infrastructures and Hazards & Threats) it is necessary to determine what concepts exist and to describe and classify them within the domain in a systematic way. THREVI2 ontologies have been developed by a joint implementation of different methodologies:

– literature review covering scientific, technical and regulatory documentation;
– experts review, to complement incomplete documentation, to validate and harmonise the proposed ontologies;
– basic ontology theory and development methodology;
– pilot testing of the SW tool in two different contexts, respectively at national and regional scale.

3 ONTOLOGICAL SPECIFICATION OF CI AND RELATED THREATS

3.1 *Critical infrastructure ontology*

For the CI System Ontology, the sectors covered include *Energy*, *Transport*, *Water* and *Telecommunications,* for a total of 11 different infrastructure subsectors (Fig. 1).

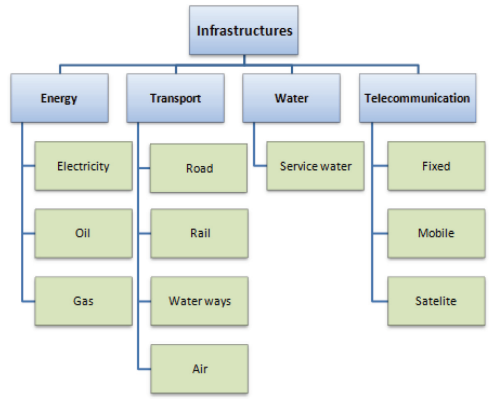

Figure 1. Covered infrastructure sectors and subsectors.

The ontology has been developed using various data sources. Globally, more than 100 references, of *scientific*, *technical* and *regulatory* nature, have been identified and systematically reviewed. After analysis, a portion of the sources turned out not to be useful for the ontology description. At the end 62 documents have been used to develop the final 22 sub-ontologies (reference list available inside the project deliverable).

Each CI is described by means of two interconnected sub-ontologies, one for the physical and the other for the functional specification. The overall infrastructure ontology framework is organized in three parts—assets, functions and services that were subsequently linked within the service delivery process.

3.2 *Hazards & threats ontology*

Hazard and Threats (H&T) Ontology aims at characterising different typologies of events, in a systematic way, to be merged in a federation of ontologies enabling a first-order recognition of:

– all the possible hazards and threats that can affect or destroy a generic CI;
– all the possible infrastructure that can be affected by a specific hazard or threat.

The H&T ontology is based on a hierarchical structure (classes and sub-classes), and is developed considering the possibility to reuse available literature on threat classification. For each class, a set of features (duration, impacted area, etc.) is assigned to better characterize the classes and to allow flexible navigation of the user within the ontology.

In literature, threat is sometimes used as a synonym of hazard, e.g. "threat: a person or

thing likely to cause damage or danger (Oxford Dictionary, 2012). However, some definitions show a distinction between both concepts. The first difference between a hazard and a threat is related to the probability of occurrence and the magnitude of the potential event. A threat is a very low-probability but serious event—to which analysts may be unable to assign a probability in a risk assessment because it has never occurred. The difference is clearly illustrated by the precautionary principle, which seeks to reduce potential threats to a set of well-defined risks before an action, project, innovation or experiment is allowed to proceed (European Commission, 2000). A threat is therefore associated with a high range of uncertainty (RGS, 2013).

The second difference is that a threat is the result of intent: "a statement of an intention to inflict pain, injury, damage, or other hostile action on someone in retribution for something done or not" (Oxford Dictionary, 2012). The US Presidential Commission on Critical Infrastructure Protection (PCCIP), for example, defines "threat" as a "foreign or domestic entity possessing both the capability to exploit a critical infrastructure's vulnerabilities and the malicious intent of debilitating defence or economic security. A threat may be an individual, an organization, or a "nation" (PCCIP, 1997) but a threat-source does not present a risk when there is no vulnerability that can be exercised (Stoneburner et al., 2002). Threats do not necessarily need to originate from human sources, but can be natural, human, or environmental (RGS, 2013).

"*Natural or technological threats*" is therefore used to define low-probability but serious events (compared to natural or technological hazards), while human threats (e.g. cyber or terrorist threats) refer to the intent of creating harm or damage (RGS, 2013).

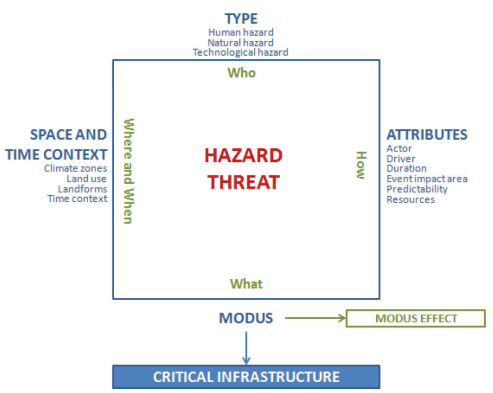

Figure 2. Hazard & threat ontology.

To be helpful in understanding hazards and threats in light of vulnerabilities and risk, need to be characterised in some detail (Fig. 2). In addition to the common attributes, *Modus* has been introduced as a feature to define and simplify in which way a given event occurs and can affect the CI. Modus has been used as the link between the ontologies of the CI and H&T, defining CI assets vulnerabilities.

4 MODELLING VULNERABILITIES & INTERDEPENDENCIES

4.1 *Vulnerability modelling*

Having developed CI assets and H&T ontologies, the following step consisted of connecting the two ontologies. It was done by assessment of actual and potential vulnerabilities of CI assets to specific hazards and threats. Vulnerability can be understood as '*the susceptibility of the infrastructure to threat scenarios*' (Ezell, 2007).

For instance (Fig. 3), **Snow Avalanche** can affect an infrastructure in different ways—either through direct impact on it, the subsequent static pressure and/or because by producing an obstruction (so it has *Static Pressure*, *Kinetic Energy* and *Obstruction Modus*).

Moduses affect (are linked to) exclusively CI assets, while impact of modus on CI functions is taken into account through possible unavailability of asset needed to execute the function.

The links have been mapped within a matrix indicating connections where modus affects an asset (Annex A contains the first assumption to be validated). In cases where modus affects an assets conditionally (e.g. depending on the asset material or position), asset has been characterised by additional attributes which define if the modus will affect the specific asset type. The typical examples of attributes are ***position*** of an asset (buried/superficial/above ground) for different types of

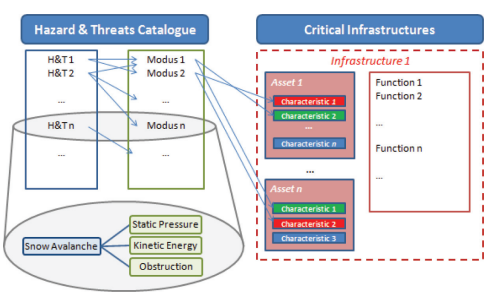

Figure 3. Impact/vulnerability modelling (links between H&T and infrastructure assets).

pipelines, or asset ***material*** (steel/concrete) in case of a bridge.

4.2 *Interdependencies modelling*

The main concepts and definitions related to critical infrastructure interdependencies are widely accepted (see, e.g., Rinaldi et al., 2001). A proper modelling of all types of interdependencies is needed to comprehensively cover all the possible vulnerabilities and risks affecting CI.

Geographic interdependency occurs if a local environmental event creates state changes in infrastructures (Rinaldi et al., 2001). For example, a disrupted asset (impacted by a hazard and/or threat) can behave as a source of a new hazard causing cascading effects through different interdependency mechanisms (Fig. 4).

Functional (or Physical) interdependency is a physical reliance on material flow from one infrastructure to another (Rinaldi et al., 2001). Within CI topologies (service delivery process) mechanism, control and material/resource inputs have been defined for each single function, as well as material flow between related functions—covering both dependencies within and between infrastructure sectors (e.g. see Fig. 5). The relations (links) between Assets and/or Functions have been defined adopting the Integration Definition Function Modeling (IDEF∅) standard, generally used for developing structured representations of a system or enterprise (Colquhoun & Baines, 1991). It relates classes to its **inputs** (e.g. requirements, materials) and **outputs** (e.g. functions, services)—white boxes; **mechanisms** (e.g. resources, assets)—blue boxes; and **controls** (e.g. plans, legislations, monitoring)—red boxes. Bold circles represent connections between different phases of service delivery process.

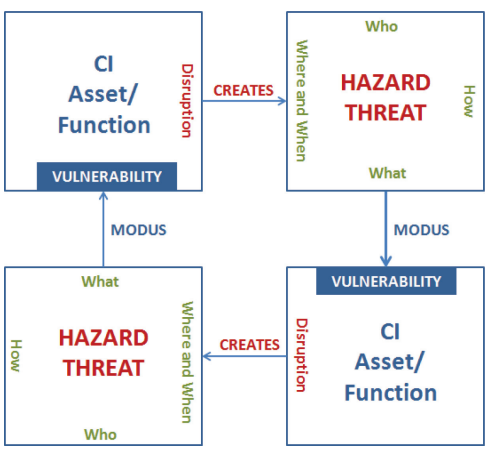

Figure 4. Modelling of geographical interdependency.

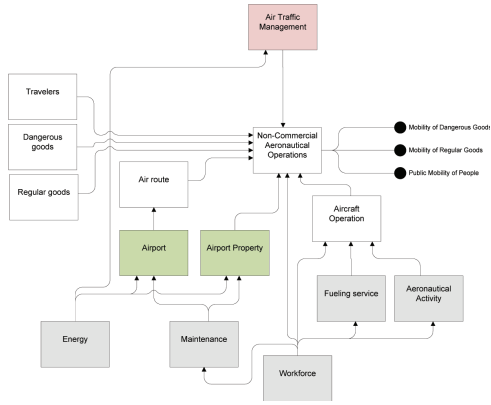

Figure 5. Service generation stage in air transport sector.

Cyber interdependency occurs if the state of an infrastructure depends on information transfer between infrastructures (e.g. SCADA, communications, monitoring, controlling) (Rinaldi et al., 2001). The information is normally transmitted through the information infrastructure. Cyber interdependencies have been modelled by connecting information (a common resource that has been identified as an input to functions) and telecommunication assets.

4.3 *Validation*

In the first phase, about 25 experts have been invited to review the Critical Infrastructure ontologies on assets and functions. Experts have been provided with an evaluation template (available on request) where they have been able to propose:

- doubts on the clarity of, or different nomenclature and description for assets/functions;
- missing relevant assets and/or functions;
- not relevant assets and/or functions (candidates to be removed);

They have also reviewed the service delivery process and validated connections (and their types) between assets and/or functions, indicating missing or wrong links.

Based on the comments and recommendations received by the experts, some of the assets and functions have not been used in the final integration of CI sub-ontologies. It is either due to a high level of detail—assumed not to be relevant to describe the effects of threats to service delivery process—, or to an activity that is not being carried out on regular bases (and thus not relevant in the standard service delivery process). However, we decided to keep these assets/functions inside the catalogue

in order to assure the completeness of the ontology and a comprehensive description of CI.

In the subsequent phase, experts are requested to validate the integration of CIs and H&T ontologies that are connected through different types of interdependencies. This part of the validation has been carried out through face-to-face interviews with technical managers and experts along with the pilot application of the PATHFINDER tool.

5 PATHFINDER SOFTWARE TOOL

The main output of the project is the PATHFINDER tool, principally planned for two types of users—*Critical Infrastructures managers/operators* and *National/Local Authorities* (*Civil Protection operators*). The general approach for identifying vulnerability paths is given in Figure 6, but may vary according to different users' needs.

It will be possible to use the tool in two main modes (Fig. 7):

- *WIZARD mode*—the order of setting the criteria (filters) necessary to delineate paths is defined. Under this mode, a minimal cut set of selection criteria is defined. The user browses through the pages in an established order that will be different according to the user type.
- *FREE mode*—the user can browse through the pages in free order without limitation (for expert users).

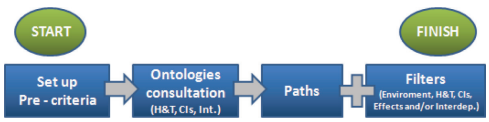

Figure 6. PATHFINDER tool utilization process.

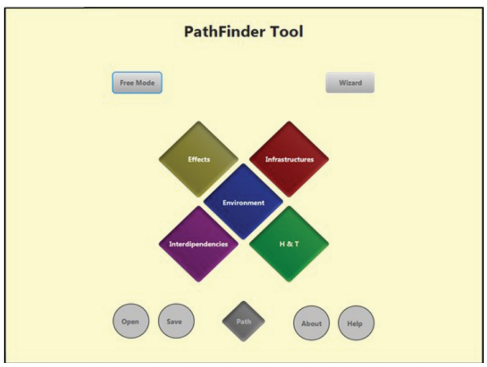

Figure 7. PATHFINDER tool: main window.

Other controls include (Fig. 7):

- *Setup pages* (middle part of the screen) that contain all the set-up options.
- *Path Button* that launches the final query, and will remain disabled until a minimal set-up will be done. Effects are the impact modes through which the hazards hit the infrastructures. In Infrastructures page the user can set one or more infrastructure he is interested in. In Environments page the user can set one or more environments, which can be associated with infrastructure or used for hazards screening. In Hazards and Threat page the user can define screening criteria for hazards and their attributes. Selection list is available within each of the sub-ontologies.

Standard options—enabling user to save on his computer the file containing the current set-up, open an existing file or use the guide.

The PATHFINDER tool has been tested in two pilot applications in collaboration with one EU Member State and one relevant CI operator.

6 CONCLUSIONS

Two main results have been achieved by the present study: a generalised and standardised specification framework for CI and services; a generalised and standardised all-hazards catalogue for CI.

By developing of a multidimensional ontology-based model it is possible to generate and document a larger set of plausible accident scenarios, fully exploiting the existing knowledge on CIP as well as all the specific knowledge on the system under analysis and its external environment. Thus, by integrating CI, Hazards & Threats and vulnerabilities, the PATHFINDER tool enables an effective risk assessment and prioritisation of activities and resources.

Indirect benefits are also expected, in terms of quality of shared information among actors, thanks to a standardised nomenclature and modelling of CI assets, functions and vulnerabilities. The contribution of the study to the general body of knowledge consists of a publicly available integrated ontology covering relevant domains when it comes to scenario identification. It enables an easy description of CI systems and their behaviour in face of H&T and under influence of interdependencies. Integration of this work with ontologies for inter-organisational information sharing presents a good opportunity for the development of a comprehensive Emergency Management ontology for CI.

However, the proposed integrated ontology suffers from some limitations. The main one is the

modelling of logical interdependencies as a further level of integration between CI sub-ontologies. Two or more infrastructures are logically interdependent if the state of each depends upon the state of the other via some mechanism that is not a physical, cyber, or geographic connection (Rinaldi et al., 2001). This category may contain policy, legal or regulatory regimes, economic systems and trends, social and human factors etc., making it very complex and uneasy to be properly addressed via ontology development.

Future planned activities include integration of Geographic Information System (GIS) that will enable visualisation as well as spatial representation of assets, systems and threats.

Renewable sources impact on power system reliability and nuclear safety

A. Volkanovski & B. Gjorgiev
Reactor Engineering Division, Jožef Stefan Institute, Ljubljana, Slovenia

ABSTRACT: The introduction of the renewable energy sources in power system result in multiple and complex challenges considering continuous and reliable operation of the power grid. One of the main challenges is intermittent power production from some renewable power sources requiring compensation of the power by the remaining power plants in the given system.

This paper presents the results of the analysis of a power system generation availability considering introduction of wind generating power units. The power system reliability is assessed by the Loss of load probability evaluated from the cumulative outage probability table. The analysis considers the uncertainty of the available power from the wind genera-tors and uncertainty of the peak load in the analyzed system. Weibull distribution is used for the characterization of the wind speed in the developed method. The consequences of the substitution of the nuclear power plants with the wind generators on the safety of the remaining operating nuclear power plants are analyzed. The core damage frequency obtained from the probabilistic safety assessment model of the nuclear power plant is used to evaluate the safety of the nuclear power plants.

Obtained results show that introduction of wind generating units in the power system results in increase of the Loss of load probability. The obtained Loss of load probability depends on uncertainty of the peak load size and shape parameters of the wind speed in the model. Increase share of wind generation in overall power system generation results in increased Loss of load probability. Substitution of the nuclear power plants with wind generation results in small decrease of the overall core damage frequency in the given system. The decrease of the overall core damage frequency depends on the characteristics of the substituted nuclear power plants and share of nuclear and wind generation in the analyzed system.

1 INTRODUCTION

The main function of the power system is to provide electrical energy to the customers as economically as possible with an acceptable degree of continuity and quality, known as reliability. The two constraints of economics and reliability are competitive since increased reliability of supply generally requires increased capital investment. These two constraints are balanced in many different ways in different countries and by different utilities, although generally they are all based on various sets of deterministic criteria.

A wide range of power system reliability indices are determined using probability theory (Billinton and Allan, 1984). The approach used and the resulting formulas depend on the problem and the assumptions utilized.

In general the two main categories of the power system reliability evaluation techniques are analytical and simulation. Analytical techniques represent the system by a mathematical model and evaluate the indices using mathematical solutions. Monte Carlo simulation methods estimate the indices by simulating the actual process and random behavior of the system. Generally Monte Carlo simulation requires a large amount of computing time and is not used extensively if alternative analytical methods are available. The obtained indices are only as good as the model derived for the system, the appropriateness of the evaluation technique and the quality of the input data used in the models and techniques.

The most important aspect in power system reliability evaluations is to have a complete understanding of the engineering implications of the system (Volkanovski et al., 2009).

The Loss of Load Probability (LOLP) or Expectation (LOLE) method is the most widely used probabilistic technique for evaluating the adequacy of a given generation configuration (Volkanovski et al., 2008, Daemi et al., 2012, Sanghvi and Shavel, 1984, Celik, 2007, Lucio et al., 2012).

Loss of load probability consists of two segments in which the generating unit unavailability is characterized by random outage rate (forced)

and scheduled outage rate. The effect of random outages is evaluated probabilistically, while that of scheduled outages is evaluated deterministically.

In power system analysis the application of LOLP is limited to the estimation of generation adequacy without consideration of the transmission system capacity or reliability.

The EU directive on the promotion of renewable energy sources sets the share of renewable energy in final energy consumption to 20% by 2020 (EC, 2009). This overall target is broken down into binding national targets for all EU member states (Klessmann et al., 2013). This target for the renewable sources together with the liberalization of the electricity market (Karova, 2011) is policy driven.

The goal of this paper is to analyze and assess implications of the introduction of the intermittent power sources on the overall reliability of the power system. In addition the implications of substitution of nuclear power plants with such sources on safety of the nuclear power plants are analyzed. The Monte Carlo sampling approach is applied for assessment of the implications of uncertainties of wind generation and peak load on the obtained results. The Probabilistic Safety Assessment (PSA) model of the nuclear power plant is used for assessment of the implications on nuclear safety.

2 METHOD DESCRIPTION

The LOLP assessment method is given in Section 2.1. Models of wind generator output power and load uncertainties are given in Section 2.2. Description of the Monte Carlo sampling and integration in the developed method is given in Section 2.3.

2.1 *LOLP assessment*

The probability of finding the generator in the forced outage at distant time in the future represents the basic parameter used in static capacity evaluation for modelling of generating unit reliability. This probability is defined as unit Unavailability (U) and in power system applications it is known as the unit Forced Outage Rate (FOR), defined as:

$$U = FOR = \frac{\lambda}{\lambda + \mu} \tag{1}$$

where λ = the expected failure rate; μ = the expected repair rate.

The unavailability (FOR) calculated with equation (1), for generating unit with relatively long operating cycles, is an adequate estimator of the probability that the unit under similar conditions will not be available for service in the future (Volkanovski et al., 2008).

Capacity outage probability table is an array of the capacity levels, or corresponding capacity out of service and the associated probabilities of existence. The associated probability of existence is the probability of the indicated amount of capacity being out of service. For capacity model is used the cumulative probability of existence and it is equal to the sum of probabilities corresponding to capacity on outage equal to or greater than the indicated amount.

Capacity model can be created using a convolution algorithm (Volkanovski et al., 2008, Billinton, 1970, Allan, 1996), which is a recursive algorithm of adding or removing units in the model and calculating the cumulative probability of a particular capacity outage state.

In case of two state units, cumulative probability of a particular capacity outage state of X (MW), after a unit of capacity C (MW) and forced outage rate U is added, is given by:

$$P(X) = (1-U)P'(X) + (U)P'(X-C) \tag{2}$$

where $P'(X)$ = the cumulative probability of the capacity outage state of X (MW) before unit is added; $P(X)$ the cumulative probability of the capacity outage state of X (MW) after the unit is added.

The equation (2) is initialized by setting $P'(X = 1.0$ for $X \leq C$ and $P'(X) = 0$ otherwise and $P'(X\text{-}C) = 1.0$ for $X \leq C$.

Generating units that are removed from system for scheduled maintenance are not available for service. New capacity model of system is created using recursive algorithm for unit removal:

$$P'(X) = \frac{P(X) - (U)P'(X-C)}{(1-U)} \tag{3}$$

where $P'(X\text{-}C) = 0$ for $X \leq C$.

The recursive algorithm given by equation (3) allows modification of the capacity outage probability table when units are taken out from system.

The load model can either be the daily peak load variation curve, which only includes the peak loads of each day, or the Load Duration Curve (LDC), which represents the hourly variation of the load. The LOLP is evaluated by convolution of the capacity and load model, obtaining the expected time interval in the specified period in which the peak load will exceed the available capacity:

$$LOLP_p = \sum_{i=1}^{n} P_i(C_i < L_i)\ time/period \tag{4}$$

where $LOLP_p$ = value of LOLP in period p with n time units; C_i = the available capacity on time i; L_i = the forecast load on time i; $P_i(C_i < L_i)$ = the

probability of loss of load on time i, obtained directly from the capacity outage cumulative probability table. In the developed method, the value of daily $LOLP_p$ is calculated using equation (4) and $n = 24$, and those values are summed to calculate the daily $LOLP_p$.

The LDC is used to evaluate the LOLP giving a risk expressed in number of hours during the day when the load will exceed available capacity (Volkanovski et al., 2008).

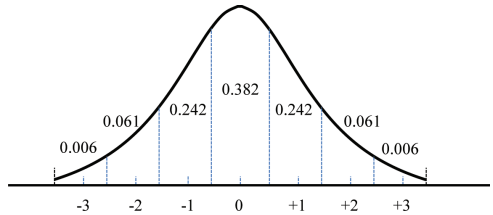

Figure 1. Seven-step approximation of the normal distribution.

2.2 *Wind power and load uncertainties*

The Weibull distribution adequately represents (Li et al., 2014, Liu, 2012) the wind speed probability distribution for most sampling times. Wind speed v is a variable generated at random (for a given time interval of one hour) with a Weibull distribution given by the following Probability Density Function (PDF):

$$f(v,c,k) = \frac{k}{c}\left(\frac{v}{c}\right)^{k-1} e^{-\left(\frac{v}{c}\right)^{k}} \tag{5}$$

where c = scale factor; k = shape factor.

The power output P of a single Wind Turbine Generator (WTG) is determined by applying a simplified input–output function:

$$P_{WTG} = \begin{cases} 0, & v < v_{ci} \quad or \quad v > v_{co} \\ \dfrac{v - v_{ci}}{v_r - v_{ci}} P_r, & v_{ci} \le v \le v_r \\ P_r, & v_r \le v \le v_{co} \end{cases} \tag{6}$$

where P_r = the rated power output; v_{ci} = the cut-in wind speed; v_r = the rated wind speed; v_{co} = the cut-out wind speed of the WTG.

The uncertainty in load forecasting can be included in the LOLP calculations by dividing the load forecast probability distribution into class intervals (Allan, 1996). The area of each class interval represents the probability that the load is the class interval mid-value. The LOLP is calculated for each load represented by the class interval multiplied by the probability of the given load.

The load forecast uncertainty was modeled using a normal distribution divided into seven discrete intervals. The probability of each area is given on Figure 1.

2.3 *Monte Carlo sampling*

Uncertainty of the wind power production is analyzed by a computerized Monte Carlo technique (Han and Lim, 2012, Tewari et al., 2011). The wind speed is sampled from probability distributions given by equation (5) used to assess power generation of single wind generator given by equation (6). The capacity outage probability table is updated considering the wind generators power obtained from the simulation. The LOLP is calculated from updated capacity outage probability table for seven different load sizes for each hour in the day. Overall LOOP for given day is calculated and stored.

High performance computer compiler (INTEL, 2013) and corresponding library (Software, 2013) were used in the computer code developed for analysis of the LOLP within this study.

3 TEST SYSTEM

The main parameters of the wind turbine generators, given in reference (Li et al., 2014) are shown in Table 1.

Peak Load of Ppeak = 9000 [MW] is used in the analysis, with Hourly Peak Load as percentage of Daily Peak Load given in reference (Grigg et al., 1999) are shown in Table 2.

The standard deviation of $\sigma = 5\%$ of peak load was used in Base model. The standard deviations of $\sigma = 2\%$ and $\sigma = 10\%$ were also analyzed. Value of $c = 7.65$ and $k = 2.06$ are used for scale and shape factors of wind speed.

Parameters of the generating units in the Base model with 5% share of the wind power in the total installed power are given in Table 3.

Table 3 shows that in Base model the installed power is for 10% larger than the peak load Ppeak. It is assumed that all units are scheduled for operation during all hours of the analyzed period.

Three case scenarios were developed and analyzed from the Base model.

First case scenario CASE1 has increased 10% share of wind power in the model. One NPP from base model is shutdown as shown on Table 4.

Second case scenario CASE2 has increased 15% share of wind power in the model. The power from

4 REFERENCE NPP MODEL

The PSA model of the NPP is developed on the basis of the plant model and Level 1 PSA analysis given in the corresponding references (NRC, 1990).

The PSA model includes 14 Event trees, 168 Fault trees and 576 Basic events.

The contribution of the Accident Groups to Core Damage Frequency (CDF) obtained for the NPP model is given in Table 7.

The LOOP Accident group, as shown on Table 7, have largest share in the overall plant CDF.

The frequency of the Loss of Offsite Power (LOOP) initiating event in reference model is LOOP = 7.7E-2 [/yr]. The share of each LOOP data category into overall LOOP with mean frequencies are given in Table 8.

In this study it is assumed that Grid related LOOP will change proportionally with the change of LOLP. The share of the CDF from the LOOP accident group will change proportionally with the change of LOOP frequency (Volkanovski et al., 2009).

Change of the frequency of other initiating events resulting from the changes in the power system is not considered in this study. The increase of the number of transients and corresponding initiating event frequency is expected in case of the NPP that are utilized for load following.

Table 7. Share of accident sequences in CDF.

No.	Accident group	Mean CDF [/yr]	Share [%]
1.	All LOOP	9.63E-06	44.9
2.	All LOCA	6.31E-06	29.4
3.	Int. LOCA	1.60E-06	7.5
4.	All transient	1.52E-06	7.1

Grid related	3.99E-02	51.8
Weather related	1.04E-02	13.4
All	7.70E-02	100

5 RESULTS

Obtained Probability Density Function (PDF) of the LOLP for Base model and different standard deviations of the peak load σ are given on Figure 2. Mean LOLP for analyzed Base models is given in Table 9.

Results on Figure 2 and Table 9 show that increase of the peak load standard deviation σ results in increase of the LOLP.

Obtained results for Case 1 and different load deviations are given on Figure 3 and Table 10.

Figure 3 and Table 10 show that increased peak load uncertainty results in larger LOLP but relative increase is smaller compared to the Base model.

Impact of wind speed parameters on the obtained results were analyzed on Case 1 model for different shape factor *k* values. Obtained results are given in Table 11 and Figure 4.

Figure 4 and Table 11 shows that decrease of the wind speed shape factor k results in change of the LOLP PDF and increase of the mean LOLP.

Figure 5 shows obtained LOLP PDF for all analyzed models and equal load standard deviation σ = 5%. Table 12 shows obtained mean LOLP for analyzed case scenarios.

Figure 5 and Table 12 shows that increase of the share of wind generation in the system results in large increase of the mean LOLP.

Figure 5 shows that LOLP PDF has increased range with the increase of the wind generation share.

The recommended annual LOLP for given power system (Billinton and Allan, 1988) is in range of

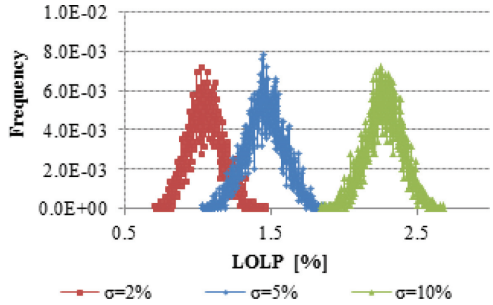

Figure 2. Obtained LOLP for Base model.

Table 9. Mean LOLP for Base model.

	σ = 2%	σ = 5%	σ = 10%
LOLP [hr/day]	1.05E-02	1.46E-02	2.28E-02

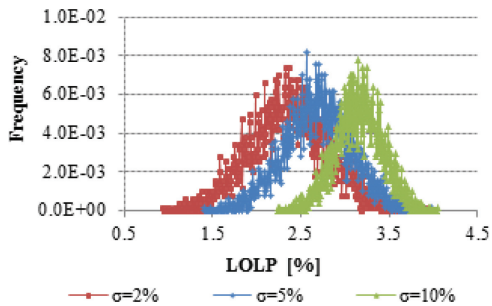

Figure 3. Obtained LOLP for Case 1.

Table 10. Mean LOLP for Case 1.

	σ = 2%	σ = 5%	σ = 10%
LOLP [hr/day]	2.35E-02	2.68E-02	3.16E-02

Table 11. Mean LOLP for different shape factor k.

	k = 2.05	k = 1.56	k = 1.06
LOLP [hr/day]	2.68E-02	2.78E-02	3.01E-02

0.1–1 days/year that is equal to 6.5E-3–6.5E-2 hr/day. Comparison with values in Table 7 shows that obtained values for analyzed scenarios are in this range. The mean LOLP for Case 3 is near the largest recommended value.

In analyzed case scenarios it is assumed closure of single (Case 1 and Case 2) or two NPP (Case 3). The closure of the NPPs results in change of the

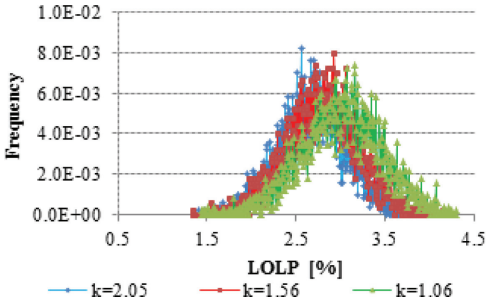

Figure 4. Obtained LOLP for different shape factors *k*.

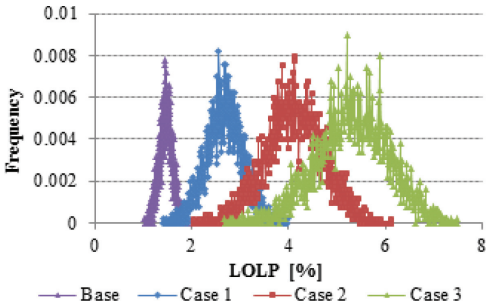

Figure 5. Obtained LOLP for analyzed case scenarios.

Table 12. Mean LOLP for analyzed case scenarios.

	Base	Case 1	Case 2	Case 3
LOLP [hr/yr]	1.46E-02	2.68E-02	4.10E-02	5.32E-02

Table 13. Change of CDF in analyzed systems.

	Case 1	Case 2	Case 3
ΔCDF+ [/yr]	8,33E-06	1,80E-05	1,32E-05
ΔCDF– [/yr]	2,15E-05	2,15E-05	4,29E-05
ΣCDF [/yr]	–1,31E-05	–3,44E-06	–2,97E-05

sum of the CDF of the NPPs in given power system ΣCDF. This decrease ΔCDF—is equal to the sum of the CDF of the closed NPPs.

Obtained results from the analysis show that introduction and increase of the share of the wind generation in the power system results in increased LOLP. The consequence is increased grid related LOOP initiating event frequency. This results in increase of the CDF of the reaming units in the system ΔCDF+.

Table 13 summarizes the changes of the CDF in the analyzed systems.

Table 13 shows that shutdown of the nuclear power plants results in decrease of the overall sum of CDF of NPP in the system indicated by negative ΣCDF and corresponding risk. Table 13 shows that obtained decrease of overall CDF and corresponding risk is small if analysis considers the increase of the CDF of the remaining NPP in the system.

6 CONCLUSIONS

Implications of introduction of wind generation on power system reliability and NPP safety was analyzed. The LOLP was used as a measure of the generation adequacy of the system. The core damage frequency was used as a measure of the NPP safety.

Obtained results show that increase uncertainty of the peak load size results in larger mean LOLP. The mean LOLP depends on the parameters of the distribution used for characterization of the wind speed. Increase of the share of the wind generation results in increased LOLP. The change of the wind generation share modifies the probability density function of the LOLP.

Analysis of the substitution of the NPP with wind generation shows that overall decrease of the CDF in the analyzed system depends on the share of the wind generation and number and characteristics of the NPP that are shutdown. Obtained results show that overall decrease of the CDF is smaller than the sum of the CDF of the NPP that are shutdown.

Titanic viewed from different perspectives on major accidents

H. Kim & S. Haugen
Department of Production and Quality Engineering NTNU, Trondheim, Norway

ABSTRACT: Several perspectives on major accidents have evolved over the last four decades to explain why accidents occur and how to prevent them. Each perspective looks at the causes of an accident in its own particular way, and may draw different conclusions about the causes of the same accident. In the paper, we have taken a look at an accident that occurred about a century ago, the sinking of the Titanic. The paper summarizes the accident using modern accident investigation techniques. Subsequently, six perspectives on major accidents are applied to identify how the accident causes can be related to the perspectives.

The result shows that none of the perspectives cover all the accident causes alone, and a combination of the perspectives can help the overall understanding of the accident. Based on this, some reflections are made on the similarities and differences between the different perspectives.

1 INTRODUCTION

Several perspectives on major accidents have evolved over the last four decades to explain why accidents occur and how to prevent them. Key are the energy-barrier model (Gibson, 1961, Haddon, 1970, Haddon, 1980), Turner's Man-Made Disasters (MMD) model (Turner and Pidgeon, 1978, Pidgeon and O'Leary, 2000), Perrow's Normal Accident Theory (NAT) (Perrow, 1984), High Reliability Organizations (HRO) theory (Rochlin et al., 1987, LaPorte and Consolini, 1991), Rasmussen's conflicting objectives perspective (Rasmussen, 1997), and resilience engineering (Hollnagel, 2004, Hollnagel, 2008). Each looks at the causes of an accident in its own particular way, and the perspectives therefore focus on different causes of the same accident.

The main objective of the paper is to study how each major accident perspective can be applied to an actual accident and to emphasize the importance of using several accident perspectives. For this purpose, the paper investigates the Titanic accident using a modern accident investigation technique, and six perspectives on major accidents are applied to identify how the accident causes can be related to the perspectives. Subsequently, the paper argues for the necessity of integrating the accident perspectives and suggests one possible approach which is based on the energy-barrier model.

The topics we cover in the paper are as follows:

1. What are the causes of the Titanic accident and how can we structure them? (Section 2)
2. What is the main idea of each accident perspective? (Section 3)
3. How can we apply each accident perspective to the causes of the Titanic accident? (Section 4)
4. Why do we need an integrated accident perspective and how can we integrate them? (Section 5 and 6)

Finally, some concluding remarks are given in Section 7.

2 INVESTIGATION INTO TITANIC ACCIDENT

2.1 *Event tree analysis*

The story of the Titanic is well-known, and the causes of the disaster have been well investigated over several decades. There were unusual amounts of icebergs, ice warnings were ignored, the Titanic made maximum speed in an ice field, and the lookout spotted the iceberg too late. After spotting the iceberg, there was a frantic manoeuver, serious hull damage due to the collision, and failure of rescue and evacuation. The combination of these events caused the disaster of the Titanic (Smith and Rayner, 1912, Eaton and Haas, 1996, Rapport, 2004, Beesley, 2008, Foecke, 2008, Lightoller, 2010, BBC, 2011, BBC, 2012, Compton, 2012, History, 2012, NationalGeographic, 2012, Ward, 2012). They are structured as an event tree given in Figure 1.

2.2 *MTO analysis*

Man, Technology and Organization (MTO) analysis has been widely used the last decade for

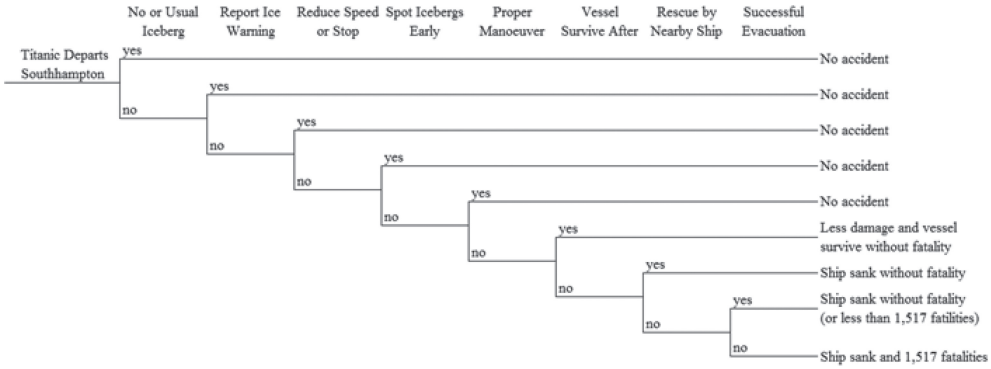

Figure 1. Event tree analysis for the Titanic accident.

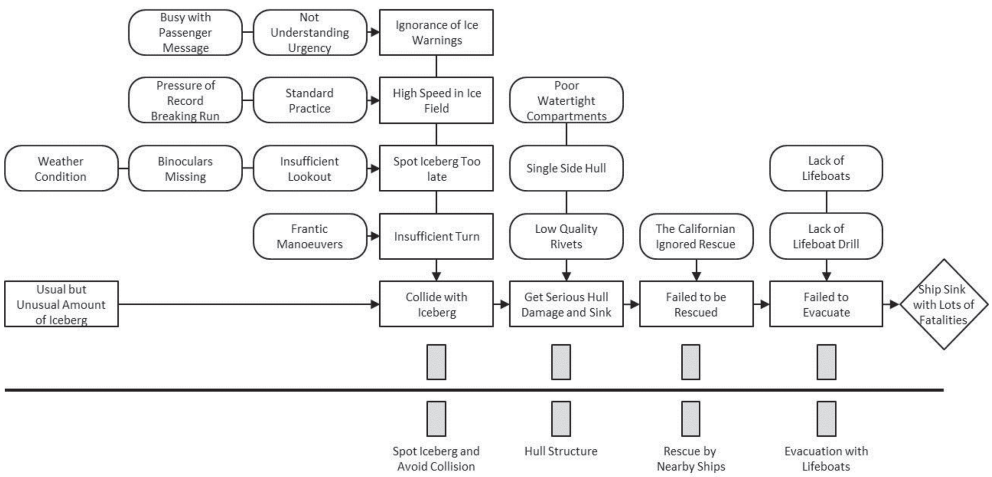

Figure 2. MTO analysis for the Titanic accident.

investigating accidents in the Norwegian offshore industry. The basis for the MTO analysis is that human, organizational and technical factors should be focused equally in an accident investigation. The analysis is based on using three methods: (Rollenhagen, 1995, Bento, 1999, Sklet, 2004)

– Structured analysis by use of event and cause diagrams
– Change analysis by describing how events have deviated from earlier events or common practice
– Barrier analysis by identifying technological and administrative barriers which have failed or are missing.

The main purpose of MTO analysis in the paper is not to investigate the accident in every detail, but to illustrate events, causes and conditions of the accident with a whole picture, and show the structure and relation of them. Thus, details of how the MTO analysis has been performed are not covered in the study.

Event and cause analysis and barrier analysis are illustrated into a single picture as shown in Figure 2. Based on this chart, the study investigates major accident perspectives in the accident of the Titanic. The change analysis is not included in Figure 2 because it has not so much relevance to this study.

3 SIX MAJOR ACCIDENT PERSPECTIVES

The paper focuses on six major accident perspectives: the energy-barrier model, MMD model, NAT,

Table 1. Comparison of six major accident perspectives.

Accident perspective	Why accidents occur?	How to prevent them?
Energy-barrier	Failure to establish and maintain adequate barrier functions	Include barrier functions in the design of the system and maintain barrier functions throughout system life
MMD	Lack of information flow and misperceptions with incubation period	Make systematic efforts to collect information about hazards and build culture for active search for signals of danger
NAT	Mismatch between complexity and coupling	Reduce complexity or loose couplings and discard high-risk systems that are both complex and tightly coupled
HRO	Not discussed explicitly but there seems to be an implicit understanding that accidents are caused by un-recovered errors	Build organizational redundancy and cultures that combines requirement for fault-free performance with openness to the fact that errors do occur (mindfulness)
Conflicting objectives	Distributed decision making in dynamic and opaque systems with invisible and untouchable boundaries	Establish counter pressures that favor safe performance and make boundaries to unacceptable performance visible and touchable
Resilience engineering	A mismatch between the coping capacity of the organization and the emerging dangerous interactive patterns	Build and maintain the abilities to anticipate, monitor, respond, and learn

HRO theory, conflicting objectives perspective, and resilience engineering. The main ideas of each accident perspective are very briefly summarized in Table 1 (Rosness et al., 2010).

4 MAJOR ACCIDENT PERSPECTIVES AND TITANIC ACCIDENT

This section applies the six major accident perspectives to the 23 causes of the Titanic accident. Each of the causes is briefly introduced and studied with regard to the six perspectives on major accidents.

4.1 *Usual but unusual amount of icebergs*

The Captain and crew of the Titanic did not pay much attention to general ice warnings because icebergs were common at that time of the year on the route of the Titanic (Lightoller, 2010, Ward, 2012). The "usual icebergs" caused the crew to be stuck in outdated behaviors which did not work in a changed situation, and therefore it is relevant to the ability to anticipate from resilience engineering. It can also be explained by mindfulness of HRO theory whose idea is to survey the existing situation based on expectations and contain unexpected events. Unusual amount of icebergs increased the hazard of iceberg. This cause is therefore related to the energy-barrier model, HRO theory and resilience engineering.

4.2 *Wireless operator busy with passenger messages*

The main role of the wireless operators was not to receive ice warnings, but to provide a luxury message service for passengers. Moreover, one day before the disaster, the transmitter broke down altogether, and it took two wireless operators seven hours to dismantle the entire system which caused a lot of backlog of messages from passengers. By the night of the disaster, both wireless operators were exhausted and could not even consider delivering the ice warnings forty feet forward to the bridge (Ward, 2012). This is relevant to the energy-barrier model, HRO theory, conflicting objectives perspective and resilience engineering. The HROs build organizational redundancy and operate in "high tempo mode" in such circumstance. It can also be explained by resilience engineering. The Titanic did not anticipate this high demand situation of wireless operators, and the Captain failed to monitor the stress and overload of the wireless operators. The conflicting role between sending passenger messages and reporting ice warnings is relevant to the conflicting objectives perspective. Lastly, it contributed to "ignorance of ice warnings" which weakened the barrier of "spot iceberg and avoid collision".

4.3 *Wireless operator not understanding the urgency of warnings*

The wireless operators knew nothing about navigation, and therefore latitude and longitude meant nothing to them. Even in the face of explicit ice warnings, they would not have known the extreme urgency (Ward, 2012). It is relevant to information flow of MMD theory, ability to monitor of resilience engineering, and mindfulness of HRO theory. It also affected "ignorance of ice warnings" and therefore influenced the barrier of "spot iceberg and avoid collision".

4.4 *Ignorance of ice warnings*

The Titanic received seven ice warnings from nearby ships on the day of the disaster (Ward, 2012). The two ice warnings from the Mesaba and the Californian were critical reports with great urgency. However, the wireless operator just put the message from the Mesaba under a paper weight (Lightoller, 2010), and replied to the Californian that "shut up, shut up, I am busy; I am working Cape Race" (Compton, 2012). It is a result of the previous two conditions: "wireless operator busy with passenger messages" and "wireless operator not understanding the urgency of warnings". It is therefore applicable to the energy-barrier model, MMD theory, HRO theory, conflicting objectives perspective and resilience engineering.

4.5 *Pressure of record breaking run*

The Titanic seemed to try to beat the time set by the Olympic on its own maiden voyage and the following three facts support it: i) Ismay, Chairman of White Star Line, repeatedly stated that "we will beat the Olympic and get in to New York on Tuesday", ii) the Titanic held a thousand ton more coal than the Olympic took on its own maiden voyage, iii) on the morning of the disaster, the Titanic seemed certain to make a record breaking trip (Ward, 2012). It is relevant to the energy-barrier model and conflicting objectives perspective. The pressure of record breaking run drove the Titanic towards the boundary of a safe performance, and it influenced the barrier of "spot iceberg and avoid collision" by encouraging "high speed in ice field".

4.6 *Standard practice*

Maintaining the speed in ice field at night was a standard practice of steamship liners using the North Atlantic track at that time (Beesley, 2008), and no captain would dream of slowing down even in the vicinity of ice at night (Ward, 2012). It is applicable to the energy-barrier model, HRO theory, and resilience engineering. The Captain was getting stuck in outdated behaviors, which is a failure of ability to anticipate in resilience engineering. It can also be explained by mindfulness of HRO theory because it is a lack of preoccupation with failure. Lastly, it promoted "high speed in ice field" and therefore weakened the barrier of "spot iceberg and avoid collision".

4.7 *High speed in ice field*

The Titanic was making its maximum speed just prior to the collision, and it was a result of the previous two conditions: "pressure of record breaking run" and "standard practice". Thus, "high speed in ice field" is relevant to the energy-barrier model, HRO theory, conflicting objectives perspective, and resilience engineering.

4.8 *Weather condition*

On the day of the disaster, the weather was calm and the sea was smooth. There was no moon, no wind, and no swell. These weather conditions precluded the lookout from spotting iceberg. If there had been either wind or swell, the outline of the iceberg would have been more visible, through the water breaking at the base, and the Titanic could avoid it (Lightoller, 2010). "Weather condition" made it difficult to spot iceberg, which influenced the barrier of "spot iceberg and avoid collision".

4.9 *Missing binoculars*

The Titanic lookouts were supposed to have binoculars, and the lookout testified to the US inquiry that if he had had binoculars to scan the horizon ahead, he would have seen the iceberg early enough for the Titanic to avoid it. However, the binoculars had accidentally been locked away because there was an unexpected reshuffle of its senior officers. (Ward, 2012). It influenced the performance of lookout, and therefore weakened the barrier of "spot iceberg and avoid collision".

4.10 *Insufficient lookout*

The weather was against the Titanic, and binoculars were missing in ice field at night. Under these circumstances, an extra lookout should have been placed at the stemhead, and a sharp lookout should have been kept from both sides of the bridge by an officer (Compton, 2012). It is applicable to the energy-barrier model, HRO theory, and resilience engineering. The Titanic should have been operated in "high tempo mode" with organizational redundancy of HRO theory. It is also relevant to

the ability to anticipate and respond of resilience engineering. It contributed to "spot iceberg too late" which weakened the barrier of "spot iceberg and avoid collision".

4.11 *Spot iceberg too late*

At 11.40 pm, the lookout of the Titanic saw the iceberg, and the original distance from the iceberg at that time was only between 600 yards and half a mile (Ward, 2012). It is a result of the combination of the above three conditions (Section 4.8–4.10), and therefore it contains the energy-barrier model, HRO theory and resilience engineering. It is also related to NAT. Spotting iceberg late decreased the buffer for preventing collision; in other word, it increased tightness of coupling.

4.12 *Frantic manoeuver and insufficient turn*

The First Officer of the Titanic ordered "Hard a-starboard" right after he was informed of the iceberg which ran completely contrary to accepted procedure. The action was much more likely to cause collisions than to prevent them (Ward, 2012). It is relevant to the energy-barrier model, HRO theory and resilience engineering. The frantic action of the First Officer can be explained by the ability to respond in resilience engineering and preoccupation with failure and sensitivity to operations of mindfulness in HRO theory. It influenced and weakened the barrier of "spot iceberg and avoid collision".

"Insufficient turn" is a result of "frantic manoeuvers", and therefore the former has the same accident perspectives with the latter.

4.13 *Collide with iceberg*

As a result of Section 4.2 to Section 4.12, the Titanic failed to spot the iceberg early and collided with it. In other words, the barrier of "spot iceberg and avoid collision" failed to maintain its function. It is caused by neither a single event nor a single condition, but by a combination of all of the above conditions and events. The event of "collide with iceberg" is therefore applicable to all of accident perspectives which are relevant to Section 4.2 to Section 4.12: the energy-barrier model, MMD model, NAT, HRO theory, conflicting objectives perspective and resilience engineering.

4.14 *Poor watertight compartment*

The Titanic was divided into 16 main watertight compartments, but only one watertight bulkhead extended to the upper most continuous deck C. The flooding over deck E contributed largely to the sinking of the Titanic (Smith and Rayner, 1912). The prime motivation for making the Titanic less safe was to increase the convenience and overall satisfaction of its passengers like huge dining rooms and saloons (Ward, 2012). It is relevant to the energy-barrier model and conflicting objectives perspective. Establishing passenger convenience is a kind of organizational pressure which resulted in imperfect watertight compartments. It also weakened the barrier of "hull structure".

4.15 *Single side hull*

The sides of the ship were just a single hull under the waterline. In the event of a glancing blow, the watertight compartment would be rendered absolutely useless, owing to the fact that there was no side protection (Compton, 2012). The weight and the cost for double side hull was so great that it was abandoned by the ship owner of the Titanic (Beesley, 2008). It is applicable to the energy-barrier model, and conflicting objectives perspective. The pressure of cost and weight exacted single side hull which weakened the barrier of "hull structure".

4.16 *Low quality of rivets*

Using sub-surface sonar, the iceberg damage has been mapped and it was found that the hull was not severely deformed, which implies that there was a failure of the riveted seams. Analysis of the wrought iron rivets has shown that they contained an average of three times more slag than optimal levels. It was seen that pressure to finish Titanic caused the company to order wrought iron that was one level below that generally specified for rivets. (Foecke, 2008). It is related to the energy-barrier model and conflicting objectives perspective. The pressure of the schedule forced the Titanic to use low quality rivets, which weakened the barrier of "hull structure".

4.17 *Get serious hull damage and sink*

As a result of the above three conditions (Section 4.14–4.16), the Titanic got serious hull damage and sank after the collision. Therefore, "get serious hull damage and sink" is applicable to the energy-barrier model and conflicting objectives perspective.

4.18 *The Californian ignored rescue signal and failed to be rescued*

The Californian was the nearest ship to the Titanic when it sank on the day of the disaster. The lookouts of the Californian saw several rockets from the Titanic and reported them to the Captain.

However, he ignored their reports because of the color and time intervals of the rockets. A distress signal should have fired at precise one-minute intervals, but the Titanic did not. Almost five hours after they saw the first rocket, they learned that the Titanic had sunk during the night. If the Carpathia had gone to the rescue of the Titanic immediately, most of the people aboard could have been rescued and survived. (Ward, 2012). This is related to the energy-barrier model and MMD model. Ignorance of the distress signal is a lack of information flow, and firing rockets at precise one minute intervals is a fantasy plan for a sinking ship. It also influenced the barrier of "rescue by nearby ships".

"Failed to be rescued" is a result of "the Californian ignored rescue signal" and therefore, the former has the same accident perspectives with the latter.

4.19 *Lack of lifeboats*

The Titanic was provided with 16 lifeboats and 4 collapsible, and total capacity of lifeboats was 1,176 persons (Smith and Rayner, 1912). Even though the Titanic was only equipped with enough lifeboats to save half the people aboard, that was still more than were required by law at that time. The Board of Trade specified required number of lifeboats, but the number of passengers and crew was not considered relevant (Ward, 2012). In 1911, a year before the Titanic sank, Alexander Carlisle, an expert witness, argued that the vessels should carry far more lifeboats for passenger safety. However, the committee actually recommended fewer lifeboats than before. In fact, the Titanic was capable of carrying sixty four lifeboats to be prepared for any change in the regulations. However, the White Star Line wanted to leave as much deck space as possible free for passengers and equipped only 20 lifeboats (Ward, 2012). This is relevant to the energy-barrier model, MMD model and conflicting objectives perspective. The Board of Trade committee tried to change their requirement, because someone knew that there was a problem in the regulation. However, the organizational pressure forced the committee to ignore the consideration and made the Titanic carry only 20 lifeboats. Lastly, it contributed to "failed to evacuate" and weakened the barrier of "evacuation with lifeboats".

4.20 *Lack of lifeboat drill*

Not only were the Titanic's lifeboats too few to save all its passengers and crew, but they were not even used to their full capacity. Total capacity of lifeboats was 1,176 persons but only 706 persons were saved. Almost five hundred of those who died could have been saved, if all the boats had departed fully laden (Ward, 2012, Smith and Rayner, 1912). The major reason affecting it was the lack of lifeboat drill. There had been no proper boat drill, nor a muster, and many of the crew did not join the ship until a few hours before sailing (Compton, 2012). As a result, the crew of the Titanic were not prepared at all when disaster hit. This is applicable to the energy-barrier model, HRO theory and resilience engineering. The crews of the Titanic were not prepared for the evacuation and failed to respond. It is a failure of ability to respond in resilience engineering and a failure of anticipation of the unexpected and contain the unexpected in HRO theory (Weick and Sutcliffe, 2001, Rosness et al., 2010). This led to "failed to evacuate" and weakened the barrier of "evacuation with lifeboats".

4.21 *Failed to evacuate*

It is a result of the above two conditions (Section 4.19 and 4.20), and therefore "failed to evacuate" is applicable to the energy-barrier model, MMD model, HRO theory, conflicting objectives perspective and resilience engineering.

5 RESULT

The relations between the 23 causes of the Titanic accident and the six accident perspectives have been discussed in Section 4, and the result is summarized in Table 2.

The result shows that the accident of the Titanic consists of causes from different accident perspectives, and none of them can explain the entire conditions and events alone, except for the energy-barrier model. MMD model and NAT are applicable to only small part of the accident. The conflicting objective perspective, HRO theory and resilience engineering are related to nearly half of the accident causes only. It means that focusing on only one perspective may narrow our viewpoint and make us omit other important causes. For example, regarding the MMD model, the disaster of the Titanic occurred because of lack of information flow. Someone in the rule making committee knew the problem of lifeboat requirements and several crew knew that something was wrong during navigation. However, they are not the only causes of the accident, but only a small part of it. There were other important causes like "pressure of record breaking run", "insufficient lookout", "low quality rivets", and so on.

NAT, HRO theory, and resilience engineering are only relevant to operational causes, while the other perspectives are applicable to both operational

Table 2. Titanic accident and six major accident perspectives.

No.	Events and conditions	Energy-barrier	MMD theory	NAT	HRO theory	CO perspective	RE
1	Usual but unusual amount of icebergs	x			x		x
2	Wireless operator busy	x			x	x	x
3	Not understanding urgency	x	x		x		x
4	Ignorance of ice warnings	x	x		x	x	x
5	Pressure of record breaking run	x				x	
6	Standard practice	x			x		x
7	High speed in ice field	x			x	x	x
8	Weather conditions	x					
9	Missing binoculars	x					
10	Insufficient lookout	x			x		x
11	Spot iceberg too late	x		x	x		x
12	Frantic manoeuver	x			x		x
13	Insufficient turn	x			x		x
14	Collide with iceberg	x	x	x	x	x	x
15	Poor watertight compartments	x				x	
16	Single side hull	x				x	
17	Low quality rivets	x				x	
18	Get serious hull damage and sink	x				x	
19	Californian ignored rescue signal	x	x				
20	Failed to be rescued	x	x				
21	Lack of lifeboats	x	x			x	
22	Lack of lifeboat drill	x			x		x
23	Failed to evacuate	x	x		x	x	x

and design matters. Too much attention to those perspectives may lead us to overlook design and installation problems.

The energy-barrier model is related to all causes of the disaster of the Titanic, but it cannot explain the reason why those causes had occurred. Details of each cause can be supported by other perspectives. For instance, "lack of lifeboats" weakened the barrier of "evacuation with lifeboats" but the energy-barrier model cannot explain why there were not enough lifeboats on the Titanic. With MMD model, we can find that there was an insufficient information flow in rule making process, and conflicting objectives perspective can point out that enough lifeboats were not equipped because the owner wanted much more free space.

6 DISCUSSION

Focusing on only one accident perspective is not enough to understand entire accident causes. All of the perspective are correct but the reason every perspective is describing it differently is because they view the accident from different viewpoints. An integrated accident model is therefore necessary for an overall understanding of an accident. The basis can be the energy-barrier model because it can provide an explicit and overall view on the causes of an accident (Rosness et al., 2010), and it has been shown that all of the causes, in the Titanic accident, are directly or indirectly relevant to the energy-barrier model. The other five perspectives can support the energy-barrier model and explain why weakening or strengthening of barriers occurs. The integrated accident model for the Titanic is given in Figure 3. The integrated accident model can help us explain the whole accident causes, and therefore we can distribute our limited resources efficiently to maintain barrier functions. For instance, the first barrier, "spot iceberg and avoid collision" is relevant to all five accident perspectives, while the second one, "hull structure", is related to only one perspective. This means that the first barrier may be influenced by much more factors than the second one, and therefore we need to pay more attention to the first barrier to maintain the entire barrier of the vessel with limited resources.

Another interesting point is that HRO theory and resilience engineering show exactly identical aspect on the result. If one is relevant to HRO theory, then it is always related to resilience engineering, and vice versa. In fact, there are many

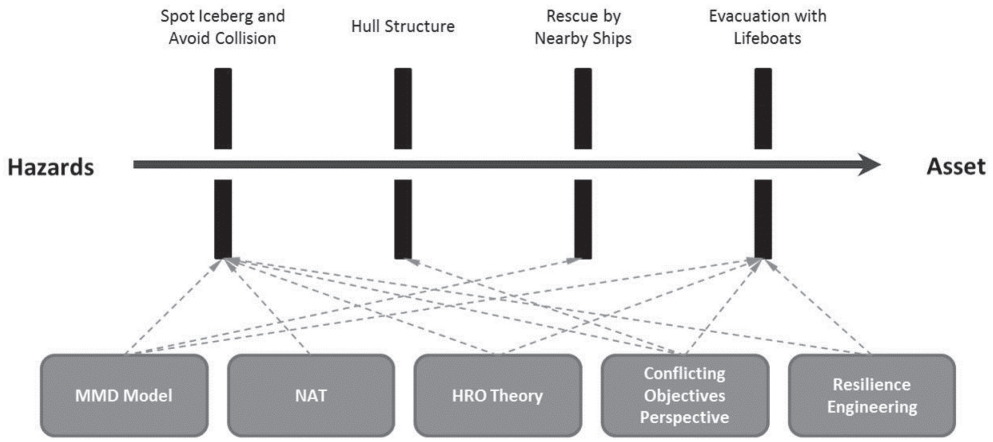

Figure 3. Integrated accident model and Titanic accident.

similarities between the two perspectives. Both of them deal with operational factors mainly and focus on successes instead of failures. Five elements of mindfulness of HRO theory resemble four abilities to succeed of resilience engineering. Comparing those two perspectives and investigating differences in actual accident cases can be an interesting future work.

Lastly, the result of applying accident perspectives to the Titanic accident has shown that all of the conditions and events are, directly or indirectly, relevant to the energy-barrier model. The reason for this may be that the paper applied MTO analysis to accident investigation, which is basically founded on the energy-barrier model. We may find other factors which are not related to the energy-barrier model if we analyze the accident with other methods like the Functional Resonance Analysis Method (FRAM) or Systems-Theoretic Accident Modelling and Process (STAMP). Applying those methods and comparing the differences can be the subject for a future study.

7 CONCLUDING REMARKS

The paper has investigated the accident of the Titanic and applied six accident perspectives to the causes. It has been found that there were a total of 23 contributed to the disaster. Some of them were related to all of the six perspectives, while the others were relevant to only small part of them. It is concluded that a single accident perspective cannot explain entire accident causes and sequences, but combination of the perspectives can help overall understanding of the accident of the Titanic. Based on this result, the paper has suggested a concept of an integrated accident model which includes every accident perspective based on the energy-barrier model. Through this integrated accident model, we can understand an accident in overall point of view and distribute limited resources to each barrier in effective way.

ACKNOWLEDGEMENTS

The authors with to thank Ann Britt Miberg Skjerve from IFE in Norway for giving us the idea to use the Titanic as a case for this paper.

Usability of accident and incident reports for evidence-based risk modeling of ship grounding

A. Mazaheri & J. Montewka
Department of Applied Mechanics, Marine Technology, Research Group on Maritime Risk and Safety, Aalto University, Espoo, Finland
Kotka Maritime Research Center, Kotka, Finland

ABSTRACT: This paper presents study of 22 grounding accident reports by the Finnish Accident Investigation Board and 73 voluntary near-miss grounding reports from the ForeSea® incident database. The objective was to find out the usability of accident and incident reports for evidence-based risk modeling of ship grounding accidents. A version of Human Factors Analysis and Classification System (HFACS) suitable for grounding accident analysis is introduced as a framework to review the accident reports. Accident reports are shown as a reliable source of evidence to extract the most significant contributing factors in grounding accidents. However, the credibility of voluntary incident reports is considered low at their current form, and their usability for the evidence-based risk modeling is questionable.

1 INTRODUCTION

Risk managers should usually use risk models to understand the behavior of a system and its components in order to mitigate the involved risks by implementing proper control measures (IMO, 2002). In this regard, a suitable model for risk management purposes should reflect the available background knowledge on the system and its components (Aven, 2013, Montewka et al., 2014). Currently available risk models for maritime risk analysis are not proper enough for risk management purposes as they are mostly based on the intuition of the developers rather than the evidence; thus they may not necessarily presenting the true available knowledge of the system. For the review of the risk models of ship grounding, the reader is referred to (Mazaheri et al., 2013b). The lack of knowledge about the underlying causes of accidents leads to the evidential uncertainty of any model attempting to describe this type of accident, (Aven and Zio, 2011). To decrease this uncertainty, evidence-based modeling that addresses real accident scenarios is encouraged, as opposed to development of imaginary scenarios, (e.g. Kristiansen, 2010, IMO, 2012).

One of the main sources of the evidence that is available and can be used for risk modeling is accident reports that are prepared by expert accident investigators (Schröder-Hinrichs et al., 2011). Since obtaining primary data about an accident that has happened in the past is nearly impossible, using accident reports as a secondary source of data is unavoidable (Mazaheri et al., 2013c). There are some concerns regarding using only accident reports for modeling, though. One is that the accidents are scarce in frequency, thus the number of scenarios that can be analyzed is limited (Ladan and Hänninen, 2012). To overcome this imperfection, one of the suggested solutions is to utilize incident reports, as incidents occur much more frequently than accidents (Bole et al., 1987). Besides, since incidents are governed by the similar mechanism and underlying factors that cause accidents (Ladan and Hänninen, 2012) but they did not end in actual accidents, analyzing the incidents may likely give insights about the in-placed risk control options that stopped the incident to become an accident. Here, an incident or near-miss refers to an individual or a series of mishaps that did not result in a serious accident like ship grounding.

Accident and incident reports are useful for uncovering the factors that have contributed to the occurrence of a mishap as well as the level of importance of each factor. Besides, the way that the contributing factors are linked together may be understood from such reports. In this regard, the aim of this paper is to study the usability of the accident and incident reports for evidence-based modeling by assessing the type of knowledge that one can extract from these reports. As Lundberg et al. (2009) highlighted, in practice the result of an accident analysis depends on two issues namely the causes and the causality. The causes are the contributing factors that their presence in the accident is observed, and the causality is related

to the mechanism that the causes are connected and cause the accident at the end. In this paper, we merely look for the presence of different causes in the causal networks of grounding accidents based on the reviewed reports, and the causality relation analysis is left for further studies.

The paper is organized as follows: Section 2 introduces the accident and incident reports that are used for the study. The applied methodology for reviewing the reports for evidence-based modeling is presented in section 3. Section 4 presents the obtained results, whereas Section 5 discusses them. Section 6 concludes the paper.

2 REVIEWED REPORTS

2.1 *Accident reports*

Accident reports are categorized as a secondary source of data, in which the reports are prepared from the primary data that the investigator obtained first-hand by interviewing the operators and analyzing the evidence after an accident (Mazaheri et al., 2013c). In maritime safety analysis, the official accident reports that are prepared by the accident investigation boards normally present valuable information and knowledge regarding why and how an accident happens. For this study, we have utilized the accident reports of the grounding accidents prepared by Accident Investigation Board of Finland (AIB). AIB has the policy to run investigations on: 1) marine accidents that happen in the Finnish water territories no matter which flag vessels are involved; 2) marine accidents that happen outside the Finnish water territories if at least one involved ship flies the Finnish flag. However, not all of the accidents falling in the above criterion will be investigated, rather only those accidents that the acquired knowledge can enhance the safety awareness in marine traffic, (AIB, 2012). In the publicly available database of AIB, there exist 77 reports of grounding accidents that happened between the years 1995–2012. The majority of the reports are written in Finnish language and few reports are also prepared in Swedish language. From among the available reports, 22 reports have English translations and they used in this study.

Although more systematic analysis and attention towards the organizational contribution factors can be seen in the recent reports of AIB, the structures of the reports have more or less the same over the last two decades. They are all started with a summary, which briefly explains the event and the findings of the investigators. The reports continue with general description of the vessel, external condition at the time of the accident, and then the accident and the possible performed rescue operations. These are followed by the analysis of the accident and the causes. At the end, the report is concluded by presenting the causal chain of events and the underlying factors in the accident, as well as some recommendations to improve maritime safety. The parts that are fully reviewed for this study are *summaries*, *analyses*, and the *conclusions*. However, for some of the reports, other parts are also browsed in order to better understand the accident and the sequence of the causal events.

2.2 *Incident reports*

On the contrary to the accidents, there is almost no available systematic reporting system for incidents. Currently, there are quite few available sources that can be used for obtaining the near-miss data, of which not all are available for public use, see for example (Ladan and Hänninen, 2012). For this study, we have used the incident reports available in the ForeSea® database, which is an anonymous, voluntary, and feed-by-users database that was initiated by Finnish and Swedish government agencies. The database was created in order to collect the hazardous conditions that are not normally reported to authorities (ForeSea, 2014). Reporting to ForeSea® can be performed only by registered users and by filling a form with four questions. The parties need to answer the questions in their own words as clearly as possible. The questions are: *What did happen?; What did cause the event?; What were the consequences of the event?; What measures were taken?* The answers are then first handled by a third party, in which the parts that can jeopardize the anonymity will be removed and some key words are assigned to each case to make it searchable, and finally it is added to the database.

In the database of ForeSea®, there exist 3046 reports (accessed on 10.05.2014), of which 1715 of them are categorized as near-misses or non-conformity. For the purpose of this study, we use 73 cases, which are returned as connected to grounding.

3 METHODOLOGY

3.1 *Accident reports*

Since the accident reports were prepared in a systematic way by expert accident investigators, in order to uniformly extract the knowledge from all the reports, a framework is needed for reviewing the reports. There are a handful of tools and frameworks available for accident and incident analyzing and reporting (Johnson, 2003), which are mostly based on linear or non-linear accident theories that deal with complex socio-technical systems.

From the way AIB reported the investigation, it is understood that a complex linear accident theory has been utilized for investigating the accidents. Therefore, we have utilized a redefined version of the well established Human Factors Analysis and Classification System (HFACS) framework to review these reports.

HFACS is based in the "Swiss Cheese" model of human error, (Reason, 1990), which looks at four levels of active errors and latent failures, including 1) unsafe acts, 2) preconditions for unsafe acts, 3) unsafe supervision, 4) organizational influences. It was initially developed to study the contribution of human elements in military aviation accidents (Shappell and Wiegmann, 1997, Shappell and Wiegmann, 2000). However, the framework has been developed further to cover environmental factors (machinery failures) and meteorological conditions (Wiegmann et al., 2005). The success of the method in detecting the contributing latent and active failures in the accident analysis made the method popular in the field of accident analysis. It is vastly used in analysis of civil aviation accidents (Shappell et al., 2007), railroad (Reinach and Viale, 2006) and maritime (Chen and Chou, 2012, Chen et al., 2013). Reinach and Viale (2006) have developed the method by adding the fifth level, namely "external factors", to the initial four levels in order to cover the latent failures, which are believed to be specific for a particular domain under study. The same practice is followed by recent studies that used HFACS; (e.g. Schröder-Hinrichs et al., 2011, Chauvin et al., 2013, Chen et al., 2013).

Since an accident is unique from its own perspective, frameworks like HFACS try to assign the unique causes of an accident into more global factors to give better understanding of the phenomena by cumulating the causes into frequent factors. In this regard, having a specific framework with more specialized global factors for each domain and purposes seems beneficial. The different versions of HFACS that are recently introduced in the maritime domain support this belief, for example HFACS-MA (Chen et al., 2013) for general maritime accidents, HFACS-Coll for collision accidents (Chauvin et al., 2013), and HFACS-MSS for machinery space accidents (Schröder-Hinrichs et al., 2011). Therefore, we have revised HFACS to a specific version suitable for grounding accidents analysis (HFACS-Ground; see Fig. 1) by implementing factors that are more related to grounding accidents. HFACS-Ground is also built as a five-level framework and has many similarities with HFACS-Coll and HFACS-MA. However, in addition to the factors that cover traffic control and piloting services as affecting factors on grounding accident, "infrastructure" is added as a latent failure subcategory to the "environmental factors" in order to cover the issues related to the complexity of waterway, like waterway design and markings, which are believed to have effect on the frequency of grounding accidents (Mazaheri et al., 2013a). The accident reports in this study were then reviewed using HFACS-Ground framework.

In order to avoid subjective interpretations of the reports, only the factors that were explicitly mentioned in the reports were extracted and classified based on the HFACS-Ground. This basically means that the reviewers avoided further investigating the causality of the mentioned causes in the reports up to the higher levels. In total, HFACS-Ground contains 147 factors. Each factor is assigned a nanocode, which are used to catch the frequency of the causal factors mentioned in the reports.

3.2 *Incident reports*

In contrary to the accident reports that were prepared in a systematic analytical way by expert accident investigators, the incident reports suffer from the lack of a systematic view of the event. The reports are short (from few sentences to maximum of half a page) and have been reported by people of different expertise. This has resulted that the reports have different qualities with regard to the provided data and information. Most of the reports have reported only what have been seen, and merely few have tried to hypothesize the possible causes of the events. Even those few reports lack the evidence to support the provided hypotheses. Therefore, using HFACS-Ground for analyzing incident reports is not practical; rather it might be misleading as normally active failures are the only causes that are reported in the incident reports. Therefore, another approach has been followed in this study for reviewing the incident reports. The incident reports were read through and the explanatory phrases from the texts were extracted as the mishaps that caused the incident. Thereafter, in order to catch more frequent causes, the extracted phrases from all the reports were grouped into 22 more general categories, see Table 2.

3.3 *Statistical analysis*

To identify any significant link between the extracted contributing factors from both types of the reports, the statistical dependencies of the factors are studied two-by-two using Pearson correlation coefficient (r). The reliabilities of the studies are tested using χ^2-goodness-of-fit test. The Spearman rank correlation coefficient (ρ) is also used to study the rank relation between the frequencies of

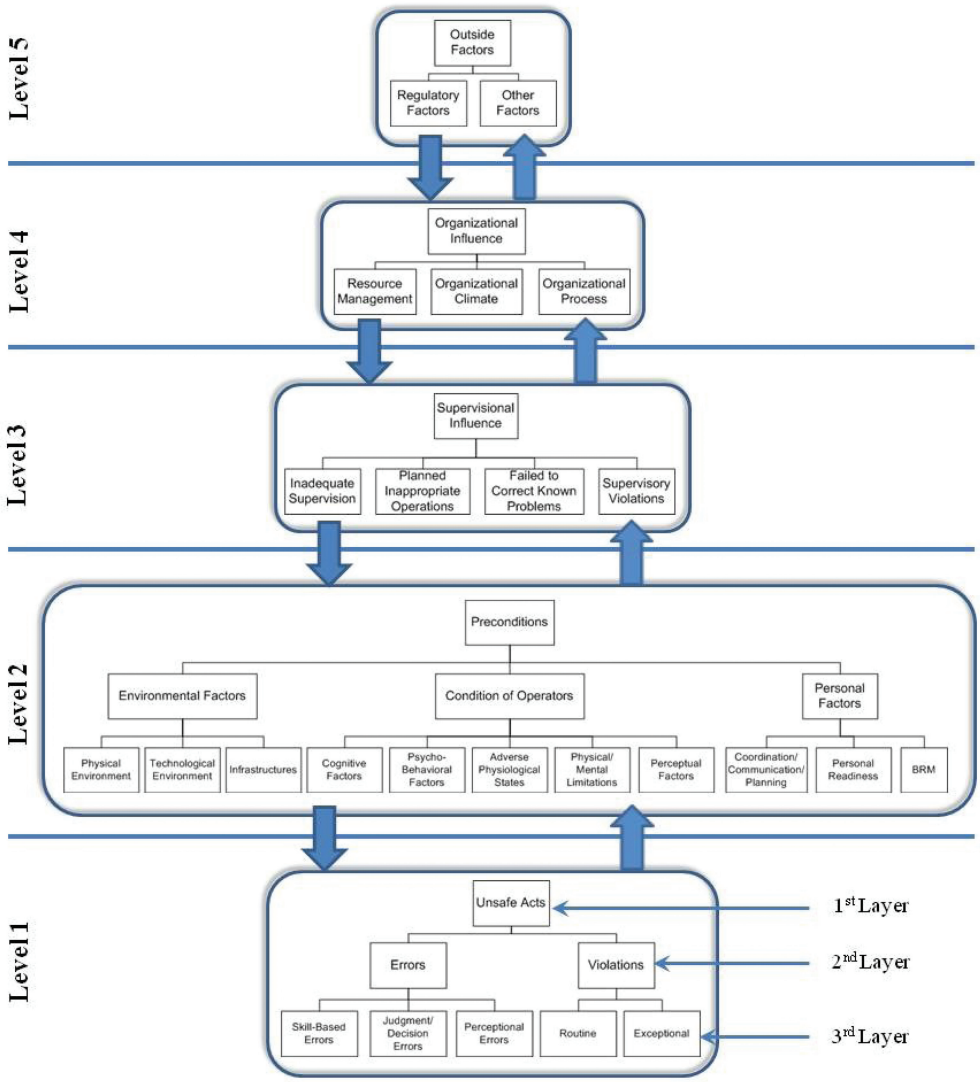

Figure 1. Human factors analysis and classification system for grounding (HFACS-Ground).

the extracted contributing factors from the accident and incident reports.

4 RESULTS

4.1 *Accident reports*

Table 1 shows the results of the reviewing of the accident reports as the relative frequency of each class of factors. The relative frequency expresses the number of a specific class of factors in the reports in relation to the number of all the other factors in each level (see Fig. 1). It is seen that levels 1 and 2 of the failures as *unsafe acts* and *preconditions* are seen more frequently in the accident reports. Level 5 of failure as the *external factors* has the smallest frequency. Level 2 of failure as *preconditions* has the highest frequency among other levels of failures, which may be the result of having the largest coverage of the factors.

Out of 147 causal factors, covered by HFACS-Ground, 88 factors belong to this level. Table 1 shows that "*judgment/decision errors*" is the most frequent active failure. When this is seen together with the most frequent latent failure, as issues related to *communication/cooperation/planning*,

Table 1. Analyzing the accident reports using HFACS-Ground.

Level		1st Layer	%	2nd Layer	%	3rd Layer	%	Rank
Active Failure	1	Unsafe Acts	16.8	Error	95.6	Skill-Based	22.7	9
						Judgment/Decision	68.2	2
						Perceptional	9.1	11
				Violation	4.4	Routine	50	13
						Exceptional	50	13
Latent Failure/Condition	2	Preconditions	55.5	Environmental Factors	33.6	Physical Environment	33.3	5
						Technological Environment	45.1	3
						Infrastructures	21.6	6
				Condition of Operator	26.3	Cognitive Factors	21.5	10
						Psycho-Behavioral Factors	57.5	4
						Adverse Physiological Sates	25	8
						Physical/Mental Limitations	7.5	12
						Perceptual Factors	2.5	15
				Personal Factors	40.1	Coordination/Communication/Planning	83.6	1
						Personal Readiness	0	25
						SRM (incl. BRM)	16.4	7
	3	Unsafe Supervision	12.8	Inadequate Supervision			51.4	16
				Planned Inappropriate Operations			11.4	22
				Failed to Correct Known Problems			17.2	20
				Supervisory Violations			20	19
	4	Organizational Influence	13.9	Resource Management			42.1	17
				Organizational Climate			15.8	21
				Organizational Process			42.1	17
	5	External Factors	1.1	Regulation Gaps			33.3	24
				Other Factors			66.7	23

one may see the importance of the proper planning and communication, since most of the errors may be avoided as a result of that. Nevertheless, this is a causality issue that needs to be further studied. Table 1 also shows that the most frequent failures are among the two first levels of failures in HFACS-Ground framework. Since these two first levels of failures are mostly related to the failures of the frontline operators, this shows that: either the reviewed accident reports somehow failed to further investigate the top tier causes as *organizational*, *supervisional*, and *external* factors; or those preconditions may have been less involved in the causality network of the accidents. If the first conclusion is true, then there is the risk that the recommendations that are made based on these investigations may not be able to tackle the actual problem.

4.2 *Incident reports*

Table 2 shows the results of the reviewing of the incident reports as the relative and observational frequencies. The relative frequency of a category is in relation to all the categories. The observational frequency puts a specific category in relation to all reviewed reports.

It can be seen that *mechanical failure or unexpected behavior* of equipment by far is the most frequent mishap category that is reported by the incident reports (74%). The next category in the list is *errors*, which stands second to mechanical failure by a great distance (23%). Knowing that the incident reports are voluntary reports written mostly by the person who was involved in the incident, this may be the sign that people tend to mostly see the technological failures as the cause of a mishap rather than a human error. Although "*errors*" comes next in the list, all the errors reported in the reviewed reports were errors made by a person other than the reporter and most of them were people out of the circle of the crew, like port operators or an individual in a third company. Only one report contained an error made by a crew member, which was reported by his superior as the cause of the mishap. This may show that despite of the existing oppose discussions for the blame culture (e.g. Russell, 1999, Bond, 2008), this culture is still alive in the mind of mariners that makes them hesitate to either see or report the mistakes made by themselves or their close colleagues.

4.3 *Statistical analysis*

Since the accident and incident reports are reviewed with different approaches, in order to be able to compare the extracted knowledge from them we transferred the results of the accident reports to the categories used for the incident reports (Table 2). Small Spearman rank correlation ($\rho \approx 0.03$) between the rank orders of causes for accident and

Table 2. Frequency of the extracted causes from the incident reports in compare with the translated causes from the accident reports.

General Categories	Incident Reports		Accident Reports	
	Relative Frequency %	Observational Frequency %	Relative Frequency %	Observational Frequency %
Accidental loss of control	9.0	20.3	0.7	4.1
Alarm missing or not clear	0.6	1.4	1.9	11.0
Bad Visibility	0.6	1.4	4.3	24.7
Darkness	0.6	1.4	2.6	15.1
Errors (Skill-based/Judgment/ Decision)	10.2	23.0	10.4	60.3
Fairway	4.2	9.5	5.2	30.1
Hazardous natural environment	2.4	5.4	5.9	34.3
Inappropriate communication & cooperation	0.6	1.4	11.6	67.1
Inappropriate maintenance	2.4	5.4	0.2	1.4

incident reports shows the difference between the most frequent causes in the accident and incident reports. This difference may be interpreted in two ways. The first interpretation comes from the way that the reports are prepared. Since a systematic approach is followed for the accident reports, they may be considered more valid. Thus, the big difference between the rank orders of the important contributing factors in accident and incidents reports may be a sign that the involved uncertainties in the incident reports are high, which then makes the incident reports almost useless for the purpose of evidence-based modeling. The reports may only act as alerts of the possible threats in the working places. The second interpretation comes from the idea that the incidents are incomplete chains of events towards an actual accident. This means that the more in deep parallel analysis of accident and incident reports may reveal the possible risk control options that were in place to stop the incident to become an accident.

For instance, although *errors* has the second rank in frequency in both types of reports, based on the frequency of *inappropriate communication and cooperation* in the accident and incident reports, we may conclude that "appropriate communication and cooperation" in the incident cases stopped the situation to become serious that it would result in an accident; thus highlighting the importance of a proper interaction between the crew. This conclusion can be confirmed at some level by the statistical results of the study. Inappropriate communication and cooperation is linked to inappropriate route planning ($r = 0.5$, $p < .05$) in the accidents. The importance of appropriate route planning, itself, can be understood by the link that it has with presence of a pilot ($r = 0.5$, $p < .05$) in accident cases, knowing that in 64% of the reviewed accident reports a licensed pilot was present onboard the vessel. It is worth to mentioned that there is a strong link between inappropriate communication and personal factors ($r = 0.7$, $p < .001$) in incident reports, which can show how personality of crew affects the safety through inappropriate communication.

The results also show that the lack of redundancy is an affecting factor in safety as it is reported by 17.6% of the incident cases and shows a strong link with the accidental loss of control ($r = 0.8$, $p < .001$) in the accidents. The results of the accident cases show that the accidental loss of control, itself, can be affected by the inappropriate training ($r = 0.8$, $p < .001$) and the inappropriate maintenance ($r = 0.7$, $p < .05$). Under-manning, which is reported by almost 25% of the accident cases, shows strong connection with inappropriate regulation and practices ($r = 0.6$, $p < .001$) that also includes BRM. This can illustrate the importance of proper policies and training, especially in human resource management, in the maritime safety.

5 DISCUSSION

The results show that the most frequent active failure contributed in the reviewed grounding accidents is the operator errors in decision or judgment, as it comes the second most frequent causes in both accident and incident reports. Combining this knowledge with the high/low frequencies of inappropriate communication and cooperation in accident/incident reports respectively, the importance of proper interaction between the crew members may be highlighted. Most of the operator

errors may be detected and avoided on time through proper monitoring and checking, which is the result of a proper communication and cooperation. Moreover, statistical analysis of the extracted causes in accident and incident reports suggests that inappropriate planning is an important factor affecting safety with regard to the grounding accident. The results show that inappropriate planning can affect maritime safety as it may even cancel out the presence of a licensed local pilot onboard.

Most of the detected contributing factors in the reviewed accident reports belong to the first and second levels of failures in Figure 1, which is mostly related to the operator failure. This may be interpreted in two ways: 1) a more conservative interpretation is that active and latent failures of the frontline operators are the most responsible failures for grounding accidents; which then suggests the need for causality analysis of these failures in order to be able to implement proper control measures; 2) another interpretation, could be that the used frameworks for accident analysis by AIB are not capable of deep analyzing an accident up to the higher levels of failures (level 3 upwards in Fig. 1); which then suggests the use of a more proper and updated framework for the investigations. It is worth mentioning that not only there was no single unique framework used in the investigation of the accidents by AIB, but also in neither of the reviewed reports HFACS has been mentioned as the used framework for investigation. Therefore, since the presented knowledge in each report is affected by the framework that is used for investigating the accident (Lundberg et al., 2009), our study shows that the use of a different framework to review the reports does not have much effect on the knowledge that can be obtained.

The analysis of the reviewed incident reports shows that the current practice of reporting the near-misses cannot contribute much to the evidence-based modeling; because the available evidence only highlight active failures as the contributing factors in the occurred mishap. Besides, incident reports have the tendency to overlook the mishaps related to organizations and operators, and emphasize more on technology failures. This is either because the reports are not prepared based on a holistic investigation and only the observations are reported; or that the blame culture is still highlighted in the minds of the crew that even in an anonymous report they hesitate to report other causes than technology failures. This may be seen as a problem of the voluntary near-miss report systems, as it makes the incident reports to be unreliable with regard to detecting the significant causes of an accident that can be used in evidence-based modeling. Nevertheless, since incidents are broken chain of hazardous events that did not end in an accident, if the current practice of reporting near-misses is changed into a more systematic way of analysis, these reports may be used in evidence-based modeling in combination with accident reports in order to find proper control options. One does not have much to say with regard to the possible controlling options only by knowing about the most frequent causes. Effective control options can be defined and implemented only if the causality has been discovered in the accident, which was not studied in this paper. However, the presented study shows that the statistical analysis on the frequency of the causes may give hints regarding the causal relations between the extracted causes. Causal relations may tell why a mishap, like inappropriate communication, has occurred.

Moreover, the majority of the reviewed near-miss grounding cases were categorized into near-miss groundings because a mechanical problem, like steering or engine malfunction, could have led to the possible loses of maneuverability. Therefore, near-miss grounding cases that are extracted from the ForeSea® database may not be precisely a near-miss accident from our perspective. This again also shows that the incident databases should be used cautiously in evidence-based modeling, as the near-miss definition of an accident may differ with the one that is used in such databases.

Despite the above discussions, the study is bounded with the involved uncertainties. Use of specific databases as AIB and ForeSea® to extract the reports may introduce some level of uncertainty that roots to the way that the databases are formulated. Thus, the study needs to be repeated using reports prepared by other authorities and data providers. The main uncertainty in the result, however, comes from the small used datasets as only 22 accident reports are reviewed. In that respect, increasing the number of reviewed reports can increase the validity of such studies.

6 CONCLUSION

The possibility of using accident reports and voluntary incident reports in evidence-based risk modeling is investigated using accident reports prepared by Finnish Accident Investigation Board and ForeSea® incident database with regard to grounding cases. A version of HFACS framework as HFACS-Ground is introduced to review the grounding accident reports. In conclusion, accident reports are shown as a reliable source of evidence to extract the most significant contributing factors in grounding accidents. Nevertheless, their validity will be better confirmed if their usability for extracting the causal relation between the contributing factors is also tested in future studies.

On the other hand, voluntary incident reports are shown as not very useful in their current form for evidence-based modeling. They may only be useful in the way that they are currently used, as the alerts for possible hazards in the daily operation of shipping. In order to make the incident reports useful for accident modeling, first they need to be prepared in a more systematic way that can address the causality of the mishaps, and second a more consistent definition of near-miss situation needs to be defined to reliably assign occurred mishaps to a specific type of accident.

Winter navigation at the Baltic Sea: An analysis of accidents occurred during winters 2002–2003 & 2009–2013

O.A. Valdez Banda, F. Goerlandt, J. Montewka & P. Kujala
Department of Applied Mechanics, Aalto University, Espoo, Finland

ABSTRACT: The Baltic Sea is the busiest area during winter ice navigation in the northern seas. The winter navigation in the zone commonly presents two main scenarios: navigation when ice is not yet present but it is approaching to the area bringing the first winter storms and extremely poor light conditions, and navigation with sea ice conditions which mainly challenges the capability of the vessels in finding the best route to reach final destination. In this paper, accidents occurred in the zone during winter 2002–2003 and winters 2009 to 2013 are quantitatively and qualitatively analyzed. The aim is to accurate detect the accidents with higher frequencies during winters, the most common vessel operations involved in those accidents, the severity of the accidents, the areas where accidents are occurring, and most important, exactly under which navigational operations and sea conditions accidents are occurring. Based on the findings of this study, collisions and groundings are the most typical accidents occurring during winter time. However, the analyzed data revealed that groundings are more frequent before ice is present, and collisions are the most frequent type of accident under ice sea conditions.

1 INTRODUCTION

Collisions and groundings are the most common accidents in the Baltic Sea, including winter season with or without the presence of ice (Goerlandt, et al., 2012). Even though some specific areas within the Baltic Sea are recognize as relative safe (e.g. the Gulf of Finland), every year approximately 22 to 34 accidents occur in this zone (Kujala, et al., 2009). The collisions and groundings reported are commonly related to human failures which endanger people, environment and the whole transportation system. In the most severe cases these accidents may lead to severe damage (e.g. to the ship structure), compromising ship's integrity, and exposing people and environment to human casualties and cargo spills. In less serious cases, these accidents may result in only small damages to the hull (Kujala, et al., 2007, Kujala, et al., 2009 and Mazaheri, et al., 2013).

In this paper, the description of accidents occurred in the Baltic Sea during the winters 2002–2003 & 2009–2013 are detailed analyzed. The data analysis presented in this paper covers accidents reported on Finnish waters and/or to Finnish vessels registered by the Finnish Transport Safety Agency during the mentioned time periods. The quantitative and qualitative analyses presented in this paper have carefully assessed the accidents occurred under sea ice conditions. Thus, the aim of this study is to present which are the most common accidents occurring in the Baltic Sea during winter time, where and when these accidents are taking place, in which conditions the accidents commonly happen, and the severity of these accidents. Thereby, the outcome of this study can be used to identify when, where and how the risk of an accident is more latent during winter navigation.

2 THE BALTIC SEA DURING WINTER

2.1 *Navigating the Baltic Sea during winter*

The Baltic Sea is composed by 7 zones: Bay of Bothnia, Sea of Bothnia, Gulf of Finland, Gulf of Riga, Central Baltic, South Baltic (coast line), and Western Baltic (Danish waters) (EfficienSea, 2011). All these zones experience different weather and light conditions during winter time. For example, the northern area (Bay of Bothnia) have long periods of darkness, and heavy winter storms which represent the first challenges for the vessels navigating the zone before sea ice is present in the area. In other areas such as central Baltic, Gulf of Finland and South and Western Baltic, the light conditions are not as drastic as in the north, but in these areas, during winter the vessels have to deal with heavy banks of fog constantly (Trafi, 2011). Once the ice is present, the Bay of Bothnia is commonly the first zone which set traffic restrictions during winter. These restrictions specify which are the merchant vessels allowed to navigate the area,

and which ones can receive icebreaker assistance if needed (Trafi, 2013). In order to set limits and designate adequate assistance, the Finnish-Swedish winter navigation system has specific "ice class rules" for the requirements of structural strength and engine output for vessels to be included within a Finnish-Swedish ice class. The system also determines the minimum ice class and deadweight permitted in a certain area for icebreaker assistance (Table 1).

The restrictions begin according to the climate conditions of the zone. For example, on winter 2010–2011 the restrictions started on the 29 of November in the Bay of Bothnia, 4 of December

Table 1. Basis of traffic restrictions (Finnish Maritime Administration).

Ice class	Ice class requirements	Ice thickness
IA super	Ships with such structure, engine output and other properties that they are normally capable of navigating in difficult ice conditions without the assistance of icebreakers.	
IA	Ships with such structure, engine output and other properties that they are capable of navigating in difficult ice conditions, with the assistance of icebreakers when necessary.	Thickness of ice: > 50 cm
IB	Ships with such structure, engine output and other properties that they are capable of navigating in moderate ice conditions, with the assistance of icebreakers when necessary.	Thickness of ice: 30–50 cm
IC	Ships with such structure, engine out and other properties that they are capable of navigating in light ice conditions, with the assistance of icebreakers when necessary.	Thickness of ice: 15–30 cm
II	Ships that have a steel hull and that are structurally fit for navigation in the open sea and that, despite not being strengthened for navigation in ice, are capable of navigating in very light ice conditions with their own propulsion machinery.	Thickness of ice: 10–15 cm
III	Ships that do not belong to the ice classes referred above.	

Table 2. Description of ice types.

Ice type	Description
Fast ice	Is the sea ice that is "fastened" to the coastline, to the sea floor along shoals or to grounded icebergs
Consolidated, compact pack ice	Pack ice in which the concentration is ten-tenths and the floes are frozen together
Close pack ice	Pack ice in which the concentration is seven-tenths to eight-tenths, composed of floes mostly in contact.
Open pack ice	Pack ice in which the ice concentration is four-tenths to six-tenths, with many leads and polynyas, and the floes are generally not in contact with one another.
Very open pack ice	Pack ice in which the concentration is one-tenth to three-tenths and water preponderates over the ice.
New ice	A general term for recently formed ice that includes frazil ice, grease ice, slush, and shuga.
Level ice	Sea ice that is unaffected by deformation.
Ice Crack	Any fracture that has not parted.
Ice boundary	The demarcation at any given time between fast ice and pack ice or between areas of pack ice of different concentrations.
Estimated ice boundary	An estimation of demarcation at any given time between fast ice and pack ice or between areas of pack ice of different concentrations.
Rafted ice	Type of deformed ice formed by one piece of ice overriding another.
Ridge and hummocked ice	Ice piled haphazardly one piece over another in the form of ridges or walls. Usually found in first-year ice. And sea ice piled haphazardly one piece over another to form an uneven surface. When weathered, it has the appearance of smooth hillocks.
Window, brash ice barrier	Accumulations of floating ice made up of fragments not more than 2 m across, the wreckage of other forms of ice.
Ice Lead	Any fracture or passageway through sea ice that is navigable by surface vessels.

in the Gulf of Finland, 12 of December in the Sea of Bothnia, 12 of December in the Gulf of Riga, 1 of January in Central Baltic (EfficienSea, 2011). In this case, the winter 2010–2011 was considered a hard winter which has around 145 000 km² of ice covering the Baltic Sea (FMI, 2011). However, winter 2002–2003 was even harder, the winter restrictions started one month earlier than commonly, and the ice extent experienced was around 232 000 km².

2.2 *Winter ice conditions and their effect on ships*

Ice conditions are the resulted of the climate prevailing during the winter. Although, all winters present different characteristics every year, ice conditions are constantly measured, monitored and shared by the Finnish & Swedish Meteorological Institutes (FMI) (SMHI). Thus, the authorities, shipping companies, and the vessels navigating the Baltic Sea can be constantly informed about the current conditions and the forecast for the zone. A winter navigation map of the Baltic Sea displays information about the characteristics of the ice prevailing in different zones (Table 2), and the ice thickness on those.

One key aspect on knowing the sea ice conditions, is the opportunity to better plan the navigational pattern of a ship. This plan also serves to anticipate the possible effect of ice on ship design and performance, and also to establish in advance the necessary propulsion and the needed characteristics for maneuvering of the ship. (Daley and Riska, 1990). Thus, having monitored and reported the daily sea ice conditions, enable to potentially link those conditions with the coordinates reported in accidents during winter ice navigation.

3 ACCIDENTS AT THE BALTIC SEA (WINTERS 2002–2003 & 2009–2013)

3.1 *Data and methods*

The marine accident statistics produced in this paper, are based on the data from winters: December 2002 to April 2003 and October 2009 to April 2013. The data sources used for this analysis are provided by the Finnish Transport Safety Agency (Trafi), which consist of marine casualties reported on Finnish waters or to vessels registered to Finland. In the particular case of the reports from winters 2009–2013, identification of the accident locations is based on the coordinates of the accidents reported in that time period. And for the purposes of this paper, those coordinates have been allocated within the ice maps reported by SMHI and FMI on those dates. More details such as the kind of vessel involved in the accidents, operations performed when the accidents occurred (only 2009–2013), outcome of the accidents, and the severity of the accidents (only 2009–2013) have resulted from a qualitative data analysis performed to the collected data. The original accident data provided by FMA and Trafi originally provided de following information:

- Number of casualty report
- Date
- Occurrence severity
- Casualty event
- Damage
- Ship(s) type involved in the accident
- Latitude
- Longitude
- Casualty event description

Thus, in order to identify and extract the information relevant for this study, a qualitative method of analysis based on the "5 whys" original method from (Jones and Womack, 1996) was implemented. The adapted method in this study basically applies a questionnaire for the identification of 5 key aspects:

1. Which vessels were involved in the accident?
2. Which type of accident occurred?
3. Which severity category was given to the event?
4. Which operation was performed? (base on the analysis of the event description, an identification of the operation performed was performed)
5. And under Which ice conditions? (base on the link between coordinates reported and the ice map)

3.2 *Analysis of general accidents*

3.2.1 *Number of accidents, vessel type involved and type of accidents*

The total number of casualties in the mentioned periods, covering accidents with and without the presence of sea ice is 119. Figure 1 presents the amount by type of vessels involved on those accidents. And Figure 2 presents the percentages of the type of accidents occurred during the analyzed periods.

3.2.2 *Severity of the accidents*

The severity of the accidents is based on the reported to the Finnish Transport Safety Agency (Trafi). This severity has a three-level categorization: less serious, serious and very serious. The categorization is based on the severity of the outcome of the accident, including damages to the ships, environment and people. A very serious accident is the one that leads to human casualty and/or seriously exposing to it, and/in combination with

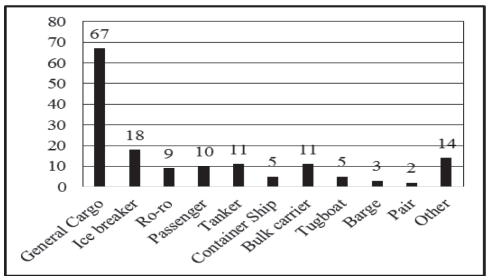

Figure 1. Type of vessels involved in accidents during winters 2009–2012 (FMA, 2003; and Trafi, 2013).

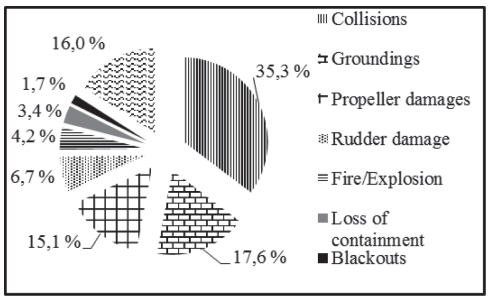

Figure 2. Percentage of the type outcome derived from the accidents (FMA, 2003; Trafi, 2013).

total lost or extremely severe damage to vessels and environment. A serious accident is the one which had severe consequences that could lead to a major impact in human safety, vessel safety and structure, and to the environment. A less serious accident is an accident which had minor repercussion in human safety, minor damage to ship machinery and structure and a no significant impact to the environment. Table 3 presents the type of accidents occurred during winters 2009–2013 and their respective designated severity.

Figure 3 presents the amount of less serious, serious and very serious accidents classified by winter and month of occurrence.

3.3 *Analysis of the accidents under ice conditions*

The accident data collected from winter 2002–2003 are all related to accidents under ice conditions. And from the 68 accidents originally reported during the winters 2009–2013, only 19 were related to operations performed under ice conditions.

3.3.1 *Vessel type, types of accidents and winter*

From the 70 accidents occurred under ice conditions 54% is related to general cargo vessels and 19% to ice breakers. Figure 4 presents the types of

Table 3. Type of accidents and severity (Trafi, 2013).

Accident type	Less serious	Serious	Very serious	Total
Collisions	21	5	1	27
With other ship	13	3	1	17
With other ship not under way	3	1	0	4
With a fixed object	5	1	0	6
Groundings	12	9	0	21
Power	7	8	0	15
Drift	5	1	0	6
Loss of containment	4	0	0	4
Oil spill	4	0	0	4
Fire/ Explosion	4	1	0	5
Fire	3	1	0	4
Explosion	1	0	0	1
Rudder damage	0	2	0	2
Loss of propulsion	1	0	0	1
Blackouts	2	0	0	2
Other accidents	6	0	0	6
Total	50	17	1	68

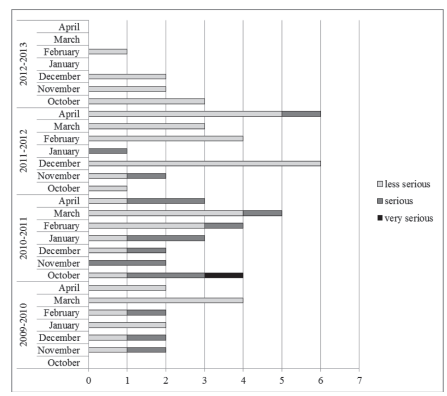

Figure 3. Accident and their severity by winter and month.

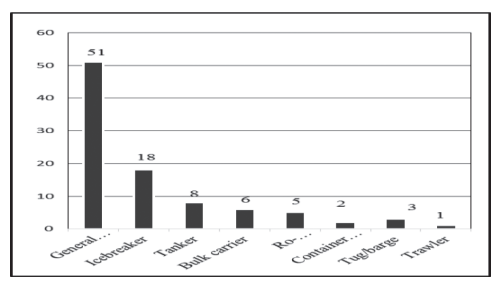

Figure 4. Type of Vessels involved in accidents under ice conditions in winters 2002–03 & 2009–13 (FMA, 2003; Trafi, 2013).

vessels involved in accidents under ice conditions. And Figure 5 presents the types of accidents occurred under ice conditions. The winter 2002–03, and the month of February were the ones with the major number of the accidents occurred.

3.3.2 *Severity of the accidents*

Table 4 presents the type of accidents occurred under ice conditions and their respective designated severity during the periods 2009–2013. Unfortunately, the data base of the winter 2002–2003 had not such classification. Thus, in winters 2009–2013, 3 accidents were designated as serious, and 16 cases were designated as less serious. There were not very serious accidents occurred under ice conditions during the analyzed time periods.

3.3.3 *Icebreaker operations*

In the 31 collisions experienced during the analyzed winters, 18 were related to the assistant operations of icebreakers. Therefore, in this section the descriptions of all icebreakers operations are introduced. There are four identified icebreaker operations (Kujala et al., 2007; Critch 2014, and Ploskonka 2013):

- *Escorting:* an ice breaker is escorting when it breaks an ice channel and the assisted ship follows the icebreaker at a recommended distance.
- *Breaking a ship loose:* an icebreaker is breaking a ship lose when it pass the ship a quite close distance and break the ice beside and in front of an assisted ship, and release the ship from ice pressure.
- *Convoy:* the operation is similar to escorting but in this case there are several ships following the icebreaker from a distance long enough to stop the ship if the ship in front gets stuck.
- *Towing:* is an operation when a ship cannot follow an icebreaker because the ice pressure makes the channel close quickly, or because the channel has too much slush ice, and/or because the assisted ship has not an appropriate performance in ice. An icebreaker may be towing one vessel while simultaneously leading a convoy of one or more other.

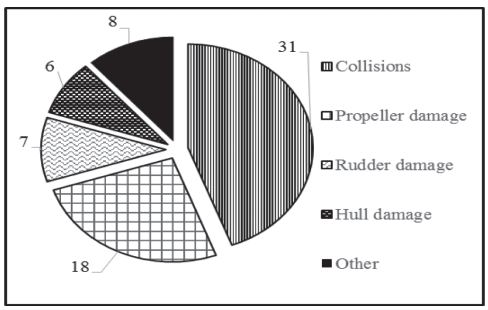

Figure 5. Types accidents under ice conditions during winters 2002–2003 & 2009–2013 (FMA, 2003; Trafi, 2013).

Table 4. Type of accidents under ice conditions and their severity (Trafi, 2013).

Accident type	Less serious	Serious	Very serious	Total
Collisions	14	2	0	16
W/ other ship	13	2	0	15
W/ other ship not under way	0	0	0	0
W/ a fixed object	1	0	0	1
Groundings	1	0	0	1
Power	1	0	0	1
Drift	0	0	0	0
Loss of containment	1	0	0	1
Oil spill	1	0	0	1
Rudder damage	0	2	0	2

3.3.4 *Ice type and ice thickness during the reported accidents*

Figure 6 presents the ice conditions and ice thickness experienced during the 19 analyzed accidents.

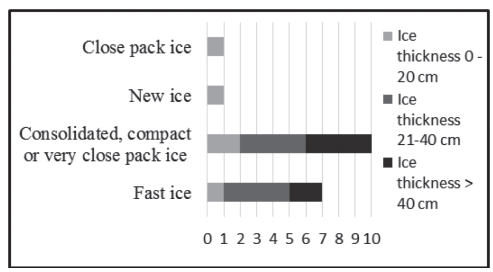

Figure 6. Ice type and ice thickness experienced when the accidents occurred (SMHI, 2013).

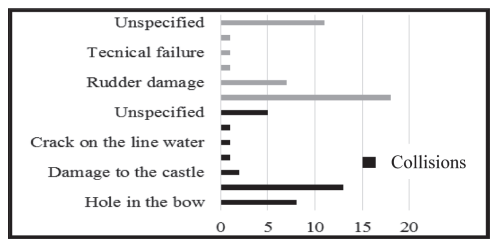

Figure 7. The generated outcome (damages) of the 70 analyzed accidents (FMA, 2003; Trafi, 2013).

3.3.5 *Outcome of the accidents*
Figure 7 presents the resulted outcome of the accidents occurred under sea ice conditions during the 5 analyzed winter periods. These outcome are presented as the common damages and ship affectations derived from the experienced accidents.

4 RESULTS

4.1 *Frequency of the maritime accidents occurred during winter*

4.1.1 *General accidents*
Based on the frequency statistical analysis, the most frequent type of accident was collision with 35% of the total accidents occurred during the analyzed winter periods. The second most frequent accident experience during winter was grounding with 17% of the total data of accidents analyzed. The frequency of collisions during winter months can be observed in Table 5. During the 5 analyzed winters in this study, the month of March has the highest frequency of collisions (2.6), and the total frequency by winter is 7.8 collisions per winter. In the case of groundings (Table 6), the month of December has the highest frequency of groundings (1.5), and the total frequency by winter is 5.25 groundings per winter.

In the case of the other type of accidents, propeller damage had a frequency of 3.6 per winter, loss of containment had a frequency of 1.2 per winter, fire/explosion a frequency of 1.2 per winter, rudder damage a frequency of 1.4 per winter, blackouts with a frequency of 0.4 per winter, and finally loss of propulsion with a frequency 0.2 per winter completes the frequencies of the identified accidents during the winters 2002–2003 & 2009–2013.

4.1.2 *Accidents occurred under sea ice conditions*
The most frequent accidents occurred under ice conditions are collisions. The Table 7 presents the frequency of the 31 collisions occurred under ice sea conditions.

The other accidents reported during sea ice conditions were: propeller damage with a 3.6 frequency per winter, rudder damage 1.4 frequency, ground-

4.2 *Operations, sea area, and sea ice conditions involved in winter accidents*

4.2.1 *Icebreaker operations*

During the analysis of the icebreaker operations in winters 2009–2013 which ended with an accident, "towing" was the operation (Fig. 8) which has reported the major number of accidents, followed by convoy and breaking a ship loose respectively.

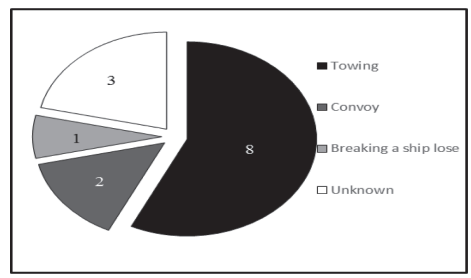

Figure 8. IB operations involved in collisions (Trafi, 2013).

4.2.2 *Sea area and sea ice conditions when accidents occurred*

The number of accidents (Fig. 9) under ice sea conditions during the analyzed winter periods were: the Gulf of Finland 24, Bay of Bothnia 24, Gulf of Riga 7, Central Baltic 5, Sea of Bothnia 2, Saimaa Lake 1, and 7 unknown locations. And about the most common ice conditions reported when collisions occurred in winters 2009–2013 were: consolidate compact or very close pack ice (10 times—63%), fast ice (5 times—31%), and new ice (1 time—6%). In 5 cases when a collision occurred in consolidate compact or very close pack ice, the conditions have also presented ridge and hummocked ice. The ice thickness when collisions occurred were in 5 cases an ice thickness of 1–20 cm, 8 cases 21–40 cm, and 6 cases with more than 40 cm ice thickness.

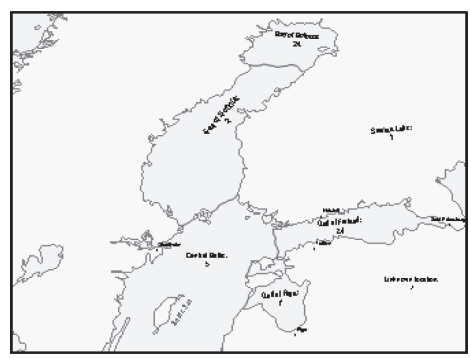

Figure 9. Location of the accidents occurred during the analyzed period (SMHI, 2013).

4.3 *Qualitative data mining to model the exposure to collision during ice breakers assistance*

Having defined the assistance operations of icebreakers and the identified ice conditions during the icebreakers assistance, enable to establish an initial input for modelling the exposure to collision during these operations based on particular ice conditions. The flowchart presented in Figure 10 indicates the ice conditions which are most commonly experienced in the collisions' scenarios during icebreaker assistance. Thus, this particular identification enable creating a structured base to set levels of risks and/or exposure to collisions during ice breaker operations.

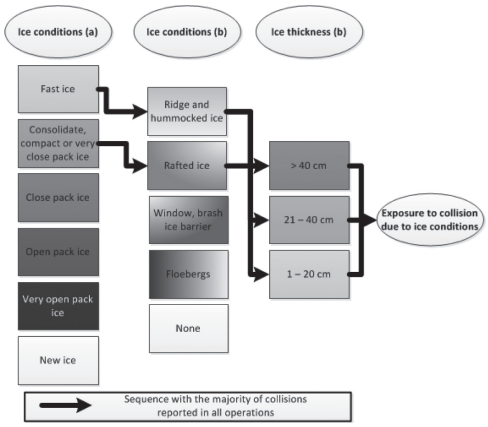

Figure 10. Flow chart with the ice conditions sequence of the collisions reported in all icebreakers operations.

Thus, the applied qualitative data mining to the accident data provided by the Finnish Safety Transport Agency (Trafi) detected that "towing" was the operation with the major number of collisions reported: 4 collisions under consolidated, compact or very close pack ice, combined with rafted ice and an ice thickness over 40 cm, also 4 collisions in fast ice combined with rafted, ridge and hummocked ice and an ice thickness between 1 to 40 cm. For convoy operations: one collision under consolidate, compact and very close pack ice, combined with rafted ice an ice thickness of 1 to 20 cm, and one collision in fast ice with an ice thickness over 40 cm. Finally, for breaking a ship loose: one collision in consolidate, compact or very close pack ice, combined with rafted ice and an ice thickness over 40 cm.

Thereby, based on the analysis of the data: consolidate, compact or very close pack ice and fast ice, combined with ridge, hummocked and rafted ice are the ice conditions whit higher exposure to collision. And the thickest is the ice, the most exposed the icebreaker operation is for ending in a collision.

5 DISCUSSION

The method for accident data analysis followed in this paper, provided a deeper view of the amount and the characteristics of accidents suffered by vessels during winter time in the Baltic Sea. This study has considered two kinds of winters in the Baltic Sea: the winter before the ice sea is present, and the winter under ice sea conditions. This differentiation allowed to accurately identify the types of accidents which are more frequently occurring on those scenarios. Thus, collisions are the most frequent accident occurred during winter time in the Baltic Sea. This statement is aligned to the findings of previous accident analyses performed in the area (e.g. Kujala, et al., 2009). In the mentioned study, groundings are the most frequent accident occurred during 1997–1999, 2001–2003, and 2004–2005. However, the analysis performed in the mentioned research has also detected that; once the Baltic Sea presents ice conditions, the number of groundings significantly decreases, but the amount of collisions significantly increases. Thus, having approximately 3 to 4 months of ice sea conditions in some areas of the Baltic Sea per year, implies an automatic decrease of groundings (the most frequent accident reported each year in the Baltic) which may considerably contributes to decrease the frequency of those reported every year.

Based on the accident data analyzed in this paper, the accident severity in most cases has been reported as less serious. Comparing this finding against previous studies (e.g. Tuominen, et al., 2010), the severity of the accidents occurred under ice conditions has also been considered as less serious in most of the cases. From the total amount of data analyzed in this paper, 75% of 68 accidents reported during the winters 2009–2013 were reported a less serious, 24% as serious, and only 1% as very serious accidents. And about the accidents occurred under ice conditions, 84% were reported as less serious, 16% reported as serious, and there were not accidents reported as very serious. Thus, these indicators may imply that the severity of the accidents may be better estimated and perhaps even controlled by the correct implementation of the current winter navigation system, a correct provision of the different sea ice services, and specially an adequate assistant by ice breakers.

The analysis of the icebreaker operations is a key aspect to consider when analyzing the number of accidents occurred during ice sea conditions. The fact that 19% of the accidents reported under ice conditions are related to the operations of icebreakers, indicates the clear need to improve the efficiency of one key player within the winter navigation system. In the analyzed data, "towing" has been detected as the operation with the major number of accidents with minor severity regarding the accidents outcome. Nevertheless, the operation needs to be analyzed more in deep in order to be improved.

During the analysis of the particular sea ice conditions, "consolidate compact and very close pack ice and fast ice with ridge and rafted ice" have been observed as the most problematic. And in the case of ice thickness, there were similar

numbers of accidents reported under different levels of ice thickness, having a slightly higher representation of thickness over 20 cm. Thus, once the icebreaker operation with the higher frequency of accidents, and the most frequent ice conditions experienced during those accidents were identified, a qualitatively and also quantitatively detection of the sequences of the icebreaker operations (e.g. Fig. 10) with more accidents experienced were extracted. These sequences and their respective numerical indicators must be utilized as an input data to identify and correctly estimate the scenarios which represent the higher risk of an accident when an icebreaker is providing assistance.

The map presented in Figure 9 has identified Gulf of Finland and Bay of Bothnia as the zones where more of the accidents occurred. However, this information is limited to the reports of accidents occurred on Finnish waters or to vessels registered to Finland. Therefore, this paper has remarked the importance of the analysis of the ice conditions experienced during the accidents and the operations of icebreakers which are also being performed in different Baltic Sea zones during winter time.

6 CONCLUSIONS

The winter navigation at the Baltic Sea commonly presents two general conditions challenging the safety performance of the vessels navigating the area: the dark sea with winter storms arriving in open waters, and the sea with harsh ice conditions. These two characteristics influence the kind of accidents typically occurring in the Baltic Sea, while groundings are the most frequent accident reported during winter before sea ice is present, collisions are the most frequent accident under sea ice conditions in the zone.

The severity of the accidents occurred under ice conditions seem to be lower than the reported on open waters during winter time. The accident data analysed in this paper identified general cargo and icebreaker as the type of vessels which are more frequently involved in accidents. In the case of icebreakers, this fact is logically understood due to the assistance operations performed by this kind of vessel. Furthermore, the statistical analysis has identified "towing" as the icebreaker operation with more accidents reported. Consolidate, compact and very close pack ice with ridge and rafted ice is the sea ice condition experienced in more of the reported accidents. Thus, it can be concluded that while there is still the need for more research to complement the analysis for determining the risk of accidents in winter navigation, the analyses performed in this paper, have identified valuable input information which is clearly needed to correctly estimate probabilities of accidents in winter navigation.

ACKNOWLEDGEMENTS

The work of this paper has been carried within Winter Navigation Risks and Oil Contingency Plan (WINOIL) Project, and in association with the Kotka Maritime Research Centre. The authors appreciate the financial contribution of the European Union, the Russian Federation and the Republic of Finland.

Structuring contributors to successful operation

Jørn Vatn
Department of Production and Quality Engineering, NTNU, Trondheim, Norway

ABSTRACT: It is often claimed that traditional safety methods and risk analysis in particular are limited by failures and error tabulation in the search for safety improvements. The main objective of this paper is to investigate whether such claims have a sound foundation. To shed light on the problem we start with defining the two terms 'normal operation' and 'successful operation' and discuss duality of these terms in relation to terms like 'failure' and 'error'. Next we introduce a near miss example in railway operation where two trains were almost directed into the same section due to several misunderstandings. The situation is analysed by a STEP (Sequentially Timed Events Plotting) analysis. In the first iteration safety problems are revealed in a standardized manner, whereas we in a second iteration investigate elements of various contributing factors to successful operation. Based on the analysis we suggest ways to improve the STEP methodology such that conditions related to success can have an equal position as conditions leading to failures and errors. Since results from investigation would be important input to risk analysis and subsequent analysis of improvement measures, we discuss how understanding of success and failures can be incorporated into risk analysis frameworks. Although "learning from successful operation" is less emphasized in many investigation and improvement programs, our analysis has not revealed principal differences between "success" and "failure" in the way such terms could be used in investigation, risk analysis, and evaluation of improvement programs.

1 INTRODUCTION

Many investigation methods and risk analysis methods have a focus on failures and what went wrong, or what may go wrong. In recent years it has been recognised that putting more emphasis on success and what goes right could bring complementary understanding and hence improve safety and risk management.

The objective of this paper is to propose ways to structure knowledge and factors related to successful operations. We first introduce a motivating example from railway operation where a disturbance lead to several misunderstanding, and the situation could easily have developed into an accident. However, important operative barriers were in place, and the accident was avoided, and the situation must be categorised as a successful operation. In the first place we use a traditional investigation approach. After introducing the event we introduce and discuss important terms related to normal operations and success. The event is then revisited where we are seeking success, and contributors to success.

2 THE EVENT

We are considering a single track railway without remote control. This means that Local Train Controllers (LTC) are transmitting train announcements to control train operation. A Southbound Train (SBT) is approaching station A while a car driver is observing sparking and smoke from the train, and reports this to station X where he knows the LTC. The LTC at station A receive the SBT unaware of the problems, and transmit necessary train announcements to station B (south of station A). Thereafter the SBT leaves station A towards station B. The LTC at station A now receive the information regarding sparking and smoke, and contact the engine driver at the SBT via train radio. The SBT then stops at position Y south of station A. The Central Train Control (CTC) is then informed about the event. But due to the fact that the train was north of station A at the time of observation (by the car driver), the CTC believes that the train also did stop *north* of station A.

According to the traffic regulation the engine driver at the SBT shall report position in a kilometre measure, but he faulty reports his position (i.e., position Y) by using a local name not familiar to the CTC.

According to the schedule, a crossing between the North Bound Train (NBT), and the SBT shall take place at station B (south of station A). Since the train controller at the CTC believes that the SBT is stopped north of station A, he decides to change the crossing from station B to station A to minimize delay

for the NBT. The new crossing order is transmitted to the LTC at station A and station B. Both LTCs accept the new crossing order. In order to effectuate the crossing order the LTC at station B ask the LTC at station A to cancel the departure announcement of the SBT, so that he can allow the NBT to enter the section between station A and station B (where, the SBT still is residing). The LTC at station A refuses to cancel the departure announcement because he knows that the SBT still is occupying the critical section, and the misunderstanding is resolved. An accident was avoided because the "last barrier" was still functioning, i.e., "make sure that a train cannot be sent into an occupied section".

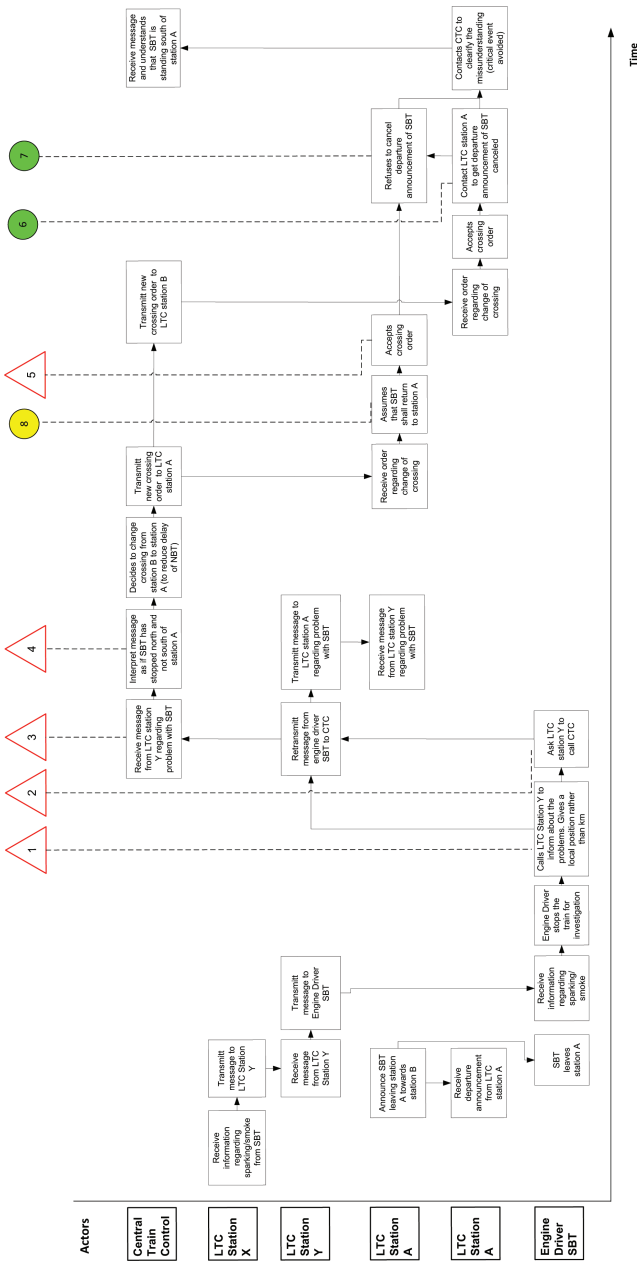

Figure 1. STEP diagram.

The situation was analysed by the STEP investigation method (Sequentially Timed Events Plotting, see Hendrick & Benner, 1987). The STEP diagram is shown in Figure 1.

The following safety problems (triangles in the STEP diagram) were obtained during the analysis:

1. The engine driver on the SBT uses a local name rather than a km specification when informing where he has stopped
2. The engine driver do not contact the CTC directly to inform about his position and his problems, but asks the LTC at station Y to inform CTC
3. Unclear orders and lines of command causes the misunderstanding
4. The operator at the CTC interchanges "south of" and "north of" in his mind since the precise km position of the stopped train was missing
5. LTC at station A accepts the new crossing order (even if he knows that the SBT has left station A)

The "magic event" that "saves the day" is performed by the LTC at station A, who refuses to cancel the departure announcement. This particular event may be seen as a real success making the entire operation that day a successful operation. Before we discuss learning from successful operations, we need some basic theory and terms.

3 THEORY AND BASIC TERMS

The objective of this section is to define the term successful operation. Although concepts like learning from "normal operation" and "successful operations" has been introduced recently to give new momentum to safety research, it is not straight forward to define such terms and contrast them to more traditional concepts like errors and failures.

3.1 *Failure, error and success*

The term 'failure' is easy to define, and the definitions are consistent across standards, textbooks and other presentation. A failure is defined as the point of time when an entity is not able to perform (one of) it's required function(s). The term 'error' is more difficult because it is used both to describe human errors, software errors and also deviations from performance of physical items. In this presentation we will use the term 'error' only related to human errors, and we define human errors as a deviation from an intention in a given context. Note that an "intention in a given context" is slightly less precise than "function" as the "hardware" counterpart since we cannot always describe in detail what is the intention of a human action. See e.g., Reason (1990) and Hollnagel (1993) for further discussions.

In a binary context where it is straight forward to distinguish a failure or an error from the "opposite", we may define the term 'success' as the opposite of a failure or an error. It could be questioned whether such a use of the term 'success' is how we think about success, the fact that an item is not failing will often not be considered as a success. However, to maintain a duality between success and failure we proceed with the proposed definition. For many functions and intention of human actions a clear binary split between success and failure does not exist. For such situations it will be more natural to use multistate formulation of the problem, and neither of the terms failure, error or success are that appropriate.

3.2 *Successful operations and related terms*

Next we will define the terms 'normal operation', 'successful operation' and 'successful recovery'. To give a mental model as a basis for the definitions we borrow the "layer of protection" concept from the process industry. A layer of protection can be seen as safety barriers, and they are often structured in the way they will be activated in an accident scenario. Compared to the presentation given by e.g., Rausand (2014) and CCPS (2007) we simplify and distinguish between:

a. Process design (by using inherently safe design principles).
b. Control, using basic control functions, alarms, and operator responses to keep the system in normal (steady) state.
c. Prevention, using Safety-Instrumented Systems (SISs) and other safety barriers to act upon deviations from normal state and thereby prevent an undesired event from occurring.
d. Mitigation, recovery and emergency response in case of control is lost.

Figure 2 shows the layers of protection.

Having these categories of layers as a basis we now define:

Normal operation corresponds to layer (b). Normal operation may involve adaption to varying conditions as emphasized by resilience engineering. But normal operation does not involve use of extraordinary safety functions representing layer (c). If the primary control is lost and there is a deviation from the normal state, layer (c) is intended to bring the system into a safe state. We define ***successful operation*** as a situation where layer (c) is invoked, and is able to bring the system back to the primary control state. In some situations layer (c) is invoked but without being able to bring the system back to the primary control state.

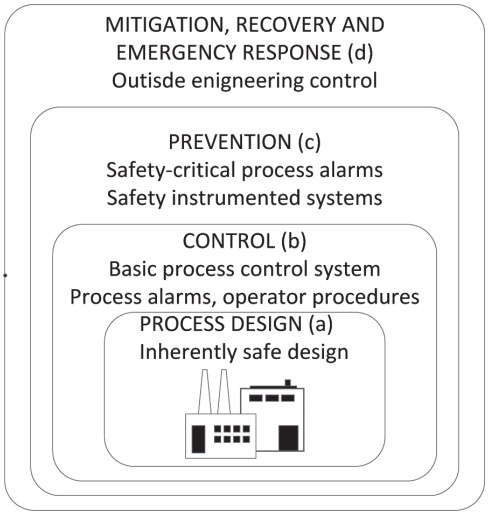

Figure 2. Protection layers (adapted and simplified from CCPS, 2007).

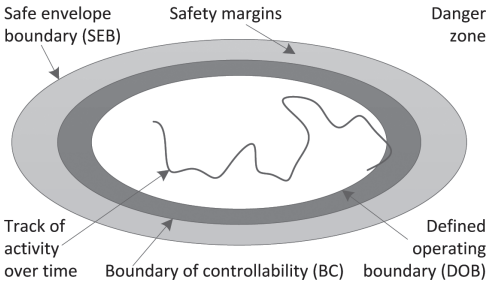

Figure 3. Safe envelope (adapted from Hale et al. 2007).

This is often referred to as a state where the system is outside engineering control. If this is the case, we define ***successful recovery*** as the situation where the system could be brought under control and back to it's normal state (after repairs, clean-up and so forth).

In the literature we also find other mental models for accident avoidance than the protection layers understanding shown in Figure 2. One class of such models is the safety envelope model shown in Figure 3. The inner ellipsis limited by the Defined Operation Boundary (DOB), corresponds broadly to what is controlled by protection layers (a) and (b) the in protection layer model in Figure 2. In some respect we may also treat the elliptical band limited by the Boundary of Controllability (BC) very similar to what is controlled by protection layer (c) in Figure 2. However, there might be differences since the layer of protection concept in Figure 2 is usually based on very explicit identification and design of safety functions, whereas the safety envelope perspective in Figure 3 does not have such an explicit understanding of safety functions. Finally the outer elliptic band limited by the Safe Envelope Boundary (SEB) represents extra safety margins where there is a conceptual link to what is controlled by protection layer (d) in Figure 2, but the similarities are not that evident at this level.

A conceptual advantage of the safe envelope model over the layer of protection model is the visualization of the track of the activity over time. Following our initial definition of success, we would by referring to the safe envelope define successful operation as an operation where defined operating boundaries are exceeded, but where the boundary of controllability is not exceeded (as illustrated in Fig. 3). So far we have not considered a process remaining within defined operating boundaries as a successful operation. However, many will consider an operation to be successful also if we are able to remain in the inner ellipsis of Figure 3. Since we have defined this situation to represent a *normal* operation we will be reluctant to define a normal operation within defined operating boundaries as a success. We will, however consider two special cases (sub sets) of normal operations as successful operation. The first situation is where there are extraordinary conditions making it very difficult to operate within defined operating boundaries. Examples could be a situation where the physical process is hard to control for example due to a situation where the quality of some raw material is low, or it could be related to extreme weather conditions. If we, despite these challenges, are able to operate within the defined boundaries we will define that the particular operation is a successful operation. Another situation we will define as a successful operation is where we are able to control the process "in the middle" of the inner ellipsis of Figure 3. There are at least two reasons why this could be considered as a success. Firstly this will most likely represent a situation where operation runs smoothly and production performance will be high. Next, the fact that the process runs smoothly represents a situation where we use minimal effort to control the operation, and presumptively we are better prepared to handle any process upset that might occur. However, there is an argument in this latter situation that would question how successful such an operation is. The fact that there are no process upsets or situations to act upon, could be passivizing the operations crew in the sharp end limiting their situation awareness (see, e.g., Endsley, 1995, for a thorough discussion on situation awareness). Little effort to control the process could also give little stimuli and training to act upon weak signals.

In the safety envelope model in Figure 3 the boundaries are illustrated as static in time. For many operations the boundaries or safety functions cannot be seen as static. We will in the following distinguish between a situation where (i) operating personnel is aware of this situation, and (ii) operating personnel is *not* aware of the status of a safety function or the limits for safe operation. A very easy example of situation (ii) is car driving where the temperature has decreased below zero degrees Celsius on a wet road without the attention of the driver. Situation (ii) is obvious very critical, and we will also here use the term successful operations in a situation where the operation is following a trajectory towards an accident without the attention of operating personnel for a while, and then operating personnel become aware of the situation, and succeed in bringing the situation under control. This is visualised in Figure 4.

3.3 *Extended definition of successful operation*

Based on the above discussion we propose the following elements to be covered in the term successful operation to be used in (i) accident and incident investigation, and (ii) risk analysis based on insight from such investigations:

1. A situation where we are able to keep the operation within defined operating boundaries and at a particularly desired level where the need of operational control is limited.
2. A situation where operational conditions are particularly challenging due to bad weather, a challenging well with unstable formation pressure etc. But despite these challenges the operation is performed within defined operation boundaries by means of normal control functions.
3. A situation where normal control was lost, and the process escaped the defined operating boundaries in the first place, but controlled was gained by prevention, such as safety critical systems or secondary human control mechanisms.
4. A situation where situation awareness is degraded below a threshold value and the subsequent course of events ultimately will result in loss of control. Then proper situation awareness is regained and the operation is brought under control.

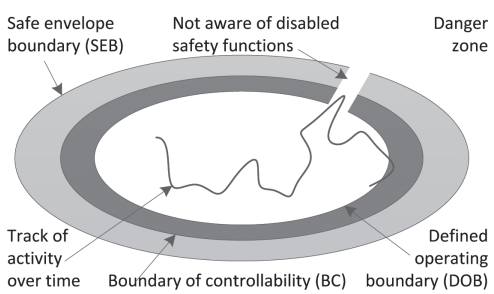

Figure 4. Safe envelope with broken boundaries due to unnoticed deficiencies or problems (based on Hale et al. 2007).

The above mentioned elements relate to the sharp end of the operations. Blunt end factors contributing to the success are not considered as successful operation in this context meaning that we will limit the term successful operation to particular cases. We will also not use the term successful operations in a statistical sense (benchmarking perspective) regarding operations that turn out to have extraordinary low incident and accident frequency. Both blunt end factors, and performance over time will be important as background in an investigation context, but the focus on success should be the particular events under consideration.

As the world is not black and white, there are situations where we have *partial* successful operation and *partial* successful recovery. For example there might be losses and even fatalities, but one may tempt to consider the situation as a successful recovery because the consequences could have been significantly worse.

3.4 *Linking investigation to risk management*

A main reason for proposing four different aspects of successful operation is to help structuring both during the investigation, but also in a learning process where the knowledge gained is to be in cooperated in the risk analysis and continuous safety improvement work. It is anticipated that success influencing factors could be of different nature for the various aspects, and hence a categorization is considered of value.

We will not present a particular accident model for the discussion. However, the conceptual models of layers of protection and safe envelopes will serve as a basis for risk modelling. In risk management and risk control it is fundamental to have a risk model as a reference point when learning from normal operation, successful operation, and successful recovery.

A risk model often comprises a formal logical representation of the system. Fault- and event tree analysis is often building blocks in such a representation. Barriers, safety functions and/or layers of protection are typically represented by basic events. Probabilities are assigned to the outcome of the basic events, i.e., success or failure. A wide range of factors and conditions will influence the outcome of the basic events, and these need to be taken into account when assigning the basic event probabili-

ties. In the literature we find many approaches to link such "soft" factors to the formal logical representation. The literature also presents different names for such factors. In Human Reliability Analysis (HRA) the term Performance Shaping Factors (PSFs) and Error Producing Conditions (EPCs) are used (see e.g., Rausand, 2011). The term contributing Success Factors (SCFs) has also been used in an attempt to establish resilience based early warning indicators (Øien et al. 2010). To avoid different set of factors for positive and negative issues, we will in the following use the term Risk Influencing Factor (RIF) as a general tem, see e.g., Vinnem et al. (2012) for risk modelling of planning and execution of critical tasks.

To define a RIF we first define a QRA parameter as *conditions that affect risk and included as a single parameter in a Quantitative Risk Analysis (QRA) model*. Examples of QRA parameters are failure rates, on demand probabilities for safety systems and ignition probabilities. Primarily we assume that QRA models comprise formal probabilistic techniques like fault- and event trees, and energy related impact techniques, e.g., an ignition model. A RIF is next defined as *a factor or condition that influences the risk*. There are three principal types of RIFs, (i) RIFs that are equal to a QRA parameter, (ii) RIFs where the value of a RIF is assumed to influence a QRA parameter, and where the influence is described in probabilistic terms, and (iii) RIFs that influence a parameter that is not explicitly modelled in the QRA. A working hypothesis is that all RIFs of type (iii) could by proper modelling be of type (i) or (ii). This is to say that all aspects of importance for the risk level could be addressed in the risk modelling. To what extent such structuring and modelling always brings value into risk management is another question.

The main objective of risk modelling is to present a reasonable subset of all accident scenarios we may imagine to reveal threats and hazards, how these threats and hazards may be mitigated, and finally quantify impacts such that there could be a reasonable balance between risk and effort spent to reduce risk. Although threats and hazards are fundamental in risk analysis, the methods and models do not by nature distinguish by failure and success. These lower level terms are ways to structure accident scenarios involving threats and hazards and to what extend one should be failure oriented or success oriented may vary from analysis to analysis.

The objective of investigation by methods like STEP is to shed light on what happened in one particular event or incident in order to learn from what happened. Usually learning is understood as a change in practice and/or an implementation of adequate measures to mitigate what went wrong, and to support and foster what went well. Another important aspect of learning is to improve the generic understanding of accident scenarios by in cooperating the lessons learned as new accident scenarios relevant for similar type of operations and/or to improve existing accident scenarios. The safety problems (triangles) identified in the diagram shown in Figure 1 are then to be considered in existing or new accident scenarios treated in the risk modelling.

4 THE CONCEPT OF SUCCESS IN INVESTIGATION AND STEP ANALYSIS

The traditional STEP diagram lists the course of events in the situation being analysed by separating actions for each actor and relation between activities. Based on the understanding of the course of events the investigator identifies safety problems (triangles in the diagram). The safety problems are linked to events that caused the situation to develop in a negative direction. We now propose to introduce a new symbol in the diagram to represent success, or potential success. A simple disk symbol is used with an identifier, i.e., ⑥, ⑦ and ⑧ in Figure 1. To make the symbols more self-explanatory one could use e.g., smiley face symbols. As for the safety problems where it is important to distinguish safety problems from the course of events, we therefore also propose to "lift" the success symbols to the top of the diagram. The success symbols represent either events in the diagram as such, or a condition or state that was a prerequisite for the events in the diagram to happen.

In the diagram in Figure 1 we have proposed to use two background colours, the green colour for symbols ⑥ and ⑦, and the yellow colour for ⑧. The distinction is related to what actually was a success (⑥ and ⑦) and what could have been a success (⑧). The explanation of the symbols related to Figure 1 is now:

⑥ The Local Train Controller (LTC) at station B is aware of what is going on, and requests a cancelation of the departure announcement of the southbound train.

⑦ The LTC at station A knows that the southbound train has left the station, and not returned to station A (as he mentally was thinking). He therefore refuses to cancel the departure announcement.

⑧ This symbol represent what could have been a success, i.e., that the situation awareness of LTC at station A could have been much better. Such a better situation awareness would most likely have caused e.g., a clarification request from LTC at station A to the Central Train Control

(CTC), and the course of events could have been stopped at an earlier stage.

A remark regarding use of ⑧ versus safety problem 5 needs to be made. Generally the safety problem symbol in the STEP diagram is used to enhance events that should not have taken place (i.e., LTC at station A accepts the crossing order which he should not have done), or a situation where one activity does not take place. For the latter, this means that "negative events" are not drawn in the diagram as an event, but rather as a safety problem, i.e., the fact that a required action is not performed is considered as a safety problem in the analysis. When we look closer to symbol ⑧ representing a not up to date situation awareness, this could have been denoted a safety problem. However, we are a bit reluctant to use the term safety problem in this case because this will emphasise that there is "something wrong", rather than what can be done to "improve" the performance. Therefore seeking for "potential successes" in the course of action could be a better way to learn from the event, and structure into improvement programs and the risk analysis models.

We also observe the different nature of symbols ⑥ and ⑦ pointing to success as dual concepts of a failure, whereas symbol ⑧ does not have such a dual "failure". The duality of symbol ⑥ representing a success, would have been that the LTC at station B did fail to request a cancelation of the departure announcement. For symbol ⑧ representing a potential success, it is not that evident that there exists a corresponding duality, i.e., a failure.

The investigation often terminates by identification of safety problems and conditions leading to success as indicated in the top row in the STEP diagram in Figure 1. In the continuous improvement work as well as for structuring in the risk modelling it is required to see beyond safety problems and success conditions as shown in the STEP. In the following discussion we will emphasize issues related to risk modelling. The STEP diagram could be seen as a way to structure one or more accident scenarios. The events in the diagram correspond more or less to basic events in a fault tree, or barriers and safety functions in an event tree. The identified safety problems and success conditions are not straight forward to include in the fault—and event trees being the basis for the risk model. It will be required to structure both the safety problems and success conditions by means of Risk Influencing Factors (RIFs), where a RIF typically is influencing event probabilities in the fault- and event trees.

For success conditions ⑥ and ⑦ the most evident risk influencing factor would be "compliance to procedures". The investigation of this particular event clearly demonstrates the importance of compliance to achieve success. It might be argued that this lesson contradicts the mantra in resilience engineering advocating adaption and denying compliance to achieve success (EUROCONTROL, 2013). We will not turn into a dispute with the resilience engineering society, but emphasise that for some systems compliance to procedures is extremely important also under so-called varying conditions. Obvious a criterion for that compliance results in success is the situation awareness in the sharp end. Compliance as a principle may fail if a wrong situation awareness exist, and we therefore also emphasise situation awareness as an important risk influencing factor related to success conditions ⑥ and ⑦. Endsley (1995) presents a model for situation awareness in dynamic decision making where the situation awareness could be seen as a first level RIF whereas abilities, experience and training could be seen as second level RIFs in a hierarchical risk influence model as proposed by Vinnem et al. (2012). Situation awareness, or rather lack of such, was considered important related to success condition ⑧. Lack of situation awareness could also be seen as an important element of safety problem 5. This demonstrates that as part of the investigation as well as for the risk modelling, it will be difficult to distinguish clearly between success and failure when we go beyond the explicit safety problems and success conditions. It could therefore be argued that the Safety-I and Safety-II perspectives seen as fundamental different approaches to safety by separating into principles of minimizing failures vs maximizing success respectively (EUROCONTROL, 2013), is not that fruitful for neither investigation nor for risk analysis. We accept that too little attention has been paid to success and conditions influencing success within safety and risk management and have therefore advocated to more explicitly address successful operation as part of investigation and modelling, but we are reluctant to contrast success and failures as proposed by EUROCONTROL (2013).

We end this section by listing some relevant risk influencing factors linked to the various elements of success:

1. Keep operation in the "middle" of the operating boundaries:
   a. Trained operating personnel
   b. Anticipation skills
   c. Understanding the "physics" of the basic operational control functions
2. Safe operations under challenging conditions:
   a. Trained operating personnel
   b. Planning and mindfulness by e.g., Safe Job Analysis
3. Regaining control by prevention mechanisms (e.g., safety critical systems):

a. Compliance
b. Trained to handle deviations

4. Degradation of situation awareness where proper situation awareness is required to regain control:
   a. Situation awareness
   b. Understanding of the "physics" of the problem
   c. Understanding the limitation of basic as well as preventive control functions
   d. Improvisation capabilities (especially in the case of successful recovery)

The purpose of the above list is to indicate that there might be different conditions and factors that are critical depending on the type of success, and should not be used as a categorization list. Further research is to be conducted to shed light on the structure of influencing factors in various types of successful operation. The objective of the project "Learning from successful operations" sponsored by the Norwegian Research Council is to shed light on how we can understand success and learn from it. Hopefully the research also will bring insight into the structuring of success and success factors to obtain a more solid list than indicated above.

5 DISCUSSION

A case study is used to shed light on the term successful operation, but such an approach cannot give general conclusions. Although "flipping the coin" and looking for success rather than failure may not represent a principal different approach, it is considered valuable in the search for more fundamental root causes or risk influencing factors in an investigation context. The case study also demonstrates that compliance could be essential to success in case of varying conditions where a resilience engineering perspective (EUROCONTROL, 2013) "advocates" adaption as a main principle for success. We claim that proper situation awareness is fundamental for "safe" compliance behavior, but we have not really investigated how situation awareness also could play the essential role in "safe adaption" and "safe improvisation". In a successful operation perspective, the four types of successful operation and the concept of successful recovery is believed to be a reasonable starting point for further research on this question.

6 SUMMARY AND CONCLUSIONS

A near miss event has been analysed with a traditional investigation method to reveal safety problems. The STEP method (Hendrick & Benner, 1987) is used as a basis for the investigation. We then propose to extend the investigation by also searching for success. It is proposed to use a dedicated symbol to visualize success issues in the diagram. For proper analysis it is proposed to introduce four different types of successful operations. In the search for underlying success factors a preliminary list of type specific success factors is proposed. The example study shows that searching for success rather than only (safety) problems may reveal other factors such that situation awareness and circumstances for compliance to meet it's intentions. The example also shows that success and failures are intervened in the course of events and should be analysed in parallel. The idea of introducing different safety perspectives (Safety-I and Safety-II) as proposed by e.g., EUROCONTROL (2013) is not seen to give much extra insight. The important message is rather to put equal emphasise both on success and failures in the investigation, with respect to learning, and with respect to improved risk modelling.

Country Safety Performance Function and the factors affecting it

Kazimierz Jamroz
Highway Engineering Department, Faculty of Civil and Environmental Engineering, Gdansk University of Technology, Gdansk, Poland

ABSTRACT: This work has been prompted by Poland's poor supply of road safety management tools which are key to developing national road safety policies. They could also be used in other developing countries. Behavioural theories and the results of literature studies have helped to develop the Country Safety Performance Function (CSPF) which describes the relationship between the normal anticipated Road Fatality Rate (RFR) in a country and the variables of its social, economic, road transport and road safety management systems. The CSPF underpins the essence of road safety measured as the national road fatality rate. It can be used to understand the current condition of road safety of a country and the forecasts.

1 INTRODUCTION

Analyses of road safety statistics show that developing Asian and African countries perform much worse than European countries just as Eastern and Central European countries fall behind the countries of Western and Northern Europe. As we know from research (van Beeck et al., 2000; Kopits & Cropper, 2003; Anbarci et al., 2006; Bishai et al., 2006; Koren & Borsos, 2006; Koornstra, 2007/1; Elvik, 2010; Law et al., 2011, Papadimitriou et al., 2013, Yannis et al., 2014) road safety largely depends on the country's social and economic development and the mobility of its population, but there are other equally important factors.

We are at the start of the Global Plan for the Decade of Action for Road Safety following from the UN Declaration and the 4th Road Safety Action Programme adopted by the European Commission for the years 2011–2020. To ensure an effective and efficient road safety policy we need tools to help with strategic decisions. Long-term strategic road safety and road infrastructure programmes and plans rely on road safety forecasts and assessments of the current situation and how it will evolve over extended periods of time (10, 20 or even 30 years).

The experience of OECD countries (1994) shows that road safety can benefit significantly from comprehensive and coordinated policies. Key to their success are well prepared and consistent road safety programmes. The effectiveness of programmes is the strongest if they have clear quantitative targets, well defined safety measures, the right set of dedicated partners and sources of funding. Sweden's Vision ZERO (Tingvall, 1998) is the leading example. This sets the context for the following questions:

- What is the impact of a country's social and economic development on road safety and what are the decisive factors of change?
- Which of the numerous road safety factors should be considered when devising strategic road safety policies?
- Can a country reduce its road deaths almost down to a zero and when can that happen?

One of the most common measures of road safety is road mortality rate, a demographically normalised way of measuring road safety (Hollo et al., 2010). It can be used to build estimation models and forecast road deaths, assess road safety and the effectiveness of treatment. The rate differs significantly from country to country.

The objective of this work is to develop a road fatality rate model to illustrate a country's accident severity at the macro (strategic) level. The paper will specifically address the strategic factors affecting road fatality. It will aim to develop a concept of a simple model looking at the effects of strategic factors on road fatality and subsequently apply the model to identify the degree of change in a country's road safety performance.

The choice of topic is directly related to the lack of road safety management tools which must form part of Poland's national road safety programmes and those that can be used in other developing countries.

This publication draws on research carried out by the author at the Department of Highway Engineering, Gdansk University of Technology between 2008 and 2010 (Jamroz, 2011).

2 THEORY

Despite its advantages, the transport system has an adverse effect on the environment, economy and health. Previous work describing the hazard of road transport has referred to many concepts and theories (Elvik & Vaa, 2004, Jamroz, 2008). Currently, the leading theories are behavioural based on road traffic risk. Societal road traffic risk is usually measured at the strategic level with the number of fatalities, considered as the absolute measure and with the RFR as the relative or normalised measure (Jamroz 2010, 2011, 2012).

Road death rates change at a different pace in developing and developed countries. Unlike the latter, developing countries register more fatalities as the economy improves. When studied over extended periods, the distribution of fatalities in the different countries shows different breakpoints (OECD), (IRTAD). The year of the breakpoint and the maximal number of fatalities mainly depend on the country's population, number of vehicles and gross national product. Breakpoints also occur in the road fatality rate.

The moment of the breakpoint is described by Al-Haji (2007) and Yannis et al. (2010, 2014) who found that for the RFR the breakpoint occurs in relation to the motorization rate in the range of 120 to 350 vehicles per 1000 population. Kopits & Cropper (2003), Anbarci et al. (2006), Bishai et al. (2006), Koren & Borsos (2006), Koornstra (2007/1) have made similar observations and said that the breakpoint can also be found in the road fatality rate and depends on the increase in national income. Koornstra (2007/1) pointed out that the breakpoint of road mortality rate occurs for a GNIPC equal to USD 5000 (US dollars), while Kopits and Cropper (2003) state that depending on the model the breakpoint occurs from ID 5,400 to 8,600 (international dollars). The authors, however, are not specific about the right side of the relationship.

Forty one countries with a RFR breakpoint have been identified. Their breakpoints, however, occur at different periods of the 20th century. For the different parameters of the scale (for X axis) the RFR breakpoints have been identified as follows:

- for time T: in the US in 1937, followed by Australia, Japan, Norway, Sweden in 1970, 1995 in Greece and 2004 in Brazil,
- for the MRMV (vehicles/1000 inhab.): from 91 in Portugal, followed by 225 in the Netherlands to 495 in Cyprus,
- for the HDI: from 0.731 in South Africa, 0.829 in Germany to 0.896 in Spain,
- for the GDPPC (thous. ID/inhab.): from 7.1 in Romania, followed by 9.6 in the US and 16.9 in France to 25.9 in Switzerland.

Based on the literature (Hakkert, 2002, Kopits & Cropper, 2003; Anbarci et al., 2006; Bishai et al., 2006; Koren & Borsos, 2006; Koornstra, 2007/1; Law et al., 2011) and the results of his research (Jamroz 2011) the Author adopted the following concept of how a country's road safety changes if measured with the RFR. According to this concept a country's road safety performance changes non-linearly in relation to changes in social and economic development.

There are different functions which we can use to describe the variability of road accident consequences. A study of available research and publications shows that authors have used different functions to show the relationship of RFR approximating the results cloud: linear functions with breakpoint (van Beeck et al., 2000; Yannis et al., 2010), logarithmic function (Bishai et al., 2006), single peaked function (Koornstra, 2007/1, Paulozzi et al., 2007), Kuznetz function (Kopis & Cropper, 2003; Law et al., 2011) and splines (Kopis & Cropper, 2003).

Of interest (for the purposes of this work) is the approach applied by (Dietze et al., 2008; CDOT, 2009; Kononov et al., 2008; Elvik 2004, Lord & Presaud, 2004) who used the Safety Performance Function (SPF) to forecast road safety on road sections and junctions based on the power and exponential function.

The SPF is a mathematical function which describes the relation between a normal and expected number of road accidents and the factors affecting road safety. Used in road safety management, the function helps to determine the potential for improvement, diagnose road safety problems, identify high risk sites and evaluate the effectiveness of proposed improvement countermeasures (Lord & Presaud, 2004; Kononov et al., 2008).

The Author's proposal is to use the Country Safety Performance Function (CSPF) as a function to describe the relation between a country's normal and expected road fatality rate and the variables of its social and economic, road transport and road safety management systems. The proposal offers a new application of the CSPF concept (Elvik 2004). The features of the function should include simplification, quantification and communications (Wegman & Oppe, 2010).

Considering the results of literature studies and the results of the Author's preliminary research, the following are the assumptions to the CSPF mathematical model:

1. The model should be simple to use for long-term forecasts of safety measures, safety assessments and decision-making.
2. The model should help to study the effects different factors have on road safety measures at

the national (macro) level and take into account area, demographic, economic, motorization, infrastructure and transport (mobility) aspects.

3. The model should meet the following boundary limits:

Condition I:

$$RFR = 0, \quad for \quad \text{GDPPC} = 0 \tag{1}$$

Condition II:

$$RFR = 0, \quad for \quad \lim_{GDPPC \to \infty} = 0 \tag{2}$$

Condition III:

$$RFR = RFR_{\max} \quad for \quad GDPPC = GDPPC_{BP} \tag{3}$$

The variables in formulas 1–3 mean: RFR—road fatality rate, GDPPC—Gross National Product per capita, HDI—Human Development Index.

Condition I is obvious—with no activity of the population there should be no road deaths. Condition II goes back to Vision Zero (Tingvall, 1998) which means no fatalities in road accidents. Condition III takes account of the fact that there is a breakpoint within the series of road fatality rate numbers as a country develops.

3 METHODS AND DATA

Using statistical mathematical models to develop the CSPF, four important scientific problems are identified: selection of data sets, selection of (independent) explanatory variables, selection of scale parameter and selection of the shape and parameters of the approximating function.

Databases (ECMT, Eurostat, FAO, IRF, IRTAD, OECD, TI, UN, WB, WHO) and a number of other sources provided empirical fatality data as well as data from 61 countries. Broken by the different years, they covered geography, demography, economy, social issues, motorisation, roads and transport. For the purposes of the CSPF, the number of countries was narrowed down to 22. The set included countries with solid road deaths statistics and ones that did not record any major changes in the RFR over time. The countries selected (such as Australia, France, Japan, Netherlands and Sweden) have similar RFR. The underlying data come from the period between 1922 and 2010 and cover 983 country-years.

To ensure that the independent variables are significant the interdependence between independent variables (X) and selected safety measures (Y) was analysed. The relationship between variables X and Y was studied using the linear correlation coefficient Pearson's R which measures the power of a straight line relation between two measurable features. Because many relations are non-linear, neural networks were used to determine the power of the relation between the variables. As a result of an in-depth analysis a group of 30 factors was narrowed down to 13 as independent variables.

Based on an analysis of the literature and own work, four parameters of scale were identified: time T, motorisation rate MRMV, human development index HDI and gross domestic product per capita GDPPC.

Eventually, two were selected for further analyses: GDPPC and HDI as parameters of scale for modelling the RFR. GDPPC, however, helps with forecasts (irrespective of time) of the human development index HDI and the motorisation rate MRMV. It can be used to simulate and analyse motorisation rates and road safety at different stages of a country's social and economic development (irrespective of time). The downside of GDPPC is that it reduces the scale as its numerical value decreases (applies mainly to historical data).

The choice of a concrete form of the approximating function depends on how well it can reflect empirical data. The literature includes several cases of RFR modelling, usually adopted as the F/P relation, using exponential models (Koornstra 2007/2) or the Kuznetz model (Kopitz & Corpper, 2003).

Based on analyses the power-exponential function was selected due to its ability of data approximation. The power-exponential function is the product of the power and exponential function. This function is known to have been used for modelling road safety measures (Kononov et al., 2008), (Elvik, 2004). The generalised form of the function is shown in formula (4).

$$Y = \alpha \cdot \prod_{i=1}^{n} X_i^{\beta_i} \cdot \exp\left(\sum_{j=1}^{m} \gamma_j \cdot X_j\right) \tag{4}$$

In this function Y is a dependent variable, X_i—i-th independent variable described with the power function (which is usually a parameter of scale), X_j—j-th independent variable described with the exponential function, m, n—number of independent variables, and α, β, γ—parameters of the equation.

To model the measures of normalised risk, the power-exponential function was used described with general formulas (5 and 6) (Jamroz, 2011):

$$\begin{aligned} RFR.a = {} & \beta_o \cdot GDPPC^{\beta_1} \cdot DP^{\beta_3} \cdot \exp(\beta_4 \cdot GDPPC \\ & + \beta_6 \cdot AVTKPC + \beta_7 \cdot MRMV \\ & + \beta_8 \cdot PMV + \beta_9 \cdot LEI + \beta_{10} \cdot CPI \\ & + \beta_{11} \cdot ACPC + \beta_{12} \cdot PUP + \beta_{13} \cdot PAL \\ & + \beta_{14} \cdot DRP + \beta_{15} \cdot DME) \end{aligned} \tag{5}$$

$$RFR.b = (1 - HDI)^{\beta_2} \cdot DP^{\beta_3} \cdot \exp(\beta_5.(1 - HDI) + \beta_6 \cdot AVTKPC + \beta_7 \cdot MRMV + \beta_8 \cdot PMV + \beta_9 \cdot LEI + \beta_{10}.CPI + \beta_{11} \cdot ACPC + \beta_{12} \cdot PUP + \beta_{13} \cdot PAL + \beta_{14} \cdot DRP + \beta_{15} \cdot DME + \beta_{16}) \quad (6)$$

where: GDPPC—gross domestic product per capita (thous. ID/inhab.), DP—population density (inhab./km^2), PUP—percentage of urban population (%), PAL—percentage of arable land (%), HDI—Human Development Index, LEI—Life Expectancy Index, CPI—Corruption Perception Index, ACPC—alcohol consumption per capita (l/inhab.), MRMV—motorisation rate—motor vehicles (except two and three wheelers) (vehicles/1 thou. inhab.), PMV—percentage of motor vehicles (%),DRP—density of paved roads (km/100 km^2), DME—density of expressways and motorways (km/100 km^2), AVTKPC—average vehicle kilometre travelled per capita per year (km/inhab./year), MRMV—motorisation rate (vehicles/1 thou. inhab.), β_0, β_1, … β_n—equation coefficients.

Some of the components of the model occur interchangeably e.g. GDPPC and HDI and ACPC and MRMV.

4 RESULTS

Two groups of RFR models were elaborated as presented in formulas 5 and 6. The parameters of the equations were calculated using STATISTICA (StatSoft,2008). Table 1 shows the equation parameters for 4 models divided into two groups (group a—GDPPC as the parameter of scale). The models use from one to eleven independent variables representing country characteristics and the relevant transport systems. The variables used in the models are only those with numerical values in the equation parameters.

Table 1 shows the statistics (p, R^2) and test results of the models (Wald test, MSE) for models of group **a**. The variables used have a high degree of significance ($p < 0{,}036$) and meet the Wald test (for a significance level of at least 1%) which shows that the independent variables are significant in the non-linear models. The R^2 coefficient of determination was within 0.46 to 0.80. An analysis of the coefficient shows that models with one variable explain only 46–48% of the variability, models with two variables explain 51–52% of the variability and models with ten or eleven variables explain 77–80% of the variability of the functions.

Table 1. List of parameters of selected RFR models.

Parameters of the model		Group **a** models			
		RFR.a1	RFR.a2	RFR.a3	RFR.a4
β_0		2.106	2.321	72.850	121.93
β_1	GDPPC	2.714	2.708	2.307	2.234
β_2	(1-HDI)				
β_3	DP			–0.072	–0.0895
β_4	GDPPC	–0.184	–0.203	–0.149	–0.127
β_5	(1-HDI)				
β_6	AVTKPC		0.0520	0.0583	
β_7	MRMV				0.00022
β_8	PMV			0.0032

β_{16}					
N		992	992	859	868
BP—breakpoint		14,75	13.32	15.47	17.54
p		<0,001	<0.001	<0.036	<0.0352
R^2		0,483	0.514	0.798	0.776
Wald test		930,5	544.4	304.2	296.9
MSE (%)		35,4	34.3	22.2	23.6

MSE (22.1–23.6% for models with many variables, models 3 and 4) suggests quite strong differences between the expected and actual value of RFR. Simple models (with one or two variables, models 1 and 2) produce much bigger differences between calculated and actual values.

The available data (for group of 22 countries) do not show the early stages of social and economic development (i.e. HDI < 0.45) or high income per capita (for GDPPC > 50 thou. ID/mk/year). The RFR changes together with the changing levels of the country's social development following the power-exponential function (models marked as 1). In the case of:

– GDPPC as the parameter of scale, in the early stages of socio-economic development the numerical value of RFR increases rapidly until it reaches its maximum (at breakpoint BP which occurs for GDPPC = 13.3–17.5 thou. ID/inhab. depending on the model) and then starts to decline at first quite rapidly to gradually slow down asymptotically to the GDPPC axis,
– HDI as the parameter of scale, in the early stages of socio-economic development the numerical value of RFR increases slowly to reach its maximum (at breakpoint BP which occurs for HDI = 0.82–0.86 depending on the model) and then starts to decrease rapidly down to zero at HDI = 1.

An analysis of Table 1 results suggests that both groups of models give a good description of the expected number of fatalities in relation to the country's changing socio-economic development. Of the two groups of models, the model using GDPPC as the parameter of scale was selected for further work. This is because it gives a better understanding of the effects of road safety policies in a country (the right hand side of the chart is longer) and as such is more practical when elaborating strategic road safety management, forecasting the number of road deaths and assessing road safety.

As mentioned before, by adding a second independent variable to the RFR models (marked 2 and 3), we can significantly improve the quality of the models. Of the other independent variables, transport variables have a significant effect. They are: average vehicle kilometre travelled per capita AVTKPC and motorisation rate relative to motor vehicles MRMV which also represent the mobility of the country's population. The quality of the models can be improved by using AVTKPC. Because this variable may be difficult to estimate for some countries it can be replaced with MRMV.

For further analyses (in this article) the RFR.a3 model was adopted for GDPPC as the parameter of scale and AVTKPC as the measure of mobility. This model was chosen as the Country Safety Performance Function for the country level. With more independent variables the quality of the models is further improved. In the case in question the most significant parameters (significance level of 5%) were those describing the system of the country, transport system, etc. Figure 1 shows the average values of elasticity of the independent variables in the ranges obtained from model RFR.a3.

An analysis of Table 1 results suggests that both groups of models give a good description of the expected number of fatalities in relation to the country's changing socio-economic development. Of the two groups of models, the model using GDPPC as the parameter of scale was selected for further work. This is because it gives a better understanding of the effects of road safety policies in a country (the right hand side of the chart is longer) and as such is more practical when elaborating strategic road safety management, forecasting the number of road deaths and assessing road safety.

As mentioned before, by adding a second independent variable to the RFR models (marked 2 and 3), we can significantly improve the quality of the models. Of the other independent variables, transport variables have a significant effect. They are: average vehicle kilometre travelled per capita AVTKPC and motorisation rate relative to motor vehicles MRMV which also represent the mobility of the country's population. The quality of the models can be improved by using AVTKPC. Because this variable may be difficult to estimate for some countries it can be replaced with MRMV.

For further analyses (in this article) the RFR.a3 model was adopted for GDPPC as the

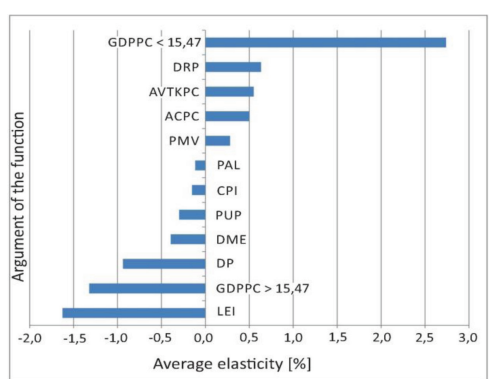

Figure 1. Distribution of Average Elasticity Rates (AER) for the selected model (RFR.a3) of fatality adopted as the RFPF for AVTKPC as parameters of scale.

parameter of scale and AVTKPC as the measure of mobility. This model was chosen as the Country Safety Performance Function for the country level. With more independent variables the quality of the models is further improved. In the case in question the most significant parameters (significance level of 5%) were those describing the system of the country, transport system, etc.

An analysis of Figure 3 shows the most significant factors which change RFR in the countries in question:

– up: GDPPC (in the range < 15.47 thou. ID/mk), DRP, AVTKPC, ACPC and PMV,
– down: LEI, GDPPC (V > 15.47 thou. ID/mk), DP, DME, PUP, CPI and PAL.

When **GDPPC** increases, road fatality RFR increases at first following the power function (AER—2.74%) until it reaches its maximum (at breakpoint BP and GDPPC = 15.47 thou. ID/mk) and after it has hit the breakpoint it decreases following the exponential function (AER—1.32%).

DP tends to increase together with growing population because the area of a country does not usually change. As DP increases, RFR decreases following the power function (AER—0.94%). With high population density, the number and duration of trips goes down and public transport increases its share in total trips.

PUP tends to increase together with the country's economy. As PUP increases, RFR decreases following the exponential function (average elasticity 0.30%). This is due to significantly lower speeds in urban areas as opposed to rural areas.

PAL changes slightly together with economic growth (it increases in some countries and decreases in others depending on the economic policy). When PAL increases, RFR decreases following the exponential function (AER—0.12%). This is due to shorter trips as a result of less fallow land.

LEI changes from 0 to 1 and tends to increase together with the country's economic growth. When LEI increases, RFR decreases following the exponential function (AER—1.63%). This is due to fewer people dying after an accident because the health care system is good.

CPI changes from 1 to 10, when CPI increases, corruption decreases. The higher the social development, the lower the corruption. When CPI increases (i.e. corruption decreases), RFR decreases following the exponential function (AER—0.15%).

ACPC depends primarily on religious and cultural factors. When ACPC increases, RFR increases following the exponential function (AER—0.50%).

PMV rate tends to increase together with the country's economic growth. When PMV increases, RFR increases following the exponential function

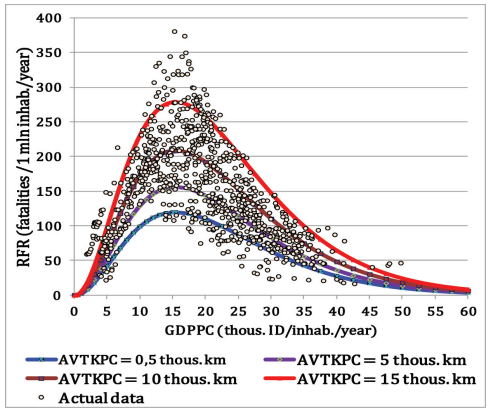

Figure 2. Charts of how the RFR changes in relation to GDPPC and AVTKPC compared to actual data in 22 countries.

(AER—0.28%). This is due to a growing fleet of motor vehicles.

DRP increases together with the country's economic growth (very quickly at first, then slowly asymptotically towards saturation). When DRP increases, RFR increases following the exponential function (AER—0.63%). This is due to higher speeds on improved roads.

DME increases together with the country's socio-economic development when a certain income threshold is exceeded. It grows asymptotically towards saturation. When DME increases, RFR decreases following the exponential function (AER—0.39%). This is due to high volume traffic moving to high quality roads.

AVTKPC increases together with the country's economic growth asymptotically towards saturation which may differ from country to country depending on its transport policy, size and land use. When AVTKPC increases, RFR increases following the exponential function (AER—0.55%). Figure 2 shows the changes in RFR depending on GDPPC and AVTKPC based on average values of the other parameters. This chart confirms that AVTKPC has a significant impact on RFR.

5 DISCUSSION OF RESULTS

The study has confirmed what many authors have postulated which is that a country's RFR depends primarily on its level of social development and a number of independent variables which represent risk exposure, sources of risks and interventions. Of the data analysed gross national product per capita GDPPC (the relation between gross domestic product and the population) was adopted as the

parameter of scale (on X axis). The GDP is on an upward trend (with slight distortions) and is the basic driving force of economic and social development in any country. The number of population changes slowly over time. This is why GDPPC can be used as a normalised measure of gross national income for direct comparisons between countries and for keeping track of the changes. As a result, the relation can be generalized and confirms the assumptions made at the beginning of this article.

If the scale of a country's socio-economic development is divided into ranges representing very low, low, medium, high and very high levels of socio-economic development and CSPF is divided into three areas (increase, breakpoint, decrease), we can say that (Fig. 3):

1. In the range of a very low to low socio-economic development of a country, growing income levels of the population increase mobility, motorisation and paved roads density which also triggers a quick **increase** in CSPF from zero until the maximum.
2. In between a low and medium socio-economic development of a country CSPF reaches its **breakpoint** as a result of a slower pace of motorisation, the launch of a safety system (improved legislation, education, leadership), use of safety management methods (improved enforcement, safety programmes) and a gradual change in road user behaviour (use of seatbelts, no drinking and driving).
3. In the range of a medium socio-economic development of a country CSPF **decreases** quite rapidly and when it reaches the range of a high and very high level of social development it continues asymptotically to zero. This is due to factors such as: levelling off of motorisation, density of paved roads and population mobility, increase in high quality roads i.e. expressways and motorways, development of state and democratic bodies and following from that less corruption, improved health care system, improved safety culture (use of seatbelts, lower alcohol consumption).

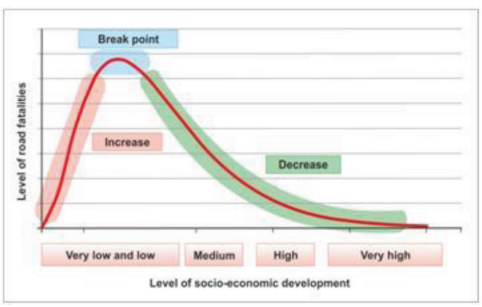

Figure 3. General model of CSPF in relation to the country's socio-economic development.

This general model has been confirmed in this work and its analyses and in earlier work (Kopits & Cropper, 2003; Anbarci et al., 2006; Bishai et al., 2006; Jamroz, 2012; Koren & Borsos, 2006; Koornstra, 2007/1; Yannis et al., 2010, 2014). The proposed model applies to the majority of countries in the world. There are deviations from the model in the group of developing countries (accelerated growth of motorisation which does not match the development of the systems of transport, health care and safety culture) and high income countries with insufficient road safety policies, i.e. significantly below the country's financial and organisational capacity.

If we assume that the resulting CSPF represents the average normalised relation between road fatality rate and the country's level of socio-economic development, the variance between expected and actual values shows:

– the match between estimated data (using the model) and actual data,
– the current level of road safety compared to the expected level in relation to the country's level of socio-economic development,
– the effectiveness of road safety improvements.

The charts above confirm that in general the CSPF has been adequately identified. What may be debatable are the rigorous requirements for the right hand side range of the function towards the target value. However, this approach can be justified by Vision Zero which is confirmed by the actual RFR values for many countries (Australia, Netherlands, Japan, Germany, Portugal). To confirm the claim, we must continue to watch the road fatality rates in these countries.

6 CONCLUSIONS

The Country Safety Performance Function presented in this article gives a good explanation of the essence of road safety measured with the country's RFR. Described with a power and exponential model, the CSPF consists of three distinct parts: increase, breakpoint and decrease. The maximal value of CSPF depends on a number of factors of which the most important ones include mobility of the population, level of health care, the country's organisational system, road network structure, land use and safety culture. This function can be used to explain the current condition of road safety and the forecasts and it shows that it is possible to reduce road deaths in a country down to zero. It is possible when the country has

a very high level of socio-economic development. This is a positive answer to the questions put in the introduction.

The results of the study were used to develop a proposed international classification of road safety and simple didactic methods for estimating the number of road deaths in specific countries. These proposals will be discussed in subsequent publications.

Method of dynamic identification of hazardous driver behaviour by traffic parameters detection

M. Sumiła & M. Siergiejczyk
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: This paper outlines a method of detecting in real-time vehicles hazardous for other drivers by employing for that purpose telematics-enabled technology. Further into in the paper discussed are reasons behind defined hazards, technical possibilities feasible thanks to modern telematics-enabled devices used for purposes of Intelligent Transport Systems as well as modelling assumptions. The method and model of selective vehicle detection was presented and discussed in main part of the paper, ended with concise summary and conclusions.

1 INTRODUCTION

Fast-paced and substantial advances in computer and mobile communication technology over the past twenty years meant an equally impressive development of information systems. This is widely experienced through ubiquitous internet access. Already back in the nineties of the last century transport related businesses and institutes saw that potential and consequently spawned a wide range of ICT solutions supporting transport logistics processes as well traffic management. That last-mentioned area of technical solutions is commonly referred to as Intelligent Transport Systems (ITS).

ITS is defined as using advanced software to deliver innovative services with regards to different means of transport and traffic management. They are aimed at different user group of the transport system to provide them with information which not only makes transport safer, more convenient and coordinated, but also makes the entire transport network more "intelligently" and efficiently used.

It is estimated that a wide-scale introduction of ITS solutions to transport could yield tangible benefits in: increasing road capacity by 20–25%, improving road safety (decreasing the number of accidents by 40–80%), bringing down travel times and energy consumption (by 45–70%), reducing environmental footprint of transport (exhaust emissions 30–50% lower), making travel more comfortable and driving conditions more enjoyable for drivers, public transport users and pedestrians, cutting traffic management costs, lowering road servicing, maintenance and renovation costs, increasing economic benefits everywhere they were deployed. (Modelewski 2012).

In its lowest layer, mobile communication is provided by telematics systems, which are responsible for technical solutions facilitating services featured by ITS architecture implemented in given country (Litwin & Modelewski 2013). Convergence of IT and ICT systems resulted in telematics solutions integrated with on-board electronic systems using satellite navigation, emergency warning systems and also electronic toll collection systems.

Many organisations and international commissions are currently developing and integrating ITS some of which are: CEN, ISO, ETSI, IEEE and other.

Among many services offered and developed under ITS, there is strong demand to advance road emergency services known popularly as eCall.

1.1 *eCall*

The method presented in this paper is a vast improvement on the eCall system currently being rolled out across EU which taps into eSafety initiative. It is part of comprehensive European Commission strategy aimed at improving road safety and transport efficiency across Europe, a joint effort of EC and Western European scientific centres. The European Committee for Standardisation CEN/TC 278 as well as organisations the likes of ETSI and 3GPP have already embraced that concept.

The eCall system is envisaged to enable manual and automatic emergency call immediately after a road accident has taken place, involving the vehicle which initiated the call. Manual emergency call may be initiated by pressing a button available to the driver. Calls are started automatically should particular conditions be met concerning seriousness of the accident, based on impact sensor information. Every call is passed to the traffic management centre over cellular network. The operator receiving the call in the Centre, should obtain a Minimum Set of Data (MSD) concerning the accident. MSD contains fundamental information about the

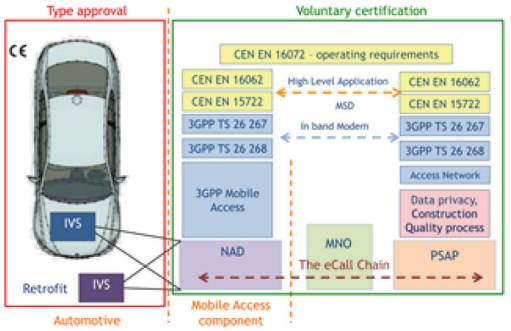

Figure 1. Certification principles (Legend: IVS—In-Vehicle Systems, MSD—Minimum Set of Data, NAD—Network Access Device, MNO—Mobile Network Operator, PSAP—Public Safety Answering Point) (Andy Rooke, iCar Support D4.2—eCall Good Practice. ERTICO, UK 30/11/2012 (http://www.imobilitysupport.eu/imobility-support/its-deployment/ecall/library/reports-13)).

incident. That information includes among other, time, precise geographical location of the vehicle during the accident, vehicle data including its VIN, eCall status including incident priority and information about the operator providing services.

In Authors' opinion eCall lags behind technology of the XXI century. It is quite antiquated and not efficient enough, an opinion which was voiced already 10 years ago (Rychlicki 2006), compared to functionalities offered by ITS. The method presented hereunder enables real-time selective vehicle detection and taking preventative action against vehicles which are identified to breach permitted behaviours and thus pose a threat to driver's life and those in his nearest proximity.

2 CURRENT STATE OF RESEARCH

The most common cause of road accidents is driver error. Typically it involves ignoring road signs, breaching road code of conduct or just plain recklessness. There is, however, a group of incidents, which are related to unforeseen and inadvertent, sudden worsening of driver's psychophysical state. Some the reasons for that deterioration include: exhaustion, influence of medication, driving under the influence of drugs or alcohol, instantaneous mental distress, fainting, cardiac arrest etc. All of the aforementioned lead to unexpected and unusual change in driving direction or speed. Under those circumstances, the vehicle affected becomes hazardous for surrounding vehicles as well as its own driver. Thus far, the only solution to this problem was imposing bans on drunken driving or under influence of drugs, preventing the driver from sitting behind the wheel should psychomotor ability be called into question and installing in-vehicle emergency call system.

The fundamentals of formal driving pattern description were presented in papers (Mac Adam 1981) and (McRuer & Weir 1969). They were expanded upon by descriptions of strategies used by drivers on the road, as presented in (Nechyba & Xu 1997). The paper (Aoude & Desaraju & Stephens & How 2012) suggests as to how to classify driver behaviours on crossroads and verify them based on real-life data provided from road-side equipment and vehicles themselves. Papers concerning modelling driver behaviours (Modjtahedzadeh & Hess 1993) present models of driving patterns used to evaluate vehicle performance, whereas (Okuda & Ikami & Suzuki 2013) puts forward a model using probabilistic "softmax" functions describing motor and decisional driver characteristics. Wide range of methods and models to simulate road safety were presented in paper (Young & Sobhani & Lenn´e & Sarvi 2014). The method presented below, is inclusive of latest advancements in technology, ITS (Intelligent Transportation System) in particular. It provides knowledge on hazardous vehicle detection and further developed, it may also enable safe vehicle management in specific road incidents.

3 HAZARDOUS VEHICLE SELECTIVE DETECTION

The term detection (identification) is defined in literature as an automated process involving operational data collection, extraction of characteristic information, classification and investigation into analysed event (Kozłowski 2010).

3.1 *Detection*

The method described below, is rather complex and thus requires close collaboration between traffic management centre and moving vehicles. To facilitate that, required are technical measures providing architecture for transfer of information between parties involved. There are two groups of detecting devices, being classified as telematics systems. The first are solutions monitoring a selected part of road infrastructure (CCTV cameras, road sensors). The second, more modern group, includes data collection solutions reading data about moving vehicles. Collected data is accessed through V2I or V2V2I solutions combined with dedicated wireless communications standards e.g. DSRC (EN 12253 2004)(EN 12795 2002)(EN 12834 2002) (EN 13372 2004) or WAVE (802.11p) (IEEE 1609 2007)(ETSI ES 202663 2013).

It was concluded that the method could only be used, when available are:

- ITS system, road infrastructure and traffic control centre,
- Devices for traffic stream control on dedicated arteries used for continuous vehicle monitoring.
- In-vehicle V2I devices (Vehicle to Infrastructure) feed information about current speed and position.
- Also on-board, should be installed V2V devices (Vehicle to Vehicle) distributing information about hazards directly between vehicles.
- The vehicle is equipped with MMI devices which facilitate vehicle to driver communication.

3.2 *General assumptions*

Real-time selective vehicle detection may be achieved by identifying parameters in the model defining behaviour of vehicle groups and individual vehicles and then comparing them against parameters obtained from observation of vehicles on roads.

The other assumptions were that observation time was discrete, because of the need to process obtained signals and produce results of analysis. Thus

$$t = t_{syg} + t_{prep} + t_{TX} + t_{net} + t_{proc} \tag{1}$$

where: t_{syg} = time to generate and collect signals from sensors, t_{prep} = time to preliminary process signals and prepare for sending, t_{TX} = message transmission time, t_{net} = message propagation time in by the network, t_{proc} = time to process the message in the centre.

Time t may be also influenced by volume of traffic. It is unrelated, on the other hand, to measuring method described above. For more details on the subject please see (Sumiła 2012). The parameter itself influences accuracy of vehicle trajectory representation, hence the more frequent location checking the higher probability of detecting potentially dangerous vehicles.

It was assumed that road observation area is described by matrix $\mathbb{D}$, size of which resembles the number of lanes in one direction R and length of analysed section W.

$$\mathbb{D}_{R\times W} \tag{2}$$

Observed traffic stream is described by matrix $\mathbb{G}_{R\times M}$, whose size resembles number of lanes R and capacity of each lane M. The maximum number of vehicles in single lane

$$\lim_{x\to M}(x\times l_{vehic} + x\times l_{dist}) = W \tag{3}$$

where: l_{vehic} = assumed vehicle length, l_{dist} = observed section length.

Vehicles can form different groups. Every group is described by matrix C, defined as selected vehicle group occupying road side-to-side (all lanes R), whose length is determined by number H of vehicles on busiest lane. At the same time it was assumed, that the distance between successive vehicles is less or equal to distance determined by either static or dynamic method described hereunder. Hence

$$l_{dist} \le l_{\min col} \tag{4}$$

Thus

$$\mathbb{C}_{R\times H}, where\ H \le M \tag{5}$$

Each of C_{rh} vehicles in the group is described by a vector of parameters

$$c_{rh}(t) = [l_{rhfront}, l_{rhrear}, V_{rh}, d_{rw}] \tag{6}$$

where: $l_{rhfront}$ = the space in front of the vehicle, l_{rhrear} = the space behind the vehicle, V_{rh} = speed of the vehicle, d_{rw} = length of the vehicle.

Those parameters will constitute the matrix of instantaneous speeds of vehicles and their location on the road.

3.3 *Selective group detection*

The first stage of selective vehicle detection is selective group selection from a traffic stream. One of three methods presented below may be used.

Static method involves detecting vehicles with space in front measured by number of average passenger car lengths. This method performs well in case of point observations by e.g. the aforementioned CCTV systems. In this particular solve should be used for observation by the camera placed above the or each lane. The image obtained from this source should be treated in real time, for example by using edge detection methods based on wavelet analysis and further based on the detection of changes in time determine the distance between vehicles.

$$l_{dist}(t) \ge l_{min} = n \times l_{vehic} \tag{7}$$

where: l_{min} = defined minimum spacing of vehicles between groups, n = number of car lengths, l_{vehic} = assumed average car length.

The essence of the method was depicted in Figure 2.

Dynamic method as a solution yields better results in terms of detecting vehicle group out of traffic stream. It involves detecting vehicle spacing within the group and then group spacing based on instantaneous statistic evaluation. Mean spacing of vehicles needs to be computed:

$$l_{śr}(t) = \frac{1}{R \times H} \sum_{r=1}^{R} \sum_{h=1}^{H} \left(\frac{l_{rhfront} + l_{rhrear}}{2} \right) \tag{8}$$

Once population average is known, variance s^2 of distribution is then calculated.

$$s_l^2(t) = \sum_{r=1}^{R} \sum_{h=1}^{H} \frac{(l_{rh}(t) + l_{śr}(t))^2}{R \times H} \tag{9}$$

Should s_1^2 tend to zero it means within observation area it is difficult to detect individual groups, because vehicle spacing is approximately the same.

Variance greater than zero means deciles of vehicle spacing (between observed vehicles) need to be checked. Approximate values of greater amount of deciles indicate homogeneity of population i.e. spacing of vehicles within groups, whilst last deciles indicate spacing of groups.

This method works well for vehicles with front and rear proximity sensors (parking and driving) as well as V2V connectivity.

3.4 *Group characteristics detection*

Once a group is selected from traffic stream, its average speed is determined. In order to do that, individual vehicle average speeds need to be known.

$$V_{śr}(t) = \frac{1}{R \times H} \sum_{r=1}^{R} \sum_{h=1}^{H} V_{rh} \tag{10}$$

By comparing that value with instantaneous speeds provided by speed matrix $\mathbb{V}_{R \times H}$, tendency of vehicle speed change over time t is determined. Also, after comparing current V_{rh} with previous instantaneous speeds, acceleration a_{rh} is determined, represented by matrix $\mathbb{A}_{R \times H}$.

Furthermore, location change of group compared to the entire traffic stream could also be determined, by comparing detected average speed of vehicle group to average speed of traffic stream V_{pot}.

$$V_{pot}(t) = \frac{1}{R \times W} \sum_{r=1}^{R} \sum_{W=1}^{W} V_{rw} \tag{11}$$

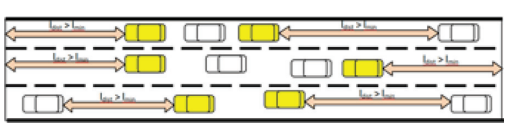

Figure 2. Vehicle group selected by vehicle spacing detection (marginal vehicles denoted in yellow).

Hence if

$V_{śr} < V_{pot}$—group is decelerating and probably will become part of closing up group

$V_{śr} = V_{pot}$—group moves consistently with the stream and maintains formation

$V_{śr} > V_{pot}$—group is accelerating and probably will become part of leading group

That change could be precisely detected based on the grounds of comparing average values for vehicles adjoining directly to analysed group.

3.5 *Detection of permitted behaviours within vehicle group*

Once fundamental group characteristics are identified, behaviours defined as permitted need to be detected whilst the vehicles remains mobile.

Based on knowledge about vehicle location d_{rh} and group average speed and instantaneous speeds of individual vehicles, the following assumptions were taken:

1. vehicles may increase or decrease spacing by accelerating and braking smoothly (meant by smooth is acceleration required by normal driving style),
2. vehicle may abruptly accelerate during overtaking manoeuvre whilst changing lane given there is enough space,
3. vehicle may abruptly brake into a standstill before an obstacle,
4. vehicle decelerates when approaching an obstacle, provided it is within vehicle's braking distance, when approaching crossroads, traffic lights or planned turning.

Above-mentioned assumptions define permitted driver behaviours within a group or in its marginal positions.

Deviation from $V_{avg}(t)$ was also calculated based on standard deviation for population of observed vehicles.

$$\sigma = \sqrt{\frac{\sum_{r=1}^{R} \sum_{h=1}^{H} (V_{rh}(t) = V_{śr}(t))^2}{R \times H}} \tag{12}$$

where: $V_{rh}(t)$ = temporary speed of the vehicle at time t, $V_{śr}(t)$ = the average speed of the column of vehicles at time t.

Given computed standard deviation, an assumption was made that deviation of instantaneous speed in instant t by one or two standard deviations from average speed is acceptable, provided there is enough space between the vehicle and its surrounding.

$$V_{accel} : \mathbb{H} \rightarrow \exists l_{rhfront} V \exists l_{rhrear} \geq n \times l_{vehic} \tag{13}$$

Above assumption does not need to be satisfied for marginal positions in formation, either its utmost front or rear positions. For those marginal cases, vehicles are entitled to accelerate or brake when space in front of them or behind them is greater than $l_{distcol}$.

$$\mathbb{C} = \begin{bmatrix} c_{11} & \dots & c_{R1} \\ c_{1H} & \dots & c_{RH} \end{bmatrix} \tag{14}$$

Hence, it is not advised to include instantaneous speeds of marginal vehicles in determining average speed of vehicle group.

$$V_{śr}(t):\mathbb{C} = \mathbb{V}_{R\times W}(t) - V_{front}(t) - V_{rear}(t)) \tag{15}$$

where

$$V_{front}(t) = [V_{11}(t), \dots V_{R1}(t)] \tag{16}$$

$$V_{rear}(t) = [V_{1W}(t), \dots V_{RW}(t)] \tag{17}$$

Then, cases of lane changing by vehicles moving within the group need to be considered. That manoeuvre is permitted when there is space in the other lane for the vehicle to drive into. When determining instantaneous speeds matrix for moving vehicles, free spaces are represented by elements whose speed V_{rh} is 0 [m/s]. Three possible cases need to be analysed at this stage (two concerning outside lanes and one inside the group). They were depicted in Figure 3.

Speed matrix for vehicles surrounding that space is represented by vector relative to distance matrix $\mathbb{D}_{R\times W}$

$$V_{space}[r,W](t) = [V_{rh}[r,w-1](t), V_{rh}[r-1,w](t), V_{rh}[r,w+1](t), V_{rh}[r+1,w](t)] \tag{18}$$

where: $V_{space}[r, w](t)$ = instantaneous speed vector of vehicles surrounding free space within the group, $V_{rh}(t)$ = next vehicle within the group surrounding the free space.

Note that in marginal cases, vehicle vector is calculated for three elements and will become:

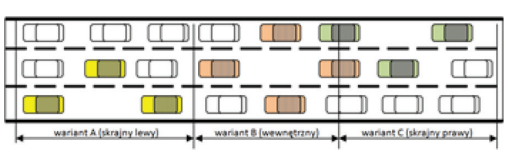

Figure 3. Three cases of spacing within group favourable for lane changing.

– for left marginal case (*option A*)

$$V_{space}[r,w](t) = [V_{rh}[r,w-1](t), V_{rh}[r,w+1](t), V_{rh}[r+1,w](t)] \tag{19}$$

– for right marginal case (*option B*)

$$V_{space}[r,w](t) = [V_{rh}[r,w-1](t), V_{rh}[r-1,\ w](t), V_{rh}[r,w+1](t)] \tag{20}$$

It is obvious that there might be a case where vehicles preceding and succeeding free space could diminish that gap by accelerating or braking. Then the V_{space} element moves in the speed matrix.

3.6 *Detecting vehicles posing potential danger*

The aforementioned selective detection on moving dynamically traffic enables to single out movement dynamics of individual vehicles with single time step precision. Changes in acceleration compared to previous instants and changes in movement trajectory may be detected by selected vehicle matrix $\mathbb{C}_{R\times H}$ and instantaneous speed matrix $\mathbb{V}(t)$ provided assumptions of the model are met. Analysis of changes in speed and trajectory compared to permitted behaviour patterns leads to selecting vehicles moving in an abnormal fashion. The detection process was depicted in Figure 4.

After filtering, based on signals S compared with parameters generated by the model, a new signal S′ may be obtained to select vehicles whose driving patterns in traffic are dubious in terms of safety. The most popular is the Kalman filter which is an algorithm that uses a series of measurements observed over time, containing noise (random variations) and other inaccuracies, and produces estimates of unknown variables. It its extended version, it produces estimates state vectors for non-linear dynamic system described by recursive system of equations. Among other filters the continuous wavelet transform was also considered.

Should results of successive measurements indicate deviation from permitted standard, the traffic management centre should undertake the following measures:

1. attempt to communicate with the driver by in-vehicle telematics-enabled devices and MMI interfaces,

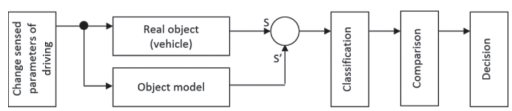

Figure 4. Detection process using output signals.

2. if abnormal activity continues posing constant threat to other road users, surrounding vehicle drivers should be informed about potential danger via available telematics-enabled systems,
3. in case of non-responsive driver, the "Auto Safety Stop" procedure should be deployed, which is subject of author's' upcoming publications,
4. pass information about initiated procedure to surrounding vehicles,
5. deploy the ASS procedure and pilot the vehicle to a safe parking spot.

4 SUMMARY

The paper presented the method of dynamic identification of hazardous driver behaviour by traffic parameters detection. Such identification is possible only when appropriate telematics' solutions are applied both in a road and a vehicle. The mathematical tools used of elements of probability to identify the columns of vehicles and a formal description of acceptable behaviour of drivers on the road led to the possibility to differentiate these vehicles, that movement differs from from the expected behaviour. In this sense proposed approach should be regarded as an innovative and far-emptive currently proposed important in the context of the eCall project.

The method described hereinbefore should be treated as work in progress, which needs further developing. In authors' opinion, the notion of vehicle group (across all lanes) should be reconsidered to concern each lane individually. It seems justified given speed differences between vehicles driving in different lanes.

Further research is expected aimed at carrying out simulations. Should simulation results prove to help increase road safety, implementation of the method may be considered once adequate technology arrives.

The method of risk management of accidental oil spills at sea

K. Łazuga & L. Gucma
Maritime University of Szczecin, Poland

ABSTRACT: The paper presents methodology of risk management of accidental oil spills at sea. The factors affecting the amount of costs incurred removing oil spills and cost and consequences estimating equations are described. The examples of spills costing in the Polish coast. New measures of costs evaluation and optimization have been proposed. These issues sought to be applied to the evaluation criteria of environmental cleanliness and specified cost that is able to bear the society to maintain pollution-free sea coast.

1 INTRODUCTION

The Baltic Sea is one of the most heavily trafficked seas in the world. The main environmental effects of shipping and other activities at sea include air pollution, illegal deliberate and accidental discharges of oil, hazardous substances and other wastes, and the unintentional introduction of invasive alien organisms via ships' ballast water or hulls.

There are around 2,000 ships at the Baltic Sea at any one time. Approximately, 20% of them are tankers, carrying as much as 166 million tons of oil per year (HELCOM, 2010). Each year there are 120–140 shipping accidents in the Baltic Sea area (Fig. 1). The majority of accidents are groundings and collisions (HELCOM, 2010). Around 7% of the shipping accidents in the Baltic Sea results in some kind of pollution, usually containing small amounts of oil (0.1–1 tones). Despite this Baltic Sea is relatively safe comparing to other regions. The largest pollutions accidents are as follows:

– 1990 'Volgoneft', 700–800 t. of waste oil; nearly all oil recovered at sea,
– 2001 'Baltic Carrier', 2,700 t. of oil; around 50% of oil recovered at sea,
– 2003 'Fu Shan Hai', 1,200 t. of fuel oil; around 1,100 tones of oil recovered at sea.

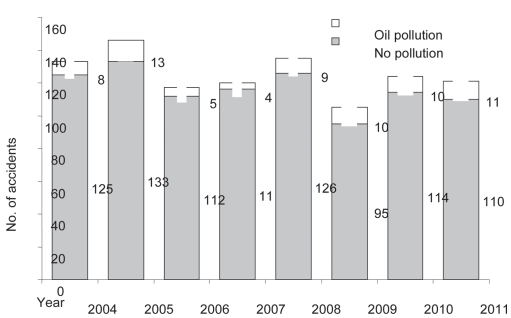

Figure 1. Accidents at the Baltic Sea with and without oil pollution (HELCOM 2011).

2 RISK MANAGEMENT OF MARINE NAVIGATIONAL OIL SPILLS AT THE BALTIC SEA

Risk (R) of accidental oils spills will be defined as:

$$R = \sum P_i C_i \tag{1}$$

where: P_i—frequency of i-tch spill, C_i—consequences of i-tch oil spill.

In further part of this paper the methods of P and C evaluation are presented. Risk management procedure is intentional multistep method consist of risk analysis assessment and control with CBA

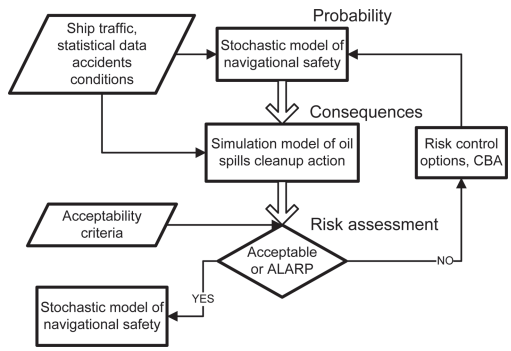

Figure 2. Risk management procedure of accidental oil spills at sea.

optimization. The procedure proposed here utilizes the stochastic model of navigational safety for probability of oil spill assessment and oil spill cleanup simulation model with cost of cleanup action estimation (Fig. 2).

3 FACTORS AFFECTING THE COST OF OIL SPILL

Knowledge of the cost of cleaning the spill provides an important framework for risk assessment and spill response plan. However, there is a very large variation cleaning costs to different incidents, depending on the leakage logistical support in the region of leakage, and the various environmental and sociological factors (Fingas M. edt. 2010).

Number of factors affecting the amount of the costs of removing spills is very large. The most important of them are: the place and time of year in which the event occurred, the type of spilled material and the speed of its spread, the volume of spill, the manner of disposal, weather conditions, the degree of pollution of the coast and others. However, regardless of the nature of the medium they are all interrelated.

As a result of such a large number of factors have been attempts to find relations, which would calculate the estimated cost of disposal of spillages. So far failed to find such a formula, among other things, because no two are the same spill. This makes it harder to take into account all the factors affecting the cost of disposal of spillages. At present, an attempt to predict the cost of the spillage is the study of registered spills, and the resulting database is based on factors that have an impact on costs. This analysis can be used to develop the estimation algorithm presumed cost of marine spills. The final model should take into account various factors simultaneously to create individual methods of forecasting the costs incurred.

4 PROBABILITY OF OIL SPILL ASSESSMENT

The stochastic model of navigational safety and oil modeling presented in (Gucma & Przywarty 2007) could be applied for the first step of risk management procedure. Oil spill accident can occur in arbitrary moment. Scenarios were simulated for risk of oil spill impact evaluation. Meteorological conditions represent average Baltic Sea conditions. On the base of wind and current data probable situations were formed. The data show simulated pollution zones.

The model output is long time spatial distribution of oil spills in given area (Fig. 3). Averaging

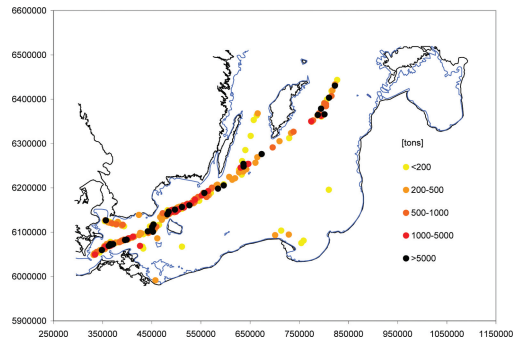

Figure 3. Simulated oil pollutions collision at the southern Baltic Sea (long time simulations results based on (Gucma & Przywarty 2007)).

the results with consideration of simulation times it is possible to find mean probabilities and amount of oil spilled per year.

5 COST OF CLEANUP ACTION BY SIMULATION MODELS

The first approximation of oil spill cost without considering damage to environment could be done by simplified statistical models. One of such model of cleanup cost reveal that unit cost is not dependant of spill size (Fig. 4). The model can be written as (Goryczko & Gucma 2006, Etkin D.S., 2000):

$$C = 255218\, v^{-04184} \tag{2}$$

where: C = cost of oil cleanup in PLN; v = the amount of oil spill (t).

The above formula is too simplify to use it in serious researches therefore the simulation model PISCES II provides the ability to develop, conduct and debrief realistic incident response exercises with reliable cost of oil spill estimation, all in one application. The application's chart and text-based status windows can be directed to large screen displays. This capability lends itself to providing informative command post status displays and is essential for post-exercise debriefing sessions (Fig. 5).

Modelling of the hydrodynamic reaction to the activities of response resources, such as booms, skimmers and chemical dispersants was performed. The simulated processes included: oil spread, evaporation, sinking in the water column, burn-off, and the pollutant's interaction with the coastline. Environmental conditions, including air temperature, wind speed and direction, wave height, current set and drift, could be adjusted dynamically during the simulation. PISCES II enables to calculate

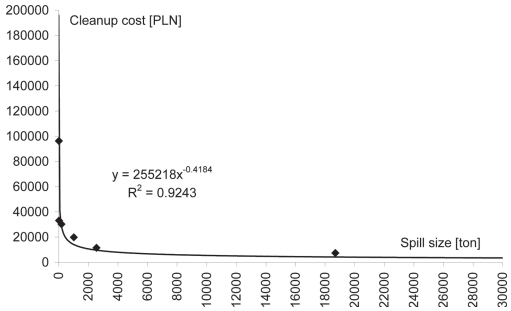

Figure 4. Theoretical model of oil sill up costs (in PLN/ton) by exponential function.

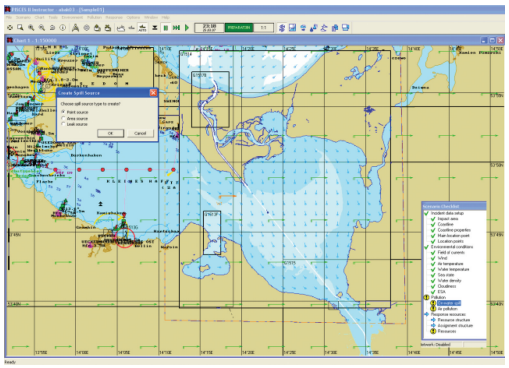

Figure 5. PISCES II graphical interface main window.

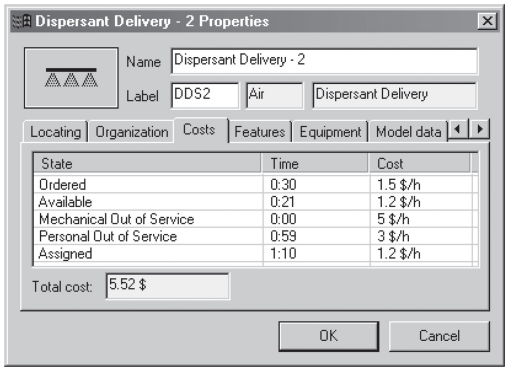

Figure 6. Cost of cleanup action input window.

the cost of applying both the individual resources and the whole operation for the current time. It can be observed the cost of using each resource in the properties window of the object in question by going to the "Total cost" field of the "Costs" tab (Fig. 6).

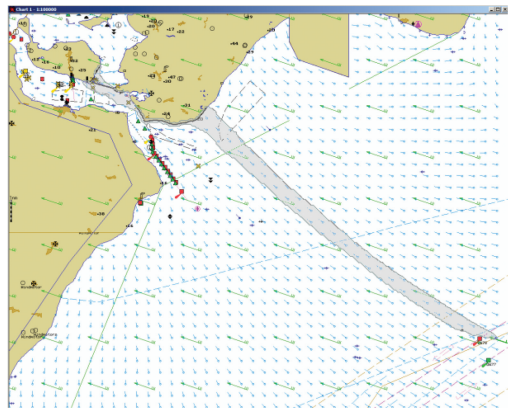

Figure 7. Simulated trajectory of m/t "Baltic Carrier" accident (spill reach Isle of Mon and Bogo).

Calculation of the resource application cost is based on duration of its application, being performed by the program automatically. The track of time is carried out for 5 statuses of the resource: "Ordered", "Available", "Assigned", "Mechanical Out of Service" and "Personal Out of Service". The user has to specify the cost of resource use for different statuses.

Example results of cleanup cost in simulation model of is presented in (Gucma, Lazuga & Perkovic 2013) where validation of m/t "Baltic Carrier" accident have been carried "Baltic Carrier" spill.

6 CRITERIA FOR EVALUATION OF LONG TERM ENVIRONMENTAL DAMAGE DUE TO OIL SPILLS

Quality of Life Index (*LQI*), was developed by the British magazine The Economist, aims to reflect in a more appropriate manner and level of life satisfaction in different countries. The LQI are combined the results of subjective life satisfaction of objective factors of quality of life. Parameters and quality of life measures, which are used to identify parameters include: financial situation, health, political stability and security, family life, community life, climate and geography, job security, political freedom and gender equality. The original definition of *LQI* is as follows (Nathwani et al.):

$$LQI = G^{w} E^{1-w} \tag{3}$$

where: *G*—gross national product per capita, *E*—the average life expectancy, *w*—the ratio of time spent at work by the time outside of work amounting to developed countries from 0.1 to 0.2 (usually a 1/8).

On the basis of the ratio of quality of life it can be possible to carry out risk analyzes and impact of investments on the environment by examining its change after the investment. In further step it could be defined as the optimal cost of protecting a human life *ICAF* (Implied Cost of Averting a Fatality) as:

$$ICAF = |dG|_{\max} dE = ((1-w)/w)GE/4 \quad (4)$$

The estimated value of *ICAF* (2004) for Poland is around 1.8 million PLN for assumptions $G = 18{,}600$ PLN, $a = 0.15$, $E = 70$.

The *NPWI* (Nature Preservation Willingness Index) is similar to *LQI* used to assess the environmental damages. It was introduced originally by (Friis-Hansen 2004) and allows you to calculate how much we are willing to pay for environmental protection. This *NPWI* ratio is calculated as:

$$NPWI = G_q \quad (5)$$

where:
G—gross national product per capita, $q = t/E$—the quality of the environment taking into account the pollution (i.e. the ratio between the time *t* for the period in which the environment remains free of contamination and the average life expectancy *E*). Assuming, as in the case of *LQI* that investment or activity does not impair the quality of the environment it means that you should ensure constancy index from the relationship:

$$dNPWI/NPWI = (G + \Delta G)(q - \Delta q) \geq 0 \quad (6)$$

where: ΔG—change of the gross national product, mostly due to an increase in investment, Δq—change indicator of environmental quality.

Rearranging above equation for the assumed size of the group that uses the values of environmental can find a socially reasonable size amount that society is willing to pay for environmental protection against pollution (μ_p):

$$\mu_p = G\Delta t \left[\left(1 - \frac{\Delta t}{t} \right)^{-1} - 1 \right] N \quad (7)$$

where: *t*—time in which the environment is not polluted, Δt—the average duration of pollution, *N*—the number of person affected by the pollution.

7 OPTIMIZATION OF CLEANUP COSTS (MINIMIZING COST OF RESCUE ACTION)

Created model of optimal allocation refers to the strategic level of response action and is designed to fit the deployment of such a rescue ships in sea rescue bases, in which the time of arrival of ships at the spill site, the cost of the shares and the environmental impact as a result of a failed rescue operation will be as small as possible (Lazuga, Gucma 2014). It is so deploy ships to minimize the sum of the following costs:

- total cost of reaching the spill site,
- the total cost of collecting the spillage by involved vessels,
- cost of contamination on the environment as a result of a failed action,
- the cost of establishing a new port (if needed),
- the cost of buying new ships and their equipment (if none of the proposed arrangements vessels does not provide complete removal of the spill),
- cost of maintaining the ships in the harbour,
- maximize profits from the use of ships for other purposes such as tugs (multi-criteria optimization).

To find minimal cost of response action the following objective function is proposed:

$$Min \quad \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} t_{ijk}c_{ik}x_{ij}y_{ik} + \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} t_{ik}c_{ik}x_{ij}y_{ij} \quad (8)$$

where: *I*—ships, *J*—ports, *K*—pollutions, t_{ijk}—time of reaching *k*-th oil spill form *j*-th port by *i*-th ship, c_{ik}—cost of reaching the spill from given port by ship and cost of given spill cleaning up, *x*—logical variable (0,1) depending of ship allocation in given port, *y*—logical variable (0,1) depending of ship scheduling in given response action.

The created model using evolutionary programming methodology for optimization (minimization) the cost of response action (Lazuga & Gucma 2014). The interface of this model is presetned in Figure 8. It enebles to observe during simulation the advance in cost minimisation throughout generations (left upper panel) of given layout of ports and oil spills (right window).

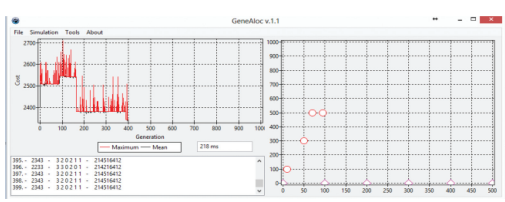

Figure 8. Computer iterface of optimal cost model based on evolutionary programming (Lazuga, Gucma 2014).

8 CONCLUSIONS

Despite much research, and attempt to create a formula for estimation of costs, it should be considered that the costs of removing spills primarily depend on the actual filling factors such as: the number and type of substance. Other factors, of which correlates the amount of costs are: geographical location, local law, or applied method of purifying contaminated sites. The paper also explores a new indicator of the environmental value that it has for society. This ratio refers to the ratio of quality of life. Using indicator of environmental quality, we can quantitatively determine the impact of the investment on the environment and evaluate the risks related to maritime transport of petroleum substances. With after—higher estimates attempted to examine how much we are willing to pay to protect the environment and compares this value with the costs of removal of the spill. For further considerations should be left how the investment made to for more secure against possible spills of petroleum substances will reduce the probability of such a spill. Knowing the value of this probability and presented in the article, the cost of spills can be carried out a full risk analysis of marine traffic engineering systems from the point of view of its impact on the environment. Use of the quality factor of the environment and the potential costs of spills may be helpful in risk analyzes of marine traffic engineering systems.

The impact of new technologies on the safety level of air traffic in Poland

K. Krzykowska & M. Siergiejczyk
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: The purpose of this article is to present the impact of implementing new solutions to increase the level of safety in air traffic. The author presents charts and statistics, which are a clear prerequisite to consideration of the need to implement innovative systems in the fastest growing modes of transport—aviation. In addition, illustrated the high demand of Polish economy to new technologies and its "backwardness" compared to other EU countries. For the preparation of this article the authors use available standards and statistics from Civil Aviation Authority.

1 INTRODUCTION

Innovation is a key element in determining the increase in productivity of the company. Understanding the sources and patterns of innovative activity in the economy is the basis for the development of better policy development. As an innovative company in the field of product and process innovations can specify the company, which in the period of time has launched at least one innovation products or process (a new or significantly improved product or a new or significantly improved process). It is worth noting that the contribution of companies in the service sector and industrial companies, which in the years 2007–2009 have introduced innovative products and/or process, in the total number of these companies, was lower than in the years 2006–2008. Decline could happened due to financial crisis attributable to years 2008–2009. Its start is determined by the date of 15 September 2008, which, together with the date of the bankruptcy of Lehman Brothers, immediately resulted in a reduced availability of credits.

2 INNOVATION DEVELOPMENT IN COMPANIES IN POLAND

The least innovative department in the years 2006–2008 was land transport and transport via pipelines, while in the years 2007–2009—air transport. In case of innovation there are particularly important financial outlays that may be incurred for this activity. These include (Proinno-Europe, 2012):

- research—development related to the development of new products and processes;
- acquisition of knowledge from external sources (patents, inventions, designs, patterns);
- purchase of appropriate software;
- purchase and installation of machinery and equipment, purchase of vehicles, buildings;
- training of a personnel;
- marketing of a new product/process;
- other preparations for the introduction of innovations.

Summary of companies that have introduced innovative products and/or process in % of enterprises by size class are shown in Table 1.

The study shall be subject of any expenditure on innovation in products and processes—current and investment incurred in the report of year finished with successful work (ie. implementation of innovation), incomplete (continued) and interrupted or discontinued, regardless of the sources of their funding. Expenditures on innovation can also be considered because of the source of funding.

Table 1. Summary of companies that have introduced innovative products and/or process in % of enterprises by size class.

	Industrial companies		Companies in the service sector	
Number of employed	2006–2008	2007–2009	2006–2008	2007–2009
Total	21,4	18,1	16,1	14,0
10–49	14,5	10,9	13,1	11,6
50–249	33,3	30,1	25,3	20,0
10–249	19,2	15,8	15,2	13,0
More than 249	60,9	59,0	48,2	45,0

We can distinguish the following funding for innovative activities:

– own;
– received from the state budget;
– obtained from abroad (non-refundable);
– from venture capital funds;
– bank loans.

The main source of funding for expenditures on innovation activities in 2009 were own funds of enterprises. They accounted 68.4% in industrial enterprises and 84.2% in the service sector (of all expenditures). In Figure 1 below expenditures for innovative activities to one company conducting innovative activity by province in Poland in 2009 are shown (INNO—Metrics, 2012).

Innovative activity has several basic objectives, including, among others (Proinno-Europe 2012):

– increasing the range of products or services;
– replacement of obsolete products or processes;
– entering new markets;
– increasing market share;
– improving the quality of products or services;
– improving production flexibility;
– increase the production capacity for products or services;
– improving the safety and health at work;
– reduction of personal labor costs per unit of product.

Poland is one of the moderate innovators with a below average performance. The strengths of the country include human resources, finance and support, investment companies and economic effects. Weaknesses are primarily quality of research systems, linkages & entrepreneurship, intellectual value and resource of innovators (INNO—Metrics, 2012).

In the Figure 2 Polish position to the chosen European Union countries in the case of trading companies based on innovation was presented (the graph shows the value in %, where 100% is the total income of the company achieved through innovative products/processes).

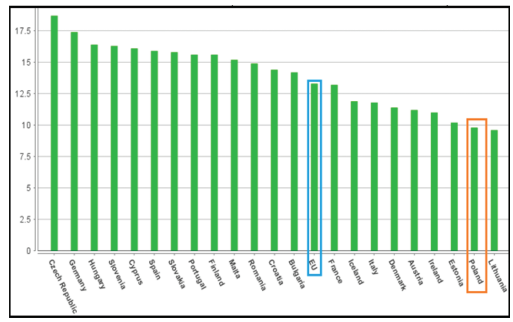

Figure 2. Polish position to the chosen European Union countries in the case of trading companies based on innovation.

3 INFLUENCE OF AIR TRANSPORT DEVELOPMENT ON AIR TRAFFIC SAFETY IN POLAND

Aviation for many years is a dynamically developing branch of the global transport system. Air transport market is dependent on general market trends of the global economy, and thus—market growth rate of air transport affects economy of the world. In Poland, for many years there was no civil aviation infrastructure development program until the adoption of the Development Programme of Network of Airports and Ground Aviation Equipment from 8th of May 2007. The program provided evidence of documents supporting the formulation of applications for funds for the development of the aviation infrastructure in the years 2007–2013 from both the Cohesion Fund and the European Regional Development Fund. Its basic aim, among other things is the development of the network of airports and navigation systems in the country in the direction of economic development, development of airports service, mainly the connection from point to point. In case of the development of navigation systems and due to the limitations of conventional systems—the programme provides for the implementation of new technologies. The aim was to ensure the implementation of European air traffic management programs, including programs for implementing the Single European Sky (SES) and the European Air Traffic Management Strategy (Siergiejczyk M. & Krzykowska K, 2013).

Implementation of new technologies in surveillance systems is considered with a view to maintaining a certain level of safety in air traffic.

Therefore, it is necessary to look at the statistics on number of air events in recent years in Poland. In Figure 3 the number of incidents in civil aviation air in Poland in the years 2006–2011 is shown (European Commision Eurostat, 2014).

Analyzing Figure 3 it should be noted a disturbing steady increase in the number of events in air traffic in commercial aviation in Poland. The number of events in 2010 is more than three times greater than the number of events in 2006. This is undoubtedly related with a constant increase of air traffic in the country. In 2010, a 240,691 of aircraft operations and were done and 20,466,876 passengers were served. The big problem is the increasing number of incursions in Polish airspace controlled. Among them are those that were the result of loss of separation. Statistics are shown in Figure 4.

There is no detailed information on the distinction of aircraft that violated controlled airspace in the years 2009–2010. In Contrast, the Civil Aviation Authority reported that in 2008, out of 47 such events—25 were related to military aircrafts, 11—general aviation, and 4 to commercial aviation. Others are unidentified. The problem of incursions

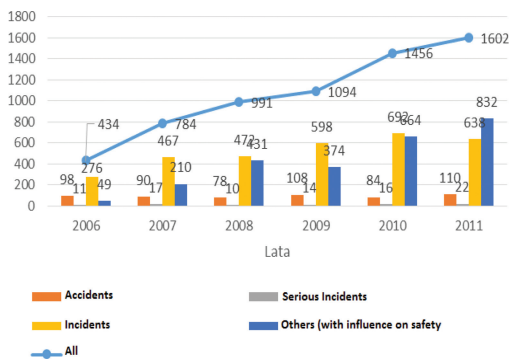

Figure 3. Number of incidents in civil aviation air in Poland in the years 2006–2011.

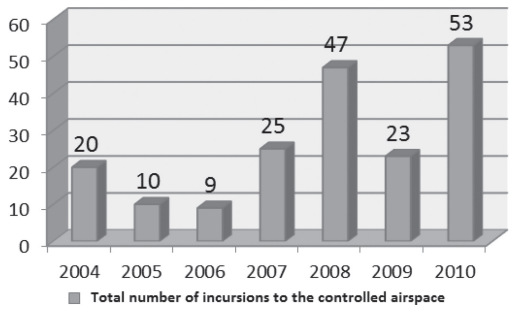

Figure 4. Number of incursions to the controlled airspace in 2004–2010 in Poland.

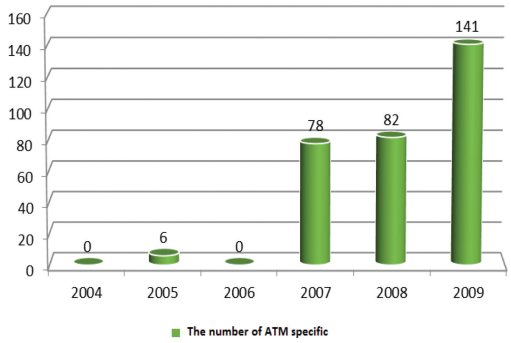

Figure 5. Number of ATM specific in 2004–2009 in Poland.

of controlled airspace could be completely eliminated by the implementation of modern surveillance systems. The basis of their operation is automatic and remote signaling an air traffic controller about the presence of an unidentified object in space.

A significant matter in the analysis of the level of safety in air traffic in Poland has a number of entries so called ATM specific. They mean a crash report of radio—navigation systems. The figure below presents a summary of specific ATM in the years 2004–2009.

In the category of ATM specific recorded events are related to the failure of ground-based radio navigation systems. The increase in the number of these events result from the introduction to the air traffic services new regulations, which are aimed at openness. It also involves the improvement of information flow of events. By 2006, these events have been reported occasionally. Worrying can be fact of the lack of information on such events disturbing comprehensive research results, particularly concerning the failure of CNS services. No precise information does not allow to follow the recommendations of ESARR 2 entitled: Submission of reports and dealing with irregularities in the traffic. Point. A—3.2.2. specifies that "should be developed recommendations for safety improvement actions, or corrective, whose implementation should be monitored. They can take a variety of forms, including the development and implementation of safety requirements, the introduction of standards, development or improving procedures, alteration of system architecture, or correcting ATM training system." (ESARR 2, 2000).

Examples of ATM may be specific events, such as (Civil Aviation Authority, 2014):

– serious incident on the Boeing 737–400, which occurred on 27 April 2006 in FIR Italy; during the flight when descent to FL 260, there was a TCAS message "Traffic Avoidance"; crew made

ATIR; this serious incident was examined by Commission;

serious incident on the Boeing 737-500, which occurred on 28 April 2006 in CTR EDDF; crew during climb after take off in Frankfurt at FL190 received a TCAS RA message "Down"; crew made a request to change the flight level; Minimum vertical separation between two aircraft was 1,000 ft; serious incident was investigated by Commission;

– serious incident on the aircraft Embraer 170, which occurred on 3 May 2006 in TMA EDDF; crew during descent received permission to occupy FL 100; while capturing the mandated level signaling appeared TCAS RA "Climb"; crew made TCAS instructions; after the communication hangman "Clear of conflict" aircraft returned to FL 100; serious incident is under investigation by Commission.

In consequence of the occurrence of such accidents must be considered on the validity of the implementation of additional surveillance systems which would not only detect situations of conflict, but also prevent from occurring such.

4 THE ROLE OF THE SAFETY LEVEL IN AIR TRAFFIC

In 1990 the world airlines consists of more than 15 000 aircraft. They were able to fly over 15 mln km to almost 10 000 airports. Sector of air transport directly employs over 3.3 million people, with more than 1.4 million in the USA. About 12 billion people and 23 mln loads are transferred over the year (Janic M., 2000). Figure 6 shows the number of km of flown routes in years 2011–2012 (Central Statistical Office of Poland, 2014).

Accidents are closely related to the scale of aviation operations. There are many different international institutions, organizations and agencies involved in forecasting future trends, including the International Civil Aviation Organisation (ICAO) and International Air Transport Association (IATA). Manufacturers of air space, such as Airbus,

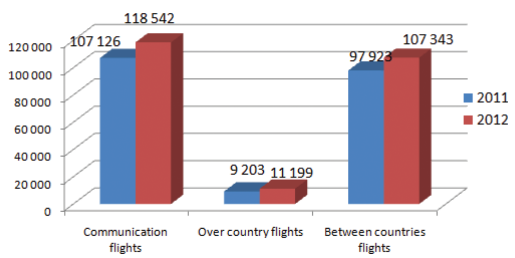

Figure 6. Number of of km of flown routes in years 2011–2012 in Poland.

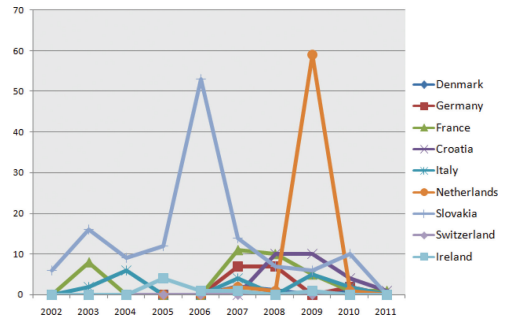

Figure 7. The position of Poland between other chosen European countries with the number of injury accidents.

Boeing and Rolls Royce do the forecast, too. Figure 7 shows the position of Poland between other chosen European countries with the number of injury accidents (Central Statistical Office of Poland, 2010).

It is common that when there is a relatively fast growth of air transport it is also often followed by a series of accidents. The occurrence of such events has stimulated an introduction of technical and operational measures. As a result, overall safety is being improved over time. Some are arguing that the scope for further improvements in safety are becoming exhausted implying that if the accident rate remains the same, while air travel increases, the number of accidents will inevitably rise.

5 CONCLUSIONS

The main problem of air traffic management in the world is to increase airport and airspace capacity and to maintain the required level of safety. Measures aimed at improving the quality of services are based primarily on forecasts of the number of flight operations. Analyzing the statistics it can be concluded that the FIR Warsaw maintains an increase in air traffic volume at the maximum European level. In this phenomenon, however, occurs both benefits and risks. Assuming an average growth of air traffic in Europe—without further delay—the capacity of the airspace required to support this movement should increase by more than 25%. In view of the presented forecasts and actual traffic situations in Poland, the Development Programme of Network of Airports and Ground Aviation Equipment from 8th of May 2007 recommends the rapid changes in the field of optimization and airspace management.

Black swan accidents: Predicting and preventing the unpredictable

D.J. Winfield
Deep River, Ontario, Canada

ABSTRACT: Three recent high consequence black swan accidents are used to illustrate the similar root cause safety barrier failures leading to these diverse events. A sampling of some of the major industrial accidents over many decades then demonstrates societal reactive responses of regulation, legislation and subsequent technical advances in process safety management. Despite significant historical advances in these responses, high consequence accidents, seemingly unpredictable and unpreventable, continue across many diverse industrial activities. Conclusions suggest areas where major accident prevention may be improved with more pro-activeness.

1 INTRODUCTION

1.1 *Black swan events*

Black swan events have been defined (Taleb 2007) as having three characteristics:

i. Following the event, explanations and analysis are presented, indicating such events are quite predictable and expected.
ii. The event has a high consequence(s).
iii. Prior to occurrence the event was not predictable or thought to be physically plausible, or assumed to be of very low frequency.

Black swan events can be experienced in a large variety of diverse activities such as finance, scientific discoveries, technological changes and politics. This paper is limited to considering major industrial accidents.

1.2 *Objectives*

The paper considers a small sample of black swan events that caused catastrophic industry related accidents with high consequences for workers and/or public for fatalities and injury, property damage and/or environmental damage. A sample of three recent accidents, 2011–2013, is used, that may all be classified as black swan type, where, to date, comprehensive reports and complete analysis are not yet available. The discussion illustrates that, despite knowledge advances in the industrialized world in all aspects of safety management, severe accidents continue to occur regularly. Failures of particular safety barriers leading to these three diverse events are highlighted.

A short list of seven major historical industrial accidents, spanning many decades, is then used to illustrate a sampling of the ensuing major regulatory and technical responses, both nationally and internationally. Lessons from these accidents are discussed, invariably showing the predominately reactive nature of societal response, rather than proactive anticipation and mitigation.

2 RECENT BLACK SWAN EVENTS

2.1 *Lac-Mégantic 2013*

The July 2013 railway disaster in Lac-Mégantic, Quebec, resulted in 47 fatalities from BLEVE explosions and fires caused by an unattended 74-railcar freight train derailment of multiple railcars containing a total of 8 M liters of petroleum crude oil. The five-locomotive headed train of the Montreal, Maine and Atlantic (MM&A) railway had been left unattended with inadequate braking and rolled uncontrolled down into the town center where it then derailed at high speed, one hour after midnight. Earlier that night a local fire department had been called by a member of the public to a fire in the one locomotive that had been left running with its unattended cab unlocked. The downtown core of businesses and homes was destroyed leaving substantial soil and water pollution requiring a currently-estimated $400M in clean up and unspecified legal costs.

No formal accident investigation report is yet completed, but many relevant facts are known. A cursory risk assessment of the MM&A railway business, requiring few resources and few analytical skills, should have been able to identify the poorly run operational and maintenance state of the company, with a susceptibility to operational incidents, (e.g. a single engineer was required to perform brakeman duties and a very large and hazardous cargo was allowed to be unattended overnight on a

main rail line on an uphill grade above a residential area with one locomotive engine left running).

Evidence of poor locomotive maintenance, inadequate operational staffing and poor track maintenance was subsequently reported. Neither the company nor the national transport regulator had produced even a rudimentary risk assessment for such hazardous material transport operations. No sophisticated quantitative risk analysis would have been needed to identify these basic shortcomings. The Canadian transport regulator had given specific exceptional permission for one-person train operation in 2012, enabling MM&A operational costs to be reduced. With the town left to pay $8M for emergency work in the immediate aftermath, short-term clean up activities were then funded by government financing of $155M. After the accident the railway filed for bankruptcy and was sold for $12M. Lawsuits and longer term clean up costs exceed assets and available insurance by well over an order of magnitude. Lack of a competent regulatory regime and a company risk management system appears, in a relatively short period of time of a year, to have allowed little to no scrutiny of significantly increased numbers of rail shipments of a highly-volatile and potentially explosive material.

For a safety analyst to predict that the Lac-Mégantic derailment would result in the BLEVE that was responsible for most fatalities, injuries and damage at that specific location, though seems unlikely. No analyst, however experienced, would likely have foreseen the extreme volatility and explosive potential of the oil shipment. The highly volatile and explosive nature of the cargo was not publically divulged, after belated testing, until as long as six months after the disaster. For an analyst therefore to probe down to a level discerning that the shipped cargo content had been falsely, and possibly deliberately, labeled as a moderate hazard Class 3 Packing Group III, seems unlikely. The cargo had though, when being shipped en route to the rail-loading facility, been classified as a higher risk PG II product with contradictory MSDS information; PG I and II (respectively very hazardous and hazardous). Additionally, transport risk is not location unique, but will vary significantly along transport corridors. A risk assessment therefore would need to consider the hazardous properties of the goods being transported, by what means and over which transportation corridors. This would have required detailed reviews of routes, towns, population density, train halt procedures, speed limits and most importantly, knowledge of the highly explosive nature of the petroleum crude oil and consideration of the suitability of the rail car design. The vulnerability of the DOT-111 type rail cars used, to failures in collisions and derailings, was though already well known to the rail industry in North America. The apparent absence of any measure of safety culture of the MM&A would additionally seem to have precluded any in-house risk identification and thus, more importantly, precluded any subsequent risk mitigation measures.

The Lac-Mégantic tragedy is the most recent example that could be suitably described with a root cause of conscious incompetence, fitting into the description (Ale 2013) that some businesses view safety costs as uneconomical, so that costs of 'un-safety' are borne by victims, their family and society (taxpayers). Accident prediction and prevention for such a serious event should have been straightforward, particularly in Canada, in view of the 1979 Mississauga, Ontario train derailment accident involving a large mixed cargo of explosive and toxic chemicals. An evacuation of about 220,000 people was required, at that time the largest peacetime evacuation in North American history. Emergency teams acquired the train's accurate manifest from the dispatch center in an adequate time, with a description of the cargo. Emergency procedures with the aid of materials experts from the shipping company then enabled a hugely successful evacuation with no fatalities or injuries.

The most important safety lesson confirmed from the Mississauga accident was the presence of a three-person train crew, including a brakeman who was credited with taking immediate emergency actions, significantly reducing potential accident consequences. Subsequent recommendations for railcar spacing for fire protection were not universally applied. What appear to be root causes of the Lac-Mégantic (self-regulation, poor proactive equipment and track maintenance and a poor safety management system) were accurately predicted precursors (Benedict 2007) anticipating, in general terms, the impending likelihood of such a major rail accident in Canada.

2.2 *West, Texas 2013*

The West, Fertilizer Plant, April 2013 explosion of 270 tons of ammonium nitrate resulted in 15 fatalities, 200 injured, 150 destroyed buildings and the obliteration of the plant. The facility did not register its ammonium nitrate, which would have required a review. A 2011 emergency planning report filing with the Environmental Protection Agency (EPA) stated there was no fire or explosion risk at the facility. The worst possible scenario was said to be a 10-minute release of ammonia gas that would kill or injure no one. Lack of regulatory control and lack of responsibility from the facility appear to be the main organizational root cause failures. As a black swan event, potential consequences though should in this case easily have been predict-

able from a chemical hazard review, knowing the amount of explosives and storage conditions and with the benefit of historical knowledge from many ammonium nitrate explosions. The potential consequences were not at all unprecedented (the largest industrial disaster in US history was a Texas City ammonium nitrate explosion in 1947 resulting in almost 600 fatalities) but the link between possible prediction and implementation of preventive measures was weak to non-existent. It was reported that the last Occupational Safety and Health Administration (OSHA) inspection was 28 years ago and a 1985 state law allowed storage of hazardous materials without liability insurance. After the explosion President Obama issued an executive order requiring federal agencies to review safety rules at chemical facilities. The same root cause description (Ale 2013) used above for Lac-Mégantic seems also quite appropriate.

2.3 *Fukushima 2011*

The tragic March 11 2011 earthquake and tsunami and the ensuing disastrous consequences for the Fukushima power reactors of Tokyo Electric Power Company (TEPCO) are now well documented. Much of the detailed accident progressions and the exact status of the three reactor cores are though still unknown, due to accessibility problems. A 2008 TEPCO in-house study had identified an immediate need to improve facility seawater flooding from possible tsunami-waves up to 10 m, but this was not acted upon. In retrospect it is hard to escape the conclusion that a combination of decisions by TEPCO and the nuclear regulator ultimately resulted in a very realistic tsunami risk being ignored, in the false belief that a severe tsunami accident was impossible. Business production was made a higher priority than safety. By contrast the small town of Fudai on Japan's north east coast had built a protective tsunami wall that was both high and robust enough to withstand the tsunami. This project was promoted and pushed through by the efforts of a non-technical member of the public, which is remarkable. Had TEPCO and the Nuclear and Industrial Safety Agency (NISA) regulator, followed international best practices and standards the Fukushima plant should have withstood the tsunami, if its design had been upgraded in accordance with state-of-the-art tsunami protection.

A number of underlying causes for TEPCO and NISA's failure to follow international best practices and standards can be identified. NISA lacked independence from the government agencies responsible for promoting nuclear power and also from the industry. Regulatory capture has been used describe this issue, where regulators charged with promoting the public interest defer to the agenda of the industry they ostensibly regulate. In the Japanese nuclear industry there was a justifiable historical focus on seismic safety, but to the exclusion of other credible natural risks.

The Fukushima accident underscores the importance of continuing periodic reevaluations of plant safety for external threats, using best international practices. The full consequences of the severe accident core damage sustained by the reactor units would though have been very difficult to predict in advance. Following the accident, the Japanese government adopted a new regulatory regime to oversee nuclear safety.

3 MAJOR HISTORICAL BLACK SWAN EVENTS

Each major and unexpected historical industrial accident, at least in the industrialized world, has prompted subsequent examinations of the existing risk management systems, if any existed, both at the national level and sometimes internationally. Invariably, large accidents have resulted in some major safety and regulatory legislation being enacted nationally. The major responses from the most prominent and well-documented accidents, that could be claimed to be black swan events, are mentioned below. The literature on such accidents, since the industrial revolution began is vast, so only a few major accidents are noted here. A large fraction of events involved releases of some form of high hazard materials. Such events continue to provide impetus for authorities to improve and modify legislation and regulations to eliminate and mitigate their potential occurrence.

3.1 *Pressure vessel explosions 1900–1910*

An average of about 30 boiler explosions were occurring per month in the US in the early 1900's. One of the most significant (Grover 1905) caused 58 fatalities and 150 injured from a fire-tube boiler explosion and resulted in the first ASME Boiler Code Committee being formed in 1911, followed by the first edition of the Boiler and Pressure Vessel Code being published in 1914.

3.2 *First reactor core melt 1952*

The world's first reactor meltdown (NRX 1952) resulted, among many other subsequent recommendations, with the inception of the world's first formal internal nuclear safety review committee, now considered essential for reactors internationally, but still today not necessarily implemented in all reactor facilities.

3.3 *Windscale 1957*

Two years after the 10 October 1957 Windscale military reactor fire and core melt accident formal external regulation of the UK civilian nuclear power industry through the Nuclear Installations Act was enacted in the UK in 1959, under the auspices of the Nuclear Installations Inspectorate. A government press release at the time nevertheless stated that the fire had *"no bearing on the safety of nuclear power stations being built for electricity authorities"*. One substantial later implication of the accident was the establishment of the UK National Radiological Protection Board (NRPB) in 1971.

One particular aspect of the public accident report was that publication was not until 31 years later, in January 1988. A very brief government report summary was produced only 2–3 weeks after the accident blaming the accident on a combination of human error, poor management and faulty instruments. Key technical details and the root technical and organization cause of the accident were not apparent publically until the 1988 report. Some activity release information on Po^{210}, one of the more significant fission products released, also remained classified until the mid 1980s. There is strong evidence in the 1988 report that the organizational root cause of the reactor fire, the first in a nuclear facility, was the relaxation of safety due to nuclear weapon material production pressure, exerted upon the reactor operations staff by the British government.

A review of international accidents on military nuclear facilities, particularly the most recently disclosed details of a potential nuclear weapons disaster (Schlosser 2013), provides a contemporary very cautious reminder that civilian nuclear accidents by no means set an upper limit on manmade disaster consequences, with military secrecy and non-public disclosure being the major barriers against prevention.

3.4 *Flixborough 1974*

The Flixborough 1974 chemical disaster (28 fatalities and 38 serious injuries) resulted in significant tightening of UK regulations of hazardous industrial processes and led directly led to the introduction of the Health and Safety at Work Act 1974, and the formation of the Advisory Committee on Major Hazards (ACMH) under the auspices of the newly formed Health and Safety Executive (HSE) 1975. The history of UK HSE from 1800 to present is instructive reading in this regard providing a more detailed and longer-term perspective to regulatory responses to severe accidents. Flixborough was a watershed event at the time, from which afterwards the term process safety management then emerged.

3.5 *Seveso 1976*

After the Seveso accident (1976) the regulatory response in Europe led to the Seveso II Directive, following the need for consistency throughout Europe. This Directive was largely influenced by the work carried out in the UK by the ACMH. In turn this led in the UK to the formation of the Control of Industrial Major Accident Hazards (CIMAH) Regulations in 1984 subsequently leading to the Control of Major Accident Hazards involving Dangerous Substances (COMAH) Regulations in 1999 and subsequent amendments, which were the enforcing regulations in the UK following the Seveso disaster.

3.6 *Bhopal 1984*

Bhopal in 1984 from the chemical industry is recognized as the worst recorded industrial disaster and led to significant improvements in plant operations in the US, but victims of Bhopal were left with little compensation. In 1986 the US Congress passed the Emergency Planning and Community Right to Know Act. Also in the US the American Institute of Chemical Engineers Centre for Chemical Process Safety was formed in 1985 as a US industry response and also, after the 1989 Phillips accident in the US, Process Safety Management standards were introduced in 1992. In Canada the Major Industrial Accidents Council of Canada (MIACC) was established in 1987 following Bhopal. This was subsequently disbanded in 1999, then leaving no effective oversight for hazardous substances on the national level. In India, the Environment Protection Act (1986), the Air Act (1987), the Manufacture, Storage and Import of Hazardous Chemical Rules (1989) and the Public Liability Insurance Act (1991) were promulgated.

Bhopal and Flixborough perhaps represent the two seminal tragedies in the last 40 years that changed the international approach to process risk management and the intensification of efforts to ensure the safety of high hazard facilities. Process safety management subsequently finally gained widespread recognition as a standard practice. These incidents spurred broad recognition that handling highly hazardous chemicals could lead to incidents that may occur relatively infrequently, but, due to their catastrophic nature, often result in multiple injuries and fatalities.

3.7 *Chernobyl 1986*

Shortly after Chernobyl (1986) the term safety culture was first introduced (INSAG-1 1988) and its development and application was then adopted internationally in the nuclear industry. The errors

and violations of operating procedures, which contributed to the disaster, were evidence of a poor safety culture at Chernobyl and the former Soviet Union nuclear industry in general. After Chernobyl the World Association of Nuclear Operators (WANO) was formed in 1989, linking 130 operators of nuclear power stations in more than 30 countries.

3.8 *Observations from historical accidents*

Observations are presented in three categories covering the process safety management, organizational and regulatory perspectives.

3.8.1 *Process safety management perspective*

Process safety management (encompassing all types of analysis techniques and safety management system techniques) has made great advances over the last 50 years. With increasing globalization, industrial development becomes more complex and change is continuous. Vigilance in maintaining updated safety knowledge and corporate memory is thus constantly relevant for high-risk industrial systems. An integrated safety management system is needed to encompass risk identification, safety analysis and risk mitigation implementation. From a risk identification and safety analytical perspective there is no shortage, amongst the myriad of application-specific safety analysis techniques, the established of which are well developed and mature. Recognition is though needed that constant updating and new areas will continue to evolve. Safety assessment should be considered a continuous process, not a one-off exercise that does not need to be revisited. Different industries tend to utilize different techniques but there may be a tendency, particularly for large organizations, to become complacent in use of their traditional methods and be reluctant to utilize different and perhaps more appropriate assessment techniques for their own industrial environment.

The lesson should be that, regardless of the industry, a suite of diverse analytic techniques should always be considered. The nuclear industry for example has for instance put much effort and resources into Probabilistic Safety Assessment (PSA), with an emphasis on the core melt frequency metric. PSA is a particularly expensive, complex and usually a very lengthy technique requiring significant training and is quite difficult to review. PSA would not though have predicted the specific accident sequences and management system failures of any of the three major power reactor accidents; Three Mile Island, Chernobyl and Fukushima. PRA quantitative absolute global frequency predictions of low-probability catastrophic accidents are particularly suspect because of fundamental limitations of the modeling technique (Raju 2014 and Cochran 2011). Regardless of the nature of any type of analysis technique no single method would be able to predict the entire realm of possible failures. Care should therefore be taken that safety analysis resources, which are always limited, are not dominated by one method at the expensive of others.

Some accidents arise from engineering errors or omissions that are epistemologically unforeseeable. Epistemic accidents then occur because a technical assumption proves to be erroneous. The Davis Besse reactor pressure vessel head massive external corrosion event in 2002 is such an event that had not been predicted. No PSA or other type of study had identified and alerted to the possibility of such an event, that in retrospect looked like a simple failure mode to predict, in view of the corrosive nature of boron in solution from reactor coolant leaks. Discovery, very belatedly, was by physical inspection. This failure mode then overcame the long held leak-before-break theory postulated for reactor pressure vessels. A similarly long held leak-before-break mantra was claimed for pressure tube reactors until a large longitudinal rupture, due to an unanticipated failure mode, occurred in 1984 in a CANDU reactor pressure tube. Events such as these, firmly established in conventional wisdom, continue to challenge engineering knowledge and the false assumption that engineering facts are always objectively known. One of the main reasons for failures of foresight lies in a misplaced, but institutionally deep-rooted confidence that such failures will not happen. Misguided believe in the infallibility of model results for example, having faith, for example in a core melt frequency metric, can leave a company ill-prepared for scenarios such as Fukushima and Chernobyl. Unpredictable hazards are such that we should always be aware of the fundamental limitations and associated uncertainties of specific modeling techniques.

Utilizing the whole range of numerous methodologies that comprise the comprehensive framework of the OSHA Process Safety Management elements should, if applied, provide excellent coverage. External peer periodic safety reviews also can often bring in fresh perspectives. Risk identification and safety analysis are predominantly objective and technical and, other than the hopefully very small residual hidden black swan design and operational flaws, most large organizations are capable of good performance. Scenarios envisioned by analysts where recommendations are implemented may then be prevented but subsequent failures still periodically seem to arise from unforeseen black swan scenarios. More problematic is then moving from analysis predictions

into risk mitigation recommendations and from there to achieving implementation. The later process includes a variety of organizational review and decision making activities that are people orientated. These are much more subjective than technical analysis.

3.8.2 *Organizational perspective*

Detailed reviews of the accidents mentioned in this paper show that organizational errors dominate the root causes. A large amount of evidence from comprehensive studies of accidents and disasters across a wide variety of industries (Reason 1998) also promotes this conclusion. Financial factors in high hazard facilities such as cost cutting, maintenance activity reductions, production pressures and staff downsizing typically result in accident-causing situations, not unexpectedly, with counterproductive effects then increasing costs and decreasing revenues. Organizational and managerial factors in the form of high level policy and decisions often set the stage for human error at the operational level and for equipment precursor failures that finally can result in a disaster. Invariably large modern organizations have in place the important pro-active features of PSM methods such as operational safety support, maintenance, inspection and audit, as part of their integrated safety management program. Organizational decisions though can negate the impact of any or all of the PSM methods if the findings are ignored.

Organizational structures can fundamentally undermine the capability of the organization to deal correctly with process safety issues if the organizational structure disempowers safety support staff experts. Failings also often result from complacency and lack of memory at the corporate level. Senior leadership may discourage bad news and may have little or no understanding of the importance of process safety. This can stem from a simple lack of technical awareness of safety culture or moral responsibility, that maybe clouded by financial incentives not structured to draw management attention to process safety hazards. Metrics such as lost time accidents may be misinterpreted as reflecting process safety. Rasmussen 2000 notes that most major accidents including Bhopal, Flixborough and Chernobyl all demonstrated that they were not caused by simple independent failures or human errors but rather by '*a systematic migration of organizational behavior under the influences* of *pressure toward cost effectiveness in an aggressive competitive environment'* and, as a result facilities were operated outside their design basis. Lac-Mégantic would also appear to demonstrate these same organizational flaws.

As sections 2.1 and 2.2 demonstrate, not only large well-financed companies operate high hazard operations. Small companies are unlikely to have full time safety staff in the operation and so external consultants would be required, the hiring of which may not be a priority for company directors and managers. For small companies in particular, safety standards and internal implementation and/or enforcement are thus more likely to be weak. Reviews, inspections and enforcement, only available through external inspection by appropriate regulators, then may or may not be effective. Regardless of the technology hazard differences, resources will always practically limit the application of any risk assessment program. Such limitations would not usually be unnecessarily restrictive for large industries but would more likely influence small companies. Small size may generally be representative of small technical complexity, but the examples of sections 2.1 and 2.2 show that severe accident consequences do not necessarily go hand in hand with lack of complexity. Duffey, 2008 notes that *'All responsible industries strive to provide safe conditions'* and that *'Management generally wants to do what is right'* but does not discuss the ensuing problems when these conditions are not met. In such cases stricter and more effective regulatory standards for facility inspections, the possibility of public access to safety information and public participation in decision-making, such as contained in the recent Seveso III Directive for Europe would seem to be very appropriate.

3.8.3 *Regulatory perspective*

As noted in section 3, in the industrialized world if major disasters are catastrophic enough for the public, the society response is usually the formation of various types of regulatory bodies, mainly government operated. Despite progress over many decades with regulation, associated legislation the occurrence of major accidents in strongly-regulated industries continues. The impact of regulation in helping to prevent and mitigating major accidents cannot very easily be quantified but it is clear from the three large nuclear accidents mentioned in this paper that the regulatory barriers failed (US, Russia, Japan). The very existence of some form of external regulatory government oversight, regardless of effectiveness, may by itself be beneficial but, as with safety improvements, trying to quantify regulatory effectiveness would likely be illusory.

A regulatory system is of course predicated on the existence of an adequately-funded and competent regulator who places the safety goal of public protection before the economic concerns of the regulated facilities. Much is made, particularly in the nuclear industry of an independent regulator.

Fukushima focused recent attention in Japan on this issue. Full regulatory independence itself is though not so easy to assure due to the many undue influences that can compromise the function of a regulatory body; changing political circumstances; funding cuts (which may or may be politically motivated); uncertainties and competing interests and influences from other government departments or other organizations. The goal should be to ensure that a nominally independent safety regulator stays independent and is not captured by the commercial industry that it regulates, but remains publicly accountable. Highly competent personnel for instance may be restricted from regulatory organization employment because they have formally worked for the regulated industry. On the other hand revolving-door staff employment between the regulator and industry has also disadvantages. More useful perhaps than just independence would be to focus on measures to assure regulatory competency and integrity. Independence by itself guarantees neither of these much more essential requirements.

One high level recommendation from the Three Mile Island accident (1979) which was, perhaps wisely, not implemented, was to establish a new independent safety group to oversee both industry and the regulator, thus potentially creating yet another layer of checks. In reality, for all types of regulation, complete independence can never be absolutely independent in all respects from the rest of government. Sources of regulatory funding, independent of state funding, are feasible but other funding sources would then be unlikely to have the public safety interest paramount and the regulatory powers would still in any case have to be enacted by government.

4 CONCLUSIONS

The historical pattern of response following major accidents has been invariably reactive to introduce institutionalized regulatory control. Within the same industries continued accidents over long periods of time has resulted in modifying and expanding existing external regulatory controls. Three recent major accident examples have indicated weak external or weak self-regulation failed to provide adequate accident barriers. While there is no evidence to claim the very existence of an external regulator reduces major accident frequency the converse, self-regulation, does indicate the likelihood of increased accidents.

The achievement of regulatory independence is not simple, because of conflicting pressures from government and industry as well as financial considerations. It is suggested that effort placed into achieving high regulatory competence, effectiveness and integrity should be as important, if not more important, than independence. Unless the public is served by effective regulatory agencies acting in the public interest there is little prospect that future severe industrial accidents will be avoided.

Safety assessment techniques, organizational safety management systems and operating and maintenance practices are all essential tools in a suite of risk management activities, but it is important to be aware of the limitations, imperfections and assumptions inherent in all these various tools and not necessarily allow over confidence from one aspect. Conventional established technical wisdom might well be challengeable. Safety assessments in particular should always be viewed as work in progress, even for old facilities, as history shows new technical insights and improved safety practices invariably arise. Design safety review can be a continuous and protracted process, but it is not a one-off exercise that does not need to be revisited. Companies perhaps rarely question the need to meet annual insurance coverage premiums. It is suggested the need for ongoing periodic safety reviews should be viewed the same way.

The long history of severe accidents indicates that black swan industrial accidents of significant impact are unlikely to be significantly reduced in the absence of a very foresighted proactive approach to process safety management. Challenges in creating and maintaining organizational memory and corporate culture at the highest management level are important reasons why incidents continue to occur. Management decisions based on ignorance of technical realities, incorrect assumptions and unrealistic production pressure can lead to ineffective risk management practices or a false sense of security. No matter how sophisticated and analytical models become it is likely they will never encompass the entire realm of what is possible.

ABSTRACT: Aircraft engines and other technical systems are controlled on the basis of responses from the set-point to the controller, while the quality control process is influenced by the response from disturbances acting on the object. However, it turns out that the airplane engine, which is tested during ground tests by inflicting setpoint to the controller is used in flight where random noises acting on the engine. Therefore the emergency operation of the object, which has the decisive influence on its safe and effective use are not tested. The article proved that it is possible to assess the state of regulation of complex technical systems and assess their response to unpredictable disturbances (including variable environmental conditions) acting on the controlled object, based on tests conducted under standard conditions (without disturbance or disturbance with a low force).

1 INTRODUCTION

Comprehensive examination of the complex technical systems operating state should include simultaneous assessment of its state of regulation the technical condition (wear parameters, service life) and the state of the reliability. Operating practice shows that special attention is given to control problems, because it gives the knowledge about technical state of the system (because each adjustment made during maintenance indicates a change in the technical condition) and binds his change of its reliability state.

Only properly adjusted technical system could wear in the optimal way. Every change of the technical state (wear) requires immediate appropriate new regulation and proper update and hence the decision about the further method of use. [4]

Air turbine jet engines are tested during periodic maintenance inspections, and after repairs carried out during the standard ground tests. It proceeds according to a strictly defined tests program. This tests are based on set signal of the turbojet engine rotational speed (its value, the rate of change and duration of the changes) delivered by the engine control lever. Disturbances during this tests are small and haven't any impact on the working engine. Input function is delivered to controller. [3]

However, during its operational use (during the flight) disturbance from signals from both the weather conditions (wind, pressure variation) and resulting from the airplanes operation (tight turns, firing rockets, the acquisition of air stream from other aircraft in group fly) become high power, and thus the importance of the quality of the engine. Disturbances during the flight are the input signal for the object (engine). During the ground tests carried out on the engine disturbance signals have low power and therefore have little effect on engine performance. [1, 7, 9, 10]

So there is a situation that the turbojet engine adjusted correctly during ground tests may be inappropriately prepared to work during the flight (in a variable environment and the difficult to predict disturbances) which may have a significant impact on the quality of engine operation and thus the safety of the flight. Hence the need for new methods to assess control quality of air turbine jet engine based on tests ground in such a way as to provide a high quality of control during flight.

2 TURBINE JET ENGINE SIMULATION MODEL

For tests of the assessment of the control quality of the turbine jet engine the simplified model of rotational speed control was built. It operates from both the input value to the controller delivered by the engine control lever ("*w*") and input from disturbance "*z*" to the object (engine). It has been shown in Figure 1 [2, 9]

The model is considered in two parts: as the model (with the transfer function $G_W(s)$) from the set value "*w*" acting on the controller ($G_R(s)$) and as a model from the disturbance "*z*" acting on the object ($G_O(s)$) with the transfer function $G_Z(s)$. [2, 5, 6]

$$G_W(s) = \frac{G_R(s) \cdot G_O(s)}{1 + G_R(s) \cdot G_O(s)} \tag{1}$$

$$G_Z(s) = \frac{G_O(s)}{1 + G_R(s) \cdot G_O(s)} \tag{2}$$

The analysis of the transfer functions (1) and (2) show that the transfer function describing the operation of the engine from the disturbance $G_Z(s)$ may be obtained by multiplying the transfer function $G_W(s)$ by the inverse of the controller transfer function $G_R(s)$.

$$G_Z(s) = G_W(s) \cdot 1/G_R(s) \tag{3}$$

Thus, it is possible to control quality evaluation of the turbine jet engine in flight (operating from disturbance "*z*") using its tests ground (from the setpoint "*w*").

3 BASIS OF THE METHOD FOR ASSESSING OF THE QUALITY OF CONTROL OF THE TURBINE JET ENGINE

3.1 *Describe using the transfer function*

Transfer functions describing simplified model of the turbine jet engine rotational speed control system from Figure 1 in form of dependences (1) and (2) are presented underneath as formulas (4) from input signal "*w*" delivered by the engine control lever acting on the controller and (5) from input signal "*z*" as random disturbances acting on the object (engine).

$$G_W(s) = \frac{15.67s^2 + 46.86s + 6}{3.916s^3 + 18.47s^2 + 46.86s + 6} \tag{4}$$

$$G_Z(s) = \frac{1.305s^2}{3.916s^3 + 18.47s^2 + 46.86s + 6} \tag{5}$$

Impulse responses of the transfer functions (4) and (5) for the impulse input signal with limited amplitude $A = 100$ and duration $t = 0.01$ s are presented on the Figures 2 and 3.

Transfer functions $G_w(s)$, $G_z(s)$ and their response functions from the setpoint input "*w*" and disturbance input "*z*" are clearly different.

Transfer function of the controller is presented as formula (6).

$$G_R(s) = \frac{31.33s^2 + 93.72s + 12}{2.611s^2} \tag{6}$$

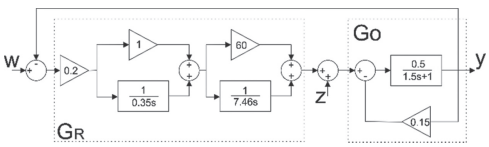

Figure 1. Simplified model of the turbine jet engine rotational speed control. [2, 5, 6, 8, 10].

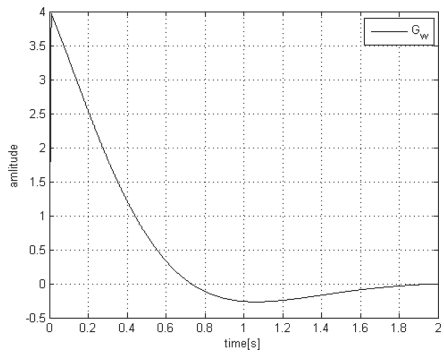

Figure 2. Impulse response of the transfer functions $G_w(s)$.

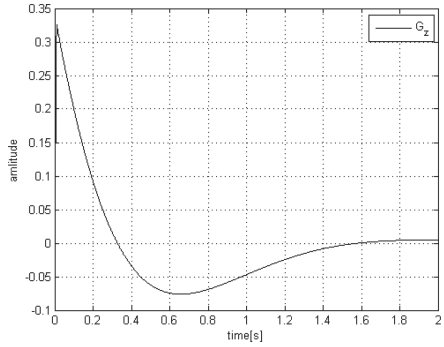

Figure 3. Impulse response of the transfer functions $G_z(s)$.

Figure 4. Impulse response of the transfer functions $G_W(s)$ and $G_Z(s)$.

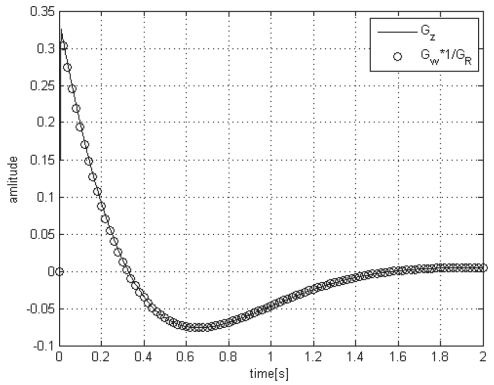

Figure 5. Impulse response of the transfer functions $G_Z(s)$ from disturbance "z" and the same transfer function obtained only from "w" as $G_W(s)$*1/$G_R(s)$.

As a result of multiplication of the transfer function $G_w(s)$ describing model from the set value "w" by the inverse of the controller transfer function $1/G_R(s)$ (being part of the transfer function $G_W(s)$) is possible to obtain the $G_Z(s)$ transfer function and thereby response from disturbance "z". Described above operation shows scheme in Figure 4. [3, 7]

As a result of multiplication of the transfer function $G_W(s)$ from the setpoint "w" describing engine during ground tests by the inverse of the controller transfer function $G_R(s)$ (from the same tests) it is possible to obtain transfer function $G_Z(s)$ from disturbance "z" describing engine during flight. This gives us a basis to assess the quality of regulation of the turbine jet engine in flight, on the basis of the standard of attempts to ground (from "w") without performing dangerous and therefore prohibited operation tests from the disturbance signal "z".

Results showing the accuracy of the operation from the Figure 3 in the form of obtained impulse responses shows Figure 4.

3.2 *Describe using the transfer function estimated from power spectral density of input and output signals*

Transfer functions $G_W(s)$ and $G_Z(s)$ describing simplified model of the turbine jet engine rotational speed control (Fig. 1) could be written as the quotient of the cross power spectral density (from input and output) and the power spectral density (of input). Transfer functions of the controller and object could be shown as formulas (7) and (8). [3]:

$$H_R(\omega) = \frac{S_{ue}}{S_{ee}} \tag{7}$$

$$H_O(\omega) = \frac{S_{y_w u}}{S_{uu}} \tag{8}$$

where "S" is the cross power spectral density.

From (7) and (8) based on (1) and (2) we can obtain:

$$H_W(\omega) = \frac{\frac{S_{ue}}{S_{ee}} \cdot \frac{S_{y_w u}}{S_{uu}}}{1 + \frac{S_{ue}}{S_{ee}} \cdot \frac{S_{y_w u}}{S_{uu}}} \tag{9}$$

$$H_Z(\omega) = \frac{\frac{S_{y_w u}}{S_{uu}}}{1 + \frac{S_{ue}}{S_{ee}} \cdot \frac{S_{y_w u}}{S_{uu}}} \tag{10}$$

From formulas (9) and (10) Figure 6 and Figure 7 were obtained. Them shows normalized impulse response of the $H_W(\omega)$ and $H_Z(\omega)$ corresponding to the absolute and normalized transfer functions $G_W(\omega)$ and $G_Z(\omega)$ (formulas 4 and 5), which shows high accuracy of the transformation.

When we multiply the power transfer function $H_W(\omega)$ by the inverse of the controller power transfer function $H_R(\omega)$ we can obtain the $H_Z(\omega)$ transfer function.

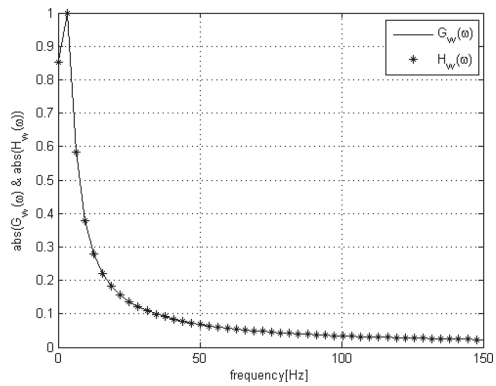

Figure 6. Normalized impulse response of the transfer functions $H_W(\omega)$ and normalized absolute transfer function $G_W(\omega)$.

$$H_W(\omega)\cdot\frac{1}{H_R(\omega)}=\frac{\dfrac{\cancel{S_{ue}}}{\cancel{S_{ee}}}\cdot\dfrac{S_{y_w u}}{S_{uu}}}{1+\dfrac{S_{ue}}{S_{ee}}\cdot\dfrac{S_{y_w u}}{S_{uu}}}\cdot\frac{\cancel{S_{ze}}}{\cancel{S_{ue}}}=H_Z(\omega) \tag{11}$$

When we multiply the power transfer function $H_W(\omega)$ by the inverse of the controller power transfer function $H_R(\omega)$ we can obtain the $H_Z(\omega)$ transfer function.

$$H_W(\omega)\cdot\frac{1}{H_R(\omega)}=\frac{\dfrac{\cancel{S_{ue}}}{\cancel{S_{ee}}}\cdot\dfrac{S_{y_w u}}{S_{uu}}}{1+\dfrac{S_{ue}}{S_{ee}}\cdot\dfrac{S_{y_w u}}{S_{uu}}}\cdot\frac{\cancel{S_{ze}}}{\cancel{S_{ue}}}=H_Z(\omega) \tag{12}$$

The results of operation shown on formula (12) compared to the results from Figure 7 was shown on Figure 8.

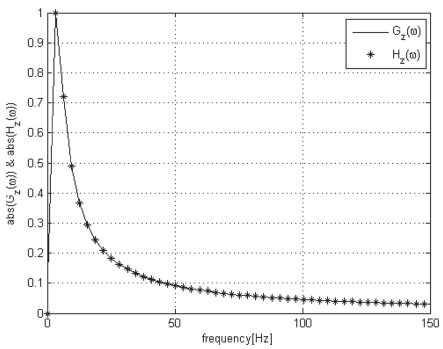

Figure 7. Normalized impulse response of the transfer functions $H_Z(\omega)$ and normalized absolute transfer function $G_Z(\omega)$.

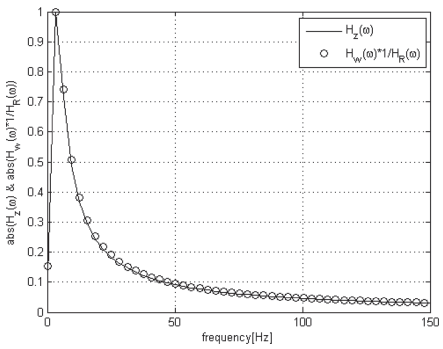

Figure 8. Differences between the normalized impulse response of the power transfer functions $H_Z(\omega)$ and $H_W(\omega)$*1/$H_R(\omega)$ in the frequency domain.

Responses obtained from normalized impulse response from the formulas (10) and (11) corresponding to power transfer function from disturbances $H_Z(\omega)$ in the frequency domain are similar.

4 SUMMARY

The article proved that it is not necessary to carry out research from disturbances "*z*" delivered to the object (for example, by partially covering of the engine nozzle what is dangerous and therefore prohibited) during turbine jet engine ground tests to evaluate its control quality during flight. It could be easily done based on the signals from the standard ground tests of the engine carried out from the input signal "*w*" delivered to the controlled by the engine control lever.

The mathematical formula of safety of aircrafts

J. Lewitowicz, S. Rutkowski, R. Tomaska & A. Żyluk
Air Force Institute of Technology, Poland

ABSTRACT: The flight of on aircraft has been realized in an operational subsystem. The operation of on aircraft and its safeability are determined for aircraft fleet the so-called flight safety. Aircraft operation and its safeability determine the flight safety of aircraft fleet. The flight safety can be modelled, condition diagnosed, put the procedures of genesis and prognosis. As the results of these activities the prevention treatments can be worked out. A aircraft safety, air system safety or air safety can be considered. Within the flight safety science.

1 INTRODUCTION

The flight safety science uses such concepts as the SP safety, aircraft system safety, and aviation (air) safety. The aircraft safety determines an aircraft capability under complex operation conditions to stay within a risk range nor exceeding a criterion value.

The aircraft system safety is a set of properties of a system comprising aircrafts, ground control measures and aviation control measures, aircraft crews, ground personnel and ground maintenance personnel taking care of aircraft proper technical condition and preventing the arising of emergency situations, protecting passengers and offering rescue measures in case of equipment breakdowns, crew errors or ground personnel errors as well as in the cases of unwanted external impacts.

2 THE MATHEMATICAL FORMULA

The aircraft safety manifests itself by dangerous situations resulting in various effects occurred in aircraft accidents due to occurrence of unwanted events. The science of aviation safety and in particular the science of flight safety concerning the system C(P)-SP-O: man (pilot, crew)-aircraft-environment researches all these phenomena, concepts and properties.

The problem of flight safety and aviation—air—safety is studied within a set of aircraft flight safety (BLSL) and a single aircraft flight safety (BLSP). The SP safety depends also on its design. It can be called a technical safety. The flight safety is dependent both on the design safety and on the design of other parts of a system, i.e. on the human (people) and environment.

The aviation—air—safety is understood as a system of knowledge the main purpose of which is to discover laws and regularities and working out rules and ways of action in order to ensure safe performance of flights by aircrafts when taking into account adverse impacts from the environment.

The safety level for systems of operating aircraft fleets is analysed in a continuous manner. The safety level and its trends are expressed with the aid of various measures: e.g. risk, factors, event probability using for it analytical methods, e.g. theory of probability, geometric methods, neural networks. According to relevant current requirements the most usual measure of the flight safety is defined by different coefficients and by the accident rate function FW.

One of the main flight safety coefficients is the coefficient of grave accidents WWc defined as a ratio: number of accidents Wc to the flying time N (in flight hours or as a standard time of 100 000 flight time in air forces or to the number of passengers L for civil aviation (standard number of 1 million of passengers).

The accident rate function (FW) is a real function $W(t)$ which for every real value of t determines the probability P of an aviation system (defined by the number of aircrafts) capable of operation expressed by a selected property (number of aircrafts capable of flying) at the t_o time, where after a $\Delta\tau$ time this capability will be decreased by a value proportional to the change of the accident rate function ΔW.

The $W(t)$ function depends on the properties of operation of the system under discussion characterized by features (k), on its operation conditions and requirements (s), which in order for the system to be accepted as fit must be met. If the accident rate is measured with the accident factor, e.g. heavy accidents WWc, when aircrafts are lost and this WWc is multiplied by a factor (average losses) of the weight p and by the planned flying

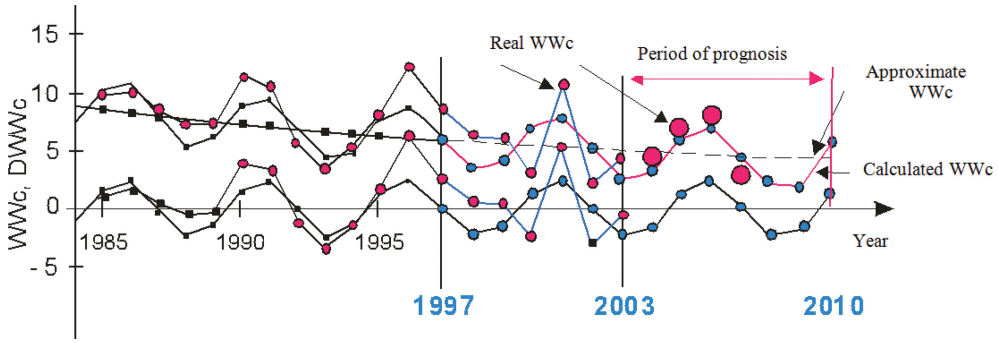

Figure 1. *WWc* and *DWWc* changing over 1984–2010.

time *Np.* (standard: 10^5 flight hours) this function can be expressed as:

$$W(t) = \mathrm{P}\{p, Np, WWc(\tau; k, s); 0 < \tau \leq t, WWc(o; k, s)\} \quad (1)$$

where: τ—prediction time interval; *WWc*—function of the heavy accident factor; *Np*—number of planned flying time over τ time; *p*—coefficient of average losses of aircrafts or crews; *k*—aviation system characterics; *s*—conditions for operating an aviation system and requirements for it.

The accident rate function in its $W(t)$ form and short-term changes *DWWc* make it possible to prognosticate changes of the *WWc* coefficient and losses of aircrafts and crews. The applied calculation method provided the basis to predict a certain growth (local maximum) of the *WWc* factor over 2005–2007 and 2005–2006 and further predicts this coefficient to rise after 2010 for Polish Air Forces (Fig. 1). As the *WWc* over 2003–2007 fairly well agrees with the theoretical predictions it demonstrates that the number and character of factors causing unwanted events did not change substantially.

3 CONCLUSIONS

The analysis of flight safety coefficients and the function of accident rate are used to work out adequate prophylactic recommendations (Lewitowicz 2006, Lewitowicz et al. 2008, Kersterson 2000).

The reliability analysis of the satellite's driving system based on the IABCBLT method

Wensheng Peng, Jianguo Zhang & Linjie Kan
Science and Technology on Reliability and Environmental Engineering Laboratory, Beijing, China
School of Reliability and Systems Engineering, Beihang University, Beijing, China

ABSTRACT: In the design and analysis process of the aeronautical & astronautic systems, some difficulties emerged: on one hand, there is not enough information that can be used directly; on the other hand, a lot empirical data can't be used well. And at the same time, the aeronautical & astronautic systems themselves are too complex, which bring difficulties in analyzing their stochastic behaviors. In order to utilize the uncertain information fully and accurately in the analysis of the aeronautical & astronautic systems, this paper proposes an system stochastic behavior analysis method named the Improved Artificial Bee Colony optimization Based Lambda-Tau (IABCBLT), and applies in the Satellite Antenna's Driving System (SADS). This method firstly models the SADS with petri net, then analyzes its failure rate λ and repair time τ based on the traditional Lambda-Tau method, the fuzzy vague theory and the improved artificial bee colony optimization algorithm. The improved ABC algorithm uses the genetic hybrid genes and the chaotic-search strategy based on the traditional ABC algorithm, and makes the optima process converge quickly and avoid getting trapped in the local optima easily. The IABCBLT method can solve the problem that the fuzzy membership function will wide spread with the increase of the complexity of the system, and it can analyze the system's behavior more accurately with the uncertainty information. At last, this paper analyzes an engineering example of the SADS to verify the availability of this method.

Keywords: the improved artificial bee colony, fuzzy logical math, Lambda-Tau methodology, satellite antenna's driving system

1 INTRODUCTION

Modern mechanical products such as aeronautical & astronautic systems show the features as follows: complex structure, nonlinear performance, limited samples, less information and strict demand of reliability and maintainability. All these features make the reliability and maintainability analysis is a huge challenge in precise and efficiency. Introducing the system engineer methodology into the mechanical products' reliability analysis is an important and practical way. The traditional system reliability analysis methods such as FTA, reliability block diagram, Markovian approach and Petri nets are on the basis of history data. These methods can't work well and even could be inadequate in system analysis because of the complexity of structure and nonlinearity of their behaviors. For example, the space satellite is a system with complex structure. Its samples are very limited because of expensive cost, and its work environment is very complicate and uncertain.

Because of these obstacles, researchers paid attention to the industrial systems' behavior analysis. For example, Gupta et al. (2005) used numerical method for behavior analysis of a dairy plant. Aksu et al. (2006) proposed a methodology based on FTA and Markovian approach for the reliability and availability assessment of a pod propulsion system. Yuzgec (2010) had optimized the feeding profile of an industrial scalefed-batch baker's yeast fermentation process using four different differential evolution algorithms. Wu et al. (2011) proposed an improved particle swarm optimization algorithm for solving the reliability problems. Additionally, there are some other types of reliability problems developed by the researchers such as process control reliability (Estevez 2000), distribution system reliability (Hosseini, 2009), reliability of dynamic systems (Fales R, 2010) and so on. Knezevic and Odoom (2001) highlighted these ideas and analyzed the behavior of a general repairable system by introducing the concept of fuzzy Lambda-Tau technique coupled with PN in terms of various reliability indices utilizing quantified data. Komal et al (2009) used this approach for behavior analysis of press unit using FTA instead of PN in a paper mill while the authors (Sharma SP, 2011, Komal, 2007, Garg H, 2012, Garg H,

2011) have analyzed the behavior of some complex repairable industrial system by using PN and fuzzy approach. But there are few researches and works in the analysis of the complex mechanical systems.

The main object of this paper is to analyze the reliability of the complex mechanical system on the base of the Lambda-Tau (L-T) methodology and fuzzy math. In order to quantify the uncertain of the system reliability more close, this paper utilizes the improved artificial bee colony algorithm to optimize the L-T methodology. The obstacle of the complex structure will be conquered with the help of the petri nets approach. An example of a satellite antenna' drive system is taken account to demonstrate this method. The system reliability model of the drive system is built by the petri net and the reliability behavior is analyzed with the IABCBLT proposed in this paper. At last, the results obtained from GABLT, PSOBLT and traditional ABCBLT are compared and it can be conducted that that the method proposed by this paper could get more precise results in uncertain mathematic.

2 FUZZY CUT-SET AND PETRI NET THEORY

In fuzzy set theory, the elements are not determined to belong to a set or not, instead, the degree presents elements belong to set is proposed. The degree of membership is described by $\mu_{\tilde{A}}(x)$ between in [0,1]. The fuzzy set is uncertain, and it has no certain range itself, so the mathematic is useful if only the fuzzy sets were transferred into the crisp sets. The cut set level technique plays an important role in the transfer procession.

Defining a fuzzy set A in the a discourse domain, for any $\alpha \in [0,10]$, the set $A_\alpha = \{u \mid \mu_{\tilde{A}} \geq \alpha, u \in U\}$ is the cut level α of A. For example, for a triangle membership function $\mu_{\tilde{A}}$:

$$\mu_{\tilde{A}}(x) = \begin{cases} \dfrac{x-a}{b-a} & a < x < b \\ 1 & x = b \\ \dfrac{c-x}{c-b} & b < x < c \end{cases} \quad (1)$$

Then the α cut set of the fuzzy set is $[a^{(\alpha)}, c^{(\alpha)}]$, as in Figure 1.

For the large complex system, when calculating the minimal cut sets in FTA, the computation is very large, even results in the NP problem. Petri net is a special directed net, which contains the static performance as well as the dynamic performance. The petri net can describe the status changing and the events developing, so the petri net is considered as the reliability modeling method instead of the FTA. The static performance of the petri net

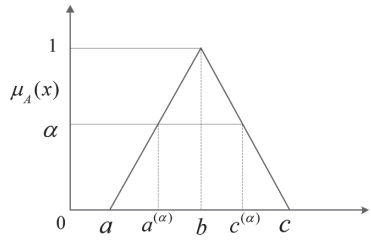

Figure 1. The cut-level of the triangle membership function.

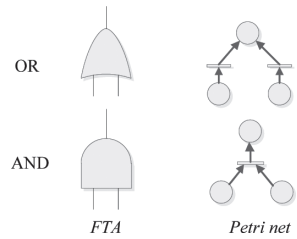

Figure 2. The expression of the logical gate in petri net.

includes three primitives: place, transition and arcs. And the dynamic performance includes the tokens and the rules firing. The systems' status change and the relationship of the changes are reflected through the flow of the tokens in the petri net. At the present, many research about the petri net and its application in improving the FTA, in the reliability qualitative analysis, quantitative calculating and the prognostic and management of the failures.

This paper utilizes the petri net to build the reliability model of the mechanical systems, the disjoint nodes of the system are the place and the transition, and the arcs present the spread relationship of the failures in the system. In case of the complex mechanical system, this paper modeling the system on the base of the static hierarchical petri net.

The expressions of the FTA logical gates in petri net are shown in Figure 2.

3 LAMBDA-TAU THEORY

The Lambda-Tau is a traditional methodology for system reliability analysis, and this method is suitable for the FTA model. The failure rate of every component required to obey exponential distribution function and the failure rate λ and the repair time τ of the system obtained by the logical gates of the system's FTA.

On the base of the traditional L-T methodology, Knezevic and Odoom analyzed the stochastic behaviors of an repairable system with the petri net

Table 1. The basic expression of Lambda-Tau methodology.

Gate	λ_{AND}	τ_{AND}	λ_{OR}	τ_{OR}
Expression	$\prod_{j=1}^{n}\lambda_j\left[\sum_{i=1}^{n}\prod_{\substack{j=1\\ j\neq i}}^{n}\tau_j\right]$	$\frac{\prod_{i=1}^{n}\tau_i}{\sum_{i=1}^{n}\left[\prod_{\substack{j=1\\ j\neq i}}^{n}\tau_j\right]}$	$\sum_{i=1}^{n}\lambda_i$	$\frac{\sum_{i=1}^{n}\lambda_i\tau_i}{\sum_{i=1}^{n}\lambda_i}$

and the fuzzy mathematic. In this theory, the fuzzy membership function combined with the Lambda-Tau methodology are utilized to analyze the fuzzy performance of the system's reliability. This is suitable for the system because of the shortage of the information and the human/environment factors. But this method has a detect that the fuzzy uncertainty of the system will be larger and larger when the system become more and more complex. In case of this situation, Harish Garg (2012) combined the fuzzy Lambda-Tau method and the particle swarm optimization algorithm, in detail, the membership of the systems reliability indices is optimized by the PSO. Thereby, the uncertain degree of the membership is dropping. The author also has verified this method with the illustration example of the feeding unit of a paper mill. However, for the large complex system, especially for the mechanical systems, the PSOBLT also has disadvantages in accuracy and the efficiency. In the intelligent optimization algorithms, the artificial bee colony algorithm is an advanced algorithm in both the accuracy and the efficiency. Inspired by the artificial bee colony algorithm and the GA algorithm, this paper improves the traditional ABC algorithm, the genetic cross factor in GA algorithm is introduced into the ABC algorithm, and then the IABC algorithm is used to optimize the fuzzy membership function of the fuzzy Lambda-Tau method. The accuracy and the calculation efficiency are improved in this paper.

4 IABCBLT METHODOLOGY

4.1 *The IABCBLT method*

IABCBLT method is the combination of two techniques: the improved artificial bee colony algorithm and the Lambda-tau method. The key point of IABCBLT is using the numerical calculation and the optimization algorithm instead of the fuzzy arithmetic, this can improve the accuracy of the reliability indices of the systems efficiently. In the fuzzy L-T methodology, the failure rate and the repair time of the top level of the system is an interval $[a^{(\alpha)}, c^{(\alpha)}]$ at the cut level α. At a determined membership function, if the range of the interval is smaller, then the reliability indices is more accuracy.

The upper boundary of the interval at the cut level α is:

$$\begin{aligned}&\text{Maximize} && \widetilde{F}(\lambda_1,\lambda_1,\ldots,\lambda_n,\tau_1,\tau_2,\ldots\tau_m) \text{ or}\\ &&& \widetilde{F}(t/\lambda_1,\lambda_1,\ldots,\lambda_n,\tau_1,\tau_2,\ldots\tau_m)\\ &\text{Subject to} && \mu_{\lambda_i}(x)\geq\alpha\\ &&& \mu_{\tau_j}(x)\geq\alpha\\ &&& 0\leq\alpha\leq 1 \quad i=1,2,\ldots n;\ j=1,2,\ldots m\end{aligned}$$

The lower boundary of the interval at the cut level α is

$$\begin{aligned}&\text{Minimize} && \widetilde{F}(\lambda_1,\lambda_1,\ldots,\lambda_n,\tau_1,\tau_2,\ldots\tau_m) \text{ or}\\ &&& \widetilde{F}(t/\lambda_1,\lambda_1,\ldots,\lambda_n,\tau_1,\tau_2,\ldots\tau_m)\\ &\text{Subject to} && \mu_{\lambda_i}(x)\geq\alpha\\ &&& \mu_{\tau_j}(x)\geq\alpha\\ &&& 0\leq\alpha\leq 1 \quad i=1,2,\ldots n;\ j=1,2,\ldots m\end{aligned}$$

The advantages of the IABC algorithm are:

(1) Avoid the traditional fuzzy arithmetic, the form of the fuzzy membership function will not widely spread due to the arithmetic, especially for the complex systems; (2) the artificial bee colony algorithm has a higher efficiency in the optimization process, so it could reduce the time cost; (3) the ABC algorithm has improved compared to the traditional ABC, it increase the ability of the global sought, so the results will more precise.

The conditions for applying the IABCBLT:

Through the literatures, the conditions for applying the IABCBLT method are:

i. component failures and repair rates are statistically independent, very small
ii. component failures and repair rates obey exponential distribution function;
iii. the failure rate λ << the repair time τ
iv. after repairs, the repaired component is considered as good as new.

The basic steps of the IABCBLT method are:

1. The FMECA and structure analysis of the mechanical system;
2. Collecting the data of the mechanical system, and identifying the failure rate and the repair time of the components;

3. Building the reliability model of the mechanical system with the petri net;
4. The obtained crisp data of failure rate and the repair time are converted into fuzzy numbers, and then putting them into the petri net;
5. Optimizing the fuzzy membership function with the improved artificial bee colony algorithm;
6. Finally the fuzzy failure rate and the fuzzy repair time of the system is obtained.

Next, the improved artificial bee colony algorithm is proposed.

4.2 *The improved Artificial Bee Colony algorithm*

Artificial Bee Colony (ABC) algorithm was proposed by Karaboga (2007, 2008) for optimizing numerical problems. In ABC algorithm, the position of a food source represents a possible solution to the optimization problem and the nectar amount of a food source corresponds to the quality (fitness) of the associated solution. The number of the employed bees or the onlooker bees is equal to the number of solutions in the population. At the first step, the ABC generates a randomly distributed initial population P ($G = 0$) of SN solutions (food source positions), where SN denotes the size of the population. Each solution $x_i (i = 1, 2, \ldots SN)$ is a D-dimensional vector. Here, D is the number of optimization parameters. After initialization, the population of the positions (solutions) is subjected to repeated cycles, $C = 1, 2, \ldots$, MCN, of the search processes of the employed bees, the onlooker bees and scout bees. An employed bee produces a modification on the position (solution) in her memory depending on the local information (visual information) and tests the nectar amount (fitness value) of the new source (new solution). Providing the nectar amount of the new one is higher than that of the previous one, the bee memorizes the new position and forgets the old one. Otherwise, she keeps the position of the previous one in her memory.

An artificial onlooker bee chooses a food source depending on the probability value associated with that food source, P_i, calculated by the following expression (1):

$$P_i = (fit_i) / \sum_{n=1}^{\mathrm{SN}} fit_n \tag{2}$$

where fit_i is the fitness value of the solution i which is proportional to the nectar amount of the food source in the position i, and SN is the number of food sources which is equal to the number of employed bees. In order to produce a candidate food position from the old one in memory, the ABC uses the following expression (3):

$$x_j = x_{ij} + \phi_{ij}(x_{ij} - x_{kj}) \tag{3}$$

where $k \in \{1, 2, \ldots, \mathrm{SN}\}$ and $j \in \{1,2, \ldots, D\}$ are randomly chosen indices. Although k is determined randomly, it has to be different from i. φ_{ij} is a random number between [0, 1]. It controls the production of neighbor food sources around x_{ij} and represents the visual comparison of two food positions by a bee.

In the ABC algorithm, in order to avoid trapped into the local optima, paper learn from the cross-portfolio and the variation in the genetic, the strongest individual fitness bee in the employed bee s is the queen bee, and its fitness is $g_i(x)$, and the onlooker bee is the drone bee. After the mating of the drone and the queen bee, it will generate a employed bee and a new drone. The stronger offspring bee will replace the parents bee, the drone colony and the employed bee colony get updated by the advantage selective. The update of the drone makes the solution convergence faster in global optimization process; and the updating of the employed bees makes the colony variable, and avoids premature convergence at the same time.

The drone colony, employed bee colony and the queen bee all have their fitness themselves. The drone colony are selected by the roulette, the individual has strong fitness would be selected in large probability, and it will mate with queen bee, transforming its genetic information to the next generation. The probability of the individual be selected is:

$$p_i = g_{m_i}(x) \Big/ \sum_{i=1}^{n} g_{m_i}(x) \tag{4}$$

where p_i is the probability, $g_{mi}(x)$ denotes the fitness of the no. i drone.

According to the fitness mating probability P and the mating times c, the drone mating with the queen bee, the fitness mating probability is:

$$P_i = p_i \left(\sum_{i=1}^{n} g_{m_i}(x) \right) \Big/ \sum_{i=1}^{n} g_{m_i}(x) + r_0 \tag{5}$$

where r_0 is the minimum probability, the function of mating times is

$$c_i = L(1 - P_i) + a_0 \tag{6}$$

where L is the length of the chromosome, a_0 is the minimum cross times.

The process of the IABC is:

1: Initialize the population of solutions x_i, $i = 1 \ldots$ SN
2: Evaluate the population
3: cycle = 1
4: repeat

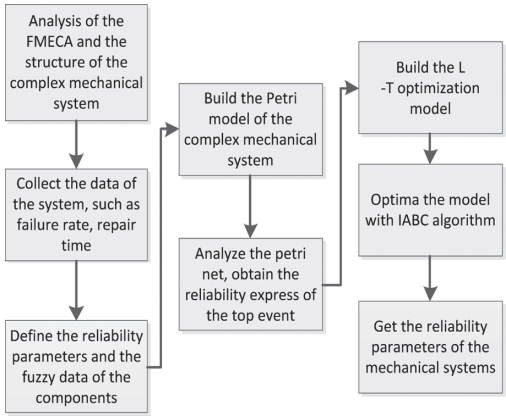

Figure 3. The flow chart of the IABCBLT technique.

5: Produce new solutions v_i for the employed bees by using (3) and evaluate them
6: Apply the greedy selection process
7: Calculate the probability values P_i for the solutions x_i by (5)
8: Produce the new solutions v_i for the onlookers from the solutions x_i selected depending on P_i and evaluate them
9: Apply the greedy selection process
10: Determine the abandoned solution for the scout, if exists, and replace it with a new randomly produced solution x_i by (3)
11: Memorize the best solution achieved so far
12: cycle = cycle + 1
13: until cycle = MCN.

The flow chart of the IABCBLT technique is as show as Figure 3.

5 THE EXAMPLE OF THE DRIVE MECHANICAL SYSTEM OF THE SATELLITE ANTENNA

5.1 *The description of the biaxial drive mechanical system*

The biaxial drive mechanism is the key component of the biaxial motion mechanism of the SAD system. The biaxial drive system contains of two drive components and these two drive components are the same in structure: a stepper motor, a harmonic reducer and an angle sensor. The angle sensor includes a photoelectric encoder and a micro switch. The harmonic reducer includes a steel gear, a flexible gear and a cam. The reliability analysis of the drive mechanical system is the critical point for guaranteeing the satellite antenna's reliability work in the orbit. The CAD model of the biaxial drive system is showed in Figure 4.

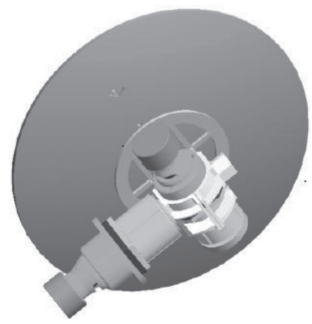

Figure 4. The CAD model of the a biaxial drive mechanical system.

5.2 *Building the FFA and Petri net of the SAD system*

Now a failure event of the drive mechanism can not move is chosen for building the FTA and the petri net. The FTA and the Petri net are in Figure 5 and Figure 6.

5.3 *Defining the reliability parameters of components*

Through the references of the simulation, the history data and the expert's estimation, we assume that the reliability parameters of components in bottom level of the system as in Table 2.

The fuzzy membership function of the failure rate and the repair time is:

$$\mu_{(x)} = \begin{cases} \dfrac{x-0.85}{0.15} & 0.85 < x < 1 \\ 1 & x = 1 \\ \dfrac{1.15-x}{0.15} & 1 < x < 1.15 \end{cases} \tag{7}$$

It means that the membership function of the λ_i and τ_i are:

$$\mu_{\lambda_i} = \mu_{(x)} \cdot \lambda_i \quad i = 1, 2, 3 \ldots, n \tag{8}$$

$$\mu_{\tau_i} = \mu_{(x)} \cdot \tau_i \quad i = 1, 2, 3 \ldots, m \tag{9}$$

5.4 *The reliability behavior analysis of the biaxial drive system with the IABCBLT methodology*

Firstly, the minimal cut sets of the petri net are obtained:

$\{P_1\},\{P_2\},\{P_3\},\{P_4\},\{P_5, P_6\},\{P_7\},\{P_8\},\{P_9\},$
$\{P_{10}\},\{P_{11}, P_{12}\},\{P_{13}, P_{14}\}, \{P_{15}\},\{P_{16}\}$

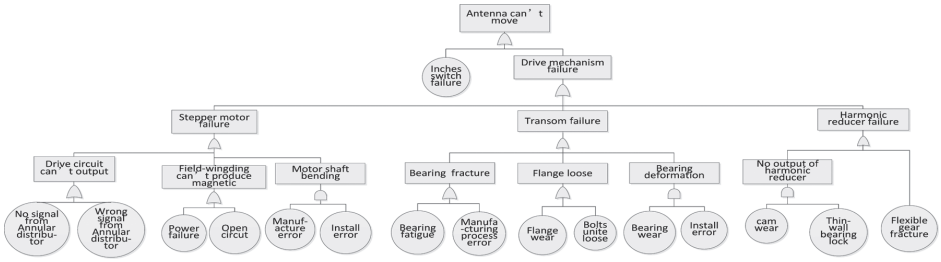

Figure 5. The fault tree of the antenna can not move.

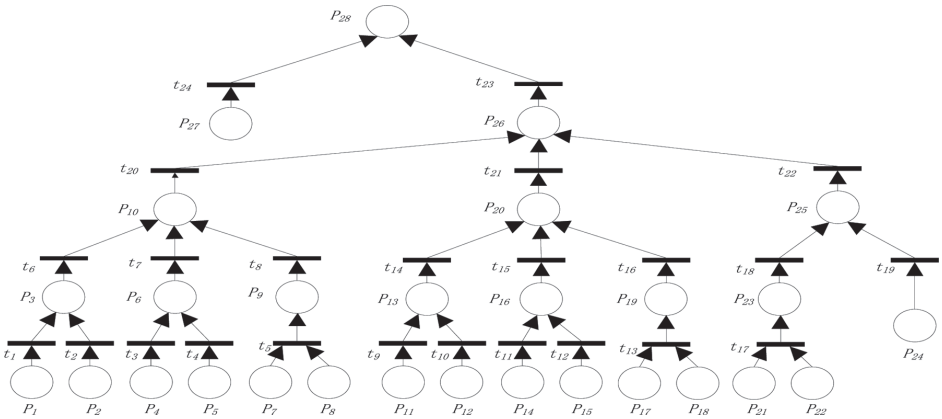

Figure 6. The petri net model of the antenna can not move.

Through the logical expression, the failure rate and the repair time of the top level in petri net are:

$$\lambda_s = \lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 + \lambda_5 \cdot \lambda_6 \cdot (\tau_5 + \tau_6) + \lambda_7 + \lambda_8 + \lambda_9 + \lambda_{10} + \lambda_{11} \cdot \lambda_{12} \cdot (\tau_{11} + \tau_{12}) + \lambda_{13} \cdot \lambda_{14} \cdot (\tau_{13} + \tau_{14}) + \lambda_{15} + \lambda_{16}$$

$$\tau_s = \frac{\lambda_1 \cdot \tau_1 + \lambda_2 \cdot \tau_2 + \lambda_3 \cdot \tau_3 + \lambda_4 \cdot \tau_4 + \lambda_5 \cdot \tau_5 \cdot \lambda_6 \cdot \tau_6 + \lambda_7 \cdot \tau_7}{\lambda_s} + \frac{+\lambda_8 \cdot \tau_8 + \lambda_9 \cdot \tau_9 \lambda_{10} \cdot \tau_{10} + \lambda_{11} \cdot \lambda_{12} \cdot \tau_{11} \cdot \tau_{12}}{\lambda_s} + \frac{\lambda_{13} \cdot \lambda_{14} \cdot \tau_{13} \cdot \tau_{14} + \lambda_{15} \cdot \tau_{15} + \lambda_{16} \cdot \tau_{16}}{\lambda_s}$$

Building the optimization model of the failure rate and the repair time, the failure event is that the drive mechanism can't move:

$$\begin{aligned} &\text{Maximize} \quad \widetilde{F}(\lambda_s, \tau_s) \\ &\text{Subject to} \quad \mu_{\lambda_i}(x) \geq \alpha; \qquad \mu_{\tau_i}(x) \geq \alpha \\ &\qquad 0 \leq \alpha \leq 1 \quad i = 1, 2, \ldots 15; j = 1, 2, \ldots 15 \end{aligned}$$

$$\begin{aligned} &\text{Minimize} \quad \widetilde{F}(\lambda_s, \tau_s) \\ &\text{Subject to} \quad \mu_{\lambda_i}(x) \geq \alpha; \qquad \mu_{\tau_i}(x) \geq \alpha \\ &\qquad 0 \leq \alpha \leq 1 \quad i = 1, 2, \ldots 15; j = 1, 2, \ldots 15 \end{aligned}$$

Optimizing the model with the IABC algorithm, choosing the α-cut at 0,0.2,0.4,0.6,0.8,1.0, the optima iteration process of the variable λs' upper boundary is as shown in the Figure 7.

The optimization results of the model can be seen in Figure 8 and Figure 9, in order to verify the efficiency and accuracy of the IABCBLT, this paper also optimize the model with the methods of GA, PSO, the traditional ABC algorithm.

6 RESULTS AND DISCUSSION

The optimization results are showed in Table 3. Comparing the variable's iteration process in IABC optimization and the ABC optimization, it can be known that the IABC has a higher efficiency in the process. For example, Figure 6 and Figure 7 show the iteration process of the variable λ_s's upper boundary, in traditional ABC algorithm, the optimization process needs 800 times to obtain the best result, while in the IABC algorithm, the iteration times are 500.This experiment shows that the convergence of the IABC is obviously better than the ABC. The reason result in this situation is that in the IABC algorithm, the search strategy is

Table 2. The failure rate and the repair time of the components.

Components	P_1 ($i=1$)	P_2 ($i=2$)	P_4 ($i=3$)	P_5 ($i=4$)	P_7 ($i=5$)	P_8 ($i=6$)	P_{11} ($i=7$)	P_{12} ($i=8$)	P_{14} ($i=9$)	P_{15} ($i=10$)	P_{17} ($i=11$)	P_{18} ($i=12$)	P_{21} ($i=13$)	P_{22} ($i=14$)	P_{24} ($i=15$)	P_{27} ($i=16$)
Failure rate λ_i (10^{-4})	1.5	8	40	0.2	1	10	6	1	15	10	70	5	40	1	2	30
Repair time τ_i (h)	10	10	1	2	3	3	3	3	3	1	2	2	3	3	5	2

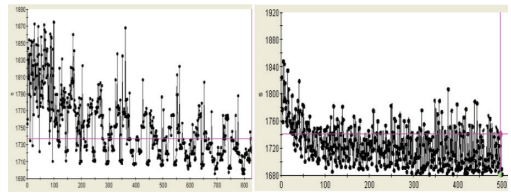

Figure 7. The iteration process of the λ_s in the level of $\alpha = 0.4$ utilize the ABC (left) and IABC (right).

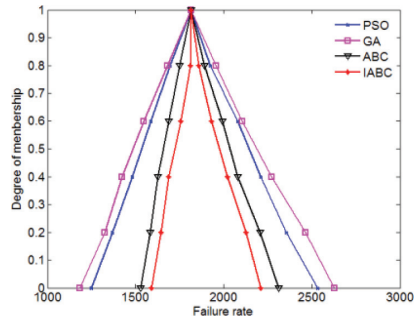

Figure 8. The degree of membership of λ in different algorithms.

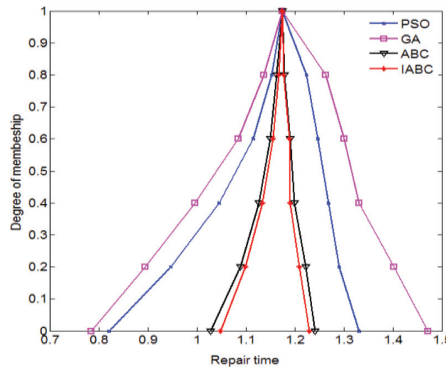

Figure 9. The degree of membership of τ in different algorithms.

chaotic serious search. The chaotic serious search is more efficient than the random search strategy. In the nonlinear, multivariable, complex mechanical system, this is very important.

At last, the paper also optimizes the model with the algorithm GA, PSO, ABC. The range of the failure rate and the repair time' cut set interval at α-cut level are used to measure the accuracy of the different algorithms. For example, when the $\alpha = 0$, the interval of the membership function is: [1249.412, 2534.1345](GA), [1183.571, 2626.8656]

Table 3. The optimization results of the IABC.

α	0	0.2	0.4	0.6	0.8	1
λ_{max}	2212.28	2126.01	2021.17	1931.23	1859.74	1813.7
λ_{max}	1588.65	1643.03	1687.37	1757.22	1809.70	1813.7
τ_{max}	1.2292	1.20851	1.18991	1.1879	1.1768	1.1746
τ_{min}	1.0482	1.09787	1.1327	1.1558	1.1661	1.1746

(PSO); [1528.65, 2312.28] (ABC); [1588.49, 2213.198] (IABC); as showed in Figure 8, the ABC algorithm is much better than the GA, PSO algorithm in accuracy. The IABC algorithm is almost the same with the ABC algorithm in the accuracy of the optimization result, but the results show that the IABC algorithm is still better than the ABC.

7 CONCLUSION

The IABCBLT methodology proposed in this paper combines the IABC optimization algorithm, the fuzzy Lambda-Tau theory and the petri net. And a satellite antenna' driving system is used for the engineering case to verify this methodology. Firstly, the petri net is used to build the reliability model. And then, the fuzzy set theory and the artificial intelligent optimization algorithm is utilized on the basis of the L-T methodology to analyze the failure rate and the repair time of the system. This method can solve the difficulties brought by the complexity of the system's structure. Also, it can solve the problem such as limited history data and available information in aeronautical & astronautic mechanical. The fuzzy theory can utilize the information fully and avoid the waste of the information in the engineering. The widely spread of the fuzzy uncertain cause by the complexity of the structure is also solved by the IABC algorithm, this can improve the accuracy the reliability indices of the system.

The effectiveness of the FMEA technology in the process of the aerospace product development

J. Shuyuan, L. Fuqiu, W. Jinjing & L. Meinan
China Aerospace Standards Institute, China

ABSTRACT: In the process of the aerospace product development and production, the technology of FMEA has been very common to recognize and analyze the failure mode. However, there are still many misunderstandings in the application of FMEA technology. In this paper, the research concerns the following aspects: the FMEA concept, the FMEA essence, various correspondences of FMEA analysis process, FMEA work form, the relationship between FMEA and other reliability work items. By analyzing the FMEA problem of the aerospace product development and production, we analyze and summarize the solutions against the FMEA work errors to enhance the effectiveness of FMEA technology.

Keywords: FMEA; effectiveness; failure; failure mode; failure cause; failure effect

1 OVERVIEW

Aerospace products have features such as exploration, advancement, high risk, small samples, high reliability, and high quality, which challenges the reliability assurance in the process of the aerospace product development. Thus, scientific and effective work of reliability must be adopted to enhance the effectiveness of reliability technology, in order to reduce launch risk and satisfy aerospace products requirements of high longevity and reliability.

In the process of the aerospace product development, Failure Mode and Effects Analysis (FMEA) can be adopted to discover product defects of design and process. Then we can locate weak point and put forward prevent and correct measures against it. Although this method does some work in many cases, the application effectiveness of FMEA technology needs to be further improved. This paper have thoroughly discussed how to improve effectiveness of FMEA technology in the process of the aerospace product development.

2 EXISTING PROBLEMS IN FMEA WORK

The essence of FMEA method is to start with unit functions, and discover failure impacts or consequences to adopt corresponding prevent and correct measures through identifying and arranging all possible failure modes and seeking the causes. It can reduce risk in the process of the aerospace product development. Nevertheless, there exists following problems in FMEA work.

2.1 *A lack of teamwork, existing situation that one designer accomplishes FMEA independently*

FMEA is a teamwork, many departments must cooperate and work together to implement the task. It is a group action instead of that by designer individual. As for aerospace products which usually have high complexity, different designers are inconsistent with the understanding of failure mode, failure cause and failure effect during FMEA development, and they easily neglect the interface problems, that leads to a lack of content coherence. The weak point discovered by it could be far from the real condition of product.

2.2 *Establishing not along with the process of product development, the lack of closed loop management*

For ensure the effectiveness of FMEA, it should be established along with the product development phase. It is common that FMEA is accomplished afterward for reparation, although some instances are not like this, there exists that FMEA development does not begin at the reasonable time. That means FMEA is not synchronous with product design. In a sense, it misses the opportunity to timely discover the weak points and improve the design in the phase of product design. Therefore, that FMEA is developed along with the product design cannot be satisfied, effectiveness of FMEA decreases enormously.

FMEA work is a repeated and dynamically iterative process along with product development. Due to

the different focus during every development stage, function FMEA should be launched in scheme stage, and iteratively carried on and modified along with product development process. In addition, failure prevention and correct measures should be practicable in relevant design tasks and technology documents, achieving the closed loop management.

2.3 *Hard to collect data, a lack of failure mode accumulation, completely analyzing failure mode by experience*

FMEA process needs mass history data information. Owing to a lack of necessary failure mode information accumulation, difficulty of collection and extensive work load, it is common that failure mode analysis mainly relies on experience and failure modes are incomplete. Consequently, how to collect failure data information becomes very significant. Due to a lack of public database of aerospace system and equipment failure, such as entire carrier rocket, control system and engine failure modes, we need accumulate these information combining with system development process. Failure information collection requirement and collection table can be established for developer to gather the finite failure information, which can effectively and entirely support FMEA work.

2.4 *Disaccord of term understanding, informal expressions*

2.4.1 *Informal and indefinite expression of failure modes*

Failure mode means manifestation of failure. Failure mode analysis in FMEA usually appears expressions like "……failure", "……fault". Describing failure modes this way which is inaccurate cannot clarify the real manifestation of failure. For example, one failure mode of some communication product is described as "communication failure", and this expression cannot demonstrate the specific form of failure. We should present that communication signals cannot be received, sent, or intermittent, from the perspective of specific function realization.

2.4.2 *Inaccurate statement of "failure impact"*

Failure effect is generally divided into three layers: local effect, higher layer effect and ultimate effect, each one respectively corresponding to lowest agreement layer, agreement layer and the initial agreement layer. When the initial agreement layer is an entire satellite or rocket while minimum agreement layer of FMEA is its components, it is difficult to describe clearly from the component layer. So FMEA designer is recommended to communicate comprehensively with system designer. Moreover, filling out all three layer failure effects with "no effect" is unreasonable, there will always be certain effect on some product layer as long as it is a failure. For some products with redundant design, even if the loss of redundancy cannot affect the final function (mission), loss of redundancy will directly cause the redundancy failure, and effectiveness of redundancy needs to be analyzed.

2.4.3 *Filling in "The failure criticality" arbitrarily*

The criticality is a qualitative description of the consequence of failure mode. Criticality level criteria should be given in advance. It is usually determined by ultimate effect, criticality level should be high corresponding to huge ultimate effect. For example, failure mode of some product can cause ultimate effect "loss of system function", while the criticality is set for "level III" which is not appropriate. For loss of product/system function, it should be at least "level II"criticality due to the severity. Moreover, many designers opine that relevant design measures have been adopted, the criticality should decrease, and that may also cause problems. The level of criticality should be in the condition that the preventive and corrective measures have not been done. If relevant preventive and corrective measures have been taken, the level of criticality in FMEA could decline next round.

2.4.4 *Poor operability of "preventive and corrective measures" and "compensatory measures"*

Preventive and corrective measures are measures that change design and process respects after discovering the failure causes, and compensatory measures means remedial actions after failure happening. Preventive and corrective measures provide design and process changing, while compensatory measures are in operation, maintenance, support even degradation ways. Generally, there could be no preventive and corrective measures, while compensatory measures is needed, corresponding plans against failure should established in serious situation.

2.5 *Informal FMEA worksheet*

FMEA work is an analytical process, while its manifestation is FMEA worksheet. The normalization of FMEA worksheet directly influence the effect of FMEA technology. The following issues should be noticed when filling in FMEA worksheet.

2.5.1 *Incomplete recognition and omission of failure modes*

Incomplete recognition of failure modes usually appears in FMEA work. Except the limited failure information, recognizing design weak points did not follow the unit functions which comprises a product,

recognizing failure modes did not follow different operation modes, and a lack of interface consideration become the main reasons for incomplete recognition of failure modes. In addition, FMEA technology is in a mono factor manner, when analyzing the failure reasons, failure modes that result of multiple reasons are likely to be missing.

For instance, there are two failure modes "cannot open" and "cannot close" of typical valve in carrier rocket. In valve design, "cannot open" is the main concern, so valves in parallel are adopted to solve the problem. However, due to the lack of the consideration to failure mode "cannot close", this failure frequently occurs in practical application. The parallel valves design increases the risk of failure "cannot close", and reduces product reliability.

2.5.2 *Inaccurate statement of "failure cause"*

In FMEA process, inaccurate and indefinite statement of failure cause frequently occurs. For example, failure cause corresponding to failure mode "dynamo conflict" is described as "reducer failure", however, "reducer failure" does not explain what the actual reason of dynamo conflict is. The reason should illustrate how the reducer fails, such as a reducer control software problem, a reducer hardware problem or an environment problem. Such relevant preventive measures can suit the remedy to the case. If it is an operating environment problem, improving environment or environment adaptability should be adopted; if it is a control software problem, work related to enhancing software reliability should be done. FMEA work is an activity that goes into the whys and wherefores, if the failure cause cannot be properly distinguished, we could not put forward appropriate technology improvement measures, so effectiveness of FMEA is doubtful. For this reason, the failure cause should be analyzed carefully instead of superficial and simple failure appearance.

2.5.3 *Insufficient criterion of failure possibility, arbitrary judgment by experience*

Failure possibility is significant composition of qualitative FMEA, which can be divided into A, B, C, D and E five levels. However, this classification is qualitative and not specific enough existing certain arbitrariness, and operability is poor as well. Failure possibility involves information sources, so it is very difficult to determine the possibility, which will influence effectiveness of qualitative FMEA.

2.5.4 *Poor pertinence and operability of measures*

"Preventive and corrective measures" and "failure cause" in some FMEA is not corresponding and a lack of pertinence. "Compensatory measures" and "failure effect" have the problems neither. Some control measures are in a slogan way, such as "enhancing analysis", "strict production procedure control", "strict product acceptance checks" and "enhancing coordinating management", which does no help with design improvement.

3 FMEA EFFECTIVENESS ASSURANCE MEASURES

3.1 *Starting lowest agreement layer with the components, raw material, software and so on*

For improving the effectiveness of FMEA and discovering the weak points of aerospace product development, the lowest agreement layer should begin with fundamental units like components, raw material and software. Because almost every product failure can be located at some specific component, raw material and some software, and the above fundamental units are also a starting point of systematical design related to reliability. Thus, these fundamental units need to be classified and defined together and relevant database should be established. For example, failure modes of electronic components include open circuit, short circuit, appearance damage, loss of function, parameter drifts, structural damage, defective insulation, poor contact and so on.

3.2 *Standardizing FMEA worksheet, straighten corresponding relationships between each section in FMEA*

In order to guarantee the effectiveness of FMEA, we need to master the core technology, and understand corresponding relationships between each FMEA section. Figure 1 shows the correspondence between the various sections. As Figure 1 shown here, the failure mode is closely related to the task and function realization, while failure cause, failure effect and failure detection correspond to the failure mode. Preventive and corrective measures correspond to failure cause and compensatory measures corresponds to failure effect. Local effect, higher layer effect and ultimate effect, each one respectively corresponds to lowest agreement layer, agreement layer and the initial agreement layer. The above correspondences will directly determine the normalization of a FMEA worksheet.

3.3 *Judging the possibility making full use of information to ensure accuracy*

In the early design phase of aerospace products, we usually only consider criticality of the severe failure effects to minimize the risk. If failures are not eliminated in early design phase, preventive and compensatory measures should be determined considering

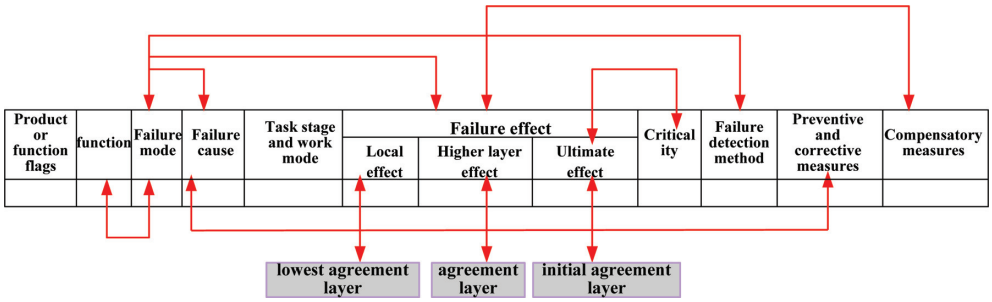

Figure 1. Corresponding relationships between each FMEA section.

the possibility and criticality of failure. Setting possibility level of failure needs to comprehensively consider information from design program itself. The following aspects are usually considered: technology (product) maturity, engineering analysis results (safety factor, degradation), design (product) producibility and testability, history experience of similar design (product), operation condition of adopted technology (product), environmental change and so on, in order to avoid arbitrary judgment.

3.4 *Identifying failure mode and failure cause comprehensively and precisely*

FMEA work should analyze functions according to product consisting of its units, and analyze functions, interfaces and characteristics according to diverse task modes and task stages, in order to conclude failure modes completely. FTA method can also assist in failure cause analysis to ensure comprehensiveness, failure causes can draw from different aspects like "personnel, equipment, material, principle, environment, measurement" as well.

3.5 *Making preventive and corrective measures and compensatory measures operational and effective*

FEMA designers should distinguish the differences between "preventive and corrective measures" and "compensatory measures" to ensure effectiveness. "Preventive and corrective measures" is proposed for recommendation from the design point of view according to design state at present. "Compensatory measures" are required to correspond to failures one by one. If one catastrophic or fatal failure mode is not able to eliminated, designers should explain the reasons to accept the failure modes, including design features, the completed testing, inspection or history information of similar design. Moreover, "preventive and corrective measures" should be highly operable, specific and quantitative to avoid "lie, boast and empty verbiage". "Strict control on productive process" and "strengthen the acceptance checks" are principles, not specific measures.

3.6 *Extending means to acquire failure data, establishing failure information database*

For effectiveness of FMEA, we need a mass of failure data. Through quality problem elimination work and continuously collecting following data, failure information provides FMEA raw material, which reflects unknown weak points of product design, process and testing, etc. Taking one equipment for example, reliability data can reflect functioning condition and performance of the product, once it failed, we can locate the failure quickly through data analysis. Therefore, the foundation of data accumulation is to adequately discover the key features including design, craft and process, and quantifying them with data, then gather certain amount of data by units.

For the problem of incomplete reliability information collection, developers should establish effective ways for reliability data collection, storage and analysis, specify content and management of reliability information data, and solve the problem of a serious shortage of basic reliability data. Data collection related to reliability and safety includes: product development requirements, reliability design analysis, reliability evaluation, safety evaluation, similar product quality problems, and failure elimination.

4 CONCLUSION

This paper studied the concepts and terms of FMEA, FMEA working essence, correspondence between the sections of FMEA, precautions in filling in the worksheet and so on. In addition, we thoroughly analyzed the FMEA work problems in aerospace product development process, and summarized responses and solutions to improve the effectiveness of FMEA. This paper can provide some reference and guidance to effectively carry out FMEA work in aerospace product development.

J.G. Zhang, P. Wang & L.J. Kan
Science and Technology on Reliability and Environment Engineering Laboratory, Beihang University, Beijing, China

ABSTRACT: As science and technology developed so fast, space mechanisms have become complex electromechanical system. With prominent characters of multi-factor, multi-level and high-dynamic, dynamical cascading reliability problems of space mechanisms have been increasingly complex and cannot match the assumptions of static state, independence and large samples of traditional reliability theory. Based on Discrete Bayesian Networks, this paper establishes dynamical cascading reliability model of space mechanisms with the introduction of dynamic response and clearance. By using hierarchies theory and uncertainty propagation directed graph thought and according to product components of system and its hierarchical relationship, this paper describes dynamical cascading reliability issues of space mechanisms in detail and works the problems that traditional reliability modeling methods cannot accurately describe and estimate results easily. In the last, the proposed reliability modeling method is verified by a two-axis-position mechanism.

1 INTRODUCTION

The assessment and prediction of reliability of space mechanisms are very critical challenges, due to multi-factor, multi-level and high-dynamic (J.Q. Hua, 2011). The reliability problem of space mechanisms have become increasingly complex, dynamical, cascading characters of and cannot match the assumptions of static state, independence and large samples in reliability theory (Joseph Homer Saleh, 2011). Traditionally, the reliability of space mechanisms has been evaluated by testing individual systems and verifying their performance is within some acceptable limits. In order to collect sufficient data, sometimes some limited testing have to be implemented for components or subsystems when full scale testing is not feasible for system under actual work environment. Simulation modeling methods are often available for whole system while the full scale testing for the environment is not feasible. The data of component level is easier and cheaper to obtain compared with the system data, so it is beneficial if establishing individual component and/or subsystem level models and incorporating them into a system level model is possible. Therefore the uncertainty in the system model is relate with the component and/or subsystem level data (Angel Urbina, 2009). Moreover because testing cannot reflect the capability of system under the whole environments, the model must extrapolate beyond the data which was developed from. To improve the confidence of an extrapolated model prediction, sources of uncertainty must be identified, quantified and propagated to the response quantity of interest at the system model (Angel Urbina, 2009).

Currently, many researches focus on developing components and/or subsystems level models using first principles. First building a model based on a sample exploratory experiment, then validating it within a different set of experiment, finally using it in a more complex model (Oberkampf, W.L. 2000) (Sindir, M.M. 1996). For example, in this work, one could reach the component of a two-axis-position mechanical by sample experiments. First a model is established which affects some phenomenon of interest, then its performance is validated under a different use environment, finally it is used as part of a larger system. The method above is defined as a hierarchical approach to building a system level model. It investigates a complex system by developing the models of its components and/or subsystems and couples them together into a full system model (Rebba, R. 2005). Several researches of this hierarchical modeling approach have been done. To improve the precision of the model, multiple tests

of these components must be taken to obtain an estimate of the variability for quantify the uncertainty of the model. But the interactions of these components were never tested. No information on the coupling of components could be available. It may add an extra uncertainty. In addition, the interactions of components could have been tested at excitation levels that arenot comparable to those of the full system. In Ref. (Urbina, A. 2006), the information available at the different levels was not used to augment the knowledge about the model of a component in a different configuration. This data was merely used to assess the model's predictive capability for the intended work environment (U.S. Department of Energy, 2000, AIAA, 1998) (i.e. model validation). By using Bayesian updating techniques and Bayesian networks, it is possible to incorporate the available data, updating the model parameters and the model predictions consequently, to reflect the new information that was previously not available for any individual level of complexity. This methodology has been explored in Ref. (Rebba, R. 2005,) for a system where one is the application domain of interest and for one component. Our paper extends that work to dynamic coupling and cascading of complexity and to a multicomponent problem and it adds the additional complications of working with actual experimental data and complex dynamics simulation models.

In this work, the aim is to quantify and propagate uncertainty to eventually use it to evaluate the confidence in the extrapolated dynamic coupling response of a prediction of a full system model. To demonstrate the reliability methodologies developed in this work, a problem developed at a two axis position mechanical is used. The following section gives a brief description of a Bayesian Network (DBN) to uncertainty quantification and its implementation to the selected problem.

2 BAYESIAN NETWORKS

A Bayesian Network (BN) (E. Zio 2009) as a probability-based knowledge representation method is appropriate for the modeling of causal processes with uncertainty. The BN is composed of nodes (variables) and arcs linking the nodes. It is a Directed Acyclic Graph (DAG) whose nodes represent random variables and links define probabilistic dependencies between variables. When the node obtain the available data (or evidence), the instantiation of that node occurs. Note that the amount or quality of the data is not required. That means the available data in this research is assumed as representative of the phenomenon observed and what is being modeled. By the Ref (Jensen, Finn V., 2001), the heart of Bayesian network is building the relationship between each variable involved in the model. These relationships are quantified by associating a conditional probability table with each node, given any possible configuration of values for its parents.

In this paper, a BN (Jensen, Finn V, 2001) is employed to represent the system structure of space mechanisms. A general BN consists of nodes, and directed arcs between some nodes (Li J, Wilson AG, 2007). Each node X_i is a response with random variable. If there is a directed arc from X_i to X_j, X_i is called a "parent" of X_j. There may be no or more than one parents for each node. An arc characterizes the probabilistic dependency of a node on its parent nodes. That is, depending on the values a node's parents take on, the conditional probability distribution of the node may be different. In this paper, a BN is employed to represent the cause-and-effect failure relationship among elements of space mechanisms, in which nodes are components responses of the space mechanisms. Since components are at different levels, a slightly different notation is adopted for nodes.

Furthermore, arcs in the BN representation of space mechanisms have some new interpretations. Specifically, arcs between nodes at the same level represent intra-level cascading failures; arcs between nodes at different levels represent inter-level failure relationship, e.g., how the failure of sub-systems affect the failure of the system (Mingyang Li, 2014).

We assume that a typical BN graph where nodes X represent the responses of different components in each subsystem (Mingyang Li, 2014). The BN model is a way to model probability distribution function on the sequence of N discrete responses $X = \{X_0, X_1, \ldots, X_n\}$ and the sequence of discrete observables $Y = \{Y_1, Y_2, \ldots, Y_N\}$ that has the following factorization, which satisfies the requirements for BNs that:

$$P(X_i) = \prod_{i=1}^{N} P(X_i | Pa(X_i)) \tag{1}$$

where, X_i is the ith node and $Pa(X_i)$ are the parents of X_i in the graph with same levels and different levels. $P(X_i|Pa(X_i))$ is the response probability density function (pdf). The network also facilitates the inclusion of new nodes that represent the observed data and thus the updated densities can be obtained for all the nodes. The joint probability density function for the network of the BN with the observation pdf $P(Y_i|X_i)$ can be updated using Bayes theorem when data is available. The expression for Bayes theorem is

$$f_\theta(\theta|Y) = \frac{f_\theta(\theta) f_\theta(Y|X(\theta))}{\int f_\theta(\theta) f_\theta(Y|X(\theta)) d\theta} \tag{2}$$

Several inference methods for a discrete-state and time BN can be used. The integration in the denominator of Equation 2 can be conveniently done using Markov Chain Monte Carlo techniques (Gilks, G.R., Richardson, S,1996). The marginal pdf of any node in the BN can be obtained by the integration of the joint pdf over all the values of the remaining variables. Thus the Bayes network approach offers a rational and effective methodology to extrapolate inferences from component level information to the system level. With this background now we look at the specific implementation of the Discrete BN (DBN) to the example problem (two-axis-position mechanism).

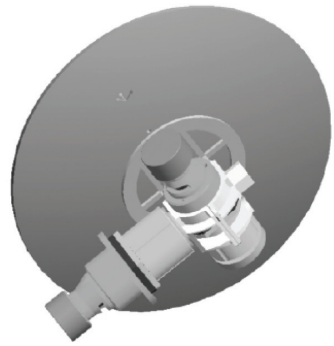

Figure 1. Two-axis-position mechanism.

3 MARKOV CHAIN MONTE CARLO (MCMC) SIMULATION

Even if the expression of posterior distribution is available as a product of likelihood and prior, the shape of distribution can only be estimated by calculating its values at different points (Dawn An., 2011). A traditional way is to compute the values of PDF at nodes after identifying the effective range and to calculate the value of the posterior distribution at each node. This method, however, has several drawbacks, such as the difficulty in selecting the location, spacing, and scale of the points (Dawn An., 2011). In addition, it becomes computationally expensive when the number of updating parameters increases. MCMC simulation is a computationally effective choice which generates a chain of samples to plot the PDF (C. Andrieu., 2003). The Metropolis–Hastings (M–H) algorithm is a common choice for MCMC simulation; Since the MCMC method is a sampling-based one, it has to include enough samples so that the statistical characteristics of the distribution can be well captured. There are some methods available to determine the convergence condition, such as El Adlouniet al. (S. El Adlouni., 2006) and Plummer et al. (M. Plummer 2006).

4 SPACE MECHANISMS RELIABILITY PROBLEM

4.1 *Problem state*

A two-axis-position mechanism of satellite antenna (shown as Fig. 1) is a typical spatial mechanism as a key component that performs two degrees of freedom movement to realize the accurate positioning, posture alignment and tracking of the satellite antenna. The reliability of this mechanism correlates with mission success (Huibo Zhang 2012). It mainly consists of rack, longitudinal shaft and cross shaft. The longitudinal shaft and the cross shaft use the same driving assembly and structure both composed by stepping motor, harmonic reducer and angular transducer. The stepping motor has a redundancy backup. The angular transducer adopts photoelectric encoder and micro-switch. The rack assembly consists of support to assemble components, support between shafts and support to assemble antenna.

It mainly consists of longitudinal shaft and cross shaft. The longitudinal shaft and the cross shaft use the same driving assembly and structure both composed by stepping motor, harmonic reducer and angular transducer. The stepping motor has a redundancy backup. The angular transducer adopts photoelectric encoder and micro-switch. The rack assembly consists of support to assemble components, support between shafts and support to assemble antenna. The constitutional diagram of system structure is shown as Figure 2.

The clearance leads to impact and contact and affected the dynamic characteristic and pointing accuracy of the two-axis-position mechanism. With the enlargement of clearance, the error of velocity and acceleration increased and it leads to descent of reliability. The problem has the following features:

1. It is a multi-component problem where one branch of the problem involves a longitudinal shaft and the other is a type of e cross shaft. Both have clearance wear.
2. It is a multi-level problem where the phenomena observed at the lowest level is assumed to be present at subsequent levels.
3. It is a dynamic problem where the response is changing all the time and the clearance becomes larger because of wear.
4. The individual component branches converge to a system level mechanism where the two couple together. The interaction of the two physics is a potential source of uncertainty since this had not been tested previously.

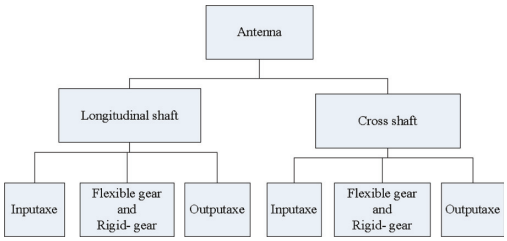

Figure 2. The constitutional diagram of system structure.

5. Experimental data consists of repeated tests on several, nominally identical mechanisms. These are intended to quantify the variability inherent in a physical system. Virtual prototype models (see Fig. 3) are built and calibrated to simulate a particular behavior of the mechanism. The model parameters have been calibrated from simple, discovery experiments aimed at isolating the particular physical phenomenon that the model is trying to represent.
6. In general, there are some correspondences between the subsystem and system that was tested at the various levels.

This paper proposed a dynamic reliability modeling method of DBN, in order to find out the solutions of comprehensive system reliability modeling issues such as the above problems with discrete responses. Using this method to build reliability models of complex mechanical systems can reduce complexity.

4.2 *Data descriptions*

1. Material Parameter Characterization

Elastic Modulus: The first step in the process is to characterize the material model that describes the behavior of axes, flexible gear and rigid gear and also to quantify the variability in the material. Through physical measurements, tension/compression and torsional experiments, the material density, elastic and shear moduli were obtained calibrating to represent the dynamic behavior of them at room temperature. Using the data obtained from these samples and from these tests, a probabilistic description of the randomness of them was obtained and subsequently used in more complex system. More specifically, for these components, the elastic modulus is treated as random variable.

Clearance: With the enlargement of clearance, the error of velocity and acceleration increased and it leads to descent of reliability. Through physical measurements, the clearances of four components (input & output axes, flexible gear & rigid—gear) were obtained at room temperature. Using the data

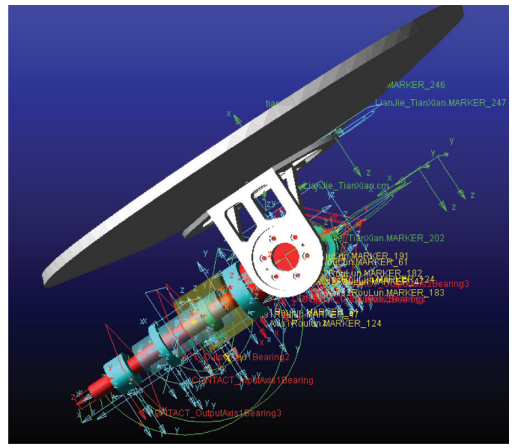

Figure 3. Virtual prototype model of two-axes-position mechanism.

obtained from these samples and from these tests, a probabilistic description of the randomness of was obtained and subsequently used in two-axes-position mechanism. More specifically, for these components, the clearance is treated as random variable.

2. Component Level/Subsystem Level

20 test samples were constructed and modal tests were conducted at component level (input & output axis, flexible gear & rigid gear). (A modal test is one in which the preferred rotating speed and torque are estimated.)

Test samples were constructed and modal testing was performed at subsystem level (longitudinal shaft & cross shaft). Material density was measured and clearance, contact forces and modulus of elasticity was calculated for each test case at both levels.

Modal frequencies of the deformation were obtained for each experiment at each level.

3. System Level

The final step in the process merges the two parallel paths (longitudinal shaft and cross shaft) into a single system. For this project, the physical system of interest simulates a two-axes-position mechanism. Each of the systems was assembled, disassembled and re-assembled and tested ten times so that a hundred tests were performed. With these test, unit to unit and test to test variability was quantified. Base rotating speed was controlled; components rotating speed and torques responses were measured at many locations.

4.3 *Discrete Bayes network*

To begin, let's construct the Bayes Network (BN) for the dynamic cascading reliability problem of two-axes-position mechanism. Considering the

discrete dynamic responses, the BN is shown in Figure 4.

The definition of the nodes in the Bayes network shown in Figure 4 is given below:

$\theta_{1\&2}{}^{f} = [E, H]$—Flexible gear parameters. The elastic modulus and gear depth.

$\theta_{1\&2}{}^{r} = [K, d]$—Rigid gear parameters, stiffness coefficient and gear diameter.

$\theta_{1\&2}{}^{w} = [F]$—Input-axe parameters, the rotating speed.

$X_{M1\&2}^{f\&r} = g\left(\theta_{1\&2}{}^{f\&r}\right)$—Function evaluation: modal rotating speed and torque from (1) component and (2) subsystem level model simulations. This takes the form of $g(\theta_{1\&2}{}^{f\&r})$ which is either a finite element model or dynamics simulation representation relating the modal of rotating speed and torque.

$X_{v1\&2}^{w} = g(\theta_{1\&2}{}^{w})$—Function evaluation: modal rotating speed and torque from input-axe. This takes the form of $g(\theta_{1\&2}{}^{f\&r})$ which is either a finite element model or dynamics simulation representation relating the modal of rotating speed and torque.

$X_{s1\&2}$—Function evaluation: modal rotating speed and torque from output-axe.

X_A—Function evaluation: modal rotating speed and torque from an antenna.

$Y_{M1\&2}^{f\&r}$—Experimental data: from (1) component and (2) subsystem level experiments.

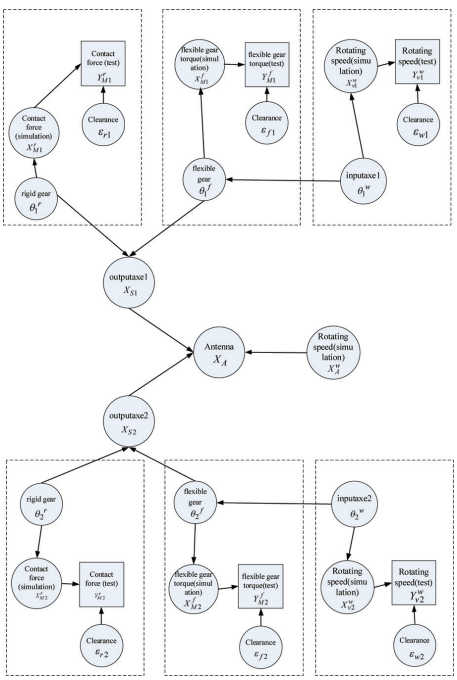

Figure 4. The BN of two-axis-position mechanism.

Y_v^w—Experimental data: from (1) component and (2) subsystem level experiments.

$\varepsilon^f, \varepsilon^r, \varepsilon^w$—The clearances of different components which are calculated by contact forces and experiments.

4.4 *Analysis result*

For the components used at each of the levels, a detailed finite element model and dynamics model were build (see Fig. 3) and it is used as the basis for training individual GP (Gaussian process) models. There is a significant amount of computation needed when performing a Bayesian updating so a fast function evaluation is highly desirable. Some selected results of the BN implementation are shown below. For the estimation of probability density functions, 10,000 samples were used. These were in addition to 20,000 samples used as burn-in samples to allow the Markov chain to become stationary.

The resulting pdf sets of parameters (partial) are shown as following (Figs. 5–7).

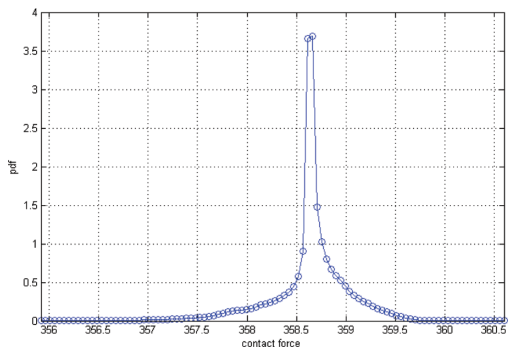

Figure 5. Rigid gear contact force.

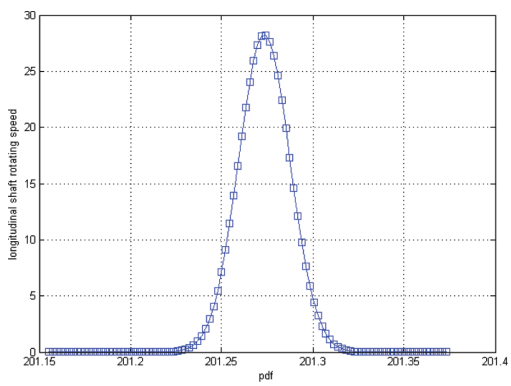

Figure 6. Longitudinal shaft rotating speed.

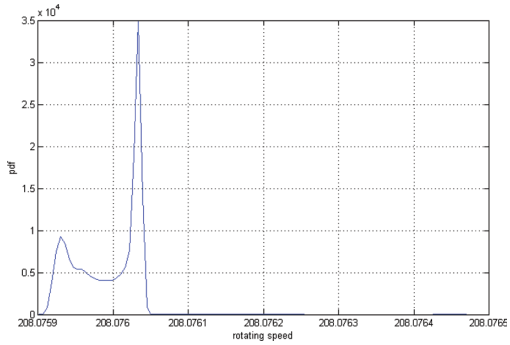

Figure 7. Antenna rotating speed ($0.01°/s$).

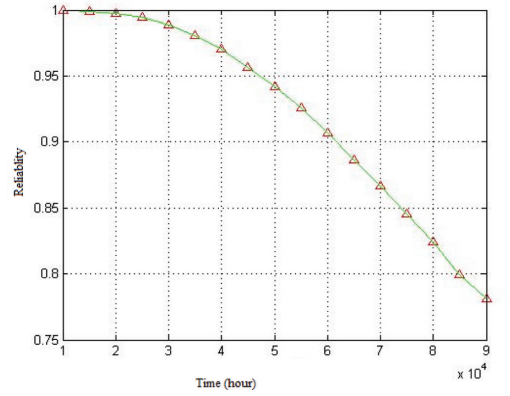

Figure 8. Time-dynamic reliability curve.

In this context the calculation of the probability of failure (or the probability of exceeding a given threshold $2.09^0/s$) needs to be performed using the results obtained from the Bayes network which results from the inclusion of uncertainty as shown in the previous section. We can obtain that the reliability of the two-axes-position mechanism is 0.9963 by MC (Monte Carlo) method at the primary clearance.

Considering the clearances in the different components become larger by the contact forces when the system is working, the reliability will decline by time changing. At last, we discrete the clearances by unit time and use the discrete Bayes network to calculate the reliability at each time with MATLAB programming. The reliability of the two-axes-position mechanism is varying as shown in Figure 8.

5 CONCLUSION

Based on Discrete Bayesian Networks, this paper establishes the dynamical cascading reliability model of space mechanisms with the introduction of dynamic response and clearance.

Using this method to build reliability models of complex mechanical systems can reduce complexity and solve the limit samples problem. It can also effectively reflect the dynamic characteristic of reliability, the feature of multiple failure modes and reliability logical relationships between different system levels of complex mechanical systems, which provides a good foundation for the future reliability design and analysis.

By using hierarchies theory and uncertainty propagation directed graph thought and according to product components of system and its hierarchical relation, this paper describes dynamical cascading reliability issues of space mechanisms in detail and works the problems that traditional reliability modeling methods cannot accurately describe and estimate these issues easily.

ABSTRACT: Despite the importance of an adequate and correct sizing of emergency relief systems, a high level of uncertainty is still present when two-phase liquid-vapor flow can establish. In such a case, no single correlation is presently generally applicable to calculate the pressure drop through a relief pipeline in a wide range of relief conditions. In the present paper a large number of new experimental data have been produced and compared with two of the most widely known and adopted calculation methods: the Friedel model and the classical Lockhart-Martinelli model. They belong to either of the two main groups of prediction models, the homogeneous and non-homogeneous models. The results provide useful insights in their accuracy and range of applicability, and are expected to be of help in the correct sizing of these fundamental safety systems.

1 INTRODUCTION

Proper sizing of relief systems is of the utmost importance both in the protection of process equipment and in the prevention of serious accidents possibly involving people and structures within or outside the plant. Reliable equations are available for single-phase flow through relief devices (safety valves, rupture disks, etc.), headers and other discharge system elements. However, when two-phase flow is possible, no single and reliable calculation method is available, but a number of procedures have been proposed in the literature over the years (see for example CCPS 1998, Fauske 1999, Fisher et al. 1992, Kim & O'Neal 1995, Leung 1996). This is because of the complex phenomena occurring between the two phases during release and of the interactions among the many parameters involved, which are difficult to be mathematically represented. With specific reference to relief devices (mainly safety valves) many analyses have been presented in the recent years with the aim of identifying the most proper models to be applied, at least for a given range of variability of the parameters (Boccardi et al. 2005, 2008, 2010, Darby 2004, Diener & Schmidt 2004, Leung 2004). As a result of this effort, despite the high level of uncertainty still present, the number of models applicable to safety valves is relatively low, and some flexible and enough reliable methodologies have been finally published (ISO, 2008). Along with the particular relief devices adopted, relief headers and pipelines also represent fundamental items of the whole relief system, and, differently from the case of valves, here the situation is even worse: in fact, depending on the particular operating conditions, different flow patterns can establish which can significantly affect the flow characteristics and, in particular, the connected pressure losses. At the same time, an accurate evaluation of the pressure drop along the discharge system is important also for a proper selection and sizing of the relief device itself.

The total pressure difference between two sections along a given pipeline, is given by three different terms:

$$\Delta P_{tot} = \Delta P_{acc} + \Delta P_h + \Delta P_{fr} \tag{1}$$

where ΔP_{acc} is the acceleration term, associated with a velocity variation, ΔP_h is linked to a height variation, and ΔP_{fr} represents the friction losses.

The acceleration term can be written as

$$\Delta P_{acc} = G_s^2 \left(v_{out} - v_{in} \right) \tag{2}$$

where G_s = specific mass flow rate, v_{out} and v_{in} the outlet and inlet specific volumes, respectively.

For horizontal pipes, the elevation term is zero. The calculation method for the friction term preliminarily depends on the type of flow elements, whether straight lengths of pipes, fittings (valves,

elbows, joints, etc.), or cross-section variations (restrictions, pipe entrances and exits and so on). Furthermore, in the case of two-phase flow, some models assume that the friction losses also depend on the specific flow pattern established.

Based on Equation 1, for horizontal pipes, the total pressure drop can be calculated by quantifying ΔP_{acc} and ΔP_{fr}. However, as can be seen from Equation (2), ΔP_{acc} depends on the pressure profile established along the flow, through v_{out} and therefore an iterative procedure is required. Furthermore, the evaluation of ΔP_{fr} is affected by a high level of uncertainty, and this makes the total pressure loss prediction quite complex.

In the present paper, an experimental rig has been adopted to measure the pressure profile along a relief header, including both straight pipe lengths and fittings. The acceleration term has thus been directly calculated from Equation 2, and the resulting friction term, derived from Equation 1, has been compared with some of the most common calculation methods.

2 CALCULATION OF PRESSURE DROP ALONG PIPELINES

Due to the complexities in the mathematical representation of the flow of a two-phase liquid-vapor mixture, different simplifying hypotheses are often introduced, giving rise to a number of different models. A preliminary distinction can be made between models assuming or neglecting the slip between the two phases. This is an important issue because, depending on the assumption adopted, the specific volume of the mixture has to be calculated with different expressions, i.e.:

$$v_m = x^2 \frac{v_g}{\varepsilon} + (1-x)^2 \frac{v_l}{(1-\varepsilon)} \tag{3}$$

$$v_h = x \cdot v_g + (1-x) \cdot v_l \tag{4}$$

respectively with or without slip, where g and l are the subscripts for vapor and liquid, x is the vapor quality of the mixture, ε the vapor hold-up, v_h the homogeneous specific volume and v_m the momentum specific volume in the presence of slip.

In the present paper, the experimental data will be compared with two models, one for each of the above categories, i.e.: the Lockhart & Martinelli (1949) model (with slip) and the Friedel (1979) model (homogeneous).

2.1 *The Lockhart and Martinelli model (1949)*

The model by Lockhart and Martinelli is widely known since long and therefore it will be recalled very briefly here.

Since it takes into account the slip between the two phases, the average specific volume has to be calculated by Equation 3.

By this simple model, the two-phase pressure drops are calculated as a function of the pressure drops generated by one of the single phases, assumed as flowing alone,

$$(dP/dL)_{fr} = \frac{2 \cdot f \cdot G_s^2}{\rho \cdot d} \tag{5}$$

corrected by a proper multiplier

$$\left[(dP/dL)_{fr}\right]_{2p} = \phi_l^2 \cdot \left[(dP/dL)_{fr}\right]_l = \phi_g^2 \cdot \left[(dP/dL)_{fr}\right]_g \tag{6}$$

In the above equations f = friction factor, G_s = specific mass flow rate, ρ = density, d = pipe diameter.

The multiplier ϕ to be introduced in Equation 6 depends on the specific single phase adopted and can be derived from graphs and correlations as a function of the Martinelli parameter X^2, defined as

$$X^2 = \frac{\left[(dP/dL)_{fr}\right]_l}{\left[(dP/dL)_{fr}\right]_g} \tag{7}$$

2.2 *Friedel model (1979)*

The equation proposed by Friedel has been derived by correlating about 25000 data obtained on a number of two-phase systems (water-steam, water-air, oil-air, and so on):

$$\frac{\left[(dP/dL)_{fr}\right]_l}{\left[(dP/dL)_{fr}\right]_g} = (1-x)^2 + x^2 \cdot \left(\frac{\rho_l \cdot \zeta_g}{\rho_g \cdot \zeta_l}\right) + 3.21 \cdot x^{0.78} \cdot (1-x)^{0.224} \cdot \left(\frac{\rho_l}{\rho_g}\right)^{0.91} \cdot \left(\frac{\mu_g}{\mu_l}\right)^{0.19} \cdot \left(1 - \frac{\mu_g}{\mu_l}\right)^{0.7} \cdot Fr_{tf}^{-0.0454} \cdot We_{tf}^{-0.035} \tag{8}$$

with

$$\left[(dP/dL)_{fr}\right]_l = \frac{\zeta_l \cdot G_s^2}{2 \cdot d \cdot \rho_l} \tag{9}$$

where

$$\zeta_j = 64/\mathrm{Re}_j \tag{10}$$

for Re < 1055

$$\zeta_j = \left[0.86859 \cdot \ln\left(\frac{\mathrm{Re}_j}{1.964 \cdot \ln(\mathrm{Re}_j) - 3.8215}\right)\right]^{-2} \tag{11}$$

for Re > 1055
and the non-dimensional numbers are, as usual,

$$\mathrm{Re}_j = \frac{G_s \cdot d}{\mu_j} \tag{12}$$

$$Fr_{tf} = \frac{G_s^2}{g \cdot d \cdot \rho_h^2} \tag{13}$$

$$We_{tf} = \frac{G_s^2 \cdot d}{\sigma \cdot \rho_h} \tag{14}$$

Since this model assumes a homogeneous flow for the two phases, the homogeneous two-phase density, ρ_h, is calculated from Equation 4.

3 PRESSURE DROPS THROUGH FITTINGS

The additional elements possibly present along a given pipeline can be widely variable: bends (elbows) and other directional variations, connections like tees and others, cross-sectional area variations (restrictions, enlargements), joints (welds, flanges, others), orifices, nozzles, sensors for instrumentation, all different kinds of valves, and many others. All these elements introduce a pressure loss to the flowing fluid, which is not easy to predict because of both the extreme variability of those elements, and the difficulties in the mathematical representation of the flow characteristics through them.

As a consequence, different approaches have been proposed in the literature over the years. One of the most widely adopted methodologies, makes use of the so-called "pipe length equivalent", which is characteristic for each specific pipe element. This parameter represents the length of a straight section of pipe (with the same characteristics of the fitting, in terms of diameter, roughness, etc.) giving rise to a pressure loss *equivalent* to that introduced by the fitting itself. This length, which can be usually derived from a number of data bases and references (Perry et al. 1997, Crane Co. 1969), is typically obtained for single-phase flow, and no specific information is available for two-phase flow. In order to check the applicability and accuracy of this methodology, the equivalent length of the first elbow of the experimentation circuit has been determined by running various tests under different operating conditions (pressure and flow-rate) with all-liquid flow: a 0.55 cm equivalent length has been thus calculated. Subsequently, the length of straight sections of pipe giving rise, under two-phase flow, to the same pressure drops measured across the elbow under the same conditions, have been derived, with varying operating conditions. The resulting two-phase equivalent lengths, as a function of the Reynolds number, are reported in Figure 1.

The Reynolds number has been calculated as

$$\mathrm{Re} = \rho_{tp} U D / \mu_{tp} \tag{15}$$

where the two-phase density ρ_{tp} and viscosity μ_{tp} have been calculated as weighted averages of the corresponding single phase values by means of the vapor quality. The inlet velocity has been calculated as:

$$U = \left[G_l\left(\frac{1}{\rho_l}\right) + G_v\left(\frac{1}{\rho_v}\right)\right] \Big/ A \tag{16}$$

where A is the cross-sectional area of the pipe (of diameter D), and $G_{l/v}$ the specific flow-rate of the liquid and vapor, respectively.

It can be seen that for Re > 10^6 the average value of the equivalent length corresponds fairly well to the value obtained for only-liquid flow. However, for Re < 10^6, a marked deviation if found. Furthermore, as reported in Figure 1, all the runs corresponding to vapor qualities higher than 8% fall in the area Re > 10^6 somehow suggesting that, under these conditions, the behavior of the mixture is close to a homogeneous flow,

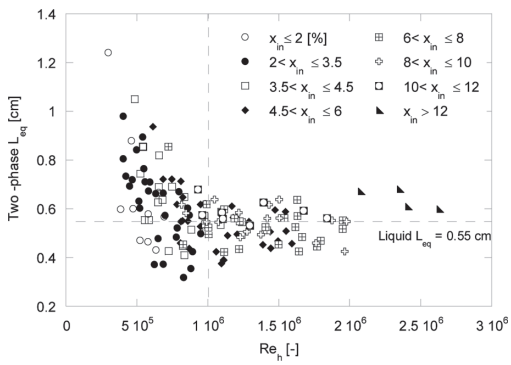

Figure 1. The equivalent length as a function of the Reynolds number, obtained from two-phase flow experiments.

as already reported in previous analyses (Fisher et al. 1992).

In the present investigation, this methodology has been applied to check the accuracy of the Lockhart-Martinelli and Friedel models also used for the straight sections. The acceleration terms have been calculated as explained in the previous section.

4 THE EXPERIMENTAL SETUP

A general view of the experimental rig adopted in the present investigation is reported in Figure 2.

The main components of the facility were:

- a volumetric pump;
- a recovery heat exchanger;
- an electric boiler;
- a control valve;
- a heat exchanger connected to an external cooling system;
- a pressurizing system.

The volumetric pump provided a fixed flow-rate independent of other test conditions, while the inlet pressure could be varied and controlled by means of the pressurizing system and the control valve downstream of the test section.

This latter consisted of a horizontal straight pipe, 2.3 m long and with 10 mm internal diameter, including one 90° elbow at each end (see Fig. 3); along that section the pressure was recorded in a number of locations (manometers from PS 3 to PS 10).

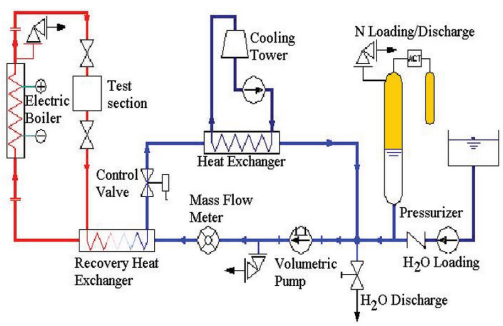

Figure 2. The experimental rig.

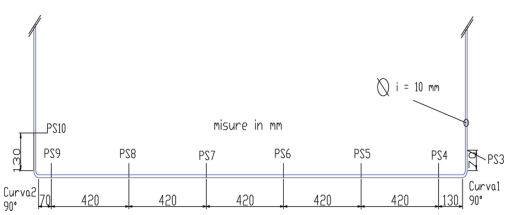

Figure 3. The test section.

Table 1. Parameters variability range.

	Straight line	Elbows
Parameter	Range	Range
Inlet pressure (bar)	3.4–17.6	4.0–17.7
Vapor quality (%)	0.1–15.4	0.1–13.3
Flow rate (kg/s)	0.083–0.35	0.083–0.35

The inlet vapour quality was controlled by varying the power input provided at the electric boiler. Since the pump did not withstand temperatures higher than 50°C, an external cooling system was required, but, in order to reduce the power consumption at the electric boiler ahead of the test section, an internal heat-recovery system has also been used, consisting of two plate-and-frame heat exchangers.

The closed loop of the facility allowed the test conditions to be maintained without time restrictions, making the measurements more stable.

By independently varying mass flow rate, inlet pressure and vapour quality, a total of 3285 effective measurements were obtained (those comparable with the instruments error were disregarded). The resulting ranges of variability of the main operating parameters, both for the straight line and for the elbows are reported in the following Table 1.

5 RESULTS AND DISCUSSION

In order to assess the level of accuracy of the models investigated and to allow their direct and immediate comparison, besides the raw data reported in the following figures, some synthetic statistical parameters have also been adopted and calculated.

The first parameter of interest is the Root Mean Square (RMS) of the relative (percentage) differences (sometimes also called *residuals*) between the calculated and the measured pressure drops with respect to the measured value (Δ_i):

$$\mathrm{RMS} = \sqrt{\frac{\sum (\Delta_i)^2}{N-1}} \tag{17}$$

where N is the total number of measurements. This parameter directly provides the magnitude of the average absolute error and therefore represents a measure of the level of accuracy of the model.

A further parameter is the standard deviation of the relative error with respect to the mean error (Δ_{av}):

$$\sigma = \sqrt{\frac{\sum \left(\Delta_i - \Delta_{av}\right)^2}{N-1}} \tag{18}$$

This parameter represents the spread of the errors with respect to the average error. It can be observed that when the average error tends to zero, RMS and σ tend to be identical. Therefore, the better the model, the lower and the closer the values of RMS and σ; conversely, high and quite different values of RMS and σ denote an inaccurate model with wide spread of the predictions.

5.1 *Models comparison for straight pipes*

In the case of the homogeneous (no slip) Friedel model, the acceleration term of the total pressure variation between two pipe cross-sections can be directly calculated from Equation 2, with the homogeneous specific volume estimated from Equation 4. This allows the direct calculation of the friction loss by Equation 1.

In Figure 4, the pressure drop per unit length (bar/m) due to friction losses calculated with the Friedel model is reported against the experimental values relative to the same pipe sections. In order to check the possible influence of some other parameters involved in the flow, the vapor quality at the entrance of each section has been classified in a discrete number of intervals, and the measurements belonging to each class have been reported with different marks in the figure (see attached key). It can be seen that no significant effect is associated with the vapor quality.

As far as the statistical parameters are taken into consideration, their values (RMS = 16.6% and σ = 16.5%) denote a quite good capability of the model in predicting the friction losses.

Despite the Friedel model is considered a general one, independent of the flow pattern, in order to assess its possible influence, the flow pattern has been characterized for all the runs. The flow pattern map proposed by Moreno-Quiben & Thome (2007) has been adopted, and it was found that, based on that classification, the flow pattern in all the runs could be associated with either the *intermittent* or *dispersed bubble* regimes. In Figure 5, the ratio between the calculated and experimental data is reported, as a function of the vapor quality, with the flow pattern as a parameter.

The pressure drops reported in Figure 5 refer to the whole straight portion of the pipeline (i.e. between manometers P4 and P9 in Fig. 3).

It can be seen that, in comparison with the dispersed bubble flow regime, the intermittent pattern is characterized by a larger deviation from the optimum condition ($\Delta p_c/\Delta p_{exp}$ = 1), as well as by a larger dispersion of the data. And, for both regimes, this is particularly true for lower values of the vapor quality. Furthermore, as already found from Figure 4, a decrease of the ratio is observed at increasing values of x, with a tendency toward underestimation.

In Figure 6, the pressure drop calculated by means of the Lockhart-Martinelli model is reported against the experimental measures. Again, a classification of the data, based on the inlet vapor quality x is also reported.

Based on the synthetic information provided by the statistical parameters, it can be observed that this model is less accurate than the Friedel one in the representation of the pressure drop by friction (RMS 25 and 16.6%, respectively). A larger

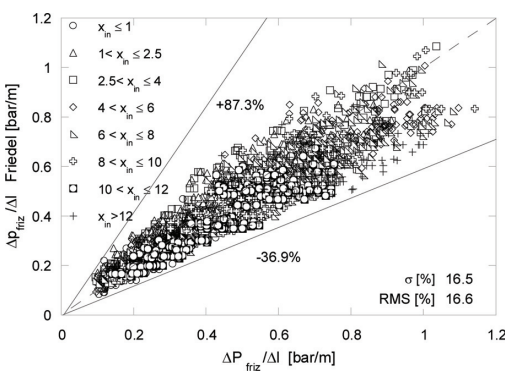

Figure 4. Pressure drop in straight pipes. Comparison between Friedel model's predictions and experimental data.

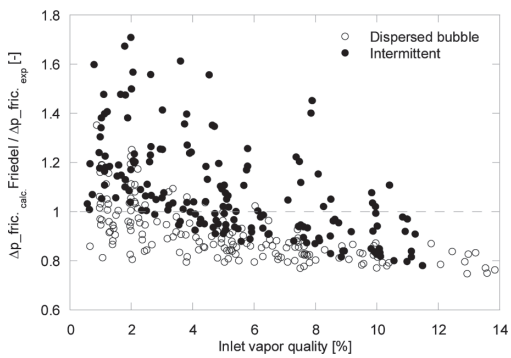

Figure 5. Friedel: $\Delta p_c/\Delta p_{exp}$ as a function of the vapor quality and for the different flow patterns.

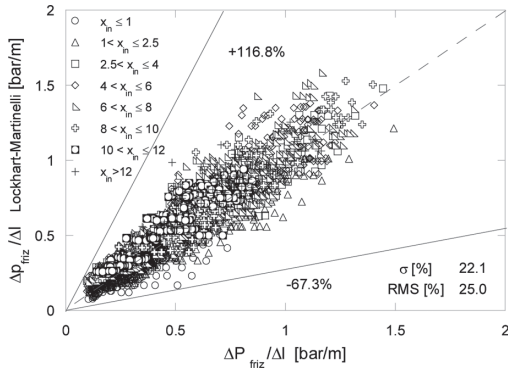

Figure 6. Pressure drop in straight pipes. Comparison between the Lockhart-Martinelli model's predictions and experimental data.

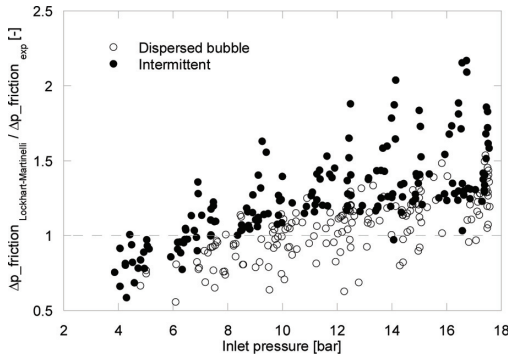

Figure 7. Lockhart-Martinelli: $\Delta p_c/\Delta p_{exp}$ as a function of the inlet pressure and for the different flow patterns.

deviation from the experimental values, as well as a higher dispersion of the data, is also found (maximum errors +116.8% and –67.3% *vs* +87% and –37%, respectively).

As already done for the Friedel model, the possible influence of the specific flow pattern has been checked also for the Lockhart-Martinelli model. However, since the influence of the vapor quality has been already found negligible from the previous results, the ratio of the predicted pressure drop over the experimental one, has been plotted as a function of the inlet pressure (Fig. 7). It can be seen that, apart from the expected marked dispersion of the data (based on the RMS value already reported in Fig. 6), a general increase of the ratio is observed at increasing inlet pressures. Again, an apparent dependency of the predictions with the flow pattern is found, with the intermittent flow regime always characterized by larger ratios of the pressure drop, compared with the dispersed bubble.

5.2 *Models comparison for fittings*

In the present section, the pressure drops calculated by means of the Friedel and the Lockhart–Martinelli models, for the first of the two elbows of the experimental rig, are compared with the measured values.

In Figure 8 the experimental pressure drops and those calculated with the Friedel model are reported for all the runs, along with the corresponding statistical indicators. The indicators present slightly higher values than in the case of straight pipelines, but the average error is still quite low.

In order to check the possible influence of the flow conditions, in the following Figures 9 and 10, the same comparison has been presented separately for the runs with $Re < 10^6$ and $Re > 10^6$, respectively, also reporting the calculated values both with the all-liquid and the two-phase equivalent lengths.

In the case of Figure 9, the statistical parameters indicate that the predictions of the model for

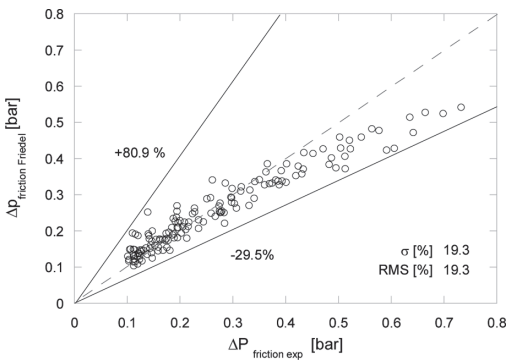

Figure 8. Δp_c calculated with Friedel correlation using the liquid equivalent length as a function of experimental Δp_{exp}.

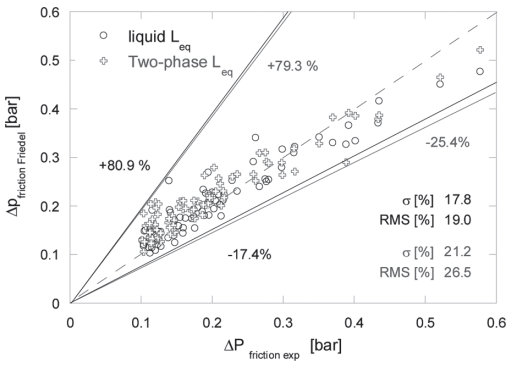

Figure 9. Δp_c calculated with Friedel correlation using the all-liquid and the two-phase equivalent lengths as a function of experimental Δp_{exp}. Tests with $Re < 10^6$.

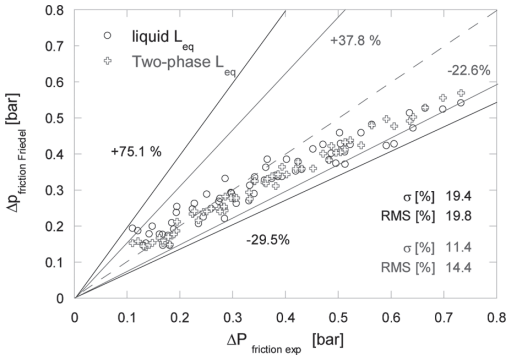

Figure 10. Δp_c calculated with Friedel correlation using the all-liquid and the two-phase equivalent lengths as a function of experimental Δp_{exp}. Tests with Re > 10^6.

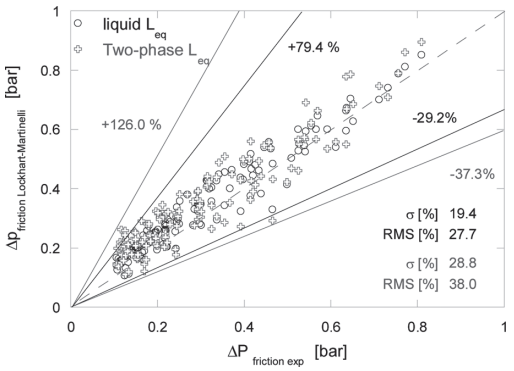

Figure 11. Friction pressure drop calculated with the Lockhart-Martinelli correlation using both liquid and two-phase equivalent length as a function of experimental friction pressure drop.

Re < 10^6 are rather good, especially when using the equivalent length calculated for the all-liquid flow, and they are comparable with the results obtained for straight pipes. Conversely, in the case of Re > 10^6 (Fig. 10), the best predictions are obtained using the two-phase equivalent length. They are definitely better than in the case of straight pipes, with RMS and σ equal to 14.4% and 11.4%, respectively, denoting a not negligible average error, but a very limited spread of the data around it. Since the Friedel model does not take into consideration any slip between the two phases, this result might be explained assuming that at higher flow rates (high Re numbers) the flowing system more likely behaves as a homogeneous mixture.

In Figure 11, the predictions obtained with the Lockhart-Martinelli model, using both the all-liquid equivalent length and that derived from two-phase flow measurements, are compared with the experimental values. As can be seen by comparing the statistical parameters there reported with those relative to the Friedel model, the accuracy is worse for the Lockhart-Martinelli model: σ is similar in both cases (around 19%), but RMS is 28 *vs* 19%, respectively. Furthermore, the accuracy becomes even much worse when the two-phase equivalent length is adopted (RMS = 38% and σ = 28.8%).

If the data corresponding to Re < 10^6 only are taken into consideration (see Fig. 12), the above results are more apparent, with the statistical parameters worse than those obtained for the Friedel model, when the single phase equivalent length is adopted, and definitely the worst in absolute when adopting the measured two-phase equivalent length (σ 34.2% and RMS 46.4%).

Finally, when the data for Re > 10^6 are considered (Fig. 13), as already found in the case of Friedel's

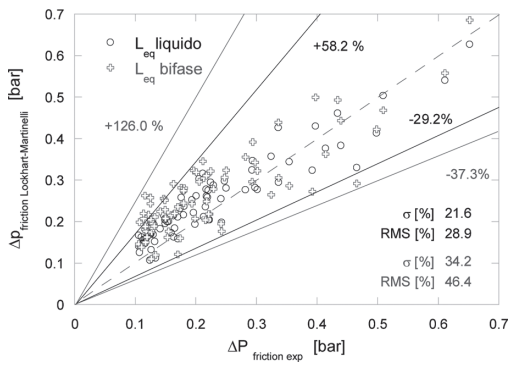

Figure 12. Friction pressure drop calculated with the Lockhart-Martinelli correlation using both liquid and two-phase equivalent length as a function of experimental friction pressure drop. Tests with Re < 10^6.

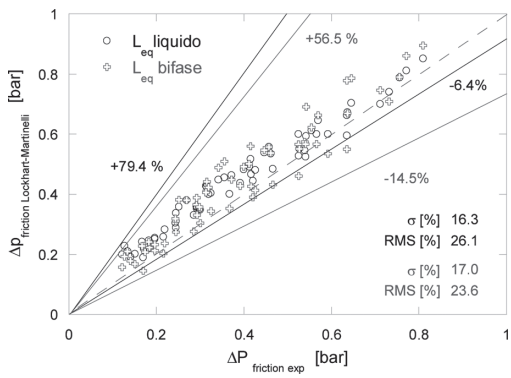

Figure 13. Friction pressure drop calculated with the Lockhart-Martinelli correlation using both liquid and two-phase equivalent length as a function of experimental friction pressure drop. Tests with Re > 10^6.

model, a remarkable improvement of all the statistical indicators is found, and in this case, the adoption of the two-phase flow equivalent length, further improves the results: quite close values of σ(16.3 and 17% respectively), but a noticeable reduction of RMS (26.1 *vs* 23.6% for the two-phase equivalent length).

6 CONCLUSIONS

Based on the presented results, different conclusions can be drawn with reference to the straight sections of pipeline and the connected elbows.

In the case of the straight sections, the Friedel model has proved to provide better predictions of the friction losses for a two-phase steam-water system, at least within the tested ranges of variability of the involved parameters. Despite a rather limited spread of the theoretical predictions, the average error is extremely low. No significant influence of the vapor quality has been detected, whereas the specific flow pattern assumed by the flowing system seems to affect the prediction accuracy: a small error is found for dispersed bubble flow, while a much larger deviation of the results is observed for the intermittent flow pattern. A similar effect has been observed also for the Lockhart-Martinelli model, thus suggesting that general models are more suited for homogeneous flow conditions. This latter model proved to be less accurate overall.

As far as the friction losses generated by the elbows are concerned, more complex considerations can be derived. Generally speaking, the prediction capability of both models is worse, compared with the results obtained for straight pipes. The Friedel model still proves to be much more accurate than the Lockhart-Martinelli, especially in terms of average error, but other parameters can play a significant role here. In particular, both models behave differently at different Reynolds numbers, with better results at high Re and worse predictions at low Re. Furthermore, this discontinuity is also dependent on the particular equivalent pipe length calculation method adopted: the experimentally determined two-phase equivalent pipe length markedly emphasizes the different behavior with the Reynolds number, but while the average Friedel model's behavior does not change so much with respect to the straight pipe sections, the Lockhart-Martinelli model's calculations become much more inaccurate.

In conclusion, based on the present experimentation, the Friedel model resulted to be characterized by a higher level of accuracy in the calculation of the friction losses for two-phase vapor-liquid flows. However, further work is needed for the characterization of the pressure losses connected with fittings, where the particular method adopted for the calculation of the equivalent pipe length can play a significant role.

Empirical Bayes inference with nonlinear homogenizations and correlated intensity functions: Use in asset degradation modelling

G. Blair
Scottish Water, Dunfermline, Scotland, UK

J. Quigley & L. Walls
University of Strathclyde, Glasgow, Scotland, UK

ABSTRACT: We develop and evaluate a method to estimate the frequency of an asset failure when experience event data are available for multiple assets of a given type. Typically such data contains information on assets of mixed ages, operating in different environments and in many cases the number of recorded events might be few or even zero. Assets are known to have slow age-related degradation and we have access to engineering experts who are able to provide judgment about the degradation rates. An empirical Bayes method is developed to allow us to estimate the failure rates for an asset on a particular site by using the available observational data pool together with structured engineering judgment of the degradation rate for the asset type. Our method aims to address the challenges of asset pool heterogeneity and environmental conditions across sites. We describe our practical motivation which is informed by a real problem facing a water utility. We explain the principles and mathematics underpinning the new methods, before describing a simulation based evaluation of their accuracy. We show that the empirical Bayes methods provide accurate estimates of the failure intensities for a range of parameters considered in this controlled study and that empirical Bayes estimators can compensate for bias in initial judgmental assessments of degradation rates. We discuss how the method can be applied in the industry context.

1 INTRODUCTION

Scottish Water is a statutory organisation that provides water and sewerage services to the people of Scotland. It is accountable to the public through the Scottish Government. Scottish Water is the sole provider of water and waste water services to an area of over 77,000 square kilometres (km), a third of the area of Britain. The organisation operates and manages over 48,000 km of water mains, approximately 50,000 km of sewers, and over 6000 above ground assets, which consist of treatment works, pumping stations and storage facilities.

The Asset Management directorate, within Scottish Water, is responsible for 'long-term planning at lowest cost' to ensure customers pay the lowest water bills while assets are being managed and operated in an optimal way. Scottish Water use data and modelling to inform and shape its policy, decisions and business plans. For example, analytical methods are used to predict economic levels of leakage, hydraulic modelling is used to predict security of supply.

Some models require predictions of the frequency of events affecting individual assets in some future time interval. This can be challenging because Scottish Water manages many types of assets with complex histories and incomplete historical data records. Indeed there are many assets which have very few or no failures in their recorded history.

To address this challenge we develop a new method of estimation drawing upon the principles of empirical Bayes inference (Carlin and Louis, 2000; Efron, 2005; Quigley and Walls, 2011). Our proposed method is distinctive because we need to develop an appropriate means of homogenising the pooled asset experience data to support better estimation when the underlying failure intensity function is dynamic. We also need to capture the relationships that may exist between the asset degradation rates due to the environmental conditions to which they are exposed.

We develop a new method for the general data structures present in the Scottish Water context. Our method aims to combine the relevant empirical data on historical assets failure events with engineering judgement for the following reasons. The historical event data provides useful information about the underlying level of the asset failure intensity, while structured engineering judgment can provide information about the underlying rate of asset degradation in given environmental conditions. We focus upon expressing the mathematical estimators assuming a time-dependent Non-Homogeneous

Poisson Process for the event process and presenting an evaluation of performance of the estimation methods. We conduct a controlled simulation experiment to examine the accuracy of the estimation methods under two situations: first when expert judgement is perfectly calibrated and unbiased; second when the judged rate of asset degradation is subject to positive or negative bias. We examine the simulation results in relation to some theoretical properties of the proposed estimators. We conclude by discussing how the method might be implemented in the industrial context.

Section 2 describes the empirical data characteristics in more depth. Section 3 presents the mathematical estimation methods including a discussion of assumptions made and some consideration of theoretical properties of the proposed estimators. Section 4 outlines the design of the simulation experiment, while Section 5 presents and discusses selected results. Section 6 suggests ways of expanding this work both methodologically and in application.

2 INDUSTRY MOTIVATION AND DATA

Scottish Water, like many organisations, maintains inventory and event databases. The inventory database contains information about asset characteristics, such as type, location, date installed. The event data base contains information about where and when an asset failed. Table 1 shows typical failure event data while Table 2 describes some of the asset characteristics. See Rausand and Hoyland (2004) for a general discussion of such field data.

It is relatively inexpensive to collect asset characteristics as shown in Table 1, but it can be costly to collect data on all the characteristics that potentially affect asset reliability. This is why we believe an empirical Bayes method which combines the available empirical data with expert judgment on the degradation is an efficient approach for estimating the failure intensity and supporting prediction of future failure frequencies. By forming an empirical data pool by selecting related assets, for example, of the same type, then we can use failure event data for similar assets to estimate the typical level of the failure intensity. Practically this reduces the need to model each asset characteristic individually, which might not only be inefficient but also ineffective since we might have poor statistical estimates for sparse event data sets. By using expert judgment to understand the degradation rate in different environments we are effectively using a proxy for the distinguishing characteristics of an individual asset.

Table 1. Example asset event data structures.

Asset identifier	Asset type	Location	Date installed	Number of failures in year 1	2	…	Y
X1	Pump	East	01/06/2001	0	1	…	0
X2	Pump	West	10/01/2010	0	0	…	1
X3	Pump	North	27/03/2003	1	0	…	3

Table 2. Description of asset characteristics.

Asset characteristics	Description
Asset identifier	Unique reference code to distinguish one asset from another and to provide link between failure and inventory data.
Asset type	Grouping classification for an asset, may be high or low level information. e.g. High level: Pump, Filter, etc. e.g. Low level: Submersible pump, Screw pump, etc.
Location	High level or low level information e.g. High level: North, South, East, West. e.g. Low level: Address of the site where the asset is held.
Date installed	Date at which the asset was installed and can be used to estimate asset age.
Date failure reported	Date at which the asset was reported to have failed.

Given the heterogeneity in the environment for Scottish Water assets, but yet information about the relationships between assets of the same type across these environments, a method for estimating failure intensity grounded in empirical Bayes provides a potentially effective and efficient approach. The method logic is to pool failure events across assets by essentially averaging over differing operating environments but then adjust the pooled event frequency using the empirical data and the judgmental assessments of degradation for a particular asset on a given site. Therefore the failure frequency estimate is a weighted average of the pool of historical experience and information relating to the past and future of a particular asset. Thus we develop a method that uses the data available and, if we can establish the performance of the estimation method, then we can also reduce the burden of collecting costly data in future.

3 EMPIRICAL BAYES INFERENCE METHOD

3.1 *Modelling assumptions & asset heterogeneity*

We assume a Non Homogeneous Poisson Process (NHPP) to describe the stochastic behavior of the

failure of assets subject to age-related degradation. Specifically, we assume a Power Law intensity function for each asset, as given in Equation (1), to model the number of events $N_i(t)$ realized over operating time (0, t) for asset i.

$$P\left[N_i(t)=n_i\middle|\alpha_i,\beta_i\right]=\frac{\left(\alpha_i t^{\beta_i}\right)^{n_i}e^{-\alpha_i t^{\beta_i}}}{n_i!} \tag{1}$$

Such an approach to modeling allows each asset to have its own scale parameter, α_i and degradation parameter β_i, thus acknowledging the heterogeneity within the asset pool due to variation in asset type and operational environment.

3.2 *Approach to inference*

When historical data indicates that failures are too infrequent to empirically estimate the model in Equation (1) for each asset, pooling the data available to obtain estimates is feasible but questionable when the assets represented by the model form a heterogeneous pool. Therefore we propose to use expert judgment to estimate the degradation rate for each asset, β_i, and use empirical Bayes methods to estimate the scale parameter by first pooling the empirical data to estimate the scale parameter across the pool and then adjust the estimate for each asset in-line with its experience.

Mathematically this is accomplished by assuming the scale parameter for each asset is realized from a common Gamma distribution with shape parameter a and rate parameter b, given by the following probability density function,

$$f(\alpha;a,b)=\frac{b^a\alpha^{a-1}e^{-b\alpha}}{\Gamma(a)}. \tag{2}$$

This results in a predictive distribution for the number of failure events, which is in the form of a Negative Binomial distribution as shown in Equation (3). This is akin to assuming that a prior distribution has been provided for the scale parameter in the form of a Gamma distribution.

$$\begin{aligned}P\left[N_i(t)=n_i\middle|\beta_i\right]&=\int_0^\infty\frac{\left(\alpha_i t^{\beta_i}\right)^{n_i}e^{-\alpha_i t^{\beta_i}}}{n_i!}\frac{b^a\alpha_i^{a-1}e^{-b\alpha_i}}{\Gamma(a)}d\alpha_i\\&=\frac{\Gamma(n_i+a)b^a t^{n_i\beta_i}}{\Gamma(a)n_i!\left(b+t^{\beta_i}\right)^{n_i+a}}\\&=\frac{\Gamma(n_i+a)}{\Gamma(a)n_i!}\left(\frac{b}{b+t^{\beta_i}}\right)^a\left(\frac{t^{\beta_i}}{b+t^{\beta_i}}\right)^{n_i}\end{aligned} \tag{3}$$

This model is expressed in terms of the parameters (a,b) which are common to the pool and so the pooled empirical data can be used to obtain estimates of these parameters using either maximum likelihood estimation or moment matching methods. Once the pool parameters have been estimated, Bayes Theorem can be used to update the prior for each asset to obtain its posterior based on the individual asset experience. The resulting posterior distribution for the failure frequencies over a given time horizon for a particular asset is a Poisson distribution with a mean that is a weighted average of the pooled mean and the individual asset experience.

3.3 *Moment matching estimates of* (a,b)

Moment matching for parameter estimation ensures that the first and second moment of the model for the pool experience equals the observed first and second moment in the data. The moment estimates for the pool parameters are given by

$$\hat{a}=\frac{U^2}{W-U^2}\quad\text{and}\quad\hat{b}=\frac{U}{W-U^2} \tag{4}$$

where

$$U=\frac{\sum_{i=1}^m n_i}{\sum_{i=1}^m t^{\beta_i}}\quad\text{and}\quad W=\frac{\sum_{i=1}^m n_i^2-\sum_{i=1}^m n_i}{\sum_{i=1}^m t^{2\beta_i}}. \tag{5}$$

We can show that these are consistent estimators of the pool parameters under the modeling assumptions. As pool size, m, increases the estimates converge to the true values of the distribution. Since

$$\begin{aligned}E[U]&=\frac{a}{b}\frac{\sum_{i=1}^m t^{\beta_i}}{\sum_{i=1}^m t^{\beta_i}}=\frac{a}{b}\\E[W]&=\frac{\sum_{i=1}^m E\left(\alpha_i t^{\beta_i}+\alpha_i^2 t^{2\beta_i}\right)-\frac{a}{b}\sum_{i=1}^m t^{\beta_i}}{\sum_{i=1}^m t^{2\beta_i}}=\frac{a(a+1)}{b^2}\end{aligned} \tag{6}$$

then

$$\begin{aligned}\lim_{m\to\infty}\frac{U^2}{W-U^2}&=\frac{\left(\frac{a}{b}\right)^2}{\frac{a(a+1)}{b^2}-\left(\frac{a}{b}\right)^2}=a\\\lim_{m\to\infty}\hat{b}&=b.\end{aligned} \tag{7}$$

3.4 *Effect of biased judgment on estimates*

Consider the effects on inference of bias in the engineering judgment assessment of the degradation rate. Assume a true underlying rate of degradation for asset i is denoted by β_i. Further assume that at the time of analysis, t, an engineering expert has provided an estimate of the form $S_i t^{\beta_i}$, where a value of $S_i = 1$ indicates an unbiased estimate. Using moment matching we obtain the following

$$U = \frac{\sum_{i=1}^{m} n_i}{\sum_{i=1}^{m} S_i t^{\beta_i}} \quad \text{and} \quad W = \frac{\sum_{i=1}^{m} n_i^2 - \sum_{i=1}^{m} n_i}{\sum_{i=1}^{m} S_i^2 t^{2\beta_i}}. \tag{8}$$

Assume also that the degree of bias changes from one asset to another but all S_i have a common distribution with mean and standard deviation

$$E[S_i] = \theta \quad \text{and} \quad Var[S_i] = \sigma^2.$$

Then we obtain the following limit as the number of assets in the pool, m, tends to infinity

$$\lim_{m\to\infty} U = \frac{\frac{a}{b}\sum_{i=1}^{m} t^{\beta_i}}{\sum_{i=1}^{m} \theta t^{\beta_i}} \underset{m\to\infty}{\underset{m\to\infty}{=}} \frac{a}{b\theta}$$

$$\lim_{m\to\infty} W = \frac{\sum_{i=1}^{m} E\left(\alpha_i t^{\beta_i} + \alpha_i^2 t^{2\beta_i}\right) - \frac{a}{b}\sum_{i=1}^{m} t^{\beta_i}}{\sum_{i=1}^{m} \left(\sigma^2 + \theta^2\right) t^{2\beta_i}} \underset{m\to\infty}{\underset{m\to\infty}{=}}$$

$$= \frac{a(a+1)}{b^2\left(\sigma^2 + \theta^2\right)} \tag{9}$$

This implies the following

$$\lim_{m\to\infty} \frac{U^2}{W - U^2} = \frac{a}{\frac{1}{\gamma^2+1} - a\frac{\gamma^2}{\gamma^2+1}} \tag{10}$$

$$\lim_{m\to\infty} \frac{U}{W - U^2} = \frac{b\theta}{\frac{1}{\gamma^2+1} - a\frac{\gamma^2}{\gamma^2+1}} \tag{11}$$

where $\gamma = \sigma/\theta$.

Therefore,

$$\lim_{m\to\infty} \hat{a} = \frac{a}{\frac{1}{\gamma^2+1} - a\frac{\gamma^2}{\gamma^2+1}}$$

and

$$\lim_{m\to\infty} \hat{b} = \frac{b\theta}{\frac{1}{\gamma^2+1} - a\frac{\gamma^2}{\gamma^2+1}} \tag{12}$$

The empirical Bayes estimator for a given asset of the expected number of failure events at time $(t+x)$ given the observations for that asset up to time t, is the mean of the posterior distribution of the scale parameter for the asset estimated using all observations for all assets up to time t multiplied by $(t+x)^{\beta}$, which reflects the non-linear degradation rate. Let $\underline{n}(t)$ denote the vector representing the event history up to time t, where the ith element is the history of the ith asset denoted by $n_i(t_i)$, then the empirical Bayes estimate is given by

$$E\left[N(t_i + x)\middle|\underline{n}(t)\right] = E\left[\lambda_i (t_i + x)^{\beta_i}\middle| n_i\right] = \frac{\hat{a} + n_i}{\hat{b} + t^{\beta_i + \varepsilon_i}} (t+x)^{\beta_i + \varepsilon_i} \tag{13}$$

where $\varepsilon_i = \ln(S_i)/\ln(t)$.

As pool size increases the estimates of the parameters of the prior distribution approach those given in Equation (12). Hence for large pools we can obtain the expectation for the accumulated number of events x time units beyond the time t as follows

$$\lim_{m\to\infty} E\left[N_i(t+x)\middle|\underset{\sim}{n(t)}\right] = \frac{a + n_i(t)}{b\theta + t^{\beta_i + \varepsilon_i}} (t+x)^{\beta_i + \varepsilon_i}. \tag{14}$$

The form of Equation (14) indicates that the error in expert judgment, ε_i, affects future predictions of the expected accumulated number of failures by either decreasing (increasing) the scale estimate or increasing (decreasing) the degradation rate. By examining the percentage change in the predicted expected number of failures as a function of this error, we find that the net effect is an increase in error as the predicted time horizon lengthens, as follows

$$\frac{d\ln\left(\lim_{m\to\infty} E\left[N_i(t+x)\middle|\underline{n}(t)\right]\right)}{d\varepsilon_i} = \ln(t+x) - \frac{t^{\beta_i+\varepsilon_i}}{b\theta + t^{\beta_i+\varepsilon_i}} \ln(t) > 0 \tag{15}$$

If engineering experts are consistently biased in their judgments, such that $\sigma = 0$, then the ratio between the predicted mean and the actual mean has the following simple expression for large pool size.

$$\lim_{m\to\infty} \frac{E\left[N_i(t+x)\middle|\underline{n}(t)\right]}{\frac{a+n_i(t)}{b+t^{\beta_i}}(t+x)^{\beta_i}} = \frac{\frac{a+n_i(t)}{a+n_i(t)}}{\frac{b\theta+t^{\beta_i+\varepsilon}}{b+t^{\beta_i}}}(t+x)^{\varepsilon} = \left(1+\frac{x}{t}\right)^{\varepsilon} \quad (16)$$

Equation (16) allows the impact of the error assessment of the degradation parameter to be established. Since $\varepsilon = 0$ for an unbiased expert judgment, the ratio between the expected mean and the true mean is 1. However, an expert who under (over) estimates degradation would have a negative (positive) ε.

3.5 *Maximum likelihood estimates of* (a,b)

We also show the derivation of the Maximum Likelihood Estimates (MLE) of the model parameters as an alternative inference approach to the moment method. While MLE's provide more accurate estimates for this model there is not a closed form expression, so numerical methods are required to obtain a solution.

The log-likelihood function for the model obtained from Equation (2) is expressed as follows,

$$l(a,b) \propto \sum_{i=1}^{m}\left[\ln(\Gamma(n_i+a)) - a\ln(b+t^{\beta_i}) - n_i\ln(b+t^{\beta_i})\right] - m\ln(\Gamma(a)) + ma\ln(b)$$

The resulting score functions are then given by

$$S_a(a,b) \propto \sum_{i=1}^{m}\left[\sum_{k=0}^{n_i-1}\frac{1}{k+a} + \ln(b) - \ln\left(b+t^{\beta_i}\right)\right]$$

and

$$S_b(a,b) \propto \sum_{i=1}^{m}\left[\frac{a}{b} - \frac{a+n_i}{b+t^{\beta_i}}\right]. \quad (17)$$

Setting both functions in Equation (17) to 0 and solving provides the MLE of the parameters (a,b). Note that the form of $S_b(a,b)$ implies that the prior mean scale parameter equals the posterior for the pool. The solution to these expressions can be simplified slightly. We can isolate a in $S_b(a,b)$ to obtain the following

$$\hat{a} = \frac{\sum_{i=1}^{m}\frac{n_i}{\hat{b}+t^{\beta_i}}}{\sum_{i=1}^{m}\left(\frac{1}{\hat{b}} - \frac{1}{\hat{b}+t^{\beta_i}}\right)}. \quad (18)$$

In turn this can be substituted into $S_a(a,b)$ to reduce it to a one parameter function, allowing us to solve,

$$\sum_{i=1}^{m}\left[\sum_{k=0}^{n_i-1}\frac{1}{k+\frac{\sum_{i=1}^{m}n_i\hat{p}_i}{\sum_{i=1}^{m}\left(1-\hat{p}_i\right)}} + \ln\left(\hat{p}_i\right)\right] = 0 \quad (19)$$

where $\hat{p}_i = \frac{\hat{b}}{\hat{b}+t^{\beta_i}}$.

4 SIMULATION EVALUATION DESIGN

The purpose of the simulation is to further evaluate the performance of the proposed estimation methods to better understand the accuracy and the impact on estimation error of any bias in expert judgement prior to application to real data. The design of the simulation is informed by the typical characteristics of the data context of Scottish Water in terms of the typical number of assets per class, the relative size of failure intensities and the relative time horizons for the historical data records as well as for future predictions. Our simulation study is not exhaustive since it is constrained to a set of possible situations as summarised in Figure 1.

4.1 *Set-up to assess estimation accuracy*

Here we consider the cases of pool sizes of 20 and 40 assets to examine the effect of amount of empirical data being used. For each pool size we consider the same sets of parameter values for the prior distributions for each asset as given in Equation (3). That is, combinations of the shape parameter, a, which is set to 0.1, 0.5, 0.9, 1, and 2, and the scale parameter, b, which is set to values of 1, 10, and 100. The α_i are simulated from a $\Gamma(a,b)$ distribution with parameters (a,b). We set the true value of β to be 2, which represents an increasing intensity function for the Power Law process and hence represents asset degradation. The numbers of failure in the time interval (t_j, t_{j+1}) are then simulated from a Poisson distribution with mean $\alpha_i(t_{j+1}^{\beta_i} - t_j^{\beta_i})$.

Through simulation we effectively create a sample data set of the form shown for the Scottish

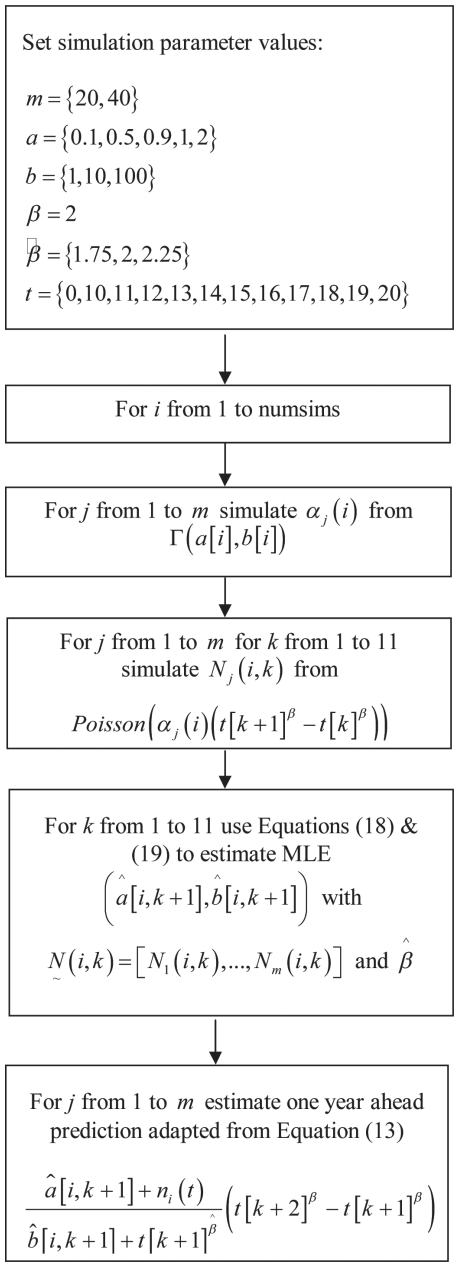

Figure 1. Simplified simulation logic diagram.

Water data in Table 1, but where we have a record of the annual number of failures over a 10 year period. Note that unlike the real data, we are making a simplifying assumption in this initial simulation by treating all simulated assets as new at the start of observation. That is, we create simulated data records over the period (0,10) years for each asset in the first instance. We use k as a counter for the years in our simulation of the empirical data history. Our goal is then to use the proposed inference method to estimate the number of failures in the next year. Since we are simulating reality we can also extend our simulated sample paths for each asset for years 11–20 thereby giving us an ability not only to make dynamic one year ahead predictions but also to compare our predicted estimate for each of years 11–20 with our simulated observations.

4.2 *Design to assess bias in engineering judgment*

To examine the effect of possible bias in the engineering judgement of the true degradation rate, β, we examine three scenarios by setting the judged value, $\hat{\beta}_i$ to be set to 1.75, 2, and 2.25 which corresponds to an underestimation, perfect estimation and overestimation of the degradation rate respectively.

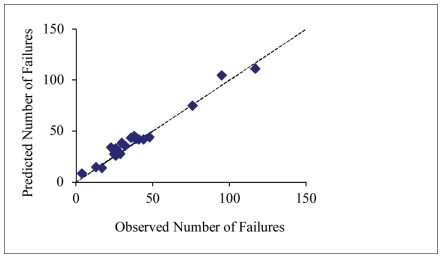
5 SIMULATION EVALUATION FINDINGS

Table 3 shows a summary of means and standard deviations for the simulated scale parameter of the Power Law process, α_i, for each size of asset group. Since α_i were generated for each asset from a gamma distribution, $\Gamma(a,b)$, the mean and standard deviation, respectively, should be

$$\mu \approx a/b \quad \text{and} \quad \sigma \approx \sqrt{a/b^2}.$$

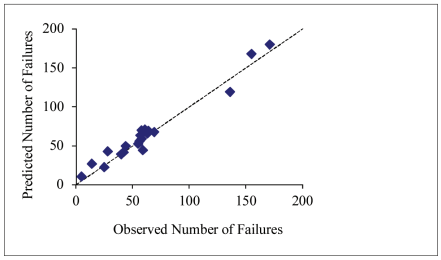
Table 3. Mean and standard deviation of power law scale parameter for simulated asset groups.

		Number of assets in the group			
		20		40	
a	b	Mean	Standard deviation	Mean	Standard deviation
0.1	1	0.0314	0.0841	0.0624	0.1709
0.1	10	0.0056	0.0116	0.0079	0.0211
0.1	100	0.0008	0.0021	0.0008	0.0019
0.5	1	0.3767	0.4665	0.4372	0.6232
0.5	10	0.0323	0.0411	0.0465	0.0579
0.5	100	0.0094	0.0132	0.0044	0.0073
0.9	1	0.7439	0.6526	0.9232	0.8204
0.9	10	0.0966	0.0820	0.1075	0.0985
0.9	100	0.0094	0.0109	0.0086	0.0075
1	1	0.8716	0.8564	1.1704	1.0053
1	10	0.1146	0.1211	0.0798	0.0745
1	100	0.0068	0.0061	0.0117	0.0099
2	1	1.9745	1.3172	2.1822	1.7062
2	10	0.2133	0.1589	0.1894	0.1497
2	100	0.0205	0.0155	0.0201	0.0141



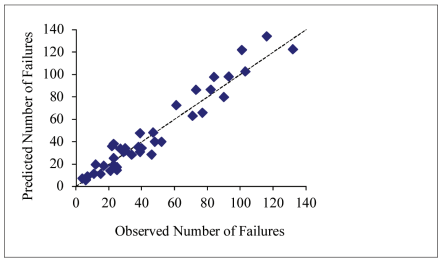
We find that the scale of the simulated mean failure intensity functions range from just over 0 failures per annum (i.e. 0.0008) at a = 0.1 and b = 100 to around 2 failures per annum at $a = 2$ and $b = 1$.

5.1 *Estimation accuracy*

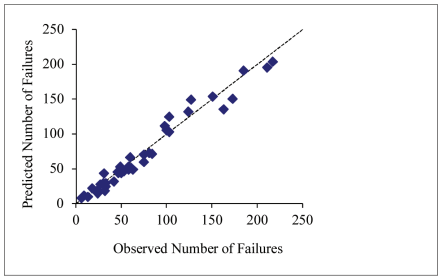


Generally our preliminary results indicate that prediction accuracy is good. We present only a selection of results to illustrate our indicative findings for changing α_i, when β is fixed at a value of 2.

Figure 2 shows plots of the predicted against observed number of failures in years 11 and 17 for single simulations of each of the two cases where there are 20 and 40 assets in the pool when the level of the intensity is around 2 failures per annum (i.e. $a = 2$ and $b = 1$). The patterns in these selected diagrams are indicative of those found in all simulations for this case. It appears that our method produces accurate estimates, on average, since the predicted against observed accumulated number of failure profiles vary randomly around the 45° line. The densities of points also typify the forms of the underlying Poisson models. The degree of accuracy seems to increase through time, as we might expect as more empirical observations are used in estimation.



For the situation where we have the lowest level of the intensity at 0.0008 failures per annum, then we inevitably simulate many asset sample data sets with zero observed failures in a given year. For example, in some years we find that none of the assets experienced a failure event, but in other years only a single asset experienced a failure. Due to the properties of empirical Bayes estimation we find that in such circumstances an average weighted towards the pooled mean is allocated for zero event assets. In years when there is a failure event, even if only for one out of say the 20 assets in the pool, then this tends to increase the pool mean and hence the year ahead predicted number of failures. Equally in years where there are no observed failure events then the pooled mean decreases due to the additional exposure accumulated. It is also clear that the predicted number of failures for those particular assets which experience events are increased above the pool mean to account for their local history.



m=20, t=11, a=2, b=1

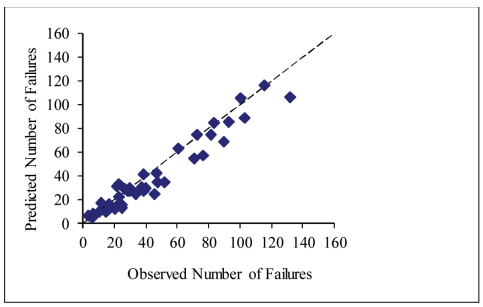
m=20, t=17, a=2, b=1

m=40, t=11, a=2, b=1

m=40, t=17, a=2, b=1

Figure 2. Predicted against the observed number of failures for selected scenarios of *m, t, a* and *b* when $\beta = 2$ and mean α_i is simulated to be approximately 2.

5.2 *Estimation accuracy in presence of judgmental bias in degradation rate*



Now let us examine the effects on estimation accuracy when we control the degree of bias in the judgemental assessment of the degradation rate. We investigate this accuracy by simulating the number of failures under the true degradation state when $\beta = 2$, but compute the expected number of failures using the assumed subjective judgement values of $\hat{\beta}_i = 1.75$, 2 and 2.25. Since we have established that there is no discernable difference between size of the asset pool we only present selected results for the case of 40 assets.

Equally for comparison with the unbiased scenario shown in Figure 2 we only present results for the case of $a = 2$, $b = 1$.

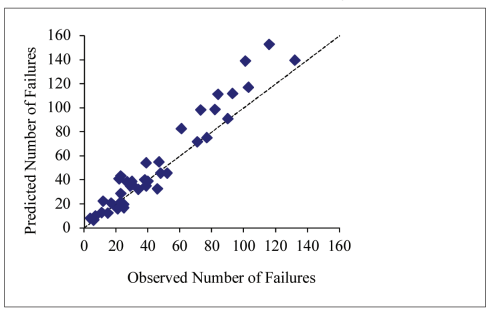


Figure 3 shows plots of the predicted number of failures against the true observed number of failures at year 11 for the scenarios mentioned above, while Figure 4 shows the equivalent plots for the predicted failure frequencies for year 17 based on updated estimate using empirical data available up to year 16.

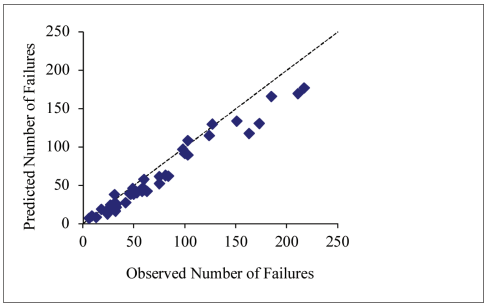
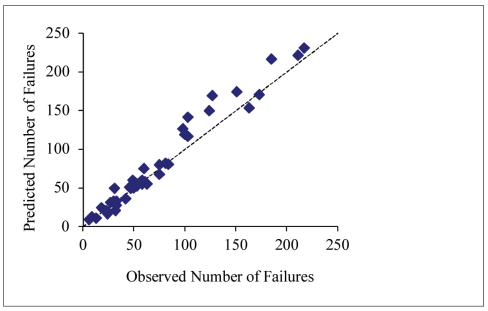
We find that when the degradation rate is judged to be 1.75, and so less than the true rate, that the predicted number of failures tends to underestimate those observed under the true model, but the degree of underestimation visually appears to reduce as more experience is accumulated. Likewise, if the degradation rate is assumed to be judged by an expert to be 2.25, and so higher than its true value, then the predicted number of failures is slightly greater than observed under the true model.

For the case of unbiased assessment of the degradation rate, the judged and true values of β are 2. We find the predicted number of failures is an accurate estimate of the observed under the true model as we have shown earlier in, for example, Figure 2.



m=40, t=11, a=2, b=1, β_i=1.75



m=40, t=11, a=2, b=1, β_i=2.25

Figure 3. Predicted against the observed number of failures for 40 assets at t = 11 for true degradation of β = 2.

m=40, t=17, a=2, b=1, β_i=1.75

m=40, t=17, a=2, b=1, β_i=2.25

Figure 4. Predicted against the observed number of failures for 40 assets at t = 17 for true degradation of β = 2.

6 CONCLUSIONS AND FURTHER WORK

A method, based on the principles of empirical Bayes, is developed to support prediction of failure rates for a particular asset by using the available observational data for a pool of like assets together with engineering judgment for the asset degradation rate. We have conducted a preliminary theoretical and simulation evaluation of the performance characteristics of our proposed estimation method.

From our simulation study we find that we can obtain accurate estimates especially when the judgmental assessment of the degradation rate is unbiased. Even when there is bias in the expert judgment, then we can quantify its effect as a function of the prediction time horizon and the model parameters. For example, as we might anticipate accuracy will be better for shorter prediction time horizons and for larger asset pool sizes where empirical data has been accumulated over longer observation periods. Our preliminary simulation results suggest that the empirical Bayes method appears to allow the observational data to compensate for any initial bias in the engineering judgment of the degradation rate as the estimates

are updated dynamically as operational experience increases.

Our simulation study is limited to a selected set of parameter values and only a limited number of simulation runs. We need to investigate a more rich experimental space and to increase the number of simulation repetitions to more fully investigate the degree of any learning in the failure intensity predictions under an empirical Bayes approach for situations such as that motivated by Scottish Water.

Our motivation for this study was a need to estimate future number of failure of control and monitoring assets which, in the broadest terms, are pieces of electrical equipment. To apply the proposed empirical Bayes approach we require Scottish Water analysts to form sound engineering classes of control and monitoring asset types so that the data from these assets will then form the empirical pool of data to be used in estimation. Scottish Water also require subject matter experts who are well qualified to assess changes in failure patterns throughout the asset lifetime based in an understanding of the degradation process under the operating environment at particular sites.

From our evaluation it is evident that bias in such expert judgment of the assessed degradation rate will impact the accuracy of any estimates, especially in the initial stage of making predictions using past records. Therefore in terms of practically applying our method to Scottish Water assets, we require to ensure that a structured expert judgment elicitation is conducted according to one of the recognized scientific processes (Cooke, 1991). Preliminary expert judgment studies have been conducted with engineers and scientists working with assets, such as control and monitoring equipment and rapid gravity filters, hence the principle of combing judgmental with empirical data for better predictive accuracy has been established as practically feasible.

ABSTRACT: The country's energy systems are closely related with other systems. The prosperity of country depends on the well-run operation of each of the systems. The disruption in the energy systems can affect the activities of all systems. System criticality level is one of the most important indicators of reliable power supply. The criticality of the system depends on the relations with other parts of energy system. In energy sector, natural gas supply system is one of the most related systems to other systems. Elements of gas supply system have high value of criticality indicator within energy sector. Natural gas is the most commonly used by the heat and electricity generation technologies over the world. The natural-gas supply system was selected as a case study involving analyses of the operability and availability. The pilot numerical calculation was performed to demonstrate how this model is useful to assess the impact of gas supply system to heat and power systems criticality. The natural gas system simulation was performed by optimization method. The probability distribution of criticality indicator is obtained as a result of this study using a Monte Carlo method. The results of this analysis may also be used in the development of energy infrastructure criticality analysis.

1 INTRODUCTION

In this paper we made assumption, and we analyzed just single country critical infrastructure. The failure of critical infrastructures may adversely affect the functioning of the country. Disruptions in one type of infrastructure often transverse to other dependent infrastructures and possibly even back to the infrastructure, where the failure emerged.

Some energy infrastructure interferences which occurred in the last decay are the following:

- 2013 December (Blackout) in Venezuela, affected 15 states of Venezuela (70% of the country);
- 2012 October (Gas dispute), in Turkey (disrupted by Iran), disruption of gas supply;
- 2012 July (Blackout) in India, affected over 620 million people;
- 2011 August (Blackout) in the East Coast and Puerto Rico, affected more than 9.3 million customers;
- 2011 September (Gas disruption) in the USA (The Gulf of Mexico), the shut-in a peak of 2.2 Bcf/d of gas production;
- 2011 February (Gas disruption) in the Texas, the shut-in of 600 (MMcf/d) The grid lost 7000 megawatts of capacity, 50 power plants stopped working;
- 2011 September (Blackout) in the area around San Diego, California, USA, affected 2.7 million customers;
- 2009 (Gas dispute) in the European Union, Balkan region, affected 18 countries in European Union and Balkan region;
- 2006 in Lithuania, Telšiai, an accident at –26.5 °C in the district heating system led to the loss of heat supply for thousands of people for almost a week.
- 2003 (Blackout) In north USA and Canada, affected approximately 10 million people in Ontario and 45 million people in eight U.S. States;
- Some authors analyzed critical local cities of critical infrastructures. For example, Gdnask city [Kulawiak et al, 2013]. Authors usually used GIS system to visualize the infrastructure [Kulawiak et al, 2013; Jenelius et al, in press 2014; Rodríguez-Núñez et al, 2014].

The other authors propose to analyze separate infrastructures, such as power grid, road network, etc. [Zonouz et al, 2013; Jenelius et al, in press 2014; Roelich et al, 2014], authors [Zonouz et al, 2013] propose the algorithm for power control networks, that combines information from different sources.

The security level of states individual system are assessed by authors.

Authors usually estimated the risk level of infrastructure [Salling, 2013] or performed the vulnerability analysis [Jenelius et al, in press 2014].

Often authors analyze in detail the separate objects of infrastructure. They used the criticality assessment methods, such as Failure Modes their Effects and Criticality Analysis [Hammoum et al, 2013].

Some authors analyze interdependencies of infrastructure and analyze theoretical (or expert evaluation) assessment among the infrastructure layers [Huang et al, 2014], or used topological network analysis of infrastructure [Shuang et al, 2014], this analysis are the most commonly used with one type of infrastructure.

The criticality measurement could be related with consumers demand and with satisfaction percent of demands [Rodríguez-Núñez et al, 2014].

The criticality assessment method was used in the paper [Augutis et al, in press 2014]. The infrastructure system is supplemented by new objects. The criticality of elements of gas supply system was evaluated according to the presented method and performed important measurement (Fussell-Vesely and Birnbaum) of those elements. Also the logistic regression analysis was used for the first time to assess the components' influence on system criticality value.

2 PROPOSED CRITICALITY ASSESSMENT METHOD

In this paper we analyze infrastructure of heat, power and gas supply systems. These systems are very important for each country to ensure the economic prosperity and national energy security, especially in cold period (extreme weather conditions). To ensure the social prosperity, it is necessary to ensure uninterrupted heat and power supply for the consumers. Our model analyzes energy infrastructure composed of different type of energy generation technologies, such as Boiler Houses (BH), combined heat and power plants with back-pressure units (CHP), combined heat and power plants with extraction units (PP); renewable energy resources: hydro power plants (HP), wind villages (WP), biomass boiler houses and CHP (BIOchp). The generation technologies, such as CHP, BH and PP use natural gas as main fuel. Oil is used as alternative fuel in the CHP and PP. Each generation technology is defined as a functional unit with characteristic parameters and algorithms of operation. The system of heat, power and gas supply has internal functional relations. The function of the one subsystem depends on operating of other subsystems. The structural scheme of system is presented in the Figure 1. The disturbance occurred in any part of the system affects all subsystems (directly and indirectly).

The generation technologies used in our model are defined in more detail (functionality expression) in the paper (Augutis et al, in press 2014).

Each system element is described by functional expression:

$$Tch_i = (P_i,\ Q_i,\ \eta_{el},\ \eta_h), \tag{1}$$

where P_i—the installed electric capacity in to ith technology (MW); Q_i—the installed thermal capacity in to ith technology (MW); η_{el}—the efficiency of primary energy conversion for electricity using main fuel; η_h—the efficiency of primary energy conversion for heat using main fuel.

All generation technologies are simulated by input-output method. The demands of heat and electricity are allocated for generation technologies by the Simplex optimization method. The optimization is performed to maximize energy generation in each analyzed city. The mathematical model of this problem could be written:

$$\max_x \mathbf{b}^T \cdot \mathbf{x},\ when \begin{cases} \mathbf{T}_H \cdot \mathbf{x} \le \mathbf{C}_T, \\ \mathbf{T}_A \cdot \mathbf{x} = \mathbf{D}_{HL}, \\ \mathbf{L}_{capacity} \le \mathbf{x}, \end{cases} \tag{2}$$

where $\mathbf{b}$—the objective coefficients vector (in our case it could be economic coefficients of generation technologies), $\mathbf{T}_A$—coefficients matrix of equations constraints; $\mathbf{T}_H$—coefficients matrix of linear inequality constraints; $\mathbf{C}_T$—the vector of the generation technologies capacity; $\mathbf{D}_{HL}$—the vector of the local heat demands quantities; $\mathbf{L}_{capacity}$—the low boundary vector of minimal capacity load of technologies.

This mathematical model allows to distribute local heat demand for local generation technologies with regard to economic aspect. The elements of

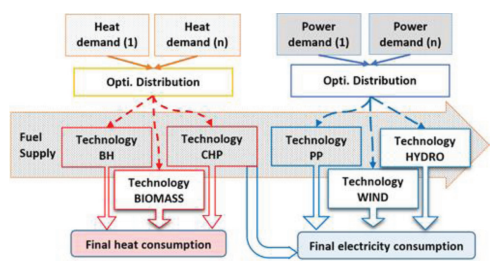

Figure 1. Structural scheme of system criticality assessment method.

matrix of equations constraints $\mathbf{T}_A$ are composed of coefficients of generation technologies, which could be used in generation process. The elements of matrix of linear inequality constraints $\mathbf{T}_H$ are identification of local generation technologies.

The demand of electricity is distributed for generation technologies by the same optimization model as heat demand. Preference is given to technologies using renewable energy sources (hydro power plants, wind power plants, etc.).

Gas supply system is defined by graph of 89 main pipelines. The natural gas is supplied to the system from two sources: the debit of import from neighbor country is 31.2 Mm^3/day and the other source is terminal of liquid natural gas, the debit is 11 Mm^3/day. The mathematical optimization model (optimization of maximum flow with goal programing) is used to simulate gas supply system.

Gas supply network is represented as graph:

$$G = (V, E),\ V = V_{FN} \cup V_{CN},\ \text{there } V_{FN} \cap V_{CN} = \varnothing \tag{3}$$

where V_{FN}—set of the final pipeline nodes of graph; V_{CN}—set of the pipeline connection nodes of graph; E—set of the edges (edge represents physical pipelines), which connect nodes V.

One of the model aims is to maximize the satisfaction of consumer demands. The maximum flow optimization method was used to achieve this goal. Simplex method of linear programing was used to find the maximum flow in the pipeline network. The mathematical model of this problem could be written as:

$$\max_x \mathbf{f}^T \cdot \mathbf{x},\ \text{when } \begin{cases} \mathbf{C}_M \cdot \mathbf{x} = 0, \\ \mathbf{C}_{FN} \cdot \mathbf{x} \le \mathbf{D}_{FN}, \\ \mathbf{L}_{flow} \le \mathbf{x} \le \mathbf{M}_{flow}, \end{cases} \tag{4}$$

where $\mathbf{f}$—is the objective coefficients vector (in our case the edges of incoming flow into final nodes), $\mathbf{C}_M$—coefficients matrix of equations constraints; $\mathbf{C}_{FN}$—coefficients matrix of linear inequality constraints; $\mathbf{D}_{FN}$—the vector of the demands quantities of final nodes; $\mathbf{L}_{flow}$—the low flow boundary vector of pipeline edges; $\mathbf{M}_{flow}$—the maximum flow boundary vector of pipeline edges; $\mathbf{x}$—the vector of pipeline edges.

This mathematical model allows to evaluate the quantities of supplied gas to the final nodes (consumers). The constraints of the matrix elements $\mathbf{C}_M$ are coefficients of directed graph (it means that in connection nodes should be balance). The coefficients values of incoming edges into the node V_{CN} are equal to –1, and the coefficients values of outgoing edges from the node are equal to 1. The balance of incoming and outgoing flow must be on each pipeline connection node of graph.

The elements of matrix of linear inequality constraints $\mathbf{C}_{FN}$ are composed by coefficients of incoming edges to final nodes V_{FN}. And the coefficients' values of matrix of linear inequality constraints are equal to 4. The elements of low flow boundary vector of pipeline edges are composed of 0. The values of elements of maximum flow boundary vector are dependent on pipeline diameter, pipeline length, the pressure in the system, specific gravity of the gas and other coefficients.

All these optimization models enable the implementation of directives (economical, ecological, etc.) and emergency management plans. Monte Carlo method (MC) was used to obtain simulated data of the operation of the system. Operation statement of system element was generated in each iteration to simulate the real system work. The estimates of failure probability of system elements were used from reports and journals: Security of supply of electricity market Lithuania monitoring report, 2012; Energy in Lithuania 2012, 2013; Gas pipeline incidents, 2011; Lurie, 2008.

The criticality of the kth element may be estimated using the reliability indicators of final consumers obtained in case when kth element is out of order

$$C^{(k)}(t) = 1 - \sum_{i=1}^{M} cf_i^{(k)}(t) \cdot \beta_r,\ k = 1, 2, \ldots, N, \tag{5}$$

where N—number of the elements in the energy system; $cf_i^{(k)}(t)$—the reliability indicator that shows how much the energy demand is satisfied for the ith element; β_r—the weighted coefficient of the rth final consumer within system (for instance, weighted coefficients are estimated with regards to the energy demand of consumer, and they satisfy equality $\beta_1 + \cdots + \beta_M = 1$; M—number of the final consumers in the energy system).

The system element criticality value is from interval [0; 1]. For example, $C^{(k)}(t) = 1$ means that disruption of the kth element work stops the operation of all energy infrastructure at time moment t. The criticality rage could be described as shown in Figure 2.

The importance measures were estimated to compare the impact of gas supply system elements with the baseline scenario (all system elements availability are random). Fussell-Vesely (FV) and Birnbaum Importance (BI) measures of gas supply system elements were estimated in this work. The purpose of this analysis was to identify components with high value of FV and BI. When both importance measurements are high, the criticality can be

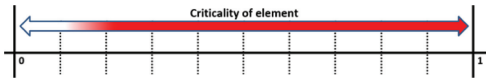

Figure 2. The element criticality value range.

reduced by decreasing the components unavailability or by improving the defense in depth against a failure of the component (Borst et al, 2001; Kim et al, 2009; Espiritu et al, 2007; Baroud et al, 2014). The selection of system components whose criticality needs to be reduced are performed by *FV*.

$$I_k^{FV} = \frac{C(base) - C(x_k = 0)}{C(base)}, \tag{6}$$

where $C(base)$ is the average of criticality, when all system elements availability is random; $C(x_k = 0)$ is average criticality, when kth element is working (with probability equals to 1) and other elements availability is random.

The *BI* is completely dependent on the structure of the system model and is independent on the current probability of the basic event.

$$I_k^{BI} = C(x_k = 1) - C(x_k = 0), \tag{7}$$

where $C(x_k = 1)$ is kth element is 100% unreliable and availability of other elements is random.

The logistic regression model was designed to examine how functionality of the gas supply system elements affect energy system criticality value by using probability scores as the predicted values of the dependent variable of gas supply system. The purpose of this statistical analysis is to determine which elements of gas supply system influence high value of system criticality (statistical classification model) (Ozdemir, 2011; Flahaut, 2004; Fang et al, 2012).

Categorical variable Y is defined

$$Y = \begin{cases} 0, & C^{(0)} \notin I, \\ 1, & C^{(0)} \in I, \end{cases} \tag{8}$$

where $C^{(0)}$—criticality of system when operating statement of all elements are random with regard to its failure probabilities; I—analyzed interval of criticality.

The mathematical model is expressed as

$$p_i = \frac{e^{z(x_i)}}{1 + e^{z(x_i)}}, \quad z(x_i) = b_0 + \sum_{j=1}^{N} b_j x_{ji}, \tag{9}$$

where $i = 1, \ldots, n$, $j = 1, .., N$, p_i—probability that criticality value is from analyzed interval I $p_i = P(Y = 1)$, i—iteration; N—number of explanatory; x_i—the realization of system elements availability; b_j—coefficients of logistic regression.

Simulation data of system functionality: availabilities elements, criticality value of system with regard to availabilities elements. The effect of jth element unavailability to system criticality is estimated by the odds ratio of system element.

3 THE CRITICALITY ANALYSIS AND MEASUREMENT OF ENERGY SYSTEM

The pilot numerical calculations were performed to demonstrate our criticality the applicability of assessment method for any system. The assumptions of the system: closed energy system; the demands of heat and power were selected from statistical sources (Energy in Lithuania 2012, 2013). The system was composed of 151 elements. The parameters of generation technologies are presented in Table 1 and Table 2.

The energy system scheme is presented in Figure 3.

The criticality assessment was performed when analyzed kth element is out of order, operating statement of other elements is obtained using random number generator with respect to its failure probability: scenario of elements availability is generated (generation process is repeated 100000 times). The experiment is repeated when kth element operates with probability equal to 1, operating statement of other elements is obtained using random number generator with respect to its failure probability.

The estimate of system criticality is calculated in each case. Obtained conditional probability distributions of elements criticality of power system, when kth element is out of order and operating statements of other elements are random, are presented in Figure 4.

This graph shows the relative frequency of each element (of gas supply system) criticality of the power system. According to relative frequency, the range of criticality value can be divided into intervals: 1st interval [0, 0.05)—the vicinity of zero, the

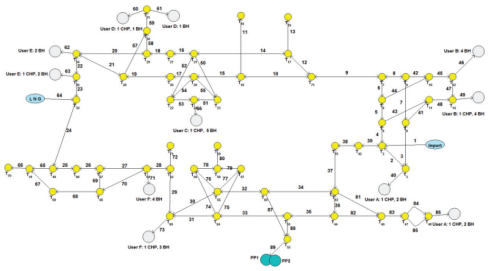

Figure 3. The scheme of analyzed energy system.

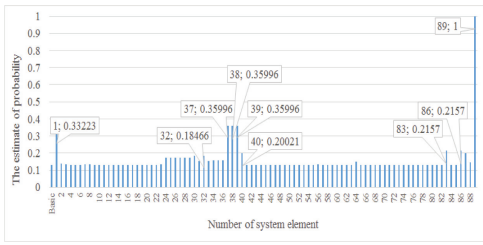

Figure 5. The estimate of probability of non-null criticality of power system in case of analyzed kth element is out of order.

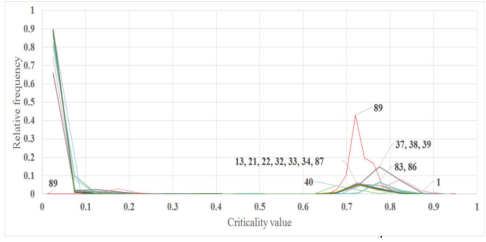

Figure 4. The relative frequency distribution of kth element criticality of the power system $k = 1, \ldots, 89$th.

completely functionality state is the most common state of the system; 2nd interval [0.05, 0.25); 3rd interval [0.25, 0.6); 4th interval [0.6, 1]. The criticality is described by mixture distribution according to the graphs of relative frequencies, see Figure 4.

The 89th element of gas supply system is the most critical element for the power system: in most cases, its criticality value is from the interval [0.56, 0.947]; mode is 0.72, median is 0.727 and mean is 0.733, and the estimate of probabilities of non-null criticality is 1, as shown in Figure 5. The other critical elements are: 1th, 37th, 38th, 39th, 86th. The group of element (37th, 38th, 39th) has important transmission elements in the gas network and connect major customers. The relative frequencies of the 1st and the 2nd intervals are high, but the criticality values are low, detailed analysis is not essential for these intervals. The power system criticality interval $I = [0.6, 1]$ is analyzed in more detail only (in the next step).

The obtained conditional probability density functions (Fig. 4) are used to calculate characteristics of element criticality: the estimate of probability of non-null criticality $P(X > 0 \mid e_k)$, e_k—kth element is out of order, $k = 1, \ldots, 89$th is presented in Figure 5.

Obtained conditional probability distributions of elements criticality of heat system, when kth element is out of order and the operation statements of other elements are random, are presented in Figure 6.

The situation of criticality of heat system is much better than the power system, as shown in Figure 6.

Generation capacity is much larger than customers demand, and there are more generation technologies with different types of fuel (gas, oil, biofuel, etc.). The most critical element is the 1th element (main gas import pipeline), see in Figure 7. There are several critical elements in both systems (power and heat): 37th, 38th, 39th, see Figure 5 and Figure 7. The critical element of heat system depends on the location, its mean, element that connects large customers with main pipeline networks. The estimates of probability of non-null criticality (of heat system) of gas supplies system elements is shown in Figure 7.

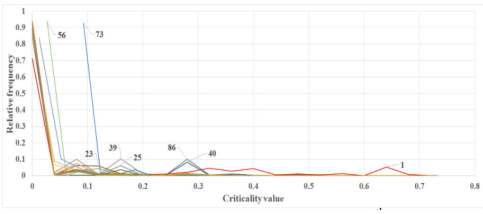

Figure 6. The relative frequency distribution of kth element criticality of the heat system $k = 1, \ldots, 89$th.

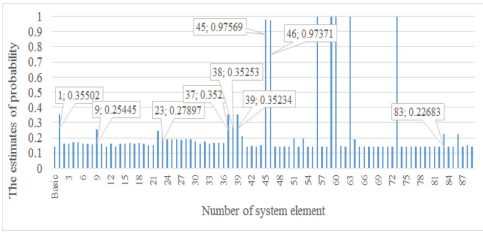

Figure 7. The estimates of probability of non-null criticality of heat system in case of analyzed kth element is out of order.

The other elements to be noticed are 56th, 59th, 60th, 73th elements. As shown in Figure 7, the estimate of probability value of non-null criticality is 1. The 9th and the 23th elements are connections between the main pipeline and the consumers. The estimate of probability of non-null criticality are 0.25 (9th) and 0.27 (23th), they are higher than average probability (0.14) of other system elements.

To identify the most important elements of the energy system we used the importance measurement of Fussell-Vesely and Birnbaum importance. The importance measurement of Fussell-Vesely and Birnbaum importance of all gas supply system elements were calculated to determine the most critical elements of the system.

The result (only with not null importance measurements) for the criticality of power system and heat system are presented in Figure 8 and Figure 9.

There is one important element of gas supply system for the power system, as shown in Figure 8. This element is 89th: $FV = 0.82$ and $BI = 0.72$ (the values of FV and BI are high). The other elements of the gas supply system are not so important neither for power system, neither for heat system. The results of importance measurement of heat system showed that other elements of gas supply system have no significant impact on the heat system.

The criticality assessment results show that the gas supply system has more influence on the power system than the heat system.

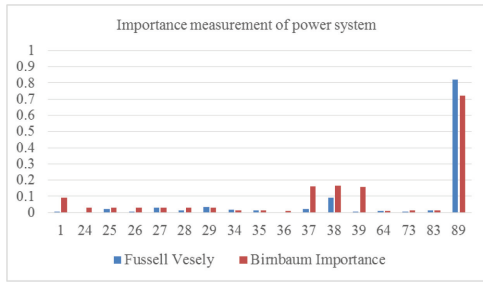

Figure 8. Importance measurements of power system.

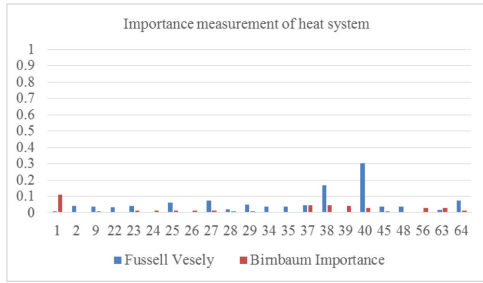

Figure 9. Importance measurements of heat system.

It is important to determine which combination of gas supply system elements more affects power system.

The logistic regression result is the list of gas supply system that have the greatest impact on the system criticality value.

The simulation data for logistic regression analysis was composed of basic scenario (the operating statements of all elements are random). Data was obtained by Monte Carlo method (with 100000 repeats). The categorical variable Y is estimated by the equation (7), the interval of power system criticality which is analyzed in the logistic regression analysis is $I = [0.6, 1]$.

The statistically significant ($\alpha = 0.05$) odds ratios of gas supply system elements are presented in Figure 10.

The gas supply system elements that have the greatest impact on power system criticality value: 89th, 32th, 33th, 34th (from the results presented in Figs. 4, 5, 7 and 8).

When element 89th is out of order, the power system criticality value belongs to considered interval. 89th element is excluded from the analysis because of quazi separation problem.

When element 33th is out of order, it increases the chance (4.7 time) that criticality value of power system will be from the interval [0.6, 1]. The 32th and 34th elements increase the chance 3.8

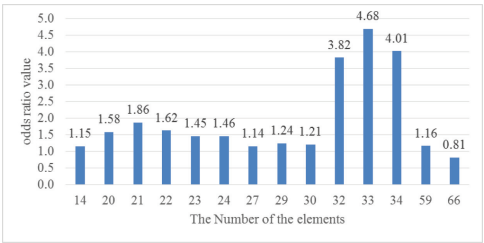

Figure 10. Odds ratio of gas supply system elements.

and 4 times the criticality value will be from the interval [0.6, 1].

4 CONCLUSIONS AND RESULTS

The criticality assessment method supplemented by importance measurements and elements classification method (by logistic regression) was presented in this paper.

The criticality assessment pilot calculation of hypothetical system was performed to demonstrate the practical application of the method: gas supply system reliability influence on power and heat systems and to identify most critical elements.

Criticality characteristics of gas supply system (the estimate of probability of non-null criticality, mean value of criticality, the importance measurements and odds ratio for each element) were estimated. The estimates of probability of non-null criticality (of power system) are from interval [0.13, 1], the mean values of criticality (power system) are from interval [0.065, 0.733]. The estimates of probability of non-null criticality (heat system) are from interval [0.163, 1], the mean values of criticality (heat system) are from interval [0.009, 0.118].

The identification of the most critical components (or their groups) of gas supply system and assessment of their impact on power and heat system could be performed by the proposed method.

The more detailed analysis of power system allowed to determine the group of elements, which failures increase the odds to achieve the high value of criticality (i.e. value greater than 0.6) by logistic regression model.

The estimation of importance measurements (*FV* and *BI*) allows to determine system elements which criticality could be reduced by decreasing unavailability of these element. In the numerical example the 89th element was determined.

The list of elements obtained by logistic regression correlates with the list of elements determined by criticality assessment method.

The implementation of this assessment method could be performed for real country energy system, ensuring privacy of results for security.

Comparing societal consequence measures of outages in electrical distribution systems

F. Landegren, J. Johansson & O. Samuelsson
Department of Industrial Electrical Engineering and Automation, Lund University, Sweden
Lund University Centre for Risk Assessment and Management, Sweden

ABSTRACT: Quality of supply regulations are today in use in a large number of countries. While these regulations are likely to decrease the direct economical consequences from power outages it is less clear to what extent they take into account the societal criticality of consumers. In order to advance knowledge in this area, two different ways of estimating consequences of power outages are here contrasted. In recent years a system, named Styrel, has been introduced in Sweden, intended to enable prioritization of critical power customers from a societal perspective during times of power shortage. The Styrel prioritizations are here used as a proxy for the societal consequences of power outages. The second way of measuring consequences that arise makes use of the Swedish power outage regulation concerning outage compensations to customers. A case study is carried out for a real-life distribution system in Sweden, where failures of different sizes are simulated and the two consequence measures are calculated for each failure scenario. The overall result is that the present power outage regulation poorly mirrors the societal consequences as estimated by the Styrel prioritizations, leading to the conclusion that present day power outage regulation in Sweden is not satisfactorily taking some aspects of societal criticality into account.

1 INTRODUCTION

Society is today highly dependent on a number of critical infrastructures. Among these, arguably, few are as vital as the electrical power system, considering that many other critical infrastructures are to some extent dependent on a reliable supply of electricity. Not only is the power system of vital importance for society, its importance is also increasing, something which is reflected in steeply increasing customer costs from power outages. A Norwegian study showed that within the short time span of 10 years, from 1991 to 2001, costs for a 1 h interruption grew by a factor of 4 within the commercial sector and with as much as a factor of 12 in the agricultural sector. Cost also nearly doubled among residential customers and in the industrial sector, with inflation taken into account (Kjolle et al. 2008). Besides the direct costs that outages give rise to, power outages might also give rise to indirect consequences. As discussed by Rao et al. (2010), while interruptions in a small residential area will normally only cause direct damage, such as food spoilage or inconvenient building temperatures, more widespread interruptions with a longer duration might cause indirect damage such as civil disobedience, breakdown of logistic chains, etc. There has for a long time existed an awareness that the power system should be managed in a way that takes into account the economic costs that an outage will entail for different consumer groups (Sanghvi 1982). In order to achieve this power quality regulations have been introduced in a number of countries. (For a review of regulations in European countries see Tahvanainen et al. (2004), for a review of regulations in American states see Sappington et al. (2001)). However, these regulations, although beneficial for individual customers, might not lead to a result that is favorable when the well-being of society is taken into account. This difficulty is high-lighted by Linares and Rey (2012). They suggest that the consequences of electricity outages can be classified into three categories: direct economic impacts, indirect economic impacts and social impacts and they claim that an optimal analysis should capture all three impact categories. The regulations in place today in Europe and America are likely to take account of the first of these categories. It is however an open question to what extent the second and third categories are taken into account.

Linares & Rey point out that a major obstacle to attaining an optimal analysis is lack of data. It is hard to find credible data concerning the indirect and the overall societal consequences from power outages. To overcome this obstacle assessments that have been done as part of a Swedish power regulation, Styrel, are here used as a proxy for the societal criticality of power customers.

The purpose of the paper is to provide insights concerning how well a present day quality of supply regulation in Sweden reflect societal consequences as measured through the Styrel prioritizations system. The quality of supply regulation, which is one of the two power quality regulations in use in Sweden today, has been chosen because it has a major impact on the revenue of power companies and can therefore be assumed to have a large influence on how power companies invest in as well as restore their networks.

1.1 *Background*

A large number of studies assess the economic costs incurred by power outages. Woo and Pupp (1992) review 16 such studies and identify four principal methods that are used for making these economic assessments, they are briefly presented below:

Customer surveys: This method, which is the one used most frequently, consists in asking consumers questions concerning perceived consequences of a power outage of certain duration. The question can be either direct or indirect. In the former case the customer is asked to assess the cost of the outage. In the latter case the customer will instead be asked questions concerning what they would pay to avoid the outage, known as the Willingness To Pay (WTP), or how much the customer would demand in return for accepting to suffer the outage, known as the Willingness To Accept (WTA).

Case studies: In this method a past power outage is analysed in order to determine the consequences that resulted from it. Widely studied power outage are the New York outage in 1977 and the blackout of Northeast US in 2003.

Market based methods: This is also known as revealed preference, as opposed to the stated preference obtained through surveys. When using this method the consequences of an outage are assessed based on the customers' behavior on the market. Expenditures on backup facilities and the use of interruptible contracts can, for instance, provide information on how households or industries value interruptions of the power supply.

The production function approach: This method estimates the consequences of outages through lost production (for firms) or lost leisure time (for households). The cost is calculated as the ratio of an economic measure (e.g., gross output, gross domestic product GDP) and a measure of electricity consumption. The main benefit of the approach is that it makes use of readily obtainable data. The draw-back is that it makes unrealistic assumptions. For instance it says that if x% of the yearly power supply of a company is lost its yearly productivity will decrease by x%. However this could lead to overestimations in case some form of production can go on also without power supply and it can lead to underestimations if power outages cause reduction in productivity not only during the time of the outage but afterwards as well due to long term damages. (De Nooij 2007: Balducci et al. 2002; Linares & Rey 2012; Samdal 2003; Kjolle 2008).

Once data has been gathered concerning outage consequences, they can be used to create a cost model. Three main kinds of cost models are used by power system planners. Customer Damage Function (CDF) models represent the costs as a function of the interruption duration. Cost of Energy Not Supplied (CENS) models represent the costs as a function of the unsupplied energy. Finally, Combined Cost Models (CCM) represent interruption costs as a sum of two components: one is a function of the interruption load demand ILD, another is a function of the expected energy not served EENS. (Raesaar et al. 2006, Bozic 2000).

Among the categories defined by Linares & Rey, referred to above, present methods for assessing consequences from power outages are likely to take direct economic impacts into account in a satisfactory way. However, it is less likely that indirect economical or societal consequences are taken into account satisfactorily. Customer surveys measure only the economic consequences for the informant not for those actors depending on the informant or the interests of society in general. The market based approach reflects only the interests of the consumer, which is likely to be mostly concerned with how outages will affect their own revenue or household economy. Therefore it will mainly assess the size of primary economic consequences. The product function approach by its very nature will focus on the direct economic consequences. The case study is clearly advantageous for assessing societal consequences since in hindsight the relevant data is obtainable, although perhaps not easily so. Its weakness though is that it is far from clear what inferences that can be justifiably drawn from past accidents with respect to future ones. When, for instance, studies based on evidence from the 1977 New York black-out are used as guides to understanding the consequences from present day outages it should be borne in mind what remarkable changes society and technology have undergone in the meantime. Conclusions should therefore be based primarily on the relatively few events that have occurred in recent time.

In the following a Swedish quality of supply regulation is described and the Styrel system is also introduced. The Styrel system is here used as a new means of estimating societal consequences from power outages.

1.2 *Outage compensation*

The present regulatory system for outage compensation was initiated by the Swedish government in 2005. In this regulation the compensation increases with the outage time (see Table 1.) and hence the regulation acts as an incentive to make the power companies improve the reliability of their systems so that long power outages will be less likely.

Table 1. Disruption compensations for different power outage lengths.

Outage time (days)	Compensation (% of yearly fee)	Minimum compensation (SEK)
>0.5	12.5	900
>1	37.5	1,800
>2	62.5	3,600
>3	87.5	4,500
>4	112.5	5,400
>5	137.5	6,300
>6	162.5	7,200
>7	187.5	8,100
>8	212.5	9,000
>9	237.5	9,900
>10	262.5	10,800
>11	287.5	11,700
>12	300	12,600

Table 2. Consumer categories as defined in Styrel (The number of points given to customers is in most, but not all cases, in accordance with below).

Priority class	Point	Power customer
0	8	Critical facilities belonging to the power company
1	8	Consumers that in a short time span (hours) have a large impact on life and health
2	7	Consumers that in a short time span (hours) have a large impact on the functioning of society
3	6	Consumers that in a longer time span (days) have a large impact on life and health
4	5	Consumers that in a longer time span (days) have a large impact on the functioning of society
5	4	Consumers that represents large economic values
6	3	Consumers that have a major importance for the environment
7	2	Consumers that have importance for societal and cultural values
8	1	Other consumers

1.3 *Styrel*

The Swedish Energy agency has in cooperation with the Swedish Civil Contingencies Agency and Swedish national grid developed Styrel (MSB 2010). It is meant to be used during times of power shortage to prioritize consumers based on their importance to society. Consumers are grouped into nine predefined priority classes and each consumer is also given a number of points (see Table 2). Governmental, county and municipal levels are all involved in the process of deciding which power customers to prioritize. The prioritizations of customers to supply in case of power shortages are made according to the following rules:

1. The overall number of non-supplied customers with priority 0 or 1 should be minimized
2. The sum of points for all non-supplied customers with priority 2 or less should be minimized
3. Rule 1) has precedence over rule 2).

2 METHODOLOGY

As explained in the previous section, the purpose of this paper is to contrast present Swedish outage regulation against societal consequences that arise as estimated through Styrel.

To do this a case study of a distribution system of a midsize city in Sweden (see Fig. 1) is carried out. The system has also been studied in (Jönsson et al. 2008). The distribution system is an 11 kV system consisting of altogether 1203 components, 539 nodes (representing network stations, transformers, bus bars and feeder station breakers) and 664 edges (representing underground cables). The network is supplied from 10 in-feed transformers from higher voltage levels and serves roughly 40,000 customers. Only topology is considered in the model of the network using a graph model where the graph $G(V, E)$ is defined by two sets, V consisting of

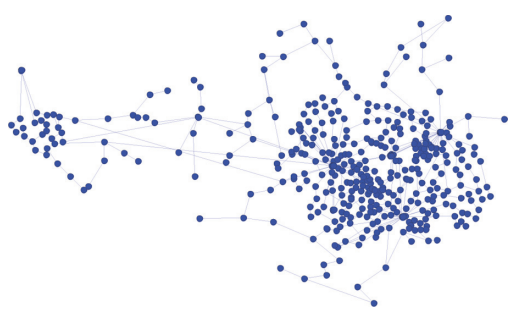

Figure 1. The power distribution network.

the N nodes and E consisting of the M edges (or links), defined as (Johansson 2010):

$$V = n_1 \quad n_2 \quad \dots \quad n_N$$

$$E = e_1 \quad e_2 \quad \dots \quad e_M$$

The complete set of components in the network C is constituted by the sets V and E, i.e.:

$$\begin{aligned} C &= n_1\, n_2 \quad \dots \quad n_N \quad e_1 \quad e_2 \quad \dots \quad e_M \\ &= c_1 \quad c_2 \quad \dots \quad c_{N+M} \end{aligned}$$

An adjacency matrix A is used to represent the connections in the network:

$$A = \begin{pmatrix} a_{11} & \cdots & a_{1N} \\ \vdots & \ddots & \vdots \\ a_{N1} & \cdots & a_{NN} \end{pmatrix}$$

where a_{ij} is 1 if n_i is connected to n_j by means of an edge and 0 if no connection exists. A failure of node n_i is simulated by setting all elements in row i and column i of the adjacency matrix A to 0. A failure of edge e_i connecting n_j and n_k is simulated by setting a_{kj} and a_{jk} to 0.

Capacity is not considered in the network model, e.g. there is no limit concerning the amount of power that can pass through nodes or edges. A customer is therefore considered to be supplied with power if there is at least one unbroken path leading from the network station supplying the customer to at least one of the ten in-feed transformers.

A customer is considered to be supplied with power if there is at least one unbroken path leading from at least one of the ten in-feed transformers to the network station supplying the customer. A breadth-first search strategy is used to find all nodes that can be reached from at least one transformer. The possible drawbacks of only considering topology are discussed in 4.1.

The effect of outages are simulated using the network model, altogether 6 different strain sizes are studied: N-1, N-2, N-3, N-6, N-9 and N-12. (N-x denotes a failure of x components among the total number of components, N, in the system.) For N-1 and N-2 all possible failure scenarios are analyzed. The strain vectors for the N-1 and N-2 strain sizes ($SV_{N\text{-}1}$ and $[\![SV]\!]_{\downarrow}(N-2)$) are defined:

$$SV_{N-1} = \begin{matrix} C_1 \\ C_2 \\ \vdots \\ C_{N-1} \\ C_N \end{matrix}$$

$$SV_{N-2} = \begin{matrix} C_1 & C_2 \\ C_1 & C_3 \\ \vdots & \vdots \\ C_{N-2} & C_N \\ C_{N-1} & C_N \end{matrix}$$

For higher strain sizes sampled scenarios are used due to the excessive simulation times that would result if a complete scenario set was used. One failure scenario takes about 15 ms to calculate (using a DELL laptop with 5 core processor, 8 GB RAM and 64-bite OS) therefore a complete N-3 analysis, encompassing about 578 million scenarios, would require roughly 7 weeks of simulation time. The strain vectors containing sampled scenarios have the following form:

$$SV_{N-x} = \begin{matrix} c_{r1} & \cdots & c_{rx} \\ \vdots & \ddots & \vdots \\ c_{r1} & \cdots & c_{rx} \end{matrix}$$

where C_{ri} denotes the i:th component randomly chosen among the set of still functioning components. One million randomly generated failure scenarios are used for the N-3, N-6, N-9 and N-12 strain sizes.

For each failure scenario, outage compensation and Styrel consequence is calculated. The overall Outage Compensation (OC) for a certain scenario is calculated in the following way:

$$OC = \sum_{i=1}^{N_1} Fee_i * NormComp(t) + MinComp(t) * N_2$$

$N_1 + N_2$ is the number of customers without power. N_1 is the number of customers that are receiving more than the minimum compensation (see Table 1) and Fee_i is the yearly fee for customer i. *NormComp* and *MinComp* are functions of the outage time of the particular distribution stations (see Table 1). In this paper the outage time for all customers is assumed to be 12 h meaning that *NormComp* is 12.5% and *MinComp* is SEK 900. As is seen in Figure 2 the number of customers (87% of customers) that will get the minimum compensation after a 12 h outage is relatively high since all customers with a yearly fee of SEK 7,200 or less will get this. This means that small customers will carry more weight, relatively, than if a longer outage time was chosen.

By ranking the OC consequence values for all simulated scenarios (see Table 4) the outage compensation Normalised Rank (ONR) can be obtained using the following formula:

ONR = (N-*Rank*)/(N-1)

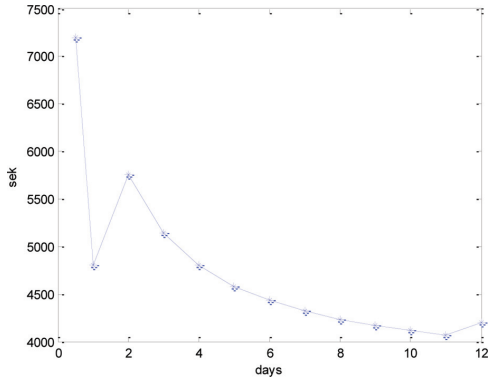

Figure 2. Highest yearly fee that will give minimum compensation as function of days of outage.

Scenarios are ranked in descending order and scenarios with the same consequence are given the same rank, N is the number of different rank levels.

The Styrel Normalized Rank (SNR) is determined by using the Styrel prioritization rules (see 1.3). A scenario A has higher rank than a scenario B if the number of non-supplied customers with priority 0 or 1 is larger in A than in B or, if the number of non-supplied customers with priority 0 or 1 is the same in A and B, the sum of points for all non-supplied customers with priority 2 or less is higher in A than in B. When the scenarios for a certain strain level have been ranked according to this ranking procedure the Styrel Normalized Rank (SNR) of each scenario is described as follows:

$$\text{SNR} = (N\text{-}Rank)/(N\text{-}1)$$

As before, scenarios with the same consequence will get the same rank and N is the number of different rank levels.

The following simple example illustrates how ONR and SNR is calculated: a scenario ranked nr 577 (concerning outage compensation or Styrel) among a total number of 1000 rank levels will be given the ONR/SNR (1000–577)/1000 = 0.423. The ONR and SNR will always vary within the interval [0,1]. For the subset of scenarios without affected top priority customers (priority 0 or 1) the correlation between the two ranking methods are analysed. In order to do this we use Spearmans rank correlation coefficient.

In order to test how well the result converges, for this number of scenarios, the coefficient of variation, α, is applied to the outage compensation results.

$$v_i = [x_1, x_2, \ldots, x_i]$$

$$\alpha_i = \frac{std(v_i)}{mean(v_i)}$$

Std denotes standard deviation and v_i is a vector containing the first i simulation results. We use simulation results concerning outage compensation, then $\alpha_{1,000,000}$ is 1.48 for N-3, 1.06 for N-6, 0.88 for N-9 and 0.76 for N-12 and it quickly converges to these final values meaning that one million samples should be sufficient.

3 RESULTS

Using the ranking methodology described in the previous section we have ordered outage scenarios in accordance with how a DSO would prioritize them based on the two schemes. This is done for 6 different scenario runs, N-1, N-2, N-3, N-6, N-9 and N-12. On the x-axis is shown the ONR, i.e. how the scenarios would be ranked based on the outage compensation scheme, on the y-axis is shown the SNR, i.e. the scenarios as ranked based on the Styrel scheme. By arranging the plots in this way the decision making perspective of the DSO is captured and it can easily be seen if the two ways of reaching a decision concerning investments in the network are consistent or not. If there is indeed a close agreement between the two measures the scenario points will form a more or less straight line, and the correlation between ONR and SNR will be close to 1. On the other hand, any major aberration from this straight line, or a correlation significantly lower than 1, indicates that the ONR is not reflecting the societal consequences shown by the SNR.

The results from the simulations of N-1, N-2 and N-3 are given in Figure 2 to 4. As can be seen in Figure 2, for N-1, there is a high correlation between the results given by the two ranking schemes, but several scenarios get high SNR

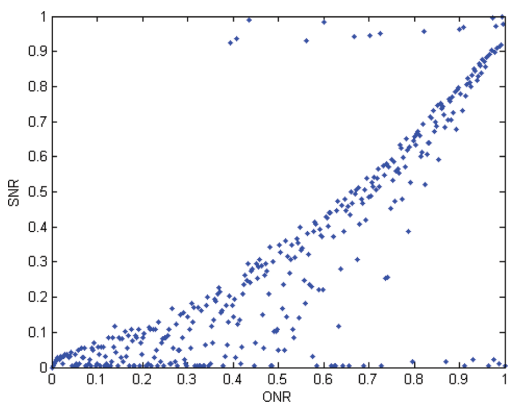

Figure 3. All N-1 scenarios.

and low ONR and vice versa. In *N*-2 (Fig. 4) and *N*-3 (Fig. 5) patterns emerge that are not evident for N-1. The scenarios are divided into several segments, i.e. groups of scenarios that are separated in space from other groups of scenarios. It can be seen that they are separated along the y-dimension, based on the SNR values of the scenarios (distribution of the segments is indicated in Fig. 5). Investigation has shown that each such segment contains scenarios in which a certain number of top priority customers (priority 0 or 1) are affected. The lowest segment contains scenarios with no affected top priority customers, the next higher segment contains scenarios in which one top priority customer is affected, the following segment contains scenarios with two affected top priority customers, and so forth. The total number of these segments increases with the magnitude of the strain since the likelihood of several top priority customers being out at once increases with increasing strain size. It can be seen also that within each segment there is a clear correlation

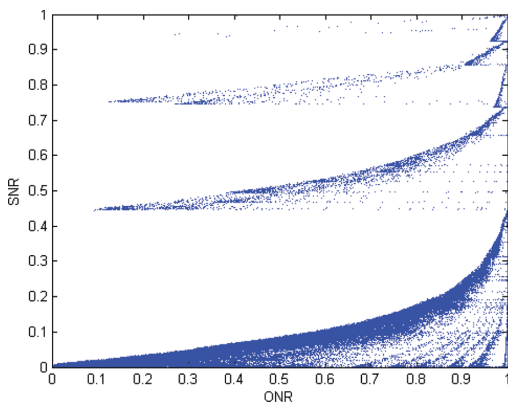

Figure 4. All *N*-2 scenarios.

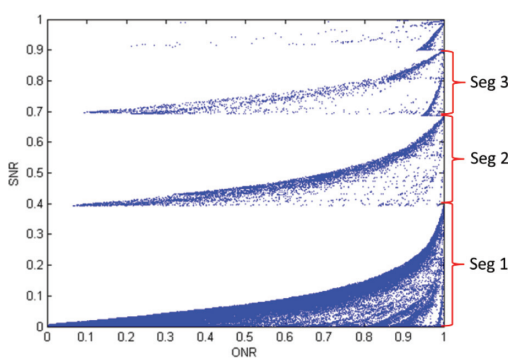

Figure 5. *N*-3, segments 1-3 marked out, 1M iterations.

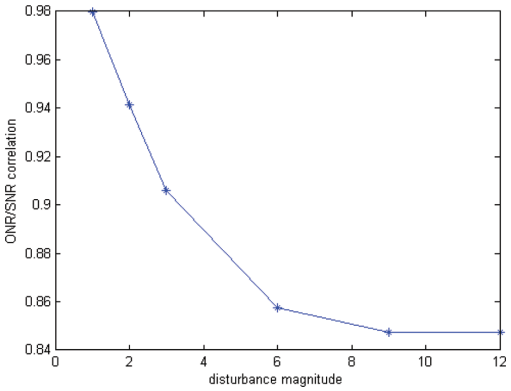

Figure 6. Correlation between ONR and SNR as a function of size of strain, only scenarios with lower priority customers considered.

between SNR and ONR and that the scenarios are distributed in a lower triangle shape. The latter means that no scenarios get higher SNR, within the segment, than ONR, while the opposite may be the case. The graphs for the higher strain levels repeat the pattern seen in the *N*-2 and *N*-3 graphs, and they are therefore left out. As can be seen in the graphs there is a poor correlation between the ranking results for strain sizes >1.

As it is apparent that ONR and SNR correlates poorly for top priority customers in Figures 4 and 5, Spearman rank correlation is instead calculated only for those scenarios that does not contain any top priority customers for the different simulated strain sizes (see Fig. 6). Here the focus is to evaluate the correlation between ONR and SNR for customers with lower prioritization values. The result reveal that the correlation decreases with increasing strain size, although the correlation is relatively high for all strain sizes. This suggests that although there is a poor correlation between ONR and SNR when all scenarios are included, there is a higher degree of correlation for lower priortized customers. As discussed further in the next section, this implies that high prioritized customers need to be treated separately and are not sufficiently considered in the outage compensation scheme.

4 DISCUSSION

Outage compensation is one of two existing power quality regulations in Sweden, and it has major impact on the revenue for Swedish DSOs. It can therefore be assumed that investments in the network as well as the way in which outages are

handled, both being performed by the DSO, will be decided to a large extent by the outage compensation regulation (this is a valid assumption only to the extent that DSOs strive to reduce their costs and increase their profit). Since the ONR is based solely on the customers' yearly fee, it is reasonable to ask if it takes aspects such as the societal criticality of the customer into account in a satisfactory way. In this paper the customer prioritizations made within the Styrel project were aggregated and used as a proxy for the societal criticality of customers supplied by a power distribution system. The results revealed that there is a clear correlation between SNR and ONR for the *N*-1 strain size while for larger sizes of strain the scenarios are divided into several distinct segments and the correlation between SNR and ONR is consequently low. Within each segment the scenarios form lower triangles, meaning that no scenario receives higher SNR than ONR. In other words, within each segment ONR reflect SNR in the sense that a high SNR implies a high ONR although the reverse is not the case. Since the scenarios are divided into segments based on the number of affected top priority customers (customers with priority 0 or 1) it is the existence of such customers that is responsible for the big overall disagreements between the SNR and ONR. This implies that customers given top priority in the Styrel system need to be treated separately and are not sufficiently considered in the outage compensation scheme.

Strandén et al. (2010) discuss the outage compensation scheme used in Finland, which is similar to the Swedish one, and point out that with present day regulations "small even if very critical customers, […], are more or less ignored", and this as well as the inverse situation, when large although socially non-critical customers are given a high priority, is the main reasons behind the discrepancies found between the rankings in this paper. A possible way to improve this situation is to take SNR, or other indicators of the societal criticality of power customers, into account when calculating the compensation that DSOs should pay to customers that have suffered outages. It is especially important that top priority customers are given more weight in the outage compensation regulation. If such changes were made it would be likely to steer the investments in the power grid so that the overall societal consequences from power outages are reduced.

4.1 *Validity*

The validity of the presented results depends on several factors. One factor is that only topology, but not capacity, is taken into account in the network model. This might lead to underestimations when the largest strain sizes are simulated. For instance, when capacity is not considered, the entire system could be supplied from one single infeed-point. Another issue is how well the Styrel priority values reflect the actual societal criticality of the power customers. The Styrel priorities are decided in cooperation between all political levels in Swedish society, which means that detailed knowledge as well as overview of the customers criticality for society should be reflected in the prioritizations. However, it could be questioned if the points given to customers can indeed, as is the practice of the DSO, be used as weights. This implies that 4 normal households, which have 1 point each, carry as much weight as a large industrial facility and that 7 households have equal weight as one customer that has large impact on the functioning of society in the short time span. This apparent weakness should be considered when judging the results. Another concern is, as mentioned in part 2, that the outage duration was assumed to be 12 hours for all affected customers. For a 12 hour outage all customers with a yearly fee of SEK 7,200 or less will get the minimum compensation (see Fig. 2), meaning that they are raised above what they would get if the compensation in percentage (12.5%) is used. As the outage time increases the number of customers that are raised to the minimum amount will decrease and they will thereby become relatively less important. Overall small customers will, due to this, carry less weight in determining outage compensation as the outage time increases.

5 CONCLUSIONS

It has been found that outage compensation, reflecting the economic cost of outage scenarios for a DSO, have a poor correlation with results given by Styrel priorities, reflecting the societal consequence of outages. The two correlate well for single component failures, but worse as the magnitude of strain increases. It is found that the low correlation is due to the influence of top priority customers, and this implies that this small group of customers is not sufficiently considered in the outage compensation scheme. It can be concluded, from observing the low correlation, that the investments in the system, motivated by cost-cutting efforts, will not reflect the priorities that society has with regard to protecting critical power customers. A compensation scheme that weighted outage compensation according to the criticality of the customer (using Styrel priority or some other criticality measure) would be likely to steer investments in the network as well as repair

work so that overall societal consequences from power outages are reduced.

ACKNOWLEDGEMENT

The DSO that supplied the data on which this paper is based and the Swedish Civil Contingencies Agency (the PRIVAD-project) which funded the research are both greatly acknowledged.

ABSTRACT: The paper deals with the resilience analysis of critical infrastructure systems. An infrastructure system is a network of subsystems, which interoperate through dependencies of various types. The interaction and dependency among the subsystems make the entire infrastructure system more complex and possibly vulnerable. We interpret resilience as a system property related to the prevention of, robustness to and recovery from undesired disturbances and events. Such resilience property of interconnected systems depends also on their structure and design parameters. In this paper, we abstract the structure of the system by a directed graph. A state dynamics is associated to each of the subsystems, with interdependent terms that can represent different types of interdependencies. The system response to undesired disturbances and events could, then, be analyzed using notions from set theory, to identify regions of operation and recoverable or non-recoverable conditions. Moreover, a characterization of the system resilience as a function of the design parameters can be provided, which is useful for resilient design and operation purposes. The benefits of the proposed approach are highlighted through an illustrative, numerical application.

1 INTRODUCTION

In recent years, the protection of critical infrastructure systems (e.g., electric power grids, telecommunication systems, transportation systems and so on) has become an important topic. The notion itself of "critical infrastructure" implies that these interconnected systems are important. They serve our everyday life, e.g. they provide the water and electricity in our homes, for our physical and financial welfare, and support the development of modern societies.

As all systems, these critical infrastructures are exposed to hazardous natural and artificial events, such as earthquake, hurricanes, random failures and sabotages etc., which make them vulnerable (Wolfgang & Zio 2011) Given their importance, the critical infrastructures need very high-levels of reliability and protection (Carlyle et al. 2006, O'Rourke 2007, Murray & Grubesic 2007).

A critical infrastructure is composed of subsystems whose operation is interdependent in different ways and to different degrees (Rinaldi et al. 2001, Rinaldi 2004). The interdependencies and the interactions among the subsystems are the force and the weakness of the critical infrastructures. With respect to the latter, the major risk is that of an initiating failure which propagates from one subsystem to another rendering the global system dysfunctional and unstable. The modeling of this dynamics is quite a challenging task (Buldyrev et al. 2010, Dobson 2008, Pederson et al. 2006).

Several properties make up the capability of a system to provide its function and continue to do so or recover it, in the presence of failures of some of its subsystems. The system must have built-in capacity to resist to the disturbances and be capable to adapt to changing environments. The resilience of a system includes all these properties, specifically, the prevention of and robustness to disturbances, and the capability of recovery from failure.

The analysis and characterization of the resilience of critical infrastructures is receiving a lot of attention from the scientific and technical community. For example, (Nozick et al. 2005) uses a supply-demand graph to represent the interdependency between infrastructures, and Markov and semi-Markov processes for describing the state transitions dynamics. Furthermore, the system performance is measured and analyzed using a probabilistic distribution. Reference (Faraji &

Kiyono 2012) proposes a weighted stochastic Petri Net modeling approach for the analysis of critical infrastructures to describe the cascading failure impacts and assess the reliability of the infrastructure. The work in (Bloomfield et al. 2010) builds a stochastic model for the interconnected critical infrastructures, whereby each component is modeled as a random process with a probability to switch between two states, operational and failed. The metric to measure system performance is given in terms of the cascade size resulting from the failure process. A System Dynamics (SD) infrastructure vulnerability assessment framework is proposed in (Tonmoy & El-Zein 2014) to simulate the dependent behaviors of the infrastructure subsystems, and a measure of system performance is provided. An extensible graph-theoretical model is provided in (Svendsen & Wolthusen 2007) for investigating the interdependencies among critical infrastructures. The interactions between their components are modeled through a set of response functions on the graph edges and resources on the nodes. Reference (Reed et al. 2009) introduces a linear input-output model for describing the interdependencies among infrastructures. Methods based on fragility measures and quality functions are proposed to evaluate the system restoration from natural hazards.

Furthermore, (Filippini & Zio 2013, Angelo & Filippini 2013) represent the infrastructure systems in a directed graph and a state dynamics is associated to each subsystem for describing the failure and recovery processes and their interdependent effects. A first attempt of resilience analysis is proposed based on invariance concepts and asymptotic stability. However, a thorough characterization of the resilience and a metric of the system resilience are not provided.

In the present paper, we embrace a similar approach as in (Angelo & Filippini 2013). We consider a topological model of the infrastructure systems described by a directed graph, with nodes and edges representing the subsystems and the functional dependencies between the subsystems, respectively. Next, we proceed with the modeling of the dynamics of each subsystem and the related interdependencies. For this, we use a state space model with specific dynamics governed by parameters characteristic of the failure and recovery processes. The analysis of the interconnected systems dynamics is performed with the objective of identifying the resilience region for which the system state converges to the operation mode, no matter the disturbances affecting the system. Invariance concepts are used to find the resilience region and to provide conditions on the design parameters, which ensure the successful operation of the interconnected systems. Some interesting behaviors of the system are highlighted, e.g. a chattering behavior.

The rest of the paper is organized as follows. Section 2 introduces the topological description of the interdependent systems, and their associated dynamic model. Section 3 presents the conditions on the design parameters, which ensure the existence of a resilience region. Discussions based on simulation results are presented in Section 4. Finally, Section 5 draws the conclusions and presents the future work.

2 PRELIMINARIES AND PREREQUISITE

This section provides a detailed description of the system modeling and also introduces set invariance notions, which will be instrumental for the resilience analysis of infrastructure systems.

2.1 *System modeling*

The entire interconnected system can be represented by a directed graph, with nodes and directed edges describing the network structural characteristics. Figure 1 shows such an interconnected system as a directed graph, where each node represents a subsystem and the direction of the edge connecting two nodes indicates the dependency relationship between two subsystems (i.e., the head node is dependent on the tail node).

Within one interdependent infrastructure system, its subsystems depend on each other by different types of interdependencies. These have different causes and modes of manifestations (Buldyrev et al. 2010, Dobson 2008); formally, these can be described in terms of dynamic models and input/output constraints.

In this paper, we refer in particular to physical interdependencies, cyber interdependencies and also logical interdependencies. In other words, we describe the situation for which one subsystem needs the resources such as power, control signal, water and so on, from another subsystem to keep its functionality. Logical interdependencies can also

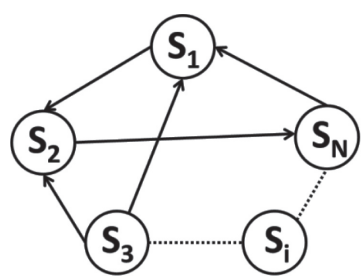

Figure 1. Interconnected system.

be taken into account by adding coupling factors to adjust the states of the subsystems depending on their logic configuration. When all the resources needed are provided, the subsystem works in its nominal operation mode; otherwise, it switches into the out-of-operation mode. This is a dynamic behavior common to many interdependent systems and it is well captured by the switching model considered here.

In a switching dynamic model, as the functionality of a subsystem relies on the production or the service provided by other subsystems, the conditions of the switching of this subsystem depend on its input subsystems. From a system-level point of view, a subsystem may continue operating even when the inputs of certain resources are partially unavailable; in this sense, the buffering and restoration processes are both taken into account as two different dynamic modes.

The dynamic model for any subsystem S_i is given by the switching dynamical equations below:

$$\dot{x}_i(t) = \begin{cases} -\mu_i(x_i(t) \\ \quad -\sum_{j\in I_i} \alpha_{ji} x_j(t)) + d_i, & \text{for } x_j \le \sigma_j,\ \forall j \in I_i \\ \lambda_i(1 - x_i(t)), & \text{for } x_j \ge \sigma_j,\ \exists j \in I_i \end{cases} \tag{1}$$

where, I_i is the set of input subsystems of S_i.

Equation (1) represents a switched dynamics in the sense that the value of $\dot{x}_i$ alternates between an operation and a failure mode, depending on the value taken by the current state x_i and the state x_j of all of its input subsystems S_j. Subsystem S_i is in a nominal operation state if all the states of its input subsystems are within their corresponding thresholds σ_j, as described by the first equation in (1). Conversely, if one of its input subsystems fails, the subsystem is in an off-operation state and its dynamical behavior is described by the second equation as a failure process.

Note that for N subsystems we have a total of 2^N modes of functioning for the interconnected system, depending where each of the states x_i resides.

Taking into account the dynamics of the entire system, we can use a switched Linear Time-Invariant (LTI) dynamic equation to describe system behavior:

$$\dot{x}(t) = A_m x(t) + b_m, \tag{2}$$

where, $x(t) = [x_1^T(t), \ldots, x_N^T(t)]^T$ represents the state vector of the interconnected system, and matrices $A_m \in \mathrm{R}^{N\times N}$ and $b_m \in R^{N\times 1}$ are constructed accordingly, where $m = 1, \ldots, 2^N$.

To describe the interdependencies and the related dynamics of the interconnected infrastructure system, we introduce the following variables and parameters in the system model:

$x_i(t) \in [0, 1]$ represents the percentage of the loss of service or the production unrealized by subsystem S_i at time t.

For the subsystem S_i, $x_i(t) = 0$ means that S_i can provide full service, or enough products to meet the requirement, or other resource support, to the other subsystems connected to it as expected/demanded. When the subsystem S_i cannot do so, the value of its state variable augments, $x_i(t) > 0$.

Under the assumption that the actual amount of power produced cannot exceed the intended/demanded service, the value of the state variable is $x_i(t) \in [0, 1]$.

The following parameters are introduced to describe the state dynamics:

$\sigma_i \in [0, 1]$ indicates the threshold for state variable $x_i(t)$, which allows evaluating if the subsystem S_i can provide the output required for the functioning of its connected subsystems; in other words, it represents the tolerance of system S_i for the percentage of loss of service: if $x_i(t) > \sigma_i$, then the output is insufficient.

$d_i(t) \in [0, 1]$ represents both external and internal perturbations, which affect the behavior of the system in nominal operation. It can be instantaneous and more or less strong (e.g. caused by natural disasters, such as earthquake, hurricane or a random fault) or continuous and relatively mild (such as sustained wind, electromagnetic interference, degradation etc.).

In some situations, instantaneous and continuous perturbations can co-exist.

$\lambda_i \in [0, 1]$ represents the failure rate for the *ith* subsystem S_i. The time for the state x_i of S_i to reach the threshold is the time to failure TTF_i, introduced in the following equation:

$$\int_0^{TTF_i} \lambda_i e^{-\lambda_i t} = \sigma_i. \tag{3}$$

From equation (3), we obtain:

$$\lambda_i = \frac{log(1-\sigma_i)}{TTF_i}. \tag{4}$$

Figure 2 illustrates the variation of the time to failure with the threshold, for a given value of the failure rate. As illustrated, the time to failure increases with the threshold and for larger failure rate values the curve gets closer to the horizontal axis, which means that the subsystem fails earlier at a lower threshold, as reasonable.

$\mu_i \in [0, 1]$ represents the recovery rate for subsystem S_i. The Time to Recovery (TTR_i) is the time that subsystem S_i takes to recover from the failed state to the threshold:

$$\int_0^{TTR_i} \mu_i e^{-\mu_i t} = 1 - \sigma_i. \tag{5}$$

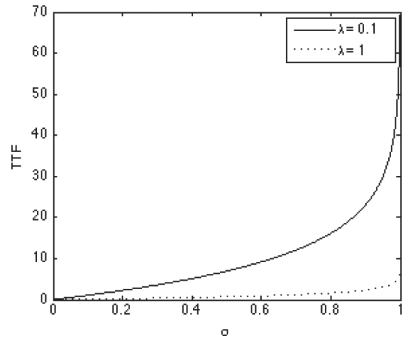

Figure 2. Variation of the Time to Failure (TTF) as a function of the threshold σ.

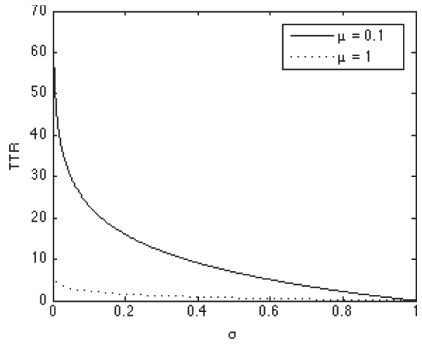

Figure 3. Variation of the Time to Recovery (TTR) as a function of the threshold σ.

From equation (5), the recovery rate is obtained as:

$$\mu_i = -\frac{log(\sigma_i)}{TTR_i}. \quad (6)$$

The recovery process describes a resilience feature of the system. The time to recovery is a critical characteristic of the resilience of infrastructure systems. In Figure 3, we can see that the time to recovery decreases with the value of the threshold and for large recovery rates the time to recovery is small, as logical.

The parameter $\alpha_{ij} \in [0, 1]$ is the coupling factor representing the dependency of the subsystem S_i on the subsystem S_j. The term associated to it in the equation (1) represents the rate of the loss of service that the *jth* subsystem contributes to the *ith* subsystem due to the logical dependencies between them.

The dependency relationships among the subsystems represent the logics between producer and user, supplier and consumer, controller and controlled, etc. In these functional relationships, physical quantities and information are produced, consumed or/and transmitted among the subsystems to ensure their functionality. The threshold for one subsystem state is set with respect to all its downstream or output subsystems controlled by it. The value of the threshold indicates the level of tolerance for the downstream subsystems with respect to the acceptable percentage of lost input from the controlling subsystem.

The proposed model not only captures the functional relationship between the subsystems (e.g. due to physical and cyber dependencies) but also takes into account the logical dependency among the subsystems. These are originated from human decisions and actions. The coupling factor allows considering the degree of logical interdependencies in the dynamic process of system evolution.

2.2 *Invariance notions*

In this sub-section, few basic concepts related to the set-theoretic approach are introduced as necessary.

Definition 1 (Equilibrium point). *The point $x_f \in R^n$ is an equilibrium point (or fixed point) for the differential equation,*

$$\dot{x}(t) = f(x(t)).$$

If $f(x_f) = 0$.

Definition 2 (Positive invariance). *(Blanchini, 1999) A set $P \subset R^n$ is said to be positively invariant for a system of the form*

$$\dot{x}(t) = f(x(t)).$$

If every solution of the equation with initial condition $x(0) \in P$ verifies $x(t) \in P$ for $t > 0$.

Definition 3 (Robust positive invariance, RPI). *(Blanchini, 1999) A set $P \subset R^n$ is said to be robustly positively invariant for a system of the form*

$$\dot{x}(t) = f(x(t), w(t)),$$

where $w(t) \in W$ is an exogenous input. If for all $x(0) \in P$ and $w(t) \in W$, the condition $x(t) \in P$ holds for all $t \geq 0$.

3 DETERMINATION OF THE RESILIENCE REGION

This section presents the necessary conditions on the design parameters for the existence of a resilience region. The region is identified using the invariance concepts introduced in Section 2.2 above.

Proposition 1. *Let there be a convex and compact set $O \in R^n$ and consider the dynamics from (2). Whenever equilibrium point x_f associated with these dynamics lies into O, we have that there exists a subset of O which is an invariant set.*

Proof. If x_f is an equilibrium point for one mode of the switched system

$$\dot{x}(t) = A_m \cdot x(t) + bm,$$

where $m = 1, \ldots, 2^N$.

In any functioning mode of the system, the dynamic equation of each subsystem is an affine equation. Moreover, the eigenvalues λ_A of matrix A satisfy $|\lambda_A| \leq 1$, according to the setting of the parameters. Hence, the system given by (2) is asymptotically stable.

Therefore, $O \in R^n$ is a domain of attraction and we can say that all initial states entering in set O will remain within the set at all future instances, thus O is an invariant set.

We assume that x_f is an equilibrium point in a certain dynamic mode of the system, so for the differential equation that describes the system dynamics, the equilibrium point satisfies:

$$0 = A_m \cdot x_f + b_m. \tag{7}$$

In our case, we can compute the equilibrium point for each operation mode:

$$x_f = (I - A_m)^{-1} \cdot b_m. \tag{8}$$

For a system with N subsystems, there are 2^N dynamic modes and the system switches from one to another depending on the states of each subsystem. The state space of the entire system is a hyper-cube $[0, 1]^N$, a set divided into 3 main parts: operation region, failure-recovery region and out-of-operation region. In the operation region, all the trajectories of the systems lie in the set $O := [0, \sigma_1] \times [0, \sigma_2] \times \ldots \times [0, \underline{\sigma}_N]$. The out-of-operation region is the opposite, $\overline{O} := [\sigma_1, 1] \times [\sigma_2, 1] \times \ldots \times [\sigma_N, 1]$, whereby all the states of all subsystems are of failure and the trajectories converge to an equilibrium point inside this failure region. In the proposed model, the equilibrium points may exist in the operation and out-of-operation regions.

For the operation mode, all the subsystems take the first differential equation:

$$\begin{cases} \dot{x}_1 = -\mu_1 \left(x_1 - \sum_{j \in I_1} \alpha_{j1} x_j \right) + d_1 \\ \quad \vdots \\ \dot{x}_i = -\mu_i \left(x_i - \sum_{j \in I_i} \alpha_{ji} x_j \right) + d_i \\ \quad \vdots \\ \dot{x}_N = -\mu_N \left(x_N - \sum_{j \in I_N} \alpha_{jN} x_j \right) + d_N \end{cases}, \tag{9}$$

So the equilibrium point of the operation mode is

$$x_0 = (I - A_o)^{-1} \cdot b_o, \tag{10}$$

where, A_O and b_O are matrices with appropriate dimensions.

If the equilibrium point is situated inside the operation region we can say that it is invariant: $x_O \in O$. Thus, one of the conditions on the design parameters for the existence of a resilience region is:

$$[0, \ldots, 0]^T \leq x_O \leq [\sigma_1, \ldots, \sigma_N]^T. \tag{11}$$

For all the initial states in the operation region, the trajectories of system dynamics remain inside the operation region and converge to x_O.

Similarly, the out-of-operation region has the dynamics:

$$\begin{cases} \dot{x}_1 = \lambda_1 (1 - x_1) \\ \quad \vdots \\ \dot{x}_i = \lambda_i (1 - x_i) \\ \quad \vdots \\ \dot{x}_N = \lambda_N (1 - x_N) \end{cases}. \tag{12}$$

If there is an equilibrium point,

$$x_{\overline{o}} = (I - A\overline{o})^{-1} \cdot b_{\overline{o}}, \tag{13}$$

it satisfies $x_{\overline{O}} \in \overline{O}$:

$$[\sigma_1, \ldots, \sigma_N]^T \leq x_{\overline{o}} \leq [1, \ldots, 1]^T. \tag{14}$$

Once the state of the system enters the out-of-operation mode, the system cannot recover to the operation region. The next Proposition demonstrates the existence of a resilience region.

Proposition 2. *Let there be a set R_m, which is RPI under the mth functioning mode of dynamics (2). Hence, the resilience region of the interconnected system given in (2) is described by:*

$$R = \bigcup_{m=1}^{2^N} R_m.$$

Proof. In the following, we propose a sketch of the proof. Consider a set R_{ms}, which represents the collection of all the sets where the system initial states reside to O through the corresponding dynamic equation of the *mth* functioning mode, after s time steps. Therefore, the RPI set under the *mth* functioning mode can be written as $R_m = \bigcup_{s=1}^{s_{max}} R_{ms}$, where s_{max} is the number of time steps for which the initial states in R_m converge to O. From Proposition 1, we have that O is invariant. This implies that the resilience region of the interconnected system (2) is given by:

$$R = \bigcup_{\substack{m=1 \\ s=1}}^{\substack{m=2^N \\ s=s_{max}}} R_{ms} = \bigcup_{m=1}^{2^N} R_m.$$

We denote the region outside the operation and out-of-operation regions as the failure-recovery

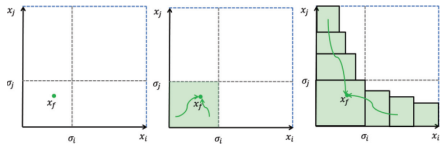

Figure 4. Steps for describing the resilience.

region. For initial states inside this region, they may converge either to the operation region or to the out-of-operation region in a finite time. We denote by reachable regions all those regions composed by the system initial states, which converge to the operation region in a finite time. Consequently, the overall resilience region is represented by the union of the operation region and the reachable regions. In other words, the resilience region is defined as the set of all initial states of the system that eventually will reside into the operation region in finite time (i.e. it is composed by the operation region itself plus the reachable regions situated within the failure-recovery region).

Figure 4 illustrates the steps for describing the resilience region.

Up to this point we can describe the resilience regions as they appear from the interdependencies relationships and the subsystems' characteristics. Indeed, the maximization of the system resilience region is the final design, operation and maintenance goal. We exemplify this by analyzing the response of the system as a function of its parameters, adding an element of control in the dynamics such that a supervisor can actively counteract failure modes and steer the overall system towards the operational functioning region.

4 EXAMPLE AND SIMULATION RESULTS

In this section, we consider a simple example of an interconnected system composed by two subsystems as in Figure 4. Given the methodological flavor of the work, the structure of the system is purposely chosen as simple as possible, in order to not add complexity to the study of the interdependencies among the subsystems and their dynamical behavior, aimed at characterizing the system resilience as a function of the design parameters. The interconnected system in Figure 4 could, for example, represent a system composed by a power supply system and a telecommunication system, whereby the components of the telecommunication system depend on the power supplied by the power supply system which, in turn, for its functioning makes use of the control and monitoring signals provided by the telecommunication system. A theoretical analysis of system resilience is performed and the results are collected into a Table which reports the parameters values of different scenarios of system evolution.

Consider each subsystem in Figure 5 described by the dynamic equation given in (2). There are four operation modes for the interconnected system, in which the dynamics is represented by the following equations:

Operation mode, where $x(t) \in O := [0, \sigma_1] \times [0, \sigma_2]$:

$$\begin{cases} \dot{x}_1(t) = -\mu_1(x_1(t) - \alpha_{21}x_2(t)) + d_1 \\ \dot{x}_2(t) = -\mu_2(x_2(t) - \alpha_{12}x_1(t)) + d_2 \end{cases}; \tag{15}$$

Failure-recovery mode 1, where $x(t) \in R_1 := [0, \sigma_1] \times [\sigma_{2,1}]$:

$$\begin{cases} \dot{x}_1(t) = \lambda_1(1 - x_1(t)) \\ \dot{x}_2(t) = -\mu_2(x_2(t) - \alpha_{12}x_1(t)) \end{cases}; \tag{16}$$

Failure-recovery mode 2, where $x(t) \in R_2 := [\sigma_{1,1}] \times [0, \sigma_2]$:

$$\begin{cases} \dot{x}_1(t) = -\mu_1(x_1(t) - \alpha_{21}x_2(t)) \\ \dot{x}_2(t) = \lambda_2(1 - x_1(t)) \end{cases}; \tag{17}$$

Out-of-operation mode, where $x(t) \in \bar{O} := [\sigma_{1,1}] \times [\sigma_2, 1]$:

$$\begin{cases} \dot{x}_1(t) = \lambda_1(1 - x_2(t)) \\ \dot{x}_2(t) = \lambda_2(1 - x_1(t)) \end{cases}. \tag{18}$$

Following the procedure described in Section III, the equilibrium states for the operation mode and the out-of-operation mode are identified:

$$x_o = \left[\frac{\mu_2 d_1 + \alpha_{21}\mu_1 d_2}{(1 - \alpha_{12}\alpha_{21})\mu_1\mu_2} \; \frac{\mu_1 d_2 + \alpha_{12}\mu_2 d_1}{(1 - \alpha_{12}\alpha_{21})\mu_1\mu_2} \right]^T$$

and $x_{\bar{O}} = [1\,1]^T$.

According to Proposition 1, if x_O is inside the operation region, there exists an invariant set and the equilibrium point locus is the location where all the states in the invariant set will converge. In this case, the invariant set is the operation region itself.

A similar result is found for the out-of operation region, which is also an invariant set with the

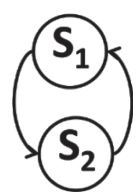

Figure 5. Interconnected system composed by two subsystems.

equilibrium point (1,1) being the attractor in this region.

The conditions for the equilibrium point to be inside the operation region are the following:

$$\begin{cases} 0 \le \dfrac{\mu_2 d_1 + \alpha_{21}\mu_1 d_2}{(1-\alpha_{12}\alpha_{21})\mu_1\mu_2} \le \sigma_1 \\ 0 \le \dfrac{\mu_1 d_2 + \alpha_{12}\mu_2 d_1}{(1-\alpha_{12}\alpha_{21})\mu_1\mu_2} \le \sigma_2 \end{cases}. \tag{19}$$

In order to analyze the intrinsic characteristics of the equilibrium point, we simplify by neglecting the logical interdependencies between the subsystems, i.e., $\alpha_{12} = \alpha_{21} = 0$. In this case, the above conditions become:

$$\begin{cases} 0 \le \dfrac{d_1}{\mu_1} \le \sigma_1 \\ 0 \le \dfrac{d_2}{\mu_2} \le \sigma_2 \end{cases}. \tag{20}$$

Replacing relation (7) in the above equations, we obtain:

$$\begin{cases} TTR_1 \le -\dfrac{\log(\sigma_1)}{d_1}\sigma_1 \\ TTR_2 \le -\dfrac{\log(\sigma_2)}{d_2}\sigma_2 \end{cases}. \tag{21}$$

This allows highlighting directly the dependence of the time to recovery from the threshold and disturbance values (Fig. 6).

If we fix the disturbance d, we can observe the invariance of TTR with the threshold: in the space of parameters (see Fig. 5), the time to recovery reaches its maximal value when the threshold is around 0.36.

The next step is the computation of the resilience regions within the two failure-recovery regions, as described in Section III.

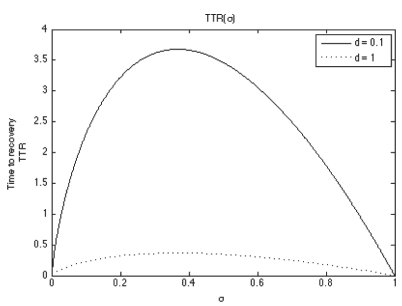

Figure 6. TTR (σ) with fixed disturbance.

Once the states x_1, x_2 enter the out-of-operation region $\bar{O}$ at a certain finite time, the system cannot recover back to the operation region O. But in the two failure-recovery regions R_1 and R_2, it is possible for the system to return to the operation region.

To find the specific resilience region, we compute a resilience curve to separate the end-to-failure and end-to-recovery parts in the failure-recovery region. The situation in R_1 is considered first, whose dynamic equations are (the coupling factors are neglected at first):

$$\begin{cases} \dot{x}_1(t) = -\lambda_1(1 - x_1(t)) \\ \dot{x}_2(t) = -\mu_2 x_2(t) \end{cases}. \tag{22}$$

After integration, we obtain:

$$\begin{cases} x_1(t) = 1 + (x_1(0) - 1)e^{-\lambda_1 t} \\ x_2(t) = x_2(0)e^{-\mu_2 t} \end{cases}. \tag{23}$$

From the equations above, we observe that state x_1 tends to diverge to 1 whereas state x_2 converges exponentially to 0. Therefore, there exists a set of states $M \in R_1$ which pass the point (σ_1, σ_2) at a certain time $t = T$. The set M is represented by the following state equations, with initial conditions $x_1(0)$ and $x_2(0)$:

$$\begin{cases} x_1(T) = 1 + (x_1(0) - 1)e^{-\lambda_1 T} = \sigma_1 \\ x_2(T) = x_2(0)e^{-\mu_2 T} = \sigma_2 \end{cases}. \tag{24}$$

The set of the initial states which pass the point (σ_1, σ_2) at time T is the curve described by:

$$x_1(0) = 1 + (\sigma_1 - 1)\left(\frac{x_2(0)}{\sigma_2}\right)^{\frac{\lambda_1}{\mu_2}}, \tag{25}$$

where $x_1(0) \in [0, \sigma_1]$ and $x_2(0) \in [\sigma_2, 1]$.

In R_2 where the failure is generated in S_1, the set of initial states who pass the point (σ_1, σ_2) can be identified similarly, and we have the curve:

$$x_2(0) = 1 + (\sigma_2 - 1)\left(\frac{x_1(0)}{\sigma_1}\right)^{\frac{\lambda_2}{\mu_1}}, \tag{26}$$

where $x_1(0) \in [\sigma_1, 1]$ and $x_2(0) \in [0, \sigma_2]$.

Figure 7 illustrates the resilience curves, which separate the resilience regions from the non-resilience regions within the failure-recovery region, as described by the equations (25) and (26).

When the design parameters are outside the bounds imposed by conditions (19), the system will not recover i.e., the state trajectories will always

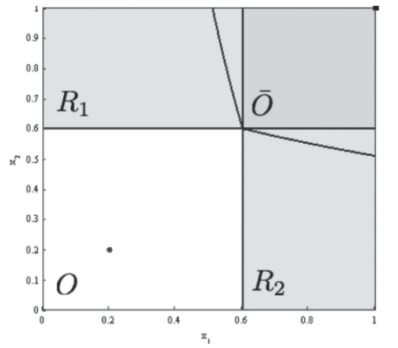

Figure 7. Four operation regions and the curves separating the resilience region and non-resilience region.

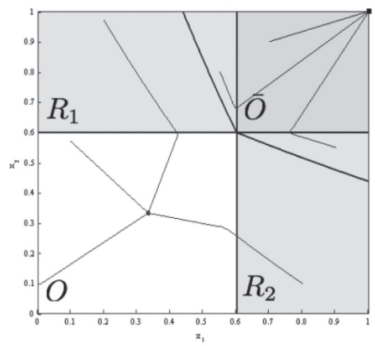

Figure 8. Resilience curve and system trajectories with different initial conditions.

converge to the (1,1) equilibrium point outside the (white) operation region as in Figure 8.

Figure 8 depicts several state trajectories for different initial conditions of the system. We observe that as long as the equilibrium point (denoted as the black dot) is inside the operation region (denoted in white) the system trajectories reside at all times in the resilience region. This means that for the design parameters fulfilling conditions (19) the system will always recover from unexpected event.

The equilibrium point locus is another important aspect for the system resilience. For example, if the equilibrium point of the operation mode resides in the failure-recovery region, we can observe a chattering behavior like the one shown in Figure 9.

Similarly with the previous case, we can determine some conditions on the model parameters such that we can a priori identify the chattering behavior:

In R_1: = $[\sigma_1, 1] \times [0, \sigma_2]$

If the equilibrium point is located in the resilience region of R_1, then:

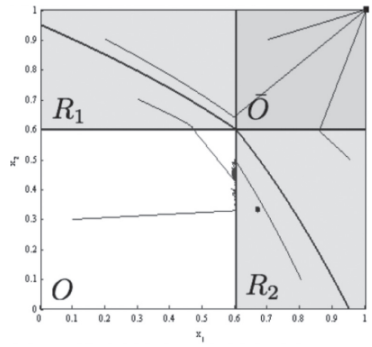

Figure 9. Chattering behavior for the system trajectories with different initial conditions.

Table 1. Parameters values.

Parameters	Resilience scenario	Chattering scenario 1	Chattering scenario 2
σ_1	0.6	0.6	0.6
σ_2	0.7	0.7	0.7
d_1	0.3	0.3	0.3
d_2	0.4	0.4	0.4
λ_1	0.1	0.1	0.1
λ_2	0.2	0.2	0.2
μ_1	[0.5,1]	0.7	[0.49,1]
μ_2	[0.57,1]	[0.55,1]	0.8

$$\begin{cases} x_{f_1} = \dfrac{d_1}{\mu_1} \\ x_{f_2} = \dfrac{d_2}{\mu_2} \end{cases}. \tag{27}$$

Then, we get the inequalities:

$$\begin{cases} 0 \le \dfrac{d_1}{\mu_1} \le 1 + (\sigma_1 - 1)\left(\dfrac{d_2}{\sigma_2 \mu_2}\right)^{\frac{\lambda_1}{\mu_2}} \\ \sigma_2 < \dfrac{d_2}{\mu_2} \le 1 \end{cases}. \tag{28}$$

In R_2: = $[\sigma_1, 1] \times [0, \sigma_2]$
We get similar results:

$$\begin{cases} \sigma_1 < \dfrac{d_1}{\mu_1} \le 1 \\ 0 \le \dfrac{d_2}{\mu_2} \le 1 + (\sigma_2 - 1)\left(\dfrac{d_1}{\sigma_1 \mu_1}\right)^{\frac{\lambda_2}{\mu_1}} \end{cases}. \tag{29}$$

The conditions (20), (28), (29) allow steering the parameters values in a way to get different scenarios of system evolution, as in Table 1.

The resilience scenario and the chattering scenario are those observed in Figures 7 and 8. To eliminate the chattering behavior, a control law can be added into the model of the interconnected system. Further work will be devoted in the future to the design of control strategies aimed at system chattering behavior elimination.

5 CONCLUSION

This paper adopts a set-theory framework for the resilience analysis of interconnected infrastructure systems. A detailed description of the system dynamics modeling is provided and invariance properties are analyzed to define and identify the resilience region, as a function of the governing parameters. This allows controlling the characteristics of the system resilience properties by design, operation and maintenance properties as represented by the values of the related parameters. An illustration of the analytical power of the framework adopted is provided on an interconnected interconnected system case study, with detailed discussions of its behavior and response to failures and/or disturbances, based on simulation results.

A brief note on the ratio of the rectilinear and shortest distance between two arbitrary points on the 3-sphere

M.A. Odijk
Gouda, The Netherlands

P.H.A.J.M. van Gelder
Delft University of Technology, Delft, The Netherlands

ABSTRACT: In Odijk and Van Gelder (2013) we considered the length of rectilinear paths between arbitrary points on the plane, which we refer to as Flatland, relative to their straight line distance. We refer to this entity as the diversion ratio. In this note we discuss the extension of this concept to the surface of the 3-dimensional sphere, which we refer to as Planet Earth, and to the skewed case, i.e. orientations are not orthogonal, but angled instead. Considering arbitrary points, the diversion ratios become stochastic by nature. The main point of this paper is to relate the mean (skewed) diversion ratios in Flatland and on Planet Earth.

1 INTRODUCTION

In flat cultivated landscapes it is often not possible to walk in a straight line from one point to another point. Instead, paths are more or less rectilinear. Think for example of urban environments or rectangular patches of farmland, where transportation routes or pipeline infrastructure often must follow public roads. Let ρ be the length of such diversion connecting two arbitrary points relative to their straight line distance. Below we refer to this ratio as the diversion ratio. For a random variable X we denote with $\mu(X)$ its mean.

Without loss of generality we fix one of both arbitrary points and call it the origin. Then, if $x \in R^2$, with $\rho(x)$ we denote the length of the diversion that must be undertaken to move from the origin to x relative to moving in a straight line. Formally, let $L_p(x)$ be the well-known p-norm of $x = (x_1, x_2)$, i.e. $L_p(x) = (x_1^p + x_2^p)^{1/p}$, then $\rho(x) = L_1(x)/L_2(x)$. As $\rho(\alpha x) = \rho(x)$ for all $\alpha \neq 0$, we restrict ourselves to $x \in B_2$ without loss of generality, where B_2 is the boundary of the unit circle. We model arbitrariness by stipulating that x is uniformly distributed on B_2, denoted by $x \sim U(B_2)$. Hence, $\rho = \rho(X)$, where $X \sim U(B_2)$. This note extends the work by Odijk and Van Gelder (2013) in which the k-th moment and asymptotics of ρ has been investigated. In Section 2 of this note we briefly discuss the comparison between the mean value of ρ and of ρ_γ, being the diversion ratio in case the landscape is not exactly rectilinear, but skewed with angle γ instead. That is, the north-south orientation makes an angle $\gamma \in (0, \pi/2]$ with the east-west orientation. We refer to this as skewness or the skewed diversion ratio.

As over long distances the curvature of the earth influences the (skewed) diversion ratio, we discuss in Sections 3 and 4 the 3-dimensional analogues τ and τ_γ of ρ and ρ_γ.

Referring to the flat situation as Flatland, after Abott's Flatland—A romance of many dimensions from 1884 [Lindgren 2010], and to the curved situation as Planet Earth, in Section 5 we arrive at our main point we would like to make with this paper. That is we relate mean (skewed) diversion ratios in Flatland and on Planet Earth.

2 FLATLAND

Trivially, using symmetries, we have

$$\mu(\rho) = \frac{1}{2\pi}\int_0^{2\pi} |\sin(\varphi)| + |\cos(\varphi)| d\varphi = \frac{4}{\pi}\int_0^{\pi/4} \sin(\varphi) + \cos(\varphi) d\varphi = \frac{4}{\pi} \quad (1)$$

To study the skewed case, let $0 < \gamma \leq \pi/2$, and consider the basis $\{(1,0),(\cos(\gamma),\sin(\gamma))\}$ of R^2, having basis transformation matrix

$$D = \begin{pmatrix} 1 & \cos(\gamma) \\ 0 & \sin(\gamma) \end{pmatrix}^{-1} = \frac{1}{\sin(\gamma)} \begin{pmatrix} \sin(\gamma) & -\cos(\gamma) \\ 0 & 1 \end{pmatrix} \quad (2)$$

Then,

$$\mu(\rho_\gamma) = \frac{1}{2\pi\sin(\gamma)} \int_0^{2\pi} \begin{matrix} |\sin(\gamma)\cos(\varphi) - \cos(\gamma)\sin(\varphi)| \\ + |\sin(\varphi)| \, d\varphi \end{matrix}$$

$$= \frac{4}{\pi\sin(\gamma)} = \frac{\mu(\rho)}{\sin(\gamma)} \quad (3)$$

For more details and extensions, we refer to Odijk and Van Gelder (2013).

3 PLANET EARTH (SPHERICAL GEOMETRY)

In practice, Flatland approximates Planet Earth's curvature locally sufficiently accurate. Still, we could raise the question what happens with ρ and ρ_γ if we consider distances between points on Planet Earth that are so far apart that curvature does play a role.

Assume Planet Earth is a perfect sphere and let $(\phi_1, \phi_2) = (0,0$ be the spherical coordinates of the origin of Planet Earth's surface, where $\phi_1 \in [0, 2\pi]$ is the latitude ($\phi_1 = 0$ marking the Prime Meridian crossing Greenwich) and $\phi_2 \in [-\pi/2, \pi/2]$ the longitude ($\phi_2 = 0$ being the equator). Below we assume without loss of generality that $(\phi_1, \phi_2) \in [0, \pi] \times [0, \pi/2]$, i.e. (ϕ_1, ϕ_2) lies on the intersection Q of the northern and eastern hemispheres. Below assume without loss of generality that Planet Earth has radius 1.

Consider the spherical rectilinear distance between $(0,0)$ and (ϕ_1, ϕ_2) , i.e. the length of a connecting path running eastward over parallel arcs and heading north over meridian arcs. In contrast to Flatland, it matters how the path is organised. For example, the path $(0,0) \to (0, \phi_2) \to (\phi_1, \phi_2)$, i.e. first moving north and from there continuing east, has length $L_1^{\min}(\phi_1, \phi_2) = \phi_1 \cos(\phi_2) + \phi_2$, whereas the path $(0,0) \to (\phi_1, 0) \to (\phi_1, \phi_2)$, i.e. first moving east and from there continuing north, has length $L_1^{\max}(\phi_1, \phi_2) = \phi_1 + \phi_2$, which is longer. $L_1^{\min}(\phi_1, \phi_2)$ and $L_1^{\max}(\phi_1, \phi_2)$ are Flatland's analogue of the 1-norm. The superscripts min and max denote that these are the shortest and longest spherically rectilinear paths between $(0,0)$ and (ϕ_1, ϕ_2). That is, for just any path p between the origin and (ϕ_1, ϕ_2) consisting of an alternating chain of pieces of meridian arcs and pieces of parallel arcs, it is not difficult to see that its length is bounded by $L_1^{\min}(\phi_1, \phi_2)$ and $L_1^{\max}(\phi_1, \phi_2)$.

Let $\Delta(\phi_1, \phi_2) = \arccos(\cos(\phi_1)\cos(\phi_2))$ be the great circle distance between $(0,0)$ and (ϕ_1, ϕ_2), the spherical analogue of Flatland's 2-norm.

For $(\varphi_1, \varphi_2) \neq (0,0)$, let

$$\tau^{\min}(\phi_1, \phi_2) = \frac{L_1^{\min}(\phi_1, \phi_2)}{\Delta(\phi_1, \phi_2)} \quad (4)$$

and

$$\tau^{\max}(\phi_1, \phi_2) = \frac{L_1^{\max}(\phi_1, \phi_2)}{\Delta(\phi_1, \phi_2)} \quad (5)$$

be the spherical analogues of $\rho(x)$, $x \in B$. We set $\tau^{\min}(0,0) = \tau^{\max}(0,0) = 1$, which makes sense given the meaning of $\tau^{\min}(\phi_1, \phi_2)$ and $\tau^{\max}(\phi_1, \phi_2)$.

Note that $\tau^{\min}(\phi_1, \phi_2)$ and $\tau^{\max}(\phi_1, \phi_2)$ are discontinuous at $(0,0)$. To see this note that $\tau^{\min}(\phi_1, 0) = \tau^{\min}(0, \phi_2) = 1$ and that (apply l'Hopital's rule)

$$\lim_{\varphi \downarrow 0} \tau^{\min}(\varphi, \varphi) = \frac{\lim_{\varphi \downarrow 0} \cos(\varphi) - \varphi\sin(\varphi) + 1}{\lim_{\varphi \downarrow 0} 2\sin(\varphi)\cos(\varphi) \Big/ \sqrt{1 - \cos^4(\varphi)}}$$

$$= \frac{2}{\lim_{\varphi \downarrow 0} 2\cos(\varphi) \Big/ \sqrt{1 + \cos^2(\varphi)}} = \sqrt{2} \quad (6)$$

For $\tau^{\max}(\phi_1, \phi_2)$ a similar reasoning holds true.

Also, $\tau^{\max}(\phi_1, \phi_2)$ is not well defined for $\phi_2 = \pi/2$. To see this, note that this is the north pole and that $\tau^{\max}(\phi_1, \phi_2)$ is discontinuous at this point as all points $(\phi_1, \pi/2)$ map on it and $\tau^{\max}(\phi_1, \phi_2) \to 1 + 2\phi_1/\pi$ ($\phi_2 \uparrow \pi/2$). So close to the north pole, $\tau^{\max}(\phi_1, \phi_2)$ varies between 1 and 3, depending on ϕ_1. Since the point $(0, \pi/2)$ can be reached directly from the origin over a meridian, it makes sense to define $\tau^{\max}(\phi_1, \pi/2) = 1$ for all ϕ_1. To see that 3 is also the supremum of $\tau^{\max}(\phi_1, \phi_2)$, first note that on the boundaries we have $\tau^{\max}(0, \phi_2) = 1$, $\tau^{\max}(\phi_1, 0) = 1$, and $\tau^{\max}(\pi, \phi_2) = (\pi + \phi_2)/(\pi - \phi_2) \uparrow 3$ ($\phi_2 \uparrow \pi/2$). As to the interior, consider the first order condition

$$\Delta^2(\phi_1, \phi_2) \frac{\partial \tau^{\max}(\phi_1, \phi_2)}{\partial \phi_1}$$

$$= \Delta(\phi_1, \phi_2) - \frac{(\phi_1 + \varphi_2)\cos(\phi_2)\sin(\phi_1)}{\sqrt{1 - \cos^2(\phi_1)\cos^2(\phi_2)}} = 0$$

$$\Delta^2(\phi_1, \phi_2) \frac{\partial \tau^{\max}(\phi_1, \phi_2)}{\partial \phi_1}$$

$$= \Delta(\phi_1, \phi_2) - \frac{(\phi_1 + \phi_2)\cos(\phi_1)\sin(\phi_2)}{\sqrt{1 - \cos^2(\phi_1)\cos^2(\phi_2)}} = 0 \quad (7)$$

implying that local maxima on the interior of the domain of $\tau^{\max}(\phi_1,\phi_2)$ are necessarily on the line $\phi_1=\phi_2$. However, on the interior

$$\tau^{\max}(\varphi_1,\varphi_1)=\frac{2\varphi_1}{\arccos(\cos^2(\varphi_1))}<\frac{2\varphi_1}{\arccos(\cos(\varphi_1))}=2 \tag{8}$$

Therefore, we conclude that 3 is the supremum of $\tau^{\max}(\phi_1,\phi_2)$.

Finally, for $x\in Q$, let $(\phi_1(x),\phi_2(x))\in[0,\pi]\times[0,\pi/2]$ be its pole coordinates and define $\tau^{\min}=\tau^{\min}(\phi_1(X),\phi_2(X))$ and $\tau^{\max}=\tau^{\max}(\phi_1(X),\phi_2(X))$, where $X\sim U(Q)$ i.e. we randomise $\tau^{\min}$ and $\tau^{\max}$. Numerically we find $\mu(\tau^{\min})\approx 1.168$ and $\mu(\tau^{\max})\approx 1.365$. As $\mu(\rho)\approx 1.273$, we see that, loosely speaking, on average the curvature of the sphere causes the diversion ratio to deviate about 8% from the Flatland situation.

4 THE SKEWED CASE ON PLANET EARTH

Next, like in Flatland, assume the situation in which the rectilinear paths are skewed with parameter γ, where γ is the angle between the equator and the path as it starts in the origin. So, we consider paths starting in the origin, "climbing" with slope γ to the ϕ_2-parallel (below called the skewed section of the path), and then proceed over this parallel to the ϕ_1-meridian either clockwise or anti-clockwise, whichever route is shortest (below called the parallel section of the path). Like in Section 3, this is the shortest path of this kind. By moving first over the equator and starting the climb up north after that, the longest path of this kind is defined. Below we refer to these extreme variants as the shortest and longest paths.

Below we exclude throughout the cases $\gamma=0$ and $\phi_2=\pi/2$, representing situations in which the skewed path has infinite length. Whereas in Flatland it suffices to consider the northeastern part Q of Planet Earth, in the skewed case we need to consider the entire northern hemisphere H i.e. below $(\phi_1,\phi_2)\in[0,2\pi]\times[0,\pi/2]$.

As the skewed section is a loxodrome, i.e. a path over Planet Earth under constant compass direction, it is well known that the length of this section equals $\phi_2/\sin(\gamma)$. As to the length of the parallel section, consider the mercator projection of Planet Earth. It is well known that on this projection the projected distance of the ϕ_2-parallel to the equator equals $gd^{-1}(\phi_2)=\ln(\tan(\pi/4+\phi_2/2))$, where gd^{-1} is the inverse gudermannian or lambertian. Also, it is well known that the mercator projection is a conformal mapping of Planet Earth's surface, i.e. it preserves angles, and that it also preserves distances on the equator. Hence, in case of the shortest path the skewed section ends on the $gd^{-1}(\phi_2)/\tan(\gamma)$-meridian. So, the length $x_\gamma^{\min}(\phi_1,\phi_2)$ of the parallel section is equal to the shortest distance over the ϕ_2-parallel between the ϕ_1-meridian and the $gd^{-1}(\phi_2)/\tan(\gamma)$-meridian, i.e.

$$\begin{aligned}x_\gamma^{\min}(\varphi_1,\varphi_2)&\\ =\cos(\varphi_2)\min\{z_\gamma(\varphi_1,\varphi_2),2\pi-z_\gamma(\varphi_1,\varphi_2)\}&\end{aligned} \tag{9}$$

with

$$z_\gamma(\phi_1,\phi_2)=(\phi_1-gd^{-1}(\phi_2)/\tan(\gamma))\bmod(2\pi) \tag{10}$$

In case of the longest path, it is not difficult to see that, likewise

$$\begin{aligned}x_\gamma^{\max}(\phi_1,\phi_2)&=\min\{z_\gamma(\phi_1,\phi_2),2\pi-z_\gamma(\phi_1,\phi_2)\}\\&=x_\gamma^{\min}(\phi_1,\phi_2)/\cos(\phi_2)\end{aligned} \tag{11}$$

Then the shortest and longest skewed rectilinear distances between the origin and (ϕ_1,ϕ_2) read

$$L_1^{\gamma,\min}(\phi_1,\phi_2)=\frac{\phi_2}{\sin(\gamma)}+x_\gamma^{\min}(\phi_1,\phi_2) \tag{12}$$

and

$$L_1^{\gamma,\max}(\phi_1,\phi_2)=\frac{\phi_2}{\sin(\gamma)}+x_\gamma^{\max}(\phi_1,\phi_2) \tag{13}$$

so that for $(\varphi_1,\varphi_2)\neq(0,0)$ and $\varphi_2\neq\pi/2$ the shortest and longest skewed diversion ratios read

$$\tau_\gamma^{\min}(\phi_1,\phi_2)=\frac{L_{\gamma,1}^{\min}(\phi_1,\phi_2)}{\Delta(\phi_1,\phi_2)} \tag{14}$$

and

$$\tau_\gamma^{\max}(\phi_1,\phi_2)=\frac{L_{\gamma,1}^{\max}(\phi_1,\phi_2)}{\Delta(\phi_1,\phi_2)} \tag{15}$$

Like in Flatland, for $x\in H$, let $(\phi_1(x),\phi_2(x))\in[0,2\pi]\times[0,\pi/2]$ be its pole coordinates and define

$$\tau_\gamma^{\min}=\tau_\gamma^{\min}(\phi_1(X),\phi_2(X)) \tag{16}$$

and

$$\tau_\gamma^{\max}=\tau_\gamma^{\max}(\phi_1(X),\phi_2(X)) \tag{17}$$

where $X\sim U(H)$, i.e. we randomise $\tau_\gamma^{\min}$ and $\tau_\gamma^{\max}$. Note that

$$\mu(\tau_\gamma^{\min})\sin(\gamma) \to \frac{1}{2\pi}\int_0^{\pi/2}\int_0^{2\pi}\frac{\varphi_2\cos(\varphi_2)}{\Delta(\varphi_1,\varphi_2)}d\varphi_1 d\varphi_2$$
$$= \frac{4\kappa}{\pi}(\gamma \downarrow 0) \tag{18}$$

with $\kappa \approx 0.344$ and, likewise, $\mu(\tau_\gamma^{\max})\sin(\gamma) \to 4\kappa/\pi(\gamma \downarrow 0)$.

5 RELATING FLATLAND AND PLANET EARTH

First of all, recall that in the above we concluded that, loosely speaking, in the non-skewed case on average the curvature of the sphere causes the diversion ratio to deviate about 8% from the Flatland situation. More precisely,

$$\frac{\mu(\tau^{\min})}{\mu(\rho)} \approx 91.75\% \tag{19}$$

and

$$\frac{\mu(\tau^{\max})}{\mu(\rho)} \approx 107.23\% \tag{20}$$

In the skewed case we see that for $\gamma \downarrow 0$

$$\frac{\mu(\tau_\gamma^{\min})}{\mu(\rho_\lambda)} \to \kappa \approx 34.4\% \tag{21}$$

and

$$\frac{\mu(\tau_\gamma^{\max})}{\mu(\rho_\lambda)} \to \kappa \approx 34.4\% \tag{22}$$

i.e. for small values of skewness, the ratio is about 34.4% independent of taking the shortest or longest path on Planet Earth or anything in between.

Secondly, in Section 2 we derived $\mu(\rho_\gamma) = 4/\pi\sin(\gamma)$ for fixed γ. However, in landscapes where the level of skewness differs regionally, it makes sense to randomise γ as well, when considering the mean diversion ratio. To this end, for $0 < \varepsilon < \pi/2$ define $\rho_\varepsilon^{U(\gamma)} = \rho_\gamma$, where $\gamma \sim U[\varepsilon, \pi - \varepsilon]$. As to its mean, we can calculate

$$\mu(\rho_\varepsilon^{U(\gamma)}) = \frac{1}{\pi - 2\varepsilon}\int_\varepsilon^{\pi-\varepsilon}\mu(\rho_\gamma)dy$$
$$= \frac{4}{\pi}\frac{\ln(\tan(\pi/2 - \varepsilon/2))}{\pi/2 - \varepsilon}$$
$$= \mu(\rho)\frac{gd^{-1}(\pi/2 - \varepsilon)}{\pi/2 - \varepsilon} \tag{23}$$

Recalling that $\delta_\varepsilon^{mercator} = gd^{-1}(\pi/2 - \varepsilon)$ is the mercator projection the projected distance of the equator to the $(\pi/2 - \varepsilon)$-parallel and that $\delta_\varepsilon^{true} = \pi/2 - \varepsilon$ is the true distance from the equator to the $(\pi/2 - \varepsilon)$-parallel, we see that

$$\frac{\mu(\rho_\varepsilon^{U(\gamma)})}{\mu(\rho)} = \frac{\delta_\varepsilon^{mercator}}{\delta_\varepsilon^{true}} \tag{24}$$

Finally, let $\eta(\gamma)$ be the pole-to-pole distance on Planet Earth along a path with skewness γ. As this path is a loxodrome, its distance measures $\eta(\gamma) = \pi/\sin\gamma$. Also, let $\zeta = \Delta(\pi, 0) = \pi$ be the great circle distance between the poles. Then

$$\frac{\mu(\rho_\gamma)}{\mu(\rho)} = \frac{4/(\pi\sin(\gamma))}{4/\pi} = \frac{\eta(\gamma)}{\zeta} \tag{25}$$

ABSTRACT: In this paper we present a model to allocate security resources within a chemical supply chain which is characterized by the use of different transportation modes, each having their own security features. We consider security-related risks so asto take measures against terrorist acts which could target critical transportation systems. The idea of addressing security-related issues, by supporting decisions for preventing or mitigating intentional acts on transportation infrastructure, has gainedattention in academic research only recently. The decision model presented in this paper is based on game theory. The **M**ult**I**-modal **S**ecurity-**TRA**nsportation mode**L**, that we named *MISTRAL* for short, can be employed to organize intelligence capabilities aimed at securing chemical supply chains. It enables detection and warning against impending attacks on transportation infrastructures and the subsequent adoption of security countermeasures. This is of extreme importance for preventing terrorist attacks and for avoiding (possibly huge) human and economic losses.

Keywords: multi-modal transportation; security risk analysis; game-theory; multi-attribute utility

1 INTRODUCTION

Daily shipments of dangerous goods are critical to global economies. However, these transportation activities involve a variety of security risks. In case of incidents, dangerous freights would obviously attract the attention of the general public, policy-makers and industrialists. Therefore, both for the responsible government and the private authorities, it is essential to efficiently secure these hazardous transports. Since a lot of stakeholders are involved in a chemical supply chain, it is not easy to adequately and efficiently securing it. Moreover, while the *unintentional accident* likelihood depends on (relatively) well-known parameters such as maintenance of infrastructure, speed characteristics and the presence of junctions, the *intentional accident* likelihood relates to much less known factors such as vulnerabilities, consequences, and intentions.

One of the key factors of the chemical supply chain is multi modality; i.e., the use of different transport modes, each having their own characteristics with respect to economic and environmental parameters, as well as characterized with safety and security mode-specific features. Multi-modal transportation indeed is very important and it is widely adopted in the chemical industry to transport goods, using e.g. road, railway, barges, ships, and pipelines combined together. A variety of companies are active usually within one of the available transport modi; and rarely they operate within several of the modi at the same time. Nonetheless, by transporting chemical products employing different modes, the chemical industry and its Logistics Service Providerscan probably greatly improve their security scores.

Allocating security resources is essential on both intra- and inter-modal levels. On an intra-modal dimension, the authorities or the companies responsible for the transport have to decide on which transportation routes, belonging to the same mode, available between point A and point B, security measures have to be taken. This decision regarding security resources allocations should take into account all existing and feasible uni-modal transportation routes between A and B and it should be repeated for every dangerous freight the authorities or the companies wish to investigate. On an inter-modal dimension, the different available modi for transporting a certain hazardous cargo between A and B should be investigated and security resources need to be allocated

between the different modi, which forms an extra complexity to the uni-modal security resources allocation problem. Since multi-modal planning is even more difficult than uni-modal planning an even stronger need for support by a mathematical model is present in the multi-modal case.

Three research lines are present in scientific literature regarding the development of safety decision support software in order to transport dangerous freights: (i) safety-related risk assessment software packages; (ii) route selection and vehicle scheduling software packages; and (iii) hazardous materials network design software. Note that these software packages that deal with *safety*-related transport problems are designed to guide uni-modal decisions. Among them, it is worth mentioning probabilistic tools, GIS-based tools, tools ensuring an equitable distribution of risk, tools based on the iterative application of minimum path algorithms, tools based on the generation of minimum paths, tools based on multi-objective algorithms, bi-levels programming tools (taking into account two distinct decision-makers: the government and transport companies), and tools based on heuristic algorithms.

However, the idea of developing such software packages addressing security-related issues and specifically aiming them at supporting decisions for preventing or mitigating intentional designed malicious acts on transportation infrastructure, has only very recently gained attention in the academic world.

We are aware that various conceptualisations and software packages (GIS-based or not) for dangerous freight risk assessments capturing one or several of the transport modes, have been elaborated and are explained in literature. However, as mentioned before, these software applications are aimed at safety related (nonintentional) risks and they could not be used for taking measures against intentional (terrorist) acts. In fact, to our knowledge, at present there is no model for the transportation of dangerous substances available for governmental or industrial decision makers, which is based on a multi-attribute terrorist utility and which provides recommendations on where to optimally allocate security measures and resources in a multi-modal chemical transportation network. This paper elaborates such a model and uses game theory to do so.

2 RELATED SECURITY PROBLEMS AND RESEARCH QUESTIONS

Since the terrorist attacks on 11 September 2001, game theory has been increasingly employed as a mathematical tool to deal with security decisions facing with adaptive adversaries. In particular, recent literature includes Bier et al. (2008); Dighe et al. (2009); Guikema and Aven (2010) and Zhuang et al. (2010). More specifically, gaining insights into the nature of optimal defensive investments which yield the best trade-off between investment costs and critical infrastructure security was also already subject of an important amount of scientific research, e.g., Gao et al. (2013b); Golany et al. (2009); Hausken and Levitin (2009); Hausken and Zhuang (2013); Merrick and Parnell (2011); Reniers (2010); Roy and Jomon Aliyas (2013). In order to have more details about these methods the reader is referred to an extensive survey made by Sandler and Siqueira (2009).

However, to date, no concrete attention has been paid to decision problems arising in the allocation of security resources in a multi-modal transportation network. This is thus a research subject deserving much more attention from the academic world as well as from governmental authorities.

We agree with Cox (2009) that game theory and risk analysis are mutually reinforcing in order to obtain effective risk management recommendations for allocating security resources. In case of our multi-modal transportation problem, we choose to focus on the development of an attacker-defender model based on game theory. We consider a dynamic game with incomplete information in which the defender chooses how to allocate the security resources, and then an attacker chooses which target to attack according to a multi-attribute utility function. A model focusing on multi-modal transportations of dangerous goods should make the decision process of taking security countermeasures allocations in a complex transportation network more objective and (subsequently) more justified.

In the remainder of the paper we will refer to a *strategic game* as a model in which a set of decision makers interact with each others. In recognition of the interaction, we will use the term *players* to identify the decision makers.

The research questions of this paper therefore (i) include a ranking of transportation routes and modes where to allocate security countermeasures based on certain assumptions; and (ii) provide this ranking considering both inter—and intra-modal transports of hazardous goods.

In the next section the characteristics of a multi-modal supply chain are briefly mentioned and in Section 4 a one-period $\mathcal{MISTRAL}$ model is defined. The model has been used within a solution approach in order to simulate different realistic scenarios which might affect a chemical supply chain. Detailed results will be illustrated during the conference.

3 CHARACTERISTICS OF A MULTI-MODAL CHEMICAL SUPPLY CHAIN

Supply chains used to transport hazardous materials represent a viable target for terrorist groups mainly due to two factors:

1. the physical and chemical properties of the transported material may cause a malicious release which could potentially engender public injuries to a neighbouring population and/or environmental damages;
2. the critical importance of the products may determine the disruption of operations of the whole industry along the supply chain.

In general, terrorists' actions are targeted at critical infrastructures, suggesting that attackers select their targets for strategic reasons in order to maximize the consequences of the damages. The transported material and its operating conditions (e.g. pressure, temperature, density, volume) are both crucial to determine the criticality of the supply chain. In fact the possible scenarios (e.g. explosions, toxic cloud migrations, thermal radiation effects, toxic releases), that can arise after an attack, influence the level of criticality of a certain supply chain.

In our study, we focus on four real and tangible transportation modes which are commonly encountered within chemical supply chain: inland waterways ($i = 1$), road transport ($i = 2$), railway ($i = 3$), and pipeline ($i = 4$). Considering the system structure of the different transport modes, we assume that road ($i = 2$) and pipeline ($i = 4$) have a parallel structure, whereas inland waterways ($i = 1$) and railway ($i = 3$) have a serial structure[1].

It should be noted that by enlarging the set of available transportation modes the *MISTRAL* model could be generalized and extended to other supply chains which are used for non chemical products that might be a potential target for terrorists-attackers.

4 MISTRAL MODEL

In the *MISTRAL* model, here proposed, we consider that r_i routes for each mode i are present in a chemical supply chain as described in the previous section. Therefore, there are altogether $r_1 + r_2 + r_3 + r_4$ routes in the system. For route j in mode i, we let the government's defense level be d_{ij} and let the terrorist's attack level be A_{ij}, for $i = 1, \ldots, 4$ and $j = 1, \ldots, r_i$. The probability of damage conditional on an attack happening on each route is a function of d_{ij} and A_{ij}. In particular, we apply the common ratio form contest success function (Skaperdas (1996); Tullock (1980)), that is:

$$P_{ij}(A_{ij}, d_{ij}) = \frac{A_{ij}}{A_{ij} + \beta_i \cdot d_{ij}} \tag{1}$$

where β_i is the relative defense/attack effectiveness ratio for mode i. We assume that $\beta_1 > \beta_2 > \beta_3 > \beta_4$ (i.e., the inland waterways transports are easiest to defend while pipeline transports are most difficult to defend). Note that we have $\partial P_{ij}/\partial d_{ij} \leq 0$ and $\partial P_{ij}/\partial A_{ij} \geq 0$. We define $P_{ij}(0, d_{ij}) = 0 \ \forall d_{ij}$.

Assuming performance independence among routes $j = 1, \ldots, r_i$ within a mode i, the vulnerability Q_i associated to mode i is calculated as:

$$Q_i(A_i, d_i) = \begin{cases} \prod_{j=1}^{r_i} P_{ij}(A_{ij}, d_{ij}), & \text{if } i = 2,4 \\ 1 - \prod_{j=1}^{r_i} [1 - P_{ij}(A_{ij}, d_{ij})], & \text{if } i = 1,3 \end{cases} \tag{2}$$

where $A_i = (A_{i1}, \ldots, A_{ir_i})$ and $d_i = (d_{i1}, \ldots, d_{ir_i})$. Now we consider the valuation of route i, namely the expected loss conditional on a successful attack, v_i. We consider two types of losses (financial loss fi and human loss h_i) and use the following multi-attribute utility function:

$$v_i = f_i + c \cdot h_i \tag{3}$$

In formula (3) c represents a factor translating human loss into financial terms. Furthermore, we assume that $f_2 < f_4 < f_1 < f_3$ and $h_1 < h_4 < h_2 < h_3$; in other words, road transportation and inland waterways would lead to the lowest possible financial and human losses, respectively, and railway would lead to the highest financial and human losses. These are just some assumptions that we made without loss of generality which can be easily changed by the user of the *MISTRAL* model to fulfill the requirements of a specific chemical supply chain.

We assume that the government desires to maximize the total expected averted losses, subtracting the total defense costs, while the terrorist wants to maximize the total expected damage, subtracting the total attack costs. In other words, government and terrorist maximize their utilities $u(A,d)$ and $U(A,d)$, respectively as follows:

$$\max_d u(A,d) = \sum_{i=1}^{4} \left\{ v_i \cdot [1 - Q_i(A_i, d_i)] - b \cdot \sum_{j=1}^{n_i} d_{ij} \right\} \tag{4}$$

[1]We acknowledge that this assumption on system structure depends on the scope of the security study, but we believe that these assumptions are generally reasonable.

$$\max_{A} U(A,d) = \sum_{i=1}^{4} \left[v_i \cdot Q_i(A_i,d_i) - B \cdot \sum_{j=1}^{n_i} A_{ij} \right] \qquad (5)$$

In formulae (4)-(5) b and B are unit costs for defense and attacks, respectively and $A = (A_1 \ldots, A_4)$ and $d = (d_1, \ldots, d_4)$ represent a specific set of possible actions to be adopted by the attacker and the government respectively. In particular these actions are addressed to a specific transportation mode (e.g. $A_i = (A_{i1}, \ldots, A_{in_i})$ or $d_i = (d_{i1}, \ldots, d_{in_i})$) each containing j routes. In the remainder of the paper we will refer to A and d with the term text it *strategies* to denote a specific attack (for A) and defense (for d) actions. The quality of each strategy is measured by using the *utility functions*, mentioned before, which are able to capture and quantify players' preferences.

It should be noted that in the strategic game the players' payoffs have only a ordinal significance. For example, if a player has three available (attack or defense) strategies named a, b, and c for which the resulting payoff is respectively 1, 2, and 10, the only conclusion that it is possible to draw is that the player prefers c to b and b to a. In other words the values associated to the payoff in themselves do not imply that the player's preference between c and b is stronger than his preference between a and b (see e.g., Osborne (2003)).

Below we consider two possible sequences of moves: simultaneous-move and sequential move (where the defender is the first mover). Both sequences have been studied in literature by e.g., Gao et al. (2013a), Shan and Zhuang (2013) and Bakir (2011). If the defense is public information and terrorists know the defense allocation before making the attacking decisions, a sequential-move model should be used. Otherwise, if both players make decisions at the same time, or at least they do not know the other player's choice at the time that they make their own decisions, a simultaneous-move model should be used.

Definition 1. *We call a pair* (A^*, d^*) *an equilibrium for a simulataneous-move* $\mathcal{MISTRAL}$ *game if and only if* $A^* = \arg\max_A U(A, d^*)$ *and* $d^* = \arg\max_d u(A^*, d)$.

Definition 2. *We call a pair* (A^*, d^*) *an equilibrium for a sequential-move* $\mathcal{MISTRAL}$ *game (where the government is the first mover) if and only if* $A^* = \hat{A}^*$ *and* $d^* = \arg\max_d u(\hat{A}^*, d)$, *where the best response function* $\hat{A}^*$ *is defined as* $\hat{A}^* = \arg\max_A U(A,d)$.

5 CONCLUSIONS

In this work a model which can guarantee the security of a multi-modal transportation system facing adaptive adversaries has been presented. The model, named $\mathcal{MISTRAL}$, can be used by public and private organizations in order to establish the appropriate allocation of security countermeasures for each route belonging to a specific transportation mode within a chemical supply chain.

Using theorems and concepts borrowed from game theory the $\mathcal{MISTRAL}$ model can be solved by evaluating and analysing the utilities associated to the two players with different interests that are involved in the strategic game. On one side there is the government (or a public-private institution) who intends to protect a given critical infrastructure by allocating adequate security measures on both the inter-modal and intra-modal levels, and on the other side there is the attacker whose goal is to destroy a targeted supply chain. A methodological scheme to find the equilibrium, has been applied to a variety of illustrative examples that will be presented at the conference.

When no limitations or constraints on the defensive or attack strategies are applied, the solution of the $\mathcal{MISTRAL}$ game consists of an imitation of the opponent's strategy. In other words, by using intelligence services the government should try to anticipate the terrorists' moves and guarantee appropriate security levels, which could at least counterbalance the intensity levels of the attacks. This concept is applied to specific prevention mechanisms adopted by several nations, such as those based on a "terror alert level" scale (HSAC, 2009; UK Cabinet Office, 2006).

Possible applications of the $\mathcal{MISTRAL}$ model pertain to the anticipation of potential attacks to a targeted chemical supply chain and the limitation of the consequences of these attacks thanks to an appropriate evaluation of terrorist threats. Additionally, the $\mathcal{MISTRAL}$ model can lead to a better definition and allocation of the security countermeasures for both intra-modal and inter-modal levels.

Future research will be aimed at extending the current $\mathcal{MISTRAL}$ model to incorporate the case of repeated games. In so doing, it will be possible to simulate realistic scenarios in which continuous attacks are directed to the same supply chain, e.g. the repeated attacks performed on a specific critical pipeline infrastructure Talarico et al. (2014). Moreover, additional real-life constraints can be included in the model such as a limited budged for security (or for the attacks), criticality of the infrastructures constituting the whole supply chain and so forth. Additional information about the characteristics of the transported goods can be included in the model. As a matter of fact, the hazardousness of these materials can influence the consequences of a potential attack.

Assessment of the critical events sequences of systems by means of probabilistic languages

D. Ionescu, N. Brînzei & J.F. Pétin
CRAN, UMR 7039, Université de Lorraine, Vandœuvre-lès-Nancy, France
CNRS, CRAN, UMR 7039, Vandœuvre-lès-Nancy, France

ABSTRACT: In dependability studies of dynamic systems it is important to assess the probability of occurrence for the events sequences which describe the system evolution or which are critical for the mission of the system or for the humans and environment safety. In this paper we use the probabilistic languages framework in order to realize the quantitative assessment and we start by modeling the system as a finite state automaton. This is ulterior transformed in a probabilistic automaton using the embedded discrete Time Markov Chain. The determination of the languages afferents at each state of the automaton enable to calculate the probability of occurrence for every events sequence that can be subtract from these languages.

1 INTRODUCTION

Assessing the dependability of a critical system generally relies on Boolean models (Fault Trees models, Reliability block diagrams, etc.) for:

- qualitative analysis, such as the determination of the sets of component's failures that cause a critical or undesired system situation (it is defined as the *cut* set),
- quantitative analysis to evaluate the probabilities of undesired events or RAMS indicators, that can be based on the Sylvester-Poincaré Theorem or Binary Decision Diagrams technique (Dutuit & Rauzy 2005, Ibanez-Llano et al. 2010).

This paper explores the use of probabilistic languages introduced by (Garg et al. 1999) as a formal framework for qualitative/quantitative analyze of the event sequences. Before to describe the *probabilistic languages* concept, we will present some reasons that motivate the choice of *events sequences* in dependability studies.

Evaluation using *cut* analysis requires a full independence of the events involved in the *cut* set. However, this assumption cannot be stated in the case of dynamic reparable systems due to the order relationship between events occurrence:

- occurrence of event may depend on previous occurrence of other events; *e.g.* in the dynamic controlled systems event occurrence may be prohibited by its control according to a previous occurrence, or not, of some other events,
- impact of event sequence on the system failure may be different according to the scheduling of the event occurrence within the sequence; *e.g.* event e_1 followed by event e_2 leads to an undesired event while e_2 followed by e_1 has no impact.

In these cases, the value of the obtained probability, based on *cut-set* calculus, represents an overstatement of the real probability that is searched, corresponding no longer with the actual needs of dependability studies.

Moreover, the *cut*-based analysis approaches fit well to the non-reparable systems. However, in dynamic reliability context, it is necessary to take in consideration the changes between the different modes of functioning/failure or when the systems turns back into a functioning state after having passed in a failure state. In this case the systems must be considered like reparable and only dynamic models are able to capture system reconfigurations.

For all these reasons, the *cut-set* based analysis needs to be enriched by the determination and assessment of event sequences within the *cut-set*. This evolution justifies the use of state space models to capture the system dynamic and the impact of component's failures and reparation on the system state. Some approaches have been recently developed to determine the critical sequences of events and some basic properties such as minimality and consistency has been proposed for dynamic reparable system (Bouissou & Bon 2003, Chaux et al. 2013). However, these approaches are based on deterministic language theory and focus on the identification of a set of events sequences but present some limitations and divergences for

qualitative and quantitative assessment due to modeling and sequence calculus assumptions.

The paper is organized as follows. Section 2 presents the state of the art and highlights the current limitations of existing approaches for sequences assessment. Section 3 introduces the theoretical framework of the probabilistic languages (Garg et al. 1999) and the used notations. In section 4 is introduced the case study which is used like a support for the rest of the paper. Section 5 develops a theoretical framework based on probabilistic languages for quantitative assessment of events sequences. This proposed approach is illustrated using the case study in the section 6. Finally, section 7 presents the conclusions of this work and identifies some future research directions.

2 STATE OF THE ART

The existing approaches in quantitative assessment area can be classified in two categories:

- *Boolean models* where the failure of the system is expressed using the Boolean structure function;
- *state space models* where the system behavior is represented by states and transitions and his evolution is described by the associated language.

2.1 *Boolean models*

The most important Boolean models are: Event Trees and Fault Trees (classics/dynamics). *Event Trees* (Papazoglou 1998) are graphical models that can be discretized according to their possible effects or distinction in a series of simple events. In the same time *Event Trees* are adapted for modeling and assessment of the events sequences for non-reparable systems such as safety or protection systems. Instead, the reparable systems or instrumentation and control systems can not be modeled by *Event Trees*. *Fault Trees* are built according to an undesired event that is decomposed into basic events till this decomposition becomes impossible or judged useless (Dutuit & Rauzy 2005). These models are efficient for *cut*-based analysis but have limitations for *sequence*-based analysis because of the static point of view they consider.

2.2 *State space models*

The most currently used state space models in the context dependability studies are (Cassandras & Lafortune 2008): Finite State Automata and Language theory, Petri Nets and Markov chains. Other models can also be mentioned in the context of this paper. *Boolean logic Driven Markov Process* (*BDMP*) developed by Bouissou & Bon (2003) replaces the basic events of a fault tree with Markov chains; this combination introduces dynamic features to cover the order and impact of events occurrence. Events sequences are determined by exploration of the model starting with the initial state of the system (Bouissou 2006). *Stochastic Hybrid Automaton* is a stochastic temporized finite state automaton with embedded differential equations for each mode (Perez Castaneda et al. 2011); this model enables to determine sequences of events and their probabilities thanks to Monte-Carlo simulation, but it is not possible to obtain analytical solution.

All these models can be used, according to their deterministic or stochastic features for event sequences analysis (Bouissou & Bon 2003, Chaux et al. 2013) with two kinds of problem solving: *determination* and *probability assessment* of the event sequences.

For the determination problem, approaches based on the language theory are efficient to compute some event sequences leading to a given state. Calculus is possible only for coherent systems and helps to determine the minimal set of sequences aiming to reconstruct the whole failure language (Chaux et al. 2013). This approach does not allow quantitative assessment for the determined events sequences.

For the assessment of sequence probability, some limitations are encountered by the existing approaches:

- state space models such as Markov chains are efficient for determining a state probability. Consequently, a sequence needs to be assimilated to its final state that must be considered as an absorbing state. In this case, probability of this state represents the probability of the language reaching this state.
- the sequence probability calculus is based on the events occurrence probability; in existing approaches, the value of this probability remains the same whatever is the state from which the event occurs. However, in dynamic system, a given event may have different occurrence probability in different system states even if its meaning—failure or reparation of the component c_i—remains the same in all sequences.

Probabilistic Languages (Garg et al. 1999), that takes advantages from both languages theory and stochastic process theory, appears to be an interesting way towards a formal framework for the analysis of event critical sequences. The next section presents the theory foundation of the *probabilistic languages* concept.

3 PROBABILISTIC LANGUAGES FRAMEWORK

The theory of probabilistic languages was developed by Garg, Kumar & Marcus (1999) in order to model the stochastic Discrete Event Systems (DES) behavior.

To simplify the formal definition of the probabilistic language, a special event called "termination event", noted e_Δ, is used to represent the fact that the state of the system obtained after the occurrence of a sequence is a terminal state. A system state is terminal if it represents a special interest for the study (e.g. system mission achievement, dangerous failure state). Thus the system behavior is given by the set Ω of finite length sequences followed or not by the termination event:

$$\Omega = \sum^* (e_\Delta + \varepsilon) = \sum^* e_\Delta \cup \sum^* \tag{1}$$

In this equation Σ is the set of all events called alphabet, Σ* is the set of all finite events sequences of the alphabet Σ (* is the iteration operation called also Kleene-closure) and ε represents an empty sequence of events.

To determine the occurrence probability for an events sequence *s,* should be considered not only the independent occurrence of this sequence but also the occurrence of all sequences that starts with *s* (all the sequences which have *s* like prefix). The set of all the sequences having a given prefix sequence *s* is given by:

$$< s >= \{st \mid st \in \Omega\} \tag{2}$$

Definition 1 (Garg et al. 1999): Consider the measurable space (Ω,F), where $\Omega = \Sigma^*(e_\Delta + \varepsilon)$ and F is the σ-algebra generated by $\{<s>|s \in \Omega\}$. Then a *probabilistic language* (p-language) $\mathbb{P}$ is a probability measure on the measurable space (Ω,F).

Thereby *the termination probability for a sequence s* (the probability that the evolution of a system ends after the occurrence of *s*) is given by the following expression:

$$\mathbb{P}(se_\Delta) = \mathbb{P}(s) - \sum_{e\in\Sigma} \mathbb{P}(se),\ \forall s \in \sum^* \tag{3}$$

where $\mathbb{P}(s)$ represents the occurrence probability of *s* and $\Sigma_{e\in\Sigma}\ \mathbb{P}(se)$ represents the probability of continuous operation beyond *s*.

The probabilities of termination corresponding to different sequences are mutually exclusive, so the cumulative probability that the system arrives in a terminal state can be obtained by adding the individual probabilities for all possible sequences:

$$\mathbb{P}(Syst\ e_\Delta) = \sum_{s\in\Sigma^*} \mathbb{P}(se_\Delta) \tag{4}$$

Sometimes it is easier to describe a *p-language* using an associated automaton that can recognize this language.

Definition 2: A probabilistic automaton (or p-automaton) over the alphabet (set of events) Σ is defined by the following quintuple:

$$A_p = (X, \Sigma, f, \mathbb{P}, x_0) \tag{5}$$

where:

- X is a finite set of states;
- Σ is a finite set of events called alphabet;
- f: $X \times \Sigma \to X$ is the transition function that associates to each initial state and each event an arrival state;
- $\mathbb{P}$: $X \times \Sigma \times X \to [0,1]$ is the probability transition function affecting to each transition a discrete occurrence probability which satisfies the following relation:

$$\sum_{x_j\in X} \sum_{e\in\Sigma} \mathbb{P}(x_i, e, x_j) \le 1,\ \forall x_i \in X \tag{6}$$

- x_0 represents the initial state.

The evolution of a p-automaton is the following: if the system is in the state x_i, the transition e to the state x_j is done with the probability $\mathbb{P}(x_i,e,x_j)$. The probability transition function can be extended to the paths $\pi \subset X(\Sigma X)^*$ in the p-automaton A_p (a path is obtaining by concatenating the transitions, where the end state and the initial state of two consecutive transitions coincide). The probability of the paths is defined by the next equation:

$$x_j \in X : \mathbb{P}\left(\pi e x_j\right) = \mathbb{P}\left(\pi\right)\mathbb{P}\left(x \mid \pi \mid e x_j\right) \tag{7}$$

Each p-automaton defines a p-language and inversely each p-language can be represented by a p-automaton.

Definition 3 (Garg et al. 1999): The p-automaton $A_p = (X, \Sigma, f, \mathbb{P}, x_0)$ with:

$$\forall s,t \in \sum^*, e \in \sum : \mathbb{P}\left(s,e,t\right) = \begin{cases} \dfrac{L(t)}{L(S)}, \text{if t} = se \\ 0, \text{otherwise.} \end{cases} \tag{8}$$

generates a L p-language.

4 PRESENTATION OF THE CASE STUDY

In order to present the application of probabilistic languages we start by considering an oven

temperature control system (Fig. 1). It operates in the following manner: the oven temperature can be controlled by a Proportional Integral controller (PI) or by an On/Off controller.

The Proportional Integral controller (PI) has the role of keeping the temperature at a given target value and is characterized by a failure rate λ_{PI} and by a probability of failure on demand p_{refPI}. The role of On/Off controller is to maintain the temperature in a given range and is also characterized by a failure rate $\lambda_{on/off}$ and by a probability of failure on demand $p_{refon/off}$. When the controller PI fails, the On/Off controller provides the temperature control if this one is not failing on demand. In the same manner if the On/Off controller fails the PI controller will provide the temperature control (if it not fails on demand).

When either of the controllers is failed it will be repaired, the repair process being characterized by a repair rate μ_{PI} respectively $\mu_{On/Off}$. This operating mode represents the simplified operating mode (obtained by removing the continuous part of the system describing the temperature evolution) of the case study defined in (Perez et al. 2011).

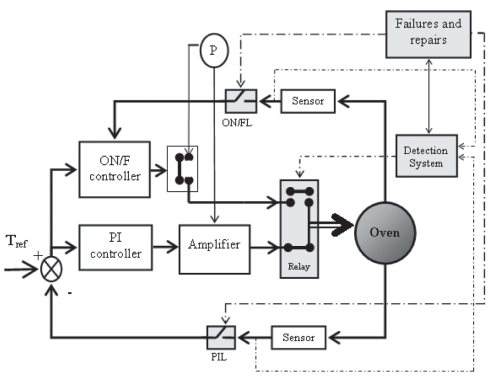

Figure 1. Structural diagram of the temperature control system of an oven.

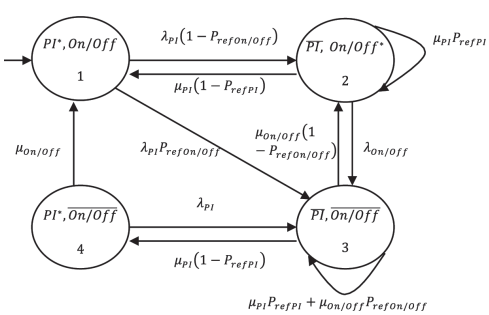

Figure 2. Continuous Time Markov Chain of the case study.

The values for the different rates that characterize the system transitions are:

$$\lambda_{PI} = 3.5 \cdot 10^{-5} h^{-1}, \lambda_{On/Off} = 2 \cdot 10^{-5} h^{-1},$$

$$\mu_{PI} = 8 \cdot 10^{-2} h^{-1}, \mu_{On/Off} = 10 \cdot 10^{-2} h^{-1},$$

$$p_{refPI} = 0.03, p_{refOn/Off} = 0.05.$$

The automaton that describes this system is presented in Figure 2.

5 PROPOSED APPROACH

The proposed approach is decomposed into four steps.

5.1 *Step 0: system modelling*

The approach based on probabilistic languages theory proposed by Garg et al. needs to give a priori the p-language (the set of sequences and for each sequence s the occurrence probability of sequences sub set that have s like prefix). In other words, the p-language is built from equation (3). This knowledge (the whole set of sequences and their probabilities) is not aware in the dependability studies. In dependability studies, the problem is rather reverse: giving a system, we need to determine the events sequences and, after that, to calculate their occurrence probabilities. Thus, we propose to work with, as initial data, the p-automaton.

5.2 *Step 1: events probability determination*

The p-automaton needs to be provided with event occurrence discrete probability for each transition (as in definition 2). As in dependability studies the probability laws describing the stochastic phenomena are rather continuous, we propose to determine discrete probabilities required by p-automata theory using embedded Discrete Time Markov Chain (DTMC) (Fig. 3) in a continous time stochastic process. This embedded DTMC is obtained by considering only the instants of transition firing between states. Using embedded DTMC ensures that the system reaches a stationnary probabilities distribution of states. Consequently, the probability p_{ij} of a transition e_{ij} that starts from a given state s_i to another state s_j is determined as the ratio between the rate of this transition and the sum of the rates for all transitions starting from state s_i. This probability is given by the following relation:

$$\mathbb{P}(e_{ij}) = p_{ij} = \lambda_{ij} / \sum_{j \neq i} (\lambda_{ij}) \quad (9)$$

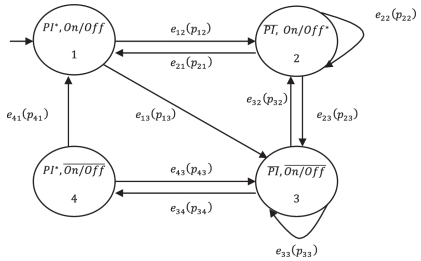

Figure 3. Discrete Time Markov Chain representing the p-automaton for the case study.

For example on the case study, the occurrence probabilities for the transitions e_{32}, e_{33} and e_{34} are:

$$\mathbb{P}(e_{32}) = p_{32} = \frac{\mu_{On/Off}\left(1 - p_{refOn/Off}\right)}{\mu_{On/Off} + \mu_{PI}}$$

$$\mathbb{P}(e_{33}) = p_{33} = \frac{(\mu_{On/Off}\, p_{refOn/Off} + \mu_{PI}\, p_{refPI})}{\mu_{On/Off} + \mu_{PI}}$$

$$\mathbb{P}(e_{34}) = p_{34} = \frac{\mu_{PI}(1 - p_{refPI})}{\mu_{On/Off} + \mu_{PI}}$$

Note that the sum off all the transitions, which can start from a given state, is equal to one.

5.3 *Step 2: sublanguages determination*

After event probability determination, next step is about probability sequence calculus.

Considering the case study, we focus on the analysis of the sequences that reach the state 3 (dangerous state). Indeed, in this state, the system is completely failed and the temperature oven is uncontrolled.

To use the equation (3), which gives the expression of the probability of these sequences, state 3 must be considered as a terminal state. Thus for a sequence, which terminates in state 3, considering first that the occurrence probability of a sequence is equal with the product between transitions probabilities (equation 7) and also considering the events e_{32}, e_{33} and e_{34}, which allowed the system to continue his evolution beyond the state 3, the termination probability for the sequence s it is:

$$\begin{aligned}
\mathbb{P}(se_{\Delta}) &= \mathbb{P}(s) - \sum \mathbb{P}(se) \\
&= \mathbb{P}(s) - \left(\mathbb{P}(se_{32}) + \mathbb{P}(se_{33}) + \mathbb{P}(se_{34})\right) \\
&= \mathbb{P}(s) - (\mathbb{P}(s)\mathbb{P}(e_{32}) + \mathbb{P}(s)\mathbb{P}(e_{33}) \\
&\quad + \mathbb{P}(s)\mathbb{P}(e_{34})) \\
&= \mathbb{P}(s) - \mathbb{P}(s)(\mathbb{P}(e_{32}) + \mathbb{P}(e_{33}) + \mathbb{P}(e_{34})) \\
&= \mathbb{P}(s) - \mathbb{P}(s)(p_{32} + p_{33} + p_{34}) \\
&= \mathbb{P}(s) - \mathbb{P}(s) \cdot 1 = 0
\end{aligned}$$

This approach is proposed in the p-languages theory and it was developed in the context of synthesis of control strategy by supervision (Wang & Ray 2004). The obtained result shows that, in dependability studies, the calculus of events sequences probability is not possible if this p-language is coupled with embedded DTMC without any cautions (if the terminal state of a sequence is not an absorbent state, its probability is always equal to zero).

To avoid this, we propose to determine firstly the whole set of events sequences of the system, that is represented by the language L_{sys}. This language can be represented as the union of sublanguages associated with the states of the system. A sublanguage associated to a state s_i is defined as the set of all events sequences, which lead the system from its initial state to the considered state.

$$L_{syys} = \bigcup_{s_i} L_i \tag{10}$$

To determine the sublanguages L_i we propose to use the theory of rational languages and more precisely the Arden lemma (Carton 2008).

Arden Lemma: Being two languages A and B and being the equation:

$$L_i = L_i A + B \tag{11}$$

where L_i represents the unknown language:

1. if $\varepsilon \notin A$, the only solution of the equation is $L_i = BA^*$.
2. if $\varepsilon \in A$, the solutions have the form $L_i = (B + C)A^*$ where $C \subseteq \Sigma^*$.

The lemma is mainly used in the case where $\varepsilon \notin A$ and the language L_i=$BA^*$is the unique solution.

For each state s_i of the system the equation (11) can be written, considering the sequences starting from all the other states $s_j \neq s_i$ and arriving in the state s_i by only one transition. The set of n equations (11) (where n is the number of system states) allow to obtain all the sublanguages L_i.

Having a system represented by a p-automaton and using this approach we can determine all the events sequences without model exploring.

5.4 *Step 3: sequences probability calculation*

Each events sequence of the system $s = e_{12}e_{23} \ldots e(n-1)n$ that starts from the initial state s_1 and arrives in the state s_n can be extracted from the language L_{syys} otained in the previous step. Using the probability for each transition of the p-automaton obtained in step 1, we propose to use the following equation in order to obtain

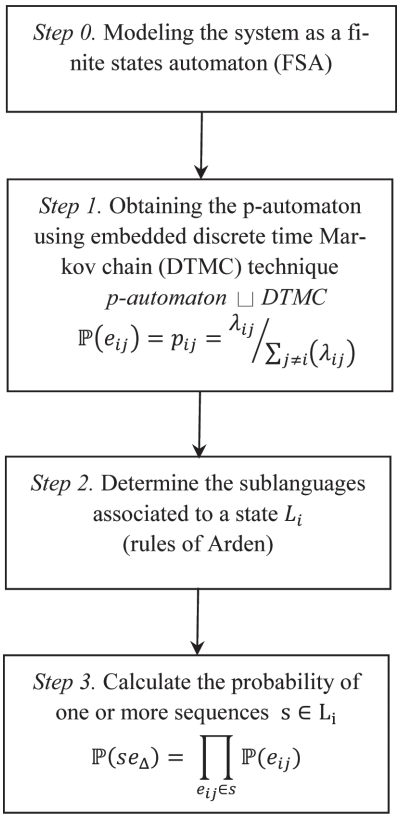

Figure 4. Approach proposed for the probabilistic assessment of events sequences.

the termination probability for the sequence $s = e_{12}e_{23} \ldots e(n-1)n$:

$$\mathbb{P}(se\Delta) = \prod_{e_{ij} \in s} \mathbb{P}(e_{ij}), \forall s \in \sum^{*} \tag{12}$$

The meaning of this equation is that the probability of a events sequence is equal with the product of the probabilities of all of its events e_{ij}.

Figure 4 summerizes the different steps of our proposed approach to formally determine the whole set of events sequences and to assess their probability using the probabilistic languages.

6 APPLICATION ON THE CASE STUDY

6.1 *Application of the proposed approach*

Step 0: Figure 3 shows the embedded Discrete Time Markov Chain representing the p-automaton of the case study.

Step 1: The transition probabilities p_{ij} are calculated using the equation (9).

Step 2: The sublanguages associated to each state represent the sub set of the sequences that lead the system from the initial state 1 to one of his states. Considering each state of the automaton as terminal state (not absorbing) we obtain the next equations:

$$L_1 = L_2e_{21} + L_4e_{41} \tag{13}$$

$$L_2 = L_1e_{12} + L_2e_{22} + L_3e_{32} \tag{14}$$

$$L_3 = L_1e_{13} + L_2e_{23} + L_3e_{33} + L_4e_{43} \tag{15}$$

$$L_4 = L_3e_{34} \tag{16}$$

For example the first equation (13) denote the sublanguage associate to state S_1 as being the all events sequences arriving in this state by only one transition: from state s_2 (all the events sequences previously terminated in s_2:L_2) followed by the transition e_{21} or from state s_4 (all the events sequences previously terminated in s_4:L_4) followed by the transition e_{41} (according to Fig. 3).

Using the Arden lemma, the equations (13–16) give the next expressions for the sublanguages:

- to state 1:

$$\begin{aligned} L_1 = {} & (e_{12} + e_{13}(e_{33} + e_{34}e_{43})^{*}e_{32}) \\ & \times (e_{22} + e_{23}(e_{33} + e_{34}e_{43})^{*}e_{32})^{*}e_{23} \\ & \times (e_{33} + e_{34}e_{43})^{*}e_{34}e_{41} \\ & \times [(e_{12} + e_{13}(e_{33} + e_{34}e_{43})^{*}e_{32})(e_{22} + e_{23} \\ & \times (e_{33} + e_{34}e_{43})^{*}e_{32})^{*}e_{21} \\ & + e_{13}(e_{33} + e_{34}e_{43})^{*}e_{34}e_{41}]^{*} \end{aligned} \tag{17}$$

- to state 2:

$$\begin{aligned} L_2 = {} & L_1(e_{12} + e_{13}(e_{33} + e_{34}e_{43})^{*}e_{32}) \\ & \times (e_{22} + e_{23}(e_{33} + e_{34}e_{43})^{*}e_{32})^{*} \end{aligned} \tag{18}$$

- to state 3:

$$L_3 = (L_1e_{13} + L_2e_{23})(e_{33} + e_{34}e_{43})^{*} \tag{19}$$

- to state 4:

$$L_4 = L_3e_{34} \tag{20}$$

Step 3: Having the sublanguage defined for each state of the considered system we can obtain firstly the probability for a sublanguage and secondly the probabilities for events sequences belonging to this sublanguage. To illustrate the sequence probabilities assessment, the results obtained for two sublanguages (L_1 and L_3) are presented in this paper.

For the simplification we will use the following notations:

$$p_{12} = p; p_{13} = 1 - p; p_{21} = p_1; p_{23} = p_2;$$
$$p_{22} = 1 - p_1 - p_2; p_{32} = p_3; p_{34} = p_4;$$
$$p_{33} = 1 - p_3 - p_4; p_{41} = p_5; p_{43} = 1 - p_5.$$

6.1.1 *Probabilities assessment for the sublanguage L_1*

Using the expression (17) we can calculate the probabilities of different iterations that compose the regular expression of the sublanguage L_1 and, after that, we obtain the final analytic expression:

$$\mathbb{P}(L_1) = \sum_{s \in \Sigma^*} \mathbb{P}(se_\Delta) = \frac{p_2 p_4 p_5}{p_2(p_3 + p_4 p_5) - p_2 p_3} = 1 \tag{21}$$

This result, the probability of the sublanguage $\mathbb{P}(L_1)$, is compliant with the expected one: indeed, for the p-automaton of the Figure 3, the probability of all sequences starting from state 1 and reaching back to state 1 must be obviously equal to one. Nevertheless, the approach is able to provide the probability of all individual sequences reaching to this state. To illustrate this fact, the occurrence probability for some particular sequences, extracted from L_1 and that lead the system in the state 1, are obtained doing the numerical calculus. Their values are presented in Table 1. Firstly we can observe that the sum of probabilities of considered events sequences is approximately equal with 1 and this corresponds to analytical solution of the sublanguage probability (eq. 21). Secondly we can identify the most relevant events sequences (by the greatest values of their probability).

Table 1. Occurrence probabilities for few sequences that lead the system in the state 1.

Sequence (s_i)	Sequence probability ($\mathbb{P}(s_i)$)
$S_1 = e_{12}e_{21}$	0.9213
$S_2 = e_{12}e_{22}e_{21}$	0.0276
$S_3 = e_{12}e_{23}e_{33}e_{32}e_{21}$	4.9961e-06
$S_4 = e_{12}e_{22}e_{23}e_{32}e_{23}e_{32}e_{21}$	4.8080e-10
$S_5 = e_{12}e_{23}e_{34}e_{43}e_{32}e_{21}$	1.8331e-08
$S_6 = e_{12}e_{22}e_{23}e_{33}e_{34}e_{43}e_{32}e_{21}$	2.2602e-11
$S_7 = e_{12}e_{23}e_{34}e_{41}$	1.0233e-04
$S_8 = e_{13}e_{34}e_{41}$	0.0215
$S_9 = e_{13}e_{33}e_{34}e_{41}$	8.8586e-04
$S_{10} = e_{13}e_{34}e_{43}e_{34}e_{41}$	3.2502e-06
$S_{11} = e_{13}e_{32}e_{21}$	0.0256
$S_{12} = e_{13}e_{33}e_{32}e_{22}e_{23}e_{32}e_{21}$	4.1624e-09
	$\mathbb{P}(L_1) = \Sigma_{s_i} \mathbb{P}(s_i) \cong 1$

6.1.1 *Probabilities assessment for the sublanguage L_3*

The sublanguage L_3 describes infinity sequences which bring the system in the failure state 3 from the initial state 1:

$$\mathbb{P}(L_3) = \frac{p_1 + p_2 - pp_1}{p_1(p_3 + p_4 p_5) + p_2 p_4 p_5} \tag{22}$$

Calculating the numerical values for some sequences we obtain the values from Table 2. The state 3 represents the dangerous state because the oven temperature is uncontrolled and thus we can identify the most critical events sequences (with the greatest values of their probability) of the system.

6.2 *Analytic validation of the results*

In order to check the validity of the results (sequences probabilities), we propose the next approach:

1. To determine the stationary distribution of states probabilities for embedded DTMC [π_1 π_2 π_3 π_4] by using the equations:

$$\pi = \pi \cdot M \text{ and } \pi \cdot \overline{1} = 1 \tag{23}$$

   where the vector π represents the state probability distribution, M is the matrix of transitions probabilities and $\overline{1}$ is a vector with all elements 1. Using the equations (23) we determined the analytic form for the state probabilities.
2. To prouve that the probabilities for different sublanguages, obtained by the equations (17–20), the following relation is to be validated:

$$\mathbb{P}(s_i) \cdot \sum_{\substack{s \in \Sigma^* \\ s \\ i \to j}} \mathbb{P}(se_\Delta) = \mathbb{P}(s_i) \cdot \mathbb{P}(L_{i \to j}) = \mathbb{P}(s_j) \tag{24}$$

It means that the probability to reach state S_j is equal to the product of the probability of the

Table 2. Occurrence probabilities for few sequences that lead the system in the state 3.

Sequence (s_i)	Sequence probability ($\mathbb{P}(s_i)$)
$S_1 = e_{12}e_{23}$	2.3744e-04
$S_2 = e_{12}e_{22}e_{21}e_{13}$	0.0014
$S_3 = e_{13}e_{33}$	0.0021
$S_4 = e_{12}e_{22}e_{23}e_{32}e_{23}e_{33}$	3.8620e-11
$S_5 = e_{12}e_{23}e_{33}e_{34}e_{43}$	1.4724e-09
$S_6 = e_{13}e_{33}e_{34}e_{43}e_{32}e_{23}$	4.0899e-11
	$\mathbb{P}(L_3) = \Sigma_{s_i} \mathbb{P}(s_i) \cong 0.0037$

initial state S_i and the probability of the sublanguage from S_i to S_j.

- for L_1: $\pi_i\mathbb{P}(L_1) = \pi_1$
- for L_2: $\pi_i\mathbb{P}(L_2) = \pi_2$
- for L_3: $\pi_i\mathbb{P}(L_3) = \pi_3$
- for L_4: $\pi_i\mathbb{P}(L_4) = \pi_4$

7 CONCLUSIONS

In this paper, we presented the use of the theory of probabilistic language for the assessment of the occurrence probability of events sequences that describe the system evolutions. In order to be able to apply this theory, for a system modelled by a finite state automaton, we proposed a 3 steps approach.

The use of the embedded Discrete Time Markov Chain in a continuous stochastic process for determining the events probability makes assumption that the system is in a stationary state characterizing by stationary distribution probabilities over its states. But the embedded DTMC is not limited to Continuous Time Markov Chain; a DTMC can also be defined from semi-Markov or under some hypothesis from more generally stochastic processes. Another advantage to use the DTMC to obtain the events probability is that the probability of an event is not the same during the system evolution, but can depends on the state where it occurs (in other words the same event can be characterized by different occurrence probabilities). The use of the Arden lemma permits to formally determine the whole set of events sequences, without model exploring. Finally, the probability occurrence for relevant or critical events sequences and for a sublanguage is determined.

The approach is applied on a control system temperature. This case study shows the ability of the proposed approach to take into account together stochastic phenomena characterized by continuous laws of probability (such as failures and reparations processes) and phenomena characterized by discrete laws of probability (such as failures on demand).

This work opens several ways of research in our future activity. First of all, it will be interesting to propose an approach that allows calculating the probabilities of events sequences in a transient system state before reaching the stationary distribution. Secondly, we are interested to apply this approach in more complex systems including components ageing with the more generally underlying stochastic continuous process. Also, an extension of the operations provided by the p-languages theory should be useful for taking in account different types of systems (non-deterministic systems, reconfigurable systems, systems composed of several sub-systems) in dependability studies.

RAM analysis applied to decommissioning phase: Comparison and assessment of different methods to predict future failures

E. Calixto
Genesis Oil and Gas Consultants, UK

Yizhak Bot
BQR Reliability Engineering Ltd., Israel

ABSTRACT: Reliability Engineering methods are applied throughout asset lifecycle, but the greatest challenge is in decommissioning phase, as it requires the equipment degradation after repair and its effects on system operational availability to be considered in order to better predict future equipment performance.

In order to predict future failures and define critical equipment it is necessary to take into account the positive or negative maintenance effect on equipment reliability. Therefore, the Reliability Growth Analysis (RGA) applied to a repairable system can be performed to predict the cumulative number of failures, considering the degradation effect of repairable equipment.

Despite RGA being the best approach, in some cases it is necessary to consider the system configuration modelling RBD (Reliability Block Diagram) and perform a direct simulation to predict system operational availability and expected number of future failures. Therefore, the General Renewal Model is required to define the restoration factor of each equipment item in order to take into account the degradation effect on equipment performance and apply these factors to RBD configuration in order to predict the system operational availability and future expected number of failures with respect to the degradation effect. The restoration factor is minted to give values between zero and one. In other words, a restoration level between "as bad as old" and "as good as new". The RGA model deems the restoration levels as "as bad as old" and "as good as new" and "better than as good as new". Therefore, the proposal methodology predicts the restoration factor from the RGA model, based on a likelihood method. In addition, the expected number of future failures is determined by comparing the prediction results from RGA model (Crown AMSAA Model) and direct simulation which considers the restoration factor.

The main objective of this paper is to present these particular reliability engineering methods and demonstrate the application on an asset case study in decommissioning phase. The simulation for cumulative time as well as a specific period of four months was carried out in order to predict the effect of critical failures on system operational availability during a specific range of time.

1 INTRODUCTION

The RAM analysis is a recognized management and engineering discipline for the purpose of guaranteeing the specified functionality of a system over its complete lifecycle. RAM analysis also aims to ensure the operation, maintenance and disposal costs remain below the acceptable level, by establishing the relevant performance characteristics at the beginning of the procurement cycle, and through monitoring and control of their implementation throughout all asset life cycle phases (Vozella, 2006).

The general definition of reliability used throughout industry and quoted in many engineering books published on this subject follows the example as taken from MIL-STD-785:

Reliability: the ability of an product to perform a required function under given conditions for a given time interval.

Availability: ability of an item to be in a state to perform a required function under given conditions at a given instant of time or over a given time interval, assuming that the required external resources are provided.

Maintainability: a state in which an item can perform a required function, when maintenance is performed under given conditions and using stated procedures and resources.

Despite the RAM analysis being the most common method utilized by reliability engineers, most of time the degradation caused by equipment age and maintenance effects is not taken into account. In many cases, the reliability data are obtained from

a generic database concerning constant failure rate, and the equipment failure-rate data obtained are treated as an average (Gerbec, M. et al. 2010).

The null hypothesis of the HPP (Homogeneous Poisson Process) with the alternative being a NHPP (NonHomogeneous Poisson Process) is defined by a trend test such as the Laplace Test or the Military Handbook test (Lindqvist, et al. 2006).

The degradation effect must be taken into account to represent the increasing number of asset failures during asset wear out. Whenever this type of degradation is not represented by "Direct simulation", the equipment is considered as good as new after repair.

The RAM analysis performed concerning decommissioning phase must take into account the degradation effect in order to predict the future failures of the assets.

Indeed, nowadays many RAM analyses use data from generic databases (exponential PDF) that in most of cases will not represent the real performance of the system assessed. In addition, these databases do not consider the restoration factor or the different PDFs (probability density functions) which are more applicable to failure modes in the analysis.

This paper will discuss the importance of considering the restoration factor by comparing the reliability growth analysis (Crow AMSSA Model) and General Renewal Model when performing a RAM analysis to predict system performance by applying a case study concerning decommissioning phase.

2 RAM ANALYSIS IN DECOMMISSIONING PHASE

In order to understand the application of RAM analysis in asset decommissioning phase it is necessary to first understand the asset management concept, as well as how reliability engineering is applied during asset lifecycle.

Asset Management is defined as the best practices applied during asset lifecycle in order to achieve the best performance result. Indeed, such practices are carried out with support of a leader at different organizational levels, specifically strategic, tactical and operational.

Therefore, different reliability engineering methods must be used in different asset lifecycle phases, as shown in Figure 1. The optimal asset performance is achieved when most early life failures are eliminated during design phase, which enables excellent performance during operational phase. This is shown by the green bathtub curve in Figure 1, representing a lower failure rate, or in other words, higher reliability.

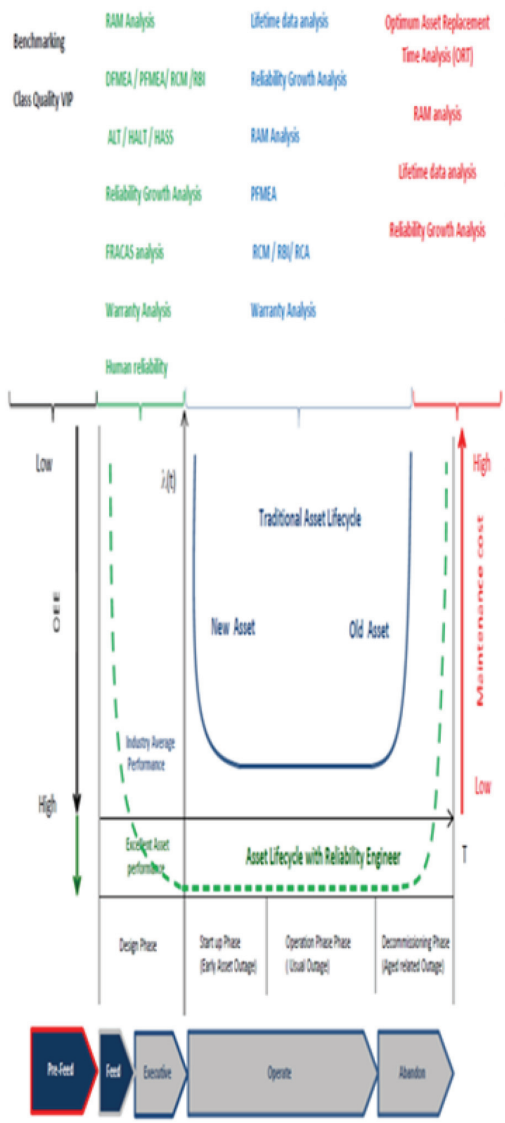

Figure 1. Asset Management Source: Calixto, E. 2014.

In order to achieve optimal performance, it is necessary to implement different methods throughout asset lifecycle. Indeed, all efforts begin in design phase, applying different qualitative (DFMEA, RCM, RBI, HALT, FRACAS, human reliability) and quantitative (RAM, ALT, Reliability Growth analysis and warranty analysis) methods. The main objective of these methods is to identify the early-life failure during design and eliminate them whenever it is possible. During operational phase, different qualitative (PFMEA,

RCM, RBI) and quantitative (Lifetime data analysis and RAM analysis) methods must be utilized to maintain asset performance until the end of asset life, when decommissioning of the equipment is defined and supported by RAM analysis, ORT (Optimum Replacement Time) and Reliability Growth analysis.

The Optimum replacement time for all equipment must be analyzed in order to reduce operational cost, maintain high availability of the system and below the acceptable risk level for failure.

The decommissioning phase is the most challenging in terms of RAM analysis because it requires different analyses to be performed, such as Reliability Growth Analysis, General Renewal Model and the usual Lifetime data analysis during the lifetime data analysis step in order to predict the future system performance.

In addition, in some cases, it is also important to carry out the Optimum Replacement Time analysis in order to define when it is best to replace equipment based on operational cost analysis.

In general terms, the RAM analysis methodology applied for decommissioning phase can be defined by the following steps represented in Figure 2.

Regarding decommissioning phase, it is very important to take into account the equipment age in order to predict future failures that will reduce system performance in decommissioning phase. Therefore, it is important to perform the Reliability Growth Analysis (RGA) using the Crow AMSAA method, as well as performing the General Renewal Model in order to accurately predict the expected number of future failures.

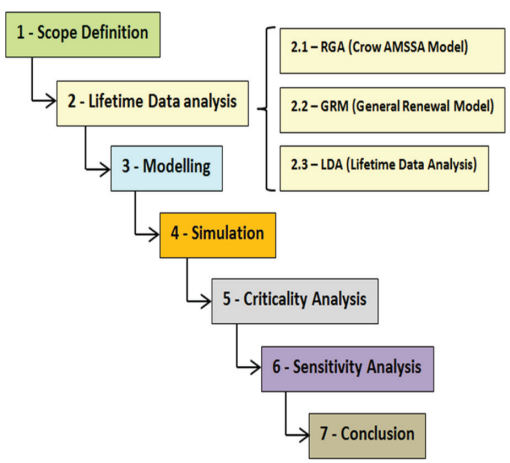

Figure 2. RAM Methodology in decommissioning phase.

Indeed, these methods are applied for single equipment and components but it is a very important result for comparison with the Monte Carlo (MC) Simulation result from RAM analysis. In fact, the best approach is to carry out RGA analysis and then adjust the MC simulation for each equipment item.

Despite a good approach, the software packages which perform system direct simulation (Monte Carlo simulation) have some limitations and are not able to predict the exact expected number of failures predicted by RGA. Indeed, it is possible to take into account the restoration factor predicted by the General Renewal Model, but it is only possible to have equipment in the state "as good as new" or "as bad as old".

Theoretically, this is the best condition that some equipment can achieve in terms of performance after preventive or corrective maintenance, but in some cases it is possible to have reliability growth. This is achieved by swapping internal components for more reliable ones or even modifications which increase equipment reliability when performed.

3 RELIABILITY GROWTH ANALYSIS

The Crow AMSAA model was introduced by Dr.Larry H. Crow in 1974 in order to be applied to product improvement assessment during design phase. Nowadays, this model is also applied during the operational phase of asset life cycle to assess the equipment degradation over time, as well as the effect of maintenance on repairable equipment in order to predict future failures.

The Crow AMSSA is a statistical model which uses the Weibull failure rate function to describe the relationship between accumulated time to failure and test time, being a Non-Homogeneous Poisson Process Model. This approach is applied in order to demonstrate the effect of corrective and preventive actions on reliability when a product is being developed or for repairable systems during operation phase (Crow, 2012). Thus, whenever improvement is implemented during test (Test-Fix-Test) or maintenance, the Crow AMSAA model is appropriated to predict reliability growth and expected cumulative number of failures. The expected cumulative number of failures is mathematically represented by the following equation:

That is approximately:

$$E(N_i) = \int_o^T \rho(t)dt \quad (1)$$

$$E(N) = \lambda T^{\beta} \quad (2)$$

The Crow AMSAA Model assumes that intensity failure is approximately Weibull failure rate, thus intensity of failure on time is:

$$\rho(t) = \frac{\beta}{\eta^{\beta}} T^{\beta-1}$$

where initial failure rate as:

$$\lambda = \frac{1}{\eta^{\beta}}$$

If cumulative failure rate is approximately failure intensity we have:

$$\lambda_i = \beta\lambda T^{\beta-1}$$

The equation above describes failure intensity during the test and depends on the β value increasing, decreasing or staying constant through time. It's very important to bear in mind that β in the Crow AMSAA Model describes intensity failure behavior and does not have same meaning as the Weibull PDF shape parameter.

An example of an application of this methodology is demonstrated in Figure 3, which shows the cumulative number of failures over time for different compressors.

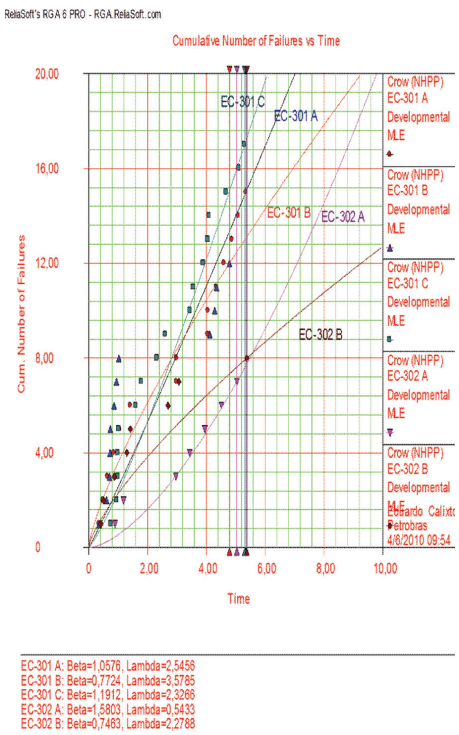

Figure 3. Reliability Growth Analysis. Source: Calixto E, 2011.

In Figure 3, for each compressor, there are different β and λ values, which describe the effect of improvement actions as well as the cumulative failure rate.

In fact, β is a shape parameter of Intensity Failure Function in the Crow AMSAA Model. Thus, in this model when $\beta > 1$, reliability decreases through time because failure intensity is increasing. In other words, corrective product actions are not improving the product. When $\beta < 1$, intensity of failure decreases through time; in other words, reliability is increasing. Therefore, corrective product actions are improving product reliability. When $\beta = 1$, there's no improvement or product reliability degradation. In this case, the product behaves as if no corrective action takes place and intensity failure is constant through time. The Growth rate in the Crow AMSAA Model is $1-\beta$.

The Crow AMSSA model is the best model to predict future failures and analyse the effect of maintenance and operational environment on equipment performance. Indeed, Power Law processes (Crow AMSAA Model) are often sufficient for simple reliability studies, but in the case of complex system, there is a need for more complex model (Verrier, V. et al. 2010).

Indeed, it is not possible to use the Crow AMSAA model to predict the expected number of future failures for different equipment in complex configurations. In this case, it is necessary to represent complex systems with an RBD model.

Once the system is represented by RBD and the direct simulation is performed to predict the expected number of future failures, it is necessary to take into account the degradation factor that will be explained in the next section.

4 GENERAL RENEWAL PROCESS

The General Renewal Model (Kijima I and II) was proposed by Kijima and Sumita in 1986. The Kijima Model, known as "General Renovation Process" or "General Renewal Process", is based on component virtual life concept. This method considers the reduction in component age when an intervention is performed; it can be described in two forms:

⇒Age re-establishment based in last intervention (Kijima I);

⇒Age re-establishment based in all intervention (Kijima II);

In first case, the "Model Kijima I" assumes that reestablishment of component age occurs only for the last repair. Therefore, the model assumes that the "ith" repair does not remove all reliability

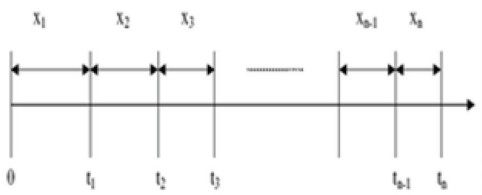

Figure 4. General renewal model.

losses until the "ith" failure. Therefore, if "t_i" is time between failures, the component age through time is represented by equation:

$$V_n = V_{n-1} + qX_n \quad (3)$$

where,

X_n = time between (n – 1)th and a nth failure
q^n = restoration factor
V_n = age in time n
V_{n-1} = age in time n–1.

In the second case, the Model Kijima II assumes that re-establishment of component age occurs for all failures throughout component life since the first repair. Thus, this model regards that the "ith" repair remove all reliability losses until "ith" failure. Therefore, the component age through time is represented by equation:

$$V_n = q\left(V_n + X_n\right) \quad (4)$$

Figure 4 graphically represents the concept of the General Renewal Model that takes into account the effect of maintenance. The Kijima factor applied in the case study was defined using the software "Weibull 9.0" based on the likelihood method applied in Crown AMSSA Model parameters.

5 LIFETIME DATA ANALYSIS

In order to define equipment, product and services reliability it is necessary to collect historical failure data and treat them statistically.

Therefore, the first step in a lifetime data analysis study is to know how failures occur through time; this is critical for definition of indexes such as failure rate, reliability, availability, reliability through time, in order to support decisions in defining best time to inspection), and maintenance, to check if equipment achieves reliability warranty requirement and to support information to new projects.

Indeed, the decisions based on reliability are based on lifetime data analysis results. This analysis requires historical data about failure modes and repair time. The failure mode is the way that the equipment or product lost part or total capacity to carry out their function.

Therefore, understanding the type of data required is the first step in the lifetime data analysis process. Essentially, the type of data sample can be grouped or not grouped, meaning that reliability is predicted based on only one equipment item or based on a group of similar equipment. In most cases, when equipment from a process plant is being assessed, the sample is not grouped because, when comparing the equipment to the sample from a similar process plant, factors such as maintenance policy, operational environment and process variation affect equipment reliability differently.

Regarding the data, it is important to understand how data are recorded. Indeed, the data can be complete, right suspension, left suspension, in interval, or a combination of such configurations.

The next step is to apply different goodness of fit methods, such as Rank regression and Maximum Likelihood, to estimate the PDF parameters as well as the best PDF which fits the data assessed.

The final product of lifetime data analysis is the PDF and its parameters that best fit the failure or repair data assessed, as shown in Figure 5.

The Probability Density Function (PDF) describes the possibility of events occurring

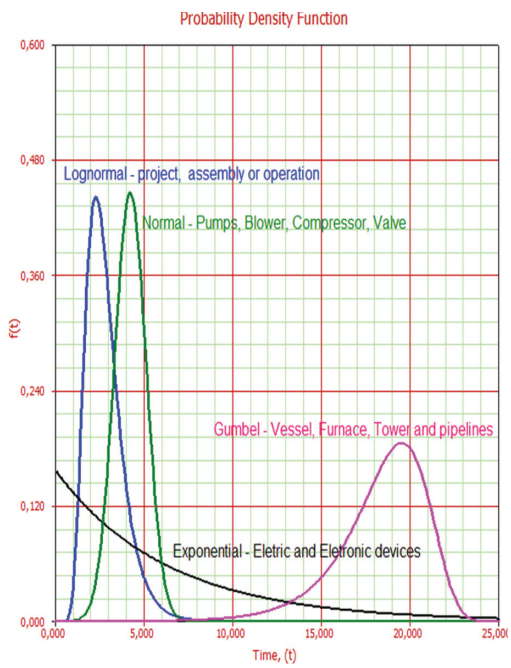

Figure 5. Oil and Gas equipment PDF. Source: Calixto E, 2012.

through time. In equipment life cycle analysis, it describes failure or repair time occurrence through time. This provides good information to a maintenance and reliability professional to make decisions regarding maintenance policy, inspection policy and failure behavior. However, in order to make these decisions, other indexes are required, such as failure rate and reliability function. Figure 6 summarizes the main steps of lifetime data analysis.

Despite a very important method, the lifetime data analysis does not consider the effect of maintenance on equipment degradation. In fact, when applying the PDF parameters to RBD models and then running the direct simulation in RAM analysis, the following events will be similar to the first one.

Therefore, it is important to take into account the degradation effect analysis which is defined by applying the General Renewal Model and Crow AMSSA model, as will be demonstrated in the next section.

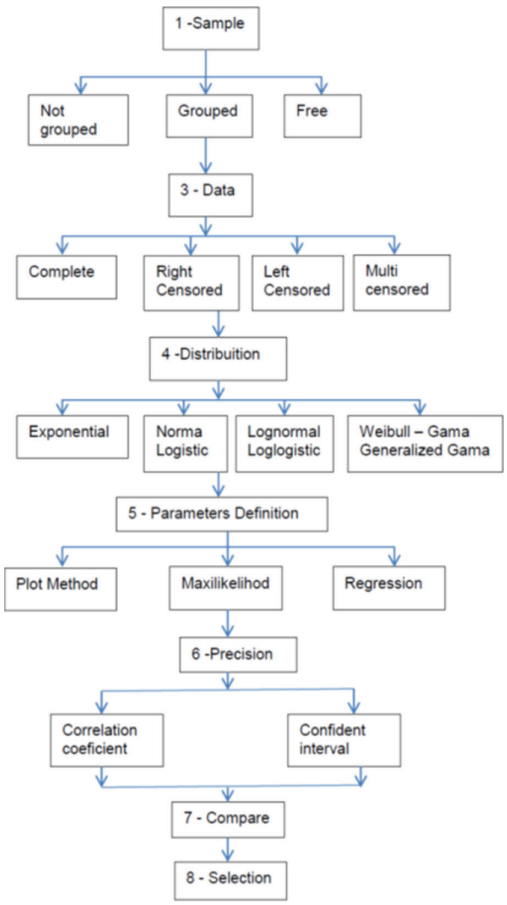

Figure 6. Lifetime data analysis steps.

6 COMPARING DIFFERENT METHODS

In order to predict future failures, it is necessary to take into account the positive or negative maintenance and environment effect on equipment reliability. Therefore, the Reliability Growth Analysis (RGA) can be performed to predict the cumulative number of failures regarding the degradation effect on repairable equipment. The second option is to perform the General Renewal Method to predict the restoration factor and apply it to the RBD for each equipment item or failure mode and run the direct simulation.

In the first case, in order to predict future failures, the Reliability Growth Analysis (Crow AMSSA Model) is applied to define the improvement or degradation in each equipment item as well as taking into account the effect of corrective and preventive maintenance.

This analysis is the most accurate in predicting future failures because it considers all positive or negative effects on equipment performance.

Certainly, the ideal situation is performing this analysis for each component, but due to a lack of precise information in the historical data archive, the analysis is carried out at the equipment level. Figure 7 shows an example of an RGA carried out for a blower.

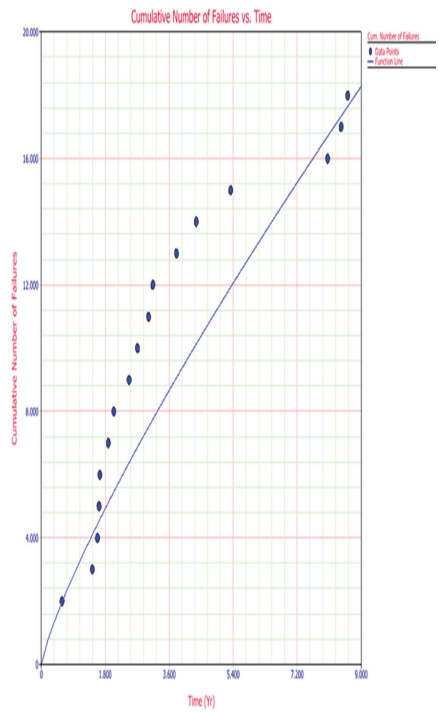

Figure 7. RGA analysis.

The cumulative number of failures during the assessed period is exactly what it is recorded on the database. In addition, the beta parameter, $\beta>1$, indicates that reliability of this Blower decreases over time ($\beta = 1.74$).

Similar analyses were carried out for other equipment in order to define the cumulative number of failures, as well as to evaluate the effect of maintenance and operational environment by assessing the beta parameter value.

Regarding the second option, the General Renewal Model which defines the type of restoration factor (Kijima I or II) can also be applied. Indeed, this analysis might be adjusted to achieve similar results provided by RGA analysis in terms of cumulative number of failures. Considering that the restoration factor is on the maximum, 1 (100% of restoration), some adjustment is necessary when adjusting the GRM based on RGA results. This adjustment is based on the assumption that the RGA represents the best prediction of future failures. Once the equipment needs to be assessed in the context of a system and not individually, it is necessary to define the PDF and restoration factor for each one and then input the values into the RBD model.

Table 1 shows an example of the final reliability data as result of the RGA, GRM an LDA analyses.

The final step is to validate the reliability database presented in Table 1 by performing individual Direct Simulations (Monte Carlo—MC) in order to check if the PDF and restoration factor were adjusted well to the RGA model prediction. Therefore, the simulation was performed for 10, 15 and 20 years. Table 2 shows an example of future predictions for some equipment, comparing the RGA and MC methods result.

Tank 1 was assessed only through the MC method because the small number of failures does not enable the RGA analysis. The pumps were assessed by both methods and achieve a similar expected number of failures.

Finally, this approach was applied to all Boiler systems. Thus, it was demonstrated that the PDF and restoration factor were accurate enough to predict future number of failures by the MC method, as the RGA method produced similar results. The next section demonstrates the Boiler system modelled by RBD (reliability diagram block) and the final direct simulation results.

7 RAM ANALYSIS IN DECOMMISSIONING PHASE CASE STUDY

In order to demonstrate the importance of all methods described in previous section, the RAM analysis performed to assess the Boiler system in decommissioning phase will be carried out. The main objective is to define the critical equipment in terms of performance and support decision about which one must to be taken place for a new one.

In this particular case, the boiler system may cause loss of production in the whole refinery in case of outage during winter time. Therefore the RAM analysis took into account the simulation for a specific range of time that in this case is winter time.

Table 1. Reliability data base.

Equipment	Failure				Repair			Kijima factor			Crow AMSSA model	
Tank 1	PDF 2	Parameter (year)			PDF	Parameter (hours)		Type	q	RF	λ	β
	Gumbel	μ	σ		Normal	μ	σ					
		7.48	0.01			120	20					
Pump 2	PDF 2	Parameter (year)			PDF	Parameter (hours)		Type	q	RF	λ	β
	Weibull	β	η	γ	Constant	Repair time						
		0.56	0.695	0.052		24		II	0	1	6.1044	1.0655
Pump 3	PDF 2	Parameter (year)			PDF	Parameter (hours)		Type	q	RF	λ	β
	Weibull	β	η	γ	Constant	Repair time						
		0.47	0.46	1.35		24		I	0	1	0.6777	0.583
Pump 4	PDF 2	Parameter (year)			PDF	Parameter (hours)		Type	q	RF	λ	β
	Weibull	β	η		Constant	Repair time						
		0.7285	0.564			24		II	0	1	0.6522	1.6522
Pump 5	PDF 2	Parameter (year)			PDF	Parameter (hours)		Type	q	RF	λ	β
	Weibull	β	η		Constant	Repair time						
		0.6363	0.8888			24		I	0	1	1.4076	0.5716

Table 2. RGA × MC.

Equipment	10 years		15 years		20 years	
Tank 1	MC	RGA	MC	RGA	MC	RGA
	1		1.99		2	
Pump 2	MC	RGA	MC	RGA	MC	RGA
	9.7	8.89	14.09	10.98	18.3	12.76
Pump 3	MC	RGA	MC	RGA	MC	RGA
	4.24	3.15	6.44	4.28	8.56	5.28
Pump 4	MC	RGA	MC	RGA	MC	RGA
	15.37	12.88	22.6	19.3	29.91	25.27
Pump 5	MC	RGA	MC	RGA	MC	RGA
	9.06	8.87	13.23	12.13	17.42	15.24

In addition, the LDA, RGA and GRM are part of "RAM model in decommissioning phase" as shown in Figure 2 and such accuracy was demonstrated on Figure 7, Table 1 and 2.

Once the lifetime data analysis step is complete the following step is to Model the RDB and perform the direct simulation.

Figure 8 shows the Boiler System RDB (RDB BQR software) which basically has two subsystem that are Hot Water Boiler and Hot Water Distribution.

The Hot Water Boiler subsystem is represented by the RBD (RDB-BQR software) in Figure 9. In this case, all equipment has standby configuration that enable a high operational availability. Despite high operational availability, the operational cost is high due to number of failures in such equipment.

Figure 10 shows the Hot Water Distribution Subsystem RBD (RDB BQR software) which has the pipes 1, 7 and 8 as the most critical in terms of boiler system unavailability.

After modeling the system the next step is to carry out the direct simulation (MC-Monte Carlo). In this particular case, for the cumulative time of 8 years the boiler has 97.48% of operational availability. The most critical equipment are the pipes 1, 7 and 8 because are those which presents the lower operational availability that is 97%, 97,1% and 97.4% respectively.

Based on simulation result, the future loss of production was predicted based on failure on critical pipes (1,7 and 8). The simulation to predict future loss of production regarded that once the pipes fails during the winter such pipes will be out until the end of the winter. That is a worse scenario as shows picture 11. From the top t the bottom, the first red line represents the pipe 1 shutdown during the winter time. The second red line show the impact of such failure in the boiler system that will be unavailable during the winter once the pipe 1 shutdown.

Based on Boiler system direct simulation, was recommended to take place those critical pipes

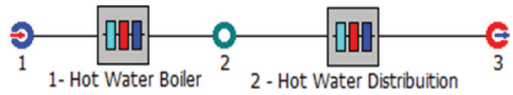

Figure 8. Boiler system.

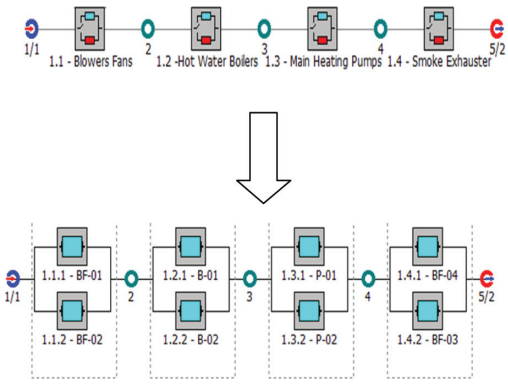

Figure 9. Hot water boiler subsystem.

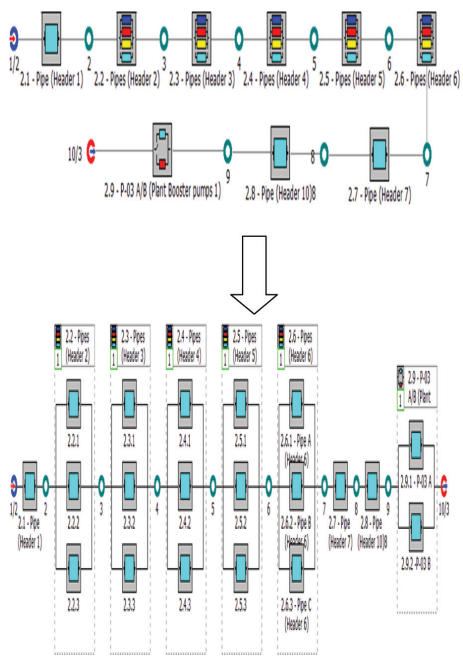

Figure 10. Hot water distribution subsystem.

because based on direct simulation prediction the chance to have such pipe failure during the winter time is 60%. Such probability regards all type of failures on pipes. In case of corrosion, the probability reduces for 10%.

The sensitivity case regarding new subsystems was carried out and in this case the operational availability will achieve 99.92% of operational availability for the next five years if the Hot Water Boiler remains the same and a new Hot Water Boiler will take place. Whether all system be replaced for a new one the operational availability will be 100% in the next 5 years.

The important aspect related decision in decommissioning phase is the Optimum Replace time assessment that defines when each equipment item must be replaced due to the increase operational cost. Regarding this analysis, the boilers must be replaced at 2.34 years because despite not cause impact on system operational availability due to standby configuration the operational cost increase on time as shows the Figure 12.

Similar OPT assessment was carry out for other equipment of Hot Water Boiler in order to define which one must to be replaced for the new one due to increasing operational cost. In this particular case, because of redundancy configuration the equipment has no impact on Hot Water Boiler operational availability but have high operational cost related to failures.

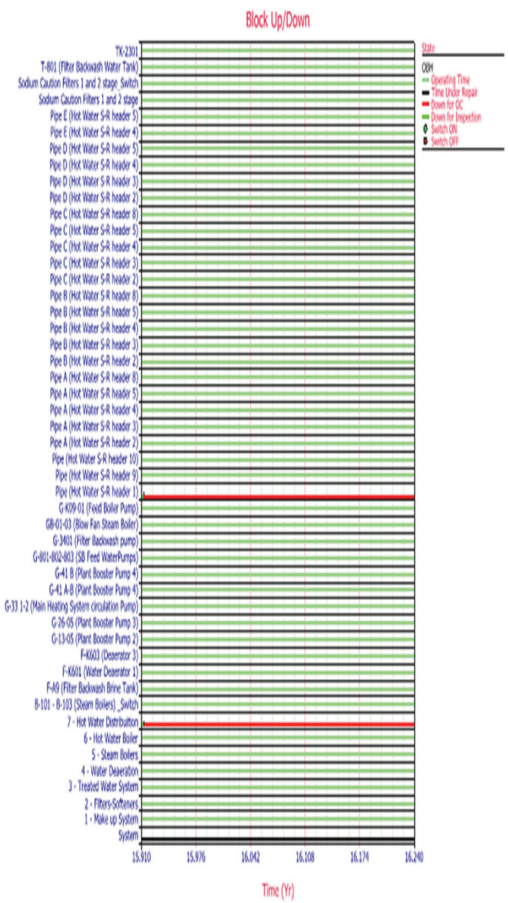

Figure 11. Loss of production during winter.

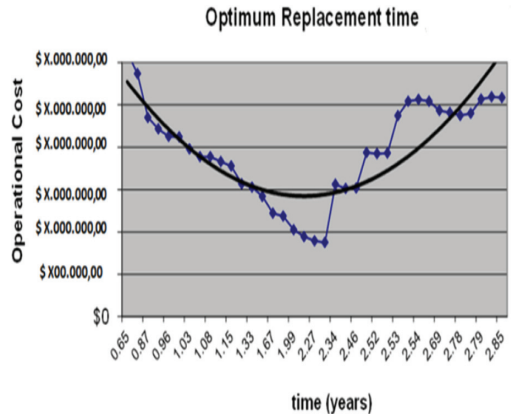

Figure 12. Optimum replace time—water boiler.

8 CONCLUSION

The main objective of this paper was to demonstrate the importance of RAM analysis to support decisions regarding asset improvement during decommissioning phase.

In addition, the paper has demonstrated the importance of restoration factors in predicting the future failures of assets that require additional models such as the General Renewal Model and Crow AMSSA model.

The Direct Simulation (MC-Monte Carlo) and CROW AMSAA model were compared and demonstrated to achieve similar results related to equipment future failure prediction. It is important to highlight that it is only possible when is regarded the restoration factor in Direct Simulation and the PDF as well as Restoration factor are adjusted to predict the similar number of failure obtained on the Crow AMSSA method.

In this particular case study, the simulation during a specific range of time (winter) allows prediction of the loss of production. These model characteristics are not present in all software packages, but must be considered as an opportunity to improve, in order to enable simulations for a specific period of time.

The Decommissioning phase is critical in the asset lifecycle and an accurate decision about which equipment must or must not be replaced should be supported by the best Reliability Engineering methods.

The Optimum Replace Time method is not applied in many cases and must be considered in decommissioning phase for all equipment, even for those that do not have a direct impact on system availability in of the event of failure. In many cases the operational cost increases with time, making the asset inefficient from an economic point of view.

Reliability indices computation for a flow network with a series-parallel-reducible structure

J. Malinowski
Systems Research Institute, Polish Academy of Sciences, Poland
Warsaw School of Information Technology, Poland

ABSTRACT: A flow network with multiple inflow and outflow points, and a series-parallel-reducible structure is considered. It is composed of independent components with constant failure and repair rates. The author has defined indices that characterize the dynamically changing throughput between inflow points and a given internal point. He has also constructed an algorithm to compute these indices. The algorithm is based on the stepwise aggregation of the network structure, it operates on integer numbers, and has relatively low numerical complexity. A crucial role in the computations is played by the notions of c-importance of components and c-availability at network junctions, introduced by the author. The presented results can be applied in the reliability analysis of various types of flow networks, e.g. water supply systems, gas and/or oil pipelines, power transmission and/or distribution networks, etc.

1 INTRODUCTION

The current paper is a continuation of Malinowski (2013), where a series-parallel-reducible system characterized by its capacity defined as a function of component capacities was considered. Its subject is a flow network via which a commodity (water, gas, electric power, etc.) is delivered from inflow to outflow points. The paper can be classified as a contribution to the field of reliability of flow networks regarded as multi-state repairable systems. Multi-state systems with binary or multi-state components have been studied with increasing interest during the recent decades. A broad overview of multi-state reliability models and methods used for their analysis, along with the comprehensive survey of relevant literature can be found in Lisnianski et al. (2010) and Lisnianski & Levitin (2003). Methods of computing failure/repair frequencies, intensities, and availabilities of multi-state systems are investigated in Chang et al. (2004), Druault-Vicard & Tanguy (2006), and Korczak (2007). As far as series-parallel flow networks are concerned, the literature on this subject is rather scarce, however some interesting results, related to the topic of this paper, can be found in Klinz & Woeginger (2004) and Krumke & Zeck (2013).

A network investigated in the current paper has the following characteristics:

1. It is composed of two-state independent components: inflow nodes, transit nodes, outflow nodes, and directed links.
2. It has a series-parallel-reducible structure that can be reduced to a single component by stepwise series-parallel aggregation.
3. To the inflow nodes only outbound links are connected, to the transit nodes—both inbound and outbound links, a node to which only inbound links are connected is called terminal. An outflow node can be either a transit or a terminal one.
4. Each component has certain throughput. The throughput of a non-terminal node is the sum of its outlets' throughputs. One of the outlets of an outflow node supplies a commodity to the customer. An operable component has non-zero integer throughput, a failed one has zero throughput.
5. When a component fails its repair is started immediately. The time-to-failure and time-to-repair of each component are independent, exponentially distributed random variables.
6. The network state is defined w.r.t. a given point, as the effective throughput between this point and all the preceding inflow nodes, i.e. the residual throughput after all the outflow nodes preceding this point are supplied. This state is an integer-valued function of the throughputs and demands of individual components, determined by the system structure. It will be defined later in the paper.
7. The network is operable at an outflow node if the network state at the point just before this node is greater or equal to the node's demand.

In Fig. 1 the Reliability Block Diagram (RBD) of a small exemplary network is presented; e_1 and e_6

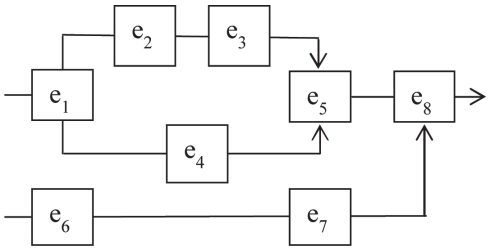

Figure 1. The RBD of a small exemplary network.

are inflow nodes, e_2, e_3, e_4, e_7—outflow nodes, and e_5, e_8—transit nodes. This network is a fragment of a bigger one, as it extends beyond e_8 which is a transit node. For simplicity, pipes are considered failure-free; otherwise, additional boxes should be inserted between the existing ones.

The above described systems can be used as reliability models of various types of flow networks with series-parallel-reducible structures. Systems of this kind are usually considered functional if the effective throughputs at given points are greater or equal to certain threshold values. Their reliability analysis is thus based on parameters related to the time-points in which theses values are reached from above or below during the system operation.

We will consider three such parameters, namely the c-availability and the two c-intensities. They correspond to analogous characteristics for two-state systems. The first parameter, denoted $A(c,t,z)$, is the probability that at time t the network state at a point z is greater or equal to c. The remaining two, denoted $\Lambda^+(c,t,z)$ and $\Lambda^-(c,t,z)$, are the intensities with which the network state crosses the level c from below or above respectively. They will be referred to as transition intensities, where a transition takes place between the states "$\geq c$" and "$<c$". It will be shown how to compute asymptotic ($t\to\infty$) values of these parameters, and how several other frequently used reliability parameters of repairable systems can be derived from the asymptotic intensities. The presented method is illustrated by the calculation of $A(c,t,z)$ for the exemplary network.

2 DETAILED ASSUMPTIONS AND NOTATION

2.1 *Regarding individual components*

e_i—the i-th component of the network; i∈ S, where S is the index set of the components set.

c_i—the throughput of the operable e_i; an integer number.

x_i—the state of e_i; $x_i = c_i$ or $x_i = 0$ depending whether e_i is operable or failed.

$\underline{x}$—the vector of x_i, i∈ S, i.e. $\underline{x} = [x_i, i\in S]$.

$X_i(t)$—the (random) state of e_i at time t.

$\underline{X}(t)$—the (random) vector of the components' states at time t, i.e. $\underline{X}(t) = [X_i(t), i\in S]$.

λ_i, μ_i—the failure or repair intensity of e_i, i.e.

$$\lambda_i = \lim_{u\to 0} \Pr[X_i(t+u) = 0 \mid X_i(t) = c_i]/u,$$
$$\mu_i = \lim_{u\to 0} \Pr[X_i(t+u) = c_i \mid X_i(t) = 0]/u \qquad (1)$$

It is assumed that both intensities are constant, i.e. they do not depend on t. Clearly, this occurs if the time-to-failure and time-to-repair of e_i are exponentially distributed.

$p_i(t)$, $q_i(t)$—the probability of e_i being operable or failed at time t, i.e.

$$p_i(t) = \Pr[X_i(t) = c_i],$$
$$q_i(t) = \Pr[X_i(t) = 0] = 1 - p_i(t) \qquad (2)$$

As shown in Barlow & Proschan (1975), the above probabilities are related to the failure/repair intensities of e_i in the following way:

$$p_i(t) = \frac{\mu_i}{\lambda_i+\mu_i} + \frac{\lambda_i}{\lambda_i+\mu_i}\exp[-(\lambda_i+\mu_i)t],$$
$$q_i(t) = \frac{\lambda_i}{\lambda_i+\mu_i} + \frac{\lambda_i}{\lambda_i+\mu_i}\exp[-(\lambda_i+\mu_i)t] \qquad (3)$$

$A_i(c,t)$—the c-availability of e_i at time t, i.e.

$$A_i(c,t) = \Pr[X_i(t)\geq c] = \begin{cases} 1, & c\leq 0 \\ p_i(t), & 0 < c \leq c_i \\ 0, & c > c_i \end{cases} \qquad (4)$$

2.2 *Regarding a two-state general system*

$\Phi(\underline{x})$—a binary function expressing the system state in relation to the states of its components; $\Phi(\underline{x}) = 1$ or $\Phi(\underline{x}) = 0$ depending whether the system is operable or failed.

A system is called coherent if Φ is non-decreasing, and each component is relevant. See Barlow & Proschan (1975) for details.

$Y(t)$—the system state at time t, i.e. $Y(t) = \Phi(\underline{X}(t))$.

$I_i^B(t)$—the Birnbaum importance of e_i at time t, defined as follows:

$$I_i^B(t) = \frac{\partial \Pr[Y(t)=1]}{\partial p_i(t)} = \Pr[Y(t)=1 \mid X_i(t)=c_i] - \Pr[Y(t)=1 \mid X_i(t)=0] \qquad (5)$$

$I_i^B(t)$ can be interpreted as the probability that the failure of e_i results in the system failure.

$A(t)$, $U(t)$—the system availability or unavailability at time t, i.e.

$$A(t) = E[Y(t)] = \Pr[Y(t) = 1],$$
$$U(t) = 1 - E[Y(t)] = \Pr[Y(t) = 0] \quad (6)$$

$N_{0,1}(s,t)$, $N_{1,0}(s,t)$—the (random) number of times the system is repaired or fails in time interval (s,t).

$V(t)$, $W(t)$—the instantaneous system repair or failure frequency at time t, i.e.

$$V(t) = \lim_{u\to 0} E[N_{0,1}(t,t+u)]/u,$$
$$W(t) = \lim_{u\to 0} E[N_{1,0}(t,t+u)]/u \quad (7)$$

$\Lambda_{0,1}(t)$, $\Lambda_{1,0}(t)$—the system repair or failure intensity at time t, i.e.

$$\wedge_{0,1}(t) = \lim_{u\to 0} \Pr[Y(t+u) = 1 \mid Y(t) = 0]/u,$$
$$\wedge_{1,0}(t) = \lim_{u\to 0} \Pr[Y(t+u) = 0 \mid Y(t) = 1]/u \quad (8)$$

Clearly, (7) and (8) hold if the respective limits exist.

2.3 *Regarding a multi-state network*

We assume that in the below definitions the defined characteristic is measured at a given junction in the network structure.

$\Psi(\underline{x})$—an integer-valued function expressing the network state in relation to the components states.

$Y(t)$—the network state at time t, i.e. $Y(t) = \Psi(\underline{X}(t))$.

$\Phi_c(\underline{x})$—a binary function indicating whether the network state exceeds or is equal to c, defined as follows:

$$\Phi_c(\underline{x}) = \begin{cases} 0, & \Psi(\underline{x}) < c \\ 1, & \Psi(\underline{x}) \geq c \end{cases} \quad (9)$$

$I_i^B(c,t)$—the Birnbaum c-importance of e_i at time t, defined as follows:

$$I_i^B(c,t) = \frac{\partial Pr[Y(t) \geq c]}{\partial p_i(t)} = Pr[Y(t) \geq c \mid X_i(t) = c_i] - Pr[Y(t) \geq c \mid \boldsymbol{X}_i(t) = 0] \quad (10)$$

$I_i^B(c,t)$ can be interpreted as the probability of the event {e_i's failure causes the network state to fall from a level $\geq c$ to a level $<c$}.

$A(c,t)$, $U(c,t)$—the network c-availability or c-unavailability at time t, i.e.

$$A(c,t) = \Pr[Y(t) \geq c],$$
$$U(c,t) = 1 - A(c,t) = \Pr[Y(t) < c] \quad (11)$$

E_c^+—the event {the network state rises from a level <c to a level $\geq c$}.

E_c^-—the event {the network state falls from a level $\geq$c to a level $<c$}.

$N_c^+(s,t)$, $N_c^-(s,t)$—the (random) number of times the event E_c^+ or E_c^- occurs in time interval (s,t].

$V(c,t)$, $W(c,t)$—the instantaneous frequency with which the event E_c^+ or E_c^- occurs at time t, i.e.

$$V(c,t) = \lim_{u\to 0} E[N_c^+(t,t+u)]/u,$$
$$W(c,t) = \lim_{u\to 0} E[N_c^-(t,t+u)]/u \quad (12)$$

$\Lambda^+(c,t)$, $\Lambda^-(c,t)$—the intensity with which the event E_c^+ or E_c^- occurs at time t, i.e.

$$\wedge^+(c,t) = \lim_{u\to 0} \Pr[Y(t+u) \geq c \mid Y(t) < 0]/u$$
$$\wedge^-(c,t) = \lim_{u\to 0} \Pr[Y(t+u) < c \mid Y(t) \geq c]/u \quad (13)$$

Clearly, (12) and (13) hold if the respective limits exist. It should also be noted that the above defined frequencies and intensities are functions of t, unlike the failure/repair intensities of single components.

3 FORMULAS FOR THE TRANSITION FREQUENCIES AND INTENSITIES

Let us first consider a two-state repairable system with independent two-state components. The instantaneous repair and failure frequencies of such a system are given by the following formulas:

$$V(t) = \sum_{i=1}^{n} \mu_i q_i(t) I_i^B(t),$$
$$W(t) = \sum_{i=1}^{n} \lambda_i p_i(t) I_i^B(t) \quad (14)$$

The system repair and failure intensities are related to the repair and failure frequencies in the following way:

$$\wedge_{0,1}(t) = V(t)/U(t), \wedge_{0,1}(t) = W(t)/A(t) \quad (15)$$

The proofs of (14) and (15) can be found in Schneeweiss (1981).

Clearly, the quantities defined in Section 2 for multi-state systems can be expressed in terms of binary systems. For this purpose it is sufficient to assume that the system fails or its repair is completed when the event E_c^- or E_c^+ occurs, and use Φ_c instead of Φ in (5), (6) and (8). In consequence, (14) and (15) are transformed to the following formulas:

$$V(c,t) = \sum_{i=1}^{n} \mu_i q_i(t) I_i(c,t),$$
$$W(c,t) = \sum_{i=1}^{n} \lambda_i p_i(t) I_i(c,t) \quad (16)$$

and

$$\wedge^+(c,t) = V(c,t)/U(c,t),$$
$$\wedge^-(c,t) = W(c,t)/A(c,t) \quad (17)$$

To apply (16) and (17) for the purpose of computing $\Lambda^+(c,t)$ and $\Lambda^-(c,t)$, it is first necessary to find $A(c,t)$, and $I_i^B(c,t)$: $i \in S$ (we assume that λ_i, μ_i, and, in view of (3), $p_i(t)$ for $i \in \underline{S}$ are known). The knowledge of $\Lambda^+(c,t)$ and $\Lambda^-(c,t)$ has a key significance, because, as will be shown in Section 5, other frequently used reliability parameters of repairable systems can be calculated based on $\Lambda^+(c,t)$, and $\Lambda^-(c,t)$. Let us also note that $A(c,t)$ and $I_i^B(c,t)$: $i \in S$, are functions of $p_i(t)$: $i \in S$, thus their asymptotic values for $t \to \infty$, denoted by $A(c)$ and $I_i^B(c)$: $i \in S$, are functions of $p_i = \lim_{t\to\infty} p_i(t)$: $i \in S$. As follows from (3), $p_i(t)$ quickly converges to p_i, hence these asymptotic values characterize, with good accuracy, the network's behavior in the long time horizon. In the next section it will be shown how to compute $A(c)$ and $I_i^B(c)$ for series-parallel-reducible structures.

4 THE SERIES-PARALLEL AGGREGATION

This technique consists in stepwise aggregation of components and/or sub-modules arranged in series or in parallel into a module subsequently regarded as one component. In the last step the whole system is aggregated into a single component. Below, the aggregation steps for the network in Fig. 1 are specified.

Step 1: e2, e3 → M1 = ser(e2, e3)
Step 2: M1, e4 → M2 = par(M1, e4)
Step 3: e1, M2, e5 → M3 = ser(e1, M2, e5)
Step 4: e6, e7 → M4 = ser(e6, e7)
Step 5: M3, M4 → M5 = par(M3, M4)
Step 6: M5, e8 → M6 = ser(M5, e8)

At each aggregation step, maximum effective throughput and c-availability of the obtained module will be calculated. The respective formulas are given in Lemmas 1–6. The first two lemmas give the formulas for maximum effective throughput of a module composed of single components connected in series or in parallel. The RBDs of such modules are shown in Figs. 2 and 3.

Let us adopt the following notation:

M—a module
$e_1,\ldots,e_k$: components of M
$c_1,\ldots,c_k$: throughputs of operable $e_1,\ldots,e_k$
$d_1,\ldots,d_k$: demands at $e_1,\ldots,e_k$ (if e_j is not a customer supply point, then $d_j = 0$)

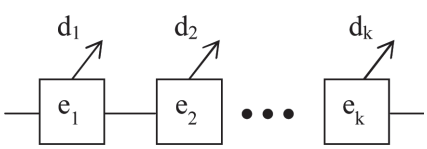

Figure 2. The RBD of ser($e_1,\ldots,e_k$).

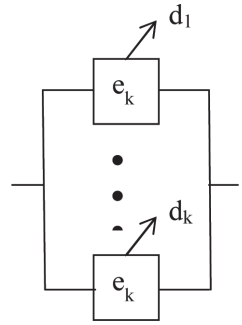

Figure 3. The RBD of par($e_1,\ldots,e_k$).

C_M: maximum (i.e. if $e_1,\ldots,e_k$ are all operable) effective throughput of M

Lemma 1
For M = ser($e_1,\ldots,e_k$) we have:

$$C_M = \min[\max(c_1 - \sum_{i=1}^{k} d_i, 0), \max(c_2 - \sum_{i=2}^{k} d_i, 0), \ldots, \max(c_k - d_k, 0)] \quad (18)$$

Lemma 2
For M = par($e_1,\ldots,e_k$) we have:

$$C_M = \sum_{j=1}^{k} \max[(c_j - d_j), 0] \quad (19)$$

The proofs of Lemmas 1 and 2 will be published in the extended version of this paper.

The two following lemmas show how to compute c-availabilities of the modules presented in Figs. 2 and 3. Let Φ_M and $A_M(c) = \Pr(\Phi_M \geq c)$ denote respectively the (random) effective throughput and the effective c-availability of the module M.

Lemma 3
For M = ser($e_1,\ldots,e_k$) it holds that

$$A_M(c) = \begin{cases} 1, & c \leq 0 \\ p_i \ldots p_k, & 1 \leq c \leq C_M \\ 0, & c \geq C_M + 1 \end{cases} \quad (20)$$

Let us note that the effective throughput of ser($e_1,\ldots,e_k$) can be equal to either 0 or C_M, where C_M is given by (18).

Lemma 4
For M = par($e_1,\ldots,e_k$) the following recursive formula holds:

$$A_{\{1,\ldots,j\}}(c) = p_j A_{\{1,\ldots,j-1\}}[c - \max(c_j - d_j, 0)] + q_i A_{\{1,\ldots,j-1\}}(c), \; j = 2,\ldots,k$$
$$A_M(c) = A_{\{1,\ldots,k\}}(c) \quad (21)$$

where

$$A_{\{1\}}(c) = \begin{cases} 1, & c \le 0 \\ p_i, & 1 \le c \le \max(c_1 - d_1, 0) \\ 0, & c \ge \max(c_1 - d_1, 0) + 1 \end{cases} \quad (22)$$

$A_M(c)$ should be computed for all integer $c \in [1, C_M]$, where C_M is given by (19).

The proofs of Lemmas 3 and 4 are based on Lemmas 1 and 2, and formulas for the distribution functions of the minimum and sum of independent, integer-valued random variables.

Finally, we give the formulas allowing to calculate the effective c-availabilities of modules composed of sub-modules rather than single components.

Lemma 5

If $M = ser(M_1,\ldots,M_k)$ then we have:

$$A_M(c) = \prod_{i=1}^{k} \Pr[\Phi_{M_i} \ge c + \sum_{j=1+1}^{k} d_{M_j}] = \\ = \prod_{i=1}^{k} A_{M_i}(c + \sum_{j=1+1}^{k} d_{M_j}) \quad (23)$$

where d_{Mj} is the total demand of all components of M_j. $A_M(c)$ should be computed for all integer c such that

$$1 \le c \le \min_{i=1,\ldots,k} \left[C_{M_i} - \sum_{j=1+1}^{k} d_{M_j} \right]$$

which is equivalent to the following condition, better suited for computational purposes:

$$A_{M_i}(c + \sum_{j=1+1}^{k} d_{M_j}) > 0, i = 1,\ldots,k$$

Lemma 6

If $M = par(M_1,\ldots,M_k)$ then the following recursive formula holds:

$$A_{M_1 \cup \ldots \cup M_j}(c) = \\ = \sum_{\beta=0}^{C_{M_j}} \Pr\left(\Phi_{M_j} = \beta\right) \Pr(\sum_{i=1}^{j-1} \Phi_{M_i} \ge c - \beta) = \\ = \sum_{\beta=0}^{C_{M_j}} \Pr\left[A_{M_j} = (\beta) - A_{M_j}(\beta+1) \right] \times \\ \times A_{M_1 \cup \ldots \cup M_{j-1}}(c - \beta), j = 2,\ldots,k \quad (24)$$

$A_M(c)$ should be computed for all integer c in the interval $[1, C_{M1} + \ldots + C_{Mk}]$.

Lemmas 5 and 6 are proved in a similar way as Lemmas 3 and 4.

To illustrate the presented method, let us find A(c) for the network presented in Fig 1. We assume that $c_1 = 9$, $c_2 = 4$, $c_3 = 3$, $c_4 = 5$, $c_5 = 4$, $c_6 = 5$, $c_7 = 4$, $c_8 = 7$, and $d_2 = 1$, $d_3 = 1$, $d_4 = 2$, $d_7 = 2$, $d_i = 0$ for i = 1, 5, 6, 8. The following calculations are performed in the successive aggregation steps:

Step 1. According to (20):
$A_{\{2,3\}}(c) = p_2p_3$, $1 \le c \le 2$
$A_{\{2,3\}}(c) = 0$, $c \ge 3$

Step 2. According to (24):
$A_{\{2,3,4\}}(c) = [A_{\{4\}}(0) - A_{\{4\}}(1)]\, A_{\{2,3\}}(c) +$
$+\ldots+ [A_{\{4\}}(3) - A_{\{4\}}(4)]\, A_{\{2,3\}}(c-3) =$
$= q_4\, A_{\{2,3\}}(c) + p_4\, A_{\{2,3\}}(c-3)$
hence
$A_{\{2,3,4\}}(1) = A_{\{2,3,4\}}(2) = q_4p_2p_3 + p_4$
$A_{\{2,3,4\}}(3) = p_4$
$A_{\{2,3,4\}}(4) = A_{\{2,3,4\}}(5) = p_4p_2p_3$
$A_{\{2,3,4\}}(c) = 0$, $c \ge 6$

Step 3. According to (23):
$A_{\{1,\ldots5\}}(c) = A_{\{1\}}(c + d_2 + d_3 + d_4) A_{\{2,3,4\}}(c) A_{\{5\}}(c)$
hence
$A_{\{1,\ldots,5\}}(1) = A_{\{1,\ldots,5\}}(2) = p_1(q_4p_2p_3 + p_4)p_5$
$A_{\{1,\ldots,5\}}(3) = p_1p_4p_5$
$A_{\{1,\ldots,5\}}(4) = p_1p_4p_2p_3p_5$
$A_{\{1,\ldots,5\}}(c) = 0$, $c \ge 5$

Step 4. According to (20):
$A_{\{6,7\}}(c) = 1$, $c \le 0$
$A_{\{6,7\}}(c) = p_6p_7$, $1 \le c \le 2$
$A_{\{6,7\}}(c) = 0$, $c \ge 3$

Step 5. According to (24):
$A_{\{1,\ldots,7\}}(c) = [A_{\{6,7\}}(0) - A_{\{6,7\}}(1)]\, A_{\{1,\ldots,5\}}(c) +$
$+\ldots+ [A_{\{6,7\}}(2) - A_{\{6,7\}}(3)]\, A_{\{1,\ldots,5\}}(c-2) =$
$= (1 - p_6p_7) A_{\{1,\ldots,5\}}(c) + p_6p_7\, A_{\{1,\ldots,5\}}(c-2)$
hence
$A_{\{1,\ldots,7\}}(1) = A_{\{1,\ldots,7\}}(2) =$
$= (1 - p_6p_7)p_1(q_4p_2p_3 + p_4)p_5 + p_6p_7$
$A_{\{1,\ldots,7\}}(3) = (1 - p_6p_7)p_1p_4p_5 +$
$+ p_6p_7p_1(q_4p_2p_3 + p_4)p_5$
$A_{\{1,\ldots,7\}}(4) = (1 - p_6p_7)p_1p_4p_2p_3p_5 +$
$+ p_6p_7p_1(q_4p_2p_3 + p_4)p_5$
$A_{\{1,\ldots,7\}}(5) = p_6p_7p_1p_4p_5$
$A_{\{1,\ldots,7\}}(6) = p_6p_7p_1p_4p_2p_3p_5$
$A_{\{1,\ldots,7\}}(c) = 0$, $c \ge 7$

Step 6. According to (23):
$A_{\{1,\ldots,8\}}(c) = A_{\{1,\ldots,7\}}(c)\, A_{\{8\}}(c)$
hence
$A_{\{1,\ldots,8\}}(c) = A_{\{1,\ldots,7\}}(c)p_8$, $1 \le c \le 6$
$A_{\{1,\ldots,8\}}(c) = 0$, $c \ge 7$

Once A(c) is computed, $I_i^B(c)$ can be found from the following equality:

$$I_i^B(c) = A(c)|_{p_i=1} - A(c)|_{p_i=0} \quad (25)$$

which is a direct consequence of (10) and (11). Thus, to obtain the c-importance of e_i, one has to find $A(c)$ for $p_i = 1$ and $p_i = 0$, p_j being fixed for $j \ne i$, and apply (25). Subsequently, $\Lambda^+(c)$, and $\Lambda^-(c)$ can be calculated from (16) and (17).

Let us note that if e_8 were a terminal node with $d_8 = c \le 6$, then the network would be operable at e_8 for $\Phi_{\{1,\ldots,7\}} \ge c$. Also note that the c-availability at, for example, e_3 is equal to $A_{\{1,2\}}(c)$, where c_1 has

to be replaced with the capacity of the outlet from e_1 towards e_2.

We conclude this section with one important remark: in case of a larger network it is possible to compute only the numerical values of $A(c)$ and $I_i^B(c)$. It is clear that deriving a closed formula, as in the given example, would be too complex a task.

5 OTHER RELIABILITY PARAMETERS EXPRESSED BY THE C-INTENSITIES

It turns out that, using the intensities $\Lambda^+(c)$ and $\Lambda^-(c)$, it is possible to compute other important reliability parameters characterizing the network state fluctuations.

Let us first define a stochastic process Y_c as follows

$$Y_c(t) = \begin{cases} 1, & Y(t) \geq c \\ 0, & Y(t) < c \end{cases} \tag{26}$$

Let, by definition

T_k—the length of the k-th period in which $Y_c(t) = 1$,

R_k—the length of the k-th period in which $Y_c(t) = 0$,

τ_k, ρ_k—the expected lengths T_k and R_k respectively,

$n_c^-(t)$, $n_c^+(t)$—the expected number of occurrences of the event E_c^- or E_c^+ respectively in a time interval of length t (e.g., in a month), provided that the system has long been in operation at the beginning of this interval.

It was shown in Malinowski (2013) that T_k and R_k have asymptotically ($k \to \infty$) exponential distributions with the parameters $\Lambda^-(c)$ and $\Lambda^+(c)$ respectively, hence it holds that

$$\begin{aligned} \tau_c &= \lim_{k\to\infty} \tau_k = 1/\wedge^-(c), \\ \rho_c &= \lim_{k\to\infty} \rho_k = 1/\wedge^+(c) \end{aligned} \tag{27}$$

Ibidem, it was also shown that

$$n_c^-(t) = n_c^+(t) = \frac{t}{\dfrac{1}{\wedge^+(c)} + \dfrac{1}{\wedge^-(c)}} = \frac{t}{\rho_c + \tau_c} \tag{28}$$

It is important to consistently use the same units of time for the parameters in (27) and (28). For example, if $\Lambda^-(c)$ and $\Lambda^+(c)$ are given in h^{-1} (hour to the power –1), then $n_c^-(t)$ is the expected number of occurrences of E_c^- in t hours. In such a case the expected number of occurrences of E_c^- in a year is equal to $n_c^-(8760)$.

6 CONCLUSION

A flow network with directed links, multiple inflow and outflow points, and a structure that can be reduced to a single component by series-parallel aggregation was considered. For such a network three basic reliability parameters were defined: c-availability—the probability with which the network's effective throughput is greater or equal to c, denoted A(c), and two c-intensities with which that throughput is reached from below or above in the course of the failure-repair process, denoted $\Lambda^+(c)$, $\Lambda^-(c)$ respectively. Assuming that the individual components' throughputs are integer valued, a method of computing these parameters was developed. This method has rather low numerical complexity compared to most known methods for network reliability calculation. It was also demonstrated how other parameters, frequently used in the reliability analysis of flow networks, can be found using A(c), $\Lambda^+(c)$ and $\Lambda^-(c)$. The obtained results can be applied to water supply, pipeline (oil or gas), power networks, etc.

Minimal cut sets and direct partial logic derivatives in reliability analysis

M. Kvassay, E. Zaitseva & V. Levashenko
University of Zilina, Zilina, Slovakia

ABSTRACT: A Multi-state system is a mathematical model in reliability engineering, which allows considering some performance level in the system reliability behavior. The principal problem in reliability engineering is identification of system components that have the most influence on the system reliability. direct partial logic derivatives are one of possible approaches. In this paper, the development of direct partial logic derivatives to identify minimal cut sets (or minimal cut vectors) is considered. This development is used for calculation of the Fussell-Vesely importance measure.

1 INTRODUCTION

A system failure is investigated in reliability engineering mostly. But analysis of other system states before a failure is important problem too, that permits to investigate the system performance levels which cause a system failure. A *Multi-State System* (MSS) is one of mathematical models in reliability analysis that allows estimating some performance levels from complete failure to the perfect functioning (Lisnianski & Levitin 2003). This mathematical model is exploited in reliability analysis for detail estimation of a system instead of a *Binary-State System* (BSS) that allows defining only two states for a system and its components: failure and functioning.

Investigation of a MSS is based on the calculation of different reliability indices and measures. The group of *Importance Measures* (IMs) is used for the estimation of the influence of the fixed component state change on the system performance level change (Kuo & Zhu 2012). There are some mathematical approaches for the calculation of these measures. Most of them are based on generalization of methods that have been proposed and used for a BSS analysis. For example, Lisnianski & Levitin (2003) proposed methods for a MSS importance analysis based on the Universal Generating Function. These methods have been developed by Ramirez-Marquez & Coit (2005). In papers Zaitseva 2003, Zaitseva & Levashenko 2013 the Logic Differential Calculus has been used for calculation of IMs. In particular, the Direct Partial Logic Derivatives have been considered as the background for the definition and calculation of IMs. The Direct Partial Logic Derivatives permit to investigate the correlation between the system performance level change and the system component state change. New algorithms for the calculation of the Birnbaum IM and some other measures based on the application of these derivatives have been proposed by Zaitseva 2012 and Zaitseva & Levashenko 2013. But the definition of the Fussell-Vesely IM in terms of Direct Partial Logic Derivatives has not been considered yet. The Fussell-Vesely IM is defined by the conception of Minimal Cut Sets (Kuo & Zhu 2012). Therefore the correlation between Direct Partial Logic Derivatives and Minimal Cut Sets has to be defined.

In this paper, the development of the Direct Partial Logic Derivatives application in reliability analysis is considered and new definitions of the derivatives that are named as the union and the merge of unions of Direct Partial Logic Derivatives are proposed. The new definitions allow uniting two conceptions: the Direct Partial Logic Derivatives and the Minimal Cut Sets. Based on these Direct Partial Logic Derivatives, new definition and algorithms for calculation of IMs as the Structural Importance, Birnbaum Importance and Fussell-Vesely Importance are proposed in this paper.

2 BOUNDARY STATES

2.1 *Structure function of MSS*

The structure function defines the system state (system reliability/performance level) depending on the system components states (Zaitseva 2012):

$$\phi(\boldsymbol{x}) = \phi(x_1, \ldots, x_n):$$
$$\{0, \ldots, m_1 - 1\} \times \ldots \times \{0, \ldots, m_n - 1\} \rightarrow \{0, \ldots, M - 1\}, \quad (1)$$

where $\phi(\boldsymbol{x})$ is the system state from failure ($\phi(\boldsymbol{x}) = 0$) to perfect functioning ($\phi(\boldsymbol{x}) = M - 1$); $\boldsymbol{x} = (x_1, \ldots, x_n)$ is a state vector; x_i is the i-th component state that

changes from failure ($x_i = 0$) to perfect functioning ($x_i = m_i - 1$).

Every system component is characterized by the probabilities of its state:

$$p_{i,s} = \Pr\{x_i = s\},\ s = 0,\ \ldots,\ m_i - 1. \quad (2)$$

Note that the structure function of a MSS (1) is transformed into the structure function of a BSS if $m_i = m_j = M = 2$ (for all $i, j \in \{1, \ldots, n$ where $i \neq j$):

$$\phi(\boldsymbol{x}) = \phi(x_1, ..., x_n) : \{0,1\}^n \to \{0,1\} \quad (3)$$

A MSS reliability and unreliability based on the conception of the structure function (1) are defined as follows (Lisnianski & Levitin 2003):

$$R(j) = \Pr\{\phi(\boldsymbol{x}) \geq j\},\ j = 1,\ldots,\ M - 1, \quad (4)$$

$$U = \Pr\{\phi(\boldsymbol{x}) = 0\}. \quad (5)$$

We will consider a coherent system in this paper. Such system has two principal assumptions for the structure function (Lisnianski & Levitin 2003): (a) the structure function (1) and (3) is monotone (the system component state decrease does not improve the system reliability), and (b) the system components states are s-independent.

2.2 *Boundary states of a MSS*

The boundary state is important conception in the reliability analysis. We consider the boundary states as states for which the change of one system component causes the change of the system performance level. But this system performance level change can be caused by any component or fixed component. Therefore, two types of boundary states are considered. The first type is a boundary state for which the system state change is caused by the change of the fixed component state. These types of states are named as exact boundary states. The second type is boundary state for which the change of any system component state results change in the system state. This type is known as Minimal Cut Set.

2.2.1 *Exact boundary vector*

The exact boundary states have been considered in paper (Zaitseva 2003). These states are system states for which the change of the i-th component state from s to $\tilde{s}$ causes the system performance level change from j to $\tilde{j}$ ($s, \tilde{s} \in \{0,\ldots, m_i - 1\}$, $s \neq \tilde{s}$ and $j, \tilde{j} \in \{0,\ldots, M - 1\}$, $j \neq \tilde{j}$). The exact boundary state is defined by the exact boundary vector unambiguously. Illustrate the correlation of a system exact boundary state and an exact boundary vector by the example.

For example, consider a simple service system (Fig. 1) in a region that consists of three components (n = 3)—service point 1 (x_1—component 1), service point 2 (x_2—component 2) and infrastructure (x_3—component 3). This system has four performance levels: 0—non-operational (no customer is satisfied), 1—partially operational (some customers are satisfied), 2—partially non-operational (some customers are not satisfied), 3—fully operational (all customers are satisfied). Next, we assume that the service points are only functional (state 1) or dysfunctional (state 0). The infrastructure can be modelled by 4 quality levels, i.e. from 0 (the quality of the infrastructure is poor) to 3 (the quality is perfect). The structure function of this system is defined in Table 1 ($m_1 = m_2 = 2$, $m_3 = 4$ and $M = 4$) and components states probabilities are in Table 2.

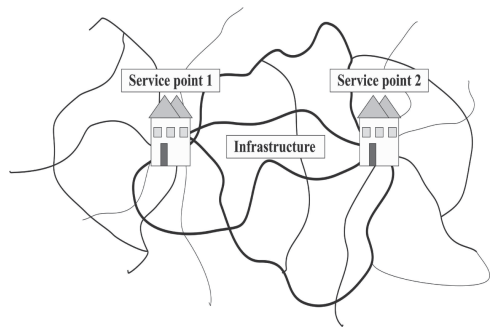

Figure 1. A simple service system.

Table 1. The structure function of the simple service system.

Components states		x_3			
x_1	x_2	0	1	2	3
0	0	0	0	0	0
0	1	0	1	1	2
1	0	0	1	1	2
1	1	0	2	3	3

Table 2. The components states probabilities of the simple service system.

	Components states							
	x_1		x_2		x_3			
	0	1	0	1	0	1	2	3
$p_{i,s}$	0.3	0.7	0.2	0.8	0.2	0.6	0.1	0.1

Determine the exact boundary states of this service system for which the failure of the first component causes the system failure as the change of the system performance level from state "1" to "0". According to Table 1, there are two situations that agree to this condition. They are possible for the failure of the second component and the third component state "1"or "2". These exact boundary states can be presented as vector states: $\boldsymbol{x} = (x_1, x_2, x_3) = (1 \rightarrow 0,0,1)$ and $\boldsymbol{x} = (x_1, x_2, x_3) = (1 \rightarrow 0,0,2)$. Note that the boundary state $\boldsymbol{x} = (x_1, x_2, x_3) = (1 \rightarrow 0,0,3)$ does not satisfy the condition because the system performance level changes from "1" to "2" depending on the failure of the first component in this case.

2.2.2 *Minimal cut vectors*

There are a lot of methods in reliability analysis that use conception of *Minimal Cut Sets* (MCSs). For example, some of them are presented by Choi & Cho (2007) and Yeh (2008). These methods have been proposed for BSS reliability analysis firstly (Shooman 1968, Rosenberg 1996).

Shooman (1968) defined a cut set of a BSS as the system components set whose simultaneous failure leads into the failure of the system (if the system has been functional). A cut set is minimal, if no component can be removed from it without losing its status as a cut set.

In the terms of the structure function, a (minimal) cut set can be interpreted by a special state vector, which is known as a (*Minimal*) *Cut Vector*. According to the definition of a cut set, the system state for a state vector covered by a cut set is zero. Therefore, *state vector* $\boldsymbol{x}$ *is a cut vector if* $\phi(\boldsymbol{x}) = 0$.

A state vector that coincides with a MCS is a *Minimal Cut Vector* (MCV). A *cut vector* $\boldsymbol{x}$ *is minimal if* $\phi(\boldsymbol{y}) = 1$ *for any* $\boldsymbol{y} > \boldsymbol{x}$, where $\boldsymbol{y}$ is state vector, for which $y_i \geq x_i$ $(i = 1, \ldots, n)$ and there exists at least one i such that $y_i > x_i$.

So, if all components of a cut set are failed and components out of the cut set are functioning, then the system is failed.

Butler (1979) generalized the definition of a MCS for MSSs and its other developments have been considered in (Aven 1985, Lisnianski & Levitin 2003, Soh & Rai 2005). Boedigheimer & Kapur (1994) proposed a conception of lower (upper) boundary points for level j ($j = 1, \ldots, M - 1$) that is similar to MCVs. Yeh (2002) and (2008) proposed to use MCVs for a network system that is interpreted as a MSS. However, those algorithms assume that source-sink cuts (in the sense of graph theory) of a network are known and therefore they cannot be used to find MCVs in other types of systems.

The generalization of MCV definition for a MSS takes into account that components of a MSS have more than two states. This extension is based on the assumption that a MCV is defined for every relevant system state, i.e. for states $1,\ldots, M-1$. According to (Aven 1985, Lisnianski & Levitin 2003), a MCV of a MSS is defined as follows: *a state vector* $\boldsymbol{x}$ *is a cut vector for demand state* j *of the system if* $\phi(\boldsymbol{x}) < j$. *A cut vector* $\boldsymbol{x}$ *is minimal if* $\phi(\boldsymbol{y}) \geq j$ *for any* $\boldsymbol{y} > \boldsymbol{x}$.

For example, consider the service system in Table 1. This system has 2 MCVs for level "1", 4 for level "2" and 3 for level "3" (Table 3).

Table 3. MCVs of the simple service system.

System state	MCVs
1	(0,0,3) (1,1,0)
2	(0,0,3) (0,1,2) (1,0,2) (1,1,0)
3	(0,1,3) (1,0,3) (1,1,1)

3 DIRECT PARTIAL LOGIC DERIVATIVES FOR CALCULATION OF BOUNDARY STATES

The mathematical tool of Direct Partial Logic Derivatives has been proposed in (Zaitseva 2003) for calculation of an exact boundary states of a MSS. The Direct Partial Logic Derivative with respect to variable x_i for the structure function (1) permits to analyze the system performance level change from j to $\tilde{j}$ when the i-th component state changes from s to $\tilde{s}$ (Zaitseva 2012, Zaitseva & Levashenko 2013):

$$\partial\phi(j \rightarrow \tilde{j}) / \partial x_i(s \rightarrow \tilde{s}) = \begin{cases} 1, & \text{if } \phi(s_i, \boldsymbol{x}) = j \text{ and } \phi(\tilde{s}_i, \boldsymbol{x}) = \tilde{j} \\ 0, & \text{other} \end{cases} \quad (6)$$

where $\phi(s_i, \boldsymbol{x}) = \phi(x_1,\ldots, x_{i-1}, s, x_{i+1},\ldots, x_n)$; $\phi(\tilde{s}, \boldsymbol{x}) = \phi(x_1,\ldots, x_{i-1}, \tilde{s}, x_{i+1},\ldots, x_n)$; $s, \tilde{s} \in \{0,\ldots, m_i - 1\}$, $s \neq \tilde{s}$ and $j, \tilde{j} \in \{0,\ldots, M-1\}$, $j \neq \tilde{j}$.

The Direct Partial Logic Derivative (6) allows investigating boundary states of a MSS for which component state x_i change from s to $\tilde{s}$ causes the system performance level change from j to $\tilde{j}$. Therefore, this derivative allows calculating exact boundary states that agree to state vectors $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)$.

For example, consider the service system with the structure function in Table 1. The calculation of the Direct Partial Logic Derivative $\partial\phi(1\rightarrow0)/\partial x_1(1\rightarrow0)$ according to (6) is presented in Figure 2 (Zaitseva 2003). The exact boundary states agree to nonzero values of the derivative: $\boldsymbol{x} = (x_1, x_2, x_3) = (1 \rightarrow 0,0,1)$ and $\boldsymbol{x} = (x_1, x_2, x_3) = (1 \rightarrow 0,0,2)$.

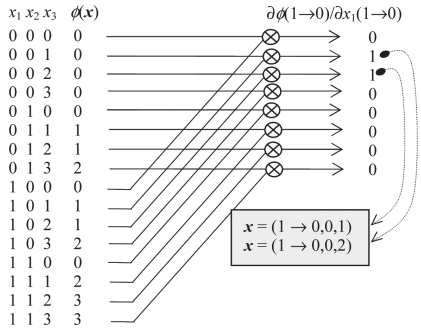

Figure 2. Calculation of the direct partial logic derivative $\partial\phi(1 \to 0)/\partial x_1(1 \to 0)$.

There is one more type of the Direct Partial Logic Derivatives that allows investigating the influence of all changes of the component to the system reliability. It is the union of all Direct Partial Logic Derivatives $\partial\phi(j \to \tilde{j})/\partial x_i(s \to (s+1))$. This union of derivatives identifies all situations in which the improvement of the fixed component state results into the transition of the system from state less than j to state greater than or equal to j:

$$\frac{\partial\phi(\uparrow\ j\uparrow)}{\partial x_i(s \to s+1)} = \bigcup_{w=0}^{j-1}\left(\bigcup_{v=j}^{M-1}\frac{\partial\phi(w \to v)}{\partial x_i(s \to s+1)}\right) \tag{7}$$

for $s = 0, \ldots, m_i - 2$ and $j = 1, \ldots, M-1$.

The Direct Partial Logic Derivative union (7) can be defined as:

$$\partial\phi(\uparrow j\uparrow)/\partial x_i(s \to s+1) = \begin{cases} 1, & \text{if } \phi(s_i, \boldsymbol{x}) < j \text{ and } \phi((s+1)_i, \boldsymbol{x}) \geq j \\ 0, & \text{other} \end{cases} \tag{8}$$

for $s = 0, \ldots, m_i - 2$ and $j = 1, \ldots, M-1$.

The dimension of the Direct Partial Logic Derivative with respect to the variable x_i is defined as $m_{1\ldots}\ m_{i\ -1} m_{i\ +1\ldots} m_n$ (Tapia et al 1991). Therefore the Direct Partial Logic Derivative union (7) and (8) for the i-th variable has dimension $m_{1\ldots}\ m_{i\ -1}\ m_{i\ +1\ldots} m_n$ too. But, the structure function investigation supposes the analysis of the all possible system states. Therefore the Direct Partial Logic Derivative union (7) and (8) has to be transformed for dimension $m_{1\ldots} m_n$ in the following way:

$$\partial\phi(\uparrow j\uparrow)/\partial x_i(s \to s+1) = \begin{cases} 1 & \text{if } x_i = s \text{ and } \phi(s_i, \boldsymbol{x}) < j \text{ and } \phi((s+1)_i, \boldsymbol{x}) \geq j \\ 0 & \text{if } x_i = s \text{ and } \left(\phi(s_i, \boldsymbol{x}) \geq j \text{ or } \phi((s+1)_i, \boldsymbol{x}) < j\right) \\ * & \text{if } x_i \neq s \end{cases}. \tag{9}$$

Table 4. The intersection of two merges of unions of direct partial logic derivatives.

$(\partial\phi\uparrow j\uparrow/\partial x_i)$	*	0	1
*	*	0	1
0	0	0	0
1	1	0	1

The merge (union) of unions (9) of Direct Partial Logic Derivatives has to be computed to identify all situations in which any improvement of a given component causes the transition of the system from state less than j to state greater than or equal to j:

$$\frac{\partial\phi(\uparrow j\uparrow)}{\partial x_i} = \bigcup_{s=0}^{m_i-2}\frac{\partial\phi(\uparrow j\uparrow)}{\partial x_i(s \to s+1)}. \tag{10}$$

The intersection of two merges (10) of two different variables (components) is defined in Table 4. This intersection identifies state vectors in which the change of states of both components (if component state can be changed) results the change of the system state from value less than j to value greater than or equal to j. In Table 4, symbol "1" means that at least state of one component from components i_1 and i_2 can be changed and all those changes result the required change of the system state (from state less than j to state greater than or equal to j). Symbol "0" identifies those state vectors in which at least one component change does not cause the required change of the system state. Finally, symbol "*" correlates with those situations, when neither component i_1 nor component i_2 can be changed from state s to state $s+1$, because both components are in state $m_{i_1} - 1$, $m_{i_2} - 1$, respectively.

The intersection of two merges of extended unions of Direct Partial Logic Derivatives identifies state vectors, in which the improvement of both components (if component can be repaired, i.e. if component is not in state $M-1$) results in the improvement of the system from state less than j to state greater than or equal to j.

The merge (10) of extended unions of Direct Partial Logic Derivatives has to be computed for all components of the system and then their "intersection" allows identifying MCVs for system state j.

4 IMPORTANCE MEASURES

Direct Partial Logic Derivative is one of possible approaches for the calculation of *Importance*

Measures (IMs) (Zaitseva 2012). The importance analysis is a part of reliability analysis that allows investigating the structural and topological aspects of the system from the reliability point of view. The IMs permit to discover the system component with maximal/minimal influence on the MSS performance level. In this paper, the applications of Direct Partial Logic Derivative are used for the computation of IMs, such as the *Structural Importance* (SI), *Birnbaum Importance* (BI), *Fussell-Vesely Importance* (FVI). The basic charcteristics of these measures are in Table 5 (Lisnianski and Levitin 2003, Zaitseva 2012).

According to (Zaitseva 2012), the Direct Partial Logic Derivative has been used for calculation of the SI and BI. The FVI definition is based on the MCS that is calculated based on the Direct Partial Logic Derivative (10) too.

In this a paper, we propose unifying method for calculation of the IMs based on the Direct Partial Logic Derivative (6) and (10).

4.1 *The Structural importance*

The SI is one of the simplest measures of the component importance. This measure focuses on the topological aspects of the system. According to the definition in paper (Armstrong 1997), this measure determines the proportion of working states of the system in which the working of the *i*-th component makes the difference between system failure and its working:

$$IS_i^{s,j} = \frac{\rho_i^{s,j}}{\rho_j} \tag{11}$$

Table 5. Importance measures.

Short name	Description
SI	The SI concentrates on the topological structure of the system and determines the proportion of working states of the system in which the working of the *i*-th component makes the difference between system failure and working state.
BI	The BI of a given component is defined as the probability that such a component is critical to MSS functioning and represents loss in MSS when the *i*-th component fails.
FVI	The FVI quantifies the maximum decrement in MSS reliability caused by the *i*-th system component state deterioration and it also allows estimating system performance level decrease for full unreliability of the *i*-th system component.

where $\rho_i^{s,j}$ is a number of system states when the change of component state from s to $s-1$ results in the system reliability change from j to h (for $h < j$); ρ_j is number of the states for which $\phi(\boldsymbol{x}) = j$ and is calculated by the structure function.

The number $\rho_i^{s,j}$ can be computed as the number of nonzero values of the Direct Partial Logic Derivative (6).

For example, the Direct Partial Logic Derivatives for the structure function in Table 1 with respect to the first variable are in Table 6. Based on these derivatives, we define the SI according to (11). Values of this measure for the first variable are shown Table 6 too. These values indicate that the failure of the first component does not cause the system skip down if the system has performance level 3. The probability of the system failure from performance level 2 and 1 depending on the first component failure is 0.3 and 0.5 accordingly. The degradation of the system performance level 3 has probability 0.5. And degradation of the performance level is possible with probability 0.3.

4.2 *The Birnbaum importance*

Note the SI (11) investigates correlation and influence of system component from the topological point of view. But this measure does not take into account the probabilities of states of system components. This disadvantage is eliminated in the calculation of another IM that is known as the BI. The BI of a given component is defined as the probability that system is sensitive to inoperative of the *i*-th system component (Lisnianski and Levitin 2003). Let us consider the Direct Partial Logical Derivatives for calculation of the BI. In paper (Zaitseva 2012), the BI has been defined as

$$IB_i^{s,j} = \Pr\{\partial\phi(j \to h)/\partial x_i(s \to s-1) \neq 0\} \tag{12}$$

Table 6. Direct Partial Logic Derivatives and SI for the first component of the simple service system.

x_2		
x_3	0 0 0 0 1 1 1 1	
$\partial\phi(j \to h)/\partial x_1(1 \to 0)$	0 1 2 3 0 1 2 3	$IS_1^{1,j}$
$\partial\phi(1 \to 0)/\partial x_1(1 \to 0)$	0 1 1 0 0 0 0 0	0.5
$\partial\phi(2 \to 0)/\partial x_1(1 \to 0)$	0 0 0 1 0 0 0 0	0.3
$\partial\phi(3 \to 0)/\partial x_1(1 \to 0)$	0 0 0 0 0 0 0 0	0
$\partial\phi(2 \to 1)/\partial x_1(1 \to 0)$	0 0 0 0 0 1 0 0	0.3
$\partial\phi(3 \to 1)/\partial x_1(1 \to 0)$	0 0 0 0 0 0 1 0	0.5
$\partial\phi(3 \to 2)/\partial x_1(1 \to 0)$	0 0 0 0 0 0 0 1	0.5

The equation (12) supposes the BI calculation as the probabilities of non-zero values of Direct Partial Logic Derivative $\partial\phi(j \to h)/\partial x_i(s \to s-1)$.

For example, consider the BI for the first component of the system with structure function in Table 1. According to (12) this measure is calculated as probability of nonzero values of Direct Partial Logic Derivatives (see Table 6). Therefore the BI for this system failure depending on the failure of the first system component is defined as:

$$\begin{aligned} IB_1^{1,1} &= \Pr\{\partial\phi(1\to 0)/\partial x_i(1\to 0)\neq 0\} \\ &= \Pr\{\{x_2=0 \text{ and } x_3=1\} \text{ OR } \{x_2=0 \text{ and } x_3=2\}\} \\ &= p_{2,0}\cdot p_{3,1} + p_{2,0}\cdot p_{3,2} \end{aligned}$$

The calculation of other measures is similar.

4.3 *The Fussell-Vesely importance*

There is one more measure that allows investigating the influence of the component state change on the system performance level. It is the FVI that represents the contribution of each component to the system failure probability and, for a BSS; it is calculated by the next equation (Meng 2009):

$$IFV_i = \frac{F_{\min\,\text{cut}}(x_i)}{Q} \tag{13}$$

where $F_{\min\,\text{cut}}(x_i)$ is the probability that at least one minimal cut set that includes the *i*-th system component is failed and Q is the function of the system unreliability (Meng 2009):

$$Q = \Pr\{\phi(\boldsymbol{x}) = 0\}. \tag{14}$$

Now, consider definition (13) of the FVI for a BSS in terms of MCVs. Every MCS can be transformed into a MCV using the following rules (Kvassay et al 2014):

a. every system component that exists in the considered MCS has value 0 in the corresponding MCV,
b. every system component that does not appear in the MCS is represented by value 1 in the corresponding MCV.

Then, the probability that at least one minimal cut set that includes the *i*-th system component is failed can be expressed as follows:

$$F_{\min\,\text{cut}}(x_i) = \Pr\{\boldsymbol{x} \le MCV_i\}, \tag{15}$$

where MCV_i denotes set of all MCVs of the system that have value 0 at the position of the *i*-th component and event $\{\boldsymbol{x} \le MCV_i\}$ means that there is at least one MCV for component *i* that is greater than or equal to arbitrary state vector $\boldsymbol{x}$.

Using (15), the FVI (13) of the *i*-th component for a BSS can be defined as follows:

$$IFV_i = \frac{\Pr\{\boldsymbol{x} \le MCV_i\}}{\Pr\{\phi(\boldsymbol{x})=0\}} = \frac{\Pr\{\boldsymbol{x} \le MCV_i\}}{1-R(1)}. \tag{16}$$

Definition (16) of the FVI for a BSS uses MCVs instead of MCSs and therefore, it is easier to extend it on MSSs.

In a BSS, MCVs exist for one working performance level of the system only, i.e. $\phi(\boldsymbol{x}) = 1$. However, a MSS has more than one working performance level and MCVs are defined for all these levels, i.e. for levels 1, 2,…, $m-1$. Therefore, we use MCV^j to denote MCVs for system performance level *j*.

In addition, MCVs for BSS with respect to component *i* have $x_i = 0$ always, because a BSS component has only two possible states. However, a MSS allows defining more than two states of any component, therefore, we denote MCVs for system state *j* with respect to state *s* of the *i*-th component as $MCV_i^{s,j}$. $MCV_i^{s,j}$ is a subset of MCV^j that contains those MCVs for system state *j* that have value $s-1$ at position *i* in a MCV. So, $MCV_i^{s,j}$ represent situations in which the repair of any damaged component different from component *i* results improvement of the MSS to state *j* or greater and transition of the *i*-th component from state $s-1$ to state *s* (minor improvement of component *i*) causes the similar improvement of MSS performance level.

Now, define the FVI of given component for a MSS in the following way:

$$IFV_i^{s,j} = \frac{\Pr\{\boldsymbol{x} \le MCV_i^{s,j}\}}{1-R(j)} = \frac{\Pr\{\boldsymbol{x} \le MCV_i^{s,j}\}}{\Pr\{\phi(\boldsymbol{x}) < j\}}, \tag{17}$$

where event $\{\boldsymbol{x} \le MCV_i^{s,j}\}$ means that there is at least one MCV for system state *j* and component state *s* which is greater than arbitrary state vector $\boldsymbol{x}$.

Clearly, event $\{\boldsymbol{x} \le MCV_i^{s,j}\}$ is a subset of event $\{\boldsymbol{x} \le MCV^j\}$. Therefore, the FVI (17) can be interpreted as the contribution of the *i*-th component transition from state *s* to state $s-1$ to system unreliability with respect to system state *j* and this is very closely to meaning of the FVI for a BSS (13).

Now, assume that we want to compute the FVIs of individual components of the simple service system defined in Table 1 and identify which component has the most influence on the system state "1". Firstly, we have to compute MCVs of the system. According to the previous section,

Direct Partial Logic Derivatives can be used for this task. In Table 7, there are computed unions (10) of Direct Partial Logic Derivatives (the white columns) and their intersection (the gray columns). Value "1" in the gray columns identifies MCVs for system state "1". According to Table 7, set MCV^1 consists of two state vectors: (1,1,0) and (0,0,3). As we can see, the found MCVs for system state "1" are same as in Table 3.

Next, we identify sets $MCV_i^{s,1}$ from MCV^1 for individual system components and their states (Table 8).

According to Table 8, there exists no MCV for states "2" or "3" of the third component of the simple service system. It means, when the third component is in state "2" or "3", then its minor failure (by one state) does not contribute to system failure.

Using Table 8, we can compute the FVI (17) for system state "1". The calculated FVI are in Table 9.

As we can see from Table 9, state "1" of the third component has the most contribution to system failure. This implies that the majority of situations in which the system fails coincide with the total failure of the 3-rd component.

Table 7. The merges of unions of direct partial logic derivatives and their intersection for state "1" of the service system.

Components states		x_3			
x_1	x_2	0	1	2	3
0	0	0 0 0 0	1 1 0 0	1 1 0 0	1 1 * 1

$IFV_i^{s,1}$	0.2419	0.2419	0.8065	0	0

5 CONCLUSIONS

The principal result of this paper is development of mathematical approach of Direct Partial Logic Derivatives for the calculation of MCVs of a MSS. Mathematical background for this development is considered and used for new definition of FVI measure of a MSS. New method application is presented based on the hand calculation example (it is the system in Fig. 1). The next step of the investigation will be implemented for the comparison of proposed methods and other calculation methods for the FVI measure of a MSS that are considered by Kuo & Zhu (2012) and Ramirez-Marquez & Coit (2005).

On the probability of escaping a cell—in wireless networks

Christian Tanguy
Orange Labs Networks (ONL/NMP/TRM), Issy-les-Moulineaux, France

ABSTRACT: The availability and Quality of Service (QoS) of wireless network connections are crucial for telecommunications companies. The network is constituted by emitters, each devoted to a specific area called "cell". When a user moves from one cell to a neighbouring one, a "handover" (also called "hand-off") procedure must take place for the call to proceed seamlessly. Such a procedure requires network resources, also used for the establishment of new calls. If these resources are not sufficient, the forced termination probability (a call is not completed because of an unsuccessful handover attempt) and the call blocking probability (a new connection request is rejected) may be too large. Our aim is to provide simple, analytical expressions to calculate the above-mentioned probabilities of failure.

In this work we address the probability for a mobile to leave a cell represented by a few n-regular polygons, such as can be used for a two-dimensional tiling/coverage, thereby generalizing existing results on disks and rectangles. We provide the full distributions of probabilities of escaping the cell as a function of displacement, for triangles, squares, hexagons and octagons, along with the asymptotic limit for the disk. The connection with the distance distribution function is also given, along with the asymptotic average distance $\ell(n)$. These formulas could be useful for the reliability practitioner.

1 INTRODUCTION

Cellular networks have been investigated for several decades (Mac Donald 1979). Quite naturally, the advances of wireless communications have made necessary the consideration of several aspects linked to reliability. How can one ensure that communications are indeed made possible, and are not untimely terminated ? Failure protection and Quality of Service are very important issues for network operators, which are constrained by a few factors. For instance, the range of each base station is limited, so that the radius of each "cell" does not extend infinitely. When a user moves to another cell, he/she expects the call to proceed seamlessly. Resources for such a continuation of the call are required, which are also used to process new calls. Cell switching (and the associated handover procedures) also consume some of the resources. A proper optimization of resources is therefore crucial, to say nothing of financial aspects.

Handovers may lead to cut calls, which in turn can lead to customer dissatisfaction. Knowing the probability of escapes from cells is therefore one of the key aspects of wireless network management. Our aim in this work is to show very simply how to compute this probability of escape, which depends on the geometry of the cell, for several regular polygons, which as can be used for a two-dimensional covering.

Our paper is organized as follows. After a quick survey of the literature in Section 2, we introduce in Section 3 a simple way to compute the probability of staying in the initial cell, assuming that that positions at which calls are initiated are uniformly distributed, while the direction of movement of the mobile user is isotropic. We then devote the next Section to the catalog of fully analytical expressions valid for regular polygons such as equilateral triangles, squares, hexagons and octagons (they can pave the two-dimensional space when used with smaller squares). In Section 5 we link the obtained expressions to the more traditional chord length and distance density distributions, which have been studied since the nineteenth century in the field of stochastic geometry and for which considerable progress has been made in very recent years.

2 STATE OF THE ART

Traffic models and performance analysis have long been considered in cellular radio systems (Hong & Rappaport 1986, Guérin 1987). When the mobile user crosses the boundary between a cell and the next one while the call is in progress, the call requires a new base station and a new channel frequency. The procedure that allows to provide the new channel is called handover (or handoff, depending

on the source). Hong & Rappaport (1986) chose to replace a hexagonal cell by an effective circular one, because computations are easier. Their assumption is that the mobile user is moving in any direction, and that the direction remains constant throughout the call. Guérin (1987) considered hexagonal networks too, but limited the directions followed by the use to only four—north, south, east and west—in his assessment of the channel occupancy time in a cellular radio system.

More recent studies have been devoted to the channel occupancy times, handover rates for mobile computing and outage probabilities (Nanda 1993, Fang, Chlamtac, & Lin 1998, Fang & Chlamtac 2002, Zhang, Shao, & Fujise 2005, Trajanov, Filiposka, & Grnarov 2005, Tanbourgi & Sand 2010, Jain & Gupta 2011, Khan, Abbas, & Khan 2011). Note that the successive versions—going from 2.5G to 5G—of smartphones require to adapt the procedures, and the associated outage probabilities. Various mathematical frameworks are being used, from Monte Carlo simulations to renewal theory; queueing theory is also well represented, with Markov systems at the forefront.

A few other studies go beyond the mere calculation of outage probabilities is order to provision adequate resources, for instance in the future network LTE (Blogowski, Klopfenstein, & Renard 2012) and design adaptative resource allocation for prioritized call admission (Yu & Leung 1997).

Of course, the mobility of the user is a crucial parameter of the problem. This issue has been quite investigated by numerous authors (Zonoozi & Dassanayake 1997, Navidi & Camp 2004, Bettstetter 2001, Bettstetter, Hartenstein, & Pérez-Costa 2002, Bettstetter, Resta, & Santi 2003, Bettstetter, Hartenstein, & Pérez-Costa 2004, Hyytiä, Lassila, &Virtamo 2006, Hyytiä & Virtamo 2007, Le Boudec 2005a, Le Boudec 2005b). One may observe, under certain conditions, steady-state regimes for the position and velocity of the mobile user. Note that the "equilibrium" position distribution is not uniform anymore (see also (Miller 2001)). The velocity distribution, for instance, should not include the null velocity.

A few authors have been also able to show that under such conditions, simple geometric parameters are extremely useful, since they essentially provide the main result. For instance, the average chord length and the average distance $\overline{\ell}$ between points of the same cell appear quite naturally in the picture. Note that this is not only confined to cellular network studies: it also appears in models for efficient flight schedules in the fight against fires (Greulich 2008).

The calculation of the average distance between random points in a cell has been studied for many years by experts in probabilistic geometry (Santaló 1976, Lazoff & Sherman 1994, Mathai, Moschopoulos, & Pederzoli 1999) (The values of $\overline{\ell}$ for the disk, the square and the equilateral triangle are indeed given in page 49 of (Santaló 1976)). Recently, huge progress has been made which has led to new results for regular polygons or more general cells (Harutyunyan & Ohanyan 2009, Zhuang & Pan 2011, Zhuang & Pan 2012b, Aharonyan 2012, Bäsel 2012b, Bäsel 2012a). In turn, these results have been applied to very practical issues such as the minimization of energy consumption in wireless sensor networks (Zhuang, Pan, & Cai 2010) or the definition of network performance metrics (Zhuang & Pan 2012a). A nice overview of these very active fields can be found in (Moltchanov 2012).

Let us now turn to our calculation of the probability of escaping a cell, which is a major ingredient of the aforementioned calculations.

3 GEOMETRICAL METHOD

3.1 *A simple case: The circular cell*

As is usually done, we consider that the calls originate at random in the cell, and that the direction followed by the mobile user is arbitrary (and uniformly distributed). After some time t, the user has moved by some distance d, given by $d = vt$, where v is its (constant) velocity. These assumptions make the calculation quite easy, since it boils down to the assessment of the surface of the set of points belonging to both the original cell and the displaced one. In the case of a circular cell, this is very easy, since all directions are equivalent (see Figure 1).

The corresponding expression for the probability of staying in the disk is therefore easy to calculate; it has been reproduced in various papers and

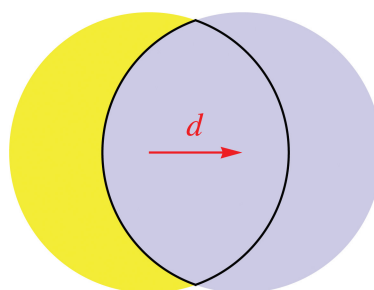

Figure 1. Circular cell and its displaced self. The area of the intersection, when divided by the area of the original disk, is nothing but the probability P_r of staying in the cell after a displacement d. The escape probability is given by $P_e = 1 - P_r$.

books (Trajanov, Filiposka, Makraduli, & Grnarov 2004, Blogowski, Klopfenstein, & Renard 2012). We now turn to more realistic cells, used in tiling the two-dimensional plane.

3.2 *A case study: The octagon*

In the case of an n-regular polygon of radius a, the invariance by rotation is broken, even though some amount of symmetry is preserved (a rotation by π/n leaves the structure unchanged). The area of the intersection of the initial and displaced cell will vary with each angle ϕ and displacement d, as shown in Figures 2–4.

We see in Figures 2–4 that the shape of the intersection goes from octagon to hexagon to lozenge. Each of the areas can be obtained effortlessly, leading to a probability of staying $P_r(d,\phi)$. For each stage, we have a specific area, namely $A_1(d,a,\phi)$, $A_2(d,a,\phi)$, and $A_3(d,a,\phi)$. Going from stage 1 to stage 2 implies a constraint on d and ϕ. This is also true for the transition from stage 2 to stage 3. When d is larger that the diameter of the octagon, namely $D = 2a$, the area of the intersection is zero, meaning that the probability of escape is equal to one.

We have to average $P_r(d,\phi)$ over ϕ, which then gives $\overline{P}_r(d)$. Because of symmetry, we need only consider $0 \le \phi \le \pi/8$. However, the constraints translate into conditions on ϕ for the integration. We have reproduced in Figure 5 the various conditions.

For instance, if $0 \le d \le 2a\sin\frac{\pi}{8}$, the average probability is given by

$$\overline{P}_r(0 \le d \le 2a\sin\frac{\pi}{8}) = \frac{8}{\pi A_0}\int_0^{\frac{\pi}{8}} A_1(d,a,\phi)\,d\phi, \tag{1}$$

Where A_0 is the area of the initial cell, namely $2\sqrt{2}\,a^2$.

For $2a\sin\frac{\pi}{8} \le d \le 2a\sin\frac{\pi}{4}$, we have

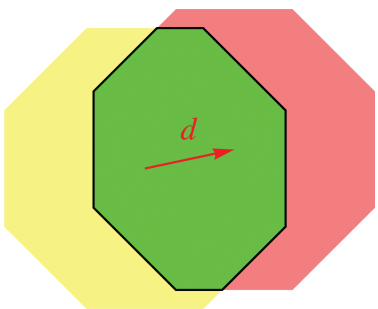

Figure 2. First stage of the displacement of the octagon.

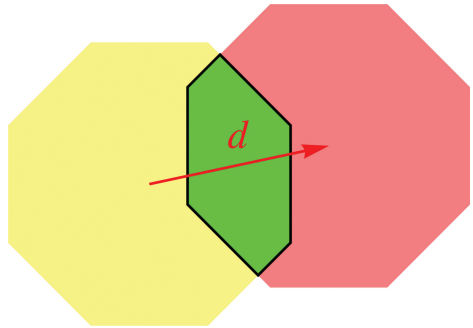

Figure 3. Second stage of the displacement of the octagon.

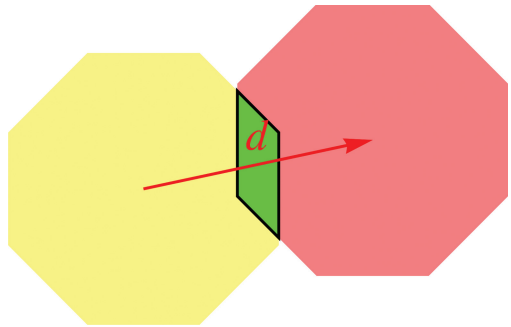

Figure 4. Third stage of the displacement of the octagon.

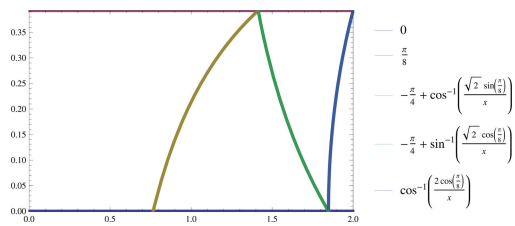

Figure 5. Various boundary functions for integrations over ϕ in the case of the octagon.

$$\overline{P}_r(0 \le d \le 2a\sin\frac{\pi}{8}) = \frac{8}{\pi A_0}\left(\int_0^{h_3} A_2(d,a,\phi)\,d\phi + \int_{h_3}^{\frac{\pi}{8}} A_1(d,a,\phi)\,d\phi\right), \tag{2}$$

with

$$h_3 = \arccos\left(\frac{\sqrt{2}\,a\sin\frac{\pi}{8}}{d}\right) - \frac{\pi}{4}. \tag{3}$$

The limits of the various integration ranges are actually $2a\sin\frac{m\pi}{8}$ $(0 \le m \le 4)$. Note that

integrations are easy—and tedious—to perform, since the $A_i(d,a,\phi)$ are simple expressions of $\cos\phi$, $\sin\phi$, plus constant terms.

The complete results are detailed in the following Section.

4 CATALOG OF ESCAPE PROBABILITIES

We provide a simple list of exact results for the escape probability $\overline{P}_e(x)$, where $x = d/a$ is a dimensionless parameter, for various configurations.

4.1 *Disk*

$$\overline{P}_e(x) = 1 - \frac{2\left(\cos^{-1}(x) - x\sqrt{1-x^2}\right)}{\pi} \quad (0 \le x \le 1) \tag{4}$$

4.2 *Equilateral triangle*

$$\begin{aligned}\overline{P}_e(x) &= \frac{4x\left(1-\frac{1}{36}\left(3\sqrt{3}+2\pi\right)x\right)}{\pi} \quad \left(0 \le x \le \frac{3}{2}\right)\\ &= \frac{6\left(\left(\frac{2x^2}{9}+1\right)\cos^{-1}\left(\frac{3}{2x}\right) - \sqrt{x^2-\frac{9}{4}}\right)}{\pi}\\ &\quad + \frac{4x\left(1-\frac{1}{36}\left(3\sqrt{3}+2\pi\right)x\right)}{\pi}\\ &\quad \left(\frac{3}{2} \le x \le \sqrt{3}\right).\end{aligned} \tag{5}$$

4.3 *Square*

Let us remember here, in order to avoid confusion with previously published results, that a represents the square's *radius* a, not the length of its sides.

$$\begin{aligned}\overline{P}_e(x) &= \frac{4\left(1-\frac{x}{4}\right)x}{\pi} \quad (0 \le x \le 1)\\ &= \frac{4\left(\frac{x^2}{4} - \sqrt{x^2-1} + \cos^{-1}\left(\frac{1}{x}\right) + \frac{1}{2}\right)}{\pi}\\ &\quad (1 \le x \le \sqrt{2})\end{aligned} \tag{6}$$

4.4 *Hexagon*

$$\begin{aligned}\overline{P}_e(x) &= -\frac{x^2}{\sqrt{3}\pi} + \frac{x^2}{9} + \frac{4x}{\sqrt{3}\pi} \quad (0 \le x \le 1)\\ &= -\frac{x^2}{3} + \frac{\sqrt{12x^2-9}}{\pi} + \frac{\left(4x^2+6\right)\sin^{-1}\left(\frac{\sqrt{3}}{2x}\right)}{3\pi}\\ &\quad -\frac{2}{3} \quad (1 \le x \le \sqrt{3})\\ &= \frac{x^2}{\sqrt{3}\pi} - \frac{x^2}{9} - \frac{10\sqrt{3x^2-9}}{3\pi} - \frac{1}{3}\\ &\quad + \frac{\left(2x^2+24\right)\cos^{-1}\left(\frac{\sqrt{3}}{x}\right)}{3\pi} + \frac{2\sqrt{3}}{\pi}\\ &\quad (\sqrt{3} \le x \le 2)\end{aligned} \tag{7}$$

4.5 *Octagon*

$$\begin{aligned}\overline{P}_e(x) &= \frac{(\pi-4)x^2}{4\sqrt{2}\pi} + \frac{4\sqrt{2}x\sin\left(\frac{\pi}{8}\right)}{\pi}\\ &\quad \left(0 \le x \le 2\sin\frac{\pi}{8}\right)\\ &= \frac{1}{8}\left(3\sqrt{2}x^2 + 4\sqrt{2} - 4\right)\\ &\quad + \frac{3\left(\sqrt{2}-1\right)\sqrt{\left(2+\sqrt{2}\right)x^2-1}}{\pi}\\ &\quad - \frac{\left(\sqrt{2}x^2 + 2\sqrt{2} - 2\right)\cos^{-1}\left(\frac{1}{\sqrt{2+\sqrt{2}}x}\right)}{\pi}\\ &\quad \left(2\sin\frac{\pi}{8} \le x \le \sqrt{2}\right)\\ &= \frac{1}{8}\left(\sqrt{2}x^2 + 4\right)\\ &\quad - \frac{\left(\sqrt{2}x^2 + 2\sqrt{2} + 2\right)\cos^{-1}\left(\frac{1}{2x\sin\frac{\pi}{8}}\right)}{\pi}\\ &\quad + \frac{3\left(1+\sqrt{2}\right)\sqrt{\left(2-\sqrt{2}\right)x^2-1}}{\pi}\\ &\quad \left(\sqrt{2} \le x \le 2\sin\frac{3\pi}{8}\right)\\ &= -\frac{\sqrt{2}\pi x^2 - 4\sqrt{2}x^2 + 4\sqrt{2}\pi - 16\left(1+\sqrt{2}\right)}{8\pi}\\ &\quad + \frac{\left(\sqrt{2}x^2 + 4\sqrt{2} + 8\right)\cos^{-1}\left(\frac{2\cos\left(\frac{\pi}{8}\right)}{x}\right)}{\pi}\\ &\quad - \frac{\left(1+2\sqrt{2}\right)\sqrt{x^2-\sqrt{2}-2}\csc\left(\frac{\pi}{8}\right)}{\pi}\\ &\quad \left(2\sin\frac{3\pi}{8} \le x \le 2\right)\end{aligned} \tag{8}$$

We have represented in Figure 6 the behavior of these escape probabilities. We see that the approach to the boundary manifests itself with

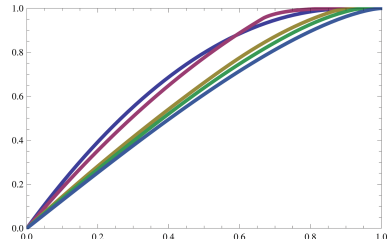

Figure 6. Comparison of the rescaled escape probabilities of the configurations detailed in Section 4 as a function of the displacement x^*, so that these probabilities are equal to 1 for $x^* = 1$. The general trend for the curves is a rightward move as n increases, with the exception of $n = 4$ (violet curve).

quite noticeable differences between the disk and other cell geometries. This is of the utmost importance, because most outages correspond to mobile users about to cross the boundary and change cells. This means that using "effective" circular cells may be not so accurate for subsequent numerical assessments of failure probabilities.

5 LINK WITH STOCHASTIC GEOMETRY

As mentioned in Section 2, there is a large body of work in stochastic geometry concerning the chord length and distance density distributions. New results have been proposed quite recently for regular n-polygons (Bäsel 2012b, Harutyunyan & Ohanyan 2009). These functions have been, in some instances, given explicitly (Zhuang & Pan 2011, Zhuang & Pan 2012b, Aharonyan 2012). The (normalized) distance density of probability is often defined as $g(l)$, so that the average distance $e\ell$ is given quite generally by

$$\bar{\ell} = \int_0^D g(l)\,dl. \tag{9}$$

where D is again the diameter of the cell.

Actually, the probability of remaining in the cell, $\overline{P}_r(l) = 1 - \overline{P}_e(l)$ is very closely connected to $g(l)$. We have

$$g(d) = \frac{2\pi d}{A_0}\overline{P}_r(d). \tag{10}$$

This means that we can recover the average length already obtained by other groups in a simple way:

$$\bar{\ell} = \int_0^D \frac{2\pi l^2}{A_0}\overline{P}_r(l)\,dl. \tag{11}$$

An analytical value is actually obtained for $\bar{\ell}(8) = 0.860007978015497247289475476698a$ for the octagon, but its expression is rather lengthy, and will not be given here It is in agreement with the value given in (Hsu 1990), once proper rescaling has been performed. In this reference, the author remarks that Monte Carlo simulations could not give information about the way the average distance in a n-regular polygon approaches that of the disk. We decided to give it a try, and numerically obtained the following asymptotic expansion, which is

$$\bar{\ell}_{\text{approx}}(n) \approx \frac{128a}{45\pi}\left(1 - \frac{1}{3}\frac{\pi^2}{n^2} + \frac{19}{360}\frac{\pi^4}{n^4} + \cdots\right). \tag{12}$$

Considering $n = 8$ in equation (12), we get $\bar{\ell}_{\text{approx}}(8) \approx 0.8600090923$, which is already satisfactory. By contrast, the average of the *s*quare of the distance is simply

$$\overline{\ell^2}(n) = \frac{2 + \cos\frac{2\pi}{n}}{3}a^2. \tag{13}$$

6 CONCLUSION

We have provided the full distributions of probabilities of escaping the cell as a function of displacement for triangles, squares, hexagons and octagons, along with their asymptotic limit: the disk. This catalog of formulas could be useful for the reliability practitioner. Besides, they show the notable difference between polygons and the limiting circle, especially close to the boundary, which is the region where hand-over procedures are most likely to occur. We have also shown that the probability of staying in such cells is closely related to the distance distribution of uniformly distributed points, which has recently been addressed for regular n-polygons (but not only) by several authors working in statistical geometry. We have also given an asymptotic expansion of the average distance $\bar{\ell}(n)$, which is an important parameter when using the random way-point mobility model for the performance assessment of mobile ad hoc networks (MANETs). After inclusion of relevant traffic and mobility data, our results will allow an efficient provisioning and optimization of network resources: cell area, energy consumption of emitters (in a green context), etc. Note that these calculations may be used, not only for wireless networks, but in a wide range of applications, such as vehicular technologies and mobile systems.

Reliability analysis of ship-rope transporter with dependent components

A. Blokus-Roszkowska & K. Kołowrocki
Maritime University, Gdynia, Poland

ABSTRACT: In the paper, an innovative model of combination of the influence of complex systems' inside-dependences and the influence coming from their outside-dependencies on their reliability are presented. Further, the model is practically applied to the reliability evaluation of the ground ship-rope transporter operating in a shipyard at variable operation conditions and changing in time its reliability structure, its components' reliability parameters and among its components and subsystems dependencies. As a result of this application, the multi-state reliability function of the shipyard transportation system is determined in case when its components have exponential reliability functions with interdependent departures rates from the subsets of their reliability states. At the end, discussion of how changing the reliability structure, components' reliability parameters and inside and outside this transportation system dependencies result in changes of its reliability characteristics is performed.

1 INTRODUCTION

Currently, newest trends in the reliability analysis of technical systems are directed to the complex systems. These are complex systems that significant features are inside-system dependencies and outside-system dependencies, that in case of damage have significantly destructive influence on safety of the environment where they are operating. These systems are made of large number of interacting components and even small perturbations can trigger large scale consequences. For above reason, as an extended failure within one of the complex system may result in critical incapacity or destruction and can significantly damage many aspects of human life. This development of suitable tools for their reliability analysis is of great value.

From the point of view of more precise reliability analysis, developed methods should be based on a multi-state approach (Kołowrocki 2014, Kołowrocki & Soszyńska-Budny 2011, Xue 1985, Xue & Yang 1995a, b, Yu et al. 1994) instead of normally used two-state approach. This will enable different complex system's inside and outside reliability states to be distinguished, such that they ensure a demanded level of system operation effectiveness with accepted consequences of their dangerous accidents.

In most reliability analyses, it is assumed that components of a system are independent. But in reality, especially in case of complex systems, this assumption is not true, so that dependencies among the complex systems' components and subsystems should be assumed and considered. It is a natural assumption, as after decreasing the reliability state by one of components in a subsystem, inside interactions among remaining components may cause further components reliability states decrease (Blokus-Roszkowska 2007a, Pradhan et al. 2003, Pradhan & Hansen 2005).

To tie results of investigations of complex systems inside-dependences together with results coming from assumed their outside-dependencies, the semi-Markov model (Grabski 2002, Kołowrocki 2013, Limnios & Oprisan 2005) can be used to describe those systems operation processes. This linking of inside and outside of complex systems dependencies under assumed their structures multi-state models, is the main idea of the systems' reliability analysis methodology presented in the paper.

2 RELIABILITY ANALYSIS OF SYSTEMS WITH DEPENDENT COMPONENTS

2.1 *Multi-state "m out of n" system*

In the multi-state reliability analysis to define a system with degrading components, we assume that (Kołowrocki 2004):

- n is a number of system components,
- E_i, $i = 1,2, \ldots, n$, are components of a system,
- all components and a system under consideration have the reliability state set $\{0,1, \ldots, z\}$, $z \geq 1$,

– the reliability states are ordered, the reliability state 0 is the worst and the reliability state z is the best,
– $T_i(u)$, $i = 1,2, \ldots, n$, are independent random variables representing lifetimes of components E_i in the reliability state subset $\{u, u+1, \ldots, z\}$, while they were in the reliability state z at the moment $t = 0$,
– $T(u)$ is a random variable representing lifetime of a system in the reliability state subset $\{u, u+1, \ldots, z\}$ while it was in the reliability state z at the moment $t = 0$,
– the system states degrades with time t,
– $E_i(t)$ is a component E_i reliability state at the moment t, $t \in < 0,\infty)$, given that it was in the reliability state z at the moment $t = 0$.

In a multi-state "m out of n" system with dependent components we may consider the dependency of changes of their ageing reliability states and assume that after changing the reliability state subset by one of system components to the worse reliability state subset, lifetimes of remaining system components in this reliability state subset decrease (Blokus-Roszkowska 2007b, Kołowrocki 2013). More exactly, we assume that if anyone of system components gets out of the reliability state subset $\{u, u+1, \ldots, z\}$, then the reliability of remaining ones is getting worse so that their mean values of lifetimes $T_i'(u)$ in reliability state subset $\{u, u+1, \ldots, z\}$ become less according to the formula

$$E[T_i'(u)] = c(u)\frac{n-1}{n}E[T_i(u)], i = 1, \ldots, n, u = 1, \ldots, z, \tag{1}$$

where $c(u)$ are component stress proportionality correction coefficients (Kołowrocki 2013).

Generalizing, if $\upsilon, \upsilon = 0,1,2, \ldots, n-1$, components of a system are out of the reliability state subset $\{u, u+1, \ldots, z\}$, the mean values of the lifetimes $T_i'(u)$ in the reliability state subset $\{u, u+1, \ldots, z\}$ of system remaining components are given by

$$E[T_i'(u)] = c(u)\frac{n-\upsilon}{n}E[T_i(u)], i = 1, \ldots, n, u = 1, \ldots, z. \tag{2}$$

Hence, for case when considered system is homogeneous with components having exponential reliability functions of the form

$$R_i(t,\cdot) = [1, R_i(t,1), \ldots, R_i(t,z)], \quad t \in < 0,\infty), i = 1,2, \ldots, n, \tag{3}$$

where

$$R_i(t,u) = \begin{cases} 1, & t < 0 \\ \exp[-\lambda(u)t], & t \geq 0, \ i = 1, \ldots, n, \end{cases} \tag{4}$$

with intensity of departure $\lambda(u) \geq 0$ from the reliability state subset $\{u, u+1, \ldots, z\}$, according to the well known relationship between the lifetime mean value in this reliability state subset and intensity of departure from this reliability state subset of the form

$$E[T_i(u)] = \frac{1}{\lambda(u)}, i = 1,\ldots,n, u = 1,\ldots,z,$$

we get following formula for intensities of departure from this reliability state subset of remaining components

$$\lambda^{(\upsilon)}(u) = \frac{1}{c(u)}\frac{n}{n-\upsilon}\lambda(u) \quad \upsilon = 0,1, \ldots, n-1, u = 1, \ldots, z. \tag{5}$$

With this simple approach to inside dependencies of complex systems with homogeneous components we can find analytical solutions for reliability characteristics of selected reliability structures. The main theoretical result presented below in the form of Proposition 1 is a generalization of the results given in (Blokus-Roszkowska 2007b, Kołowrocki 2013).

Proposition 1. If in a homogeneous multi-state "m out of n" system

i. components have exponential reliability function given by (3)–(4),
ii. components are dependent,
iii. intensities of departure from the reliability state subsets of components are given by (5),

then the multi-state system reliability function is given by the formula

$$\boldsymbol{R}(t,\cdot) = [1, \boldsymbol{R}(t,1), \ldots, \boldsymbol{R}(t,z)], \tag{6}$$

where

$$\boldsymbol{R}(t,u) = \sum_{\upsilon=0}^{n-m} \frac{\left[\frac{n\lambda(u)}{c(u)}t\right]^{\upsilon}}{\upsilon!} \times \exp\left[-\frac{n\lambda(u)}{c(u)}t\right], t \geq 0, u = 1, \ldots, z. \tag{7}$$

Proof: We denote by $N(t,u)$ a number of components that got out of the reliability state subset $\{u, u+1, \ldots, z\}$ up to the moment t, $t \geq 0$. Then the number $N(t,u)$ is a process with states

0,1,2, …, n, and probability of its particular state is given by

$$P_\upsilon(t,u) = P(N(t,u) = \upsilon), \upsilon = 0,1,2, \ldots, n, u = 1, \ldots, z.$$

The above definition and formula (5) mean that the process $N(t,u)$ is a Markov process with the transition rates

$$\lambda_{ij}(u) = \begin{cases} -\dfrac{n\lambda(u)}{c(u)}, & j = i, \\ \dfrac{n\lambda(u)}{c(u)}, & j = i+1, \\ 0, & j \neq i \wedge j \neq i+1, i = 0,1, ..., n. \end{cases}$$

Since a "m out of n" system is out of the reliability state subset $\{u, u+1, \ldots, z\}$ if at least m its components are in the reliability state subset $\{u, u+1, \ldots, z\}$, i.e. the system is out of this reliability state subset when the process $N(t,u)$ is at the state $n-m+1$. Then the state $n-m+1$ is an absorbing state and the matrix of transition rates between states takes the following form

$$\begin{array}{c} state \\ 0 \\ 1 \\ \vdots \\ n-m \\ n-m+1 \\ \vdots \\ n \end{array} \begin{array}{c} \begin{array}{ccccccccc} 0 & 1 & 2 & \ldots & n-m & n-m+1 & \ldots & n \end{array} \\ \begin{bmatrix} -\dfrac{n\lambda(u)}{c(u)} & \dfrac{n\lambda(u)}{c(u)} & 0 & \ldots & 0 & 0 & 0 \ldots & 0 \\ 0 & -\dfrac{n\lambda(u)}{c(u)} & \dfrac{n\lambda(u)}{c(u)} & \ldots & 0 & 0 & 0 \ldots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \ \vdots \ \vdots & \\ 0 & 0 & 0 & \ldots & -\dfrac{n\lambda(u)}{c(u)} & \dfrac{n\lambda(u)}{c(u)} & 0 \ldots & 0 \\ 0 & 0 & 0 & \ldots & 0 & 0 & 0 \ldots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \ \vdots \ \vdots & \\ 0 & 0 & 0 & \ldots & 0 & 0 & 0 \ldots & 0 \end{bmatrix} \end{array} \tag{8}$$

Thus, the distribution function of system lifetime in the state subset $\{u, u+1, \ldots, z\}$ is given by

$$\begin{aligned} \boldsymbol{F}(t,u) &= P(T(u) < t) \\ &= P(N(t,u) = n-m+1) = P_{n-m+1}(t,u) \end{aligned}$$

for $t \geq 0$, $u = 1,\ldots,z$,

and the suitable reliability function component of this system is of the form

$$\boldsymbol{R}(t,u) = 1 - P_{n-m+1}(t,u), t \geq 0, u = 1, \ldots, z. \tag{9}$$

From the stochastic processes theory it follows that having given the matrix (8) of transition rates between states, it is possible to find the probability $P_{n-m+1}(t,u)$ from following system of differential equations:

$$\begin{cases} P_0'(t,u) = -\dfrac{n\lambda(u)}{c(u)} P_0(t,u) \\ P_1'(t,u) = \dfrac{n\lambda(u)}{c(u)} P_0(t,u) - \dfrac{n\lambda(u)}{c(u)} P_1(t,u) \\ P_2'(t,u) = \dfrac{n\lambda(u)}{c(u)} P_1(t,u) - \dfrac{n\lambda(u)}{c(u)} P_2(t,u) \\ \quad \vdots \\ P_{n-m}'(t,u) = \dfrac{n\lambda(u)}{c(u)} P_{n-m-1}(t,u) - \dfrac{n\lambda(u)}{c(u)} P_{n-m}(t,u) \\ P_{n-m+1}'(t,u) = \dfrac{n\lambda(u)}{c(u)} P_{n-m}(t,u) \end{cases} \tag{10}$$

for $t \geq 0$, $u = 1,\ldots,z$.

It is supposed that all components of analyzed system at the beginning are in the state subset $\{u, u+1, \ldots, z\}$, and therefore at the moment $t = 0$ the process $N(t,u)$ $u = 1,2, \ldots, z$, is at the state 0. It means that probability of its particular states $\upsilon = 0,1,2, \ldots, n-m+1$, of the process $N(t,u)$, $u = 1,2, \ldots, z$, at the moment $t = 0$ are given by

$$P_0(0,u) = 1, P_\upsilon(0,u) = 0, \upsilon = 1,2, \ldots, n-m+1, \quad u = 1, \ldots, z. \tag{11}$$

Applying Laplace's transform to the system of equations (10) with the initial conditions (11), we obtain

$$\begin{cases} s\boldsymbol{P}_0(s,u) - 1 = -\dfrac{n\lambda(u)}{c(u)} \boldsymbol{P}_0(s,u) \\ s\boldsymbol{P}_1(s,u) = \dfrac{n\lambda(u)}{c(u)} \boldsymbol{P}_0(s,u) - \dfrac{n\lambda(u)}{c(u)} \boldsymbol{P}_1(s,u) \\ \quad \vdots \\ s\boldsymbol{P}_{n-m}(s,u) = \dfrac{n\lambda(u)}{c(u)} \boldsymbol{P}_{n-m-1}(s,u) - \dfrac{n\lambda(u)}{c(u)} \boldsymbol{P}_{n-m}(s,u) \\ s\boldsymbol{P}_{n-m+1}(s,u) = \dfrac{n\lambda(u)}{c(u)} \boldsymbol{P}_{n-m}(s,u), \end{cases}$$

where

$$\boldsymbol{P}_\upsilon(s,u) = \int_0^\infty P_\upsilon(t,u) \exp[-st] dt, \upsilon = 1,2, \ldots, n-m+1, \quad u = 1,2, \ldots, z,$$

is a transform of the probability $P_\upsilon(t,u)$ of its particular states $\upsilon = 1,2, \ldots, n-m+1$.

Further, for $u = 1,2, \ldots, z$, we have

$$\begin{cases} \boldsymbol{P}_0(s,u) = \dfrac{c(u)}{s\cdot c(u)+n\lambda(u)} \\ \boldsymbol{P}_1(s,u) = \dfrac{n\lambda(u)}{s\cdot c(u)+n\lambda(u)}\boldsymbol{P}_0(s,u) \\ \quad\vdots \\ \boldsymbol{P}_{n-m}(s,u) = \dfrac{n\lambda(u)}{s\cdot c(u)+n\lambda(u)}\boldsymbol{P}_{n-m-1}(s,u) \\ \boldsymbol{P}_{n-m+1}(s,u) = \dfrac{n\lambda(u)}{s\cdot c(u)}\boldsymbol{P}_{n-m}(s,u). \end{cases}$$

From this system of equations we conclude that transforms of the probability $\boldsymbol{P}_{n-m+1}(s,u)$ are equal

$$\boldsymbol{P}_{n-m+1}(s,u) = \frac{[n\lambda(u)]^{n-m+1}}{s[s\cdot c(u)+n\lambda(u)]^{n-m+1}}, u = 1, \ldots, z,$$

which may be written in the form of following series

$$\boldsymbol{P}_{n-m+1}(s,u) = \frac{1}{s} - \sum_{\upsilon=0}^{n-m} \frac{\left[\dfrac{n\lambda(u)}{c(u)}\right]^{\upsilon}}{\left[s+\dfrac{n\lambda(u)}{c(u)}\right]^{\upsilon+1}}, u = 1, \ldots, z.$$

After application of inverse Laplace's transform to above equation, we have

$$P_{n-m+1}(t,u) = 1 - \sum_{\upsilon=0}^{n-m} \frac{\left[\dfrac{n\lambda(u)}{c(u)}t\right]^{\upsilon}}{\upsilon!}\exp\left[-\frac{n\lambda(u)}{c(u)}t\right], t \geq 0,$$
$$u = 1, \ldots, z.$$

Taking into account the last result and (9) we get (7), which completes the proof. #

2.2 *Multi-state "m out of l"-series system*

To define a "*m* out of *l*"-series system, we assume that (Kołowrocki 2004):

- k is a number of "*m* out of *l*" subsystems of a system,
- l is a number of components of "*m* out of *l*" subsystems,
- E_{ij}, $i = 1,2, \ldots, k$, $j = 1,2, \ldots, l$, $k, l \in N$, are components of a system,
- all components E_{ij} have the same reliability state set as before $\{0,1, \ldots, z\}$,
- $T_{ij}(u)$, $i = 1,2, \ldots, k$, $j = 1,2, \ldots, l$, $k, l \in N$, are random variables representing lifetimes of components E_{ij} in the reliability state subset $\{u, u+1, \ldots, z\}$, while they were in the reliability state z at the moment $t = 0$.

Then we can consider a multi-state "*m* out of *l*"-series system defined in (Kołowrocki 2004) and its multi-state reliability function in case its components are dependent. To this end, we assume similarly as in formula (2) for a "*m* out of *n*" system that if $\upsilon, \upsilon = 0,1,2, \ldots, l-1$, components of each "*m* out of *l*" subsystem of a system are out of the reliability state subset $\{u, u+1, \ldots, z\}$, the mean values of lifetimes $T_{ij}'(u)$ in the reliability state subset $\{u, u+1, \ldots, z\}$ of this subsystem remaining components are given by

$$E[T_{ij}'(u)] = c(u)\frac{l-\upsilon}{l}E[T_{ij}(u)] \tag{12}$$

for $i = 1,2, \ldots, k$, $j = 1,2, \ldots, l$, $u = 1,2, \ldots, z$, where $c(u)$ are component stress proportionality correction coefficients (Kołowrocki 2013).

Hence, in case subsystem components have exponential reliability functions with intensity of departure $\lambda(u)$ from the reliability state subset $\{u, u+1, \ldots, z\}$, according to the well known relationship between the lifetime mean value in this reliability state subset and the intensity of departure from this reliability state subset we get following formula for intensities of departure from this reliability state subset of subsystem remaining components

$$\lambda^{(\upsilon)}(u) = \frac{1}{c(u)}\frac{l}{l-\upsilon}\lambda(u) \tag{13}$$

for $\upsilon = 0,1,2, \ldots, l-1$, $u = 1,2, \ldots, z$.

Proposition 1 slight extension yields the following result.

Proposition 2. If in a homogeneous multi-state "*m* out of *l*"-series system.

i. components have exponential reliability function given by

$$R_{ij}(t,\cdot) = [1, R_{ij}(t,1), \ldots, R_{ij}(t,z)] \tag{14}$$

where

$$R_{ij}(t,u) = \begin{cases} 1, & t < 0, \\ \exp[-\lambda(u)t], & t \geq 0, \end{cases} \tag{15}$$

for $u = 1,2, \ldots, z$, $i = 1,2, \ldots, k$, $j = 1,2, \ldots, l$, with intensity $\lambda(u) \geq 0$ of departure from the reliability state subset $\{u, u+1, \ldots, z\}$,

ii. components are dependent,

iii. intensities of departure from the reliability state subsets of components are given by (13),

then the multi-state system reliability function is given by the formula

$$\boldsymbol{R}(t,\cdot) = [1, \boldsymbol{R}(t,1), \ldots, \boldsymbol{R}(t,z)], \tag{16}$$

where

$$\boldsymbol{R}(t,u)=\left[\sum_{v=0}^{l-m}\frac{\left[\frac{l\lambda(u)}{c(u)}t\right]^{v}}{v!}\exp\left[-\frac{l\lambda(u)}{c(u)}t\right]\right]^{k} \tag{17}$$

for $t \geq 0$, $u = 1, \ldots, z$.

3 RELIABILITY OF A GROUND SHIP-ROPE TRANSPORTER

3.1 *System's description*

The ground ship-rope transporter is used to transfer ships coming to a shipyard for repairs from a platform to a repair post and back from a repair post to a platform. First during ship docking a ship settled in special supporting carriages on the platform is raised to the wharf level, then a ship is transferred from the platform with rope broaching machines on a traverser. Next a ship with the traverser, on which a ship is settled, is shifted in the repair post direction. After some repair measures, a ship is transferred back to the traverser and next on the platform. Finally, during undocking a ship on the platform is moved down to the water.

There are nine repair posts, denoted by symbols R1–R9. First repair post R1 can be lengthening to the post R1/B1 for long ships. There are also available two repair depots denoted by symbols B and D. Generally all kind of repairs can be carried out in any repair post. The repair posts R1 and R2 are equipped in a crane. Submarines are repaired in the depot. Additionally large vessels are transferred to the repair post R1/B1. The scheme of a plan of repair post placing is given in Figure 1.

The ground ship-rope transporter is composed of three broaching machines working independently

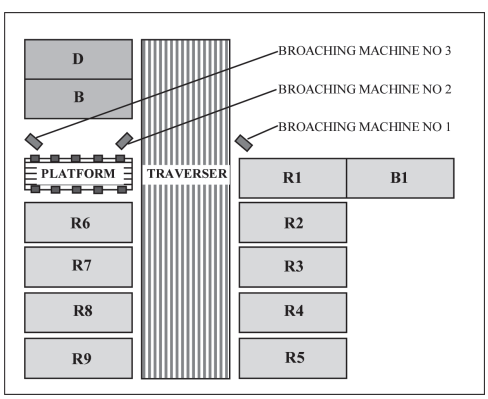

Figure 1. The scheme of a plan repair post placing.

equipped in steel ropes. The ground ship-rope transporter reliability depends strongly on a tonnage of transferred ships and the place where a ship should be transferred. These broaching machines in the transportation system are numbered 1, 2, 3. There is used one or there are used two or possibly three broaching machines depending on weight and length of a ship and on which repair post a ship should be transferred. All three broaching machines are working in extreme situation when large vessel over 1800 tons is transferred.

3.2 *System's operation process*

We analyze the ground ship-rope transporter taking into account the system operation process and its varying in time reliability structures. Considering weight and size of vessels i.e. the system's loading and the place where the ship is transferred, that has influence on the decision which broaching machines are used we can distinguish following eight operation states:

- an operation state z_1, the system is without loading, the time of waiting for a ship,
- an operation state z_2, a ship with a tonnage up to 1300 tons is transferred from the platform to the traverse, from the traverse to the repair posts R1-R5 and from the repair posts R6-R9 to the traverse (the broaching machine no. 1 is used),
- an operation state z_3, a ship with a tonnage up to 1300 tons is transferred from the traverse to the repair posts R6-R9, from the repair posts R1-R5 to the traverse and from the traverse to the platform (the broaching machine no. 3 is used),
- an operation state z_4, a ship with a tonnage up to 1300 tons is transferred from the repair posts R1-R5 to the traverse and the access to the broaching machine number 3 is difficult (the broaching machine no. 2 is used),
- an operation state z_5, a ship with a tonnage over 1300 up to 1800 tons is transferred from the platform to the traverse, from the traverse to the repair posts R1-R5 or from the repair posts R6-R9 to the traverse (the broaching machines 1 and 3 are used),
- an operation state z_6, a ship with a tonnage over 1300 up to 1800 tons is transferred from the platform to the traverse, from the traverse to the repair posts R1-R5 or from the repair posts R6-R9 to the traverser and the access to the broaching machine number 3 is difficult (the broaching machines 1 and 2 are used),
- an operation state z_7, a ship with a tonnage over 1300 up to 1800 tons is transferred from the traverse to the repair posts R6-R9, from the repair posts R1-R5 to the traverse or from the traverse to the platform (the broaching machines 2 and 3 are used),

– an operation state z_8, a ship with a tonnage over 1800 tons is transferred (all broaching machines 1, 2 and 3 are used).

From the operation process analysis and its statistical identification presented in (Blokus-Roszkowska & Kołowrocki 2009a) we obtain limit values of transient probabilities $p_b(t)$ at particular operational states z_b, $b = 1,2, \ldots, 8$, that respectively amount:

$$p_1 = 0.9790,\ p_2 = 0.0064,\ p_3 = 0.0065,\ p_4 = 0,$$
$$p_5 = 0.0009,\ p_6 = 0, p_7 = 0.0042,\ p_8 = 0.0030. \tag{18}$$

3.3 *System's reliability*

The system consists of three broaching machines subsystems S_1, S_2, S_3 linked in series. Each broaching machine S_1, S_2, S_3 is equipped with one rope that is composed of 6 identical strands. Each strand consists of 36 wires with a webbing core. We consider wires as basic components of the system.

According to rope reliability data given in their technical certificates and experts' opinions, based on nature of wire failures, following reliability states of the ropes' components have been distinguished:

– a reliability state 3, the wire is new, without any defects,
– a reliability state 2, the corrosion of wire is greater than 0% and less than 25%,
– a reliability state 1, the corrosion of wire is greater than or equal to 25% and less than 50%,
– a reliability state 0, otherwise (a wire is failed).

A rope is in the reliability state subset {1,2,3}, {2,3}, {3}, if all 6 strand are in this subset, so it is a series system. After some consultations with experts we assume that a strand does not satisfy technical conditions after breaking 6 of its 36 wires. With this assumption we conclude that a rope is in the reliability state subset {1,2,3}, {2,3}, {3}, when all six strands of a rope are in this state subset and each of strands is in the reliability state subset {1,2,3}, {2,3}, {3}, if at least 30 out of its 36 wires are in this state subset. Thus, we obtain that a rope is a regular 4-states "30 out of 36"-series system composed of $k = 6$ series-linked strands with $l = 36$ parallel-linked components (wires). As each broaching machine has only one rope we can say that broaching machines i.e. subsystems S_1, S_2, S_3, are also regular 4-state "30 out of 36"-series systems.

Further assuming that the ground ship-rope transporter is in the reliability state subset {1,2,3}, {2,3}, {3}, when all its subsystems are in this subset of reliability states, we conclude that the ground ship-rope transporter is a series system of subsystems S_1, S_2, S_3. In our further analysis considering broaching machines we will discuss reliability of rope system only, so we say that the broaching machine is in the reliability state subset {1,2,3}, {2,3}, {3}, if the rope in this broaching machine is in this state subset.

The ground ship-rope transporter and its operation process is widely described and illustrated in (Blokus-Roszkowska & Kołowrocki 2009a). At system operational state z_1 the system is composed of subsystems S_1, S_2 and S_3 linked in series. At the operational states z_2, z_3 and z_4 a ship is transferred using one broaching machine, so the system is composed of one of subsystems S_1, S_2, S_3. At the operational states z_5, z_6 and z_7 a ship is transferred using two broaching machines, so the system is composed of two of subsystems S_1, S_2, S_3 linked in series. At the operational state z_8 a ship is transferred using all three broaching machines, so the system is composed of subsystems S_1, S_2 and S_3 linked in series.

Moreover we assume that subsystems S_1, S_2, S_3 of the ground ship-rope transporter are composed of identical 4-state components (wires), having the multi-state conditional reliability functions

$$R^{(b)}(t,\cdot) = [1, R^{(b)}(t,1), R^{(b)}(t,2), R^{(b)}(t,3)],$$

with following exponential co-ordinates $R^{(b)}(t,1)$, $R^{(b)}(t,2)$ and $R^{(b)}(t,3)$ different in various operation states z_b, $b = 1,2, \ldots, 8$.

These are, at the system operational state z_1:

$$R^{(1)}(t,1) = \exp[-0.0097t],\ R^{(1)}(t,2) = \exp[-0.0147t],$$
$$R^{(1)}(t,3) = \exp[-0.0278t],\ t \geq 0,$$

at the operational states z_2, z_3 and z_4:

$$R^{(b)}(t,1) = \exp[-0.0158t],\ R^{(b)}(t,2) = \exp[-0.0235t],$$
$$R^{(b)}(t,3) = \exp[-0.0388t],\ t \geq 0, b = 2,3,4,$$

at the operational states z_5, z_6 and z_7:

$$R^{(b)}(t,1) = \exp[-0.0175t],\ R^{(b)}(t,2) = \exp[-0.0361t],$$
$$R^{(b)}(t,3) = \exp[-0.0551t],\ t \geq 0, b = 5,6,7,$$

at the system operational state z_8:

$$R^{(8)}(t,1) = \exp[-0.0215t],\ R^{(8)}(t,2) = \exp[-0.0394t],$$
$$R^{(8)}(t,3) = \exp[-0.0607t],\ t \geq 0.$$

In case system operation time is large enough, coordinates of the system unconditional reliability function is given by (Soszyńska 2007)

$$\boldsymbol{R}(t,u) \cong \sum_{b=1}^{v} p_b [\boldsymbol{R}(t,u)]^{(b)}, \; t \geq 0, \tag{19}$$

where $[\boldsymbol{R}(t,u)]^{(b)}$, $u = 1,2,3$, $b = 1,2, \ldots, 8$, are coordinates of the system conditional reliability functions and p_b are limit transient probabilities of the system operation process at the operation state z_b, $b = 1,2, \ldots, 8$, given by (18).

In reliability analysis of the ground ship-rope transporter with dependent components at variable operation conditions we assume that both intensities of departure $\lambda(u)$, $u = 1,2,3$, from the reliability state subset $\{1,2,3\}$, $\{2,3\}$, $\{3\}$, and component stress proportionality correction coefficients $c(u)$, $u = 1,2,3$, are influenced by changes of the system operation process states and their values can differ at various operation states z_b, $b = 1,2, \ldots, 8$.

Then assuming system components' dependence defined by (13) and applying directly the formulae (16)–(17) and (19), we get the system reliability function

$$\boldsymbol{R}(t,\cdot) = [1, \boldsymbol{R}(t,1), \boldsymbol{R}(t,2), \boldsymbol{R}(t,3)], \; t \geq 0, \tag{20}$$

where

$$\begin{aligned}
\boldsymbol{R}(t,1) &\cong \sum_{b=1}^{v} p_b \left[\sum_{\upsilon=0}^{l-m} \frac{[(l[\lambda(1)]^{(b)}/[c(1)]^{(b)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(l[\lambda(1)]^{(b)}/[c(1)]^{(b)})t] \right]^{k} \\
&= 0.979 \left[\sum_{\upsilon=0}^{6} \frac{[(0.3492/[c(1)]^{(1)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.3492/[c(1)]^{(1)})t] \right]^{18} \\
&\quad + 0.0064 \left[\sum_{\upsilon=0}^{6} \frac{[(0.5688/[c(1)]^{(2)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.5688/[c(1)]^{(2)})t] \right]^{6} \\
&\quad + 0.0065 \left[\sum_{\upsilon=0}^{6} \frac{[(0.5688/[c(1)]^{(3)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.5688/[c(1)]^{(3)})t] \right]^{6} \\
&\quad + 0.0009 \left[\sum_{\upsilon=0}^{6} \frac{[(0.63/[c(1)]^{(5)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.63/[c(1)]^{(5)})t] \right]^{12} \\
&\quad + 0.0042 \left[\sum_{\upsilon=0}^{6} \frac{[(0.63/[c(1)]^{(7)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.63/[c(1)]^{(7)})t] \right]^{12} \\
&\quad + 0.003 \left[\sum_{\upsilon=0}^{6} \frac{[(0.774/[c(1)]^{(8)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.774/[c(1)]^{(8)})t] \right]^{18}, \; t \geq 0,
\end{aligned} \tag{21}$$

$$\begin{aligned}
\boldsymbol{R}(t,2) &\cong \sum_{b=1}^{v} p_b \left[\sum_{\upsilon=0}^{l-m} \frac{[(l[\lambda(2)]^{(b)}/[c(2)]^{(b)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(l[\lambda(2)]^{(b)}/[c(2)]^{(b)})t] \right]^{k} \\
&= 0.979 \left[\sum_{\upsilon=0}^{6} \frac{[(0.5292/[c(2)]^{(1)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.5292/[c(2)]^{(1)})t] \right]^{18} \\
&\quad + 0.0064 \left[\sum_{\upsilon=0}^{6} \frac{[(0.846/[c(2)]^{(2)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.846/[c(2)]^{(2)})t] \right]^{6} \\
&\quad + 0.0065 \left[\sum_{\upsilon=0}^{6} \frac{[(0.846/[c(2)]^{(3)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(0.846/[c(2)]^{(3)})t] \right]^{6} \\
&\quad + 0.0009 \left[\sum_{\upsilon=0}^{6} \frac{[(1.2996/[c(2)]^{(5)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(1.2996/[c(2)]^{(5)})t] \right]^{12} \\
&\quad + 0.0042 \left[\sum_{\upsilon=0}^{6} \frac{[(1.2996/[c(2)]^{(7)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(1.2996/[c(2)]^{(7)})t] \right]^{12} \\
&\quad + 0.003 \left[\sum_{\upsilon=0}^{6} \frac{[(1.4184/[c(2)]^{(8)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(1.4184/[c(2)]^{(8)})t] \right]^{18}, \; t \geq 0,
\end{aligned} \tag{22}$$

$$\begin{aligned}
\boldsymbol{R}(t,3) &\cong \sum_{b=1}^{v} p_b \left[\sum_{\upsilon=0}^{l-m} \frac{[(l[\lambda(3)]^{(b)}/[c(3)]^{(b)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(l[\lambda(3)]^{(b)}/[c(3)]^{(b)})t] \right]^{k} \\
&= 0.979 \left[\sum_{\upsilon=0}^{6} \frac{[(1.0008/[c(3)]^{(1)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(1.0008/[c(3)]^{(1)})t] \right]^{18} \\
&\quad + 0.0064 \left[\sum_{\upsilon=0}^{6} \frac{[(1.3968/[c(3)]^{(2)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(1.3968/[c(3)]^{(2)})t] \right]^{6} \\
&\quad + 0.0065 \left[\sum_{\upsilon=0}^{6} \frac{[(1.3968/[c(3)]^{(3)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(1.3968/[c(3)]^{(3)})t] \right]^{6} \\
&\quad + 0.0009 \left[\sum_{\upsilon=0}^{6} \frac{[(1.9836/[c(3)]^{(5)})t]^{\upsilon}}{\upsilon!} \cdot \exp[-(1.9836/[c(3)]^{(5)})t] \right]^{12}
\end{aligned}$$

$$+ 0.0042\left[\sum_{\upsilon=0}^{6}\frac{[(1.9836/[c(3)]^{(7)})t]^{\upsilon}}{\upsilon!}\cdot\exp[-(1.9836/[c(3)]^{(7)})t]\right]^{12}$$

$$+ 0.003\left[\sum_{\upsilon=0}^{6}\frac{[(2.1852/[c(3)]^{(8)})t]^{\upsilon}}{\upsilon!}\cdot\exp[-(2.1852/[c(3)]^{(8)})t]\right]^{18}\quad t\geq 0, \tag{23}$$

Approximate graphs of coordinates of the complex system reliability function are presented in Figure 2.

The expected values and standard deviations of the shipyard rope transportation system unconditional lifetimes in the reliability state subsets {1,2,3}, {2,3}, {3}, calculated from results given by (20)–(23), according to formula given in (Soszyńska 2007), for $[c(u)]^{(b)} = 1$, $u = 1,2,3$, $b = 1, \ldots, 8$, respectively are:

$$\mu(1) = \sum_{i=1}^{8} p_i \mu_i(1) \cong 8.7945, \sigma(1) \cong 2.2375 \text{ years}, \tag{24}$$

$$\mu(2) = \sum_{i=1}^{8} p_i \mu_i(2) \cong 5.7981, \sigma(2) \cong 1.4870 \text{ years}, \tag{25}$$

$$\mu(3) = \sum_{i=1}^{8} p_i \mu_i(3) \cong 3.0731, \sigma(3) \cong 0.7804 \text{ years}. \tag{26}$$

and further, considering (24)–(26), the mean values of unconditional lifetimes in particular reliability states 1, 2, 3, (Soszyńska 2007) for $[c(u)]^{(b)} = 1$, $u = 1, 2, 3$, $b = 1, \ldots, 8$, respectively are:

$$\begin{aligned}\bar{\mu}(1) &= \mu(1) - \mu(2) = 2.9964,\\ \bar{\mu}(2) &= \mu(2) - \mu(3) = 2.725,\\ \bar{\mu}(3) &= \mu(3) = 3.0731 \text{ years}.\end{aligned} \tag{27}$$

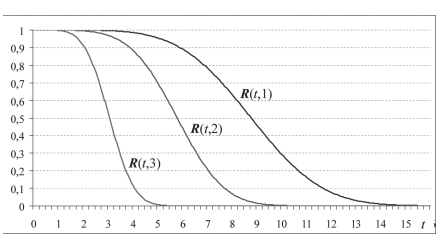

Figure 2. The graph of coordinates of the ground shiprope transporter reliability function $\boldsymbol{R}(t,\cdot)$ for $[c(u)]^{(b)} = 1$, $u = 1,2,3$, $b = 1, \ldots, 8$.

Since the critical reliability state is $r = 2$, then the system risk function, according to definition presented in (Kołowrocki 2004), is given by

$$\boldsymbol{r}(t) = 1 - \boldsymbol{R}(t,2)$$

where coordinate of the system unconditional reliability function $\boldsymbol{R}(t,2)$ is given by (22).

Hence, the moment when the system risk function exceeds a permitted level, for instance $\delta = 0.05$, for $[c(2)]^{(b)} = 1$, $b = 1, \ldots, 8$, is:

$$\tau = \boldsymbol{r}^{-1}(\delta) \cong 3.35 \text{ years} \cong 3 \text{ years } 128 \text{ days}. \tag{28}$$

Assuming different values of component stress proportionality correction coefficients $[c(u)]^{(b)}$, $u = 1, 2, 3$, $b = 1, \ldots, 8$, at variable operation conditions we can observe changes of expected values and standard deviations of the shipyard rope transportation system unconditional lifetimes in the reliability state subsets {1,2,3}, {2,3}, {3}. In case:

$$\begin{aligned}&[c(1)]^{(1)} = 1.0, [c(1)]^{(b)} = 0.7, b = 2,3,4,\\ &[c(1)]^{(b)} = 0.4, b = 5,6,7, [c(1)]^{(8)} = 0.2,\end{aligned} \tag{29}$$

$$\begin{aligned}&[c(2)]^{(1)} = 1.0, [c(2)]^{(b)} = 0.7, b = 2,3,4,\\ &[c(2)]^{(b)} = 0.4, b = 5,6,7, [c(2)]^{(8)} = 0.3,\end{aligned} \tag{30}$$

$$\begin{aligned}&[c(3)]^{(1)} = 0.9, [c(3)]^{(b)} = 0.8, b = 2,3,4,\\ &[c(3)]^{(b)} = 0.5, b = 5,6,7, [c(3)]^{(8)} = 0.4,\end{aligned} \tag{31}$$

we obtain following values:

$$\begin{aligned}&\mu(1) \cong 8.7409, \mu(2) \cong 5.7671, \mu(3) \cong 2.7565 \text{ years},\\ &\sigma(1) \cong 2.3251, \sigma(2) \cong 1.5373, \sigma(3) \cong 0.7156 \text{ years}.\end{aligned}$$

For following values of component stress proportionality correction coefficients:

$$\begin{aligned}&[c(1)]^{(1)} = 0.9, [c(1)]^{(b)} = 0.7, b = 2,3,4,\\ &[c(1)]^{(b)} = 0.4, b = 5,6,7, [c(1)]^{(8)} = 0.2,\end{aligned} \tag{32}$$

$$\begin{aligned}&[c(2)]^{(1)} = 0.9, [c(2)]^{(b)} = 0.7, b = 2,3,4,\\ &[c(2)]^{(b)} = 0.4, b = 5,6,7, [c(2)]^{(8)} = 0.3,\end{aligned} \tag{33}$$

$$\begin{aligned}&[c(3)]^{(1)} = 0.9, [c(3)]^{(b)} = 0.7, b = 2,3,4,\\ &[c(3)]^{(b)} = 0.5, b = 5,6,7, [c(3)]^{(8)} = 0.3,\end{aligned} \tag{34}$$

we obtain expected values and standard deviations:

$$\begin{aligned}&\mu(1) \cong 7.8746, \mu(2) \cong 5.1954, \mu(3) \cong 2.7523 \text{ years},\\ &\sigma(1) \cong 2.0802, \sigma(2) \cong 1.3758, \sigma(3) \cong 0.7190 \text{ years}.\end{aligned}$$

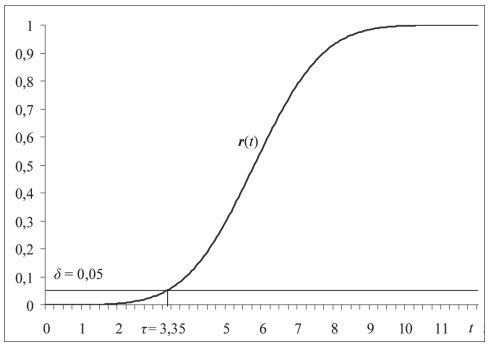

Figure 3. The graph of the ground ship-rope transporter risk function $\boldsymbol{r}(t)$ for $[c(2)]^{(b)} = 1$, $b = 1, \ldots, 8$.

Then the moment when the system risk function exceeds a permitted level $\delta = 0.05$, for values of component stress proportionality correction coefficients given by (29)–(31), is:

$$\tau = \boldsymbol{r}^{-1}(\delta) \cong 3.267 \text{ years} \cong 3 \text{ years } 97 \text{ days}$$

and for values of component stress proportionality correction coefficients given by (32)–(34), equivalently:

$$\tau = \boldsymbol{r}^{-1}(\delta) \cong 2.965 \text{ years} \cong 2 \text{ years } 352 \text{ days}.$$

4 CONCLUSIONS

Many technical systems belong to the class of complex systems as a result of large number of interacting components and subsystems they are built of and their complicated operating processes having significant influence on their reliability. In the paper we present an analytical model of reliability analysis of complex systems and their reliability characteristics evaluation considering the influence of the inside-system and outside-system dependencies. The multi-state reliability function of homogeneous multi-state "*m* out of *n*" and "*m* out of *l*"-series systems are determined in case when the systems' components have exponential reliability functions with interdependent departures rates from the subsets of their reliability states.

The ship-rope transporter is analyzed at variable operation conditions and its changing in time reliability structure, its components' reliability parameters and among its components dependability are considered. The influence of changing at operation states intensities of departure from the reliability state subset, as well as components' stress proportionality correction coefficients on mean values and standard deviations of the ship-rope transporter unconditional lifetimes states is investigated. Obtained results illustrate that after decreasing the reliability state by some of components, the inside interactions among remaining components may cause further components reliability states decrease.

Maritime traffic flow simulation in the Intelligent Transportation Systems theme

A. Blokus-Roszkowska & L. Smolarek
Maritime University, Gdynia, Poland

ABSTRACT: The paper proposes safety analysis of waterways' crossings in restricted area using simulation and describes maritime traffic phenomena with application of cellular automata. There is presented a cellular automaton model with introduced rules of vessels movement and collision avoidance manoeuvre. This model is able to describe different types of vessels evolving different type of intersections and provides the basis for simulation. In simulation there is considered simple crossing with distinguished main flow having priority and a roundabout with three different priority scenarios. As a result of simulation there are given probabilities of transitions between system safety states and probabilities of system's being in particular safety states during simulation time. Analysis and comparison of simulation results for various crossing's geometry and priority traffic schemes can potentially affect the tasks and decisions of authorities related to maritime transport and traffic in area with developed vessel traffic management including vessel traffic services.

1 INTRODUCTION

Permanent development of transportation systems and its infrastructure has influence on increasing demand on Vessel Traffic Management and Information Systems to improve safety and effectiveness of maritime transportation. Intelligent Transport Systems (ITS), using a range of information and communication technologies, can face problems associated with maritime traffic management and safety improvement (Perera et al. 2012, Pietrzykowski 2011). One of maritime safety tasks is to reduce the risk of collisions at waterways' crossings. In this paper there is presented simulation approach to this topic with application of cellular automaton model.

Using mathematical models we can simulate real-life situations. In this paper a cellular automaton model is applied to simulate maritime traffic at waterways' crossing in VTS (Vessel Traffic Services) area. With simulation model representing both vessels and waterway organization it is possible to analyze the effects of changing waterway priority, vessel type and human behaviour. Vessels are classified by their type, departure port and destination (input and output flow). Each type of vessel is characterized by its velocity, size, acceleration, maneuverability, probability of taking evasive action. With development and improvement of models reproducing maritime traffic features including waterways, vessels and humans we can simulate and plan more efficient ITS systems. Simulation models can support analysis and understanding of likely impacts and effects of some maritime traffic features. Thus ITS can be applied in the domain of transport to improve system performance, transport safety and efficiency (Jamroz & Krystek 2006, Wibowo & Deng 2012).

2 A CELLULAR AUTOMATON MODEL FOR MARITIME TRAFFIC

This paper presents cellular approach to analysis of influence of maritime traffic organization on the collision risk. Cellular automata are often applied to road traffic simulation and are very useful in emulating priority rules of the road are supposed to work in traffic (Maerivoet & De Moor 2005, Wolfram 1986), especially in a roundabout (Chen et al. 2006). However, this approach has not been used for describing vessels motion. The problem of traffic simulation in an intersection can be solved by multi-agent system approach (Doniec et al. 2008). Specifically, a multi-agent model using priority relations allows for simulating traffic at road junction for different priority scenarios. Then, agents approaching an intersection coordinate their actions in order to avoid collision. Similar approach is presented in this paper to describe vessel dynamic and behavior at waterways' crossing including various priority scenarios at restricted area. Detailed analysis of simulation results for different traffic schemes can be effectively used in

evaluation of maritime traffic organization and optimization at waterways in VTS area.

As we focus on simulation of waterways' crossing, we do not consider overtaking rule. The rule of vessel movement is introduced and a set of rules is applied to provide collision avoidance manoeuvre.

2.1 *Movement rule*

To describe main features of maritime traffic we use Nagel-Schreckenberg model with some modifications (Nagel & Schreckenberg 1992). Vessels usually move with constant velocity, thus we can adapt to our model following modification of movement rule:

$$x_i^{(t+\Delta t)} = x_i^{(t)} + v_i \,, \tag{1}$$

if ith vessel is not performing an avoidance manoeuvre, where $x_i^{(t)}$ is the position of ith vessel at time t, $t \geq 0$, v_i is velocity of ith vessel and Δt is a time step.

Velocity of a vessel does not depend on parameter t as we assume that in considered distance of lanes' crossing vessels move with constant velocity. However we can consider extension of presented model by taking into account speed interval for each type of vessel and observing some speed alteration while vessel movement with assumed a priori lower and upper bound.

2.2 *Collision avoidance rules*

As a next step, we add to our model collision avoidance rule. In maritime traffic the distance between vessels being on collision courses (the number of empty cells between two vessels) must be known in order to perform collision avoidance manoeuvre. The necessary distance to take evasive action depends on vessel size, velocity and maneuverability. Thus, for vessels performing an avoidance manoeuvre we can implement some collision avoidance rules depending on vessel size, velocity, type (maneuverability) and distance to lanes' crossing.

A collision avoidance manoeuvre should be preceded by starting evasive action rule that determine whether a vessel starts collision avoidance manoeuvre taking into account distance between vessels and probability of taking evasive action by give-way and stand-on vessel.

Starting evasive action rule:

(if the vessel is on collision course) and (distance between vessels $d < 3704$ m) and ($rand < p_{EA}$) then (start evasive action),

where p_{EA} denotes probability of taking evasive action by the vessel and *rand* is a variable with generated random positive decimal value that ranges between 0.0 and 1.0. The third condition in this rule means that taking evasive action occurs randomly with assumed probability p_{EA}, even if the first two conditions are met.

Described in this paper rules can be applied for all vessels, however for different type of vessels rules are used with different parameters affecting probability of taking evasive action, time of performing collision avoidance manoeuvre as well as velocity in movement rule. Another factor that influence the decision of taking evasive action and its performance is vessel priority.

The decision of taking collision avoidance manoeuvre by the vessel i.e. determining probability p_{EA}, can be described by following rule:

if (the vessel is a give-way vessel)
  if ($d \geq 2$ nm) then $p_{EA} = 0$
    else if ($d \geq d_3$) then $p_{EA} = 0.5 p_{EA_GW}$
    else if ($d \geq d_1$) then $p_{EA} = p_{EA_GW}$
    else ($d < d_1$) there is a collision
if (the vessel is a stand-on vessel)
  if ($d \geq d_3$) then $p_{EA} = 0$
    else if ($d \geq d_2$) then $p_{EA} = p_{EA_SO}$
    else if ($d \geq d_1$) then
      $p_{EA} = 2p_{EA_SO}$ if $p_{EA_SO} < 0.5$
      $p_{EA} = 1$ if $p_{EA_SO} \geq 0.5$
    else ($d < d_1$) there is a collision

where p_{EA_GW} denotes probability of taking evasive action by give-way vessel and p_{EA_SO} by stand-on vessel, respectively. These probabilities can be assumed a priori (as a value or interval) for different type of vessels depending on their size, velocity, maneuverability. In simulation we randomly choose from fixed interval the probability p_{EA_GW} and p_{EA_SO} on basis of modelling of vessel behaviour presented in (Chauvin & Lardjane 2008).

We assume a navigator during encountered crossing situation perform collision avoidance manoeuvre in a proper way at safe distance without deceleration and a vessel while taking evasive action is safe and can not cause collision with other vessels on its scheduled destination waterway. We distinguish two types of collision avoidance rule:

I case—a collision avoidance rule by changing vessel velocity (vessel acceleration),
II case—a collision avoidance rule by changing vessel course.

In simulation program we consider eight major ship types. The simulation is carried out with randomly generated initial configuration on vessel parameters and behaviour (vessels type, size and velocity, maneuverability, probability of taking evasive action). For each class of vessels these data are taken into model with different conditions and initial values. Further, we divide ship types into two groups with respect to model of collision

avoidance group. Some types of vessels can reach much higher velocities than limit value in restricted area and in collision situation they can speed up to 20 knots i.e. 10 m/s, in case of fast ferry can reach speed even over 30 knots i.e. 15 m/s. These vessels constitute first group: a container carrier, a RoPax, a passenger ship, a reefer and a fast ferry. The second group of vessels is made by a tanker, a bulk carrier and a general cargo ship.

Collision avoidance rule in first case takes form:

if (vessel_type is container carrier or RoPax or passenger ship or reefer or fast ferry) and ($v_i < 8$ m/s) and ($d_{EA} > 556$ m) then

$$x_i^{(t+\Delta t)} = x_i^{(t)} + v_{i_A}, \tag{2}$$

where v_{i_A} is velocity of a vessel after acceleration and d_{EA} denotes minimal distance between target vessel and collision point in a moment home ship leaves waterways' crossing and can be estimated from formula:

$$d_{EA} = d_{C_other} - \frac{d_C + LOA_i}{v_{i_A}} \cdot v_{i_other} \tag{3}$$

where:
v_{i_other}—velocity of a vessel being on collision course,
LOA_i—length of home ship,
d_c—distance between home ship and collision point,
d_{C_other}—distance to collision point on a route of target ship.

Time during that vessels move with higher speed t_A can be estimated from formula:

$$t_A = \frac{d_c - \frac{1}{6}v_i}{v_i + 4} \tag{4}$$

and time to reach collision point by target ship t_{C_other} is counted from formula:

$$t_{C_other} = \frac{d_{C_other} - d_T}{v_{i_other}}, \; d_T = \max\{370\ m; 2LOA_{other}\}, \tag{5}$$

where LOA_{other} denotes length of target vessel.

Following rule defines when collision avoidance manoeuvre by vessels acceleration can be used.

$$\text{If } ((t_A + 600s) < t_{C_other}) \text{ then} \tag{6}$$

(it is possible to avoid collision by vessel acceleration assuming that after a period of time equal 10 minutes a vessel will accelerate about 2 m/s) else (a vessel should perform collision avoidance manoeuvre by course changing).

Taking into account that any change of vessel velocity takes time and do not influence on distance between vessels significantly, a collision avoidance manoeuvre by vessel acceleration can be performed in larger distance from collision point. What is more, as this procedure is not recommended as navigation rule is rarely used. In simulation program we assume that collision avoidance manoeuvre by vessel acceleration is used in less than 10% cases (with probability under 10%) assuming that condition (6) holds and distance of a vessel to collision point is larger than 3704 m.

As in our model we focus on safety analysis of waterways' crossing the exact trajectory of a vessel does not play a key role, and we are only interested in the moment when the vessel is at the point of collision. Some deviations from the vessel trajectory and drift angle affecting the time to reach the waterways' crossing can be included i.e. simulated by generating the velocity from a fixed interval instead of adopting a constant velocity of a vessel. Similarly, in second model of collision avoidance rule we can assume it is not important the exact vessel collision avoidance manoeuvre trajectory but time of performing evasive action and place where the vessel will be after ending collision avoidance manoeuvre. Considering this we can implement following rule for collision avoidance manoeuvre:

$$x_i^{(t+\Delta t)} = x_i^{(t)} + v_{i_EA}, \tag{7}$$

if ith vessel is performing avoidance manoeuvre,

where v_{i_EA} is vessel velocity, if a vessel would move on scheduled route during time equivalent to time of performing collision avoidance manoeuvre, moving on collision avoidance route with velocity v_i. We assume a ship is performing turning motion moving at constant speed and at constant rudder angle. Vessel velocity is expressed in cells per time step Δt. Then the velocity v_{i_EA} can be determined by the formula:

$$v_{i_EA} = \frac{S_{i_EA} \cdot \Delta t}{T_{i_EA} \cdot CS \cdot 60}, \tag{8}$$

where S_{i_EA} denotes a distance on scheduled course line during performing collision avoidance manoeuvre expressed in m, T_{i_EA} is time of performing collision avoidance manoeuvre expressed in minutes and CS denotes a cell size in m.

For simulation simplification, we assume time of navigational restore is equal to time of collision avoidance (Fig. 1). Under assumption that vessels move with constant speed and at constant turning angle, we can also assume that a dis-

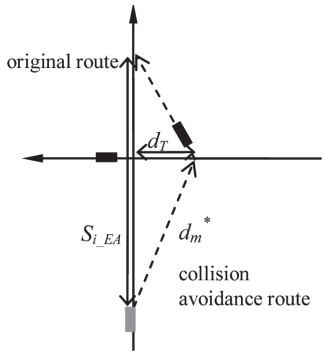

Figure 1. Navigational restore manoeuvre.

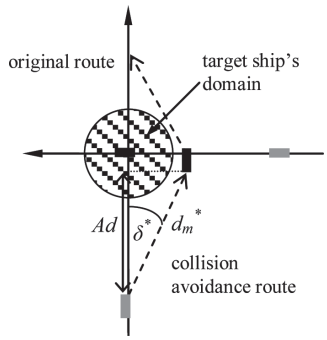

Figure 2. Collision avoidance manoeuvre including constraints.

tance from the beginning of turning to restoring is equal to a distance of restoring of scheduled course line (to the end of collision avoidance manoeuvre).

We have $S_{i_EA} = 2Ad$, where the advance for performed manoeuvre can by counted from:

$$Ad = d_m^* \cdot \cos\delta^*, \tag{9}$$

and

$$T_{i_EA} = 2t_m^*, \tag{10}$$

where d_m* is a distance after collision avoidance before starting navigational restore and t_m* is navigational time after collision avoidance i.e. time of evasive action not including time of navigational restore. A turning angle δ* (Fig. 2) allows to determine required advance for collision avoidance in order to avoid entering target ship domain (Fujii & Tanaka 1971).

Further, taking into account constraints for turning angle δ* we assume staring rudder angle δ_0 for example $\delta_0 = 10°$ or $\delta_0 = 5°$ in case a vessel starts evasive action in long distance from collision point. This rudder angle must be verified by real situation and the upper bound of turning angle. In (Su et al. 2012) authors assume that the shortest required advance to prevent a collision and perform turning motion can be obtain for full rudder equal to 35°. However full rudder angle 35° is practiced only for slowly moved unit with speed around 3 m/s or in extremely dangerous collision situation. This is caused by the fact that vessels during course changing over 10° lose their velocities. In presented simulation model, we assume the upper bound of turning angle depending on vessel type and its manoeuvring characteristics. We denote it by $\delta_{full}^{(c)}$ for each of vessel class c. In case a distance between home ship and collision point is short, it could be required larger rudder angle δ than δ_0. Then, real turning angle δ* can be defined by:

$$\delta^* = \min\left\{\max\left\{\delta_0;\delta\right\};\delta_{full}^{(c)}\right\}, \tag{11}$$

where rudder angle δ is determined form the condition not to cross target vessel domain and taking into account experts' opinion that a vessel usually passes target vessel in a distance not shorter than 2 cables (370 m) in restricted area:

$$\delta = \arcsin\frac{d_T}{d_m^*},\ d_T = \max\left\{370m;\ 2LOA_{other}\right\}. \tag{12}$$

As shown in Figure 3, the distance d_m after collision avoidance before starting navigational restore (before taking into account constraint conditions) can be determined as:

$$d_m = \frac{d_C}{\cos\delta_0}, \tag{13}$$

where d_c is a distance between home ship and collision point and δ_0 denotes starting rudder angle.

By t_{C_max} we denote maximum time to reach collision point by target ship:

$$t_{C_\max} = \frac{d_{C_other}}{v_{\min_other}}, \tag{14}$$

where v_{min_other} is minimum velocity of target ship.

Further, the distance d_m* after collision avoidance before starting navigational restore can by given by:

$$d_m^* = t_m^* \cdot v_i. \tag{15}$$

Including constraint conditions, presented in (Tsou & Hsueh 2010), time after collision avoidance

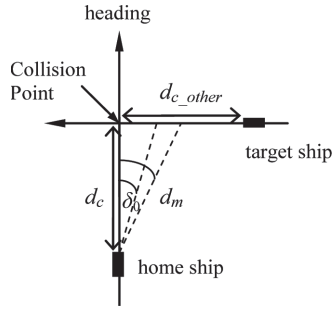

Figure 3. Starting position of evasive action.

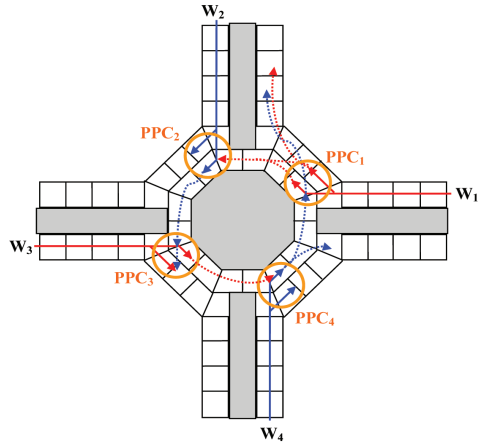
and navigational restore time should not exceed 60 minutes and should be at least larger than time of closest point of approach. Then, we can determine navigational time after collision avoidance t_m* by formula:

$$t_m^* = \min\left\{\max\left\{\frac{d_m}{v_i}, t_{C_\max}\right\}, 3600s\right\}. \quad (16)$$

Time of taking evasive action can be also affected by many other factors including ship type and basic manoeuvring performance characteristics. Then, we can modify formula (16) to make it more realistic by:



$$t_m^* = \min\left\{\max\left\{\frac{d_m}{v_i} + t_{RA}, t_{C_\max}\right\}, 3600s\right\}, \quad (17)$$

where t_{RA} is time required for a ship to turn its heading by rudder angle. Maneuverability of a ship can be expressed by measures such as Turning Ability, Initial Turning Ability, Course Changing and Yaw Checking Ability. Details for these measures and rating system taking into account requirements of the IMO standards can be found in (ABS Guide 2006).

3 SIMULATION RESULTS AND ITS ANALYSIS

3.1 *Crossing's situation*

In simulation we consider simple crossing and a roundabout as a junction of four routes with four point of potential collision (Fig. 4). We assume traffic lanes 1 and 3 are main routes on that there are usually large vessels with less maneuverability. The vessels are observed in lanes entering the roundabout-lane with a distance 4 nautical mile and we assume distances between collision points

W_1, W_2, W_3, W_4 – enter lines for roundabout

PPC_1, PPC_2, PPC_3, PPC_4 – Potential Points of Collision

Figure 4. The scheme of grade roundabout crossing.

are equal to 1 nautical mile i.e. 1852 m. A crossing's geometry for considered situation is widely described in (Blokus-Roszkowska & Smolarek 2012a, 2013).

In maritime traffic scenario with a roundabout we consider three different priority scenarios (Blokus-Roszkowska & Smolarek 2012b). First case, when a vessel having another vessel on her own starboard side shall keep out of the way. Second scenario, when a vessel being on a roundabout-lane has priority and a vessel entering a roundabout crossing is directed to keep out of the way. And third case—a roundabout with distinguished main flow having priority. Then, we assume that traffic lanes 1 and 3 are main routs with stand-on vessels and on routs 2 and 4 moves give-way vessels that should keep out of the way of vessels being on routs 1 and 3.

According to the rule 15, in case of risk collision during crossing situation, the vessel which has another vessel on her own starboard side shall keep out of the way and shall avoid crossing ahead of another vessel. However, considering roundabout crossing, we distinguish some situation when the vessel being on the roundabout-lane has priority. When the vessel on the roundabout is very large and with less maneuverability we assume it has priority and the vessel entering roundabout crossing is directed to keep out of the way of vessel being on the roundabout-lane. Considered priority scenarios and performed traffic simulation at waterways' crossing are not devoted to change rules on the level of vessel navigation. They can be applied during creating concepts of maritime traffic organization and management in restricted area.

3.2 *Assumptions and simulation results*

We take into consideration following four states corresponding to risk levels depending on mutual distance of vessels that are on collision courses in restricted area:

– state 3 (negligible risk of collision)—both ships being in cells are in safety distance defined in simulation program as 1852 m, i.e. the number of cells between two ships being in state 3 is equal at least d_3, determined from the formula:

$$d_3 = \left\lceil \frac{1852}{CS} \right\rceil, \tag{18}$$

where $\lceil d \rceil$ denotes the smallest integer number not lower than d and CS is a cell size depending on flow intensities, velocities and lengths of vessels (Blokus-Roszkowska & Smolarek 2013);

– state 2 (low risk of collision)—both ships being in cells are in a distance of passing clear, assumed to be equal to 926 m; it means that the number of cells between two ships being in state 2 is equal at least d_2, were d_2 is given by the formula:

$$d_2 = \left\lceil \frac{926}{CS} \right\rceil; \tag{19}$$

– state 1 (high risk of collision)—both ships being on collision courses are in cells in a distance concerned with their lengths and number of cells between two ships being in state 1 is equal at least d_1, where d_1 is defined by the formula:

$$d_1 = \left\lceil \frac{2LOA_{\max}}{CS} \right\rceil, \tag{20}$$

where $LOA_{max} = \max\{LOA_M, LOA_L\}$ and LOA_M is a length of a vessel moving on main waterway, LOA_L is a length of a vessel being on collision lateral waterway;

– state 0 (collision alert)—the number of cells between two ships being in state 0 is lower than d_1 defined by (20).

In simulation we compare time to point of collision expressed in time steps. If time of vessels being on collision courses is shorten than time of vessels reaching collision point and none of vessels take evasive action at this moment, we check the distance between vessels. Then, we compare obtained distance with the threshold values of safety states defined before and according to this definition we assign the proper state of the vessel. If the vessel status state has changed, this information is saved along with time after that transition has occurred, i.e. time during which ship was in the previous safety state.

Simulation run under various crossing's geometric conditions for fixed, on the basis of results presented in (Montewka et al. 2010) and (Blokus-Roszkowska et al. 2012), traffic flow parameters. For the simulation, we assume starting times of vessels on main waterway follow normal distribution with mean value 2.21 h and standard deviation 0.52 h. On lateral waterways we assume Erlang distribution with mean time between ships departing equal to 1.21 h and standard deviation 0.95 h and 1.03 h, equivalently for both directions. Following these, numbers of system's transitions between the states, obtained during simulation time equivalent to four months of real time, are derived for introduced three different models of priority in a roundabout.

I scenario—a vessel having another vessel on her own starboard side shall keep out of the way.

Matrix of transitions' numbers between states is the following:

$$[n_{ij}]^I = \begin{bmatrix} 0 & 0 & 1 & 33 \\ 32 & 0 & 1 & 89 \\ 0 & 110 & 0 & 747 \\ 2 & 12 & 855 & 0 \end{bmatrix}, \; i, j = 0, 1, 2, 3, \tag{21}$$

and the vector of total numbers of transitions from each state:

$$[n_0, n_1, n_2, n_3]^I = [34, 122, 857, 869].$$

On the basis of obtained form simulation program number of system's transitions between states (21) we can estimate the matrix of transitions' probabilities:

$$[p_{ij}]^I = \begin{bmatrix} 0 & 0 & 0.0294 & 0.9706 \\ 0.2623 & 0 & 0.0082 & 0.7295 \\ 0 & 0.1284 & 0 & 0.8716 \\ 0.0023 & 0.0138 & 0.9839 & 0 \end{bmatrix}, \tag{22}$$

$$i, j = 0, 1, 2, 3.$$

Analysing probabilities of transitions between states (22) we can conclude that the most of observed transition during simulation time is from ship safety state 3 (negligible risk of collision) to safety state 2 (low risk of collision) and from state 2 to state 3. This relationship can be observed in all cases. Quite frequent are also transitions from state 2 to state 1 (high risk of collision). From state 1 transitions the most often appeared to state 3. This could be caused by the fact that in a situation of high risk of collision both vessels i.e. stand-on and give-way vessels take evasive action with high

probability. However, there are situations in which vessels did not take evasive action and transitions form state 1 to state 0 occurred.

Simulation requires modeling of human behaviour, namely the reaction to information that represents the choice between different alternatives. In this paper, we assume a priori probability of taking evasive action by give-way and stand-on vessels according to modeling of vessel behaviour conducted in (Chauvin & Lardjane 2008, Blokus-Roszkowska & Smolarek 2013). This probability is randomly chosen from fixed interval depending on vessel type and velocity in case it is stand-on and give-way vessel. Taking into account results of simulation, the probability of taking action by give-way and stand-on vessels should be verified a posteriori by real data. We assume that in case the risk of collision is negligible, give-way vessel will take evasive action with probability $0.5p_{EA_GW}$, otherwise with probability p_{EA_GW}. In case the risk of collision is high, we assume stand-on vessel will start evasive action with higher probability than mentioned before i.e. $2p_{EA_SO}$ if $p_{EA_SO} < 0.5$ and 1 if $p_{EA_SO} \geq 0.5$, otherwise with probability p_{EA_SO}. Figure 5 illustrates the behaviour of stand-on and give-way vessel in terms of manoeuvring.

From simulation we also obtain realizations of conditional sojourn times at the state until transition to another state. From these results there is determined a vector of probabilities of system's being in particular states during simulation time. Namely, from simulation there are given both probabilities of ship collision alert and probabilities of occurrence high, low or negligible risk of collision. Figure 6 presents the output window showing the results of simulation, i.e. probabilities of vessels being in safety states, in a bar chart. In first scenario of priority, these probabilities are as follows (Fig. 6):

$$p(0) = 0.0001,\ p(1) = 0.0006,$$
$$p(2) = 0.0171,\ p(3) = 0.9822.$$

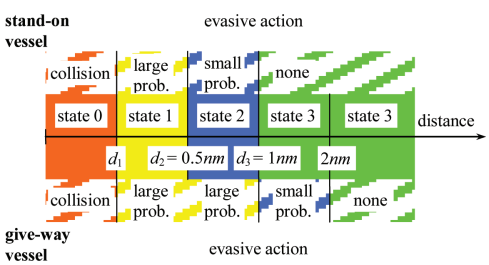


Figure 5. The probability of taking evasive action by give-way and stand-on vessels in restricted area assumed in simulation.

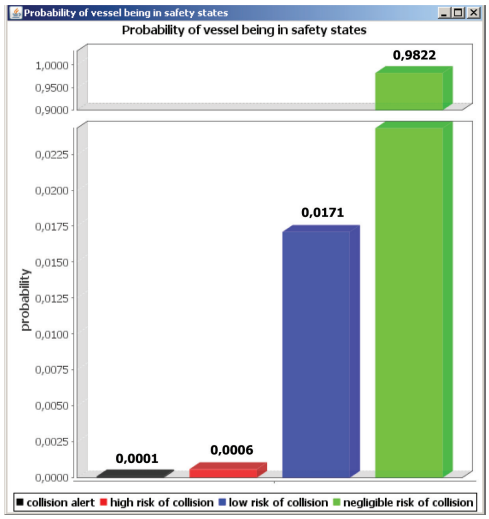

Figure 6. Probability of vessels being in safety states obtained from simulation for a roundabout with I priority scenario.

II scenario—a vessel being on a roundabout-lane has priority and vessel entering roundabout crossing is directed to keep out of the way. In this scenario of traffic organization the matrix of transitions' numbers between states takes form:

$$[n_{ij}]^{II} = \begin{bmatrix} 0 & 0 & 2 & 52 \\ 52 & 0 & 2 & 71 \\ 1 & 118 & 0 & 731 \\ 1 & 7 & 846 & 0 \end{bmatrix},\ i,\ j = 0, 1, 2, 3, \quad (23)$$

and the vector of total numbers of transitions:

$$[n_0, n_1, n_2, n_3]^{II} = [54, 125, 850, 854].$$

Then, the matrix of transitions' probabilities is:

$$[p_{ij}]^{II} = \begin{bmatrix} 0 & 0 & 0.0370 & 0.9630 \\ 0.4160 & 0 & 0.0160 & 0.5680 \\ 0.0012 & 0.1388 & 0 & 0.8600 \\ 0.0012 & 0.0082 & 0.9906 & 0 \end{bmatrix}, \quad (24)$$
$$i,\ j = 0, 1, 2, 3.$$

In second scenario, probabilities of ship collision alert, occurrence of high, low or negligible risk of collision are equal equivalently:

$$p(0) = 0.0003,\ p(1) = 0.0006,$$
$$p(2) = 0.0118,\ p(3) = 0.9873.$$

III scenario—a roundabout with distinguished main flow having priority.

In last model of traffic organization for a roundabout, the matrix of transitions' numbers between states is:

$$[n_{ij}]^{III} = \begin{bmatrix} 0 & 0 & 0 & 32 \\ 32 & 0 & 2 & 95 \\ 0 & 122 & 0 & 705 \\ 0 & 7 & 825 & 0 \end{bmatrix}, \; i, j = 0, 1, 2, 3, \quad (25)$$

and the vector of total numbers of transitions:

$$[n_0, n_1, n_2, n_3]^{III} = [32, 129, 827, 832].$$

Then, the matrix of transitions' probabilities takes values:

$$[p_{ij}]^{III} = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0.2481 & 0 & 0.0155 & 0.7364 \\ 0 & 0.1475 & 0 & 0.8525 \\ 0 & 0.0084 & 0.9916 & 0 \end{bmatrix}, \quad (26)$$
$$i, j = 0, 1, 2, 3.$$

The worst results from simulation, for assumed parameters of flows, are given for a model of roundabout traffic organization in which a roundabout-lane has priority. The results are comparable in case of a roundabout with distinguished main flow having priority and for a roundabout, when a vessel having another vessel on her own starboard side shall keep out of the way. Besides, the number of transitions to state 0 (collision alert) is the lowest for a roundabout with distinguished main flow having priority. This can suggest that in this maritime traffic scenario the performance of collision avoidance manoeuvre, according to rules presented in Section 2 of this paper, is the most effective.

In third case, probabilities of being in particular safety states, defined before, are:

$$p(0) = 0.0002, \; p(1) = 0.0006,$$
$$p(2) = 0.0125, \; p(3) = 0.9867.$$

In case of simple crossing with distinguished main flow having priority we obtain results presented below. Simulation was also performed in time equivalent to four months of real time observation.

Then, the matrix of transitions' numbers between states is given by:

$$[n_{ij}]^{II} = \begin{bmatrix} 0 & 3 & 0 & 35 \\ 33 & 0 & 4 & 77 \\ 0 & 83 & 0 & 347 \\ 5 & 28 & 426 & 0 \end{bmatrix}, \; i, j = 0, 1, 2, 3, \quad (27)$$

and the vector of total numbers of transitions:

$$[n_0, n_1, n_2, n_3]^{II} = [38, 114, 430, 459].$$

Matrix of transitions' probabilities is the following:

$$[p_{ij}]^{II} = \begin{bmatrix} 0 & 0.0789 & 0 & 0.9211 \\ 0.2895 & 0 & 0.0351 & 0.6754 \\ 0 & 0.1930 & 0 & 0.8070 \\ 0.0109 & 0.0610 & 0.9281 & 0 \end{bmatrix}, \quad (28)$$
$$i, j = 0, 1, 2, 3.$$

Then, probabilities of system's being in particular safety states during simulation time are:

$$p(0) = 0.0002, \; p(1) = 0.0007,$$
$$p(2) = 0.1736, \; p(3) = 0.8255.$$

Drawn from simulation results conclusion that a roundabout with distinguished main flow having priority as traffic organization model is the most safe, as the probability of transition to state 0 (collision alert) is the lowest, is even more noticeable for other values of flow parameters.

Assuming that starting times of vessels on main waterway follow normal distribution with mean value 1.2 h and standard deviation 0.52 h and on lateral waterways we have Erlang distribution with mean time between ships departing equal to 1.3 h and 1.4 h and standard deviation 0.65 h and 0.75 h, equivalently for both directions, we obtain results presented below. For a roundabout with distinguished main flow having priority (III scenario) the matrix of transitions' numbers between states is:

$$[n_{ij}]^{III} = \begin{bmatrix} 0 & 0 & 0 & 42 \\ 33 & 0 & 0 & 129 \\ 0 & 146 & 0 & 1192 \\ 9 & 16 & 1338 & 0 \end{bmatrix}, \; i, j = 0, 1, 2, 3, \quad (29)$$

and the matrix of transitions' probabilities takes form:

$$[p_{ij}]^{III} = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0.2037 & 0 & 0 & 0.7963 \\ 0 & 0.1091 & 0 & 0.8909 \\ 0.0066 & 0.0117 & 0.9817 & 0 \end{bmatrix}, \quad (30)$$
$$i,\ j = 0, 1, 2, 3.$$

In case of I scenario i.e. when a vessel having another vessel on her own starboard side shall keep out of the way, we get:

$$[n_{ij}]^{I} = \begin{bmatrix} 0 & 0 & 0 & 67 \\ 62 & 0 & 0 & 103 \\ 0 & 149 & 0 & 1134 \\ 5 & 16 & 1283 & 0 \end{bmatrix}, \ i,\ j = 0, 1, 2, 3, \quad (31)$$

and for the matrix of transitions' probabilities:

$$[p_{ij}]^{I} = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0.3758 & 0 & 0 & 0.6242 \\ 0 & 0.1161 & 0 & 0.8839 \\ 0.0038 & 0.0123 & 0.9839 & 0 \end{bmatrix}, \quad (32)$$
$$i,\ j = 0, 1, 2, 3.$$

For these parameters, probabilities of ship collision alert, occurrence of high, low or negligible risk of collision, during simulation time, for III scenario are:

$$p(0) = 0.0001,\ p(1) = 0.0004,$$
$$p(2) = 0.0202,\ p(3) = 0.9792$$

and for I scenario, equivalently are:

$$p(0) = 0.0002,\ p(1) = 0.0005,$$
$$p(2) = 0.0166,\ p(3) = 0.9827.$$

4 CONCLUSIONS

ITS involves a large number of research areas, one of them is maritime traffic and its safety. Applying intelligent transportation systems technologies Vessel Traffic Services can improve maritime transport efficiency and safety. This paper introduces the model of basic cellular automaton for the description of maritime traffic flow in restricted area and brief view how it can be useful in maritime transport safety analysis. Detailed analysis of the simulation results for different traffic schemes can be effectively used in evaluation of waterways traffic organization and optimization. Thereby, the simulation model with some further development can be helpful as a tool on the level of safety management or safety-based spatial planning of restricted areas.

Simulation and modeling are tools that can identify, quantify and analyze maritime transportation phenomena and in the ITS context they can influence on development of maritime traffic control systems. Maritime traffic systems incorporate some intelligent systems technology to assist human operators. Therefore further research on dynamic models and parameter identification is still needed.

Modeling of event trees for the rapid scenario development

M.K. Gerigk
Gdańsk University of Technology, Gdańsk, Poland

ABSTRACT: The paper concerns the safety of ships in abnormal/damage conditions. Some conclusions following from the research associated with development of a method for safety assessment of ships in abnormal/damage conditions is presented in the paper. The method called SSAMADC (Ship Safety Assessment Method in Abnormal/Damage Conditions) is a risk-based method and is connected with application of the quantitative risk assessment QRA approach. The method is an alternative method of safety assessment of ships in abnormal/damage conditions in comparison with the method included within the SOLAS 2009 regulations. The aim of the research is to work out a proposal of an alternative method of safety assessment of ships in damaged conditions. There is a lack of such the method for the certain type of ships.

1 INTRODUCTION

The aim of the research is to work out a proposal of an alternative method of safety assessment of ships in damaged conditions. The research has been done because the method included in the SOLAS regulations does not cover certain type of ships.

The key issue in application of the method is to model the event tress for the scenario development under consideration.

There is a market need for good methods enabling the assessment of safety of damaged ships at the design stage, in operation and during the ship salvage. The existing methods for the salvage purposes are mainly based on the expert assessment using the brain storming techniques. The methods based on the requirements included in the SOLAS 2009 regulations (Chapter II-1) are of the prescriptive character and devoted to solve the ship design problems, IMO (2005). This is the reason why it is very difficult to apply such a method for assessing the safety of ships in damage conditions at the design stage, in operation, after the collision at sea and later during the ship salvage procedure.

2 THE PROPOSED METHOD

The proposed method called SSAMADC (Ship Safety Assessment Method in Abnormal/Damage Conditions) is a risk-based method and is connected with application of the quantitative risk assessment QRA approach. The method is an alternative method of safety assessment of ships in abnormal/damage conditions in comparison with the method included within the SOLAS 2009 regulations.

The method combines the ship performance-oriented approach with the risk-based approach, Gerigk (2010). The holistic approach to safety assessment is applied. An influence of design, operational, management-related and human factors on safety is taken into account. Then, the matrix type risk model is applied. This model has a holistic character. Next, it is possible to take into account almost all the possible scenarios of an accident.

The risk model may be defined using the multi-level event tree ETA which general structure is shown in Figure 1.

The accident scenarios may consist of the hazards, intermediate events, additional events and consequences. It is important to define the initial events (hazards). The measure of safety of ships in damage conditions is the risk level. The risk acceptance criteria can be the risk matrix or ALARP concept.

The methodology where the risk-based design and a formalized design methodology were

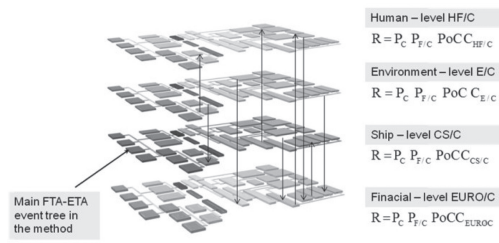

Figure 1. General structure of the multi-level event tree divided into four basic modules: human, environment, ship (property), finance, Gerigk (2010).

integrated together in the design process with the prevention/reduction of risk as a design objective, along the standard design objectives was first introduced by Vassalos, (Arangio 2012, Jasionowski et al. 2006, Mohaghegh 2009, Nowakowski et al. 2009, Skjong et al. 2006, Soares C.G. et al. 2001, Stephans 2012, Stewart et al. 2012, Suddle, 2001, Vassalos 2006).

For the ship performance evaluation the statistics, investigations using the physical models and numerical simulation techniques can be applied. The ship performance evaluation enables to determine the intermediate events, additional events (releases) and consequences and risk of each accident scenario. The aim is to achieve an adequate level of risk by reducing the risk if necessary. Providing a sufficient level of safety based on the risk assessment is the main objective. It is either the design, operational or organizational objective. Then, safety is not a limitation any more, existing in the regulations. It is just the objective. The measure of safety of a ship in damaged conditions is the level of risk.

The proposed method may be used at any ship's life circle, including safety assessment of the ship during a catastrophe. Some elements of the method can be used for safety assessment of different means and systems of seaborne transportation. In the future the method can be useful in elaboration of a new methodology of safety assessment of ships, which bases on the application of risk analysis.

The method is based on the following steps:

- setting the requirements, criteria, limitations, risk acceptance criteria and safety objectives,
- definition of ship and environment,
- hazard identification and scenarios development,
- assessment of ship performance for the data sequence of events,
- risk estimation using the matrix type risk model,
- risk assessment according to the risk acceptance criteria,
- risk control (prevention, reduction),
- selection of designs (operational procedures) that meet the objectives,
- making decisions on safety.

The structure of the method is presented in Figure 2, Gerigk (2010).

The risk and safety assessment of ships in damaged conditions requires modeling of the risk contribution tree. For each hazard a separate event tree may be modeled using the Event Tree Analysis ETA. The basic event tree ETA for the safety assessment of ships in damaged conditions is presented in Figure 3.

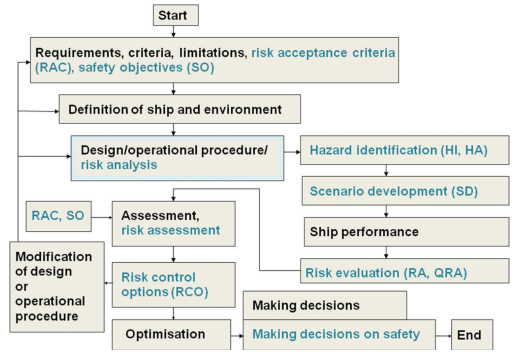

Figure 2. Structure of the method of risk and safety assessment of ships in damaged conditions.

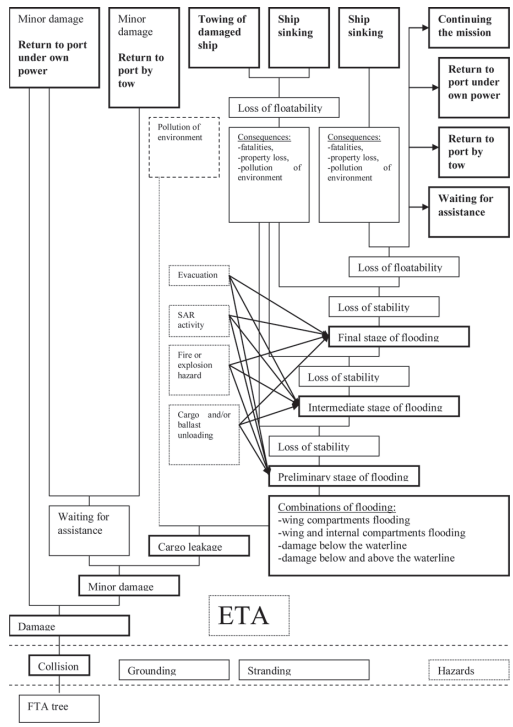

Figure 3. A Basic Event Tree (ETA) for safety assessment of ships in damaged conditions and salvage purposes.

Generally, sixteen safety functions may be defined for each event tree considering a ship safety in damaged conditions, Gerigk (2010).

A location of each function can easily be found in Figure 3. The starting functions are: function 1 (avoiding the hazard), function 2 (hull skin damage (flooding) and function 3 (position and extension of damage). The final functions can be: function

8 (loss of the ship floatability at the final stage of flooding) or function 9 (ship is waiting for assistance), (Abramowicz-Gerigk 2006, Abramowicz et al. 2008, Abramowicz-Gerigk et al. 2013, Gerigk 2004, Gerigk 2006, Gerigk 2008, Gerigk 2010, Gerigk 2012, Perera 2011).

It is important to notice that each event tree may have a dynamical character.

3 THE RISK ESTIMATION USING THE MATRIX TYPE RISK MODEL

The risk associated with the data sequence of events may be estimated according to the well known general formulae, Gerigk (2010):

$$R_i = P_i \times C_i \tag{1}$$

where P_i = probability of occurrence of a given hazard; C_i = consequences following the occurrence of the data hazard and scenario development, in terms of fatalities, injuries, property losses and damage to the environment.

The risk model (1) may concern four different kinds of losses regarding the human fatalities (HF), cargo and ship losses (CS), environment pollution (E) and financial losses ($).

The risk formulae for the risk estimation for a ship in damaged conditions can be presented as follows:

$$R = P_c \, P_{c/f} \, PoC_{dam} \times C \tag{2}$$

where P_c = probability of collision (hazard); $P_{c/f}$ = probability of flooding having the ship hit from given direction at data position with given extent conditional on collision; PoC_{dam} = probability of capsizing in damaged conditions in given time conditional on having flooding when the ship is hit from given direction at data position with given extent conditional on collision; C = consequences regarding the fatalities, property (cargo, ship), environment and finance ($C = C_{HF/C}, C_{CS/C}, C_{E/C}, C_{\$/C}$).

The PoC_{dam} probability of capsizing in damaged conditions in the given time can be calculated according to the following formulae, Gerigk (2010):

$$PoC_{dam} = P_{c/f/ns} \, P_{c/f/ns/tts} \tag{3}$$

where $P_{c/f/ns}$ = probability of not surviving conditional on having flooding when the ship is hit from given direction at data position with given extent conditional on collision; $P_{c/f/ns/tts}$ = probability of given time to sink conditional on not surviving the conditional on having flooding when the ship is hit from given direction at data position with given extent conditional on collision.

The PoC_{dam} probability can be estimated using the following methods, Gerigk (2010):

- binary method;
- method based on definition of the probability of surviving a collision;
- method based on definition of the damage stability;
- method based on definition of the ship performance during the accident.

In the case of the last method the roll function in time domain has been anticipated as a major function enabling the risk assessment, Gerigk (2010).

The risk estimation requires to calculate the conditional probabilities regarding the initial events ZI_i, major events (hazards) ZG_j, intermediate events ZP_k and final events ZK_l which are the consequences.

The basic mathematical formulas are as follows, Gerigk (2010).

First of all the row matrix of initial events is evaluated:

$$P(ZI) = P(ZI_i) = [\, P(ZI_1), P(ZI_2), ..., P(ZI_n)] \quad \text{for } i = 1 \text{ to } n \tag{4}$$

Then the matrix of major events is calculated:

$$MP_{ZG} = P(ZG_j/ZI_i) \quad \text{for } j = 1 \text{ to } m \tag{5}$$

where the $P(ZG_j/ZI_i)$ conditional probabilities belong to the data sequences of events and may be presented as the matrix of conditional probabilities as follows:

$$\begin{bmatrix} P(ZG_1/ZI_1) & P(ZG_2/ZI_1) & ... & P(ZG_m/ZI_1) \\ P(ZG_1/ZI_2) & P(ZG_2/ZI_2) & ... & P(ZG_m/ZI_2) \\ ... & ... & ... & ... \\ P(ZG_1/ZI_n) & P(ZG_2/ZI_n) & ... & P(ZG_m/ZI_n) \end{bmatrix}$$

After that the matrix of intermediate events is calculated:

$$MP_{ZP} = P(ZP_k/ZG_j) \text{ for } k = 1 \text{ to } m1 \tag{6}$$

where the $P(ZP_k/ZG_j)$ conditional probabilities belong to the data sequences of events and may be presented as the matrix of conditional probabilities as follows:

$$\begin{bmatrix} P(ZP_1/ZG_1) & P(ZP_2/ZG_1) & ... & P(ZP_{m1}/ZG_1) \\ P(ZP_1/ZG_2) & P(ZP_2/ZG_2) & ... & P(ZP_{m1}/ZG_2) \\ ... & ... & ... & ... \\ P(ZP_1/ZG_m) & P(ZP_2/ZG_m) & ... & P(ZP_{m1}/ZG_m) \end{bmatrix}$$

Then the matrix of final events is calculated:

$$MP_{ZK} = P(ZK_l/ZP_k) \text{ for } l = 1 \text{ do } m2 \quad (7)$$

where the $P(ZK_l/ZP_k)$ conditional probabilities belong to the data sequences of events and may be presented as the matrix of conditional probabilities as follows:

$$\begin{bmatrix} P(ZK_1/ZP_1) & P(ZK_2/ZP_1) & \ldots & P(ZK_{m2}/ZP_1) \\ P(ZK_1/ZP_2) & P(ZK_2/ZP_2) & \ldots & P(ZK_{m2}/ZP_2) \\ \ldots & \ldots & \ldots & \ldots \\ P(ZK_1/ZP_{m1}) & P(ZK_2/ZP_{m1}) & \ldots & P(ZK_{m2}/ZP_{m1}) \end{bmatrix}$$

Finally, the row matrix for the final events may be estimated as follows:

$$P(ZK) = P(ZI)\, MP_{ZG}\, MP_{ZP}\, MP_{ZK} = P(ZI_i)\, P(ZG_j/ZI_i)\, P(ZP_k/ZG_j)\, P(ZK_l/ZP_k) \quad (8)$$

where i = 1 to n, j = 1 to m, k = 1 to m1 and l = 1 do m2.

Because of the above mathematical model used the entire risk model is called as the matrix type risk model. In the case when the additional events occur the $PoC(C_i)$ probability of occurring the C_i given consequences can be calculated according to the formula worked out by Gerigk, Gerigk (2010). The typical additional events may concern the water on deck, air cushions, cargo leakage, additional heeling moments or passenger behaviour.

4 APPLICATION OF THE METHOD

The ship accidents at sea may lead to the loss of life, loss of properties (ship and cargo) and pollution of environment. The modern approach to safety of seaborne transportation requires to apply the so-called life-circle approach by integrating the design for safety, safe operation and safe salvage methods. Most of the salvage activities have been associated with using the rules of thumb without a support based on the safety assessment process. The effective and safe ship salvage requires to develop the methods, models and tools for the assessment of risk and safety of ships in damaged conditions, Gerigk et al. (2012).

The proposed method of risk and safety assessment of ships in damaged conditions together with the matrix type risk model enables to assess a ship survivability at each stage of flooding including the preliminary, intermediate and final stages of flooding. Such an assessment is necessary to predict any further deterioration of the damage condition. It may be connected with further flooding of compartments and ship listing increase. This assessment also regards predicting how long it would take the ship to capsize or sink. If the ship survives flooding (a ship remains upright (or heeled) and afloat) and is unable to return to port under own power it is necessary to solve the problems associated with the towing when waiting for an assistance. The number of towing points and towing speed in the calm and rough weather conditions should be evaluated. During the towing the risk and safety assessment of the ship should be permanently conducted.

The structure of the procedure for the assessment of safety of ships in damaged conditions during the accident at sea and for the salvage purposes is presented in Figure 4, Gerigk (2010).

The procedure of assessment of safety of damaged ships during the catastrophe at sea should enable as follows:

- assessment of safety of ships in damaged conditions (stages/phases of flooding);
- identification of changes;
- estimation of time of flooding (time for evacuation, time of SAR activity);
- method of ship salvage (RTP, WFA, AS), method of towing.

The key element of the procedure presented in Figure 4 is the decision support system. An idea of this system is based is the approach to safety management. The structure of this approach is presented in Figure 5.

For making the decisions on safety (see Fig. 2) a method of the knowledge representation and efficient reasoning under uncertainties has been applied using the Bayesian Belief Networks (BBN).

The basic structure of the method of knowledge representation and efficient reasoning under

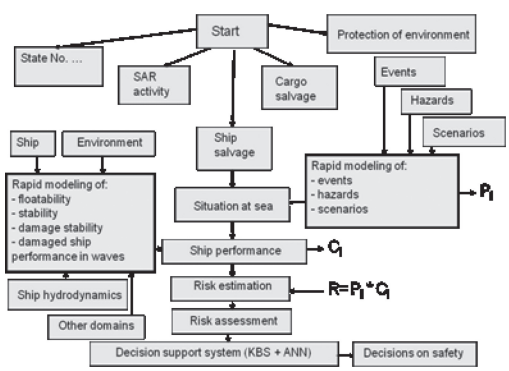

Figure 4. The structure of the procedure for the assessment of safety of ships in damaged conditions during the accident at sea and for the salvage purposes.

uncertainties for the safety assessment of ships in damaged conditions is presented in Figure 6.

An example of the basic structure of this method in the case of collision is presented in Figure 7.

For constructing the safety management network within the decision support system (see Fig. 4) the Hugin Researcher 7.4 has been used.

Figure 5. The structure of the approach to safety management.

Figure 6. The basic structure of the method of knowledge representation and efficient reasoning under uncertainties for the safety assessment of ships in damaged conditions.

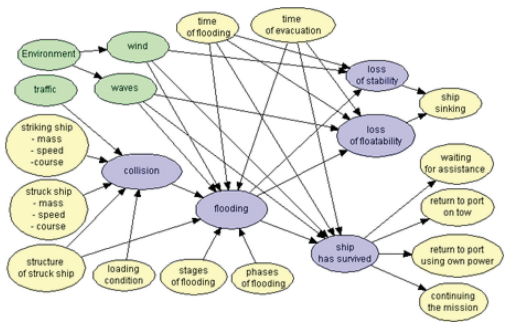

Figure 7. The structure of the method in the case of the collision.

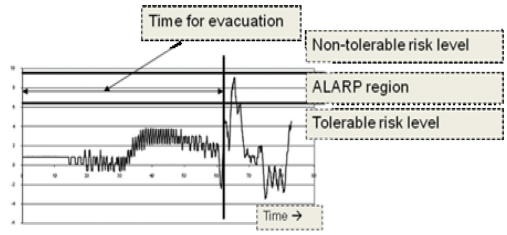

Figure 8. An example of the roll function in time domain and ALARP risk evaluation criteria applied for the assessment of safety of a ship in damaged conditions.

In practice using the proposed concept of a risk-based decision support system for the ship safety assessment in damaged conditions the following major steps are necessary to be done:

- assessment of ship performance,
- risk assessment using the risk acceptance criteria,
- risk management using the risk control options.

An example of application of the ship performance data regarding the ship roll function in time domain and ALARP risk evaluation criteria for assessment of a ship safety in damage conditions is presented in Figure 8. The vertical axis in Figure 8 regards the angle of heel in degrees and the horizontal axis concerns the time in seconds.

5 CONCLUSIONS

The method presented in the paper is based on combining the ship performance-oriented approach and risk-based approach.

The method has the following features:

- no disadvantages which exist in SOLAS;
- holistic approach to safety (design, operation, catastrophe, salvage);
- holistic approach to safety: safety factors (sources of factors: design, operation, management, human factor);
- holistic approach regarding the risk model;
- assessment of safety for all the possible scenarios.

The key issue to apply the method is to have the proper matrix type holistic risk model. The proposed risk model is rather complicated in practice but it seems to be more suitable for the design, operational and salvage purposes than the models published in literature.

The risk model depends on the structure of event tree.

In the case of a risk-based decision support system which is a part of the procedure for the assessment of safety of ships in damaged conditions presented in Figure 4 the decisions of safety should be done performing the following steps:

– assessment of ship performance,
– risk assessment using the risk acceptance criteria,
– risk management using the risk control options.

The current research is associated with further development of the risk models, ship performance procedures and risk acceptance criteria.

ACKNOWLEDGMENTS

The research has been carried out at the Gdansk University of Technology according to support obtained from the Ministry of Science and Higher Education in Warsaw. The author would like to express his sincere gratitude to the above organisations.

The influence of screw propellers manufacturing accuracy on conditions of the propulsion system operating

E. Skupień
Institute of Machine Design and Operation, Wroclaw University of Technology, Poland

ABSTRACT: The paper presents an analysis of deviations in diameter D and pitch coefficient P/D and their impact on the determination of efficiency, torque, thrust and power calculated using the exact differential method.

The results of the presented analysis, were applied into the characteristics of propulsion system. On this basis, the operating point has changed in the area. Further analysis allowed to identify, among others, maximum power requirements for obtaining a desired speed under certain navigation conditions.

1 INTRODUCTION

Operating condition on Polish inland waterways significantly differ from conditions on other European waterways. Therefore problems considered in Polish society are often not encountered anywhere else. One of those issues is determinating operating conditions of propulsion system in frequently changing navigation conditions (it is extremely rare not to keep still navigation conditions on specific parts of river). (Kulczyk & Winter, 2003).

Calculating the optimal operating parameters of the inland ship's propulsion system, requires performing many intermediate calculations. At each of the steps, accuracy of the calculations is correlated with the rounding precision, but also with the accuracy of the characteristics and the geometry of the propeller. For this reason, one notes the impact of these errors on the final results. (Eloot & Vantorre, 2011).

Thorough analysis the impact of geometric parameters for further calculations, one can get on the basis of a model tests or theoretical algorithms. Presentation of the hydrodynamic characteristics of the propeller in the form of polynomials, allows to analyze the impact of propeller's workmanship inaccuracy on the operating parameters of the drive system, that is: power, thrust or efficiency.

Measurement errors can be calculated using the total differential method (Hansel, 1968).

$$df(x) = \sum_{i=1}^{n} \frac{\partial f(x)}{\partial x_i} dx_i \tag{1}$$

For indirect measurements, if the measured value is the sum of the values of x_i to x_n:

$$df(x) = \sum_{i=1}^{n} \frac{\partial f(x)}{\partial x_i} dx_i \tag{2}$$

Taking into account all the indirect errors, the result will therefore be the sum of the errors obtained at each stage (Piotrowski, 2002).

Further provided calculations were based on the example of the Ka series ducted propellers.

2 THE IMPACT OF THE ACCURACY OF THE PROPELLER DIAMETER D

Propellers of inland vessels often work in very difficult conditions. This results in a fairly rapid mechanical consumption of propellers (abrasion and deformation). Propellers are also mostly performed in a technology giving low accuracy (welded carbon steel). Most of these results in negligently manufacturing of propellers (Dudziak, 1988).

The accuracy of the propellers manufacturing has an impact on the efficiency of those, obtained thrust, the required torque on the cone bolts and curves of thrust and power on the driving characteristics of the ship (Kulczyk & Winter, 2003; Holtrop & Mennen, 1982).

The efficiency of the propeller, defined by the equation:

$$\eta_0 = \frac{K_T}{K_Q} \frac{J}{2\pi} \tag{3}$$

Can be written indicating dependence:

$$\eta_0 = \frac{K_T\left(\frac{P}{D}, J(D)\right)}{K_Q\left(\frac{P}{D}, J(D)\right)} \frac{J(D)}{2\pi} \tag{4}$$

Calculating the differential of the efficiency assuming as variable a diameter D, relative error equation is obtained:

$$\frac{d\eta_0}{\eta_0} = J\frac{dD}{D}\left(\frac{1}{K_Q}\frac{\partial K_Q}{\partial J} - \frac{1}{K_T}\frac{\partial K_T}{\partial J} - \frac{1}{J}\right) \tag{5}$$

where: $\partial K_Q / \partial J$ and $\partial K_T / \partial J$ are derivatives of torque and thrust coefficients with respect to the feed ratio J.

Relative errors of thrust for constant rotation and torque can be calculated using the equation:

$$T = K_T \cdot \rho \cdot n^2 \cdot D^4 \tag{6}$$

And are:

$$\frac{dT}{T}|_{n=const} = \frac{dD}{D}\left(4 - \frac{J}{K_T}\frac{\partial K_T}{\partial J}\right) \tag{7}$$

$$\frac{dQ}{Q} = \frac{dD}{D}\left(5 - \frac{J}{K_Q}\frac{\partial K_Q}{\partial J}\right) \tag{8}$$

The relative error of power for constant rotation is:

$$\frac{dP_D}{P_D}|_{n=const} = \frac{dD}{D}\left(5 - \frac{J}{K_Q}\frac{\partial K_Q}{\partial J}\right) \tag{9}$$

Assuming constant torque, takes a form:

$$\frac{dP_D}{P_D}|_{Q=const} = \frac{1}{2}\frac{dD}{D}\left(\frac{J}{K_Q}\frac{\partial K_Q}{\partial J} - 5\right) \tag{10}$$

An error of thrust for constant torque is:

$$\frac{dT}{T}|_{Q=const} = J\frac{dD}{D}\left(\frac{1}{K_Q}\frac{\partial K_Q}{\partial J} - \frac{1}{K_T}\frac{\partial K_T}{\partial J} - \frac{1}{J}\right) \tag{11}$$

For these calculations, resulting from the propeller's diameter error, a knowledge of derivatives ∂J and ∂J is required. Presentation of these coefficients as polynomials (for ducted propellers series Ka):

$$K_T = \sum_{s,t}\left[A_{s,t} \cdot J^s \left(\frac{P}{D}\right)^t\right] \tag{12}$$

$$\frac{\partial K_T}{\partial J} = \sum_{s,t}\left[A_{s,t} \cdot t \cdot J^{t-1}\left(\frac{P}{D}\right)^s\right] \tag{13}$$

$$K_Q = \sum_{s,t}\left[B_{s,t} \cdot J^s \left(\frac{P}{D}\right)^t\right] \tag{14}$$

$$\frac{\partial K_Q}{\partial J} = \sum_{s,t}\left[B_{s,t} \cdot t \cdot J^{t-1}\left(\frac{P}{D}\right)^s\right] \tag{15}$$

allows for the calculation of the respective propellers and assumed feed ratio *J*.

For the range of the feed rate J used in practice, an increase in diameter would cause the reduction in efficiency, increasing the thrust, but also torque. In addition, for smaller values of pitch ratio *P*/*D* and *J*, the impact of the error of diameter is smaller.

Increasing the diameter of the propeller causes the risk of overloading the propulsion system (propeller would be to heavy). Therefore, it is safer to allow an error of –5% than +5%.

3 THE IMPACT OF THE ACCURACY OF THE PITCH RATIO P/D

Similar calculations as for the diameter of the propellers, carried out for the pitch ratio will give the following results:

$$\frac{d\eta_0}{\eta_0} = \frac{d\left(\frac{P}{D}\right)}{\left(\frac{P}{D}\right)} \cdot \left(\frac{P}{D}\right)\left(\frac{1}{K_T}\frac{\partial K_T}{\partial\left(\frac{P}{D}\right)} - \frac{1}{K_Q}\frac{\partial K_Q}{\partial\left(\frac{P}{D}\right)}\right) \tag{16}$$

$$\frac{dT}{T}|_{n=const} = \frac{d\left(\frac{P}{D}\right)}{\left(\frac{P}{D}\right)} \cdot \left(\frac{P}{D}\right)\left(\frac{1}{K_T}\frac{\partial K_T}{\partial\left(\frac{P}{D}\right)}\right) \tag{17}$$

$$\frac{dQ}{Q} = \frac{d\left(\frac{P}{D}\right)}{\left(\frac{P}{D}\right)} \cdot \left(\frac{P}{D}\right)\left(\frac{1}{K_Q}\frac{\partial K_Q}{\partial\left(\frac{P}{D}\right)}\right) \tag{18}$$

$$\frac{dP_D}{P_D}|_{n=const} = \frac{d\left(\frac{P}{D}\right)}{\left(\frac{P}{D}\right)} \cdot \left(\frac{P}{D}\right)\left(\frac{1}{K_Q}\frac{\partial K_Q}{\partial\left(\frac{P}{D}\right)}\right) \tag{19}$$

$$\frac{dP_D}{P_D}|_{Q=const} = -\frac{1}{2}\frac{d\left(\frac{P}{D}\right)}{\left(\frac{P}{D}\right)} \cdot \left(\frac{P}{D}\right)\left(\frac{1}{K_Q}\frac{\partial K_Q}{\partial\left(\frac{P}{D}\right)}\right) \tag{20}$$

$$\frac{dT}{T}\Big|_{Q=const} = \frac{d\left(\frac{P}{D}\right)}{\left(\frac{P}{D}\right)} \cdot \left(\frac{P}{D}\right)\left(\frac{1}{K_T}\frac{\partial K_T}{\partial\left(\frac{P}{D}\right)} - \frac{1}{K_Q}\frac{\partial K_Q}{\partial\left(\frac{P}{D}\right)}\right) \tag{21}$$

Increasing the P/D ratio has the same effect as increasing the diameter, but the impact is much smaller. For the torque, there is no unambiguous impact of P/D ratio. The smallest errors are achieved for the lowest P/D ratio.

Derivative $\partial K_Q/\partial(P/D)$ and $\partial K_T/\partial(P/D)$ take the analogous form to the derivatives of diameter:

$$\frac{\partial K_Q}{\partial\left(\frac{P}{D}\right)} = \sum_{s,t}\left[A_{s,t}\cdot s\cdot J^t\left(\frac{P}{D}\right)^{s-1}\right] \tag{22}$$

$$\frac{\partial K_T}{\partial\left(\frac{P}{D}\right)} = \sum_{s,t}\left[B_{s,t}\cdot s\cdot J^t\left(\frac{P}{D}\right)^{s-1}\right] \tag{23}$$

4 ACCURACY CALCULATIONS—SUMMARY

Practice shows that the above-mentioned errors most often take the values: for diameter: $\partial D/D \approx 3\%$, for (P/D) ratio: $(\partial(P/D))/(P/D) \approx 10\%$.

Drawings 1 to 13 show the influence of error of 3% in diameter and 10% in P/D ratio, on efficiency, thrust and torque.

The charts show the calculation for the propeller Ka4-55, with a diameter $D = 1.26$ m, with pitch ratio $P/D = 0.6$; $P/D = 0.778$ (such propeller is

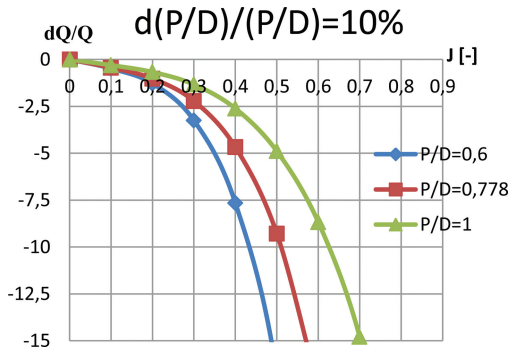

Figure 6. Changes in the torque with an error of pitch ratio $\partial(P/D)/(P/D)$ = 10%, for different pitch ratios of Ka4-55 propeller.

operated on Bison pushers); $P/D = 1$ and $P/D = 1.4$. Different values of pitch ratio illustrate the nature of the changes, along with increases in feed rate. The nature of the changes of errors is similar for all the ducted propellers.

From the graphs above it can be concluded that an increase of the pitch ratio reduces the impact of the accuracy of the propeller on the analyzed parameters for the same value of the feed rate.

5 THE TOTAL VALUE OF ERROR

Knowledge of value of the total error affects the determination of fuel consumption (the accuracy of the determination), but also affects the correct determination of the optimal operating parameters of the propulsion system. Operation the propulsion system outside the optimal operating parameters can lead to overload the system, which in turn can damage it.

The calculations of the effect of errors on the operating parameters of the propulsion system, allow to establish optimum operating conditions of the propulsion system on the ship's propulsion characteristics, not by a point, but as a field.

Each of the analyzed elements affects the operating parameters of the propulsion system. Therefore, their impact should be presented as a sum of errors.

To illustrate, on the characteristics of the thrust T (V) the values of individual errors and their sum was applied.

Figure 7 shows the propulsion characteristics of ship with the Ka4-55 propeller in the nozzle 19A. On the graph curves corresponding to the values of errors resulting from the implementation of the propeller diameter of 3% accuracy were plotted

The following figure double lines mark characteristics of the propulsion system, namely: the nominal speed (double blue line), the nominal torque (double green line) and the needed thrust resulting from the geometry of the vessel and the depth of the waterway (double yellow line). The intersection of these lines represents the theoretical operating point. To obtain the ship speed Vs = 2.95 m/s, the propulsion system must generate thrust TN = 21500 N.

Figure 7 shows extension of the single lines the range of rotation and torque of the system under the assumption of error of 3% of the propeller diameter.

In practice, this means that the operating point extended to the field bounded by the curves taking into account the value of errors. The following situation is possible: the thrust 23500 N (upper point of intersection the needed thrust curve and the

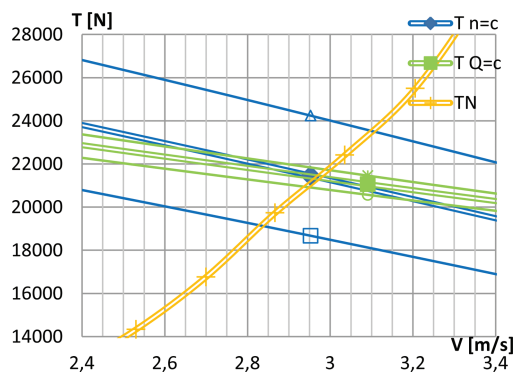

Figure 7. Propulsion characteristics of ship with the Ka4i55 propeller, with the accuracy of propellers diameter $\partial D/D = 3\%$.

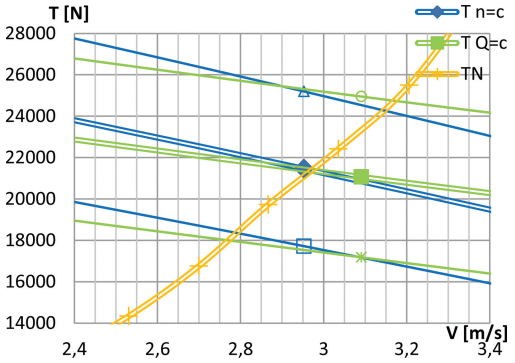

Figure 8. Propulsion characteristics of ship with the Ka4-55 propeller, with the accuracy of pitch ratio $\partial(P/D)/(P/D) = 10\%$.

constant RPM curve) get speed of 2.83 m/s (lower intersection point). It is equally probable, that the thrust 19200 N, gives the ship speed of 3.1 m/s. The situation that occurs depends on the exact value and the direction of errors.

Figure 8 shows the propulsion characteristics of the ship, taking into account the corresponding error of pitch ratio.

As in the previous case, the system may be at the optimal point of work, but also in each of the points lying along the curve of needed thrust, located between the extreme lines of errors arising from the implementation of pitch ratio.

6 CONCLUSION

These values may be questionable. However, to obtain a state where more than 27 kN thrust would not give a greater speed of 2.5 m/s (9 km/h), all the analyzed errors would have to co-exist and would not alleviate.

Going forward, the range of rotation and torque needed to achieve that speed can be determined. Knowing the maximum values of these parameters, corresponding to not overloading operation parameters of the propulsion system, it is possible to exploit the propulsion system to prevent overloading.

Contribution to oil data assessment for system condition determination

D. Vališ
University of Defence, Brno, Czech Republic

L. Žák
University of Technology, Brno, Czech Republic

ABSTRACT: The paper deals with application of selected analytical methods for analysing field data from heavy off-road military vehicles. It is the vehicle engine and its oil data which are explored for further utilisation. There is available reasonable set of vehicles and their oil data from in-field-operation. Based on the data we assume it will be possible to determine some changes in the system operation. We apply and will present methods of multi-variate and multi-shape regression analysis to model the data and provide outcomes + estimations for system operation so far and also for system further operation. The novelty is to providing inputs for helping to change e.g. the system maintenance policy, system operation and mission planning.

1 INTRODUCTION

The growing dependability and operation safety requirements for modern equipment together with the increasing complexity and continuous attempts to reduce operation and maintenance costs might be satisfied among others by the consistent use of modern diagnostic systems. The main task of object technical state diagnostics is not only to find out incurred failures, but also to prevent from the failure occurrence with the help of sensible detection and changes localization in the object structure and in its behaviour changes. Many various approaches have been published on system diagnostics and CBM (Condition Based Maintenance).

A tribotechnical system (TTS), friction in it, wear and lubrication, and especially the outcomes of it are the subjects of our major concern. We would like to analyse the outcomes from technical diagnostics of TTS. There exists wide range of data from the TTS which are not analysed further. We find this is a pity. Our main objective is to extract maximum information from the diagnostic of TTS in order to gain tools for optimising: maintenance, cost-benefit processes, operation and mission planning. The authors will apply selected mathematical tools to get some inputs into previously mentioned areas. Regarding the tribotechnical system, the basic information about tribological process, operating and loss variables are provided (Gesellschaft für Tribologie 2002; Czichos & Habig 2003; Koucky & Valis 2011, Valis et al. 2012, 2014).

Owing to the TTS we have got a lot of diagnostic oil data. In view of tribo-diagnostics this data is considered to be the final outcome. This data can tell us a lot about lubricants/life fluids quality itself as well as about system condition. Such data are very valuable. System operation, taking the oil samples and the outcomes themselves, are very fuzzy therefore we further plan using approaches from the fuzzy logic theory in our future research. The procedure and results presented below are based on standard mathematical principles—a regression function and a regression analysis which later will be supported with fuzzy logic. From both presumptions we can expect reasonable costs savings (see e.g. Stodola & Mazal 2012, Stodola et al. 2013). As from the military point of view we would like to determine remaining residual life to be able to perform a mission. Following the regression analysis it is possible among others to assess the operating history of an observed vehicle.

The main goal of the paper is to study and to understand the courses of oil particles generations at the beginning part of the system technical life.

2 OBJECTS OF DIAGNOSTICS AND METHODS

The assumed objects of diagnostics in our case the medium lorry T810 engines have not been ready yet in terms of design to use the ON-LINE system, though in practice similar possibilities for other applications have already existed. It results from the information stated above that we are

still supposed to use OFF-LINE engine diagnostics system when sampling lubrication fluid at certain intervals, and using known and optimised special tribodiagnostic methods (Lippay 1991). In our case we use the results and information from atomic emission spectrometry. Following this analysis we can obtain the information about the presence of the elements of a specific kind and the amount of elements. If the vagueness in classes distribution is not given by a stochastic character of measured characteristics but by the fact that the exact line among states classes does not exists, it will be later on good to use fuzzy set theory and adequate multi-criteria fuzzy logic. However, we cannot identify their real origin—e.g. as a result of fatigue, cutting or sliding.

Therefore in our further research we try to identify where the elements might come from. We base our assumptions on idea to increase the potential for maintenance optimisation inputs and cost benefit analysis inputs. Usable diagnostic approaches might be found e.g. in Klimaszewski & Woch 2012 and Woch 2013.

3 OIL FIELD DATA ASSESSMENT AND MATHEMATICAL MODEL

There is enough statistically important set of field data obtained from the diagnosed objects. It fulfils the basic assumption that we might be capable to solve this problem successfully. Since the data sets are very extensive, we are not going to introduce them here except for a part/example of Ferrum particles representing the sample of T810—it is presented in modified form in Table 1. While Mh is number of motor-hours and ppm is number of particles per milion.

We deal with dozens of samples taken and analysed at different types of observed engines. In certain aspects we consider the engine from an infantry fighting vehicle to be a reference object, because the event of a failure type has occurred in it. All tribodiagnostic processes related to the failure occurrence have been recorded. We assume that we have potential for obtaining inputs for system maintenance optimisation and system residual life estimation.

Table 1. Input data of Fe particles.

Sample/Mh	Fe particles (ppm)	Sample/Mh	Fe particles (ppm)
1/0	4.34	26/233	5.77
2/8	5.11	27/244	5.27
3/11	5.62	28/255	4.35

3.1 *Utilisation of regression model—theory*

When analysing diagnostic data, the question arises whether the data is described by only one regression function across all measurement interval, or there are areas of a different regression function in the data record. If the data is divided into more areas for which relevant regression functions will be calculated, in most cases the regression functions will have a different functional value at the point where the data is divided. When looking for a suitable regression function, a continuity requirement is often set. We would like to modify the form of our data regression functions so that they could have the same value at the point where the data is divided into single areas. At the beginning let us presume that the system is in two states. The diagnostic data will be therefore divided into two parts/areas and in each of them we will look for the regression functions whose functional value at a dividing point will be the same.

An independent variable is with a view of its random character represented by a random variable X (motohours—Mh), while a dependent variable is represented by a random variable Y (the number of Fe particles). The breakpoint for two parts will be defined by the value x_0. In the first area we are searching for the following regression function:

$y = \varphi_1(x, \boldsymbol{\beta}^1) = E(Y|X = x)$ for the data for which it applies: $x < x_0$.

In the second area we are looking for the regression function as follows:

$y = \varphi_2(x, \boldsymbol{\beta}^2) = E(Y|X = x)$ for the data for which it applies: $x > x_0$

and at the same time we require that the following equation applies:

$$\varphi_1(x_0, \boldsymbol{\beta}^1) = \varphi_2(x_0, \boldsymbol{\beta}^2)$$

We are looking for both regression functions for the whole area of data concurrently. As for our data, the regression functions will be searched for in a linear form and we will use a linear regression model:

$$y = \sum_{j=1}^{m} \beta_j f_j(x),$$

where $f_j(x)$ are known functions not containing $\beta_1, ..., \beta_m$.

This model is based on the assumptions listed below:

1. Values x are non-random so the functions $f_j(x)$ acquire non-random values $f_{ji} = f_j(x_i)$ for $j = 1, ..., m$ a $i = 1, ..., n$.
2. Matrix $F = \begin{pmatrix} f_{11} & \cdots & f_{1n} \\ \vdots & \ddots & \vdots \\ f_{m1} & \cdots & f_{mn} \end{pmatrix}$ of the type (m, n) with the elements f_{ji} is of the rank $m_m \leq n$.
3. Random variable Y_i, where $E(Y_i) = \sum_{j=1} \beta_j f_{ji}$ and $D(Y_i) = \sigma^2 > 0$ for $i = 1, ..., n$.
4. Random variables Y_i are non-correlated and have a regular probability distribution for $i = 1, ..., n$.

In the single areas we have selected the following regression functions:

for the first area: $m = 2, f_1(x) = 1, f_2(x) = x$, the regression function is: $y = \beta_1^1 + \beta_2^1 x$

for the second area: $m = 2, f_1(x) = 1, f_2(x) = x$, the regression function is: $y = \beta_1^2 + \beta_2^2 x$

For the required dependency we select the model which will fit the data and at the same time will be as simple as possible. We are going to do it like this:

1. Gradually we will select the value x_0 and a relevant regression function in the following manner: we are looking for the values $b_1^1, b_2^1, b_1^2, b_2^2$ (the point estimation of the parameters: $\beta_1^1, \beta_2^1, \beta_1^2, \beta_2^2$) so that the function:

$$S = \sum_{x<x_0} (y - (\beta_1^1 + \beta_2^1 x))^2 + \sum_{x>x_0} (y - (\beta_1^2 + \beta_2^2 x))^2$$

could acquire minimum value when:

$$\beta_1^1 + \beta_2^1 x_0 = \beta_1^2 + \beta_2^2 x_0.$$

The minimum is marked as ${}^{x_0}S^*_{\min}$

2. Out of the regression functions we select the one for which the value ${}^{x_0}S^*_{\min}$ is as low as possible. This value will be denoted as $S^*_{\min}$.

The parameters of required points might be obtained by solving the following equation:

$$\left\{ \min_{\beta_1^1, \beta_2^1, \beta_1^2, \beta_2^2} \left\{ \sum_{x<x_0} (y - (\beta_1^1 + \beta_2^1 x))^2 + \cdots + \right\} \right\}$$

$$+ \sum_{x>x_0} (y - (\beta_1^2 + \beta_2^2 x))^2 \Big| \beta_1^1 + \beta_2^1 x_0 = \beta_1^2 + \beta_2^2 x_0 \Bigg\}$$

Limitation: To keep the model simple, in both areas we have chosen linear dependability which is line-shaped. Owing to a large data spread for low values at motohours, we have selected the value x_0 from the value 20.

3.2 *Utilisation of regression model—results*

The lowest value $S^*_{\min}$ we have obtained for $x_0 = 178$ (motohours). $S^*_{\min} = 2817.053$.

The dependency ${}^{x_0}S^*_{\min}$ on the value x_0 is shown in the graph in Figure 1.

For the value $x_0 = 178$ we acquired the following regression coefficients values:

First area: Point estimation of the parameter

$$\beta_1^1 : b_1^1 = 13.039100221$$

$$\beta_2^1 : b_2^1 = 0.0425359370$$

Interval estimations: 95% dependability interval for

$$\beta_1^1 : 12.38572268,\ 13{,}69247777$$

$$\beta_2^1 : 0.033147272,\ 0.051924603$$

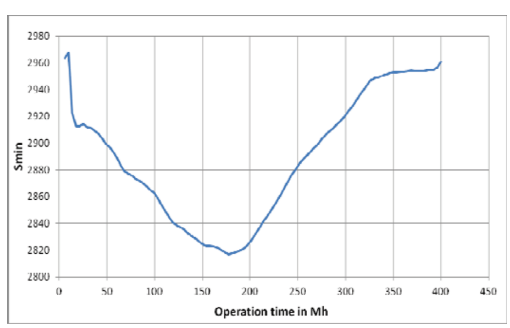

Figure 1. The dependency ${}^{x_0}S^*_{\min}$ on the value x_0.

p-value for the hypothesis H:$\beta_2^1 = 0$:1.50082E-16

Second area: Point estimation of the parameter

$\beta_1^2 : b_1^2 = 19.91494523$

$\beta_2^2 : b_2^2 = 0.003907594$

Interval estimations: 95% dependability interval for

β_1^2 :16.32517339, 23.50471707

β_2^2 : –0.0105137, 0.018328889

p-value for the hypothesis H:$\beta_2^2 = 0$:0.593893926.

As for the values of regression lines, it is important to estimate the coefficient β_2. We are testing the hypothesis H:$\beta_2 = 0$. It results from p-values that in the first area the hypothesis H:$\beta_2^1 = 0$ is rejected at the confidence level of 0.05 (p-value 1.50082E-16). As to the second area the hypothesis H:$\beta_2^2 = 0$ is not rejected at the confidence level 0.05 (p-value 0.593893926). The data in the second area then might be approximated with an invariable without diminishing the mathematical value of determination.

Original intention was to create two regression courses for the two sets of clusters in data. This is presented in Figure 2—for individual vehicle and in Figure 3 for mean value. This expression however does not provide continuous course of the curve which is important for further calculations.

Therefore the "continuous broken function" for the data was constructed. The confidence intervals might be also drawn for both an individual value y (see Fig. 4) and a mean value y (see Fig. 5).

While using the broken function we try to approximate the data by the regression function with more parameters. The value $S^*_{\min}$ then is lower than if all the area is approximated by the regression function of the same type. For two areas divided in $x_0 = 178$ and regression lines we obtained $S^*_{\min} = 2817.053$. If the data is approximated by

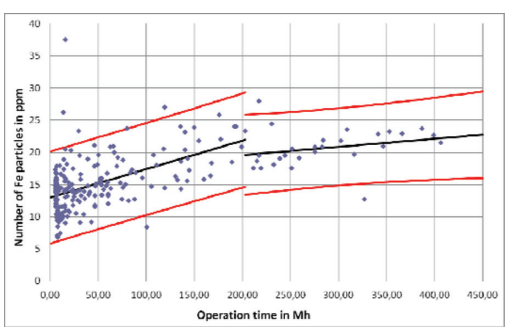

Figure 2. Course of the broken function with 95% confidence interval for individual value.

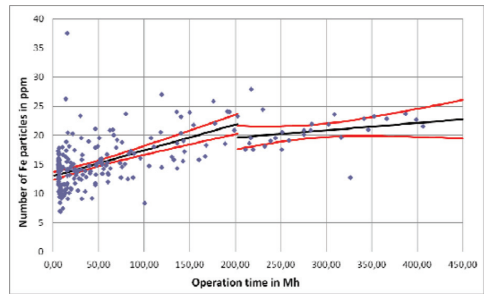

Figure 3. Course of the broken function with 95% confidence interval for individual value.

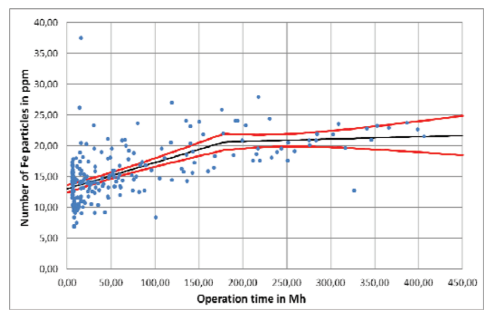

Figure 4. Course of the broken function with 95% confidence interval for individual value.

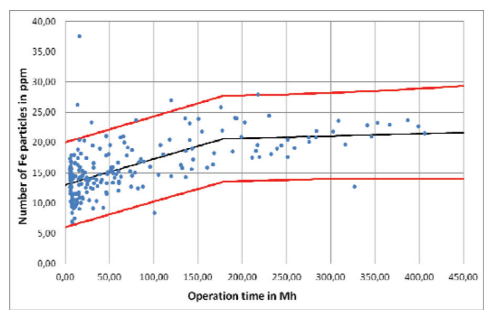

Figure 5. Course of the broken function with 95% confidence interval for mean value.

one line, then $S^*_{\min} = 2974.261342$. When approximating by a second degree polynomial, there is $S^*_{\min} = 2840.857439$, while approximating by a third degree polynomial, there is $S^*_{\min} = 2836.353795$, and with a fourth degree polynomial there is $S^*_{\min} = 2821.54932$. Approximating by a broken function is then more appropriate than using even a fourth degree polynomial. If we do not take into account continuity requirement, the regression function will have a higher degree of freedom and

S^*_{min} will get lower. For two lines we get the value $S^*_{min} = 2795.694467$.

3.3 *Summary*

It is remarkable that the *Fe* particles generation based on oil field data might have the broken form of the course. This co-relation outcome is based on the analysis performed above and will be in later research supported with the fuzzy approach. The fuzzy approach has the chance to capture the course more precisely and may suit better with the coefficient of determination R^2.

The authors hope for having broadened the possibilities of extracting and utilisation of pieces of information from TTS diagnostics- and respective interesting elements indicators. Although the regression analysis and expected utilisation of FIS are common mathematical tools they have never been properly applied for analysis of TTS oil data. Whereas the potential of the TTS oil data is actually big valuable. The authors describe just small portion of the capabilities. Application of FIS will support our idea of describing some data generation course by selected regression forms.

The authors present capabilities of the analysis results which play significant role as inputs e.g. for the system Residual Life Estimation (RLE), maintenance optimisation, mission planning, etc. Some inspirational proposals for further development especially in terms of diagnostics and maintenance optimisation are mentioned e.g. in (Babiarz 2006; Babiarz 2014a,b; Bartlett et al. 2009; Edleston & Bartlett 2012; Jodejko-Pietruczuk et al. 2010; Kierzkowski et al. 2012a,b; Kierzkowski 2010; Klimaszewski & Woch 2012, Kowalski et al. 2011, Nowakowski & Werbińska-Wojciechowska 2009, Quigley & Walls 2007; Rak & Pietrucha 2008; Revie et al. 2011; Stodola & Stodola 2010; Stodola & Stodola 2009a,b; Stodola et al. 2012; Studzinski & Pietrucha-Urbanik 2012; Valis et al. 2010, 2012, 2014; Vintr & Valis 2007, Werbińska-Wojciechowska 2013, Werbińska 2007, Woch 2013, Woch, M. 2014; Zajac et al. 2012). Using the TTS oil data from reference engine it is found that RLE might be determined for the other similar units. This approach will be further extended and developed into more precise RLE approaches.

4 CONCLUSIONS

In this paper we were looking for dependencies among measured values using statistical methods. While have applied two non-typical approaches therefore the comparison of acquired results is reasonable. At the beginning we did not know the exact theoretical background of the possible dependence of *Fe* particles occurrence on operating time.

We were looking for this dependence using suitable approximate methods. The regression analysis and the expected use of Fuzzy Inference System serve as starting methods. When dealing with the regression analysis, it is necessary to choose a regression analysis form in advance. If the regression analysis form cannot be deduced theoretically, it is necessary to select relevant regression functions and then compare them with the measured data. In the case of fuzzy methods we will not have to select the form of an expected function, but need to determine the form and the amount of language values. It follows from the other results of other sets of field data obtained from different vehicle types that when combining properly both methods, we can find out that the dependence of measured data correspond with a real process. When dealing with the assessed data, it is advisable to use the FIS first, and then, following the form of a found dependence, select a relevant regression function. Despite taking a different analytical approach when applying single methods, the results are very similar to each other (see e.g. Figs. 3 and 5). It can be then assumed that the processed dependencies can be used for describing expected development under real operating conditions.

The obtained results will be used for further research, e.g. exact determination of end of the "run-in" period, the optimising of maintenance procedures, mission planning, or the estimation of residual operating units, etc.

ACKNOWLEDGEMENTS

Dependability and safety analysis of ERTMS level 3 using analytic estimation

T. Babczyński & J. Magott
Wrocław University of Technology, Wrocław, Poland

ABSTRACT: Dependability and safety in European Rail Traffic Management System (ERTMS) level 3 are influenced by quality of train localisation and GSM-R communication. In ERTMS level 3, traffic is controlled by so called moving block that is associated with the distance between subsequent trains. In order to satisfy strong safety-related railway standards, GNSS (Global Navigation Satellite System) is supported by odometry, e.g. Eddy Current Sensors (ECSs). In the paper, the relationship between probability of emergency train braking as a function of distance between subsequent trains for dependability parameters of GNSS plus ECS train localisation, and GSM-R is studied. Tunnel environment only is considered. An analytic estimations of this relationship has been proposed.

1 INTRODUCTION

Dependability and safety parameters in Europe railway domain are specified in standards (CENELEC, 2000, CENELEC, 2003). According to standard (IEC, 1990): "dependability is the collective term used to describe the availability performance and its influencing factors: reliability performance, maintainability performance and maintenance support performance". Safety levels are characterized by tolerable hazard rate for Safety Integrity Levels (SIL) (CENELEC, 2003).

European Rail Traffic Management System (ERTMS) is the European standard for train control and command systems, which is intended to unify all European systems and to enhance cross-border interoperability. There are three levels of ERTMS, with level 3 as the highest. In ERTMS level 3, traffic is controlled by so called moving block that is associated with the distance between subsequent trains. Dependability and safety are influenced by quality of localisation of trains (Beugin & Marais, 2012, Lu et al., 2013, Nguyen et al., 2013) and communication (Flammini et al., 2006, Hermanns et al., 2005, Qiu et al., 2014, Trowitzsch & Zimmermann, 2006, Zimmermann & Hommel, 2005). Information is exchanged between trains and trackside coordination unit so-called Radio Block Centres (RBCs) via GSM-R (rail GSM communication). A train needs to receive so-called movement authorities from the RBC in order to continuously run at high speed. Data processing on board the train and in the RBCs, and radio communication link are crucial factors for safety and efficient operation. Train localization, speed, and integrity information is prepared on board the train, and reported from train to RBC at regular intervals. Train localization is based on GNSS (Global Navigation Satellite System). GNSS is not sufficient to satisfy the strong safety-related requirements of railway standards (Beugin & Marais, 2012, Lu et al., 2013). Hence, GNSS is supported by odometry (Acharya et al., 2011, GRAIL2, 2012), e.g. Eddy Current Sensors (ECSs) (Nguyen et al., 2013) in order to provide a safe, accurate and continuous train position. The RBC declares the track space behind the train clear which is used in moving block operation mode.

The relationship between probability of train stopping as a function of distance between subsequent trains, for given dependability parameters of GNSS and ECS train localisation, and GSM-R is studied in the paper. Tunnel environment only is considered.

The *problem* investigated in the paper is as follows.

Input:

- Dependability parameters of GNSS plus ECS train position localization in tunnel environment,
- Train speed,
- Emergency braking distance,
- Train length,
- Maximal position localization error,
- Random variable of emergency braking and stopping time,
- Probability of incorrect transmission from train to RBC and from RBC to train,
- Random variable of duration time of correct transmissions from train to RBC and from RBC to train,
- Processing time in RBC.

Output:

– Probability of stopping as a function of distance between subsequent trains.

The above problem with less detailed treatment of train position localization dependability has been studied in the papers (Trowitzsch & Zimmermann, 2006, Zimmermann & Hommel, 2005). Our study is based on GSM-R communication and operation parameters from these papers.

Train position localisation service availability for GNSS and ECS unit has been presented in (Nguyen et al., 2013). The results for GNSS localisation service have been obtained using Ergospace software (Ergospace, 2008). Hence, obtained results are approximate only. Our study is based on these data.

Petri nets (Barger et al., 2009, Nguyen et al., 2013, Trowitzsch & Zimmermann, 2006, Zimmermann & Hommel, 2005), and statecharts or state machines (Hermanns et al., 2005, Qiu et al., 2014, Trowitzsch & Zimmermann, 2006, Zimmermann & Hommel, 2005) are often used in dependability or safety analysis of ERTMS systems. The examples of other modelling languages used in dependability or safety analysis are fault trees and Bayesian networks (Flammini et al., 2006).

In papers (Hermanns et al., 2005, Nguyen et al., 2013, Qiu et al., 2014, Trowitzsch & Zimmermann, 2006, Zimmermann & Hommel, 2005), in order to solve dependability or safety problems, simulation experiments are performed or linear equation systems are solved.

The analytical estimation of the probability of stopping as a function of distance between subsequent trains is subject of this paper. This estimation is expressed by simple formula.

Analytic solutions and estimations seems to be valuable research direction in dependability studies of transport systems. This is a complementing approach to Petri net based, or Monte-Carlo simulation. For instance, in paper (Kowalski et al., 2014), exact and approximation methods for dependability assessment of tram system with spare trams and repair under time window constraint have been presented.

Structure of the paper is as follows. Dependability features of GNSS and ECS based train localisation unit (Nguyen et al., 2013) are recalled in Section 2. Communication and operation for ERTMS 3 is given in next section. Analytic estimation of the probability that a train is stopped after emergency braking is presented in Section 4. In this section, train localisation error given in meters is taken into account. An integration of a result given in (Nguyen et al., 2013) and the estimation is given in Section 5. In this section, more dependability aspects of train localisation than in previous section are considered. Finally, there are conclusions.

2 GNSS AND ECS BASED TRAIN POSITION LOCALIZATION

In ERTMS level 3, train position localisation is GNSS based. However, GNSS's do not satisfies safety-related railway requirements. Even GNSS supported by inertial navigation systems do not meet these requirements. Hence, data fusion options of GNSS and other sensors signals is interesting field of studies. In papers (Acharya et al., 2011, Nguyen et al., 2013), integration of GNSS and ECS signals is considered. This section is based on paper (Nguyen et al., 2013).

When analysing dependability of train localisation unit, the following cases can be considered:

Case A—unavailable output of GNSS and EDS signals fusion based component, i.e. localisation service is interrupted.
Case B—untrustworthy position, i.e. the position result has a large estimated confidence interval. Localisation information is delivered, however, it cannot be used safety critical train control.
Case C—estimated position is outside accuracy limits. Localisation service is failed but it is not recognized by the system or by the user.

Train position localisation service availability for single GNSS unit, ECS and GNSS unit, respectively, have been presented in (Beugin & Marais, 2012, Nguyen et al., 2013). The results for GNSS localisation service have been obtained using Ergospace software (Ergospace, 2008). Hence, obtained results are approximate only.

For each case, the following causes (Nguyen et al., 2013) are considered:

Case A—Fusion component failure,
Case B—Missing GNSS during 60 s, Missing ECS & GNSS during 3 s,
Case C—Failed ECS & two consecutive GNSS position errors greater than 50 m, six consecutive GNSS position errors greater than 50 m.

Failure rates for the following hardware components:

GNSS antenna,
GNSS receiver,
ECS device,
fusion component,

have been the input parameters for calculating the probability of service failure.

Failed components are repaired.

Software error in the fusion component has not been taken into account in calculation of dependability.

The research has been done for four environments:

– urban,
– tunnel,

– woody,
– railway cutting.

Now, we recall two interesting results (Nguyen et al., 2013).

In woody environment, the more than six consecutive GNSS position errors greater than 50 m with occurrence probability of $7.59E^{-2}$ is the critical event which leads to the global service failure.

In tunnel environment, the occurrence probability of this factor is reduced and is non significant while the missing GNSS data for more than 60 s with its occurrence probability of $1.53E^{-2}$ is the main cause of the service failure.

In present paper, the results for tunnel environment will be applied.

3 GSM-R COMMUNICATION AND OPERATION FOR ERTMS LEVEL 3

We analyse the same scenario of two trains following one of the other on the same rail, as the authors of the papers (Trowitzsch & Zimmermann, 2006, Zimmermann & Hommel, 2005), see Figure 1. The first train automatically checks its integrity and determines its position. The goal of checking the train integrity is e.g. to identify the case when a part of train carriages are lost from the main train. This task, together with the preparing of the *status message*, takes the time of 5 s. Next, the worked up status message is sent through the GSM-R module to the nearest RBC. Due to the possible transmission errors, the message can be incorrect with the probability of 1,88%. The successful transmission takes the exponentially distributed random time with the mean value of 450 ms. Next, the RBC prepares the *authority message* for the succeeding train. This task is 500 ms long and after it the prepared message is sent using the GSM-R module again (with the same error rate and transmission time as in the previous case). The following train waits for the consequent messages. If the message lacks to come for the long time, the situation becomes hazardous and due to this fact the emergency braking procedure is initiated. After the emergency stop the train is immobilized for the exponential random time with mean value of 15 min (900 s).

The deadline used for waiting for the authority message is calculated as the value which ensures the safe stopping of the second train in the case

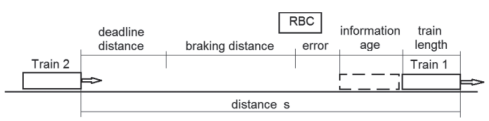

Figure 1. Distances used in eq. (1).

when the first one stops (or lost its integrity) immediately after sending the message that the second train received previously. The deadline is determined from the following equation, (Fig. 1):

$$d = \frac{s - l}{v} - a \tag{1}$$

where s is the initial distance from the head of the first train to the head of the second one, l is the sum of the train length, safety margin, the braking distance and the measured position error, and is assumed as 3000 m, v is the speed of trains—300 km/h (83 m/s), a is the information age assumed as 5 s or 9 s in the future investigations.

4 ANALYTIC ESTIMATION FOR GSM-R COMMUNICATION AND OPERATION

First, analytic estimate from paper (Babczynski & Magott, 2014) will be recalled. The derivation of the estimate in present paper is changed when comparing with the derivation from the above paper. Then an improvement of this estimate will be given.

Position/integrity package is generated by *Train* 1 (Fig. 1) each 5 s. This time will be denoted by p. Let us consider time intervals of length d, where d has been defined in previous section by expression (1). For *Train* 1 this interval is started immediately after sending the last package, while for *Train* 2—after receiving the last package. The number of the packages generated during the interval, without the package which initiates the interval, for *Train* 1 is

$$n = \mathrm{int}(d/p) \tag{2}$$

where int(x) is the integer part of x. If packages are not lost then the number of packages that are sent by *Train* 1 is equal the mean number of packages that are received by *Train* 2.

Property
The mean number of packages that should arrive *Train* 2 in time interval of length d is equal to the mean number of packages that are sent by *Train* 1 in time interval of length d, provided observation interval length is going to infinity.

Let the probability that package transmission from *Train* 1 to the RBC is incorrect be q. In considered example $q = 1.88\%$. Let the probability that package transmission from the RBC to *Train* 2 is incorrect be the same. Package transmission from *Train* 1 to *Train* 2 is incorrect in three cases:

– the package transmission from *Train* 1 to the RBC is incorrect, while the package transmission from the RBC to *Train* 2 is correct,

– the package transmission from *Train* 1 to the RBC is correct, while the package transmission from the RBC to *Train* 2 is incorrect,
– the above both transmissions are incorrect.

Hence, the probability that the package transmission from *Train* 1 to the RBC is incorrect or that the package transmission from the RBC to *Train* 2 is incorrect is equal to:

$$Q = q(1-q) + (1-q)q + q^2 = 2q - q^2 \tag{3}$$

It is the probability of incorrect transmission from *Train* 1 to *Train* 2.

The probability that each of n packages that are sent in time interval d are incorrectly transmitted is $E = Q^n$. It is probability for a train being stopped because of waiting time for the correct package is at least equal to the deadline d.

One is interested in probability of occurrence of the train being stopped event in one year (1 year) period. For one train, the number of package transmissions between *Train* 1 and *Train* 2 in 1 year is

$$k = \frac{1\,\text{year}}{p} \tag{4}$$

Mean number of occurrences of the train being stopped event in the interval is

$$S = Q^n \cdot k \tag{5}$$

Let st be the mean stopping time for one stopping. In our example $st = 900$ s. Mean time of total stopping time in 1 year is

$$T = st \cdot S \tag{6}$$

The estimate of probability that a train is stopped is given by:

$$PS = T/1\,\text{year} \tag{7}$$

Therefore, after transformations the probability estimate that *Train* 2 is stopped is:

$$PS = st \cdot \frac{Q^n}{p} \tag{8}$$

Accuracy of this estimate is illustrated in Figure 2.

Now, an improvement of the estimate will be given.

Let sp_i be a package which is sent from *Train* 1. Then it is processed by the RBC, and finally, the RBC sends packet rp_i to *Train* 2.

Package transmission times from *Train* 1 to RBC and from RBC to *Train* 2 are given by the same

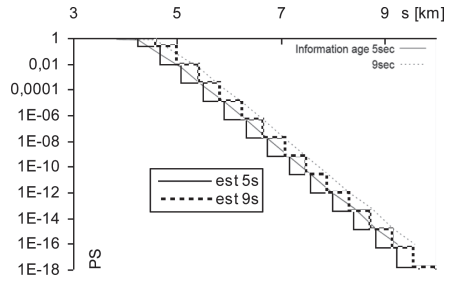

Figure 2. Estimation results (stair shape lines) (Babczynski & Magott, 2014) on the background of the chart from (Trowitzsch & Zimmermann, 2006) (smooth lines).

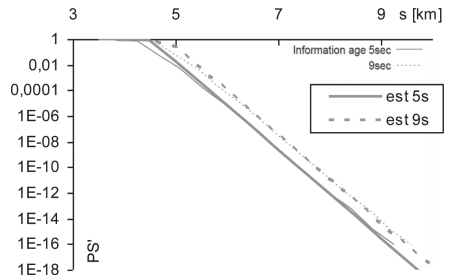

Figure 3. Results of the improved estimate of probability that *Train* 2 is stopped as a function of distance between trains (thicker lines) on the background of the chart from (Trowitzsch & Zimmermann, 2006).

exponential random variable. Hence, transmission time can be much longer than the mean value of the random variable. Let package sp_i, rp_i, respectively, be the one that opens sending, receiving, interval of length d at *Train* 1, *Train* 2, side. Some packages that are sent from *Train* 1 in the sending interval cannot reach *Train* 2 in the receiving interval. Formula of new estimate is adapted to results contained in (Trowitzsch & Zimmermann, 2006). The estimate of mean number of such packages received by *Train* 2 in the receiving interval that have been sent in the sending interval are

$$m = \max\left\{0, \frac{d}{p} - 1\right\} \tag{9}$$

New probability estimate that *Train* 2 is stopped is:

$$PS' = \min\left\{1, st \cdot \frac{Q^m}{p}\right\} \tag{10}$$

Quality of the improved estimate is illustrated by Figure 3.

Accuracy of the estimation is very good for the considered case. However, verification for wider range of parameter values is required.

5 PROBABILITY OF STOPPING AS A FUNCTION OF DISTANCE BETWEEN SUBSEQUENT TRAINS IN TUNNEL

According to approximate results contained in paper (Nguyen et al., 2013), in tunnel environment, Case A and Case B, given in Section 2 are significant factors. For each case, the contribution of them (probability) is as follows (Nguyen et al., 2013):

- Case A—Fusion component failure—$3.42E^{-6}$,
- Case B—Missing GNSS during 60 s—$1.53E^{-2}$, Missing ECS & GNSS during 3 s—$6.63E^{-7}$,
- Case C—Failed ECS & two consecutive GNSS position errors greater than 50 m—0, six consecutive GNSS position errors greater than 50 m—0.

For cases A and B, train localisation service is unavailable at *Train* 1 side.

Train localisation information is unavailable at *Train* 2 side when:

- train localisation service is unavailable at *Train* 1 side,
- the package transmission from *Train* 1 through the RBC to *Train* 2 is incorrect.

Let r be the probability that train localisation service is unavailable at *Train* 1 side. In the considered tunnel environment, $r = 1.53E^{-2}$.

The probability that train localisation information is unavailable at *Train* 2 side is:

$$R = r + (1 - r)Q. \tag{11}$$

Hence, probability estimate that *Train* 2 is stopped is:

$$PS'' = \min\left\{1, st \cdot \frac{R^m}{p}\right\} \tag{12}$$

In Section 3, according to (Zimmermann & Hommel, 2005) it has been supposed that train position localisation error is 20 m. Now, for tunnel environment and GNSS plus ECS localisation unit, it is assumed that maximal value of this error, provided the localisation information is delivered, is 200 m. The other parameters are such as in Sections 3, 4.

The probability estimate of stopping, when dependability of train localisation service and GSM-R are taken into account, as a function of distance between subsequent trains is given by Figure 4.

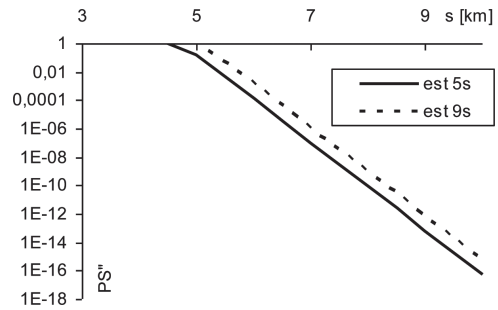

Figure 4. Results of the estimate of probability that *Train* 2 is stopped in a tunnel environment as a function of distance between trains.

6 CONCLUSIONS

New analytic estimation of probability of train stopping as a function of distance between subsequent trains has been given. Computation cost of this estimate is very small. The estimation has been verified against results obtained for GSM-R communication and operation in ERTMS level 3 using simulation approach supported by rare event analysis (Trowitzsch & Zimmermann, 2006, Zimmermann & Hommel, 2005). Standard Monte-Carlo simulation is not sufficient because of computational cost. Accuracy of the estimation is very good for the considered case. However, verification for wider extent of parameter values is required.

Then the estimation has been applied for calculating the probability of train stopping as a function of distance between subsequent trains when dependability of GNSS plus ECS train localisation unit, and GSM-R communication have been taken into account. The studies have been done for tunnel environment. Because of lack of real data, approximate dependability information (Nguyen et al., 2013) has been used. This information (Nguyen et al., 2013) has been obtained using simulation.

The research is stimulated by real life ERTMS level 3. Farther analysis for real life data is planned.

Streamlining architectures for integrated safety analysis using Design Structure Matrices (DSMs)

Kai Höfig & Joe Zhensheng Guo
Siemens AG, Corporate Technology, München, Germany

Amir Kazeminia
TRW Automotive GmbH, Krefeld, Germany

ABSTRACT: A popular trend to handle safety analysis of complex software intensive embedded systems is integrated model-based safety analysis. Well accepted safety engineering approaches like fault trees are shifted to the level of model-driven development by integrating safety models into functional development models. On the one hand this provides benefits for consistency and traceability, on the other hand the selection of appropriate model elements or level of hierarchies for such an integration is a new task to be tackled. Especially for fault tree-based approaches the existence of loops or cyclic dependencies in development models can be problematic since loops cannot be a part of a Boolean model. To prevent such loops in safety analysis models, we show how Design Structure Matrices (DSMs) can be used to cluster architecture elements with loops or with cyclic dependencies. Using this, we assume that small adjustments in the architecture model provide vast improvements when modeling a seamless integrated safety analysis model.

1 INTRODUCTION

Modern safety critical embedded systems tend to increased complexity. To handle this complexity, model-based approaches are introduced in industrial applications and even covered within standards, e.g. ISO26262 for the automotive domain (ISO26262 2009) or DO178C for airborne systems (DO-178C 2012). A popular trend for a safety analysis of such systems is to combine safety analysis models and system development models. Examples for such model-based safety analysis approaches can be found in (Rugina 2005, Fenelon & McDermid 1992, Chen, Johansson, Lnn, Papadopoulos, Sandberg, Trner, & Trngren 2009, Kaiser, Liggesmeyer, & Mäckel 2003). These widely accepted safety engineering approaches shift the task of failure logic modeling to the layer of model-driven development. They integrate or at least relate safety analysis models to elements of functional system development models. This is beneficial for the consistency and also the traceability between safety engineering- and system development models.

Some system modeling approaches such as SysML use ports and connections to model dependencies or a flow of information or goods from one component to another. In such models, loops or cyclic dependencies are unproblematic, but they mislead us to transfer such loops from the development model to the safety analysis model. Even though loops in safety analysis models can be broken up automatically, e.g. for Boolean structures as described in (Domis & Trapp 2008), this leads to confusing and hard to read safety analysis models.

This problem is addressed in this paper by re-clustering components of system development models in a way that do not contain loops. Design Structuring Matrices (DSMs) are used here to minimize the changes in system development models and also to identify such loops. Using this approach, we assume that small changes in the architecture model provide vast improvements when modeling a seamless integrated safety analysis model.

The rest of the paper is structured as follows: first, section 2 summarizes related work. In section 3, an example system is introduced to illustrate the problem of loops for integrated safety analysis models. In section 4, DSMs are used to overcome this problem by re-clustering the component hierarchy. Section 5 summarizes this paper and provides a perspective for future work.

2 RELATED WORK

Fault tree analysis is one of the major applications for Boolean models in safety analysis. Loops in such models lead to events that are caused by itself. For

analysis, they have to be removed from the model in order to solve this illogical dependency. Other models that are used for safety assessment allow loops, for example Markov chains or Petri nets (Reisig 1985, Häggström 2007), but such models are compared to fault trees less intuitive and therefore only used if more advanced logic is required.

Approaches that generate fault trees deal with the problem of loops and how to prevent them. E.g. in (Liggesmeyer & Mäckel 2000), fault trees are generated from electric design plans and a hierarchical abstraction approach is used to prevent the generation of loops. In (Papadopoulos & Maruhn 2001) fault trees are generated for Matlab models and also in (Iverson 1992), fault tree structures are generated. Digraph models are converted and valid loop free fault trees are generated. In (Banach & Bozzano 2006) fault tree structures are generated for large systems that also can contain loops and in (Rae & Lindsay 2004) fault trees are generated over different hierarchy levels and with various cycles in the system development model. In (Papadopoulos & McDermid 1999) failure propagation information is also modeled along with the information flow of components and over different levels of hierarchy. Fault tree information can be extracted from these models. Nevertheless, automatically generated fault trees require precise information about failures and their propagation or are only able to generate fault trees for specific applications.

Other approaches deal with the problem of automatically removing existing loops in fault trees. In (Ciarambino, di Torino, Contini, Demichela, & Piccinini 2002), syntax rules are used to identify and remove loops. In (Domis & Trapp 2008) Boolean structures are analyzed and loops are removed from the safety analysis model. However, these type of approaches require prior recognition by the analyst of the initiation of a loop. To enable automations for fault tree structures that do not require interactions with analysts, the prevention of loops during the design phase is most beneficial. Therefore, in the following sections a methodology is presented that prevent the modeling of loops by restructuring elements of system development models.

3 PROBLEM DESCRIPTION

Boolean safety analysis models that are highly integrated into the architecture models of a safety-critical system easily lead to model loops. Figure 1 shows a SysML Internal Block Diagram (IBD) of a small open-loop example system and the corresponding Boolean safety analysis model. On top of that figure, the model elements marked as *blocks* represent the components of the system. Here, a sensor component evaluates a sensor value and provides the signal to the component *Processing 1*. The component *Processing 2* is interacting with *Processing 1* until a result is calculated that is forwarded to a actuator. A watchdog component monitors the time the processing components requires for calculating a command. If a time line is exceeded, the watchdog sets the actuator in a safe state. This model contains a cyclic dependency. Component *Processing 1* awaits input from *Processing 2* and vice versa. This is unproblematic in this model but easily can mislead to a loop in the corresponding safety analysis model.

In the lower part of figure 1, Component Fault Trees (CFTs) are used as a safety analysis model using Boolean logic (Kaiser, Liggesmeyer, & Mäckel 2003). CFTs are an extension to classic fault trees using additionally elements from the development model, such as components, ports and interconnections. They are integrated into the model of a safety-critical system in order to model the failure logic separately for each component. A failure propagates from one component to another following the ports

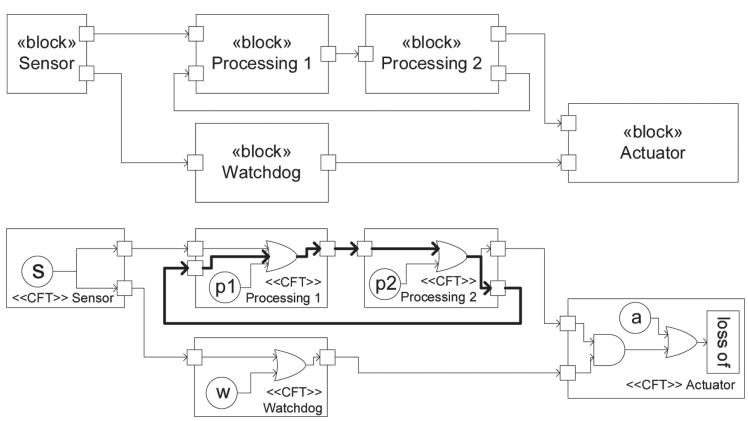

Figure 1. Two views on an example system: interacting blocks and corresponding component integrated fault trees (C^2FTs).

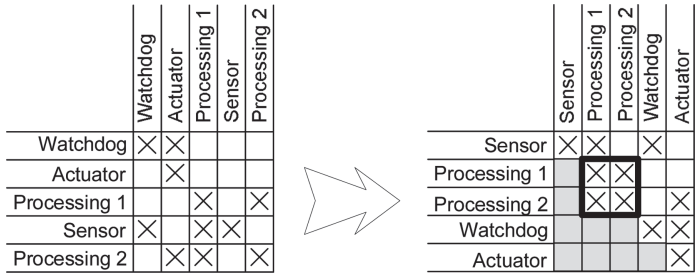

Figure 2. DSM for the example system (left matrix) and DSM after the sequencing algorithm (right matrix).

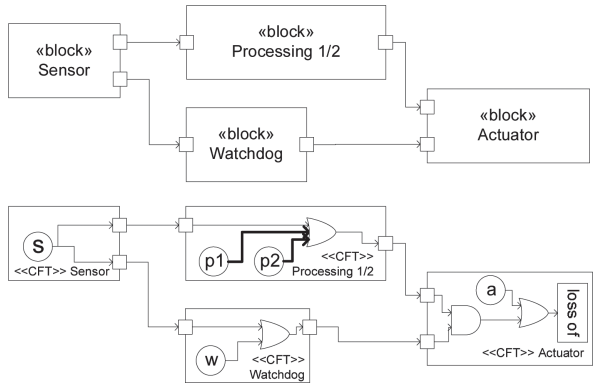

Figure 3. Example system after applying the sequencing algorithm: interacting blocks and corresponding Component Fault Trees (CFTs).

and the connections between the ports. For example, the component *watchdog* gets a signal from the sensor component and provides a signal to the actuator. The command provided to the actuator is either erroneous if the input is erroneous or if the watchdog itself contains an internal error (basic event *W* and *OR*-gate within the watchdog CFT). CFTs can contain multiple failure modes, but in this example only the failure mode *erroneous* is investigated.

If such Boolean structures are part of safety-critical systems, the architecture models can contain loops or cyclic dependencies. Such loops are unproblematic in system development models, but are prohibited in Boolean models. An example for a loop within the development model can be found in figure 1 for *Processing 1* and *Processing 2* as described earlier. If these components are developed by different teams, such a Boolean loop can easily be transferred to the safety analysis model. An example for this loop is marked by the thick black line in the safety analysis model in the lower part of figure 1. The output failure mode modeling the occurrence of an erroneous signal as an output for component *Processing 2* is cyclic. The example system is comparatively small and only contains a single failure mode, but for larger structures, many people involved in a development process and multiple failure modes, such loops can be of various complexity and have to be removed from Boolean safety analysis models such as fault trees.

In the following section, design structuring matrices are used in combination with a sequencing algorithm to prevent such loops or cyclic dependencies in component-based safety analysis models such as component fault trees.

4 USING DSMS FOR INTEGRATED SAFETY ANALYSIS

A Design Structure Matrix (DSM) represents dependencies among various items that can be processes, products, components or organizations (Browning 2001). The corresponding DSM for the example system as illustrated in figure 1 is depicted in figure 2 on the left side. Each component has a row and a column in the DSM. All components depend on themselves and so the diagonal of the matrix is crossed. The rows show provisions, e.g., the row *Sensor* shows that the sensor component sends signals to the components *Watchdog* and *Processing 1*. The columns of the DSM show dependencies, e.g., the column *Actuator* shows that the actuator component receives signals from the *Watchdog* component and the *Processing 2* component.

Using these relations within the DSM, the matrix can be *sequenced* to identify dependency loops as described in (Warfield 1973). This sequencing algorithm helps to identify loops and if found, identify components that can be merged to remove such loops or cyclic dependencies. The result of this algorithm can be seen in figure 2 on the right side. Here, all dependencies are in the right upper part of the matrix. In the left lower part (grey area) is only one dependency between *Processing 1* and *Processing 2*. Without this cross mark, the matrix would be *upper triangular*, what means that there are no loops in the development model. So, if the components *Processing 1* and *Processing 2* are encapsulated within one component, the dependencies between the components of the example system are free of loops and modeling loops in component fault trees is prevented.

Figure 3 shows the system with the encapsulation of the components *Processing 1* and *Processing 2* into one component *Processing 1/2*. As we can see in the CFT model for this encapsulated architecture, all connections between the ports of the model are straightforward and do not form loops. So, it is impossible to erroneously model loops in the safety analysis model even if the components and their component fault trees are modeled by different teams. The DSM can help to identify such loops in the architecture and to identify the corresponding components to be encapsulated for safety analysis.

5 CONCLUSION AND FUTURE WORK

In this paper, a methodology is presented that restructures system development models in order to prevent loops in fault trees using Design Structuring Matrices (DSMs). The assumption is, that small adjustments in the architecture model provide vast improvements when modeling a seamless integrated safety analysis model. Nevertheless, large systems can contain a lot of loops, what would require vast changes of the development model. Also large loops over entire architectures may result in one large component when this methodology is applied. In our future work, the approach needs to be evaluated for larger systems since the current evaluation of the methodology is only based on a small exemplary system. Even if restructuring the system development model is impossible, the DSM approach can help to identify clusters of components where loops can be expected. This can help to improve the process of modeling fault trees and gives hints where development teams for different components need frequent balancing.

The Markov reliability and safety model of the railway transportation system

F.J. Restel
Wroclaw University of Technology, Wroclaw, Poland

ABSTRACT: In this paper, the author's research work is focused on modeling of railway transportation system's reliability and safety. The paper begins with an introduction related to a literature review on railway transportation system functionality, reliability and safety modeling. The set of states can be divided into two subsets: availability set and failure set of states. Defining states in terms of railway transportation system is a complex issue, therefore the state classification into availability an failure is not sufficient. In addition to the technical effects associated with incorrect operation of system components, traffic consequences (traffic disruptions) of events are important, especially in case of railway transportation system. The Markov model was built is described in relation to the parameters above. The paper ends with validation of the model, conclusions of the analysis, dealing with applicability of the model to solve problems for the real system and a summary with prospects for further research.

1 INTRODUCTION

Transport systems are fundamental for the functioning of economy and play important social roles. Because of the far-reaching (social, economic, country defense) effects of disruptions in the operation of these systems they are classified as critical infra-structure systems (Murray & Grubesic 2007).

The task of transport systems is movement of goods and passengers from one place to another. The importance of transport systems increases with rising mobility of the population. Economic development entails the needs to improve transport services. Passengers expect interconnected routes, with minimum travel and waiting times. On the other hand, recipients of goods, in order to effectively compete in the market, engage in optimizing activities which lead to the use of the Just-in-Time and Time Window technologies (Akbalik & Penz 2011, T'kindt 2011), etc. It is clear that a well-functioning transport system should meet the requirements for logistics systems in the form of the 7R formula (Right product, Right quantity, Right quality, Right place, Right time, Right customer, Right price) (Nowakowski 2011). A transport system functioning in a reliable way is therefore characterized by:

- availability of appropriate (planned) products in the transportation offer,
- proper number of executed transportation tasks
- proper quality of execution of transportation tasks (safety of passengers and cargo),
- the right place of destination, according to a timetable (including transportation routes),
- appropriate lead time (punctuality),
- appropriate recipients,
- appropriate price (according to rates established in the plan of the transportation by carriers).

2 LITERATURE REVIEW

2.1 *System models*

An important aspect of railway practice are issues related to determining the state of the infrastructure and linking this state with measures to improve safety (Auer & Schlöpp 2012). In this approach, an alternative to technical maintenance are train speed limits.

Both the choice of when to introduce speed limits and execution of technical maintenance entail costs. An important group of studies are analyses of life cycle costs of vehicles or infrastructure (Marschnig & Veit 2012).

In (Enzi 2012, Hansemann & Marschnig 2012) decision models for finding the time for technical maintenance of infrastructure at minimum total cost have been developed.

Another group of works on railway issues refers to dispatch activities at the time of disruption. One approach is to regulate the speed of trains in order to minimize unscheduled stays (especially felt by the passengers) and reduce energy consumption (Ding 2011). This approach does not propose any structural changes in the executed process, only

changes in the process parameters (e.g., reduction of speeds of trains which are in conflict with a delayed train). Broadly speaking, these are issues related to the reorganization of the traffic after the occurrence of disruptions whose aim is to minimize further propagation of disruptions (Caimi et al. 2012, Törnquist & Persson 2007, Törnquist Krasemann 2012).

Lin (2008) have applied Markov processes to the study of aggregation of trains in a selected portion of the rail network. Wendler (2007) uses a semi-Markov model to determine time intervals between trains of different speeds.

Kroon & Huisman (2011) proposed a model for supporting management of disrupted rail traffic. The model is based on the costs of reorganization of train traffic or cancellation of trains in the context of railroad workers (train drivers and train traffic service). What is more, Acuna-Agost et al. (2011) presents a model for supporting a decision making process while managing disrupted train traffic.

2.2 *Reliability models*

Initially, reliability studies in the rail industry focused on vehicles. Already in 1979 the need to study failures of traction motors in electric vehicles has been indicated (Plewako 1979).

In addition to research on mathematical models, operational data analyses on damage have been carried. These works has been narrowed to statistical analysis and inference made on its basis (Banek et al. 1978, Marciniak 1988, Pustelnik & Świderski 1968, Roman 1972).

Vromans (2005) narrows down the concept of reliability of rail transportation system to punctuality. Only delays are taken into consideration. The author identifies potential causes of disruptions, however, he assumes that temporary disruptions have one common source. The work focuses on max-plus algebra used to evaluation of timetables (Goverde 2007, Goverde 2010), in the context of time reserves.

Chen (2003) has presented a model of rail service reliability and a model of punctuality. The model of rail service reliability consists of three parts:

– reliability of technical objects constituting the system (independence of events occurring in subsystems has been assumed),
– interactions between the rolling stock subsystem and other subsystems,
– intensity of traffic restoration after a break due to an adverse event.

In modeling the reliability of technical systems an important role is played by models based on graphs of states-transitions. The basic mathematical tools used to describe such models are (Lisnianski et al. 2010) Markov processes and Semi-Markov processes (Kierzkowski 2010, Kierzkowski & Zając 2012).

Chandra & Kumar (1997) consider the analysis of reliability and safety of elements of train traffic control devices in terms of safe errors. The study focuses on the analysis of the reliability and safety of the junction with special computing microcomputers, called transputers. For this purpose, a nine-state Markov model has been developed.

Colini et al. (2010) have presented a Markov model of reliability of tram systems. Six possible states of reliability have been adopted for the vehicles.

A frequent subject of research is a separated element of the rail transport system. An example might be the analyses of technical objects included in the infrastructure. Krenželok et al. (2010) have developed a 40-state model of reliability and safety of rail-road transit security devices.

Transit devices, similar to rail traffic control devices work periodically during the transit of a train, and in the rest of the time they are in the so-called stand-by mode. The authors have recognized the problem of determining the time between events, and linking it with real time. In addition to the intensity of damage and repairs, the intensity of damage detection, which is the inverse of the time between inspections, have been included in the model. The first model have been simplified to 21 states.

Dolven et al. (2004) have applied Markov chains for modeling rail track, taking into consideration sudden damage and damage resulting from the technical condition of the track.

2.3 *Safety models*

Schwartz (2010) have presented a method for the identification of barriers on the basis of a fault tree. The method is based on the so-called Swiss Cheese model, in which holes must overlap so that the arrow may go through (so that safety fallibility occurs). The situation of risk, which is the peak event, is modeled by a classic fault tree with AND and OR gates.

In analyzes of risk of adverse events event tree or fault tree may be used for the case of the railway system. In (Albrechtsen & Hokstad 2003) this kind of analysis has been extended to include the risk influencing factors. The issue has been shown on the example of a single-track line, for which the peak event is the collision of two trains coming from the opposite directions. An analysis of the factors affecting the risk shows the relationships and sequences of cause and effect going beyond a simple event tree analysis. In the studies case it

has been shown that the most important factors influencing risk are: human behavior and operating conditions of the system.

The (de Boer et al. 2003a, b, Renpenning 2004) studies raise issues of safety engineering in the design of rail transport systems. The articles relate to issues of implementation of the ERTMS (European Rail Traffic Management System), which in its structure contains also a unified European GSM-Rail. The issue of security in the implementation of ERTMS is all the more important given the lack of operating experience of such a system in conditions corresponding to implementation (for the Dutch railways in 2003). The basis of considerations (de Boer et al. 2003a) is identification of hazards to the case of the implemented system. The authors propose a parallel application of three methods, concluding together in the list of hazards. The first method, namely Design based structured hazard identification, consists in inventorying risks on the basis of possible damage to the system being designed. The second method is the traditional HazOp (Hazard and Operability Analysis). The third method (hazard transfer) consists of the acquisition of already identified threats (or components of similar systems) for the purposes of the studied case. In (de Boer et al. 2003b) the works have been summarized, approximating the components of risk analysis for the rail system (ERTMS) whose design has just been started. In this aspect, the use of the two following approaches is suggested: ALARP and GAMAB. ALARP (the risk must be As Low As Reasonably practicable) aims to demonstrate that everything has been done to achieve a higher level of security than before. The approach called GAMAB (Globalement Au Moins Aussi Bon) is supposed to show that the level of security of a new system is at least equal to an old system. In both approaches the following steps are implemented: hazard identification, casual analysis (tree events with defining of the occurrence frequency), impact analysis (tree of effects), and analysis of losses. Depending on the possibilities of comparing the old system to the new one the next steps may, but need not, concern the GAMAB approach: option analysis and an analysis of the impact on the risk. To assess the safety of the ETCS system, which is a slightly simplified variant of ERTMS, the method of Functional Hazard Assessment has been proposed in (Renpenning et al. 2003).

An important aspect in the safety analysis is determining Safety Integrity Levels. The draft of a European standard (EN50129) uses a simplified SIL table for the case of devices controlling rail, communications, data processing and electronic system traffics which significantly affect the safety of rail transport.

In (Cremonini 2003) a risk assessment has been carried out in the transportation of dangerous goods by using events/vehicle kilometers as a measure of the intensity of event occurrence. According to the adopted approach the frequency of events associated with the transport of dangerous goods is determined as the product of the intensity of occurrence of all events on a homogeneous network segment (events/vehicle kilometers) and intensity of traffic of vehicles carrying dangerous substances on this segment (vehicles/year).

2.4 *Summary of literature review*

The studied models were analyzed in terms of considered essential features for the rail transport system. A collection of these features has been created based on the research on the state of knowledge in scientific publications and knowledge of railway industry experts. Consequently the following features have been focused on:

- intensity of use of the system,
- traffic dependence of trains,
- infrastructure failures,
- rolling stock failures,
- disrupted implementation of the transport process (delays and track changes),
- improper use of the system,
- human factors,
- hazards and safety failures,
- process leading to loss of safety.

The possibility of occurrence of unwanted events and the spread of effects depends on the intensity of use of the system, expressed as operational work (Restel 2012a, b) or transportation work (Bałuch 1980, Potthoff 1964). Performed transportation work directly affects the intensity of the train traffic. The increase in train traffic causes the increases in the number of situations in which trains are interdependent as far as their movement is concerned. This means that in the event of a disruption to a single train, the dependent trains will be disrupted as well. Thus, we can see that these two features are connected with each other.

Disrupted implementation of the transport process is defined as the operation of the train traffic not in accordance with the established timetable while improper use of the system means situations in which there are single errors of the system, but nevertheless the train traffic is conducted. Often, conducting traffic in such a situation takes place without traffic control devices (for account of the traffic orderly and the train driver). The human factor means the possibility of an accident due to the fault of a person.

3 RELIABILITY AND SAFETY MODEL

For the developed model, assumptions associated with the system whose reliability and security can be modeled have been made. This model was developed in its present form for the rail transport system which consists of a railway line between the two junction stations, that is a fragment of the system in which it is possible to move the trains only in two directions. So it is not possible that trains outside the start and end of the line will appear or disappear.

Furthermore, it has been assumed that the lines converging at junction stations located at the interface of the system do not affect each other in terms of disruptions.

3.1 *Defining of states*

Functional model of the rail transportation system can be presented as a process described by a set of S states (Gołąbek et al. 1993, Birolini 2010), which is divided into a definite number of subsets. The most often distinguished subsets are a fault subset and a success subset (Grabski & Jaźwiński 2009, Ważyńska-Fiok & Jaźwiński 1990). Literature research and the study of operational data indicate inadequacy of this approach in the case of the rail transport system. In order to take account of the inventoried essential characteristics of the model, the description of the states in five dimensions has been adopted:

– events related to the success feature of the system,
– correctness of use,
– disruptions of the transportation process,
– traffic dependence of trains.
– type of unwanted event.

Interconnections between train traffic dependence of trains and train traffic intensity are shown in Table 1 The values shown are for illustration only, since the exact values should be determined individually for each railway line.

Table 1. Correlation between train traffic dependence and intensity of system using.

Traffic dependence	Traffic intensity on a single-track line (trains per hour)	Traffic intensity on a double-track line (trains per hour)
Lack of trains	0	0
Independent trains	x < 0,5	x < 1,2
Partially dependent trains	0,5 < x < 1,2	1,2 < x < 6,0
Dependent trains	x > 1,2	x > 6,0

The parameters of the system are partly dependent, which is the reason for the need to assess the states in terms of compatibility of features. The feature type of adverse event is dependent on the feature of the event related to capability. The features correct use, and disruptions of the transportation process depend on the feature movement dependence of trains (which also indicates the intensity of use). The dependence of features describing states does not affect the separate character of the defined states.

Taking account of the events related to the capability of the system in conjunction with the type of adverse events enables us to include fallibility of vehicles, fallibility of infrastructure and human error in the model. Proper use allows the replication of situations in which the system is operated despite of broken train traffic control devices.

By taking into account the correctness of use and disruptions to transportation process we can replicate emergency situations. Along with the movement dependence of trains it is possible to model the process leading to the fallibility of safety. In addition, movement dependence hides information on the intensity of use, which increases with the increase of participation of the trains that are dependent in terms of movement.

In connection with the adopted approach, the so-called super cube model has been developed and successfully used in the description of the safety parameters of the rail transport system (Harms-Ringdahl & Kecklund 2004).

Given the adopted way of defining the states in five dimensions, a list of all the theoretical 288 states have been drafted. Due to the relationships between the features defining the states it has

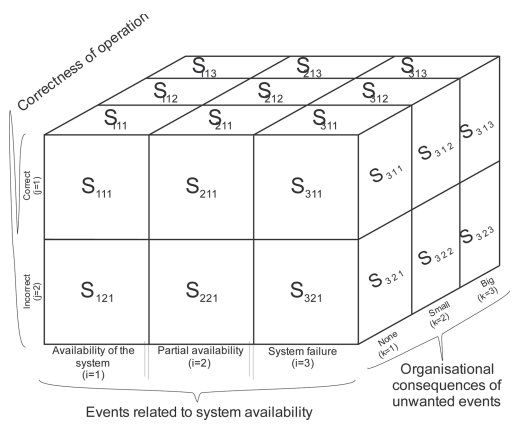

Figure 1. Three of five dimensions of the super cube used for state defining.

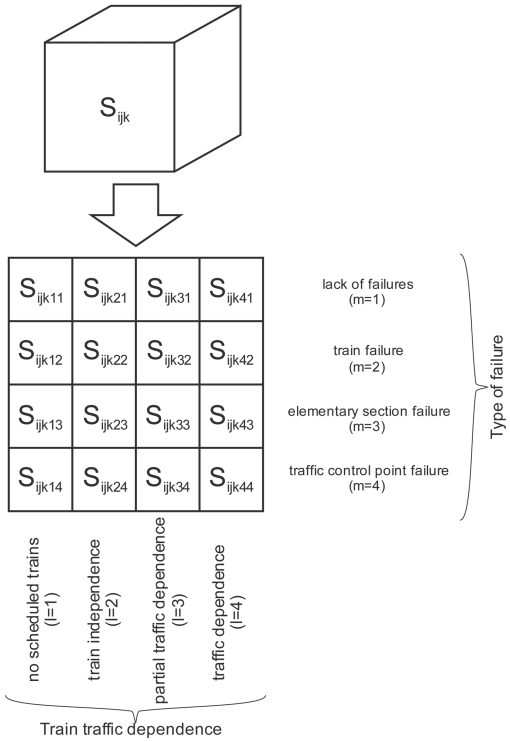

Figure 2. Remaining two dimensions of the state defining super cube.

been necessary to verify whether the features are not mutually exclusive.

In the first step the states with mutually exclusive feature values have been identified. Conflicts between the features leading to the removal of states have been of the following nature:

– lack of traffic and disruptions in traffic,
– successful system and a specific type of adverse event,
– etc.

3.2 *The Markov model*

After the first step of the selection, the operation process of the overall rail transport system has been divided into 83 separable states. These are the states that allow the modeling of each type of the rail transport system. In relation to the specific character of the varieties of the rail transport system, it is possible that some states will prove to be useless in a particular case.

The studies conducted have been based on the rail systems due to their complexity. Therefore, in the second step of the algorithm of the selection of states, these states which characterize the railway transportation systems (excluding metro and tram) have been chosen to the model.

The next step consisted in selecting the states which can be described using the collected operation data. In the last step three major fault states have been merged, thus obtaining:

– preventive maintenance of the entire system,
– accident,
– serious accident.

As a result of these proprietary operational studies the main 44 states have been determined for the model of railway transportation system reliability and safety which is being developed.

Starting from the separability of the states and the assumption that intensities of transitions between the states are independent of time, all the states which had been parallel to each other and had been characterized by transitions to and from the same states have been combined together. The action of combining have been applied to the states of partial faultiness. Intensities of transitions have been summarized after combining the particular states. A simplified model is composed of 29 states and 83 transitions. Finally the model consists of the following states:

– N1—the system is not used, but available,
– N2—the system is correctly used, with independent train traffic, without disruptions,
– N3—the system is correctly used, with partially dependent traffic, without disruptions,
– N4—the system is correctly used, with independent traffic and disruptions,
– N5—the system is correctly used, with partially dependent traffic and disruptions,
– N6—the system is not used and it is partially unavailable, because of maintenance, Train Failures (TF), Elementary Section Failures (ESF) or Traffic Control point Failures (TCF),
– N7—the system is correctly used, with independent traffic and it is partially unavailable, because of maintenance, ESF or TCF,
– N8—the system is correctly used, with independent traffic and it is partially unavailable, because TF,
– N9—the system is correctly used, with partially dependent traffic and it is partially unavailable, because of TF,
– N10—the system is correctly used, with partially dependent traffic and it is partially unavailable, because ESF or TCF,
– N11—the system is correctly used, with independent disrupted traffic and it is partially unavailable, because of maintenance or ESF,
– N12—the system is correctly used, with independent disrupted traffic and it is partially unavailable, because of TF or TCF,

– N13—the system is correctly used, with partially dependent disrupted traffic and it is partially unavailable, because of TF or TCF,
– N14—the system is correctly used, with partially dependent disrupted traffic and it is partially unavailable, because of ESF,
– N15—the system is unavailable because of preventive maintenance,
– N16—the system is unavailable because of an accident,
– N17—the system is unavailable because of serious accident,
– N18 to N29—the same as N2 to N5 and N7 to N14, but the system is incorrect used.

The states were linked with 83 transitions. For presentation the model was split into two layers—correct and incorrect using of the system.

The layer of correct use includes all states in which the system is operated in accordance with assumed procedures. The technical elements of the system are suitable to the extent which allows regulatory operation of the traffic. This means that the system will be in a state of capability even though the elements which are irrelevant to the reliable and safe operation of train traffic may be damaged.

The state of faultiness of the entire system, assigned to this layer, are related to preventive technical maintenance (N15) or accident (N16) due to accidental events (e.g. collision with a wheeled vehicle or being hit). The incident can also be caused by accidental critical damage to a technical element of the system. The state of faultiness due to an accident is a state of safety fallibility.

After a complete system fault, the restoration of capability takes place together with the transition to the state of readiness without train traffic (N1). It has been assumed that the faultiness of the system will disable traffic completely, and thus start-up of the system takes place from the state of no train traffic.

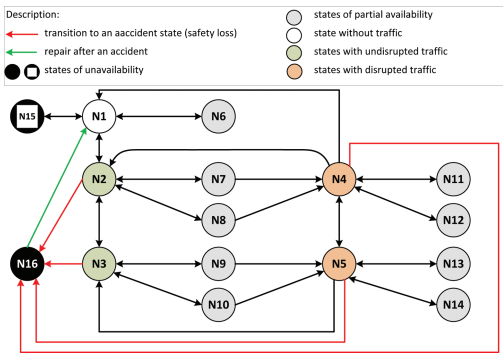

Figure 3. System correct using layer of the model.

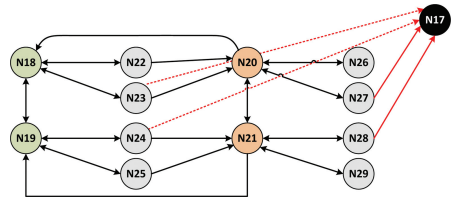

Figure 4. System incorrect using layer of the model.

The transition to a state of faultiness due to preventive technical maintenance (N15) is possible only from the state of traffic expectation, because these repair processes are planned in advance and included in the timetable (i.e., with prior zeroing of train traffic intensity).

It was assumed that the system at the time of partial faultiness (N6–N14 and N22–N29), due to the partial suspension of traffic, cannot significantly change traffic intensity, and therefore at a time of partial faultiness the change in movement dependence of trains must not happen.

Analysis of operating data from polish infrastructure manager has shown that on busy railway lines only 6% of adverse events occur before the end of the previous event. In the case of the less busy lines this phenomenon is less likely. On the lines under consideration no situation in which such impermanent damage occurred simultaneously in one minimum cross-section of faultiness has been noted. For this reason, it has been assumed that at one moment only one damage causing partial faultiness to the system can occur. The transition to a state of partial faultiness as a result of other damage is possible indirectly by one of the states of capability.

The occurrence of an incident as an accidental event is only possible from the states in which the system is capable and used for the execution of transportation tasks (N2–N5). This assumption is also based on the non-simultaneous occurrence of events. Therefore, the system cannot change the state from operating train traffic at partial faultiness to the state of faultiness (accident).

Disrupted traffic can occur only when traffic was previously conducted in the system and an adverse event occurred causing partial faultiness of the system. On the other hand, partial faultiness, as an adverse event does not necessarily disrupt train traffic.

As improper use of the system has been identified as a prerequisite of a major accident, major accidents have not been considered in this layer.

The second layer which consists of a model of reliability and safety of the rail transport system is a layer of improper use. It has been assumed that in this layer there are no states of capability and partial capability in anticipation of the transportation

tasks because the system cannot be improperly used when there is no train traffic (when it is not used).

The state of complete faultiness as a result of a serious accident (loss of security) has been assigned to this layer because improper use must take place to trigger the occurrence of the accident with catastrophic consequences. This has been identified in the chapter on an accident formation model. In the context of this layer the state of complete faultiness due to a serious accident is an absorbing state. However, when taking into account the transitions between the states of two layers it will not be an absorbing state, which is illustrated below. The transition to the state of complete faultiness of the system due to a serious accident is possible from four states:

– N23—partial faultiness of the system caused by damage/train error (in a situation of unhindered traffic, movement independent trains),
– N24—partial faultiness of the system caused by damage/train error (in a situation of unhindered traffic, partially movement dependent trains),
– N27—partial faultiness of the system caused by damage/train error (in a situation of disrupted traffic, movement independent trains); or partial faultiness of the system caused by damage/signal box error (in a situation of disrupted traffic, movement independent trains),
– N28—partial faultiness of the system caused by damage/train error (in a situation of disrupted traffic, partially movement dependent trains); or partial faultiness of the system caused by damage/signal box error (in a situation of disrupted traffic, partially movement dependent trains).

Determination of transitions to the state of a serious accident has been based on the assumption of necessary prior occurrence of a human error (a train driver's or traffic orderly's). States belonging to the layers of improper use of the system constitute a set of safety risk states. In contrast, the states of partial faultiness in this layer constitute states of a direct threat to safety (this applies to the states taking into account human errors).

Putting together the layers of correct and incorrect use results in complementing the model with transitions between these layers. It has been assumed that as a result of human decisions, it is possible to continue using the system, despite some technical or organizational constraints, which causes the transition from the state of partial faultiness of the layer of proper use to the corresponding state of partial faultiness of the layer of improper use. These transitions are the only path of changing the layer from proper to improper use.

Disappearance of the threat, or return to the layer of correct use is possible after restarting the system, that is through the state N1. The renewal of the system after a serious accident takes a similar form.

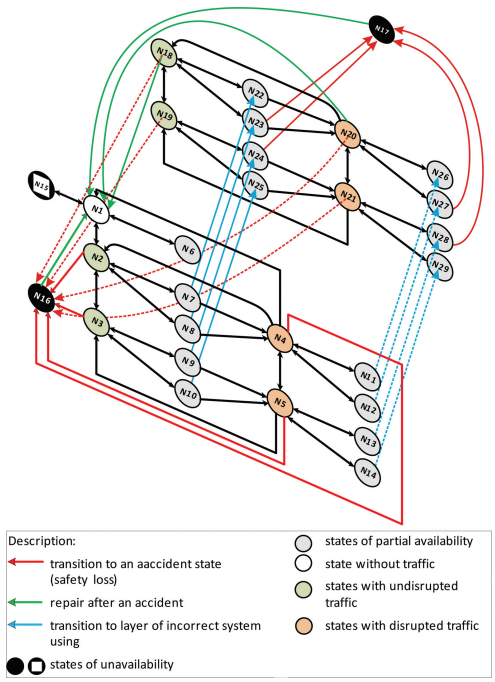

Figure 5. Complete Markov reliability and safety model.

Another path to return to proper use is through the loss of safety as a result of a random accident.

The developed model of has been mathematically described by a linear differential equation system with constant coefficients. It is therefore assumed that the probability of transitions between states is described by exponential distributions, and, consequently, the intensities of transitions between the states are independent of time. The system of forty-four Chapman-Kolmogorov differential equations have been prepared.

Simplifications related to merging of states have been introduced in the model to the process of verification.

3.3 *Model validation*

After the reduction of the number of states for the purposes of validation, a simplified model for the GRIF computing environment have been introduced. The said computing environment is used for calculation of Markov processes.

The verification of the model has been carried out with the use of three pre-estimated sets of intensities of transitions between the states. Using the GRIF computing environment stationary probability values of residing in the states have been determined for a simplified model. Stationarity have been obtained after 2–15 days.

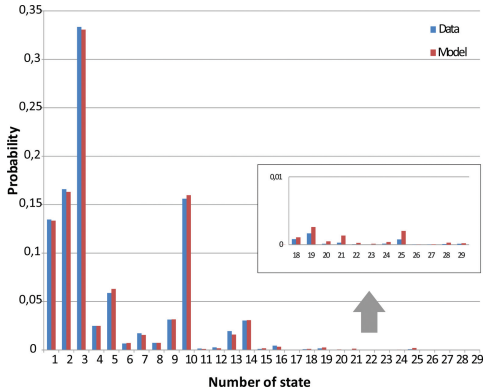

Figure 6. Comparing of empirical data with results from the proposed model.

For a real railway line, called in the paper A–B, state probabilities have been determined based on infrastructure manager's data from the year 2011. Then empirical values have been put together with the results of the model, which was parameterized by data for the same railway line, but previous operation interval (years 2009–2010). The results were shown in Figure 6.

After determining the probabilities and residence times in states on the basis of empirical data and after performing the calculations for the model, the values obtained have been put together and the test of the model compliance with reality have been conducted. The Chi squared test at the statistical significance $\alpha = 0.05$ has been chosen. The critical quantile for the distribution takes the value of 41.337 for the studied case. For line A-B it has been stated (comparing the model with data from 2011) that for the given statistical significance there is no basis to reject the null hypothesis of compatibility of the model with reality.

4 SUMMARY

The studies of the state of art have shown the lack of models of reliability and safety of the rail transportation system taking into account functional features. In particular, the need for considering the following factors has been identified: reliability of infrastructure and rolling stock subsystem, intensity of system using (traffic dependence of trains), the impact of the human factor in conjunction with the functioning of the system, disruptions in train traffic, the exposure of the system to situations of emergency and safety unreliability. Therefore, the following objective of the work has been formulated. Such conclusions have been drawn from both the research on literature sources, operation tests of the system as well as observation of the practice of conducting rail traffic and system management.

A concept of the system has been developed based on which faultiness states have been defined and the concept of partial faultiness of the rail transport system has been introduced. Barriers which have not yet been systematically taken into account and which prevent the occurrence of railway accidents have been identified.

The developed way of defining the states has made it possible to take into account the identified, significant functional, reliability and safety qualities. The formulated model based on graph of states and transitions has been mathematically described with the use of the system of 44 linear differential equations, assuming the independence of intensities of transitions between the states. With the use of the mathematical model the probabilities of occurrence of the above-defined states are calculated. The verification of the model shows a good representation of reality. This has been proven by the Chi squared test at the statistical significance $\alpha = 0.05$.

Reliability analysis of rail teleinformation system

M. Siergiejczyk
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: The paper presents the issues related to the modeling of the reliability of rail teleinformation system. This Rail ICT system is intended to modernize the technical and technological solutions in dedicated networks (communication networks, mobility, dispatcher, etc), functioning outside the railway public operating telephone network. It is presented the architecture of railway communication system and described the functions of the respective subsystems. Analyzing the functional structure and method for transmitting information in the railway technology communication system it is proposed a method for calculating the rate of system reliability. To evaluate the reliability of rail ICT system as a recoverable system it is proposed the rate of readiness.

1 INTRODUCTION

Centralised rail traffic control and management poses a considerable challenge to telecommunications infrastructure in terms of data transfer, reliability, performance and data transmission services.

Technical condition of individual system components and their maintenance processes have key influence on rail dispatcher communication system. System reliability is a good indicator of maintenance performance. By design, planned downtimes for central offices do not exceed two hours over forty years. Longer down periods are permitted for small subscriber groups or inter-office connections. Another popular indicator of reliability of ICT systems is probability of failure during a year. Mean failure time i.e. mean time to repair is also essential to evaluate ICT system reliability. An indicator connecting Mean Time To Repair (MTTR) and Mean Cycle Between Failures (MTBF) is the availability rate Kg (Jajszczyk A. 2006).

Attempt to evaluate operational reliability of Rail ICT system was presented in this paper. It is a modern, digital ICT system facilitating modernisation of technical and technological solutions in closed loop networks (shunting team radio, dispatch communications etc.) operating outside the main Polish Railways telephone network (Siergiejczyk M. and others 2001). The rationale behind closed networks using separate cables and transmission channels, including digital ones, is beyond all rail traffic safety, efficient traffic management, infrastructure maintenance as well as redundancy to provide alternative functional channels in case of failure.

The aim of the article is to assess the reliability of rail communications system of new generation that is currently being implemented to operate on Polish railways.

The correct operation of the communication system has a direct impact on the safety of railway traffic. At the stage of implementation of the exploitation there are no information on reliability properties of the railway dispatch communication system during exploitation, therefore there is a need to assess the reliability on the basis of forecasting methods. Knowledge of reliability indicators will allow for implementation of appropriate operational strategies allow for the maintenance of these systems in the states of functional and task ability.

In the area of rail transport issues of assessment of reliability are fairly well described in terms of traffic control systems, rail automation (Lewiński A, Perzyński T. 2010), ETCS systems and rail infrastructure (Flammini F. 2012). There are also publications related to the work of the dispatcher in rail transport, and specifically with the analysis of the reliability of the operator (Human Reliability Analysis) (Belmonte F, Boulanger J.-L., Schön W. 2008). In contrast, there are no publications that relate to the assessment of the reliability of a wired system of railway dispatch communication.

2 RAIL ICT SYSTEM

Rail ICT System (RICTS) is digital ICT system facilitating modernisation of technical and technological solutions in closed loop networks and thus in traffic communication. Logical architecture of the digital dispatch communication system has been illustrated on Figure 1.

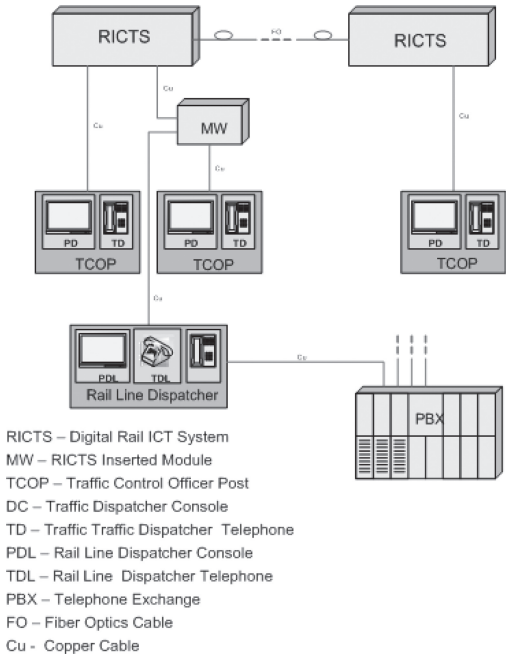

Figure 1. Architecture of rail teleinformation system (RICTS).

In its default configuration (integrated rail communication equipment for closed networks) it consists of:

– Digital server equipped with transmission and commutation modules allowing to make connections with mobile object,
– Computer equipment required for the operator to use the system i.e. LCD display, keyboard, hands-free headset with auto switching (optional) or manual switching, but note by default equipment are in "receiver" mode.
– Operator workstation (traffic controller) am integral part of the telecommunications server, which is a dedicated terminal for communication between traffic controller (dispatcher) and all connected points. That workstation features a keyboard, microtelephone, hands-free headset and readable display (min. 4 lines 40 characters each, or graphical)—optional extra.
– Operator workstation voice recorder,
– Power supply,
– Acoustic amplifiers controlled by the system, power output 100 W or 200 W (depending on ordered specification) controlling road side units,
– User terminals.

The system is built from modules, hence its configuration may be changed to suit individual user preference. Majority of system components features processors enabling distributed control. Hardware specification of the system is based on VLSI technology (very large scale integration). The modules are built using multi-layer laminates with electronic components embedded in the substrate.

Duplication or repetition of elements in electronic equipment provides alternative functional channels in case of failure thus increase reliability of:

– control unit,
– switching network,
– group processors, operating in "non-spinning reserve" arrangement, where at each given moment one can take over the function of central component.

Continuity is also assured through splitting cable harnesses and using protection fibres for rerouting traffic in case of failure.

All components are diagnosed in real time by system software. It signals failure or anomalies instantly, automatically reconfigures the system and eliminates failed component by switching to the reserve components without disconnecting traffic. The software also allows to manually initiate internal system tests. Thanks to that many reliability enhancing features improving service availability it does not go below 99.999% per annum.

System software was designed to provide all functionalities which are engaged by reconfiguring the data base. It offers flexibility to accommodate different applications, network characteristics, services, functions and interfaces.

The Rail ICT system creates a network assuring communication between traffic controllers (or other authorised personnel) and all stations located within perimeter of the railway station, dispatcher and stations track-side along the railway route. The RICTS facilitates data transmission required to assure and maintain safety and control rail traffic.

3 EVALUATION OF DIGITAL RICTS SERVER RELIABILITY

Those assumptions were made based on reliability guidelines for telecommunications lines described among other in (Kwestarz, Krygier 1999, Siergiejczyk 2000, Siergiejczyk 2009) and reliability analysis of computer and microprocessor systems (Military Handbook 1979, Siergiejczyk M., Rosinski A. 2011, Verma & Ajit & Karanki 2010). It is assumed that the stochastic process $\{X(t): t > 0\}$ describing operating principle of the system is the Markov process. The following states were defined:

S_{PZ},—system staying in state of full ability,

S_{ZB1}—one (processor A) processor is in state of full ability and the other (processor B) undergoes repair,
S_{ZB2}—one (processor B) processor is in state of full ability and the other (processor A) undergoes repair,
S_B—both processors' failure.

It was also assumed that the combinational circuit upon processor failure is in state of full ability and that uptime of combinational circuit is not independent of processor uptime. Figure 2 illustrates relationships within the system, derived based on functional analysis.

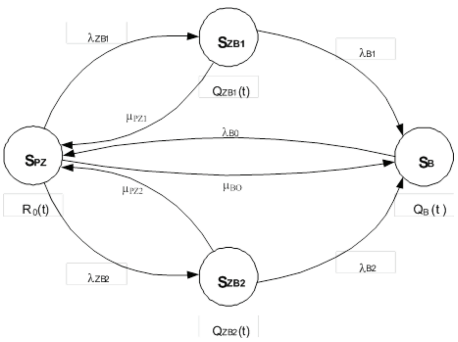

Figure 2. Relationships in the system.

Denotations in figures:
$R_O(t)$—probability of system staying in state of full ability S_{PZ},
$Q_{ZB1}(t)$—probability of event, where one (processor A) processor is in state of full ability and the other (processor B) undergoes repair,
$Q_{ZB2}(t)$—probability of event, where one (processor B) processor is in state of full ability and the other (processor A) undergoes repair,
$Q_B(t)$—probability of both processors' failure,
λ_{ZB1}—transition rate from state of full ability S_{PZ} to one (processor A) processor is in state of full ability and the other (processor B) undergoes repair,
λ_{ZB2}—transition rate from state of full ability S_{PZ} to one (processor B) processor is in state of full ability and the other (processor B) undergoes repair,
μ_{PZ1}—repair rate of failed processor B and transition to state of full ability S_{PZ},
μ_{PZ2}—repair rate of failed processor A and transition to state of full ability S_{PZ},
λ_{B0}—transition rate from state of full ability S_{PZ} to state of reached operational capability S_B after failure of combinational circuit,
μ_{B0}—repair rate after failures of combinational circuit and both processors and transition from state of reached operational capability S_B to state of full ability S_{PZ},
λ_{B1}—transition rate from state of partial ability where S_{B1} one (processor A) processor is in state of full ability and the other (processor B) undergoes repair to of reached operational capability S_B after failure of processor A,
λ_{B2}—transition rate from state of partial ability where S_{B2} one (processor B) processor is in state of full ability and the other (processor A) undergoes repair to of reached operational capability S_B after failure of processor B,

The system illustrated in Figure 1 may be described by the following Chapman–Kolmogorov equations:

$$\begin{aligned}
R_0'(t) &= -\lambda_{ZB1}\cdot R_0(t) + \mu_{PZ1}\cdot Q_{ZB1}(t) - \lambda_{ZB2}\cdot R_0(t) \\
&\quad + \mu_{PZ2}\cdot Q_{ZB2}(t) - \lambda_{B0}\cdot R_0(t) + \mu_{B0}\cdot Q_B(t) \\
Q_{ZB1}'(t) &= \lambda_{ZB1}\cdot R_0(t) - \mu_{PZ1}\cdot Q_{ZB1}(t) - \lambda_{B1}\cdot Q_{ZB1}(t \\
Q_{ZB2}'(t) &= \lambda_{ZB2}\cdot R_0(t) - \mu_{PZ2}\cdot Q_{ZB2}(t) \\
&\quad - \lambda_{B2}\cdot Q_{ZB2}(t) \\
Q_B'(t) &= \lambda_{B1}\cdot Q_{ZB1}(t) + \lambda_{B2}\cdot Q_{ZB2}(t) + \lambda_{B0}\cdot R_0(t) \\
&\quad - \mu_{B0}\cdot Q_B(t)
\end{aligned} \tag{1}$$

Given the initial conditions:

$$\begin{aligned}
R_0(0) &= 1 \\
Q_{ZB}(0) &= Q_B(0) = 0
\end{aligned} \tag{2}$$

Laplace transform yields the following system of linear equations:

$$\begin{aligned}
s\cdot R_0^*(s) - 1 &= -\lambda_{ZB1}\cdot R_0^*(s) + \mu_{PZ1}\cdot Q_{ZB1}^*(s) \\
&\quad - \lambda_{ZB2}\cdot R_0^*(s) + \mu_{PZ2}\cdot Q_{ZB2}^*(s) \\
&\quad - \lambda_{B0}\cdot R_0^*(s) + \mu_{B0}\cdot Q_B^*(s) \\
s\cdot Q_{ZB1}^*(s) &= \lambda_{ZB1}\cdot R_0^*(s) - \mu_{PZ1}\cdot Q_{ZB1}^*(s) \\
&\quad - \lambda_{B1}\cdot Q_{ZB1}^*(s) \\
s\cdot Q_{ZB2}^*(s) &= \lambda_{ZB2}\cdot R_0^*(s) - \mu_{PZ2}\cdot Q_{ZB2}^*(s) \\
&\quad - \lambda_{B2}\cdot Q_{ZB2}^*(s) \\
s\cdot Q_B^*(s) &= \lambda_{B1}\cdot Q_{ZB1}^*(s) + \lambda_{B2}\cdot Q_{ZB2}^*(s) \\
&\quad + \lambda_{B0}\cdot R_0^*(s) - \mu_{B0}\cdot Q_B^*(s)
\end{aligned} \tag{3}$$

By rearranging we get:

$$R_0^*(s) = \frac{-b_1\cdot b_2\cdot b_3}{\begin{aligned} &b_1\cdot b_2\cdot \lambda_{B0}\cdot \mu_{B0} - a\cdot b_1\cdot b_2\cdot b_3 \\ &+ b_2\cdot b_3\cdot \lambda_{ZB1}\cdot \mu_{PZ1} + b_1\cdot b_3\cdot \lambda_{ZB2}\cdot \mu_{PZ2} \\ &+ b_2\cdot \mu_{B0}\cdot \lambda_{B1}\cdot \lambda_{ZB1} + b_1\cdot \mu_{B0}\cdot \lambda_{B2}\cdot \lambda_{ZB2}\end{aligned}}$$

$$Q_{ZB1}^*(s) = \frac{-b_2\cdot b_3\cdot \lambda_{ZB1}}{\begin{aligned} &b_1\cdot b_2\cdot \lambda_{B0}\cdot \mu_{B0} - a\cdot b_1\cdot b_2\cdot b_3 \\ &+ b_2\cdot b_3\cdot \lambda_{ZB1}\cdot \mu_{PZ1} + b_1\cdot b_3\cdot \lambda_{ZB2}\cdot \mu_{PZ2} \\ &+ b_2\cdot \mu_{B0}\cdot \lambda_{B1}\cdot \lambda_{ZB1} + b_1\cdot \mu_{B0}\cdot \lambda_{B2}\cdot \lambda_{ZB2}\end{aligned}}$$

$$Q_{ZB2}^*(s) = \frac{-b_1\cdot b_3\cdot \lambda_{ZB2}}{\begin{aligned} &b_1\cdot b_2\cdot \lambda_{B0}\cdot \mu_{B0} - a\cdot b_1\cdot b_2\cdot b_3 \\ &+ b_2\cdot b_3\cdot \lambda_{ZB1}\cdot \mu_{PZ1} + b_1\cdot b_3\cdot \lambda_{ZB2}\cdot \mu_{PZ2} \\ &+ b_2\cdot \mu_{B0}\cdot \lambda_{B1}\cdot \lambda_{ZB1} + b_1\cdot \mu_{B0}\cdot \lambda_{B2}\cdot \lambda_{ZB2}\end{aligned}}$$

$$Q_B^*(s) = \frac{-b_1\cdot b_2\cdot \lambda_{B0} - b_2\cdot \lambda_{B1}\cdot \lambda_{ZB1} - b_1\cdot \lambda_{B2}\cdot \lambda_{ZB2}}{\begin{aligned} &b_1\cdot b_2\cdot \lambda_{B0}\cdot \mu_{B0} - a\cdot b_1\cdot b_2\cdot b_3 \\ &+ b_2\cdot b_3\cdot \lambda_{ZB1}\cdot \mu_{PZ1} + b_1\cdot b_3\cdot \lambda_{ZB2}\cdot \mu_{PZ2} \\ &+ b_2\cdot \mu_{B0}\cdot \lambda_{B1}\cdot \lambda_{ZB1} + b_1\cdot \mu_{B0}\cdot \lambda_{B2}\cdot \lambda_{ZB2}\end{aligned}} \tag{4}$$

where:

$$a = s + \lambda_{ZB1} + \lambda_{ZB2} + \lambda_{B0}$$

$$b_1 = s + \mu_{PZ1} + \lambda_{B1}$$

$$b_2 = s + \mu_{PZ2} + \lambda_{B2}$$

$$b_3 = s + \mu_{B0}$$

Solving above equations in time domain is a next step of the analysis which has not been included in this paper.

4 MODELLING OF PROCESS RAIL ICT MAINTENANCE

Computer simulation and computer-aided analysis facilitate to relatively quickly determine the influence of change in reliability-exploitation parameters of individual components on reliability of the entire system. Using computer aided allows to perform the calculation of the value of probability of system staying in state of full ability R_0. That procedure is illustrated with below example.

The following quantities were defined for the system:

– test duration—1 year (in [h]):

$$t = 8760 \ [h]$$

– transition rate from state of full ability SPZ to one (processor A) processor is in state of full ability and the other (processor B) undergoes repair:

$$\lambda_{ZB1} = 0{,}000000006$$

– transition rate from state of full ability SPZ to one (processor B) processor is in state of full ability and the other (processor B) undergoes repair,:

$$\lambda_{ZB2} = 0{,}000000006$$

– transition rate from state of partial ability where S_{ZB1} one (processor A) processor is in state of full ability and the other (processor B) undergoes repair to of reached operational capability SB after failure of processor A λ_{B1}:

$$\lambda_{B1} = 0{,}000000006$$

– transition rate from state of partial ability where S_{ZB2} one (processor B) processor is in state of full ability and the other (processor A) undergoes repair to of reached operational capability SB after failure of processor B λ_{B2}:

$$\lambda_{B2} = 0{,}000000006$$

– transition rate from state of full ability SPZ to state of reached operational capability SB after failure of combinational circuit λ_{B0}:

$$\lambda_{B0} = 0{,}000000001$$

– repair rate of failed processor B and transition to state of full ability SPZ:

$$\mu_{PZ1} = \frac{1}{24}$$

– repair rate of failed processor A and transition to state of full ability SPZ,:

$$\mu_{PZ2} = \frac{1}{24}$$

After using the inverse Laplace transform for equation (4) and given transition rate from state of reached operational capability to state of full ability is

$$\mu_{BO} = \frac{1}{0{,}5}$$

obtained is: $R_O = 0{,}9999997115$

After using the inverse Laplace transform for equation (4) and given transition rate from state of reached operational capability to state of full ability is

$$\mu_{BO} = \frac{1}{6}$$

obtained is: $R_O = 0{,}999999706$

5 CONCLUSION

Results suggest that proposed evaluation method for determining utilisation of rail transport telematics system support train driving is valid and viable. Furthermore reliability parameters of individual digital rail ICT system components is rather high (high availability rates). Availability rate of the entire system depends on availability rates of switching systems and does not deviate considerably from availability guidelines for digital switching systems.

Practical application of deliberations presented hereinbefore enables to determine the impact of transition rate from the state of the impendency over safety to the state of full ability μ_{PZ1} i, transition rate from the state of unreliability of safety to the state of the impendency over safety μ_{PZ2} and transition rate from the state of unreliability of safety to the state of full ability μ_{PZ} on probability

of system staying in the state of full ability. Rates μ_{PZ1}, μ_{PZ2} and μ_{PZ} should be read as inverse times t_{PZ1}, t_{PZ2} and t_{PZ} which determine the time taken to restore system elements to the state of full ability.

Premises of evaluation of the technical object suitability with including the quality of its maintenance and operation, and their initial conditions

R. Grądzki

P. Lindstedt
Air Force Institute of Technology, Warsaw, Poland

K. Golak
Bialystok University of Technology, Faculty of Mechanical Engineering, Bialystok, Poland

ABSTRACT: In this article, results of exploitation research of three various technical objects (engines of public transport buses) for different initial conditions are presented. Gathered data is presented in three sets (1—concerning object, 2—concerning driving conditions, 3—concerning driver, where sets 2 and 3 are the object environment) in form of conventional points (experts numerical assessments). Relation between point information of object and point information of environment was described by coupled equations of state (describing relations between operation condition and technical condition including initial conditions for each exploitation period). Such approach allows to determine parameters of technical condition a_T and operation condition a_R and subsequently, from the course of a_T parameter, set of parametrical damage $m_T(t)$ and from course of parameter a_R—set of momentary damage $a_R(t)$. Hence for each moment of exploitation data on technical and operation conditions of each object (bus engine) is available. This data allows to optimally control exploitation and service of particular objects as set of objects and its elements.

1 INTRODUCTION

Gradual damage of technical object (decrease in its exploitation properties and mechanical wear) occurs during the process of its exploitation. This damage consists on deregulation, wear and increase of unreliability. Hence the importance of permanent observation for changes of operation condition changes, technical condition changes and reliability changes during service and use of the object (Ashby 1963, Szczepaniak 1999).

In this article, work on new method of exploitation analysis of object aptitude is presented, based on assumption that every information (diagnostic signals, use signals, use condition signals) is expressed (presented) in form of points (numerical expert assessment).

Diagnostic signals in form of points were used for the first time in diagnostics of ship-based helicopter SH-2G (USA) (Szawłowski 2005). In this method aptitude was analyzed only by summing all the points. Next, obtained value is compared to threshold set by manufacturer (USA). Based on relation between sum of the points and allowed number of points, the machine is qualified for further exploitation or renovation.

The new method of using exploitation data presented in this article is based on transforming every signal, symptom and expert assessments to standard point form and (which is innovatory) using them to determine parameters of regulation and technical condition from model in form of coupled interaction equations of state (including initial conditions) [Cempel 2006] and subsequently from its courses—set of damages that are base for determining reliability characteristics [Bukowski 2003, Lindstedt 2006, Lindstedt & Sudakowski 2006].

Presented practical method of exploitation analysis of object aptitude (operation condition, wear, reliability) might be, and partially is, applied to process of servicing technical objects. Such data allows to decide on object further destination.

2 DIAGNOSTIC RESEARCH OF TECHNICAL OBJECT AND ITS ENVIRONMENT

The analyzed objects were three various MAN buses exploited in Municipal Transport Company of the City of Bialystok. The aim of the research was to obtain diagnostic signals D_k concerning condition of objects (data from diagnostician)

and data on their environment (expert information from driver).

Analysis was undertaken for each week of a year, thus obtaining database for twelve months.

Obtained determined (measurable), probabilistic and heuristic data was divided into two subgroups:

- signals concerning technical condition D_k
- signals concerning environment condition U.

All measured signals were presented in Table 1. These signals are of varying physical nature and thus were in each case transformed to point value.

Table 1. Expert point weights for assessment of condition of engine, driver (Table 3) and diagnostician.

Signal	Signal name	Ep	N	N + 5%	N + 10%	N + 15%	N + 20%
D_{M1}	Average fuel consumption without heating [l/100 km]	15	15	30	45	60	75
D_{M2}	Average fuel consumption with heating [l/100 km]	15	15	30	45	60	75
D_{M3}	Fogging value during engine blowout [1/m]	10	10	20	30	40	50
D_{M4}	Fogging value during engine operation [1/m]	10	10	20	30	40	50
D_{M5}	Peak value of noise level [dB]	5	5	10	15	20	25
D_{M6}	Average value of noise level [dB]	5	5	10	15	20	25

In order to obtain knowledge from specialists (experts) for expressing data in form of points, detailed questionnaires were developed in cooperation with users—bus drivers.

Research was undertaken on group of 20 experts, whose tenure as drivers was at least 5 years. Summarizing tables with importance of information D_i and U_i expressed in expert point weights for assessment of engine and its environment condition obtained from driver and diagnostician were presented in Table 1.

Based on Table 1, each situation, phenomenon and exploitation facts might be expressed using proper point value.

Values of signals $U_{P1} \div U_{P3}$ in Table 2 were taken as average values from whole month, whereas values of signal U_{P4} were most frequently occurring. In Table 3 total number of points were obtained by daily change of observed signals to point values which were subsequently, at the end of the month, summed and divided by number of days in the month.

Based on data from Table 2. and including experts weight (Table 3 and 4) point forms of signals were obtained—Table 3 (data for other two buses was filled analogically).

3 ALGORITHM OF DETERMINING PARAMETERS OF TECHNICAL AND OPERATION CONDITION OF TECHNICAL OBJECT

Object (engine) in its environment is described by coupled state equations including initial conditions describing relations between technical condition and operation condition (Cempel 2006, Lindstedt 2006, 2009, Söderström & Stoica 1997). It should be noticed that, in these equations diagnostic signals D_k are environment for operation signals U and operation signals U are environment for diagnostic signals D_k.

$$\frac{dU}{dt} = a_R U + b_{R1} D_k + b_{R0} \tag{1}$$

$$\frac{dD_k}{dt} = a_T D_k + b_{T1} U + b_{T0} \tag{2}$$

Equation (1) and (2) might be written as follows:

$$\frac{\Delta U}{\Delta \theta} = a_R U + a_R \hat{a}_{R1} D_k + a_R \hat{a}_{R0} \tag{3}$$

Table 4. Procedure of calculating technical condition and regulation parameters for bus no. 301.

$$\frac{\Delta U}{\Delta \theta} = a_R(U + \hat{a}_{R1}D_k + \hat{a}_{R0}) \tag{4}$$

$$\frac{\Delta D_k}{\Delta \theta} = a_T D_k + a_T \hat{a}_{T1} U + a_T \hat{a}_{T0} \tag{5}$$

$$\frac{\Delta D_k}{\Delta \theta} = a_T(D_k + \hat{a}_{T1}U + \hat{a}_{T0}) \tag{6}$$

where: U—operation signal (signal of use); D_k—bus diagnostic signal; a_R—operation condition parameter, dependent mostly on object operation U and influence of diagnostic signals D_k on this operation; b_{R1}, b_{R0}—parameters of influence of diagnostic signals and initial conditions on operation condition; a_T—object technical condition parameter, dependent mostly on diagnostic signals and signals coming from environment; b_{T1}, b_{T0}—parameters of influence of signals of regulation and initial conditions on technical condition of the bus.

According to rules of statistical identification $\dot{D}_k = 0$ (Söderström & Stoica 1997) from equations (2, 5, 6) we obtain::

$$\hat{a}_{T1} = \frac{n\sum_{i=1}^{n} Dk_i U_i - \sum_{i=1}^{n} Dk_i \sum_{i=1}^{n} U_i}{n\sum_{i=1}^{n} U_i^2 - \sum_{i=1}^{n} U_i \sum_{i=1}^{n} U_i} \tag{7}$$

$$\hat{a}_{T0} = \frac{\sum_{i=1}^{n} Dk_i \sum_{i=1}^{n} U_i^2 - \sum_{i=1}^{n} Dk_i U_i \sum_{i=1}^{n} U_i}{n\sum_{i=1}^{n} U_i^2 - \sum_{i=1}^{n} U_i \sum_{i=1}^{n} U_i} \tag{8}$$

and ultimately sought parameter of technical condition a_T:

$$a_T = \frac{\Delta D_k}{\frac{\Delta \Theta}{resurs}(D_k + \hat{a}_{T1}U + \hat{a}_{T0})} \tag{9}$$

Parameter a_T characterizes object technical condition and depends on diagnostic signals (D_k) and signals coming from driver's and environment influence as well as initial conditions $\hat{a}_{T0}$.

According to rules of statistical identification $\dot{U} = 0$ (Söderström & Stoica 1997) from equation (1, 3, 4) we obtain:

$$\hat{a}_{R1} = \frac{n\sum_{i=1}^{n} Dk_i U_i - \sum_{i=1}^{n} Dk_i \sum_{i=1}^{n} U_i}{n\sum_{i=1}^{n} Dk_i^2 - \sum_{i=1}^{n} Dk_i \sum_{i=1}^{n} Dk_i} \tag{10}$$

$$\hat{a}_{R0} = \frac{\sum_{i=1}^{n} U_i \sum_{i=1}^{n} Dk_i^2 - \sum_{i=1}^{n} Dk_i U_i \sum_{i=1}^{n} Dk_i}{n\sum_{i=1}^{n} Dk_i^2 - \sum_{i=1}^{n} Dk_i \sum_{i=1}^{n} Dk_i} \tag{11}$$

and ultimately sought parameter of operation condition a_R:

$$a_R = \frac{\Delta U}{\frac{\Delta \Theta}{resurs}(U + \hat{a}_{R1} D_k + \hat{a}_{R0})} \tag{12}$$

Parameter a_R characterizes object operation condition and depends on operation (utility) signals coming from driver action and environment U, diagnostic signals D_k and initial conditions $\hat{a}_{R0}$.

Signals D_k and U in homogenous point form (Table 6) were transformed to resultant diagnostic signal (D_k) and environment (U).

$$D_k = \sqrt{\begin{array}{l} D_{M1P}^2 + D_{M2P}^2 + D_{M3P}^2 + D_{M4P}^2 + D_{M5P}^2 \\ + D_{M6P}^2 + D_{M9P}^2 + D_{M12P}^2 + D_{I5P}^2 + D_{IEP}^2 \\ + D_{2EP}^2 + D_{3EP}^2 + D_{4EP}^2 \end{array}} \tag{13}$$

$$U = \sqrt{\begin{array}{l} U_{K1P}^2 + U_{K2P}^2 + U_{K3P}^2 + U_{D1P}^2 + U_{D2P}^2 + U_{D3P}^2 \\ + U_{P1P}^2 + U_{P2P}^2 + U_{P3P}^2 + U_{P4P}^2 \end{array}} \tag{14}$$

Using data from Table 3 and equations 1÷12, increases in technical condition described by parameter a_T and operation (regulation) condition described by parameter a_R are calculated.

Subsequently Σa_T describing level of object wear and Σa_R describing resource of proper operation possibility are determined.

In Table 4, row 1 data was implemented from previous year thus allowing determination of parameters a_T and a_R starting from February (row 2).

Results of courses of normalized parameters a_T and a_R changes for bus no. 301 were presented on Figure 1, for bus no. 303 on Figure 3 and for bus no. 304 on Figure 5, whereas courses of sums of these parameters were presented on Figure 2, Figure 4 and Figure 6 respectively.

On the base of data from Table 5 and charts 1, 3, 5 the following might be noted: the best technical and regulation condition is that of bus no. 301. Values of sum of a_R and a_T are the least, thus statement can be made that wear of bus no. 301 is the least and regulation potential was used to the least extent.

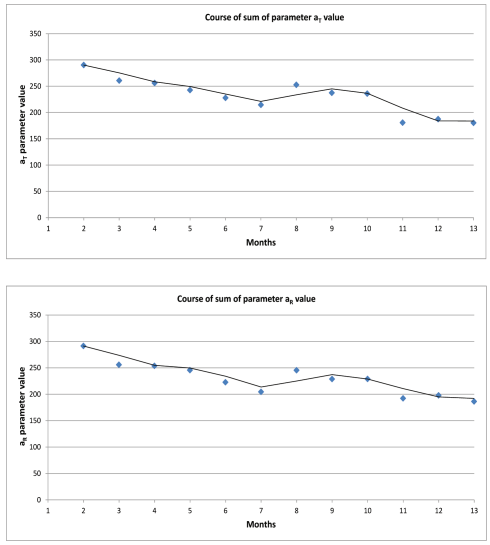

Figure 1. Changes of normalized parameter of technical condition and regulation for bus no. 301.

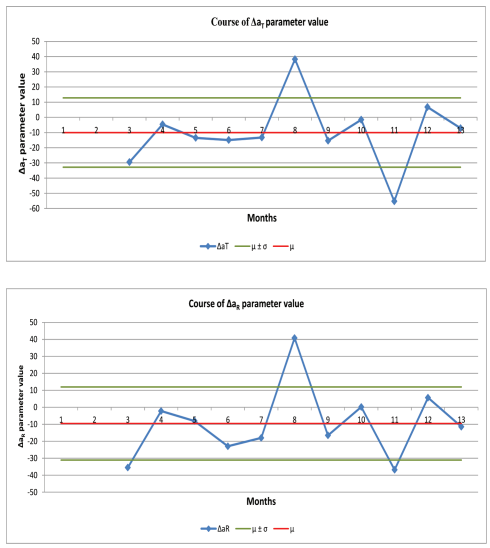

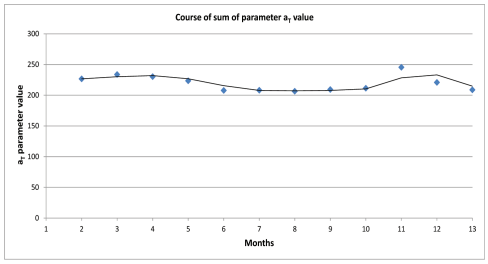

Figure 2. Course of value of technical condition and regulation parameter increase for bus no. 301.

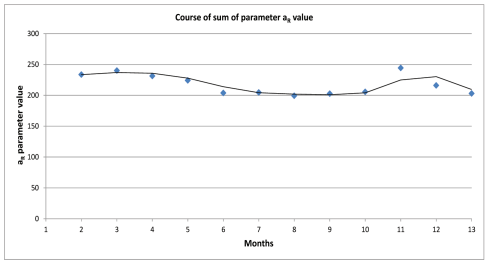
Obtained results were confirmed by discerning analysis of analytical assessments of aptitude of aforementioned buses by direct method realized by experts (diagnosticians—drivers).

Excess of increases values of technical condition and operation condition from the value of standard deviation might be observed in Figures 2, 4, 6.



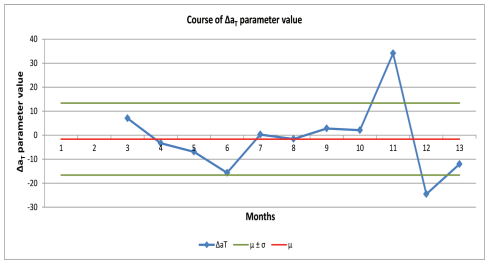


Figure 3. Changes of normalized parameter of technical condition and regulation for bus no. 303.

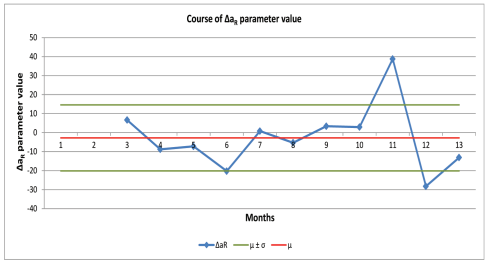

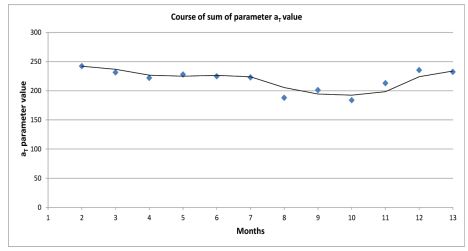

Figure 4. Course of value of technical condition and regulation parameter increase for bus no. 303.

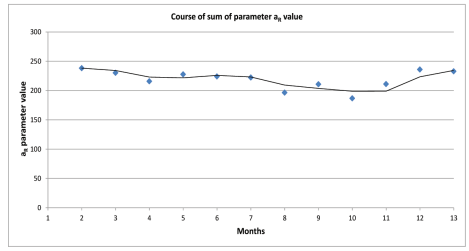
It means that in case when increase of technical condition is greater than deviation value, parametrical damage occurred, whereas in case of operation parameter exceeding deviation value, momentary damage occurred (Table 5).

Parametrical and momentary damage do not disqualify object from further exploitation, but



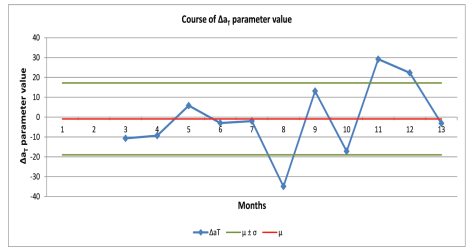


Figure 5. Changes of normalized parameter of technical condition and regulation for bus no. 304.

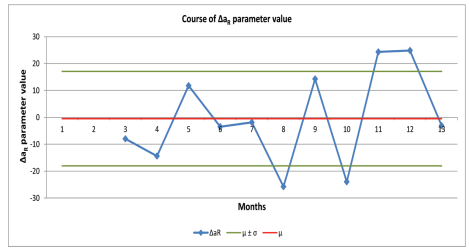

Figure 6. Course of value of technical condition and regulation parameter increase for bus no. 304.

Table 5. Summary table.

	Bus no. 301	Bus no. 303	Bus no. 304
Sum of a_T	180,272	208,792	232,173
Parametrical damage $m_T(t)$			
Sum of a_R	186,323	202,933	232,884
Momentary damage $m_R(t)$			

may be the base for determining reliability characteristics before the occurrence of dangerous catastrophic damage.

4 SUMMARY

Exploitation research activity is realized during object exploitation in order to determine its current and future operation, technical and reliability condition. In complex and advanced technical objects several research methods are used simultaneously based on data in various form (determined, probabilistic and heuristic signals).

The basis of innovatory method of using varying diagnostic data (in form of points) are presented. Each change of signal (depending on its value and moment of occurrence) corresponds with number of points predetermined by the experts. So far in such method of aptitude analysis, all the points were summed and subsequently a range was determined in which is the object, its condition and level of exploitation (Bukowski 2003, Söderström & Stoica 1997). Proposed method is based on using signals in form of points to determine parameters of regulation and technical condition (equations 3, 4) from coupled state equations (Cempel 2006, Lindstedt 2006, 2009) and subsequently reliability and safety of the object during exploitation. The described method may prove to be very useful due to unequivocal presentation of object global exploitation condition using parameters a_R, a_T and thus allows to predict how the object should be used and when the object should be serviced (repaired, overhauled).

Bivariate reliability analysis of driving profiles in automobile fleets

T. Köttermann, M. Grabert & S. Kempe

ABSTRACT: Common reliability models in the automotive industry rarely take into account the wide variety of real world customer driving profiles. The only explanatory variable very often is the lifespan variable mileage, although it alone does not give further information about the specific driving profile that caused the damage. This paper demonstrates that a vehicle's reliability can highly differ, depending on its driving profile and that many practical applications of reliability models in the automotive industry, like failure predictions, are influenced by this fact. In order to take various driving profiles into account, a bivariate approach, using the two most common explanatory variables in automotive data, i.e. time in service and mileage, is presented. It is demonstrated in case studies that this extension of reliability models to the bivariate case already offers a substantial increase in performance compared to univariate models for many reliability related questions.

1 INTRODUCTION

In practice, reliability analyses in the automotive industry are done for various purposes. First of all field data analysis is used to evaluate the potential of an emerging failure mode, to estimate the number of expected failures within a defined timespan or to get a risk estimate for single vehicles, to concentrate campaigns to the group of vehicles under the highest risk. Further manufacturers (OEMs) are often interested in information about the general failure behavior of a component, e.g. its Weibull shape parameter. This information helps, in combination with further reliability analyses of testing results, to evaluate the reliability of components during the development. The performance of all these applications highly depends on the failure model's ability to explain the actual damage process that leads to a failure. In many years of working in the automotive industry, we noticed in a lot of cases that this damage process is more complex than common univariate reliability models are able to explain. This observation is reflected in false failure prediction and significantly changing results of reliability analyses over time. The main reason for this circumstance is, that one single variable rarely includes all the necessary information, to fully describe the complexity of a failure mode. In common univariate reliability analyses, these single variables are mostly either mileage or time in service. The true stress that a component is experiencing is the result of its individual usage. We define a set of variables to describe a vehicles usage as a driving profile. These profiles give information additionally to the absolute mileage of a vehicle. This paper describes a method to include these profiles into analyses and describe their effect on the component's reliability. The first and easiest step to achieve this goal is an extension to the bivariate case, so overall two variables are included to describe the vehicle's usage. The advantage of this approach lies in a minimal extension of complexity, yet significantly increased model performance, regarding a wide set of practical applications. This paper introduces a method to allow for the influence of a covariate on the failure behavior and illustrates its effectiveness by performance comparisons in form of case studies.

2 DRIVING PROFILES

Driving profiles give further details about the way a vehicle is used in addition to its absolute mileage. We are interested in using this information for reliability analyses to improve their performance. On the most detailed level every vehicle has an individual driving profile. The set of variables which could be used for its description is large because of a wide range of customers who are using their vehicles differently. Due to global activities of today's OEMs and the increasing diversity in the vehicles' concepts and their technology, the variety continues

to increase. Some of the most relevant aspects are given by these three following categories:

- The drivers behavior
  - Sportive driving
  - Fuel efficient driving
- The driving conditions
  - Quality of the roads
  - Traffic conditions, e.g. frequent traffic jams
  - Climate
- Main purpose of the vehicle
  - Private usage
  - Commuter traffic
  - Professional usage, e.g. Taxi vehicles

Thus in general driving profiles are complex there are two reasons why only reduced profiles are often used to work with in reliability models. First of all most automotive OEM's possibilities are limited by the available data. In the case of customer data analysis, they are facing the situation of very big samples but only limited information about each vehicle. Further an obvious assumption is that only a part of the information is relevant regarding a component's failure behavior. Some of the possible variables can be excluded from the start on, due to no expected influence on the failure mode.

We consider a bivariate solution, using mileage and time in service in this paper. The time in service can be expected to be available for the whole fleet, due to the usually known day of registration. In addition information about mileage is at least available for every failed vehicle and a portion of the failure free vehicles over the time of warranty. Although the reduction to only two variables seems to be very strict, it will be shown that the increase in the model's performance in different applications, compared to a common univariate approach, is still remarkable.

In the following, two explaining variables to analyze a failure behavior are considered, i.e. mileage at the failure's appearance and the timespan between the vehicle's registration and the day of failure. It is convenient to define one of these variables as the variable in which the lifetime is measured and the other one as a covariate. In the automotive industry it is common to measure the lifetime in mileage. This idea will be followed and the time in service is taken as covariate into account. Obviously time in service and mileage depend on each other. Vehicles which reached a high mileage tend to have a longer time in service and vice versa. That means that the covariate is time dependent. This problem can be simplified by one assumption which is regularly used analyzing automotive data as by Krivtsov & Frankstein (2006), Lawless et al. (1995) or Lawless et al. (2009):

$$\frac{mileage}{time} = a = const. \tag{1}$$

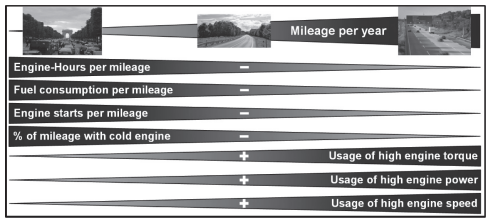

Figure 1. Correlation of the mileage accumulation rate to other driving profile variables.

where a = mileage accumulation rate. Within the warranty period, a can be treated as being constant. Besides the mentioned papers above, our practical experience strongly supports a mostly constant α.

It is worth mentioning that the mileage accumulation rate is actually able to add partially information about various other possible profile variables, due to the fact that it correlates to some specific driving patterns. A high value of a has the tendency to be observed for vehicles which are rather using highways, while a low value of a usually indicates that this vehicle is frequently used in city traffic. Driving mostly on highways or in the city, leads to specific usage characteristics regarding fuel consumption, engine starts or engine speed. Figure 1 indicates if a is positively or negatively correlated to these and several other variables that could be included into a reliability analysis but are mostly not available. This means that the use of a can lead to more informative models, even if it is not assumed that the time in service of a vehicle has a direct influence on the failure mode.

3 RELATED LITERATURE TO THIS WORK

The literature offers several methods and models to analyze survival data under the circumstance of different usage conditions. Cox (1972) introduced the Proportional Hazards Model (PHM) to allow for the influence of covariates. This approach is one of the most widely used, particularly in survival analysis. Bendell et al. (1991) discuss the application of this model especially in the context of reliability data. Case studies involving the PHM in the area of reliability were done by Kumar et al. (1992), Bendell et al. (1986) and Jardine et al. (1989). Alternatives to the PHM can be found in Oakes (1995), Kordonsky & Gertsbakh (1997) and Duchesne (1999) which follow the idea of multiple times scales to take more than one explanatory variable into account. Another possibility arises if there is some knowledge about the physical-failure mechanism. This approach is usually used with acceler-

ated testing data to estimate the failure distribution of customers in the field. This task is highly related to general influence of the specific usage on the failure behavior. Meeker et al. (1998) and Nelson (2001) discuss several examples of possible acceleration models and Escobar & Meeker (2006) describe in detail the general use of acceleration test models and necessary conditions to make them work well. The works by Hong & Meeker (2010 & 2013) refer particularly to predicting field-failures when use-rate information is available. Very similar to this work, Hong & Meeker evaluate their model by its prediction performance. All the mentioned references have in common that need assumptions about the usage's influence, some more and some less. This paper offers a rather assumption free approach to deal with the situation that reliability experts have no knowledge about the covariate's influence. It is fair to say that in many reliability analyses in automotive practice, reliability experts and engineers do not know a suitable model for the covariates' influence in advance. This circumstance is even gaining in importance, due to the increasing amount of new technologies in the automotive industry. Out of this reason it is desirable to use non-parametric methods, to allow for unspecified influences by a covariate.

4 BIVARIATE NON-PARAMETRIC APPROACH

Let us assume that a vehicle's usage can be primarily measured by its mileage in kilometer. In addition the influence of a vehicle's driving profile, i.e. a vehicle's mileage accumulation rate *a,* as defined above, is allowed. An estimate for alpha can be done by data of any visit in a workshop where the day of service and the vehicle's mileage were documented due to the assumption of *a* being time independent.

The main goal of this research, besides the bivariate approach itself, was to get a picture of the potential of taking a second usage variable into account in the context of various practical applications. To achieve that, we assumed that information about mileage and time in service is available for every vehicle. Therefore data of one production year that lies several years in the past was used. In this way an estimation of the mileage accumulation rate was available for most vehicles. Vehicles which had only a documented visit within their first three months of service or had no documented visit in a workshop at all were excluded from the dataset. In this case over 90% of the fleet was used for the analysis.

We assumed that vehicles with comparable driving profiles have a similar failure behavior. Vehicles with significantly different profiles might have different failure behaviors. The basic idea is to form clusters of vehicles with similar driving profiles and analyze the clusters' failure behaviors separately. Another way to describe the basic idea is that some amount of data is traded for a greater homogeneity. The failure probabilities can be estimated by any non-parametric univariate method, after suitable clusters were formed. A common approach is given by Kaplan & Meier (1958) in form of the Product Limit Estimator (PLE). The PLE was designed to estimate a survival probability in dependence of a lifetime variable for censored data. For this approach the PLE was slightly adapted. Equation 2 estimates the cumulative distribution function of the failure probability for a given cluster *g*:

$$F(t_j)_g = 1 - \prod_{j=1}^{kg} \left[1 - \left(\frac{\delta_{j,g}}{n_{j,g}} \right) \right] \tag{2}$$

where g is the index representing the clusters of vehicles with a similar driving profile, j is the index representing the mileage intervals within a cluster, t_j is the upper mileage of interval j, k_g is the number of mileage intervals of cluster g, $\delta_{j,g}$ is the number of failures in interval j of cluster g, $n_{j,g}$ is the number of vehicles that reached or passed interval j in cluster g. A detailed description of the PLE is given in Kaplan & Meier (1958).

It is worth pointing out that the PLE generally works better as the number of observed vehicles and the number of observed failures increase. Especially the number of observed failures is of great importance and therefore at least a minimum of failures which has to be defined by the reliability experts is needed. This means in every formed cluster this minimum of failures has to be observed. At the same time the clusters should be as homogeneous as possible regarding the mileage accumulation rate, to minimize the differences of the vehicles' failure behaviors to each other. In this trade-off situation, where bigger clusters tend to increase the PLE's performance but also decrease the clusters homogeneity and vice versa, an optimal way of forming the clusters has to be chosen. This optimum might change for various sets of data, which leads to several possible approaches to assign every single vehicle to a cluster that might be optimal. Table 1 describes three possibilities in detail. The proposed algorithm's suitability may depend on the distribution of a, the total number of vehicles and the number of observed failures.

Method 1 guarantees every cluster to have almost the same number of. The number of clusters can be raised until one of them has only a minimum of failures to achieve a well working PLE. This way

Table 1. Overview of possible approaches to cluster the vehicles regarding the mileage accumulation rate *a*.

Method	Description/steps
1) Quantiles Q_p over all vehicles	• Sort all vehicles by their mileage accumulation rate • Calculate p^* for the desired number of groups G by: $p^* = 100/G'$ • Assign every vehicle to one of the G quantiles Q_{p^*}
2) Intervals of a with a const. width	• Define a plausible range for a from a_{min} to a_{max} • Calculate an interval width w^* for the desired number of clusters G by: $w^* = (a_{max} - a_{min})/G'$ • Assign vehicle i regarding their value a_i to the interval in which a_i lies
3) Quantiles $Q_{p^*,\delta}$ over failed vehicles	• Sort failed vehicles by their mileage accumulation rate • Calculate p^* for the desired number of groups G by: $p^* = 100/G'$ • Assign every failed vehicle to the G quantiles $Q_{p^*,\delta}$ • Calculate a value $a_{p,}\delta$ which separates two groups by: $a_{p,}\delta = a_{jF} - (a_{jF} - a_{j-1,\,L})/2$, where $a_{j,F}$ is the a of the first vehicle in quantile j of the failed vehicles and $a_{j-1,\,L}$ is the a of the last vehicle in quantile $j-1$ of the failed vehicles • Assign every non-failed vehicle i to the group so that: $a_{j-1,}\delta \le a_i \le a_{j,}\delta$

a maximal number of clusters can be used and a useful estimation of the failure behavior of each cluster is guaranteed. A disadvantage should be mentioned. This method leads to a different variation of the mileage accumulation rate in every cluster, due to a usually lognormal distributed alpha. Clusters around the median of alpha are the most homogeneous while especially the last group with the highest values of α has also the highest variation. That is caused by the lognormal distribution which is skewed to the right.

Method 2 leads to clusters with a similar homogeneity but the constant width forms clusters with a high number of vehicles around the median and less crowded clusters for very high or low values of α. In order to still reach a desired minimal number of failures in each cluster, the width has to be increased which leads to fewer clusters and therefore the overall homogeneity is not necessarily better, compared to method 1. By using method 3 all the clusters are formed in a way to have the same amount of failures. By using the minimum in every cluster, the number of clusters is maximized. Again the disadvantage is that the clusters' widths regarding alpha might differ.

In the following, method 1 was used, forming quantiles regarding *a,* for the whole fleet of vehicles. The decision to cluster the data by method 1 was made because it was the target to use the non-parametric estimates in further practical applications directly, which is only possible if a PLE for every group can be calculated.

In the end the real data was divided into 25 clusters following method 1, which corresponds to $Q_{0.04}$, i.e. 4% quantiles. In addition a synthetic dataset was generated and analyzed using only 5 groups, i.e. $Q_{0.20}$, to use it in this publication. The main reason for an additional synthetic data set was to illustrate some systematic effects which can be observed for univariate analyses given an influence by a driving profile. In both cases, the data results from a production timespan of one calendar year and was observed at the end of that year, leading to a maximum time in service of one year. The majority of the fleet was less than a year in service at the day of the analysis, therefore this is meant to be an example of an early field data analysis with rather high failure probabilities.

5 BIVARIATE AND UNIVARIATE ANALYSES IN COMPARISON

Before the influence of the mileage accumulation rate on the failure behavior is described, some further steps are explained, which were done after calculating a PLE. These steps are necessary to perform failure predictions and the following procedure has proven itself in practice. In Figure 2 the univariate PLE is drawn in a Weibull Probability Plot (WPP) as small circles. The exact values had to be censored for this paper. Please note the logarithmic scaling of the WPP where $\ln(t)$ is used on the abscissa and $\ln(-\ln(1 - F(t)))$ is used on the ordinate. In addition to the PLE itself, a 90% confidence interval is given as dashed line and towards the last values of the estimator, a Weibull extrapolation was added. It is a common method in automotive practice, to use a combination of the PLE or any other non-parametric estimator and a fitted Weibull distribution for extrapolation. The extrapolation was achieved by manually selecting values of the PLE and fitting a Weibull distribution for these values by using a Maximum Likelihood Estimate (MLE). One reason why a manual selection of values is purposeful is that often the shape

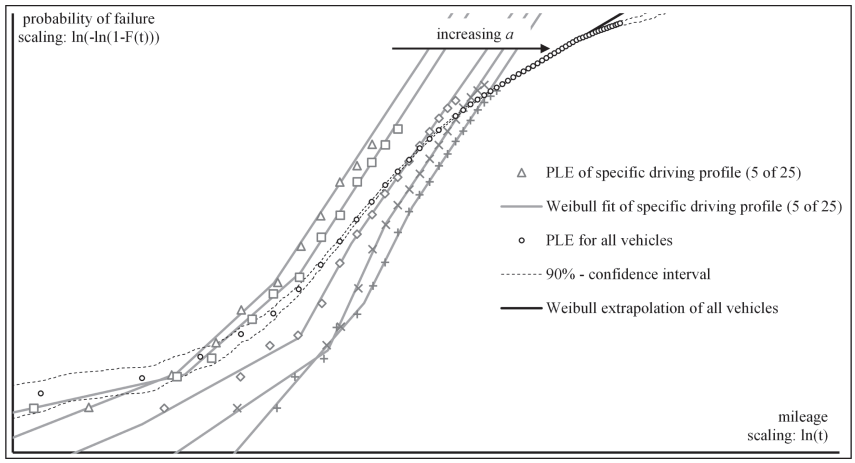

Figure 2. Selected PLE and corresponding mixed Weibull distributions of real data-analysis, plotted in censored WPP.

of the Weibull distribution is changing over mileage or time in service and therefore a fit, using the complete PLE is inaccurate. This makes it convenient to use the PLE itself for all kinds of failure prediction until the last value of the PLE and use for predictions beyond the observable mileage a Weibull extrapolation. This is done under the assumption that the failure behavior is following the slope of the last observations. A Weibull distribution is a straight line, plotted in the WPP, so those values at the end of the PLE are used, which seem to follow the shape of a straight line. In comparison to the univariate PLE, 5 out of the 25 PLE are plotted.

For each of these PLE, a Weibull interpolation was fitted due to lager intervals of the PLE step function in comparison to the univariate PLE. The reason for that is obvious because by splitting the data into 25 disjoint clusters, fewer failures are taken into account for each PLE, leading to lager intervals. Also the last fitted Weibull distribution per cluster was used to extrapolate the failure behavior for further failure predictions. As can be seen in Figure 2, up to three different shape parameters for Weibull distributions are used for the inter- and extrapolation of each PLE, so the changing failure behavior can be taken into account for prediction purposes.

It can be observed that the PLE is consistently moving from the left of the diagram to the right with an increase of the mileage accumulation rate. Please note that the observation was the same for all of the 25 clusters. Some of the PLE intersect at lower mileage where the PLE is less robust. However there was no intersection observed at higher mileage. The shift to the right implies that each driven kilometer of a vehicle tends to be all the more stressful to the analyzed component, the lower the mileage accumulation rate is. Another interesting observation is that the shift seems to be parallel and therefore the mileage accumulation rate apparently does not influence the shape of the failure behavior itself but is an indicator for the intensity of the stress.

The most important fact is revealed by the comparison to the univariate PLE. It does not show a constant shape in terms of a Weibull distribution towards higher mileage, whereas each profile cluster tends to do so. The shape parameter seems to decrease with increasing mileage which leads to an intersection with all the clustered PLE. The explanation is a change in the data structure over mileage and the influence of a on the failure behavior. At low mileage the univariate PLE is taking data of every driving profile according to its weight within the fleet into account. This changes with increasing mileage because at some point those profiles with a low mileage accumulation rate reach their maximum mileage, given the time in service that they had to accumulate mileage. In Figure 2 it can be seen that the mileage of the last observation of each clustered PLE increases with the mileage accumulation rate. This is a case of systematical censoring of high risk vehicles in terms of mileage. The univariate PLE consequently decreases to a failure probability which corresponds to the remaining structure of the data. As mentioned, the PLE is an estimator which considers censoring but assumes random censoring whereas the data is subject to the effect of a specific censoring, due to the influence of the failure behavior. If the data was randomly censored regarding mileage or

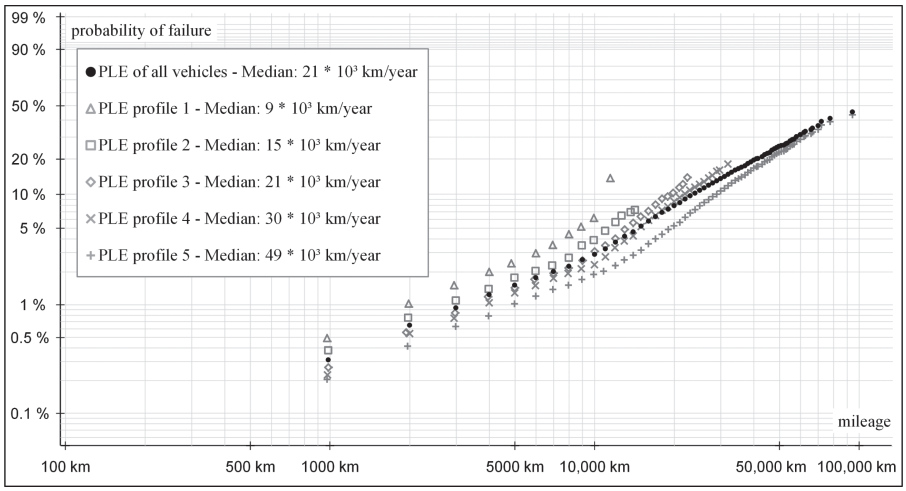

Figure 3. PLE of synthetic data plotted in WPP.

if there was no influence given by a, the standard approach by Kaplan and Meier would estimate the failure probability correctly.

To underline this statement, the assumed influence of the mileage accumulation rate, i.e. a parallel shift to the right for higher values of a, was simulated into the synthetic data set. This data was afterwards analyzed, following the same approach as on the real dataset. Out of simplicity the number of separated clusters was reduced to 5. Figure 3 shows the 5 clustered PLE in comparison to one univariate PLE. The comparison shows quite similar results to the real data set therefore only a few additional remarks are made. The univariate PLE appears to give back an average of the failure probability of the 5 clusters whereas the clusters indicate the underlying variation within the fleet. This average decreases from the point on, when profiles, which tend to have higher failure probabilities, are censored and this censoring is not considered. Hence the failure probability of the univariate PLE does not increase at the same rate anymore and adjusts to the failure behavior of the remaining vehicles. The result is a lower value for beta in comparison to the clustered PLE which all show a similar slope in comparison to each other. This is even more apparent in the synthetic data set but the underlying effect can be assumed to be the same as within the real data.

6 PERFORMANCE COMPARISON TO A UNIVARIATE METHOD

When it comes to measuring the performance of a reliability model, there is no standard approach to be used. One way to handle it is to compare competing models in practical applications, for which the models are going to be used for. This is a very pragmatic method to measure the models performance, but it makes it even more relevant for a reliability expert's daily tasks. The fundamental goal is to find the model which describes the process that leads to a failure as accurately as possible. The model which does it the best should consequently be the model that leads to the better failure prediction. This was done on the real data set by a prediction of the three month timespan following the first year which was analyzed. Only data available at the beginning of these 3 months was used. To illustrate the models' performances, an individual hazard for this prediction interval was estimated for every vehicle that had not failed so far using both models. Afterwards the accumulation of these hazards was compared to the sum of actual observed failures at the end of the three months. The cumulative hazard is a predictor of the total number of failures to expect. Hence if the model's prediction is close to every vehicle's actual hazard, the total number of failures within a fleet should be similar to the fleet's cumulative hazard. Figure 4 shows the results of this comparison. Again it was necessary to partially censor the results. The graphs were generated by sorting the vehicles according to their individual estimated hazard over the prediction interval. The estimation resulting from the bivariate approach is clearly closer to the number of failures in the field while the standard approach underestimates the number of failures by 25%. This can in fact be explained by the continuous decrease of the slope of the univariate PLE towards the last observations. Especially vehicles with a low mileage accumulation are

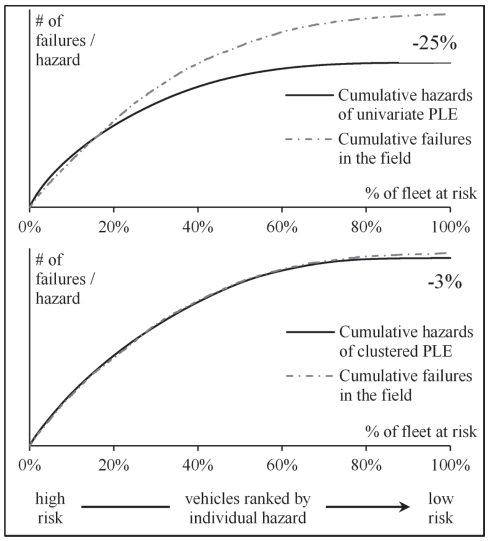

Figure 4. Short term prediction performance on real data.

subject to a systematic underestimation which even starts to increase when these vehicles are no longer part of the PLE due to their censoring. Before the censoring begins, the underestimation is mostly compensated by an overestimation of vehicles with higher mileage accumulation. That is the reason why the univariate PLE's prediction for the total number of failures is still close to number of failures occurred in the field for about the first 20% of the fleet and is below afterwards.

Table 2 shows the results based only on the synthetic data. Only the total number of expected failures and the total number of observed failures are given. In addition to the three month prediction interval, a prediction for two full years of service was added. First of all, the results show that the degree of underestimation increases with the degree of extrapolation. This is an intuitive result that can be inferred from the WPP in Figure 3, where even the vehicles of profile five are exposed to underestimation from some point on, due to the extrapolation of the univariate PLE with a lower slope.

A second performance comparison deals with the situation that an OEM wants to start a campaign in form of a customer satisfaction and cost efficiency by avoiding failures which would otherwise have occurred within the next three months. In case of the univariate, as well as the clustered PLE, the vehicles were selected according to their individual hazard to fail in those three months.

Both models succeed in sorting high-risk vehicles to the top of the selection, as can be seen in the decreasing rate of avoided failures in the field with

Table 2. Failure prediction results on synthetic data.

	3 month period		2 years of service	
Prediction model	# of failures	Deviation in %	# of failures	Deviation in %
Field (simulated)	950	–	34,560	–
Estimation by univariate PLE	828	–12.8	22,984	–33.5
Estimation by clustered PLE	965	+1.6	34,991	+1.2

Table 3. Results of theoretical recalls on synthetic data.

	Univariate PLE	Clustered PLE
# of vehicles for the recall	# of avoided failures	# of avoided failures
5000	176 (3.52%)	186 (3.72%)
10,000	290 (2.90%)	294 (2.94%)
25,000	541 (2.16%)	542 (2.17%)
50,000	776 (1.55%)	797 (1.59%)

an increase of the recall size. The absolute success rate in this performance measurement mostly depends on the timespan that is considered and on the failure probability itself and is thereby no suitable indicator of how well a model works. The reason for both models being similar successful is that the univariate PLE is still able to rank the vehicles well regarding their risk. This is because the effect of the mileage accumulation rate does not outweigh the fact that vehicles with a high a simply drive more total mileage in these three months. The results would be different analyzing a stronger effect by a covariate. Further it can be assumed that the difference between a vehicle's true hazard and the hazard estimated by the univariate PLE is higher in comparison to the clustered PLE. In case of preventive maintenance programs this would be a crucial factor for the program's effectiveness.

7 CONCLUSIONS

This paper highlights several aspects about the connection between the usage of a vehicle, i.e. its driving profile and its reliability. The analyses are limited to automotive data and several specific circumstances of the data were considered which may not be transferred to other industries completely. Nonetheless it can be assumed that with

some adjustments the presented method will lead to similar results in other industries as well. For the case of automotive data it was illustrated that the mileage accumulation rate can have a significant impact on a vehicle's reliability. Also it was shown that this impact leads to related problems if a given influence of driving profiles is ignored. One of the most relevant consequences is a false failure prediction caused by a misleading extrapolation. The data shows a systematic underestimation in case of an increase in the failure probability for decreasing mileage accumulation. Naturally a decreasing failure probability for a decreasing mileage accumulation rate would analogical lead to an overestimation. By using the approach described in this paper which takes the driving profile into account, it was shown that the quality of failure predictions is increased substantially. Further the reliability expert is given a more detailed image of the failure behavior. Consequently this approach can be a valuable input for hypothesis generation to understand the physical process in detail which leads to the failure. In order to measure a general potential of including additional data into the analysis, one assumption was made which does not hold in most of the cases in reliability practice. The analyses were done with data where all necessary information about failed vehicles, as well as not failed vehicles, was available. In practice this data mostly has to be additionally estimated before going into the actual reliability analysis. However the approach can be extended to meet the requirements of this kind of incomplete data by estimating missing information under consideration of the formed clusters. Also the given method allows for several extensions to increase its performance and allow for its applicability with fewer observed failures compared to this example. The authors see great potential in a combination of this approach and the use of parametric models. This way the advantage of analyzing with as less as necessary pre-assumptions can be combined with a parametric model derived from the non-parametric analysis. Parametric models are easier to handle in most applications like failure predictions and also allow for optimization methods like maximum likelihood. Another important improvement would be the possibility to take several covariates into account. In section 3 several approaches were mentioned which already offer this possibility. However some of these methods might demand for some adjustments and extensions to handle the specific structure of automotive data as described by Lawless et al. (1992). This initial approach motivates further research by the illustrated potential and highlighted the importance of extending reliability models, so that all available information is taken into account.

Attempt to apply the theory of reliability to assessment of signalised lane operation

K. Ostrowski
Cracow University of Technology, Poland

ABSTRACT: The paper offers an analysis of the reliability of traffic conditions measures renewable in time at an actual signalised intersection located in Krakow. The left turn lane selected for the empirical studies is notoriously congested during morning and afternoon peaks. The author designed density and reliability functions for a selected measure of traffic conditions, i.e. the proper operation of the lane between 2400 hours until the occurrence of the state of failure. The results of the analyses may be used to complement traffic signals design methodology in congestion conditions, and in modern traffic information systems.

1 INTRODUCTION

City streets and intersections have limited capacity. Capacity is not a constant but a variable whose value varies in line with deterministic factors (lane and roadway width, slope, structure of traffic by vehicle type, speed limits) and random factors (human behaviour, weather conditions). Often in the densely built-up areas of the city it is impossible to increase street or intersection capacity by changing the number of lanes or their width. Growing car ownership means that many of the streets and intersections in the cities are congested. At the same time the development of road infrastructure cannot not keep pace with the growth in car ownership and therefore traffic management methods and tools preventing congestion or minimising its effects are being looked for. In this regard, what is important is the way in which traffic information is communicated to drivers. Currently information conveyance levels are inadequate, with information often quickly becoming outdated as the situation on the road changes instantaneously, depending as it does on the number of vehicles entering the intersection or on weather conditions. In cities, traffic information is communicated mainly through the media, including the radio or websites, such as www.targeo.pl. Out of town, some roads have systems with variable displays informing about trip time needed to pass through sensitive road sections [Saleh 2009]. At present, the information is fed based on historical data for several days or months, or derived from GPS, in which case it is updated, e.g. every two minutes. These systems however often provide information which is too general, and not infrequently unreliable. There is a lack of methods that would enable the provision of real-time traffic information, along with meaningful interpretation of service levels from the viewpoint of drivers and road managers alike [Ostrowski 2010]. There is also a lack of reliable methods to predict short-term traffic condition such as 15 or 30 minutes in advance.

Often commuters encounter intersections which operate near capacity limits and do not know when they will experience unacceptable traffic conditions. There are days where they drive through such intersections without major disruption and days on which they do not accept adverse traffic conditions, which can be expressed by means of a variety of measures including delays, queues, stops etc. [Chodur 2004]. For each driver the ability to estimate the likelihood of favourable traffic conditions at the time of departure and select the best route is extremely important in terms of minimizing trip time. The aim of this paper is to show the application of elements of reliability theory to the description of the functioning of a lane with a left turn at a signalised intersection in Krakow over several successive working days in favourable weather conditions. The analysis will cover 24-hour periods and record moments in time in which there were adverse traffic conditions from the viewpoint of drivers. Lane's functioning is associated with the level and quality of service and is renewable in time. The concept of renewal in this case is directly related to theoretical renewal, when a renewed object reveals the same reliability as directly before the overload.

2 REVIEW OF PERTINENT LITERATURE

The concept of an object's reliability relates to objects which are either renewable or non-renewable in time [Słowiński 1999]. An object's reliability

means the probability that the object will be usable (efficient) during a given period (t_i, t_{i+1}). In reality, we encounter object with finite durability (e.g. light bulb, battery) or objects whose correct operation in time entails periodic renewals, i.e. repair (e.g. car, washing machine) until they reach durability and disrepair. Figure 1 presents sample of simple theoretical renewal process [Słowiński 1999].

The specificity of the operation of such objects as an intersection in conditions of congestion differs considerably from the operation of e.g. steel or reinforced concrete structures in terms of the effects of overload because once a queue of vehicles has dissipated, the intersection resumes normal operation in conditions of lesser traffic.

The concept of an object's renewal may refer to either theoretical renewal, in which case the object enjoys the same reliability as it did prior to the failure or to practical renewal when the object can resume operation after a prior loss of its operability [Migdalski 1982].

With respect to signalised intersections and the quality of service the picture is similar [Faragó 2006]. The proper operation of traffic signals usually occurs during periods when demand flows are below capacity ($Q < C$). These periods typically are between-peak spans of time or traffic peaks at under-loaded intersections. Research into the reliability of technical objects which are non-renewable in time has been conducted for many years, and its results are used in the planning of repairs, replacement of worn parts in order to reduce machine downtime and ensure continuity of production as well as to ensure the safety of operation and supply [Kołowrocki 2013]. Noteworthy are both theoretical works [Nowakowski 2009] which seek to use new theoretical methods e.g. in processes such as maintenance of technical [Jodejko-Pietruczuk 2014] and transport systems [Kowalski 2011] as well as works of a practical nature in many areas of science and operation [Babiarz 2006 and 2014]. Recently researchers have undertaken work on the reliability of complex technical objects [Cambridge Systematics 2005], such as intersection or road sections mainly to analyse travel time on road sections [Brilon 2007, Park 2007, Lam 2008, Adachi 2009, Mehran 2011, Taylor 2013] and in network of streets with signalised intersections [Lo 2006, Lam 2010]. A small number of publications relates to the analysis of functional reliability of renewable traffic conditions at entries to intersections in various traffic [Chen 2008] and weather conditions [Lam 2008, Ostrowski 2010, Tracz 2012]. Studies generally are limited to the analysis of headways between vehicles [Hung 2003, Chodur 2011, Kumar 2014] and capacity and measures of traffic conditions [Akçelik 1999, Gartner 2004, Chodur 2006 and 2011, Teply 2008, HCM 2010]. This article complements knowledge in the research field relating to the use of signalised intersections. Knowledge of the operational reliability of intersections and road sections can be used to keep drivers informed about the state of congestion and travel time (ITS equipment, variable message signs [Saleh 2009, Konior 2012]).

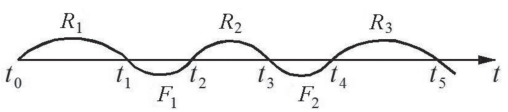

Figure 1. Renewal process (R_i—time periods of proper lane functioning, F_i—failure periods).

3 DESCRIPTION OF THE RESEARCH SITE

The study was conducted on a specially selected congested intersection in Krakow, on a lane carrying left-bound traffic (Fig. 2). The intersection is located along a dual carriageway named Powstańców Wielkopolskich, whisking traffic from the south of Krakow to its north (towards Krakow's Third Ring Road). The left turn under analysis is located on the side leading to the town of Skawina and takes traffic towards the city centre, i.e. towards ul. Limanowskiego. During peak hours the lane sustains long queues of vehicles and drivers wait a long time until exit from the intersection, incurring significant loss of time. During off-peak hours the intersection and the lane function adequately in good traffic conditions. The intersection is controlled by accommodative traffic lights, adapting their parameters to existing traffic needs.

The green signal allocated to the lane is very short relative to the length of the cycle. During the

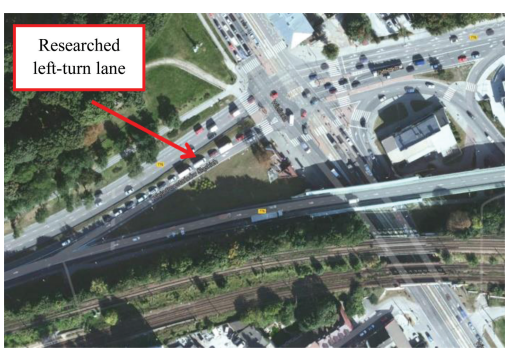

Figure 2. Location of the research site i.e. of a lane with left-bound traffic at the entry to the intersection of Powstańców Śląskich and Wielicka streets [www.google.pl].

green signal lasting an average of 10 s, an average of 130 vehicles exits the intersection in one hour peak traffic. Other vehicles (residual queue) are forced to wait in a queue at a red signal, whose average length is 140 s. According to www.targeo.pl (Fig. 3) the adverse functioning of the lane is well reflected in the colours describing the speed of a moving vehicle at the exit from the intersection.

3.1 *Capacity and traffic conditions at the intersection*

The author has conducted numerous empirical studies into capacity and traffic conditions on the lane, including surveys of drivers' feelings about the quality of the traffic conditions. In analytical methods for signalised intersections [Chodur 2004, Teply 2008, HCM 2010], the assessment of traffic conditions relies on the concept of service levels, which define the best (LOS I) and the worst traffic conditions (LOS IV). These qualitative measures result from analysis of quantitative measures of traffic conditions, i.e. delay. The methods give boundary values of delay for LOS IV, beyond which traffic conditions are considered to be unacceptable. In the Polish method [Chodur 2004] LOS IV is reached once the average delay exceeds to 80 s/P.

Field research into delay and queue (residual and maximum) length variability conducted in major cities shows that drivers are often forced to accept much worse traffic conditions, and consequently become accustomed to inconvenience. Polish studies also corroborate German research [Brilon 2008] in which service level F is divided into four sub-levels that can be used in the design of intersections in states of traffic saturation in major cities. Figure 4 shows the results of a survey of drivers who travel frequently through the given intersection. The results are combined with empirical research into variability of the delay of approaching and queued vehicles until they exit

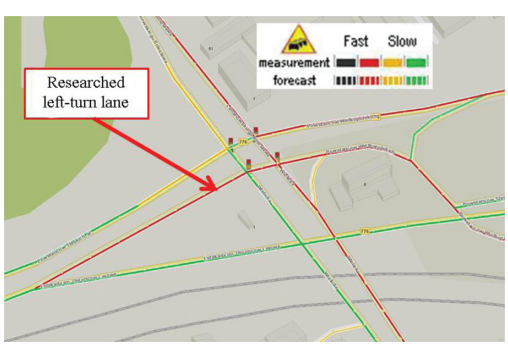

Figure 3. Congestion at the intersection during the morning hours of a working day [www.targeo.pl].

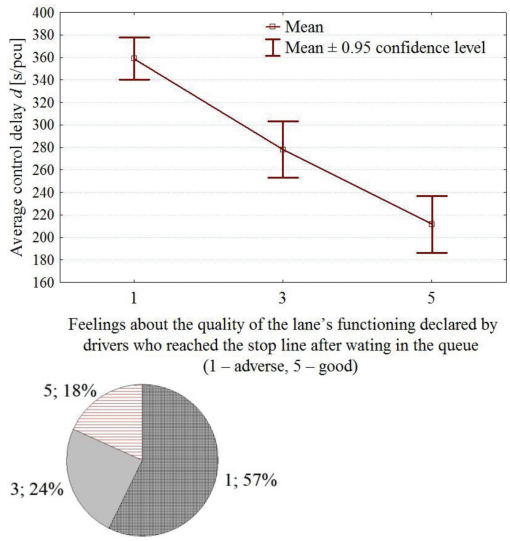

Figure 4. Survey results and average delay on the lane.

the intersection. Analyses conducted on the lane indicate that many drivers (approx. 18%) consider traffic conditions to be adequate when the average delay is approximately 210 seconds. 24% of the respondents deem traffic conditions to be average when the average delay is 280 seconds. The result is surprising if we apply the values obtained to the boundary average delay used in the analytical methods. It should be noted that the result refers to a single lane and may be different for other intersections located in other parts of the city, and for other control parameters.

The above description of the operation of the lane shows the average delay values at which drivers perceive the traffic conditions on the lane to be unreliable. Road managers may have a slightly different perception on the functioning of this lane. At the design stage, it may be difficult, for numerous reasons, to design satisfactory traffic conditions on the lane. The intersection carried and continues to carry a very large volume of traffic, approaching and sometimes exceeding its capacity. Hence, the selection of control parameters at the design stage is extremely difficult, and the accommodative signals used in congestion bring little relief. Hence, the road manager can use three approaches, in which the terms and conditions he considers as unreliable arise when:

Option (1): demand flow exceeds capacity and short residual queue develop, evidencing traffic overload. This option if highly favourable for drivers because the road manager does not accept the formation of queues and drivers experience small delays.

Option (2): average delays exceed the boundary value of 80 [s/pcu] [Chodur 2004] or another higher value—Figure 4. This option is rather unfavorable for vehicle drivers, because the road manager allows some congestion and considerable delays.
Option (3): queue exceeds the critical length in terms of the functioning of the road network and traffic safety. On the entry to intersection the queue must not extend further than the place at which vehicle routes fork into those which go to the overpass and those that lead to the intersection. The option is unfavorable for drivers, as the road manager ignores the significant level of delay.

Based on the above analysis, the paper presents reliability functions for the operation of the lane until two critical states are reached, i.e. when the average delay is 280 seconds and 360 seconds (Fig. 4), and the length of residual queues amounts to 7 and 10 vehicles (option 2).

4 EMPIRICAL RESEARCH AND STATISTICAL ANALYSES

The study into lane reliability consisted in recording the time needed by the residual queue to reach the assumed critical value of 7 and 10 vehicles and persist for at least 2 consecutive signal cycles. After the critical length of residual queues is exceeded, drivers consider traffic conditions, including the length of delay, to be unreliable. Control parameters (duration of the red and green signals) did not change significantly during the morning and afternoon peaks under analysis, and therefore their impact on traffic conditions was negligible. The study at the intersection was conducted over 100 working days in similar weather conditions, for dry surface between 500 to 2000 hours. Weather conditions' adverse effect of on throughput and traffic conditions was shown in a paper titled [Tracz & Ostrowski 2012].

Drawing on the variable values of the proper functioning of lane t_p obtained during the study period i.e. over 100 working days the author built empirical distributions, to which he fitted the following theoretical distributions: normal, log-normal, Gumbel, gamma, and Weibull. In the analysis the author used the Kolmogorov-Smirnov compatibility test ($\alpha = 0.05$), and Chi-square, which revealed two theoretical distributions that best describe the variability of the test measure, i.e. gamma and Weibull distributions (Figs. 5 and 6). These distributions are commonly used in reliability theory analysis [Rao 1992, Gertsbakh 2005].

Below are time periods density functions of the lane's proper operation t_p until the occurrence of a failure (Chapter 4), shown separately for the morning and the afternoon.

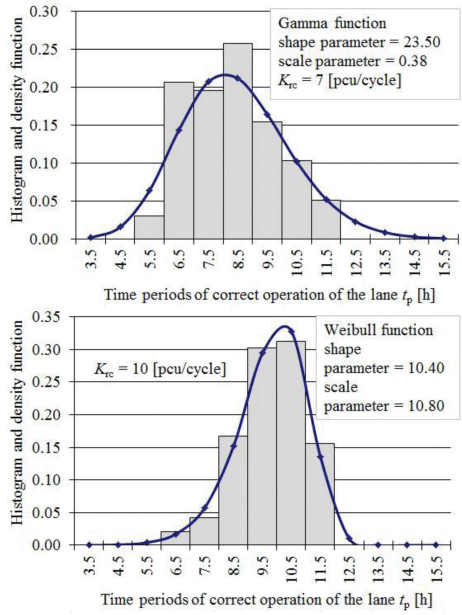

Figure 5. Density functions of the time periods of proper lane functioning until the occurrence of a failure at critical remaining queues of 7 and 10 vehicles in the morning (until 1200 hours; from 2400 to 1200 hours).

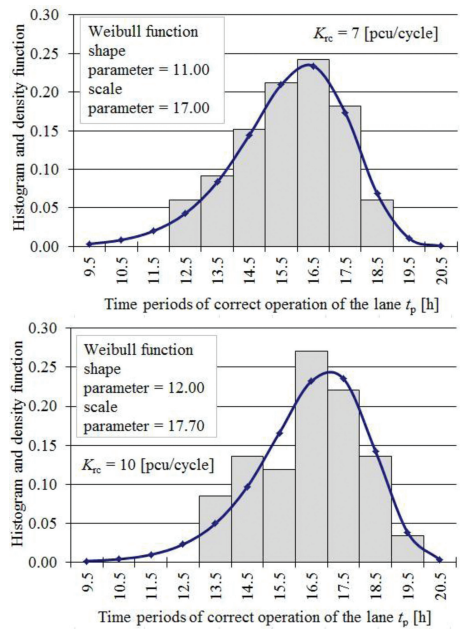

Figure 6. Density functions of the time periods of proper lane functioning until the occurrence of a failure at critical remaining queues of 7 and 10 vehicles in the afternoon (after 1200 hours).

Next, drawing on a set of determined theoretical density functions $f(t_p)$ describing the variability of the traffic conditions measure t_p one can determine reliability functions $R(t_p)$, failure function $F(t_p)$ and the renewal intensity function $\lambda_{int}(t_p)$ for its/the measure's value. In reliability theory, the proper construction and interpretation of the above reliability characteristics requires that the term "failure" be defined in relation to the unit of the analysed measure which is variable in time. In the case of time periods t_p "failure" is the case when time periods t_p of the proper functioning of the lane until occurrence of the critical length of the residual queue K_{rc} are greater then t_{pcr}. If $t_p \leq t_{pcr}$, it can be concluded that service will be reliable.

Pertinent literature [Słowiński 1999, Gertsbakh 2005] offers general formulas and ready-made procedures that can apply to both the assessment of reliability of a non-renewable object, and an object which is renewable in time. The following are reliability characteristics of measure t_p assuming that $t_p > 0$.

$$R(t_p) = P(t_{pcr} \geq t_p), \quad (1)$$

$$F(t_p) = 1 - R(t_p) \quad (2)$$

5 RELIABILITY MODELS OF LANE OPERATION

In reliability analyses of lane group operation it is key to determine boundary traffic conditions at which a transition from reliability to failure occurs. Reliability status covers the period of time in which the intersection operates without problems, i.e. when traffic intensity Q is less than capacity C (usually between peak periods or in night-time conditions). During traffic peak periods entries to intersections can also function reliably when traffic intensity is low and delays are accepted by all drivers. Where traffic intensity Q is close to or exceeds capacity C the conditions at entries to the intersection are characterized by failure and long and unacceptable queues and delays. On the lane in question unreliability occurred both in morning and afternoon peaks (Table 1).

The following graphs show the reliability functions of the proper operation time periods of the lane t_p until the occurrence of critical lengths of residual queues totalling 7 and 10 vehicles. Critical residual queues are associated with critical values of average delay, whose values are shown in Chapter 4.

The analyses show that in the morning drivers who do not accept significant delays and long queues should pass through the intersection as early as possible. The probability that they will then find reliable (acceptable) traffic conditions on the lane is the highest. Comparison of the operation of the lane at a previously assumed reliability level of 0.9 between the two K_{rc} clearly indicates that the boundary value of time t_{pcr} is 5.5 (until 530 hours) for a curve describing failure at $K_{rc} = 7$ [pcu/cycle] and 7.75 (until 745 hours) for $K_{rc} = 10$ [pcu/cycle]. The analysis shows a significant discrepancy in the course of the reliability curves of time periods of correct operation of the lane t_p in the morning between the two cases of K_{rc} under analysis. These differences arise from the variability of demand flow on the lane. In the morning, when most people commute to work, demand flow is less distributed over time compared to the afternoon peak. Figure 5 clearly indicates a greater range of variability at $K_{rc} = 7$ [pcu/cycle] and a shift in modal values.

Krakow's afternoon peak takes much longer than the morning peak, hence the reliability curves run closer to each other (Fig. 8), and the dispersal of results is similar in both cases of Krc. At the assumed reliability level of 0.9, the difference in the boundary value of time t_{pcr} is much smaller than in the morning peak and stands at 0.75 (45 mins). Thus, the probability of encountering worse traffic conditions than those at $K_{rc} = 7$ [pcu/cycle] is much higher. Figure 8 shows that in the afternoon e.g.

Table 1. Number of working days when the lane operated under conditions of failure (out of a total of 100 days).

	When failure is characterised by queue K_{rc}= 7 [pcu/cycle]	When failure is characterised by queue K_{rc}= 10 [pcu/cycle]
Morning peaks	86 days	50 days
Afternoon peaks	79 days	32 days

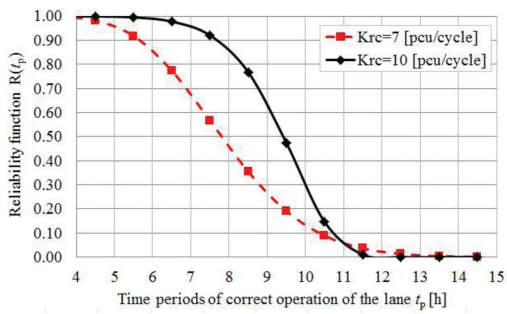

Figure 7. Reliability functions of time periods of correct operation of the lane t_p until occurrence of failure in the morning (until 1200 hours; from 2400 to 1200 hours).

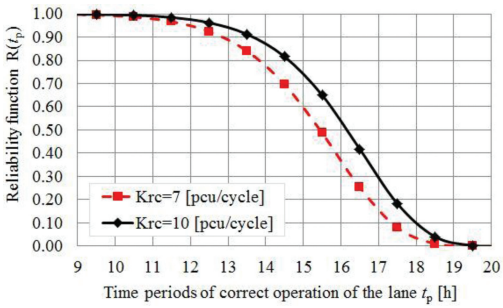

Figure 8. Reliability functions of time periods of correct operation of the lane t_p until occurrence of failure in the afternoon (after 1200 hours).

until 1500 hours drivers enjoy reliable (acceptable) traffic conditions on the lane, and a probability of 60% of drivers in the group accepting queue lengths no longer than K_{rc} = 7 [pcu/cycle] and delays no greater than d = 280 [s/pcu]. For less demanding drivers accepting a longer queue and greater delay (K_{rc} = 10 [pcu/cycle] and d = 360 [s/pcu]) the probability of encountering reliable (acceptable) traffic conditions will stand at 75%.

6 CONCLUSIONS

The analyses performed in the paper lead to the following conclusions:

- Lane operation is renewable in time. It may be assessed by both drivers who mainly consider the quality of traffic conditions and by road managers who are also interested in the impact of adverse traffic conditions on the operation of the adjacent road network;
- The author's surveys of drivers conducted to enquire about the quality of traffic conditions indicate that level IV of service [Chodur 2004] may be further subdivided. Bearing that in mind more extensive research would be needed to determine drivers' acceptance of adverse weather conditions in major cities. In the paper the author uses selected surveys to determine the beginning of two states of failure defined by means of average delay and related lengths of residual queues (K_{rc} = 7 [pcu/cycle] and K_{rc} = 10 [pcu/cycle]);
- The time periods of correct operation of the lane t_p until the occurrence of failure is highly important to drivers and helps them plan their daily commute routes;
- Reliability curves relating to values of time periods of correct operation of the lane t_p help determine the probability of the occurrence of lane service which is reliable (acceptable) to drivers;
- The introduction of several classes of service quality (e.g. by means of K_{rc}) allows describing drivers' expectations of the quality of traffic conditions at the intersection. This approach allows dividing drivers on account of the level of overload acceptance;
- If road managers define and determine service quality classes (e.g. by means of K_{rc}) determining the beginning of the occurrence of failure for lane groups at signalised intersections, this will allow them to control intersections in overload states;
- The introduction of critical lengths of residual queues K_{rc} (service quality classes) allows modelling of congestion duration.

Reliability-exploitation analysis of power supply in transport telematics system

A. Rosiński
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: Issues concerning reliability-maintenance of power-supply for transport telematics systems were presented in this paper. Relationships graph was presented, and then Chapman–Kolmogorov system of equations was derived to describe it. Drawing on those equations, relationships for calculating function of probability of system staying in state of full ability S_{PZ}, state of the impendency over safety S_{ZB1} and S_{ZB2} as well as state of unreliability of safety S_B were derived.

1 INTRODUCTION

The term "telematics" comes from the French (fr. *télématique*). In the literature it began to appear at the beginning of the seventies of the twentieth century. It is a combination of two French words: telecommunications (fr. *télécommunications*) and informatics (fr. *informatique*). In the English vocabulary it began to be used only in the late seventies of the twentieth century, however, it was not widely used. It was not until the start of the European Union EU programs for the development of telematics in various fields, caused that the term began to be used more frequently. This period falls in the nineties. Today, the term "telematics" describes a field of science that integrates telecommunications and IT solutions.

The term is used where such a combination may be beneficial compared with dedicated solutions (including synergies achieved). It can highlight several areas in which it operates:

– transport telematics,
– medical telematics,
– environment telematics,
– telematics urban,
– financial telematics,
– library telematics,
– operational telematics,
– industries telematics,
– home telematics,
– post telematics.

Among these areas of telematics applications, one of the largest and fastest-growing (both in Poland and in Europe and in the world) is the transport. Issues relating to transport telematics appeared in Polish publications in the mid-nineties of 20th century. Transport telematics was consequently defined as a field of knowledge and technical activity integrating IT with telecommunications, in applications addressed to transport systems' needs [Kasprzyk 2012, Laskowski & Łubkowki 2013, Siergiejczyk & Paś & Rosiński 2012, Sumila 2012].

Transport telematics systems work in different exploitation conditions [Duer & Zajkowski & Duer & Paś 2012, Dyduch & Paś & Rosiński 2011, Paś & Duer 2012]. As the elements of critical infrastructure they should maintain their suitability [Bajda & Wrażeń & Laskowski 2011]. One of the main problems is to ensure the continuity of supply of transport telematics systems So far it has been provided the reliability analysis of the system structures [Rosinski & Dabrowski 2013, Siergiejczyk & Rosinski 2011, Siergiejczyk & Rosinski 2011], however, it is also important to analyze the power supply relations in the system. Therefore, such an important role play the analyze of this issue.

The reliability theory in respect of general considerations has had sound footing for many years [Będkowski & Dąbrowski 2006, Epstein & Weissman 2008, Verma & Ajit & Karanki 2010]. The scope of the operation of power systems can provide the following publications [Keyhani & Marwali 2011, Soliman & Mantawy 2012]. Issues related to the reliability in power supply systems are presented in the books [Billinton & Allan 1996, Sozański 1990]. The use of the reserve power sources are presented in publications [Wiatr & Miegoń 2008, Wiatr 2009].

2 ANALYSIS OF POWER SUPPLY MAINTENANCE

In order for transport telematics systems to function properly, they require that each device

constituting the system is powered correctly. Power cut off leads to full or partial system failure. Hence, usually two power supplies are used. First one is the basic supply. If it fails, the reserve power supply starts running to keep the device powered up.

Structural sketch of the power supply system, comprising the two independent energy sources, addressed to transport telematics system is shown in Figure 1.

Figure 2 illustrates relationships within the transport telematics system, based on the exploitation-reliability analysis of dedicated power supply systems.

The state of full ability S_{PZ} is a state in which the properly functioning both power sources (both primary and reserve). State of the impendency over safety S_{ZB1} is a state in which the basic power supply is unsuitable. State of the impendency over safety S_{ZB2} is a state in which the reserve power supply is unsuitable. State of unreliability of safety S_B is a state in which the two power sources are unsuitable.

If the system is in state of full ability S_{PZ} and there occur the damage of the basic power supply that takes the system to the state the impendency over safety S_{ZB1} with intensity λ_{ZB1}. If the system is in the state the impendency over safety S_{ZB1} it is possible to come back to state of full ability S_{PZ} under condit6ion of providing the action to restore the state of full ability of the basic power supply.

When the system is in the state of the impendency over safety S_{ZB1} and additionally there occur damage to the reserve power supply, the system is a transition to state of unreliability of safety S_B with intensity λ_{B1}. Backlinks transition from the state of unreliability of safety S_B to the state of the impendency over safety S_{ZB1} is possible only if there are taken actions of bringing back the state of full ability of the reserve power supply.

If the system is in state of full ability S_{PZ} and there occur the damage of the reserve power supply that takes the system to the state the impendency over safety S_{ZB2} with intensity λ_{ZB2}. If the system is in the state the impendency over safety S_{ZB2} it is possible to come back to state of full ability S_{PZ} under condit6ion of providing the action to restore the state of full ability of the reserve power supply.

When the system is in the state of the impendency over safety S_{ZB2} and additionally there occur damage to the basic power supply, the system is a transition to state of unreliability of safety S_B with intensity λ_{B2}. Backlinks transition from the state of unreliability of safety S_B to the state of the impendency over safety S_{ZB2} is possible only if there are taken actions of bringing back the state of full ability of the basic power supply.

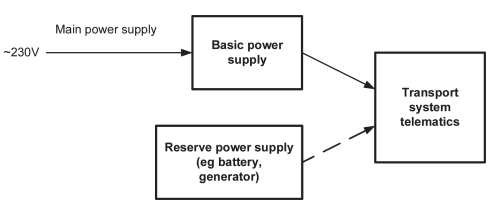

Figure 1. Basic and reserve power supply.

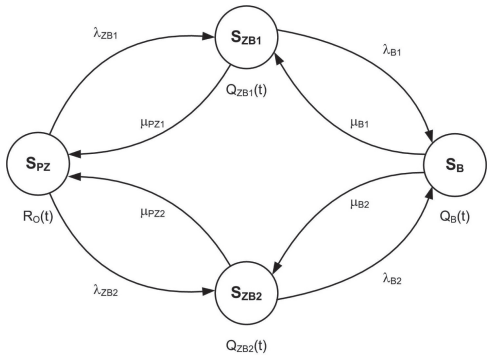

Figure 2. Relationships in the power supply system.
Denotations in figures:
$R_O(t)$—the function of probability of system staying in state of full ability S_{PZ},
$Q_{ZB1}(t)$—the function of probability of system staying in state of the impendency over safety S_{ZB1},
Q_{ZB2}(t)—the function of probability of system staying in state of the impendency over safety S_{ZB2},
$Q_B(t)$—the function of probability of system staying in state of unreliability of safety S_B,
λ_{ZB1}—transition rate from the state of full ability S_{PZ} into the state of the impendency over safety S_{ZB1},
λ_{ZB2}—transition rate from the state of full ability S_{PZ} into the state of the impendency over safety S_{ZB2},
μ_{PZ1}—transition rate from the state of the impendency over safety S_{ZB1} into the state of full ability S_{PZ},
μ_{PZ2}—transition rate from the state of the impendency over safety S_{ZB2} into the state of full ability S_{PZ},
λ_{B1}—transition rate from the state of the impendency over safety S_{ZB1} into the state of unreliability of safety S_B,
λ_{B2}—transition rate from the state of the impendency over safety S_{ZB2} into the state of unreliability of safety S_B,
μ_{B1}—transition rate from the state of unreliability of safety S_B into the state of the impendency over safety S_{ZB1},
μ_{B2}—transition rate from the state of unreliability of safety S_B into the state of the impendency over safety S_{ZB2}.

The system illustrated in Figure 2 may be described by the following Chapman–Kolmogorov equations:

$$\begin{aligned}
R_0'(t) &= -\lambda_{ZB1}\cdot R_0(t) + \mu_{PZ1}\cdot Q_{ZB1}(t) \\
&\quad -\lambda_{ZB2}\cdot R_0(t) + \mu_{PZ2}\cdot Q_{ZB2}(t) \\
Q_{ZB1}'(t) &= \lambda_{ZB1}\cdot R_0(t) - \mu_{PZ1}\cdot Q_{ZB1}(t) \\
&\quad -\lambda_{B1}\cdot Q_{ZB1}(t) + \mu_{B1}\cdot Q_B(t) \\
Q_{ZB2}'(t) &= \lambda_{ZB2}\cdot R_0(t) - \mu_{PZ2}\cdot Q_{ZB2}(t) \\
&\quad -\lambda_{B2}\cdot Q_{ZB2}(t) + \mu_{B2}\cdot Q_B(t) \\
Q_B'(t) &= \lambda_{B1}\cdot Q_{ZB1}(t) + \lambda_{B2}\cdot Q_{ZB2}(t) \\
&\quad -\mu_{B1}\cdot Q_B(t) - \mu_{B2}\cdot Q_B(t)
\end{aligned} \tag{1}$$

Given the initial conditions:

$$\begin{aligned}
&R_0(0) = 1 \\
&Q_{ZB1}(0) = Q_{ZB2}(0) = Q_B(0) = 0
\end{aligned} \tag{2}$$

Laplace transform yields the following system of linear equations:

$$\begin{aligned}
s\cdot R_0^*(s) - 1 &= -\lambda_{ZB1}\cdot R_0^*(s) + \mu_{PZ1}\cdot Q_{ZB1}^*(s) \\
&\quad -\lambda_{ZB2}\cdot R_0^*(s) + \mu_{PZ2}\cdot Q_{ZB2}^*(s) \\
s\cdot Q_{ZB1}^*(s) &= \lambda_{ZB1}\cdot R_0^*(s) - \mu_{PZ1}\cdot Q_{ZB1}^*(s) \\
&\quad -\lambda_{B1}\cdot Q_{ZB1}^*(s) + \mu_{B1}\cdot Q_B^*(s) \\
s\cdot Q_{ZB2}^*(s) &= \lambda_{ZB2}\cdot R_0^*(s) - \mu_{PZ2}\cdot Q_{ZB2}^*(s) \\
&\quad -\lambda_{B2}\cdot Q_{ZB2}^*(s) + \mu_{B2}\cdot Q_B^*(s) \\
s\cdot Q_B^*(s) &= \lambda_{B1}\cdot Q_{ZB1}^*(s) + \lambda_{B2}\cdot Q_{ZB2}^*(s) \\
&\quad -\mu_{B1}\cdot Q_B^*(s) - \mu_{B2}\cdot Q_B^*(s)
\end{aligned} \tag{3}$$

Probabilities of system staying in a distinguished functional states in symbolic (Laplace) terms have the following form:

$$\begin{aligned}
&R_0^*(s) \\
&= -\frac{\begin{array}{l} b_1\cdot b_2\cdot s + b_1\cdot b_2\cdot \mu_{B1} + b_1\cdot b_2\cdot \mu_{B2} \\ -b_2\cdot \lambda_{B1}\cdot \mu_{B1} - b_1\cdot \lambda_{B2}\cdot \mu_{B2} \end{array}}{\begin{array}{l} a\cdot b_2\cdot \lambda_{B1}\cdot \mu_{B1} - a\cdot b_1\cdot b_2\cdot \mu_{B1} - a\cdot b_1\cdot b_2\cdot \mu_{B2} \\ -a\cdot b_1\cdot b_2\cdot s + a\cdot b_1\cdot \lambda_{B2}\cdot \mu_{B2} + b_2\cdot s\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot s\cdot \lambda_{ZB2}\cdot \mu_{PZ2} + b_2\cdot \mu_{B1}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot \mu_{B1}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} + b_2\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot \mu_{B2}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} - \lambda_{B1}\cdot \mu_{B1}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} \\ +\lambda_{B1}\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ2} + \lambda_{B2}\cdot \mu_{B1}\cdot \mu_{PZ1}\cdot \lambda_{ZB2} \\ -\lambda_{B2}\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \end{array}}
\end{aligned}$$

$$\begin{aligned}
&Q_{ZB1}^*(s) \\
&= -\frac{\begin{array}{l} b_2\cdot s\cdot \lambda_{ZB1} + b_2\cdot \mu_{B1}\cdot \lambda_{ZB1} + b_2\cdot \mu_{B2}\cdot \lambda_{ZB1} \\ +\lambda_{B2}\cdot \mu_{B1}\cdot \lambda_{ZB2} - \lambda_{B2}\cdot \mu_{B2}\cdot \lambda_{ZB1} \end{array}}{\begin{array}{l} a\cdot b_2\cdot \lambda_{B1}\cdot \mu_{B1} - a\cdot b_1\cdot b_2\cdot \mu_{B1} - a\cdot b_1\cdot b_2\cdot \mu_{B2} \\ -a\cdot b_1\cdot b_2\cdot s + a\cdot b_1\cdot \lambda_{B2}\cdot \mu_{B2} + b_2\cdot s\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot s\cdot \lambda_{ZB2}\cdot \mu_{PZ2} + b_2\cdot \mu_{B1}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot \mu_{B1}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} + b_2\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot \mu_{B2}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} - \lambda_{B1}\cdot \mu_{B1}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} \\ +\lambda_{B1}\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ2} + \lambda_{B2}\cdot \mu_{B1}\cdot \mu_{PZ1}\cdot \lambda_{ZB2} \\ -\lambda_{B2}\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \end{array}}
\end{aligned}$$

$$\begin{aligned}
&Q_{ZB2}^*(s) \\
&= -\frac{\begin{array}{l} b_1\cdot s\cdot \lambda_{ZB2} + b_1\cdot \mu_{B1}\cdot \lambda_{ZB2} + b_1\cdot \mu_{B2}\cdot \lambda_{ZB2} \\ +\lambda_{B1}\cdot \mu_{B2}\cdot \lambda_{ZB1} - \lambda_{B1}\cdot \mu_{B1}\cdot \lambda_{ZB2} \end{array}}{\begin{array}{l} a\cdot b_2\cdot \lambda_{B1}\cdot \mu_{B1} - a\cdot b_1\cdot b_2\cdot \mu_{B1} - a\cdot b_1\cdot b_2\cdot \mu_{B2} \\ -a\cdot b_1\cdot b_2\cdot s + a\cdot b_1\cdot \lambda_{B2}\cdot \mu_{B2} + b_2\cdot s\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot s\cdot \lambda_{ZB2}\cdot \mu_{PZ2} + b_2\cdot \mu_{B1}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot \mu_{B1}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} + b_2\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot \mu_{B2}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} - \lambda_{B1}\cdot \mu_{B1}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} \\ +\lambda_{B1}\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ2} + \lambda_{B2}\cdot \mu_{B1}\cdot \mu_{PZ1}\cdot \lambda_{ZB2} \\ -\lambda_{B2}\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \end{array}}
\end{aligned}$$

$$\begin{aligned}
&Q_B^*(s) \\
&= -\frac{b_2\cdot \lambda_{B1}\cdot \lambda_{ZB1} + b_1\cdot \lambda_{B2}\cdot \lambda_{ZB2}}{\begin{array}{l} a\cdot b_2\cdot \lambda_{B1}\cdot \mu_{B1} - a\cdot b_1\cdot b_2\cdot \mu_{B1} - a\cdot b_1\cdot b_2\cdot \mu_{B2} \\ -a\cdot b_1\cdot b_2\cdot s + a\cdot b_1\cdot \lambda_{B2}\cdot \mu_{B2} + b_2\cdot s\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot s\cdot \lambda_{ZB2}\cdot \mu_{PZ2} + b_2\cdot \mu_{B1}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot \mu_{B1}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} + b_2\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \\ +b_1\cdot \mu_{B2}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} - \lambda_{B1}\cdot \mu_{B1}\cdot \lambda_{ZB2}\cdot \mu_{PZ2} \\ +\lambda_{B1}\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ2} + \lambda_{B2}\cdot \mu_{B1}\cdot \mu_{PZ1}\cdot \lambda_{ZB2} \\ -\lambda_{B2}\cdot \mu_{B2}\cdot \lambda_{ZB1}\cdot \mu_{PZ1} \end{array}}
\end{aligned} \tag{4}$$

where:

$$\begin{aligned}
a &= s + \lambda_{ZB1} + \lambda_{ZB2} \\
b_1 &= s + \mu_{PZ1} + \lambda_{B1} \\
b_2 &= s + \mu_{PZ2} + \lambda_{B2}
\end{aligned}$$

Solution to the above set of equations in the time domain is the next step in the analysis and is not discussed here.

3 MODELLING OF PROCESS OF POWER SUPPLY MAINTENANCE

Computer simulation and computer-aided analysis facilitate to relatively quickly determine the influence of change in reliability-exploitation parameters of individual components on reliability of the entire system. Of course, the reliability structure of both the entire system and its components has to be known beforehand.

Using computer aided allows to perform the calculation of the value of probability of system staying in state of full operational capability R_O. That procedure is illustrated with below example.

Example

The following quantities were defined for the system:

– test duration—1 year (values of this parameter is given in [h]):

$$t = 8760 \ \left[\mathrm{h}\right]$$

– reliability of basic power supply:

$$R_{ZB1}(t) = 0{,}949$$

– reliability of reserve power supply:

$$R_{ZB2}(t) = 0{,}991$$

– transition rate from the state of the impendency over safety S_{ZB1} into the state of unreliability of safety S_B (failure of reserve power supply):

$$\lambda_{B1} = 0{,}000001$$

– transition rate from the state of the impendency over safety S_{ZB2} into the state of unreliability of safety S_B (failure of basic power supply):

$$\lambda_{B2} = 0{,}000006$$

– transition rate from the state of unreliability of safety S_B into the state of the impendency over safety S_{ZB1}:

$$\mu_{B1} = 0{,}1$$

– transition rate from the state of unreliability of safety S_B into the state of the impendency over safety S_{ZB2}:

$$\mu_{B2} = 0{,}1$$

Knowing the value of reliability $R_{ZB1}(t)$, transition rate from the state of full ability into the state of the impendency over safety S_{ZB1} may be estimated. Provided the up time is described by exponential distribution, the following relationship can be used:

$$R_{ZB1}(t) = e^{-\lambda_{ZB1} t} \text{ for } t \geq 0$$

thus

$$\lambda_{ZB1} = -\frac{\ln R_{ZB1}(t)}{t}$$

For $t = 8760 \ \left[\mathrm{h}\right]$ and $R_{ZB1}(t) = 0{,}949$ we obtain:

$$\lambda_{ZB1} = -\frac{\ln R_{ZB1}(t)}{t} = -\frac{\ln 0{,}949}{8760} = 0{,}000006\left[\frac{1}{\mathrm{h}}\right]$$

Knowing the value of reliability $R_{ZB2}(t)$, transition rate from the state of full ability into the state of the impendency over safety S_{ZB2} may be estimated. Provided the up time is described by exponential distribution, the following relationship can be used:

$$R_{ZB2}(t) = e^{-\lambda_{ZB2} t} \text{ for } t \geq 0$$

thus

$$\lambda_{ZB2} = -\frac{\ln R_{ZB2}(t)}{t}$$

For $t = 8760 \ \left[\mathrm{h}\right]$ and $R_{ZB2}(t) = 0{,}991$ we obtain:

$$\lambda_{ZB2} = -\frac{\ln R_{ZB2}(t)}{t} = -\frac{\ln 0{,}991}{8760} = 0{,}000001\left[\frac{1}{\mathrm{h}}\right]$$

For the above input values according to equation (4) is obtained:

$$R_0^*(s) = \frac{\begin{aligned} &3{,}50003 \cdot 10^{11} \cdot s + 3 \cdot 10^{11} \cdot \mu_{PZ1} \\ &+ 5 \cdot 10^{10} \cdot \mu_{PZ2} + 5 \cdot 10^{17} \cdot s^2 \cdot \mu_{PZ1} \\ &+ 5 \cdot 10^{17} \cdot s^2 \cdot \mu_{PZ2} + 1{,}000035 \cdot 10^{17} \cdot s^2 \\ &+ 5 \cdot 10^{17} \cdot s^3 + 1{,}00003 \cdot 10^{17} \cdot s \cdot \mu_{PZ1} \\ &+ 1{,}000005 \cdot 10^{17} \cdot s \cdot \mu_{PZ2} \\ &+ 1 \cdot 10^{17} \cdot \mu_{PZ1} \cdot \mu_{PZ2} \\ &+ 5 \cdot 10^{17} \cdot s \cdot \mu_{PZ1} \cdot \mu_{PZ2} \end{aligned}}{\begin{aligned} &2{,}450021 \cdot 10^6 \cdot s + 1{,}000035 \cdot 10^{17} \cdot s^2 \cdot \mu_{PZ1} \\ &+ 1{,}000035 \cdot 10^{17} \cdot s^2 \cdot \mu_{PZ2} + 5 \cdot 10^{17} \cdot s^3 \cdot \mu_{PZ1} \\ &+ 5 \cdot 10^{17} \cdot s^3 \cdot \mu_{PZ2} + 1{,}0500275 \cdot 10^{12} \cdot s^2 \\ &+ 1{,}00007 \cdot 10^{17} \cdot s^3 + 5 \cdot 10^{17} \cdot s^4 \\ &+ 4{,}00003 \cdot 10^{11} \cdot s \cdot \mu_{PZ1} \\ &+ 6{,}50003 \cdot 10^{11} \cdot s \cdot \mu_{PZ2} \\ &+ 1 \cdot 10^{17} \cdot s \cdot \mu_{PZ1} \cdot \mu_{PZ2} \\ &+ 5 \cdot 10^{17} \cdot s^2 \cdot \mu_{PZ1} \cdot \mu_{PZ2} \end{aligned}}$$

Assuming $\mu_{PZ1} = 0{,}1$, $\mu_{PZ2} = 0{,}2$ and using the Laplace'a transformation we receive:

$$R_0(t) = 0{,}0000024805093 \cdot e^{-0{,}199229397513 \cdot t} + 0{,}0000599964 \cdot e^{-0{,}100006 \cdot t} + 0{,}0000025192406 \cdot e^{-0{,}200778602 \cdot t} + 0{,}99993500384977$$

Finally, we obtain:

$$R_O = 0{,}999935004$$

Using equation (4) it is possible to determine the effect of the impact of values of the transition rate from the state of the impendency over safety to the state of full ability μ_{PZ1} and μ_{PZ2} on the value of the probability of the system staying in the state of full operational capability R_O. Intensity μ_{PZ1} and μ_{PZ2} should be understood as the inverse of time t_{PZ1} and t_{PZ2} that determine the recovery time to the state of full operational capability.

4 SUMMARY

The article presents a schematic exploitation-reliability analysis of two source supply system used in transport telematics systems. There are given basic types of power supply systems and then presented the exploitation-reliability analysis of the whole system. It was assumed the four functional states (state of full ability S_{PZ}, states of the impendency over safety S_{ZB1} and $S_{ZB2,}$ state of unreliability of safety S_B) and defined basic transitions between them. This allowed for the determination of the set of equations describing the power supply system. The obtained relations allow to determine the influence of particular intensities rates on values of assigned probabilities. Further research is expected to carry out analysis aimed the rationalization of the intensity of restoring the states of full abilities of the respective tracks of power supply.

Reliability-maintenance analysis of highway emergency communication systems

M. Siergiejczyk, J. Chmiel & A. Rosiński
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: Transport telematics is defined as a field of knowledge and technical activity integrating IT with telecommunications, intended to support transport systems. The assistance comes in form of integrated sensor, telecommunications, IT and information systems complemented by telematics-enabled apps (services). An example of a telematic system is the highway emergency response system. Reliability-maintenance analysis of highway emergency communication systems was presented in this paper. The influence of time required for the system to regain its state of full ability on system's availability rate was at the centre of this analysis. In real terms, it will make possible to rationalise the process of periodic inspections.

1 INTRODUCTION

Transport telematics is defined as a field of knowledge and technical activity integrating IT with telecommunications, intended to support transport systems (Siergiejczyk 2009, Wydro 2005). The assistance comes in form of integrated sensor, telecommunications (Bajda & Wrażeń & Laskowski 2011, Laskowski & Łubkowki 2013) IT and information systems complemented by telematics-enabled apps (services) (Chowdhury & Sadek 2003, Klein 2001).

As of late, highway telematic systems have been subject of multiple papers (Kasprzyk 2012, Siergiejczyk & Paś & Rosiński 2012, Sumila 2012). There are multiple reasons behind that. It has been widely acknowledged that development of road transport, especially Polish highway network is a top priority. Traffic density on trunk roads has reached volumes so high that without high efforts aimed at building and expanding the highway network, the country could potentially face a much higher congestion. No wonder then, highway transport issues should be close to hearts of researchers.

Thus far the authors have analysed their structures in terms of reliability analysis covering both intra-system relationships as well as power supply related issues (Rosinski & Dabrowski 2013, Siergiejczyk & Rosinski 2011) and information transmission (Siergiejczyk & Rosinski 2011, Siergiejczyk 2012, Siergiejczyk 2008).

Highway emergency response system enables users to report from their current position any breakdowns, collisions etc. to the highway control centre managing that road section. The roads where the system was deployed are significantly safer.

2 HIGHWAY EMERGENCY RESPONSE SYSTEM ARCHITECTURE

The key component of a highway emergency response system is alarm indicator column. It enables either unidirectional or bidirectional communication between the person calling for help and the control centre. Unidirectional communication entails sending a request (by pressing the call help button on alarm indicator column) for help to the control centre. Bidirectional communication is possible when (also by pressing the same call help button on the column) request for help is sent to the control centre followed by voice conversation between the centre and stranded person. By pressing the call help button, the user is automatically sending identification data of the alarm indicator column it used to the control centre. Hence exact location of the accident scene or emergency and consequently the person calling for help is immediately known. Rational measures can be therefore undertaken by road rescue and/or technical services.

Figure 1 shows schematically the general architecture of emergency response network. The information is transmitted between control centre and alarm indicator columns via fibre optic cable. The rationale for using that technology is its resilience to environmental electromagnetic interference (Duer & Zajkowski & Duer & Paś 2012, Paś & Duer 2012) and high data transfer speeds. The

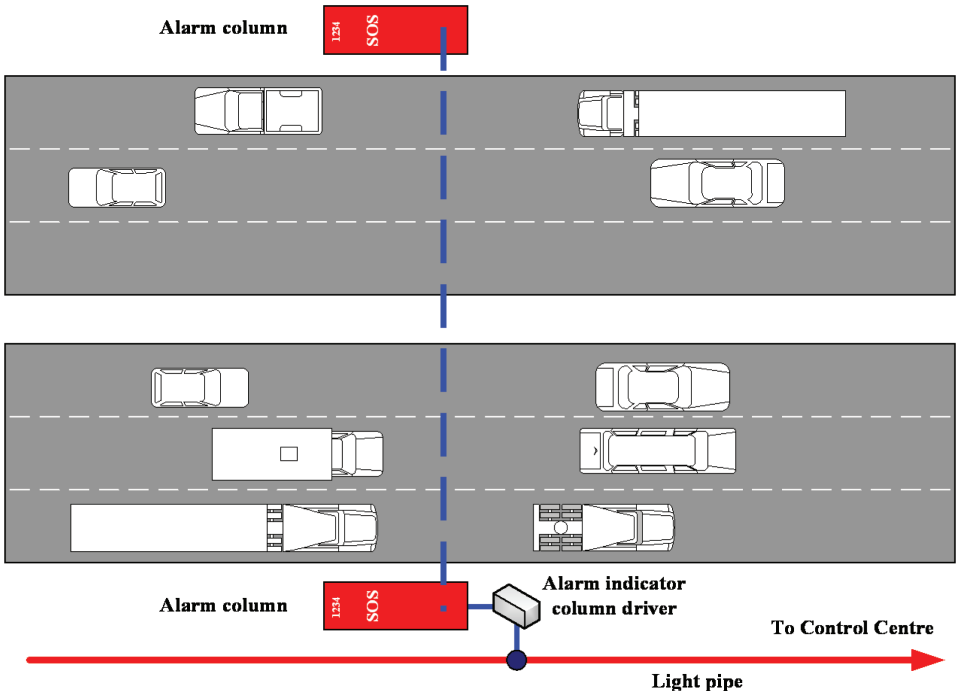

Figure 1. Architecture of emergency response network.

cable runs adjacent to the motorway buried in the ground.

Fibre optics emergency response system consists of the following elements:

- control centre—manages user requests received via alarm indicator columns and informs road rescue and/or technical services about the need to attend to a accident scene or other emergency.
- optoelectronic interface—Central Access Point (CAP) which enables two-way transmission over fibre optic cable.
- network of passive photocouplers—they are connected with optical fibre for purposes of emergency response system. They allow to connect together alarm indicator columns located in particular part of the network using only one fibre.
- optoelectronic interface i.e. Field Optical Box (FOB) assign to each alarm indicator column and to the master column. FOBs and the master column are connected using a short, copper multi-couple cable, thus facilitating maintenance and repairs/replacement (restoring the state of full ability) in case of any damage caused by ongoing traffic.
- alarm indicator columns (master and secondary)—located road-side along the highway thus creating branches leading to the control centre. Master alarm indicator columns consist of electronic setup (audio frequency amplifier, input, acoustical system with microprocessor, modem and interface), microphone, speaker, emergency button.

3 ANALYSIS OF HIGHWAY EMERGENCY COMMUNICATION SYSTEMS MAINTENANCE

In telecommunications network (including emergency response networks) readiness i.e. the network's capability to establish and maintain connection between active users over given time under specific operating conditions, is determined by readiness of its constituting elements and the network's reliability structure (Siergiejczyk 2012, Verma & Ajit & Karanki 2010).

Overview of emergency response network structure is displayed in Figure 2. It includes a control centre, two optical fibre lines and alarm indicator columns.

Relationships between structure elements, from reliability and maintenance perspective (Będkowski & Dąbrowski 2006, Dyduch & Paś & Rosiński 2011), were determined by analysing the highway emergency response system operation and are presented in Figure 3.

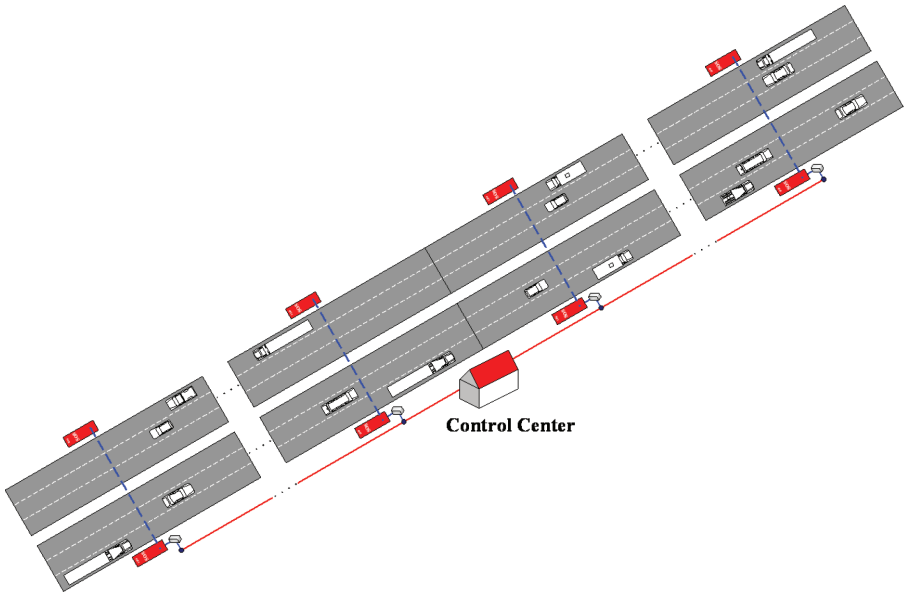

Figure 2. Highway emergency response system.

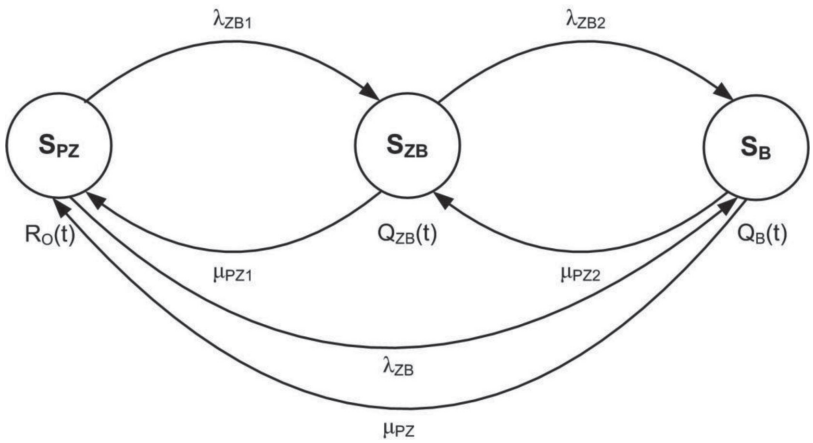

Figure 3. Relationships in the highway emergency communication system.

Denotations in figures:

$R_O(t)$—the function of probability of system staying in state of full ability S_{PZ},
$Q_{ZB}(t)$—the function of probability of system staying in state of the impendency over safety S_{ZB},
$Q_B(t)$—the function of probability of system staying in state of unreliability of safety S_B,
λ_{ZB1}—transition rate from the state of full ability S_{PZ} into the state of the impendency over safety S_{ZB},
μ_{PZ1}—transition rate from the state of the impendency over safety S_{ZB} into the state of full ability S_{PZ},
λ_{ZB2}—transition rate from the state of the impendency over safety S_{ZB} into the state of unreliability of safety S_B,
μ_{ZB1}—transition rate from the state of unreliability of safety S_B into the state of the impendency over safety S_{ZB},
λ_{ZB}—transition rate from the state of the full ability S_{PZ} into the state of unreliability of safety S_B,

μ_{PZ}—transition rate from the state of unreliability of safety S_B into the state of the full ability S_{PZ}.

Should highway emergency response system be in state of full ability S_{PZ} and one optical fibre line fails the system goes into state of the impendency over safety S_{ZB} at a rate λ_{ZB1}. A system in state of the impendency over safety S_{ZB} could go into state of full ability S_{PZ} provided adequate measures to restore the optical fibre line to be fully operational are undertaken.

Should highway emergency response system be in state of the impendency over safety S_{ZB} and second optical fibre line fails the system goes into state of unreliability of safety S_B at a rate λ_{ZB2}. A system in state of unreliability of safety S_B could go into state of the impendency over safety S_{ZB} provided adequate measures to restore the second optical fibre line to be fully operational are undertaken.

Should highway emergency response system be in state of full ability S_{PZ} and the control centre fails the system goes into state of unreliability of safety S_B at a rate λ_{ZB}. A system in state of unreliability of safety S_B could go into state of full ability S_{PZ} provided adequate measures to restore the control centre to be fully operational are undertaken.

The system illustrated in Figure 3 may be described by the following Chapman–Kolmogorov equations:

$$\begin{aligned}
R_0'(t) &= -\lambda_{ZB1}\cdot R_0(t) + \mu_{PZ1}\cdot Q_{ZB}(t)\\
&\quad -\lambda_{ZB}\cdot R_0(t) + \mu_{PZ}\cdot Q_B(t)\\
Q_{ZB}'(t) &= \lambda_{ZB1}\cdot R_0(t) - \mu_{PZ1}\cdot Q_{ZB}(t)\\
&\quad -\lambda_{ZB2}\cdot Q_{ZB}(t) + \mu_{PZ2}\cdot Q_B(t)\\
Q_B'(t) &= \lambda_{ZB2}\cdot Q_{ZB}(t) - \mu_{PZ2}\cdot Q_B(t)\\
&\quad +\lambda_{ZB}\cdot R_0(t) - \mu_{PZ}\cdot Q_B(t)
\end{aligned} \tag{1}$$

Given the initial conditions:

$$\begin{aligned}
R_0(0) &= 1\\
Q_{ZB}(0) &= Q_B(0) = 0
\end{aligned} \tag{2}$$

Laplace transform yields the following system of linear equations:

$$\begin{aligned}
s\cdot R_0^*(s) - 1 &= -\lambda_{ZB1}\cdot R_0^*(s) + \mu_{PZ1}\cdot Q_{ZB}^*(s)\\
&\quad -\lambda_{ZB}\cdot R_0^*(s) + \mu_{PZ}\cdot Q_B^*(s)\\
s\cdot Q_{ZB}^*(s) &= \lambda_{ZB1}\cdot R_0^*(s) - \mu_{PZ1}\cdot Q_{ZB}^*(s)\\
&\quad -\lambda_{ZB2}\cdot Q_{ZB}^*(s) + \mu_{PZ2}\cdot Q_B^*(s)\\
s\cdot Q_B^*(s) &= \lambda_{ZB2}\cdot Q_{ZB}^*(s) - \mu_{PZ2}\cdot Q_B^*(s)\\
&\quad +\lambda_{ZB}\cdot R_0^*(s) - \mu_{PZ}\cdot Q_B^*(s)
\end{aligned} \tag{3}$$

Probability of system staying in specific state denoted symbolically (Laplace) reads as follows:

$$\begin{aligned}
R_0^*(s) &= \frac{\begin{array}{l}s^2 + s\cdot\mu_{PZ} + s\cdot\mu_{PZ1} + s\cdot\lambda_{ZB2} + s\cdot\mu_{PZ2}\\ +\mu_{PZ}\cdot\mu_{PZ1} + \mu_{PZ}\cdot\lambda_{ZB2} + \mu_{PZ1}\cdot\mu_{PZ2}\end{array}}{\begin{array}{l}s^2\cdot\lambda_{ZB} + s^2\cdot\mu_{PZ} + s^2\cdot\lambda_{ZB1} + s^2\cdot\lambda_{PZ1}\\ + s^2\cdot\lambda_{ZB2} + s^2\cdot\mu_{PZ2} + s^3 + s\cdot\lambda_{ZB}\cdot\mu_{PZ1}\\ + s\cdot\mu_{PZ}\cdot\lambda_{ZB1} + s\cdot\mu_{PZ}\cdot\mu_{PZ1} + s\cdot\lambda_{ZB}\\ \cdot\lambda_{ZB2} + s\cdot\lambda_{ZB}\cdot\mu_{PZ2} + s\cdot\mu_{PZ}\cdot\lambda_{ZB2}\\ + s\cdot\lambda_{ZB1}\cdot\lambda_{ZB2} + s\cdot\lambda_{ZB1}\cdot\mu_{PZ2}\\ + s\cdot\mu_{PZ1}\cdot\mu_{PZ2}\end{array}}\\
Q_{ZB}^*(s) &= \frac{\begin{array}{l}s\cdot\lambda_{ZB1} + \mu_{PZ}\cdot\lambda_{ZB1} + \lambda_{ZB}\cdot\mu_{PZ2} + \lambda_{ZB1}\cdot\mu_{PZ2}\end{array}}{\begin{array}{l}s^2\cdot\lambda_{ZB} + s^2\cdot\mu_{PZ} + s^2\cdot\lambda_{ZB1} + s^2\cdot\mu_{PZ1}\\ + s^2\cdot\lambda_{ZB2} + s^2\cdot\mu_{PZ2} + s^3 + s\cdot\lambda_{ZB}\\ \cdot\mu_{PZ1} + s\cdot\mu_{PZ}\cdot\lambda_{ZB1} + s\cdot\mu_{PZ}\cdot\mu_{PZ1}\\ + s\cdot\lambda_{ZB}\cdot\lambda_{ZB2} + s\cdot\lambda_{ZB}\cdot\mu_{PZ2} + s\cdot\mu_{PZ}\\ \cdot\lambda_{ZB2} + s\cdot\lambda_{ZB1}\cdot\lambda_{ZB2} + s\cdot\lambda_{ZB1}\cdot\mu_{PZ2}\\ + s\cdot\mu_{PZ1}\cdot\mu_{PZ2}\end{array}}\\
Q_B^*(s) &= \frac{\begin{array}{l}s\cdot\lambda_{ZB} + \lambda_{ZB}\cdot\mu_{PZ1} + \lambda_{ZB}\cdot\lambda_{ZB2} + \lambda_{ZB1}\cdot\lambda_{ZB2}\end{array}}{\begin{array}{l}s^2\cdot\lambda_{ZB} + s^2\cdot\mu_{PZ} + s^2\cdot\lambda_{ZB1} + s^2\cdot\mu_{PZ1}\\ + s^2\cdot\lambda_{ZB2} + s^2\cdot\mu_{PZ2} + s^3 + s\cdot\lambda_{ZB}\cdot\mu_{PZ1}\\ + s\cdot\mu_{PZ}\cdot\lambda_{ZB1} + s\cdot\mu_{PZ}\cdot\mu_{PZ1} + s\cdot\lambda_{ZB}\\ \cdot\lambda_{ZB2} + s\cdot\lambda_{ZB}\cdot\mu_{PZ2} + s\cdot\mu_{PZ}\cdot\lambda_{ZB2}\\ + s\cdot\lambda_{ZB1}\cdot\lambda_{ZB2} + s\cdot\lambda_{ZB1}\cdot\mu_{PZ2}\\ + s\cdot\mu_{PZ1}\cdot\mu_{PZ2}\end{array}}
\end{aligned} \tag{4}$$

Solving above equations in time domain is a next step of the analysis which has not been included in this paper.

4 MODELLING OF PROCESS OF HIGHWAY EMERGENCY RESPONSE MAINTENANCE

Computer simulation and computer-aided analysis facilitate to relatively quickly determine the influence of change in reliability-exploitation parameters of individual components on reliability of the entire system. Of course, the reliability structure of both the entire system and its components has to be known beforehand.

Using computer aided allows to perform the calculation of the value of probability of system staying in state of full ability R_O. That procedure is illustrated with below example.

Example

The following quantities were defined for the system:

– test duration—1 year (values of this parameter is given in [h]):

$$t = 8760 \ [h]$$

– reliability of first optical fibre line:

$$R_{ZB1}(t) = 0{,}99$$

– reliability of second optical fibre line:

$$R_{ZB2}(t) = 0{,}999$$

– reliability of control centre:

$$R_{ZB}(t) = 0{,}9999$$

– transition rate from the state of the impendency over safety into the state of full ability:

$$\mu_{PZ1} = 0{,}1\left[\frac{1}{h}\right]$$

– transition rate from the state of unreliability of safety into the state of full ability:

$$\mu_{PZ2} = 0{,}1\left[\frac{1}{h}\right]$$

– transition rate from the state of the unreliability of safety into the state of full ability:

$$\mu_{PZ} = 0{,}05\left[\frac{1}{h}\right]$$

Provided the value of reliability $R_{ZB1}(t)$ is known, transition rate from the state of full ability into the state of the impendency over safety may be estimated. Provided the up time is described by exponential distribution, the following relationship can be used:

$$\lambda_{ZB1} = -\frac{\ln R_{ZB1}(t)}{t}$$

thus

$$R_{ZB1}(t) = e^{-\lambda_{ZB1}t} \quad \text{for} \quad t \geq 0$$

For $t = 8760 \ [h]$ and $R_{ZB1}(t) = 0{,}99$ we obtain:

$$\lambda_{ZB1} = -\frac{\ln R_{ZB1}(t)}{t} = -\frac{\ln 0{,}99}{8760} = 1{,}147298 \cdot 10^{-6}\left[\frac{1}{h}\right]$$

Provided the value of reliability $R_{ZB2}(t)$ is known, transition rate from the state of the impendency over safety into the state of unreliability of safety may be estimated. The following relationships are true for exponential distribution:

$$R_{ZB2}(t) = e^{-\lambda_{ZB2}t} \quad \text{for} \quad t \geq 0$$

thus

$$\lambda_{ZB2} = -\frac{\ln R_{ZB2}(t)}{t}$$

For $t = 8760 \ [h]$ and $R_{ZB2}(t) = 0{,}999$ we obtain:

$$\lambda_{ZB2} = -\frac{\ln R_{ZB2}(t)}{t} = -\frac{\ln 0{,}999}{8760} = 1{,}142124 \cdot 10^{-7}\left[\frac{1}{h}\right]$$

Provided the value of reliability $R_{ZB}(t)$ is known, transition rate from the state of full ability into the state of unreliability of safety may be estimated. The following relationships are true for exponential distribution:

$$R_{ZB}(t) = e^{-\lambda_{ZB}t} \quad \text{for} \quad t \geq 0$$

thus

$$\lambda_{ZB} = -\frac{\ln R_{ZB}(t)}{t}$$

For $t = 8760[h]$ and $R_{ZB}(t) = 0{,}9999$ we obtain:

$$\lambda_{ZB} = -\frac{\ln R_{ZB}(t)}{t} = -\frac{\ln 0{,}9999}{8760} = 1{,}141609 \cdot 10^{-8}\left[\frac{1}{h}\right]$$

For above input values using equation (4) we get:

$$R_0 = 0{,}9999883749$$
$$Q_{ZB} = 0{,}0000115489$$
$$Q_B = 7{,}6115 \cdot 10^{-8}$$

Practical application of deliberations presented hereinbefore enables to determine the impact of transition rate from the state of the impendency over safety to the state of full ability μ_{PZ1} i, transition rate from the state of unreliability of safety to the state of the impendency over safety μ_{PZ2} and transition rate from the state of unreliability of safety to the state of full ability μ_{PZ} on probability of system staying in the state of full ability. Rates $\mu_{PZ1,}$ μ_{PZ2} and μ_{PZ} should be read as inverse times $t_{PZ1,}$ t_{PZ2} and t_{PZ} which determine the time taken to restore system elements to the state of full ability.

5 SUMMARY

Reliability-maintenance analysis of highway emergency communication systems was presented in

this paper. Assuming three states (state of full ability R_0, state of the impendency over safety Q_{ZB} and state of unreliability of safety Q_B) and transitions, relationships for determining probability of the system staying in particular state were derived. The relationships obtained make possible to ascertain impact of transition rate on the aforementioned probabilities.

In order to determine the availability rate of emergency response network, transition rate between defined system states has to be known. Numerical values of those parameters could be estimated based on reliability prediction methods. This is justified for newly built systems. Operational tests or empirical data from system elements testing can be the other way to obtain those numerical values. This pertains among other to estimating parameters of fibre optic telecommunications networks.

Hierarchical random models in road transport safety

J. Wachnicka & K. Jamroz
Gdańsk University of Technology, Gdańsk, Poland

L. Smolarek
Gdynia Maritime University, Gdynia, Poland

ABSTRACT: In this paper multilevel approach to the issue of road safety level on the road network of European regions, classified as NUTS 2 in statistical databases of the EU, has been presented. The risk calculated as the number of death casualties in road accidents per 100,000 inhabitants of a given region has Poisson distribution. Therefore, generalized Poisson model has been assumed in the modelling process. Multilevel stochastic analysis was performed for the studied factor. Then a model was created that took into account the impact of different characteristics available on different level of aggregation, which may be helpful in the actions aimed at improvement of road safety in respective regions.

1 INTRODUCTION

In 1771 the first accident involving motor vehicle, a steam powered one, was reported. Since then several hundred million accidents have occurred, in which over 60 million people have died. Despite the activities being carried out with an aim to improve safety, over 1.2 m people die on roads each year, and even up to 50 million are injured. This is then a global issue of an epidemiologic nature. Scientists in Western Europe and United States for quite a long time have been searching for the cause of this situation. The issue is complex enough to be addressed by scientists from different fields: economy, mathematics, transport or medicine. However, so far they have focused on researches covering data for respective countries, without going deeper into differences between respective regions of a given country. Most frequently analysed were the figures of changes in number of casualties over time, by means of time series (Commandeur et al. 2012). In researches aimed at finding factors that could influence fatality on roads national product per capita (Van Beeck et al. 1991) and transport activity (Jamroz 2011) have been indicated. Unfortunately, transport activity is unavailable in regional databases. Therefore, the scientists often point to population density as a good substitute index, which may replace transport activity (Fridstrøm 1995). Literature studies showed that the researchers focus either on national characteristics or on regional characteristics alone, and do not combine both. In this paper the combination of national and regional characteristics in one model has been presented.

2 MULTILEVEL MODEL— METHODOLOGY OF THE APPROACH

Analyses of road safety at levels below the national level have usually compared selected rates of road safety (such as the road fatality rate in relation to demography). Fatality is calculated as follows:

$$\mathrm{FATALR_{ij}} = \frac{\mathrm{FATAL_{ij}}}{\mathrm{POP_{ij}}} \tag{1}$$

where:
$FATALR_{ij}$—traffic fatality rate in an i-th region in j-th year
$FATAL_{ij}$—number of fatalities of an i-th region in j-th year
POP_{ij}—number of population of an i-th region in j-th

In order to create model that combines national and regional characteristics, data concerning the number of death casualties in a given region have been collected as well as additional characteristics that describe regions and countries. The reason for this approach was the fact that there were characteristics available on national level that could effectively differentiate safety levels in the regions of respective countries, though unfortunately they were unavailable on regional level of aggregation. On the other hand, respective regions of a given country differ among each other in terms of population density or road network concentration and these elements are worth considering in the model. Since significant dispersion of fatality rate has been observed, it was decided to model demographic index of fatalities on roads (FATALR) calculated

as the number of killed per 100,000 inhabitants. The assumption was that the model should have the following formula:

$$FATALR = \alpha \cdot MODEL_{NATIONAL}^{\beta_1} \cdot MODEL_{REGION}^{\beta_2} \cdot NPPCMODEL_{NATIONAL}^{\beta_3} \quad (2)$$

where:
FATALR—demographic rate of fatalities in road accidents in a given region [fat./100 thou. inhab.]
$MODEL_{NATIONAL}$—model for national data
$MODEL_{REGION}$—model for regional data
$NPPC_{NATIONAL}$—model describing changes of average national product per capita
α, β_1,β_2,β_3—estimated parameters

FATALR estimation is based on the assumption that this parameter has Poisson distribution. National model was created on the basis of data from 11 European countries, whereas in the case of regional model in this paper the focus has been on German. Histogram of FATALR value in regions of Germany in the analysed period of 1999–2008 presented on Figure 1 shows that there are no grounds for rejecting the hypothesis of Poisson distribution, frequently assumed in the analyses of safety level (Firth 1995). In further analyses, according to this assumption, FATALR index will be alternatively referred to as λ.

2.1 *National model*

Taking into account the assumptions, λ parameter has been evaluated with 95% probability for the set of data from comparable countries. Then the set of independent variables, available only on national level of aggregation, which characterize the country, used for development of descriptive models for evaluated λ parameters ($MODEL_{NATIONAL}$), has been created. In this paper the impact of such factors were analysed as: corruption index—COR (the higher the value, the better a country is perceived, i.e. as less corrupted), percentage of passenger cars older than 10 years—OLD in the total fleet of the country, calculated as average from 10 years. Model was developed in previous article (Wachnicka & Smolarek 2013) and has a shape of linear model:

$$\lambda = 15.920 - 1.308 \cdot COR + 0.093 \cdot OLD\ ,\ R^2 = 0,87 \quad (3)$$

where:
λ—demographic rate of fatalities in road accidents in a given country [fat./100 thou. inhab.]
COR—country corruption index [–]
OLD—percentage of passenger cars older than 10 years [%]
R^2—coefficient of determination

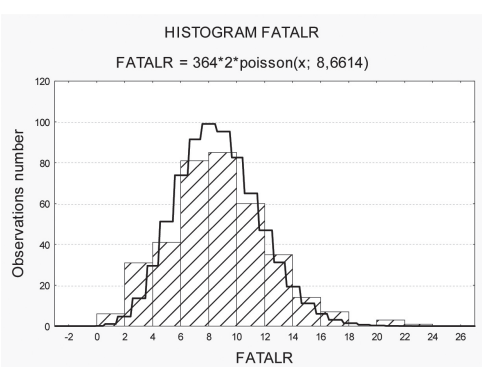

Figure 1. Histograms of analysed FATALR indices in the regions of Germany.

2.2 *Model for trend of national product per capita variation in time*

Global national and local regional models are the ones, in which the majority of independent variables are characterized by slight variability in time. The only variable dynamically changing in time, and at the same time occurring in almost all models, is national product per capita. Analysis of variations of average national product per capita NPPC over time proved that analysed country is characterized by linear type of NPPC change trend in time.

$$NPPC_{NATIONAL} = -1159,17 + 0,59 \cdot year,\ R^2 = 0,98 \quad (4)$$

2.3 *Regional model*

The next step was development of model describing the impact of regional characteristics in Germany on FATALR values in these regions. For this purpose, separated base of regional data was created the attempts were made to develop a model of impact of respective variables on modelled dependent variable. Cluster analysis allowed specification of classes of correlated variables. In individual models the impact of respective classes have been taken into account through selection of their representatives.

$$MODEL_{REGION} = Z \cdot (\ln NPPC)^{-0,54} \cdot \frac{1}{\sqrt{DPOP}} \cdot \exp(-0,369 \cdot MRV),\ R^2 = 0,74 \quad (5)$$

where:
lnNPPC—logarythm of national product per capita in each region [–]

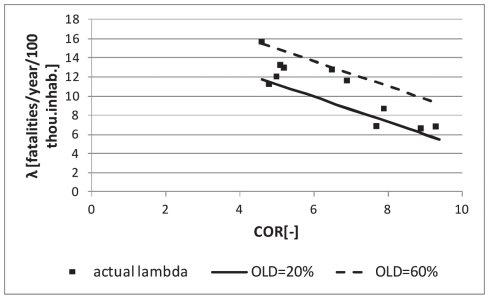

Figure 2. Illustration of linear model that takes into account corruption index and the percentage of cars older than 10 years old in the total fleet.

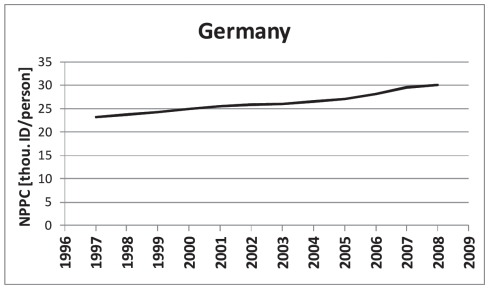

Figure 3. Graph of dependence of NPPC changes in Germany in the analysed years.

lnDPOP—logarythm of population density in each region [–]
MRV—motorisation vehicle rate [vehicle/person]

As shown in Figures 4 and 5, although theoretically quite good fit of the model to real data—$R^2 = 0.74$ much data is above or below the model functions. This may be due, inter alia, that the developed model only depends on three variables: the NPPC, DPOP and MRV.

There are probably characteristics not included in this model, because they are not available in databases. The individual NUTS 2 regions may vary among other such characteristic contacts as part of transit traffic, network routes, the type of land use (more agricultural or more industrial for example) and the age structure of the drivers in the region. Therefore, the model developed is burdened with some kind of uncertainty. That's why it is possible to perform stochastic process on developed function coefficients.

Because the most important factor in the developed model proved to be NPPC, it was decided to just the coefficient of this variable is treated as a random variable.

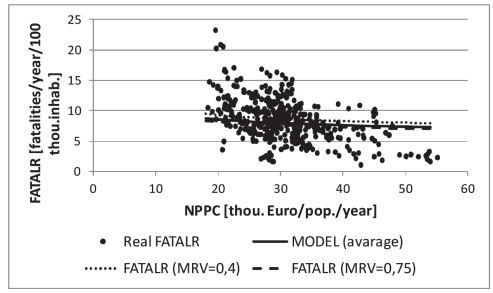

Figure 4. Graph of prepared regional FATALR model in relation to national product per capita and against the actual data—motorisation vehicle rate MRV from the model assumed as minimum, average and maximum value from data set.

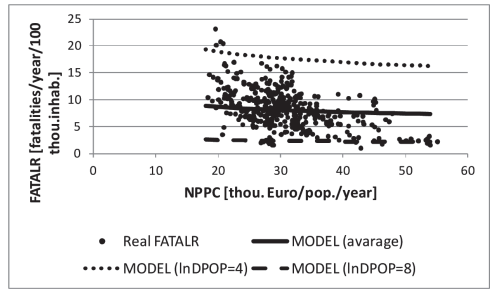

Figure 5. Graph of prepared regional FATALR model in relation to national product per capita and against the actual data—population density DPOP from the model assumed as minimum, average and maximum value from data set.

2.4 *Aggregated model*

After preparation of partial models, the model comprising all partial models has been created and it has the following formula:

$$FATALR = 0{,}7 \cdot MODEL_{NATIONAL}^{2{,}285} \cdot MODEL_{REGION}^{1{,}054} \cdot NPPC_{NATIONAL}^{-1{,}506}, R^2 = 0{,}88 \quad (6)$$

3 RANDOM MODEL

There are several alternative ways of analyzing hierarchical data, traditional statistical techniques is the first one. The problem with traditional statistical techniques is that it discards all within-group information (takes the average of the individual level variables), (Chow 1984).

Another way to analyze hierarchical data would be through a random-coefficients model. This model assumes that each group has a different

regression model with its own coefficients. Because groups are sampled, the model assumes that the regression coefficients are also randomly sampled from a population of group coefficients. The problem with using a random-coefficients model in order to analyze hierarchical data is that is still not possible to incorporate higher order variables, (De Leeuw 1985).

3.1 *Data analysis*

Based on the data shown in Figure 6 the data are divided into homogeneous groups, statistical description of which is given in Table 1. This analysis shows the results of fitting a normal distribution to the data.

The estimated parameters of the fitted distribution are shown above, Table 1.

The Table 2 shows the results of several tests run to determine whether data can be adequately modeled by a normal distribution. The Shapiro-Wilk test is based upon comparing the quantiles of the fitted normal distribution to the quantiles of the data. The standardized skewness test looks for lack of symmetry in the data. The standardized kurtosis test looks for distributional shape which is either flatter or more peaked than the normal distribution. Since the smallest P-value amongst the tests performed for each data seat is greater than or equal to 0,05, we can not reject the idea that it comes from a normal distribution with 95% confidence.

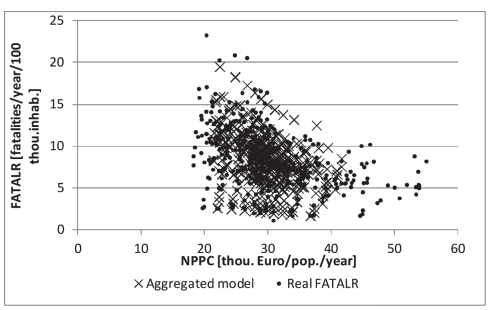

Figure 6. Graph of aggregated FATALR model in relation to national product per capita and against the actual data.

3.2 *The doubly truncated normal probability*

The doubly truncated normal probability density function (pdf) is normally distributed on the interval from a to b; and takes on a value of 0 elsewhere, (Lee 1979). Since a valid pdf must integrate to 1 over its range, the doubly truncated normal pdf must be normalized, Figure 7, and is given by formula

$$\phi_T(t;\mu,\sigma,a,b) \equiv \begin{cases} \dfrac{\phi(t;\mu,\sigma)}{\Phi(b;\mu,\sigma)-\Phi(a;\mu,\sigma)} & a<t<b \\ 0 & elsewhere \end{cases}. \quad (7)$$

A truncated normal pdf is when we have $b=\infty$ or $a=-\infty$. In such cases,

Table 1. Fitted normal distributions parameters to each group.

Data	Mean	Standard deviation
d1520	13,7033	4,49095
d2025	10,6829	3,50678
d2530	8,48976	3,18291

Data	Statistic	P-Value	Statistic	P-Value	Statistic	P-Value
d1520	0,884336	0,1146	1,21344	0,224962	Insufficient data	
d2025	0,95908	0,0801	1,69493	0,09009	1,17488	0,240041
d2530	0,973983	0,1544	0,145033	0,88468	0,121449	0,90333
d3035	0,950495	0,0515	1,3092	0,190466	–1,05747	0,290297
d3540	0,951859	0,1492	0,255812	0,798092	0,714878	0,474682
d4045	0,959896	0,5695	0,401755	0,687861	Insufficient data	
d4550	0,96418	0,8045	0,112227	0,910638	Insufficient data	
d5055	0,969501	0,8773	0,0133125	0,989373	Insufficient data	

$$\phi_T(t;\mu,\sigma,a,\infty)\equiv\begin{cases}\dfrac{\phi(t;\mu,\sigma)}{1-\Phi(a;\mu,\sigma)} & a<t\\ 0 & elsewhere\end{cases}. \quad (8)$$

$$\phi_T(t;\mu,\sigma,-\infty,b)=\begin{cases}\dfrac{\phi(t;\mu,\sigma)}{\Phi(b;\mu,\sigma)} & t<b\\ 0 & elsewhere\end{cases}. \quad (9)$$

The mean of a doubly truncated normal pdf (7) is

$$E(Y;\mu,\sigma,a,b)=\mu+\sigma\lambda$$

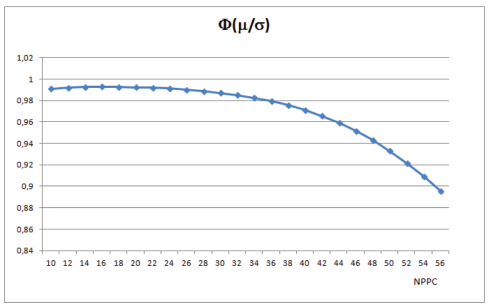

Figure 7. Normalized constant as a function of NPPC.

where $\lambda\equiv\phi_a-\phi_b/\Phi_b-\Phi_a$.

For lower and upper truncation (8,9) this formula becomes

$$\lambda\equiv\frac{\phi_a}{1-\Phi_a},\qquad \lambda\equiv\frac{-\phi_b}{\Phi_b}.$$

Using the model and logarithmic transformation we have linear model according to data transformation.

Let us now consider the regional model where coefficient Z is random variable with a truncated normal distribution with mean μ and standard deviation $\sigma>0$.

Probability density function of random variable Z is given by formula:

$$f(t)=\frac{1}{\sigma\cdot\Phi_{N(0,1)}\left(\dfrac{\mu}{\sigma}\right)\cdot\sqrt{2\pi}}e^{-\frac{(t-\mu)^2}{2\sigma^2}} \quad (10)$$

where

$$\Phi_{N(0,1)}(x)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{x}e^{-\frac{t^2}{2}}dt,$$

we use only FATALR ≥ 0 it means that for $\forall\ t<0$ the probability of FATALR is zero, Figure A, B.

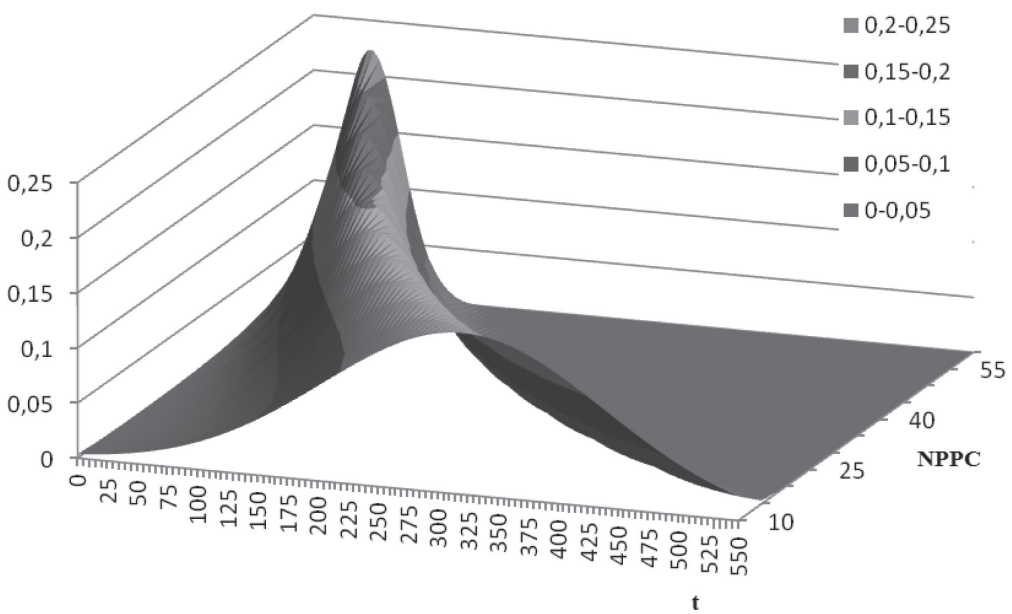

Figure 8. Probability density function (10) of the main model parameter as a function of independent variable NPPC.

The general regression modeling approach takes the standard perspective in much of statistical modeling of focusing directly on the mean responses and how they change over time (Phoebus 1986).

However, the modeling approach acknowledges the separate sources of variation we have discussed earlier.

Such models helps in controlling for unobserved heterogeneity when this heterogeneity is constant over time and correlated with independent variables, (Phoebus 1986, Wooldridge 2013).

4 CONCLUSION

The conducted heuristic statistical analysis, the results of which were presented in previous sections, indicates usefulness of employing local characteristics for evaluation of road transport safety. Due to varying availability of registered data, both at national and regional level, the cluster analysis was necessary in order to single out classes of "correlated" variables of which each one could be used in the model as representative of specified group of effects (impacts). Division into impact groups was conducted both at the level of countries and regions. All variables present in the models are significant. NPPC variable has the biggest impact.

In a multilevel modeling we want to investigate the relations between variables with different domains. The multilevel characteristics of the data also have implications for statistical modeling and analysis. In the paper we analyzed these statistical aspects of the problem. Random coefficient regression models are more appropriate than fixed coefficient models for multilevel analysis in our problem consideration.

There are two common assumptions made about the individual specific effect, the random effects assumption and the fixed effects assumption. The random effects assumption (made in a random effects model) is that the individual specific effects are uncorrelated with the independent variables. The fixed effect assumption is that the individual specific effect is correlated with the independent variables. If the random effects assumption holds, the random effects model is more efficient than the fixed effects model (Phoebus 1986, Wooldridge 2013).

Overall regional risk analysis of four Norwegian municipalities

R. Flage & Ø. Amundrud
University of Stavanger, Norway

H.S. Wiencke
Proactima, Norway

ABSTRACT: Norwegian municipalities are required by legislation to perform overall risk and vulnerability analyses covering the municipality as geographical area, as provider of public services and as a driving force in the area of societal safety and emergency preparedness. Cooperation between municipalities in this area is encouraged, if appropriate, including common risk and vulnerability analyses. This paper reports on the execution of an overall regional risk and vulnerability analysis covering four Norwegian municipalities. Selected issues are highlighted and discussed, including the structure of the hazard/threat identification, the representation of uncertainty and the presentation of the total risk picture.

1 INTRODUCTION

Since 2010 Norwegian municipalities are required by legislation to perform overall Risk and Vulnerability analyses (RVAs) (in Norwegian: "helhetlig risiko- og sårbarhetsanalyse") covering the municipality as geographical area, as provider of public services and as a driving force in the area of societal safety and emergency preparedness. The Norwegian Directorate for Civil Protection (NDCP 2012a) defines an overall RVA of a municipality as: "A systematic review of the municipality's geographic area and activities, with the aim of:

- Mapping risk and vulnerability, including adverse events that are of such a nature or extent that it involves municipal management in the assessment of preventive measures as well as in emergency preparedness and crisis management, and adverse events affecting several sectors.
- Revealing inter-sectorial vulnerabilities and interdependencies.
- Avoiding risk and vulnerability where possible.
- Reducing risk and vulnerability through preventive and mitigating measures.
- Dealing with any residual risk through emergency preparedness."

The requirement to perform such analyses applies to individual municipalities; however, cooperation between municipalities in the area of societal safety and emergency preparedness is encouraged, if appropriate, including common RVAs.

This paper reports on the execution of an overall *regional* RVA covering four Norwegian municipalities in the Stavanger region. The paper mainly covers the planning and performance of the analysis; the subsequent decision-making and risk treatment will only be briefly commented upon. In addition to reporting on the risk analysis process, selected issues are highlighted and discussed, including the structure of the hazard/threat identification, the representation of uncertainty and the presentation of the total risk picture.

As will be described in Section 2, there exist some guidelines on how to perform an overall (municipal) RVA. However, no updated, complete and application-specific authoritative guidelines have currently been published. The purpose and contribution of the present paper is to describe and discuss one possible approach to such an analysis. The presented method may be viewed as a practical implementation of theoretical risk frameworks that have been developed during the last decades, where more weight is put on uncertainty descriptions instead of calculated probabilities and expected values based on historical data, see for example (Aven & Renn 2010, Aven 2012, Aven 2013, Haimes 2009).

The remainder of the present paper is organized as follows: Section 2 reviews Norwegian legislative requirements relating to overall RVAs, as well as associated guidelines that apply. Section 3 gives a brief description of the Stavanger region, and Section 4 describes the risk analysis process that was carried out. Section 5 discusses some selected issues related to the analysis process, and Section 6 concludes.

2 LEGISLATIVE REQUIREMENTS GUIDELINES

The legislative requirements relating to overall RVAs for Norwegian municipalities can be found in the Civil Protection Act (2010) and the associated Regulations (2011). The regulations require municipalities to perform such an analysis, to use it as a basis for their work on societal safety and emergency preparedness, to update it in step with revisions of municipal plans, and to use it as a basis for developing an emergency preparedness plan. The RVA should take an all-risks approach and cover the municipality as geographical area, as provider of public services and as a driving force in the area of societal safety and emergency preparedness. The analysis is intended to be kept at a general level, taking a "bird's-view" perspective on the municipal risk factors; deferring more detailed analyses to the sectorial and individual company/organisational level. The analysis shall as a minimum cover: a) existing and future risk and vulnerability factors in the municipality; b) risk and vulnerability outside the geographical area of the municipality that could have implications for the municipality; c) how different risk and vulnerability factors can influence each other; d) specific challenges related to critical societal functions and loss of critical infrastructure; e) the municipality's ability to maintain its activity when exposed to an undesirable event and the ability to resume its activities after the event has occurred; and, f) the need for population alerting and evacuation.

The municipalities are required to use the analysis to develop long-term goals, strategies, priorities and plans for following up its work relating to societal safety and emergency preparedness. Scenarios for municipal emergency preparedness exercises should also be selected from the analysis. Collaboration between neighbouring municipalities is encouraged in the regulations, for example in terms of a common RVA process.

A guideline document to the Regulations on municipal duties relating to emergency preparedness has been published by the Norwegian Directorate for Civil Protection (NDCP 2012a). It provides detailed recommendations on inter alia how to perform and use the RVA. As for the execution of the risk analysis, the guideline refers the Norwegian standard NS 5814 (2008) containing general requirements to risk assessments, as well as to the guideline on municipal RVAs (NDCP 1994).

3 THE STAVANGER REGION

The Stavanger region here refers to the region made up by the municipalities Randaberg, Sandnes, Sola and Stavanger. Figure 1 shows a map of the region, as well as a map showing where in Norway the region is situated.

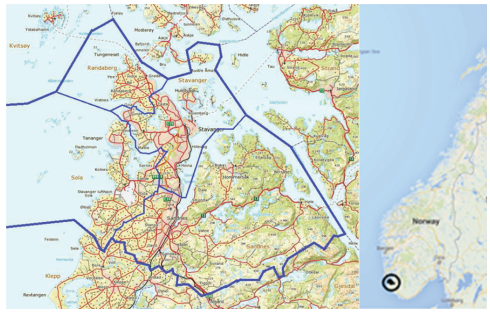

Figure 1. Map of the Stavanger region (Source: The Norwegian Mapping Authority).

The RVA includes a textual description of the individual municipalities with regard to geographical and sociotechnical factors. The region has a total population of 234.000 inhabitants (as of 1.1.2013) spread over a total area of 1150 km^2 (including territorial waters). There are significant differences between the municipalities in terms of size and population; however, the region to a large extent represents one combined labour and housing market; distances are small and the commuter rate is high. Many of the challenges that the municipalities face go across municipal borders, also in the area of societal safety and emergency preparedness. The municipalities have for several years collaborated both informally and the last few years also formally on issues and challenges related to this area.

4 THE RISK ANALYSIS PROCESS

This section describes the risk analysis process that was carried out, and follows the steps of the risk analysis process described by Aven (2009).

4.1 *Problem definition, information gathering and organisation*

4.1.1 *Problem definition*

The four municipalities had formulated a mandate for the RVA, describing inter alia the purpose, objectives, prerequisites, scope and follow-up of the analysis. The objectives of the analysis were:

- Map risk and vulnerability in the region.
- Identify risk reducing measures, both preventive and consequence reducing.
- Provide input to the development of long-term goals, strategies, priorities and plans for following up work relating to societal safety and emergency preparedness.
- Provide input to overall municipal and inter-municipal emergency planning.

- Form the basis for preparing municipal-specific RVAs.
- Uncover the need for further detailed analyses.

As mentioned in Section 1, the analysis covers the municipalities as geographical areas, as providers of services and as a driving force in the area of societal safety and emergency preparedness.

The analysis was conducted prior to corresponding municipality-specific RVAs in the municipalities. Whereas the regional analysis were to include hazards/threats affecting two or more of the municipalities simultaneously, as well as hazards/threats common to two or more of the municipalities, the municipality-specific analyses were to include hazards/threats specific to a single municipality. It was decided that the analysis should deal with the municipalities in normal operation in any season; i.e. conditions occurring during security-political crises and war were not to be included in the analysis as such scenarios are treated at the national level.

4.1.2 *Information sources*

The information gathering for the analysis took the form of review of written sources and information received from meeting participants/experts in analysis meetings. The written sources consisted of unrestricted sources in the public domain (national risk assessment, county RVA, openly available statistics, webpages, etc.). Analysis meetings were organised around critical societal functions, cf. Section 4.3. Three full-day and six half-day analysis meetings were conducted.

All existing sectorial and area RVAs were requested from the municipalities. Furthermore, all actors, public and private, who were invited to participate in the analysis process, were requested to provide their own RVAs or other relevant information. In addition, system descriptions, plans and more overall risk assessments (county, national, global) were used both to identify hazards/threats as well as to support the detailed analysis of these.

4.1.3 *Organisation*

There were mainly three actors involved in the analysis work: i) the municipalities' working group (emergency preparedness managers and advisors; responsible for political and administrative anchoring of the process, project planning and coordination, internal and external information activities regarding the analysis, and contributing to the hazard/threat identification and more detailed risk analysis); ii) consultancy company project group (responsible for the professional content of the analysis, including hazard/threat identification and detailed risk analysis; facilitation and documentation of the analysis meetings; as well as documentation of the analysis); and, iii) participants in the analysis meetings (about 100 representatives from public and private sector contributing to hazard/threat identification and more detailed risk analysis during dedicated meetings).

4.2 *Selection of analysis method*

4.2.1 *Analysis method*

Municipal RVAs in Norway are typically performed using a method best covered by the label coarse risk analysis, which is described by Aven (2009) as a qualitative risk analysis method that can be carried out with relatively modest effort. This is consistent with the recommended method in the existing guideline on municipal RVAs (NDCP 1994).

The RVA reported on in the present paper was performed using a semi-quantitative coarse risk analysis method with extended uncertainty assessment. Semi-quantitative here refers to the use of quantitative expressions for the consequence and probability assignments for individual adverse events, but no combination or aggregation of these into an overall risk index, as would typically be done in a full quantitative risk analysis. Extended uncertainty assessment refers to an assessment of uncertainty that extends beyond the quantitative consequence and probability assignments, in our case performed by qualitatively assessing the strength of knowledge of these quantitative assignments; as explained in the following sub-section.

4.2.2 *Components used to characterise risk*

In a coarse risk analysis, risk is typically characterised by assigning the probability and (expected) consequences of each identified event. The regional RVA for the Stavanger region used the following components to characterise risk:

- The consequences given occurrence of an adverse event; specifically: i) expected consequences given occurrence; and ii) potential for significant deviation between the expected consequences and actual consequences.
- The probability that the event will occur.
- The strength of knowledge underlying the consequence and probability assignments.
- Manageability of the risk related to the event, i.e. to what extent the municipalities can reduce the risk by introducing measures.

The consequence analysis followed a similar structure as that used in the Norwegian national risk picture methodology, where consequences are assessed for five so-called *societal values* (NDCP 2010): 1) life and health; 2) nature and environment; 3) economy; 4) social stability; and 5) ability to govern/territorial control.

For each societal value a set of *consequence types* has been defined (NDCP 2010), and each of these is associated with a set of *observable quantities*

Table 1. Probability categories; and consequence categories for "Life and health—Deaths".

Category	Probability	Consequences (fatalities)
5	> 10%	> 50
4	1%–10%	15–50
3	0,1%–1%	5–15
2	0,01%–0,1%	3–5
1	< 0,01%	1–2

characterising the consequences. For example, the societal value "Life and health" is broken down into the consequence types "Death", "Injuries and illnesses" and "Physical strains". Furthermore, the consequence type "Death" is associated with the observable quantities "Number of fatalities" and "Time of death"; the latter categorised as either "Within 1 year" or "Within 20 years" (to account for immediate deaths and reduced life expectancy, respectively).

This structure was adopted in the consequence analysis part of the RVA for the Stavanger region; with some modifications: Societal value 5 in the above list was not considered as it largely relates to situations outside the scope of the analysis, i.e. security-political crises and war (cf. Section 4.1.1). Moreover, a new societal value called "Cultural values" was added. Finally, a new consequence type was added to the societal value "Life and health", namely "Psychological injuries". The last modification was made as a result of the experience gained after the 22 July 2011 terrorist attacks in Norway, where municipalities all over the country were tasked with the long-term psychological follow-up of people affected by the attacks. This was an example of how a municipality could be affected by an event occurring outside the geographical area of the municipality; cf. point b) in Section 2. Table 1 shows, as an example, the consequence categories defined for the observable quantity "Number of fatalities" related to the consequence type "Deaths".

Table 1 also shows the probability categories used. Subjective probabilities were used to describe the uncertainty related to the occurrence of events; hence the probabilities express the degree of belief that the events will occur. They are conditional on the background knowledge that their assignment is based on, including data, expert opinions and assumptions. Accordingly they are sometimes also referred to as knowledge-based probabilities. These probabilities are used to describe uncertainty (about the occurrence of events) and are hence not themselves uncertain. However, because the probabilities are conditional on a particular background knowledge, such as the assumptions made in the analysis (which in reality may turn out not to be fulfilled), there may be "uncertainties hidden in the background knowledge" (Aven 2009). Furthermore, the consequence characterisation in a coarse risk analysis is based on the specification of a single consequence per event (and per consequence type). However, there will for a given event usually be a number of possible consequences of varying severity. In an attempt to compensate for these methodological shortcomings, the probability and consequence assessment in the regional RVA was supplemented by an "extended uncertainty analysis", by highlighting: i) the strength of the knowledge base for the assigned probabilities and (expected) consequences; and, ii) potential for significant deviation between the expected result and the actual result.

The deviation potential was assessed according to the analyst's judgement using a binary classification ("Yes" or "No"). Both strength of knowledge and manageability were categorised according to qualitative criteria. The strength of knowledge underlying the assigned probabilities and (expected) consequences was assessed by categorising the probability/consequence assignment for each event according to the classification scheme of Flage & Aven (2009). Weak knowledge is characterised by situations where: the assumptions made represent strong simplifications; or, data are not available or are unreliable; or, there is lack of agreement/consensus among experts; or, the phenomena involved are not well understood. Strong knowledge is characterised by fulfilling all of the following conditions: the assumptions made are seen as very reasonable; much reliable data are available; there is broad agreement/consensus among experts; and, the phenomena involved are well understood. Moderate knowledge is characterized by conditions between those characterising weak and strong knowledge.

Manageability was categorised as follows: high—the municipalities can control/reduce the risk level (with mitigating measures, by avoiding the activity, etc.); moderate—the municipalities can influence the risk level to some extent; and, low—the municipalities cannot influence the risk level.

4.3 *Identification of initiating events (hazards/threats)*

A coarse risk analysis is commonly performed by dividing the analysis object into sub-elements and then performing a risk analysis for each of these (Aven 2009). In the present analysis both geographical areas and public services provided by the municipalities can be considered main analysis objects; cf. the analysis scope described in Section 4.1.1. However, the Civil Protection Act (2010) also imposes a general emergency

preparedness duty on the municipalities, implying an inter-sectorial responsibility intended to make the municipalities assess and plan societal safety and emergency preparedness in a more overall and integrated perspective, not limited to those areas of responsibilities imposed on the municipalities through other legislation (NDCP 2012a).

As mentioned in Section 2, the overall RVA is required to address specific challenges related to critical societal functions and loss of critical infrastructure. Critical infrastructure is defined by NDCP (2012a) as "those constructions and systems that are essential for maintaining the society's critical functions which again cover the society's basic needs and people's sense of security". Furthermore, NDCP (2012b) has presented a set of *critical societal functions* and associated *basic capabilities*, as well as a set of *critical input factors*:

- Critical societal function: Societal function whose loss threatens the basic needs (food, water, heat, safety/security, etc.) of the society and the population.
- Basic capability: The functional ability that society must be able to maintain almost regardless of the stresses to which it is subjected; capability is often defined as a combination of competence and capacity.
- Critical input factor: The external deliveries public and private actors depend on to produce and deliver in order to maintain the basic needs of the society and the population.

The critical societal functions and input factors are reproduced in Table 2.

Table 2. Critical societal functions and critical input factors (NDCP 2012b).

Critical societal functions	Critical input factors
1. Maintain necessary food supply	A. Electronic communication services
2. Maintain necessary (drinking) water supply	B. Electricity supply
3. Maintain the population's need for heat	C. Water supply
4. Maintain national crisis management	D. Wastewater treatment
5. Maintain control and crisis management	E. Fuel supply
6. Maintain democratic state of justice	F. Goods and personnel transport
7. Maintain safety/ security of life and health	G. Satellite-based services
8. Maintain law and order	H. Meteorological services
9. Maintain financial stability	
10. Maintain basic security of stored information	
11. Protect cultural values of national significance	
12. Protect the nature and environment	

In the RVA for the Stavanger region, a critical societal function called "Maintain value creation" was added, as a significant percentage of the Norwegian value creation is generated by companies with headquarters in the Stavanger region. To each of the critical societal functions there is as mentioned above associated one or more basic capabilities; for example, the critical societal function "3. Maintain the population's need for heat" is associated with the two basic capabilities "3.1 Ability to provide the population with sufficient energy to heat homes" and "3.2 Ability to provide necessary temporary shelter". Critical infrastructures can be derived from the critical input factors, e.g. electricity networks from the critical input factor "Electricity supply".

The RVA process for the Stavanger region included a survey of critical elements related to critical societal functions, associated basic capabilities, and critical input factors/infrastructures in the region. The hazard/threat identification was structured around these functions, capabilities and input factors in two ways: Firstly, the analysis meetings (cf. Section 4.1.2) were put together in an attempt to cover the totality of functions, capabilities and inputs. Secondly, the final overall hazards/threats reported as initiating events in the risk picture were to a large extent formulated in terms of loss of such functions, capabilities and inputs. This is further described and discussed in Section 5.1.

The hazards/threats/adverse events identification process related to the analysis meetings was carried out in three steps: 1) Before analysis meeting: brainstorming using online questionnaire sent to meeting participants by e-mail. 2) During analysis meeting: structured review and identification based on the principle of dividing the analysis object into sub-parts. 3) During and/or after analysis meeting: review of and identification based on checklist.

4.4 *Cause and consequence analysis*

As a result of the hazard/threat identification process described in the previous section, a large number of adverse events were identified. Many of these events would lead to loss of the

same critical societal function or input factor. For example, a total of 18 events were identified that would lead to loss of the critical input factor 'Electricity supply' (e.g., national deficit of power, breakdown of critical power line, extreme weather, etc.). In order to achieve a manageable number of events and an appropriate level of analysis for further assessment and presentation of risk, these 'sub-events' were aggregated to one main event "Failure of power supply (prolonged)". This is the event that the municipalities need to handle; the sub-event (cause) "Breakdown of critical power line" per se needs to be handled by the infrastructure owner, i.e. the power company. The sub-events were then listed as causes to the main event. This provided an appropriate focus and level of detail considering the purpose of the RVA (cf. Section 4.1.1).

Existing barriers, both preventive and consequence reducing, were identified as a part of this process along with suggestion of new risk reducing measures.

4.5 *Risk picture*

The term "risk picture" is used frequently by Norwegian authorities and professionals working with risk analysis and management. The NORSOK Z-013 standard uses the following definition: "Risk picture: synthesis of the risk assessment, with the intention to provide useful and understandable information to relevant decision makers". Among other things, uncertainty factors along with prerequisites and assumptions should be clearly and explicitly documented (NORSOK 2010).

Table 3. Extract of the events list. The right column shows the corresponding societal function/input.

Event	Societal function/input factor
1. Failure of food supply	Maintain necessary food supply
2. Distribution of hazardous food	
3. Failure of drinking water supply (prolonged)	Maintain necessary (drinking) water supply
4. Distribution of contaminated drinking water	
5. Contaminated drinking water, food, air, etc. due to radioactive fallout	
6. Failure of power supply (prolonged)	Maintain the population's need for heat/electricity supply
…	…

The risk picture for the regional RVA was established based on the identification of initiating events (hazards/threats) and the cause and consequence analysis (cf. Section 4.3, 4.4). From an initial number of several hundred adverse events, the filtering, merging and aggregation process described in Section 4.4 resulted in 51 events in the final risk picture.

For each event, the following factors were covered and presented in tabular form: Causes, probability of event, expected consequence of event, potential for significant deviation between the expected consequences and actual consequences, strength-of-knowledge base for the probability and consequence assignments, description of knowledge base (statistics, historical records, previous risk assessments, etc.), barriers and mitigating measures (both existing and suggestions for new), and manageability.

The 51 events were presented in risk matrices as a combination of probability and consequence. In addition, uncertainty and strength-of-knowledge factors were indicated the following way: i) events where there is potential for significant deviation between the expected and actual consequences were indicated with an arrow, and ii) events where the strength-of-knowledge was assigned 'Weak' according to the classification scheme in Section 4.2.2 were highlighted with a grey background.

Different risk matrices were created for the different consequence types. Figure 2 shows an example for the consequence type Life and health—Deaths.

In addition to the risk matrices, a textual description was given of the principal risk factors related to each societal value, both existing and future. Interdependencies and vulnerabilities related to critical infrastructures which became apparent in the analysis were also highlighted.

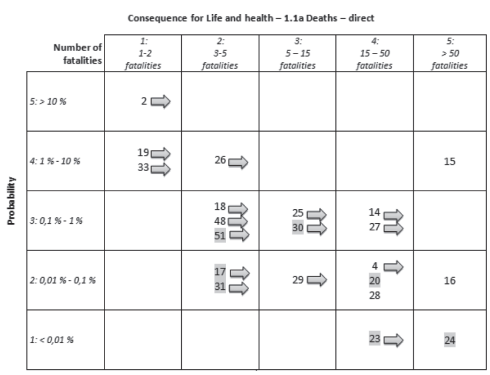

Figure 2. Risk matrix for Life and health: Deaths within 1 year.

4.6 *Compare alternatives, identification and assessment of measures*

A number of risk reducing measures were identified during the analysis process. These were structured according to whether the measure already existed or were suggested during the analysis process, and according to the level responsible for follow-up (i.e., nation or county level, regional, municipality, company/organisation—inter-municipal, municipal or private, or individual level—households/inhabitants).

Based on the analysis and the responsibilities that rest with the local authorities, 12 scenarios/events were suggested as dimensioning for the regional and municipal emergency preparedness. These events were ranging from major accidents (including terrorism and criminal acts); extreme weather and natural disasters; breakdown in critical infrastructures; and, emission of hazardous substances. The events were chosen based on the following criteria: i) events where the expected consequences are severe; ii) events where the potential for deviation from the expected consequences is considered significant or the strength of knowledge is considered weak; and, iii) events which trigger the regional and municipal top executives in the risk treatment decisions.

4.7 *Management review and judgment. Decision*

This step of the process is beyond the scope of the present paper. According to the Regulations (2011), the overall RVA shall be anchored in the municipality council, which is hence to be considered the decision-maker in this context (the decision authority possibly being delegated to other municipal political bodies or to the municipal administration). In addition to internal information activities within each municipality, the mayors and city managers of the four municipalities attended two joint project information meetings, respectively during the analysis work and after finalisation of the analysis. There were also two project information meetings for relevant actors and contributors to the analysis, respectively before and after the analysis work.

We only mention briefly two decisions that have been made based on recommendations from the analysis: Firstly, the municipalities have decided to follow up the RVA with an emergency preparedness analysis, based on the RVA results. This is inspired by the practice in the oil & gas industry (NORSOK 2010). Secondly, the municipalities have decided to establish a regional emergency preparedness council, comprising representatives from the municipality, other public actors, as well as owners of critical infrastructure. A regional council will be able to coordinate work in the area of societal safety and emergency preparedness across municipal borders.

5 DISCUSSION

In this section we discuss some selected aspects of the chosen approach to the RVA. These are methodological aspects that we consider have a transfer value to other risk analyses, in particular municipal RVAs, but also other risk analyses performed according to a semi-quantitative methodology.

5.1 *Structure of the hazard/threat identification*

The core steps taken to establish a risk picture in the regional RVA are broadly speaking the same as those taken to establish the Norwegian national risk picture (NDCP 2010); which to a large extent is based on the Dutch national risk assessment, see Veland et al. (2013) for a comparison: 1) define societal values; 2) identify hazards/threats; 3) perform risk analysis; and, 4) establish risk matrix.

A main challenge related to the hazard/threat identification is achieving some sense of completeness, i.e. identifying all relevant events. An alternative to the chosen process would be to focus on specific event types and scenarios, as done in the Norwegian national risk picture (NDCP 2013).

In the national risk picture the events are structured according to type of phenomenon: There is a phenomenological distinction between intentional and non-intentional events, and for non-intentional events we can further distinguish between natural hazards and major accidents. These three are referred to in the national risk picture as "Main categories" of hazards/threats. To each main category is associated several risk areas, e.g. "Dangerous substances" to the main category "Major accidents"; and to each risk area is associated one or more "Scenarios", e.g. "Fire at oil terminal in a city" to the risk area "Dangerous substances".

As described in Section 4.3, the hazard/threat identification in the regional RVA followed a different approach, structured around critical societal functions, associated basic capabilities, and critical inputs. The reasoning behind such an approach is that in order to safeguard societal values, certain societal functions and inputs need to be in place. Adverse events can threaten the societal values either directly or indirectly through loss of critical inputs (infrastructure) and/or critical societal functions.

For example, a car accident could threaten the societal value "Life and health" directly. Emergency services are dimensioned to handle such an event and will under normal circumstances not be challenged on the ability to handle it. However, if an event occurs (or several events simultaneously) that either "block" or "overload" the hospital, then the society value "Life and health" is also threatened indirectly through loss of the societal function

"Maintain safety/security of life and health". The selected approach involves a form of "backwards risk analysis", or risk analysis starting from the consequences, see e.g. (Aven 2009), which means that we first select the consequences that we are most concerned about, and then find events that could lead to these consequences. This of course means that not all events that could lead to consequences in terms of the societal values are included; instead, focus is placed on certain types of events that will challenge the emergency preparedness.

The chosen approach means that what enters as initiating events in the National risk picture (risk areas/scenarios), and are thus implicitly placed in the middle of a bow-tie diagram, may instead enter as causes in the regional RVA.

5.2 *Representation of uncertainty*

The risk analysis approach adopted with respect to uncertainty representation may be labelled as a predictive Bayesian approach (Aven 2012), where knowledge-based/subjective probabilities are used to express uncertainty directly about observable quantities. Frequentist probabilities were not introduced; however, the interpretation of subjective probabilities was explained such as to relate the way these were defined to long-run frequencies along the lines of the urn standard by Lindley (2006). For example, the probability category 1% – 10% (cf. Table 1 in Section 4.2.2) was explained as follows: The uncertainty related to (or degree of belief in) the event occurring is considered comparable with the uncertainty related to (or degree of belief in) drawing a coloured ball from an urn containing a total of 100 balls of which between 1 and 10 are coloured; an event that would occur on average between each 10 and 100 years if a ball is drawn (with replication) once each year in the long run.

To motivate the consequence deviation potential part of the extended uncertainty assessment (cf. Section 4.2.2), consider as an example the event "Bus Accident". The expected consequences of such an event could perhaps be a few injuries; however, the consequences could also be a large number of fatalities. If the risk analysis only reports the probability and expected consequence of this event, its consequence potential is not reflected. On the other hand, if the probability of the rather broadly defined event "Bus Accident" is linked to some sort of "worst case" scenario, there will be a mismatch between probability and consequence. One solution could be to split the single event into two events, for example "Bus Accident" and "Bus accident with multiple fatalities". This is still a simplification, as the consequences of a bus accident could be one injury, two injuries, three injuries, etc.; one fatality, two fatalities, three fatalities, etc.; or a combination of these. However, there will always be a need for a trade-off between level of detail and effort. In the regional RVA for the Stavanger region, the event "Contamination of drinking water" was split into the two events, due to a significant difference in consequence potential between these: i) distribution of contaminated drinking water; and, ii) contaminated drinking water, food, air, etc. due to radioactive fallout.

As for the strength-of-knowledge assessment, returning to the event "Bus accident" it may be assumed in the risk analysis that the bus is carrying half the number of permitted passengers at the time of the accident, and that everyone on board are using seatbelts; while in reality the bus is carrying upwards of or above the permitted number of passengers, of which only a small fraction are using seatbelts when the accident occurs.

In the regional RVA for the Stavanger several events where flagged with a 'Weak' strength-of-knowledge, due to lack of relevant data or lack of knowledge of the underlying phenomena, for example; violent acts/terror attack in the city; and, extreme weather/natural disaster.

6 CONCLUSIONS

This paper reports on the execution of an overall RVA covering four Norwegian municipalities. Selected issues are highlighted and discussed, including the structure of the hazard/threat identification, the representation of uncertainty and the presentation of the total risk picture. These are methodological aspects that we consider have a transfer value to other risk analyses, in particular municipal RVAs, but also other risk analyses performed according to a semi-quantitative methodology.

ACKNOWLEDGEMENTS

The authors would like to thank the municipalities of Randaberg, Sandnes, Sola and Stavanger for their valuable collaboration.

Modeling reliability of complex port transportation system

K. Kołowrocki & J. Soszyńska-Budny
Department of Mathematics, Maritime University, Gdynia, Poland

ABSTRACT: Modelling and prediction of the operation and reliability of technical systems related to their operation processes are presented. The emphasis is on multistate systems composed of ageing components and changing their reliability structures and their components reliability parameters during their operation processes that are called the complex systems. The integrated general model of complex systems' reliability, linking their reliability models and their operation processes models and considering variable at different operation states their reliability structures and their components reliability parameters is constructed. This theoretical tool is applied to modelling and prediction of the operation processes and reliability characteristics of the port grain transportation system composed of three multistate non-homogeneous series-parallel subsystems linked in series, changing its reliability structure and its components reliability parameters at variable operation conditions.

1 INTRODUCTION

Most real technical systems are very complex and it is difficult to analyze their reliability. Large numbers of multistate components and subsystems and their operating complexity cause that the identification, evaluation and prediction of their reliability are complicated. The complexity of the systems' operation processes and their influence on changing in time the systems' structures and their components' reliability parameters are very often met in real practice. Thus, the practical importance of an approach linking the multistate system reliability models (Hue 1985, Hue & Yang 1995a,b) and the system operation processes models (Kołowrocki & Soszyńska-Budny 2011, Kołowrocki 2006, 2008, 2014, Kołowrocki & Soszyńska 2006, 2010, Soszyńska 2007) into an integrated general model in reliability assessment of real technical systems is evident.

2 COMPLEX SYSTEM OPERATION PROCESS MODELLING

2.1 *Theoretical backgrounds*

We assume that the system during its operation process is taking v, $v \in N$, different operation states $z_1, z_2, ..., z_v$. Further, we define the system operation process $Z(t)$, $t \in <0,+\infty)$, with discrete operation states from the set $\{z_1, z_2, ..., z_v\}$. Moreover, we assume that the system operation process $Z(t)$ is a semi-Markov process (Grabski 2002, Glynn & Haas 2006, Ferreira & Pacheco 2007, Limnios & Oprisan 2001, Mercier 2008) with the conditional sojourn times θ_{bl} at the operation states z_b when its next operation state is z_l, $b, l = 1,2, ..., v$, $b \neq l$. Under these assumptions, the system operation process may be described by:

- the vector $[p_b(0)]_{1\times v}$ of the initial probabilities $p_b(0) = P(Z(0) = z_b)$, $b = 1,2, ..., v$, of the system operation process $Z(t)$ staying at particular operation states at the moment $t = 0$;
- the matrix $[p_{bl}]_{v\times v}$ of probabilities p_{bl}, $b, l = 1,2, ..., v$, $b \neq l$, of the system operation process $Z(t)$ transitions between the operation states z_b and z_l;
- the matrix $[H_{bl}(t)]_{v\times v}$ of conditional distribution functions $H_{bl}(t) = P(\theta_{bl} < t)$, $t \geq 0$, $b, l = 1,2, ..., v$, $b \neq l$, of the system operation process $Z(t)$ conditional sojourn times θ_{bl} at the operation states.

As the mean values $E[\theta_{bl}]$ of the conditional sojourn times θ_{bl} are given by

$$M_{bl} = E[\theta_{bl}] = \int_0^\infty t dH_{bl}(t), b,l = 1,2, ..., v, b \neq l, \qquad (1)$$

then from the formula for total probability, it follows that the unconditional distribution functions of the sojourn times θ_b, $b = 1,2, ..., v$, of the system operation process $Z(t)$ at the operation states z_b, $b = 1,2, ..., v$, are given by (Grabski 2002, Kołowrocki & Soszyńska-Budny 2011)

$$H_b(t) = \sum_{l=1}^{v} p_{bl} H_{bl}(t), \; t \geq 0, \; b = 1,2, ..., v.$$

Hence, the mean values $E[\theta_b]$ of the system operation process $Z(t)$ unconditional sojourn times θ_b, $b = 1,2, ..., v$, at the operation states are given by

$$M_b = E[\theta_b] = \sum_{l=1}^{v} p_{bl} M_{bl}, \; b = 1,2, ..., v, \tag{2}$$

where M_{bl} are defined by the formula (1).

The limit values of the system operation process $Z(t)$ transient probabilities at the particular operation states $p_b(t) = P(Z(t) = z_b)$, $t \in <0, +\infty)$, $b = 1,2, ..., v$, are given by Grabski 2002, Kołowrocki & Soszyńska-Budny 2011, Kołowrocki 2006, Soszyńska 2007)

$$p_b = \lim_{t \to \infty} p_b(t) = \frac{\pi_b M_b}{\sum_{l=1}^{v} \pi_l M_l}, \quad b = 1,2, ..., v, \tag{3}$$

where M_b, $b = 1,2, ..., v$, are given by (2), while the steady probabilities π_b of the vector $[\pi_b]_{1xv}$ satisfy the system of equations

$$\begin{cases} [\pi_b] = [\pi_b][p_{bl}] \\ \sum_{l=1}^{v} \pi_l = 1. \end{cases} \tag{4}$$

Other interesting characteristics of the system operation process $Z(t)$ possible to obtain are its total sojourn times $\hat{\theta}_b$ at the particular operation states z_b, $b = 1,2, ..., v$, during the fixed system opetation time. It is well known (Grabski 2002) that the system operation process total sojourn times $\hat{\theta}_b$ at the particular operation states z_b, for sufficiently large operation time θ, have approximately normal distributions with the expected value given by

$$\hat{M}_b = E[\hat{\theta}_b] = p_b \theta, \; b = 1,2, ..., v, \tag{5}$$

where p_b are given by (3).

2.2 *Example*

We consider the port grain transportation system, presented in Figure 1, assigned to handle the clearing of exported and imported grain.

The port grain transportation system function is loading railway trucks with grain. The railway truck loading is performed in the following successive grain transportation system steps:

- gravitational passing of grain from the storage placed on the 8th elevator floor through 45 hall to horizontal conveyors placed in the elevator basement,

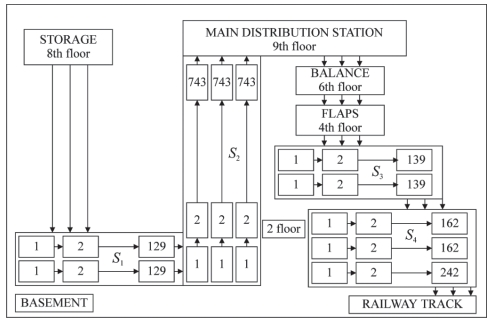

Figure 1. The scheme of the port grain transportation system structure at the operation state z_1.

- transport of grain through horizontal conveyors to vertical bucket elevators transporting grain to the main distribution station placed on the 9th floor,
- gravitational dumping of grain through the main distribution station to the balance placed on the 6th floor,
- dumping weighed grain through the complex of flaps placed on the 4th floor to horizontal conveyors placed on the 2nd floor,
- dumping of grain from horizontal conveyors to worm conveyors,
- dumping of grain from worm conveyors to railway trucks.

In loading the railway trucks with grain the following presented in Figures 1 and 2 transportation subsystems take part:

S_1—horizontal conveyors of the first type,
S_2—vertical bucket elevators,
S_3—horizontal conveyors of the second type,
S_4—worm conveyors,

the main distribution station and the balance.

The main distribution station is the system of dumping channels in the form of a steel box composed of dividing walls, which direct the grain from bucket conveyors to the balance. Its executive elements are composed of three steel sleeves and pneumatic elements in the form of three servomotors. The electronic balance weighs the dumped grain with electronic indicators. Its executive elements during loading and unloading with grain are flaps, which are opened and closed by five pneumatic servomotors. In further analysis, we omit these two subsystems and will deal with the reliability of the subsystems S_1, S_2, S_3 and S_4 only.

The transportation subsystems S_1, S_2, S_3 and S_4 have steel covers and they are provided with drives in the form of electrical engines with gears. In their reliability analysis we omit their drives as they are different types mechanisms. We also omit their

covers as they have a high reliability and, practically, do not fail.

Taking into account the operation process of the considered transportation system, described by its operators, we distinguish its following $\nu = 3$ operation states:

z_1—the system operation with the largest efficiency when all components of the subsystems S_1, S_2, S_3 and S_4 are used (Fig. 1),

z_2—the system operation with less efficiency system when the first conveyor of subsystem S_1, the first and second elevators of subsystem S_2, the first conveyor of subsystem S_3 and the first and second conveyors of subsystem S_4 are used (Fig. 3),

z_3—the system operation with least efficiency when only the first conveyor of subsystem S_1, the first elevator of subsystem S_2, the first conveyor of subsystem S_3 and the first conveyor of subsystem S_4 are used (Fig. 4).

Figure 2. The general scheme of the port grain transportation system reliability structure.

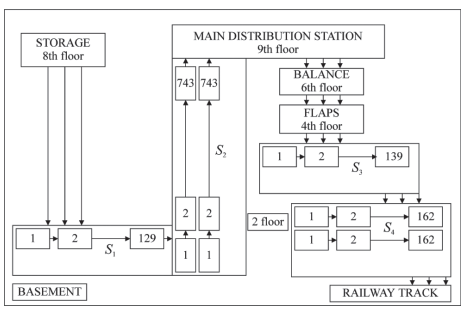

Figure 3. The scheme of the port grain transportation system structure at the operation state z_2.

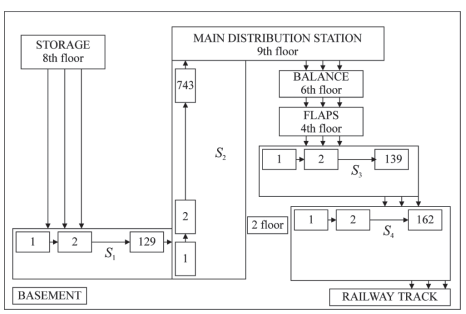

Figure 4. The scheme of the port grain transportation system structure at the operation state z_3.

At all system operation states, subsystems S_1, S_2, S_3 and S_4 become either non-homogeneous series-parallel systems or non-homogeneous series systems.

This way, the changes of the grain transportation system reliability structure at different operation states are defined. Its components reliability parameters at different operation states will be defined in this example continuation in Section 3.

Considering the system operators opinion, we assume the matrix of the probabilities of transitions between the states are given by

$$[p_{bl}]_{3x3} = \begin{bmatrix} 0 & \frac{1}{3} & \frac{2}{3} \\ \frac{4}{9} & 0 & \frac{5}{9} \\ \frac{1}{3} & \frac{2}{3} & 0 \end{bmatrix} \tag{6}$$

Moreover, we assume the following matrix of the conditional distribution functions of the system sojourn times θ_{bl}, $b, l = 1, 2, 3$,

$$[H_{bl}(t)]_{3x3} = \begin{bmatrix} 0 & 1-e^{-5t} & 1-e^{-10t} \\ 1-e^{-40t} & 0 & 1-e^{-50t} \\ 1-e^{-10t} & 1-e^{-20t} & 0 \end{bmatrix}.$$

Further, using (5), we fix the conditional mean values $M_{bl} = E[\theta_{bl}]$, $b,l = 1,2,3,4$, of the exemplary system sojourn times at the particular operation states as follows:

$$M_{12} = 0.20, \quad M_{13} = 0.10, \; M_{21} = 0.025, \\ M_{23} = 0.020, \; M_{31} = 0.10, \; M_{32} = 0.05. \tag{7}$$

This way, the exemplary system operation process is defined and we may find its main characteristics. Namely, applying (2), (6) and (7), the unconditional mean sojourn times at the particular operation states are given by:

$$M_1 = 0.133, \; M_2 = 0.022, \; M_3 = 0.067. \tag{8}$$

Further, according to (4), the system of equations after considering (6), we find the steady probabilities

$$\pi_1 \cong 0.279, \; \pi_2 \cong 0.344, \; \pi_3 \cong 0.377. \tag{9}$$

After considering the result (8) and (9), according to (3), the limit values of the exemplary system operation process transient probabilities $p_b(t)$ at the operation states z_b are given by

$$p_1 \cong 0.530, \; p_2 \cong 0.109, \; p_3 \cong 0.361. \tag{10}$$

Hence, the expected values of the total sojourn times $\hat{\theta}_b$, $b=1,2,3,4$, of the exemplary system operation process at the particular operation states z_b, $b=1,2,3,4$, during the fixed operation time $\theta=1$ year = 365 days, after applying (5), amount (in days):

$$\hat{M}_1 \cong 193.4,\ \hat{M}_2 \cong 39.8,\ \hat{M}_3 \cong 131.8. \tag{11}$$

3 COMPLEX SYSTEM RELIABILITY MODELLING

3.1 *Theoretical backgrounds*

We assume that the changes of the operation states of the system operation process $Z(t)$ have an influence on the system multistate components E_i, $i=1,2,...,n$, reliability and the system reliability structure as well. Consequently, we denote the system multistate component E_i, $i=1,2,...,n$, conditional lifetime in the reliability state subset $\{u,u+1,...,z\}$ while the system is at the operation state z_b, $b=1,2,...,v$, by $T_i^{(b)}(u)$ and its conditional reliability function by the vector

$$[R_i(t,\cdot)]^{(b)} = [1,[R_i(t,1)]^{(b)},...,[R_i(t,z)]^{(b)}],$$

with the coordinates defined by

$$[R_i(t,u)]^{(b)} = P(T_i^{(b)}(u) > t \,|\, Z(t) = z_b)$$

For $t \in <0,\infty)$, $u=1,2,...,z$, $b=1,2,...,v$.

The reliability function $[R_i(t,u)]^{(b)}$ is the conditional probability that the component E_i lifetime $T_i^{(b)}(u)$ in the reliability state subset $\{u,u+1,...,z\}$ is greater than t, while the system operation process $Z(t)$ is at the operation state z_b.

Similarly, we denote the system conditional lifetime in the reliability state subset $\{u,u+1,...,z\}$ while the system is at the operation state z_b, $b=1,2,...,v$, by $T^{(b)}(u)$ and the conditional reliability function of the system by the vector

$$[\boldsymbol{R}(t,\cdot)]^{(b)} = [1,\ [\boldsymbol{R}(t,1)]^{(b)},...,[\boldsymbol{R}(t,z)]^{(b)}],$$

with the coordinates defined by

$$[\boldsymbol{R}(t,u)]^{(b)} = P(T^{(b)}(u) > t \,|\, Z(t) = z_b) \tag{12}$$

For $t \in <0,\infty)$, $u=1,2,...,z$, $b=1,2,...,\nu$.

The reliability function $[\boldsymbol{R}(t,u)]^{(b)}$ is the conditional probability that the system lifetime $T^{(b)}(u)$ in the reliability state subset $\{u,u+1,...,z\}$ is greater than t, while the system operation process $Z(t)$ is at the operation state z_b.

Further, we denote the system unconditional lifetime in the reliability state subset $\{u,u+1,...,z\}$ by $T(u)$ and the unconditional reliability function of the system by the vector

$$\boldsymbol{R}(t,\cdot) = [1,\ \boldsymbol{R}(t,1),...,\ \boldsymbol{R}(t,z)],$$

with the coordinates defined by

$$\boldsymbol{R}(t,u) = P(T(u) > t) \tag{13}$$

For $t \in <0,\infty)$, $u=1,2,...,z$.

In the case when the system operation time θ is large enough, the coordinates of the unconditional reliability function of the system defined by (13) are given by

$$\boldsymbol{R}(t,u) \cong \sum_{b=1}^{v} p_b [\boldsymbol{R}(t,u)]^{(b)} \ for\ t \geq 0,\ u=1,2,...,z, \tag{14}$$

where $[\boldsymbol{R}(t,u)]^{(b)}$ $u=1,2,...,z$, $b=1,2,...,\nu$, are the coordinates of the system conditional reliability functions defined by (12) and p_b, $b=1,2,...,\nu$, are the system operation process limit transient probabilities given by (3).

Thus, the mean value $\mu(u)=E[T(u)]$ of the system unconditional lifetime $T(u)$ in the reliability state subset $\{u,u+1,...,z\}$ is given by (Kołowrocki & Soszyńska-Budny 2011)

$$\mu(u) \cong \sum_{b=1}^{\nu} p_b \mu_b(u),\ u=1,2,...,z, \tag{15}$$

where $M_b(u)=E[T^{(b)}(u)]$ are the mean values of the system conditional lifetimes $T^{(b)}(u)$ in the reliability state subset $\{u,u+1,...,z\}$ at the operation state z_b, $b=1,2,...,\nu$, given by

$$\mu_b(u) = \int_0^{\infty} [\boldsymbol{R}(t,u)]^{(b)} dt,\ u=1,2,...,z, \tag{16}$$

$[\boldsymbol{R}(t,u)]^{(b)}$, $u=1,2,...,z$, $b=1,2,...,\nu$, are defined by (12) and p_b are given by (3). Since the relationships between the system unconditional lifetimes $\overline{T}(u)$ in the particular reliability states and the system unconditional lifetimes $T(u)$ in the reliability state subsets can be expressed by

$$\overline{T}(u) = T(u) - T(u+1),\ u=0,1,...,z-1,$$
$$\overline{T}(z) = T(z),$$

then we get the following formulae for the mean values of the unconditional lifetimes of the system in particular reliability states

$$\overline{\mu}(u) = \mu(u) - \mu(u+1),\ u=0,1,...,z-1,$$
$$\overline{\mu}(z) = \mu(z), \tag{17}$$

where $\mu(u)$, $u = 0,1, ..., z$, are given by (15).

Moreover, if $s(t)$ is the system reliability state at he moment t, $t \in <0,\infty)$, and r, $r \in \{1,2, ..., z\}$, is the system critical reliability state, then the system risk function

$$\boldsymbol{r}(t) = P(s(t) < r \mid s(0) = z) = P(T(r) \leq t),\ t \in <0, \infty),$$

defined as the probability that the system is in the subset of states worse than the critical state r, $r \in \{1, ..., z\}$ while it was in the state z at the moment $t = 0$ is given by (Kołowrocki & Soszyńska-Budny 2011)

$$\boldsymbol{r}(t) = 1 - \boldsymbol{R}(t,r),\ t \in <0,\infty), \tag{18}$$

where $\boldsymbol{R}(t,r)$ is the coordinate of the system unconditional reliability function given by (14) for $u = r$ and if τ is the moment when the system risk function exceeds a permitted level δ, then

$$\tau = \boldsymbol{r}^{-1}(\delta), \tag{19}$$

where $\boldsymbol{r}^{-1}(t)$, if it exists, is the inverse function of the risk function $\boldsymbol{r}(t)$ given by (18).

3.2 *Example—continuation*

Taking into account the efficiency of the considered in Section 2 port grain transportation system we distinguish the following three reliability states of the systems and its components:

state 2—the state ensuring the largest efficiency of the system and its conveyors,
state 1—the state ensuring less efficiency of the system caused by throwing grain off the system conveyors,
state 0—the state involving failure of the system.

The considered here transportation system analysis of its varying in time operation process is analyzed in this paper Section 2.2. In Section 2.2, it is assumed that the system reliability structure and its subsystems and components reliability depend on its changing in time operation states. Considering the assumptions and agreements of these sections, we assume that its subsystems S_υ, $\upsilon = 1,2,3,4$, are composed of three-state, i.e. z = 3, components $E_{ij}^{(\upsilon)}$, $\upsilon = 1,2,3,4$, having the conditional reliability functions given by the vector

$$[R_{ij}^{(\upsilon)}(t,\cdot)]^{(b)} = [1,[R_{ij}^{(\upsilon)}(t,1)]^{(b)},[R_{ij}^{(\upsilon)}(t,2)]^{(b)}],$$
$$b = 1,2,3,$$

with the exponential co-ordinates

$$[R_{ij}^{(\upsilon)}(t,1)]^{(b)} = \exp[-[\lambda_{ij}^{(\upsilon)}(1)]^{(b)}t],$$
$$[R_{ij}^{(\upsilon)}(t,2)]^{(b)} = \exp[-[\lambda_{ij}^{(\upsilon)}(2)]^{(b)}t],$$

different at various operation states z_b, $b = 1,2,3$, and with the intensities of departure from the reliability state subsets $\{1,2\}$, $\{2\}$, respectively

$$[\lambda_{ij}^{(\upsilon)}(1)]^{(b)}, [\lambda_{ij}^{(\upsilon)}(2)]^{(b)},\ b = 1,2,3.$$

The influence of the system operation states changing on the changes of the system reliability structure and its components reliability functions is as follows.

At the system operation state z_1, the system is a series system with the structure showed in Figure 2, composed of four series-parallel subsystems S_1, S_2, S_3 and S_4 illustrated respectively in Figure 1.

The subsystem S_1 with the structure showed in Figure 1, consists of two identical belt conveyors forming series subsystems ($k^{(1)} = 2$) each composed of 129 components ($l_1^{(1)} = 129$, $l_2^{(1)} = 129$) with the exponential reliability functions. In both series subsystems of the subsystem S_1 there are respectively:

– 1 belt marked by $E_{ij}^{(1)}$, $i = 1,2$, $j = 1$, with a reliability function co-ordinates

$$[R_{ij}^{(1)}(t,1)]^{(1)} = \exp[-0.0125t],$$
$$[R_{ij}^{(1)}(t,2)]^{(1)} = \exp[-0.0150t],\ t \geq 0,\ i = 1,2,\ j = 1;$$

– 2 drums marked by $E_{ij}^{(1)}$, $i = 1,2$, $j = 2,3$, with a reliability function co-ordinates

$$[R_{ij}^{(1)}(t,1)]^{(1)} = \exp[-0.0015t],$$
$$[R_{ij}^{(1)}(t,2)]^{(1)} = \exp[-0.0020t],\ t \geq 0,\ i = 1,2,\ j = 2,3;$$

– 117 channeled rollers marked by $E_{ij}^{(1)}$, $i = 1,2$, $j = 4,5, ..., 120$, with a reliability function co-ordinates

$$[R_{ij}^{(1)}(t,1)]^{(1)} = \exp[-0.005t],$$
$$[R_{ij}^{(1)}(t,2)]^{(1)} = \exp[-0.010t],\ t \geq 0,$$
$$i = 1,2,\ j = 4,5, ..., 120;$$

– 9 supporting rollers marked by $E_{ij}^{(1)}$, $i = 1,2$, $j = 121,122, ..., 129$, with a reliability function co-ordinates

$$[R_{ij}^{(1)}(t,1)]^{(1)} = \exp[-0.004t],$$
$$[R_{ij}^{(1)}(t,2)]^{(1)} = \exp[-0.008t],\ t \geq 0,$$
$$i = 1,2,\ j = 121,122, ..., 129.$$

Thus, at the operation state z_1, the subsystem S_1 is a three-state series-parallel system with its structure shape parameters $k^{(1)} = 2$, $l_1^{(1)} = 129$, $l_2^{(1)} = 129$, and

according to Proposition 9.1 given in [24], its conditional reliability function is given by

$$[\boldsymbol{R}^{(1)}(t,\cdot)]^{(1)} = [1,[\boldsymbol{R}^{(1)}(t,1)]^{(1)},[\boldsymbol{R}^{(1)}(t,2)]^{(1)}],\ t \geq 0, \tag{20}$$

where

$$\begin{aligned}[\boldsymbol{R}^{(1)}(t,1)]^{(1)} &= 2\exp[-0.6365t] - \exp[-1.2730t],\\ [\boldsymbol{R}^{(1)}(t,2)]^{(1)} &= 2\exp[-1.2610t] - \exp[-2.5220t].\end{aligned} \tag{21}$$

The subsystem S_2 with the structure showed in Figure 1, consists of three identical bucket elevators forming series subsystems ($k^{(1)} = 3$) each composed of 743 components ($l_1^{(1)} = 743$, $l_2^{(1)} = 743$, $l_3^{(1)} = 743$) with the exponential reliability functions. In each series subsystems of the subsystem S_2 there are respectively:

– 1 belt marked by $E_{ij}^{(2)}$, $i = 1,2,3$, $j = 1$, with a reliability function co-ordinates

$$[R_{ij}^{(2)}(t,1)]^{(1)} = \exp[-0.025t],$$
$$[R_{ij}^{(2)}(t,2)]^{(1)} = \exp[-0.030t],\ t \geq 0,\ i = 1,2,3,\ j = 1;$$

– 2 drums marked by $E_{ij}^{(2)}$, $i = 1,2,3$, $j = 2,3$, with a reliability function co-ordinates

$$[R_{ij}^{(2)}(t,1)]^{(1)} = \exp[-0.0015t],$$
$$[R_{ij}^{(2)}(t,2)]^{(1)} = \exp[-0.0020t],\ t \geq 0,\ i = 1,2,3,\ j = 2,3;$$

– 740 buckets marked by $E_{ij}^{(2)}$, $i = 1,2,3$, $j = 4,5, ..., 743$, with a reliability function co-ordinates

$$[R_{ij}^{(2)}(t,1)]^{(1)} = \exp[-0.030t],$$
$$[R_{ij}^{(2)}(t,2)]^{(1)} = \exp[-0.035t],\ t \geq 0,$$
$$i = 1,2,3,\ j = 4,5, ..., 743.$$

Thus, at the operation state z_1, the subsystem S_2 is a three-state series-parallel system with its structure shape parameters $k^{(1)} = 3$, $l_1^{(1)} = 743$, $l_2^{(1)} = 743$, $l_3^{(1)} = 743$, and according to Proposition 9.1 given in [24], its conditional reliability function is given by

$$[\boldsymbol{R}^{(2)}(t,\cdot)]^{(1)} = [1,[\boldsymbol{R}^{(2)}(t,1)]^{(1)},[\boldsymbol{R}^{(2)}(t,2)]^{(1)}],\ t \geq 0, \tag{22}$$

where

$$\begin{aligned}[\boldsymbol{R}^{(2)}(t,1)]^{(1)} &= 3\exp[-22.2280t] - 3\exp[-44.4560t]\\ &\quad + \exp[-66.6840t],\\ [\boldsymbol{R}^{(2)}(t,2)]^{(1)} &= 3\exp[-25.9340t] - 3\exp[-51.8680t]\\ &\quad + \exp[-77.8020t],\end{aligned} \tag{23}$$

The subsystem S_3 with the structure showed in Figure 1, consists of two identical belt conveyors forming series subsystems ($k^{(1)} = 2$) each composed of 139 components ($l_1^{(1)} = 139$, $l_2^{(1)} = 139$) with the exponential reliability functions. In both series subsystems of the subsystem S_3 there are respectively:

– 1 belt marked by $E_{ij}^{(3)}$, $i = 1,2$, $j = 1$, with a reliability function co-ordinates

$$[\boldsymbol{R}_{ij}^{(3)}(t,1)]^{(1)} = \exp[-0.0125t],$$
$$[\boldsymbol{R}_{ij}^{(3)}(t,2)]^{(1)} = \exp[-0.0150t],\ t \geq 0,\ i = 1,2,\ j = 1;$$

– 2 drums marked by $E_{ij}^{(3)}$, $i = 1,2$, $j = 2,3$, with a reliability function co-ordinates

$$[R_{ij}^{(3)}(t,1)]^{(1)} = \exp[-0.0015t],$$
$$[R_{ij}^{(3)}(t,2)]^{(3)} = \exp[-0.0020t],\ t \geq 0,\ i = 1,2,\ j = 2,3;$$

– 117 channeled rollers marked by $E_{ij}^{(3)}$, $i = 1,2$, $j = 4,5, ..., 120$, with a reliability function co-ordinates

$$[R_{ij}^{(3)}(t,1)]^{(1)} = \exp[-0.005t],$$
$$[R_{ij}^{(3)}(t,2)]^{(1)} = \exp[-0.010t],\ t \geq 0,$$
$$i = 1,2,\ j = 4,5, ..., 120;$$

– 19 supporting rollers marked by $E_{ij}^{(1)}$, $i = 1,2$, $j = 121,122, ..., 139$, with a reliability function co-ordinates

$$[R_{ij}^{(3)}(t,1)]^{(1)} = \exp[-0.004t],$$
$$[R_{ij}^{(3)}(t,2)]^{(1)} = \exp[-0.008t],\ t \geq 0,$$
$$i = 1,2,\ j = 121,122, ..., 139.$$

Thus, at the operation state z_1, the subsystem S_3 is a three-state series-parallel system with its structure shape parameters $k^{(1)} = 2$, $l_1^{(1)} = 139$, $l_2^{(1)} = 139$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(3)}(t,\cdot)]^{(1)} = [1,[\boldsymbol{R}^{(3)}(t,1)]^{(1)},[\boldsymbol{R}^{(3)}(t,2)]^{(1)}],\ t \geq 0, \tag{24}$$

where

$$\begin{aligned}[\boldsymbol{R}^{(3)}(t,1)]^{(1)} &= 2\exp[-0.6765t] - \exp[-1.3530t],\\ [\boldsymbol{R}^{(3)}(t,2)]^{(1)} &= 2\exp[-1.3410t] - \exp[-2.6820t].\end{aligned} \tag{25}$$

The subsystem S_4 with the structure showed in Figure 3, consists of three chain conveyors forming series subsystems ($k^{(1)} = 3$), each composed of a wheel driving the belt, a reversible driving wheel and 160, 160 and 240 links respectively. Thus, two

conveyors have 162 components and the remaining one has 242 components ($l_1^{(1)} = 162$, $l_2^{(1)} = 162$, $l_3^{(1)} = 242$) what means that the subsystem is a non-homogeneous non-regular three-state series-parallel system with the exponential reliability functions. In two series subsystems of the subsystem S_4 there are respectively:

– 2 two driving wheels marked by $E_{ij}^{(4)}$, $i = 1,2$, $j = 2$, with a reliability function co-ordinates

$$[R_{ij}^{(4)}(t,1)]^{(1)} = \exp[-0.005t],$$
$$[R_{ij}^{(4)}(t,2)]^{(1)} = \exp[-0.006t],\ t \geq 0,\ i = 1,2,\ j = 2;$$

– 160 links marked by $E_{ij}^{(4)}$, $i = 1,2$, $j = 3,4, ..., 162$, with a reliability function co-ordinates

$$[R_{ij}^{(4)}(t,1)]^{(1)} = \exp[-0.012t],$$
$$[R_{ij}^{(4)}(t,2)]^{(1)} = \exp[-0.014t], t \geq 0,$$
$$i = 1,2, j = 3,4, ..., 162.$$

In the third series subsystems of the subsystem S_4 there are respectively:

– 2 two driving wheels marked by $E_{ij}^{(4)}$, $i = 3$, $j = 2$, with a reliability function co-ordinates

$$[R_{ij}^{(4)}(t,1)]^{(1)} = \exp[-0.022t],$$
$$[R_{ij}^{(4)}(t,2)]^{(1)} = \exp[-0.024t],\ t \geq 0,\ i = 3,\ j = 2;$$

– 240 links marked by $E_{ij}^{(4)}$, $i = 3$, $j = 3,4, ..., 242$, with a reliability function co-ordinates

$$[R_{ij}^{(4)}(t,1)]^{(1)} = \exp[-0.034t],$$
$$[R_{ij}^{(4)}(t,2)]^{(1)} = \exp[-0.040t],\ t \geq 0,$$
$$i = 3, j = 3,4, ..., 242.$$

Thus, at the operation state z_1, the subsystem S_4 is a three-state series-parallel system with its structure shape parameters $k^{(1)} = 3$, $l_1^{(1)} = 162$, $l_2^{(1)} = 162$, $l_3^{(1)} = 242$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(4)}(t,\cdot)]^{(1)} = [1,[\boldsymbol{R}^{(4)}(t,1)]^{(1)},[\boldsymbol{R}^{(4)}(t,2)]^{(1)}],\ t \geq 0, \tag{26}$$

where

$$\begin{aligned}[\boldsymbol{R}^{(4)}(t,1)]^{(1)} &= 2\exp[-1.930t] - 2\exp[-10.134t] \\ &\quad - \exp[-3.860t] + \exp[-12.064t] \\ &\quad + \exp[-8.204t], \\ [\boldsymbol{R}^{(4)}(t,2)]^{(1)} &= 2\exp[-2.252t] - 2\exp[-11.900t] \\ &\quad - \exp[-4.504t] + \exp[-14.152t] \\ &\quad + \exp[-9.648t].\end{aligned} \tag{27}$$

Considering that the system at the operation state z_1 is a three-state series system composed of subsystems S_1, S_2, S_3 and S_4, after applying the formulae appearing after Definition 3.4 given in (Kołowrocki 2014) and the results (20)-(21), (22)-(23), (24)-(25) and (26)-(27), its conditional reliability function is given by

$$[\boldsymbol{R}(t,\cdot)]^{(1)} = [1,[\boldsymbol{R}(t,1)]^{(1)},[\boldsymbol{R}(t,2)]^{(1)}],\ t \geq 0, \tag{28}$$

where

$$\begin{aligned}[R(t,1)]^{(1)} &= 24\exp[-25.4710t] - 24\exp[-47.6990t] \\ &\quad + 8\exp[-69.9270t] - 12\exp[-26.1075t] \\ &\quad + 12\exp[-48.3355t] - 4\exp[-70.5635t] \\ &\quad - 12\exp[-26.1475t] + 12\exp[-48.3755t] \\ &\quad - 4\exp[-70.6035t] + 6\exp[-26.7840t] \\ &\quad - 6\exp[-49.0120t] + 2\exp[-71.2400t] \\ &\quad - 24\exp[-33.6750t] + 24\exp[-55.9030t] \\ &\quad - 8\exp[-78.1310t] + 12\exp[-34.3115t] \\ &\quad - 12\exp[-56.5395t] + 4\exp[-78.7675t] \\ &\quad + 12\exp[-34.3515t] - 12\exp[-56.5795t] \\ &\quad + 4\exp[-78.8075t] - 6\exp[-34.9880t] \\ &\quad + 6\exp[-57.2160t] - 2\exp[-79.4440t] \\ &\quad - 12\exp[-27.4010t] + 12\exp[-49.6290t] \\ &\quad - 4\exp[-71.8570t] + 6\exp[-28.0375t] \\ &\quad - 6\exp[-50.2655t] + 2\exp[-72.4935t] \\ &\quad + 6\exp[-28.0775t] - 6\exp[-50.3055t] \\ &\quad + 2\exp[-72.5335t] - 3\exp[-28.7140t] \\ &\quad + 3\exp[-50.9420t] - \exp[-73.1700t] \\ &\quad + 12\exp[-35.6050t] - 12\exp[-57.8330t] \\ &\quad + 4\exp[-80.0610t] - 6\exp[-36.2415t] \\ &\quad + 6\exp[-58.4695t] - 2\exp[-80.9750t] \\ &\quad - 6\exp[-36.2815t] + 6\exp[-58.5095t] \\ &\quad - 2\exp[80.7375t] + 3\exp[-36.9180t] \\ &\quad - 3\exp[-59.1460t] + \exp[-81.3740t] \\ &\quad + 12\exp[-31.7450t] - 6\exp[-32.4215t] \\ &\quad - 12\exp[-53.9730t] + 6\exp[-54.6495t] \\ &\quad + 4\exp[-76.2010t] - 2\exp[-76.8775t] \\ &\quad - 6\exp[-32.3815t] + 3\exp[-33.0580t] \\ &\quad + 6\exp[-54.6095t] - 3\exp[-55.2860t] \\ &\quad - 2\exp[-76.8375t] + \exp[-77.5140t],\end{aligned}$$

$$\begin{aligned}[R(t,2)]^{(1)} &= 24\exp[-30.7880t] - 24\exp[-56.7220t] \\ &\quad + 8\exp[-82.6560t] - 12\exp[-32.0490t] \\ &\quad + 12\exp[-57.9830t] - 4\exp[-83.9170t] \\ &\quad - 12\exp[-32.1290t] + 12\exp[-58.0630t] \\ &\quad - 4\exp[-83.9970t] + 6\exp[-33.3900t] \\ &\quad - 6\exp[-59.3240t] + 2\exp[-86.1690t] \\ &\quad - 24\exp[-40.4360t] + 24\exp[-66.3700t] \\ &\quad - 8\exp[-92.3040t] + 12\exp[-41.6970t] \\ &\quad - 12\exp[-67.6310t] + 4\exp[-93.5650t] \\ &\quad + 12\exp[-41.7770t] - 12\exp[-67.7110t] \\ &\quad + 4\exp[-93.6450t] - 6\exp[-43.0380t] \\ &\quad + 6\exp[-68.9720t] - 2\exp[-94.9060t] \\ &\quad - 12\exp[-33.0400t] + 12\exp[-58.9740t]\end{aligned}$$

$$
\begin{aligned}
&- 4\exp[-84.9080t] + 6\exp[-34.3010t] \\
&- 6\exp[-60.2350t] + 2\exp[-85.2580t] \\
&+ 6\exp[-34.3810t] - 6\exp[-60.3150t] \\
&+ 2\exp[-86.2490t] - 3\exp[-35.6420t] \\
&+ 3\exp[-61.5760t] - \exp[-87.5100t] \\
&+ 12\exp[-42.6880t] - 12\exp[-68.6220t] \\
&+ 4\exp[-94.5560t] - 6\exp[-43.9490t] \\
&+ 6\exp[-69.8830t] - 2\exp[-95.8170t] \\
&- 6\exp[-44.0290t] + 6\exp[-69.9630t] \\
&- 2\exp[-95.8970t] + 3\exp[-45.2900t] \\
&- 3\exp[-71.2240t] + \exp[-97.1580t] \\
&+ 12\exp[-38.1840t] - 6\exp[-39.5250t] \\
&- 12\exp[-64.1180t] + 6\exp[-65.4590t] \\
&+ 4\exp[-90.0520t] - 2\exp[-91.3930t] \\
&- 6\exp[-39.4450t] + 3\exp[-40.7860t] \\
&+ 6\exp[-65.3790t] - 3\exp[-66.7200t] \\
&- 2\exp[-91.3130t] + \exp[-92.6540t], \qquad (29)
\end{aligned}
$$

The expected values and standard deviations of the system conditional lifetimes in the reliability state subsets {1,2}, {2} at the operation state z_1, calculated from the results given by (29), according to (16), respectively are:

$$
\begin{aligned}
\mu_1(1) &= \int_0^\infty [\mathrm{R}(t,1)]^{(1)}\,dt \cong 0.0813 \text{ month}, \\
\mu_1(2) &= \int_0^\infty [\mathrm{R}(t,2)]^{(1)}\,dt \cong 0.0691 \text{ month}. \qquad (30)
\end{aligned}
$$

At the system operation state z_2, the system is a series system with the structure showed in Figure 2, composed of four subsystems S_1, S_2, S_3 and S_4 illustrated respectively in Figure 3.

The subsystem S_1 with the structure showed in Figure 3, consists of one belt conveyor forming a series systems ($k^{(2)} = 1$) composed of 129 components ($l_1^{(2)} = 129$) with the exponential reliability functions. In the series system of the subsystem S_1 there are respectively:

– 1 belt marked by $E_{ij}^{(1)}$, $i = 1$, $j = 1$, with a reliability function co-ordinates

$$
\begin{aligned}
&[R_{ij}^{(1)}(t,1)]^{(2)} = \exp[-0.0110t], \\
&[R_{ij}^{(1)}(t,2)]^{(2)} = \exp[-0.0120t],\ t \geq 0,\ i = 1,\ j = 1;
\end{aligned}
$$

– 2 drums marked by $E_{ij}^{(1)}$ $i = 1$, $j = 2,3$, with a reliability function co-ordinates

$$
\begin{aligned}
&[R_{ij}^{(1)}(t,1)]^{(2)} = \exp[-0.0010t], \\
&[R_{ij}^{(1)}(t,2)]^{(2)} = \exp[-0.0012t],\ t \geq 0,\ i = 1,21,\ j = 2,3;
\end{aligned}
$$

– 117 channeled rollers marked by $E_{ij}^{(1)}$, $i = 1$, $j = 4,5, ..., 120$, with a reliability function co-ordinates

$$
\begin{aligned}
&[R_{ij}^{(1)}(t,1)]^{(2)} = \exp[-0.003t], \\
&[R_{ij}^{(1)}(t,2)]^{(2)} = \exp[-0.006t],\ t \geq 0, \\
&i = 1,\ j = 4,5, ..., 120;
\end{aligned}
$$

– 9 supporting rollers marked by $E_{ij}^{(1)}$, $i = 1$, $j = 121,122, ..., 129$, with a reliability function co-ordinates

$$
\begin{aligned}
&[R_{ij}^{(1)}(t,1)]^{(2)} = \exp[-0.002t], \\
&[R_{ij}^{(1)}(t,2)]^{(2)} = \exp[-0.003t],\ t \geq 0, \\
&i = 1,\ j = 121,122, ..., 129.
\end{aligned}
$$

Thus, at the operation state z_2, the subsystem S_1 is a three-state series-parallel system (a series system) with its structure shape parameters $k^{(2)} = 1$, $l_1^{(2)} = 129$, and according to the formulae appearing after according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$
[\boldsymbol{R}^{(1)}(t,\cdot)]^{(2)} = [1,[\boldsymbol{R}^{(1)}(t,1)]^{(2)},[\boldsymbol{R}^{(1)}(t,2)]^{(2)},\ t \geq 0, \qquad (31)
$$

where

$$
\begin{aligned}
&[\boldsymbol{R}^{(1)}(t,1)]^{(2)} = \exp[-0.3710t], \\
&[\boldsymbol{R}^{(1)}(t,2)]^{(2)} = \exp[-0.7434t]. \qquad (32)
\end{aligned}
$$

The subsystem S_2 with the structure showed in Figure 3, consists of two identical bucket elevators forming series subsystems ($k^{(2)} = 2$) each composed of 743 components ($l_1^{(2)} = 743$, $l_2^{(2)} = 743$) with the exponential reliability functions. In each series subsystems of the subsystem S_2 there are respectively:

– 1 belt marked by $E_{ij}^{(2)}$, $i = 1,2$, $j = 1$, with a reliability function co-ordinates

$$
\begin{aligned}
&[R_{ij}^{(2)}(t,1)]^{(2)} = \exp[-0.020t], \\
&[R_{ij}^{(2)}(t,2)]^{(2)} = \exp[-0.024t],\ t \geq 0,\ i = 1,2,\ j = 1;
\end{aligned}
$$

– 2 drums marked by $E_{ij}^{(2)}$ $i = 1,2$, $j = 2,3$, with a reliability function co-ordinates

$$
\begin{aligned}
&[R_{ij}^{(2)}(t,1)]^{(2)} = \exp[-0.0012t], \\
&[R_{ij}^{(2)}(t,2)]^{(2)} = \exp[-0.0014t],\ t \geq 0,\ i = 1,2,\ j = 2,3;
\end{aligned}
$$

– 740 buckets marked by $E_{ij}^{(2)}$ $i = 1,2$, $j = 4,5, ..., 743$, with a reliability function co-ordinates

$$
\begin{aligned}
&[R_{ij}^{(2)}(t,1)]^{(2)} = \exp[-0.022t], \\
&[R_{ij}^{(2)}(t,2)]^{(2)} = \exp[-0.025t],\ t \geq 0, \\
&i = 1,2,\ j = 4,5, ..., 743.
\end{aligned}
$$

Thus, at the operation state z_2, the subsystem S_2 is a three-state series-parallel system with its

structure shape parameters $k^{(2)}=2$, $l_1^{(2)}=743$, $l_2^{(2)}=743$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(2)}(t,\cdot)]^{(2)}=[1,[\boldsymbol{R}^{(2)}(t,1)]^{(2)},[\boldsymbol{R}^{(2)}(t,2)]^{(2)}], \tag{33}$$

where

$$\begin{aligned}[\boldsymbol{R}^{(2)}(t,1)]^{(2)}&=2\exp[-16.324t]-\exp[-32.648t],\\ [\boldsymbol{R}^{(2)}(t,2)]^{(2)}&=2\exp[-18.552t]-\exp[-37.104t].\end{aligned} \tag{34}$$

The subsystem S_3 with the structure showed in Figure 3, consists of one belt conveyors forming a series system ($k^{(1)}=1$) composed of 139 components ($l_1^{(2)}=139$) with the exponential reliability functions. In the series system of the subsystem S_3 there are respectively:

– 1 belt marked by $E_{ij}^{(1)}$, $i=1$, $j=1$, with a reliability function co-ordinates

$$\begin{aligned}&[R_{ij}^{(3)}(t,1)]^{(2)}=\exp[-0.0110t],\\ &[R_{ij}^{(2)}(t,2)]^{(2)}=\exp[-0.0120t],\ t\ge 0,\ i=1,\ j=1;\end{aligned}$$

– 2 drums marked by $E_{ij}^{(1)}$, $i=1$, $j=2,3$, with a reliability function co-ordinates

$$\begin{aligned}&[R_{ij}^{(3)}(t,1)]^{(2)}=\exp[-0.0010t],\\ &[R_{ij}^{(3)}(t,2)]^{(2)}=\exp[-0.0012t],\ t\ge 0,\ i=1,21,\ j=2,3;\end{aligned}$$

– 117 channeled rollers marked by $E_{ij}^{(1)}$, $i=1$, $j=4,5,...,120$, with a reliability function co-ordinates

$$\begin{aligned}&[R_{ij}^{(3)}(t,1)]^{(2)}=\exp[-0.003t],\\ &[R_{ij}^{(3)}(t,2)]^{(2)}=\exp[-0.006t],\ t\ge 0,\\ &i=1,\ j=4,5,...,120;\end{aligned}$$

– 19 supporting rollers marked by $E_{ij}^{(1)}$, $i=1$, $j=121,122,...,139$, with a reliability function co-ordinates

$$\begin{aligned}&[R_{ij}^{(3)}(t,1)]^{(2)}=\exp[-0.002t],\\ &[R_{ij}^{(3)}(t,2)]^{(2)}=\exp[-0.003t],\ t\ge 0,\\ &i=1,\ j=121,122,...,129.\end{aligned}$$

Thus, at the operation state z_2, the subsystem S_3 is a three-state series-parallel system (a series system) with its structure shape parameters $k^{(1)}=1$, $l_1^{(2)}=139$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(3)}(t,\cdot)]^{(2)}=[1,[\boldsymbol{R}^{(3)}(t,1)]^{(2)},[\boldsymbol{R}^{(3)}(t,2)]^{(2)}],\ t\ge 0, \tag{35}$$

where

$$\begin{aligned}&[\boldsymbol{R}^{(3)}(t,1)]^{(2)}=\exp[-0.3910t],\\ &[\boldsymbol{R}^{(3)}(t,2)]^{(2)}=\exp[-0.7734t],\end{aligned} \tag{36}$$

The subsystem S_4 with the structure showed in Figure 3, consists of three identical chain conveyors forming series subsystems ($k^{(2)}=2$), each composed of a wheel driving the belt, a reversible driving wheel and 160 links ($l_1^{(2)}=162$, $l_2^{(2)}=162$) what means that the subsystem is a non-homogeneous non-regular three-state series-parallel system with the exponential reliability functions. In the series subsystems of the subsystem S_4 there are respectively:

– 2 two driving wheels marked by $E_{ij}^{(4)}$, $i=1,2$, $j=2$, with a reliability function co-ordinates

$$\begin{aligned}&[R_{ij}^{(4)}(t,1)]^{(2)}=\exp[-0.002t],\\ &[R_{ij}^{(4)}(t,2)]^{(2)}=\exp[-0.004t],\ t\ge 0,\ i=1,2,\ j=2;\end{aligned}$$

– 160 links marked by $E_{ij}^{(4)}$, $i=1,2$, $j=3,4,...,162$, with a reliability function co-ordinates

$$\begin{aligned}&[R_{ij}^{(4)}(t,1)]^{(2)}=\exp[-0.008t],\\ &[R_{ij}^{(4)}(t,2)]^{(2)}=\exp[-0.010t],\ t\ge 0,\\ &i=1,2,\ j=3,4,...,162.\end{aligned}$$

Thus, at the operation state z_2, the subsystem S_4 is a three-state series-parallel system with its structure shape parameters $k^{(2)}=2$, $l_1^{(2)}=162$, $l_2^{(2)}=162$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(4)}(t,\cdot)]^{(2)}=[1,[\boldsymbol{R}^{(4)}(t,1)]^{(2)},[\boldsymbol{R}^{(4)}(t,2)]^{(2)}], \tag{37}$$

where

$$\begin{aligned}[\boldsymbol{R}^{(4)}(t,1)]^{(2)}&=2\exp[-1.284t]-\exp[-2.5680t],\\ [\boldsymbol{R}^{(4)}(t,2)]^{(2)}&=2\exp[-1.608t]-\exp[-3.2160t].\end{aligned} \tag{38}$$

Considering that the system at the operation state z_2 is a three-state series system composed of subsystems S_1, S_2, S_3 and S_4, after applying the formulae appearing after Definition 3.4 given in (Kołowrocki 2014) and the results (31)-(32), (33)-(34), (35)-(36) and (37)-(38), its conditional reliability function is given by

$$[\boldsymbol{R}(t,\cdot)]^{(2)}=[1,[\boldsymbol{R}(t,1)]^{(2)},[\boldsymbol{R}(t,2)]^{(2)}],\ t\ge 0, \tag{39}$$

where

$$\begin{aligned}[\boldsymbol{R}(t,1)]^{(2)}&=4\exp[-18.380t]-2\exp[-34.694t]\\ &\quad-2\exp[-19.664t]+\exp[-35.978t],\\ [\boldsymbol{R}(t,2)]^{(2)}&=4\exp[-21.6768t]-2\exp[-40.2288t]\\ &\quad-2\exp[-23.2848t]+\exp[-41.8368t].\end{aligned} \tag{40}$$

The expected values and standard deviations of the system conditional lifetimes in the reliability state subsets {1,2}, {2} at the operation state z_2, calculated from the results given by (39)-(40), according to (16), respectively are:

$$\mu_2(1) = \int_0^\infty [\boldsymbol{R}(t,1)]^{(2)}\,dt \cong 0.0861 \text{ month},$$
$$\mu_2(2) = \int_0^\infty [\boldsymbol{R}(t,2)]^{(2)}\,dt \cong 0.0728 \text{ month}. \quad (41)$$

At the system operational state z_3, the system is a series system with the structure showed in Figure 2, composed of four subsystems S_1, S_2, S_3 and S_4 illustrated respectively in Figure 4.

The subsystem S_1 with the structure showed in Figure 3, consists of one belt conveyor forming a series systems ($k^{(3)} = 1$) composed of 129 components ($l_1^{(3)} = 129$) with the exponential reliability functions. In the series system of the subsystem S_1 there are respectively:

– 1 belt marked by $E_{ij}^{(1)}$, $i = 1$, $j = 1$, with a reliability function co-ordinates

$$[R_{ij}^{(1)}(t,1)]^{(3)} = \exp[-0.0100t],$$
$$[R_{ij}^{(1)}(t,2)]^{(3)} = \exp[-0.0105t],\ t \geq 0,\ i = 1,\ j = 1;$$

– 2 drums marked by $E_{ij}^{(1)}$, $i = 1$, $j = 2,3$, with a reliability function co-ordinates

$$[R_{ij}^{(1)}(t,1)]^{(3)} = \exp[-0.0009t],$$
$$[R_{ij}^{(1)}(t,2)]^{(3)} = \exp[-0.0011t],\ t \geq 0,\ i = 1,\ j = 2,3;$$

– 117 channeled rollers marked by $E_{ij}^{(1)}$, $i = 1$, $j = 4,5, ..., 120$, with a reliability function co-ordinates

$$[R_{ij}^{(1)}(t,1)]^{(3)} = \exp[-0.002t],$$
$$[R_{ij}^{(1)}(t,2)]^{(3)} = \exp[-0.004t],\ t \geq 0,$$
$$i = 1, j = 4,5, ..., 120;$$

– 9 supporting rollers marked by $E_{ij}^{(1)}$, $i = 1$, $j = 121,122, ..., 129$, with a reliability function co-ordinates

$$[R_{ij}^{(1)}(t,1)]^{(3)} = \exp[-0.001t],$$
$$[R_{ij}^{(1)}(t,2)]^{(3)} = \exp[-0.002t],\ t \geq 0,$$
$$i = 1, j = 121,122, ..., 129.$$

Thus, at the operation state z_3, the subsystem S_1 is a three-state series-parallel system (a series system) with its structure shape parameters $k^{(3)} = 1$, $l_1^{(3)} = 129$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(1)}(t,\cdot)]^{(3)} = [1,[\boldsymbol{R}^{(1)}(t,1)]^{(3)},[\boldsymbol{R}^{(1)}(t,2)]^{(3)}],\ t \geq 0, \quad (42)$$

where

$$[\boldsymbol{R}^{(1)}(t,1)]^{(3)} = \exp[-0.2548t],$$
$$[\boldsymbol{R}^{(1)}(t,2)]^{(3)} = \exp[-0.4987t], \quad (43)$$

The subsystem S_2 with the structure showed in Figure 4, consists of one bucket elevator forming a series system ($k^{(3)} = 1$) composed of 743 components ($l_1^{(3)} = 743$) with the exponential reliability functions. In the series stem of the subsystem S_2 there are respectively:

– 1 belt marked by $E_{ij}^{(2)}$, $i = 1$, $j = 1$, with a reliability function co-ordinates

$$[R_{ij}^{(2)}(t,1)]^{(3)} = \exp[-0.018t],$$
$$[R_{ij}^{(2)}(t,2)]^{(2)} = \exp[-0.022t],\ t \geq 0,\ i = 1,\ j = 1;$$

– 2 drums marked by $E_{ij}^{(2)}$, $i = 1$, $j = 2,3$, with a reliability function co-ordinates

$$[R_{ij}^{(2)}(t,1)]^{(3)} = \exp[-0.0011t],$$
$$[R_{ij}^{(2)}(t,2)]^{(3)} = \exp[-0.0013t],\ t \geq 0,\ i = 1,\ j = 2,3;$$

– 740 buckets marked by $E_{ij}^{(2)}$, $i = 1$, $j = 4,5, ..., 743$, with a reliability function co-ordinates

$$[R_{ij}^{(2)}(t,1)]^{(3)} = \exp[-0.020t],$$
$$[R_{ij}^{(2)}(t,2)]^{(2)} = \exp[-0.024t],\ t \geq 0,$$
$$i = 1, j = 4,5, ..., 743.$$

Thus, at the operation state z_3, the subsystem S_2 is a three-state series-parallel system (a series system) with its structure shape parameters $k^{(3)} = 1$, $l_1^{(3)} = 743$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(2)}(t,\cdot)]^{(3)} = [1,[\boldsymbol{R}^{(2)}(t,1)]^{(3)},[\boldsymbol{R}^{(2)}(t,2)]^{(3)}],\ t \geq 0, \quad (44)$$

where

$$[\boldsymbol{R}^{(2)}(t,1)]^{(3)} = \exp[-14.840t],$$
$$[\boldsymbol{R}^{(2)}(t,2)]^{(3)} = \exp[-17.808t]. \quad (45)$$

The subsystem S_3 with the structure showed in Figure 4, consists of one belt conveyors forming a series system ($k^{(3)} = 1$) composed of 139 components ($l_1^{(3)} = 139$) with the exponential reliability functions. In the series system of the subsystem S_3 there are respectively:

– 1 belt marked by $E_{ij}^{(3)}$, $i=1,\ j=1$, with a reliability function co-ordinates

$$[R_{ij}^{(3)}(t,1)]^{(3)} = \exp[-0.0100t],$$
$$[R_{ij}^{(3)}(t,2)]^{(3)} = \exp[-0.0105t],\ t \geq 0,\ i=1,\ j=1;$$

– 2 drums marked by $E_{ij}^{(3)}$, $i=1,\ j=2,3$, with a reliability function co-ordinates

$$[R_{ij}^{(3)}(t,1)]^{(3)} = \exp[-0.0009t],$$
$$[R_{ij}^{(3)}(t,2)]^{(3)} = \exp[-0.0011t], t \geq 0,\ i=1,\ j=2,3;$$

– 117 channeled rollers marked by $E_{ij}^{(3)}$, $i=1,\ j=4,5,...,120$, with a reliability function co-ordinates

$$[R_{ij}^{(3)}(t,1)]^{(3)} = \exp[-0.002t],$$
$$[R_{ij}^{(3)}(t,2)]^{(3)} = \exp[-0.004t], t \geq 0,$$
$$i=1,\ j=4,5,...,120;$$

– 19 supporting rollers marked by $E_{ij}^{(3)}$, $i=1,\ j=121,122,...,129$, with a reliability function co-ordinates

$$[R_{ij}^{(3)}(t,1)]^{(3)} = \exp[-0.001t],$$
$$[R_{ij}^{(3)}(t,2)]^{(3)} = \exp[-0.002t],\ t \geq 0,$$
$$i=1, j=121,122,...,129.$$

Thus, at the operation state z_3, the subsystem S_3 is a three-state series-parallel system (a series system) with its structure shape parameters $k^{(3)}=1$, $l_1^{(3)}=139$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(3)}(t,\cdot)]^{(3)} = [1,[\boldsymbol{R}^{(3)}(t,1)]^{(3)},[\boldsymbol{R}^{(3)}(t,2)]^{(3)}],\ t \geq 0, \tag{46}$$

where

$$[\boldsymbol{R}^{(3)}(t,1)]^{(3)} = \exp[-0.2648t],$$
$$[\boldsymbol{R}^{(3)}(t,2)]^{(3)} = \exp[-0.5187t]. \tag{47}$$

The subsystem S_4 with the structure showed in Figure 4, consists of on chain conveyor forming a series system ($k^{(3)}=1$), composed of a wheel driving the belt, a reversible driving wheel and 160 links ($l_1^{(3)}=162$) with the exponential reliability functions. In the series system of the subsystem S_4 there are respectively:

– 2 two driving wheels marked by $E_{ij}^{(4)}$, $i=1,\ j=2$, with a reliability function co-ordinates

$$[R_{ij}^{(4)}(t,1)]^{(3)} = \exp[-0.001t],$$
$$[R_{ij}^{(4)}(t,2)]^{(3)} = \exp[-0.003t],\ t \geq 0,\ i=1,\ j=2;$$

– 160 links marked by $E_{ij}^{(4)}$, $i=1,\ j=3,4,...,162$, with a reliability function co-ordinates

$$[R_{ij}^{(4)}(t,1)]^{(3)} = \exp[-0.007t],$$
$$[R_{ij}^{(4)}(t,2)]^{(3)} = \exp[-0.009t],\ t \geq 0,$$
$$i=1, j=3,4,...,162.$$

Thus, at the operation state z_3, the subsystem S_4 is a three-state series-parallel system (a series system) with its structure shape parameters $k^{(3)}=1$, $l_1^{(3)}=162$, and according to Proposition 9.1 given in (Kołowrocki 2014), its conditional reliability function is given by

$$[\boldsymbol{R}^{(4)}(t,\cdot)]^{(3)} = [1,[\boldsymbol{R}^{(4)}(t,1)]^{(3)},[\boldsymbol{R}^{(4)}(t,2)]^{(3)}],\ t \geq 0, \tag{48}$$

where

$$[\boldsymbol{R}^{(4)}(t,1)]^{(3)} = \exp[-1.122t]$$
$$[\boldsymbol{R}^{(4)}(t,2)]^{(3)} = \exp[-1.446t] \tag{49}$$

Considering that the system at the operation state z_3 is a three-state series system composed of subsystems S_1, S_2, S_3 and S_4, after applying the formulae appearing after Definition 3.4 in (Kołowrocki 2014) and the results (42)-(43), (44)-(45), (46)-(47) and (48)-(49), its conditional reliability function is given by

$$[\boldsymbol{R}(t,\cdot)]^{(3)} = [1,[\boldsymbol{R}(t,1)]^{(3)},[\boldsymbol{R}(t,2)]^{(3)}],\ t \geq 0, \tag{50}$$

where

$$[\boldsymbol{R}(t,1)]^{(3)} = \exp[-16.4816t],$$
$$[\boldsymbol{R}(t,2)]^{(3)} = \exp[-20.2714t]. \tag{51}$$

The expected values and standard deviations of the system conditional lifetimes in the reliability state subsets {1,2}, {2} at the operation state z_3, calculated from the results given by (50)-(51), according to (16), respectively are:

$$\mu_3(1) = \int_0^\infty [\boldsymbol{R}(t,1)]^{(3)}\,dt / \cong 0.0607 \text{ month},$$
$$\mu_3(2) = \int_0^\infty [\boldsymbol{R}(t,2)]^{(3)}\,dt4 \cong 0.0493 \text{ month}. \tag{52}$$

In the case when the system operation time is large enough its unconditional three-state reliability function is given by the vector

$$\boldsymbol{R}(t,\cdot) = [1,\boldsymbol{R}(t,1),\boldsymbol{R}(t,2)]\ t \geq 0, \tag{53}$$

where according to (14) and considering the system operation process transient probabilities at the

operation states determined by (10), the vector coordinates are given respectively by

$$\begin{aligned}\boldsymbol{R}(t,1) &= p_1[\boldsymbol{R}(t,1)]^{(1)} + p_2[\boldsymbol{R}(t,1)]^{(2)} + p_3[\boldsymbol{R}(t,1)]^{(3)} \\ &= 0.530\cdot[\boldsymbol{R}(t,1)]^{(1)} + 0.109\cdot[\boldsymbol{R}(t,1)]^{(2)} \\ &\quad + 0.361\cdot[\boldsymbol{R}(t,1)]^{(3)} \ \text{for } t \ge 0, \\ \boldsymbol{R}(t,2) &= p_1[\boldsymbol{R}(t,2)]^{(1)} + p_2[\boldsymbol{R}(t,2)]^{(2)} + p_3[\boldsymbol{R}(t,2)]^{(3)} \\ &= 0.530\cdot[\boldsymbol{R}(t,2)]^{(1)} + 0.109\cdot[\boldsymbol{R}(t,2)]^{(2)} \\ &\quad + 0.361\cdot[\boldsymbol{R}(t,2)]^{(3)} \ \text{for } t \ge 0,\end{aligned} \tag{54}$$

where the reliability functions $[\boldsymbol{R}(t,1)]^{(1)}$, $[\boldsymbol{R}(t,1)]^{(2)}$, $[\boldsymbol{R}(t,1)]^{(3)}$, $[\boldsymbol{R}(t,2)]^{(1)}$, $[\boldsymbol{R}(t,2)]^{(2)}$, $[\boldsymbol{R}(t,2)]^{(3)}$ are given by (29), (40), (51).

In the Table 1, the values of the coordinates of the port grain transportation system unconditional reliability function $\boldsymbol{R}(t,\cdot)$ given by (53)-(54) are presented.

Table 1. The values of the port grain transportation system unconditional reliability function coordinates.

t	$R(t,1)$	$R(t,2)$
0.00	1.0000	1.0000
0.02	0.8638	0.8302
0.04	0.6884	0.6191
0.06	0.5133	0.4259
0.08	0.3665	0.2793

0.12	0.1745	0.1121
0.14	0.1184	0.0699
0.16	0.0800	0.0435
0.18	0.0540	0.0271
0.20	0.0364	0.0169
0.22	0.0246	0.0106
0.24	0.0167	0.0066
0.26	0.0113	0.0042
0.28	0.0077	0.0027
0.30	0.0053	0.0017
0.32	0.0036	0.0011
0.34	0.0025	0.0007
0.36	0.0017	0.0004
0.38	0.0012	0.0003
0.40	0.0008	0.0002
0.42	0.0006	0.0001
0.43	0.0005	0.0001
0.44	0.0004	0.0001
0.45	0.0003	0.0001
0.46	0.0003	0.0001
0.48	0.0002	0.0000
0.50	0.0001	0.0000
0.52	0.0001	0.0000
0.54	0.0001	0.0000
0.56	0.0000	0.0000

The graph of the three-state port grain transportation system unconditional reliability function is illustrated in Figure 5.

The expected value of the system unconditional lifetime in the reliability state subsets {1,2}, {2}, calculated according to (15) from the results given by (30), (41), (52) and (10), is

$$\begin{aligned}\mu(1) &= p_1\mu_1(1) + p_2\mu_2(1) + p_3\mu_3(1) \\ &= 0.530\cdot 0.0813 + 0.109\cdot 0.0861 \\ &\quad + 0.361\cdot 0.0607 \cong 0.0744 \text{ year}, \\ \mu(2) &= p_1\mu_1(2) + p_2\mu_2(2) + p_3\mu_3(2) \\ &= 0.530\cdot 0.0691 + 0.109\cdot 0.0728 \\ &\quad + 0.361\cdot 0.0493 \cong 0.0624 \text{ month}.\end{aligned} \tag{55}$$

Further, considering (17) and (55), the mean values of the unconditional lifetimes in the particular reliability states 1, 2, respectively are:

$$\begin{aligned}\bar{\mu}(1) &= \mu(1) - \mu(2) = 0.0120 \text{ month}, \\ \bar{\mu}(2) &= \mu(2) = 0.0624 \text{ month}.\end{aligned} \tag{56}$$

Since the critical reliability state is $r = 1$, then the system risk function, according to (18), is given by

$$r(t) = 1 - \boldsymbol{R}(t,1), \tag{57}$$

where $R(t,1)$ is are given by (54).

Hence, by (19), the moment when the system risk function exceeds a permitted level, for instance $\delta = 0.05$, is

$$\tau = r^{-1}(\delta) \cong 0.0100. \tag{58}$$

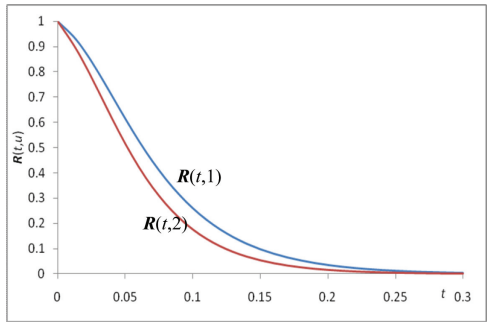

Figure 5. The graph of the port grain transportation system reliability function $\boldsymbol{R}(t,\cdot)$ coordinates.

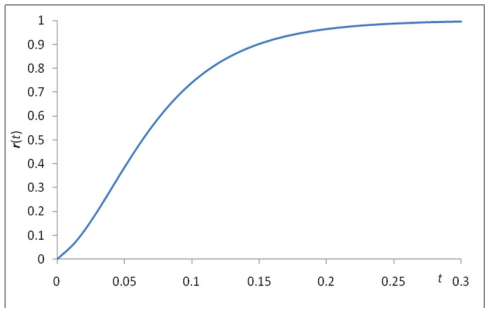

Figure 6. The graph of the port grain transportation system risk function $\boldsymbol{r}(t)$.

4 CONCLUSIONS

The integrated general model of complex systems' reliability, linking their reliability models and their operation processes models and considering variable at different operation states their reliability structures and their components reliability parameters is constructed and applied to the reliability evaluation of the port grain transportation system composed of three series-parallel subsystems linked in series. The predicted reliability characteristics of the considered system operating at the variable conditions are different from those determined for this system operating at constant conditions. This fact justifies the sensibility of considering real systems at the variable operation conditions that is appearing out in a natural way from practice. This approach, upon the good accuracy of the systems' operation processes and the systems' components reliability parameters identification, makes their reliability prediction more precise.

Reliability optimization of complex port transportation system

K. Kołowrocki & J. Soszyńska-Budny
Department of Mathematics, Maritime University, Gdynia, Poland

ABSTRACT: The method based on the results of the joint model linking a semi-Markov modelling of the system operation process with a multistate approach to system reliability and the linear programming are proposed to the operation and reliability optimization of complex technical systems at the variable operation conditions. The method consists in determining the optimal values of limit transient probabilities at the system operation states that maximize the system lifetimes in the reliability state subsets. The proposed method is applied to the operation and reliability optimization of the port grain transportation system composed of three multistate non-homogeneous series-parallel subsystems linked in series, changing its reliability structure and its components reliability parameters at variable operation conditions.

1 INTRODUCTION

The complex technical systems reliability improvement and decreasing the risk of exceeding a critical reliability state are of great value in the industrial practice (Kołowrocki & Soszyńska-Budny 2011, Kuo & Prasad 2000, Kuo & Zuo 2003, Vercellis 2009). In everyday practice, there are needed the tools that could be applied to improving the reliability characteristics of the multistate systems operating at variable conditions. There are needed the tools allowing for finding the distributions and the expected values of the optimal times until the exceeding by the system the reliability critical state, the optimal system risk function and the moment when the optimal system risk function exceeds a permitted reliability level and allowing for changing the system operation process after comparing the values of these characteristics with their values before the system operation process optimization in order to improve the system reliability (Kołowrocki & Soszyńska-Budny 2011, Klajban & Adelman 2006, Kołowrocki & Soszyńska 2010, Kołowrocki & Soszyńska-Budny 2014, Koowrocki 2014, Lisniansi & Levitin 2003, Tang, Yin & Xi 2007).

2 COMPLEX SYSTEM RELIABILITY AND OPERATION OPTIMIZATION

Considering the equation (14) in (Kołowrocki & Soszyńska-Budny 2014) it is natural to assume that the system operation process has a significant influence on the system reliability. This influence is also clearly expressed in the equation (15) in (Kołowrocki & Soszyńska-Budny 2014) for the mean values of the system unconditional lifetimes in the reliability state subsets.

From the linear equation (15) in (Kołowrocki & Soszyńska-Budny 2014), we can see that the mean value of the system unconditional lifetime $\mu(u)$, $u=1,2,...,z$, is determined by the limit values of transient probabilities p_b, $b=1,2,...,\nu$, of the system operation process at the operation states given by (3) and the mean values $\mu_b(u)$, $b=1,2,...,\nu$, $u=1,2,...,z$, of the system conditional lifetimes in the reliability state subsets $\{u,u+1,...,z\}$, $u=1,2,...,z$, given by (16) in (Kołowrocki & Soszyńska-Budny 2014). Therefore, the system lifetime optimization approach based on the linear programming ((Kołowrocki & Soszyńska-Budny 2011, Klajban & Adelman 2006, Kołowrocki & Soszyńska 2010, Tang, Yin & Xi 2007) can be proposed. Namely, we may look for the corresponding optimal values $\dot{p}_b$, $b=1,2,...,\nu$, of the transient probabilities p_b, $b=1,2,...,\nu$, of the system operation process at the operation states to maximize the mean value $\mu(u)$ of the unconditional system lifetimes in the reliability state subsets $\{u,u+1,...,z\}$, $u=1,2,...,z$, under the assumption that the mean values $\mu_b(u)$, $b=1,2,...,\nu$, $u=1,2,...,z$, of the system conditional lifetimes in the reliability state subsets are fixed. As a special and practically important case of the above formulated system lifetime optimization problem, if r, $r=1,2,...,z$ is a system critical reliability state, we may look for the optimal values $\dot{p}_b$, $b=1,2,...,\nu$, of the transient probabilities p_b, $b=1,2,...,\nu$, of the system operation process at the system operation states to maximize the mean value $\mu(r)$ of the unconditional system

lifetime in the reliability state subset $\{r, r+1, ..., z\}$, $r = 1,2, ..., z$, under the assumption that the mean values $\mu_b(r)$, $b = 1,2, ..., \nu$, $r = 1,2, ..., z$, of the system conditional lifetimes in this reliability state subset are fixed. More exactly, we may formulate the optimization problem as a linear programming model with the objective function of the following form

$$\mu(r) = \sum_{b=1}^{\nu} p_b \mu_b(r) \tag{1}$$

for a fixed $r \in \{1,2, ..., z\}$ and with the following bound constraints

$$\breve{p}_b \le p_b \le \hat{p}_b,\ b = 1,2, ..., \nu,\ \sum_{b=1}^{\nu} p_b = 1, \tag{2}$$

where $\mu_b(r)$, $\mu_b(r) \ge 0$, $b = 1,2, ..., \nu$, are fixed mean values of the system conditional lifetimes in the reliability state subset $\{r, r+1, ..., z\}$ and

$$\breve{p}_b, 0 \le \breve{p}_b \le 1 \text{ and } \hat{p}_b, 0 \le \hat{p}_b \le 1,\ \breve{p}_b \le \hat{p}_b,\ b = 1,2, ..., \nu, \tag{3}$$

are lower and upper bounds of the unknown transient probabilities p_b, $b = 1,2, ..., \nu$, respectively.

Now, we can obtain the optimal solution of the formulated by (1)–(3) the linear programming problem, i.e. we can find the optimal values $\dot{p}_b$ of the transient probabilities p_b, $b = 1,2, ..., \nu$, that maximize the objective function given by (1).

First, we arrange the system conditional lifetime mean values $\mu_b(r)$, $b = 1,2, ..., \nu$, in non-increasing order $\mu_{b_1}(r) \ge \mu_{b_2}(r) \ge \ldots \ge \mu_{b_\nu}(r)$, where $b_i \in \{1,2, ..., \nu\}$ for $i = 1,2, ..., \nu$.

Next, we substitute

$$x_i = p_{b_i},\ \breve{x}_i = \breve{p}_{b_i},\ \hat{x}_i = \hat{p}_{b_i} \text{ for } i = 1,2, ..., \nu \tag{4}$$

and we maximize with respect to x_i, $i = 1,2, ..., \nu$, the linear form (1) that after this transformation takes the form

$$\mu(r) = \sum_{i=1}^{\nu} x_i \mu_{b_i}(r) \tag{5}$$

for a fixed $r \in \{1,2, ..., z\}$ with the following bound constraints

$$\breve{x}_i \le x_i \le \hat{x}_i,\ i = 1,2, ..., \nu,\ \sum_{i=1}^{\nu} x_i = 1, \tag{6}$$

where $\mu_{b_i}(r)$, $\mu_{b_i}(r) \ge 0$, $i = 1,2, ..., \nu$, are fixed mean values of the system conditional lifetimes in the reliability state subset $\{r, r+1, ..., z\}$ arranged in non-increasing order and

$$\breve{x}_i, 0 \le \breve{x}_i \le 1 \text{ and } \hat{x}_i, 0 \le \hat{x}_i \le 1,\ \breve{x}_i \le \hat{x}_i,\ i = 1,2, ..., \nu, \tag{7}$$

are lower and upper bounds of the unknown probabilities x_i, $i = 1,2, ..., \nu$, respectively.

To find the optimal values of x_i, $i = 1,2, ..., \nu$, we define

$$\breve{x} = \sum_{i=1}^{\nu} \breve{x}_i,\ \hat{y} = 1 - \breve{x} \tag{8}$$

and

$$\breve{x}^0 = 0,\ \hat{x}^0 = 0 \text{ and } \breve{x}^I = \sum_{i=1}^{I} \breve{x}_i,\ \hat{x}^I = \sum_{i=1}^{I} \hat{x}_i \tag{9}$$

for $I = 1,2, ..., \nu$.

Next, we find the largest value $I \in \{0,1, ..., \nu\}$ such that

$$\hat{x}^I - \breve{x}^I < \hat{y} \tag{10}$$

and we fix the optimal solution that maximize (5) in the following way:

i. if $I = 0$, the optimal solution is

$$\dot{x}_1 = \hat{y} + \breve{x}_1 \text{ and } \dot{x}_i = \breve{x}_i \text{ for } i = 2,3, ..., \nu; \tag{11}$$

ii. if $0 < I < \nu$, the optimal solution is

$$\dot{x}_i = \hat{x}_i \text{ for } i = 1,2, ..., I,\ \dot{x}_{I+1} = \hat{y} - \hat{x}^I + \breve{x}^I + \breve{x}_{I+1} \text{ and } \dot{x}_i = \breve{x}_i \text{ for } i = I+2, I+3, ..., \nu; \tag{12}$$

iii. if $I = \nu$, the optimal solution is

$$\dot{x}_i = \hat{x}_i \text{ for } i = 1,2, ..., \nu. \tag{13}$$

Finally, after making the inverse to (4) substitution, we get the optimal limit transient probabilities

$$\dot{p}_{b_i} = \dot{x}_i \text{ for } i = 1,2, ..., \nu, \tag{14}$$

that maximize the system mean lifetime in the reliability state subset $\{r, r+1, ..., z\}$, defined by the linear form (1), giving its maximum value in the following form

$$\dot{\mu}(r) = \sum_{b=1}^{\nu} \dot{p}_b \mu_b(r) \tag{15}$$

for a fixed $r \in \{1,2, ..., z\}$.

From the expression (15) for the maximum mean value $\dot{\mu}(r)$ of the system unconditional lifetime in the reliability state subset $\{r, r+1, ..., z\}$, replacing

in it the critical reliability state r by the reliability state u, $u = 1,2, ..., z$, we obtain the corresponding optimal solutions for the mean values of the system unconditional lifetimes in the reliability state subsets $\{u, u+1, ..., z\}$ of the form

$$\dot{\mu}(u) = \sum_{b=1}^{\nu} \dot{p}_b \mu_b(u) \text{ for } u = 1,2, ..., z. \tag{16}$$

Further, according to (13)-(14), the corresponding optimal unconditional multistate reliability function of the system is the vector

$$\dot{\boldsymbol{R}}(t,\cdot) = [1, \dot{\boldsymbol{R}}(t,1), ..., \dot{\boldsymbol{R}}(t,z)], \tag{17}$$

with the coordinates given by

$$\dot{\boldsymbol{R}}(t,u) \cong \sum_{b=1}^{v} \dot{p}_b [\boldsymbol{R}(t,u)]^{(b)} \text{ for } t \geq 0, \tag{18}$$
$$u = 1,2, ..., z.$$

And, by (17), the optimal solutions for the mean values of the system unconditional lifetimes in the particular reliability states are

$$\ddot{\mu}(u) = \dot{\mu}(u) - \dot{\mu}(u+1), u = 1, ..., z-1,$$
$$\ddot{\mu}(z) = \dot{\mu}(z). \tag{19}$$

Moreover, considering (18) and (19), the corresponding optimal system risk function and the optimal moment when the risk exceeds a permitted level δ, respectively are given by

$$\dot{r}(t) = 1 - \dot{\boldsymbol{R}}(t,r), t \geq 0, \tag{20}$$

and

$$\dot{\tau} = \dot{r}^{-1}(\delta), \tag{21}$$

where $\dot{\boldsymbol{R}}(t,r)$ is given by (18) for $u = r$ and $\dot{r}^{-1}(t)$, if it exists, is the inverse function of the optimal risk function $\dot{r}(t)$.

Replacing in (3) given in (Kołowrocki & Soszyńska-Budny 2014), the limit transient probabilities p_b of the system operation process at the operation states by their optimal values $\dot{p}_b$, maximizing the mean value $\mu(r)$ of the system lifetime in the reliability states subset $\{r, r+1, ..., z\}$ defined by (1) and the mean values M_b of the unconditional sojourn times at the operation states by their corresponding unknown optimal values $\dot{M}_b$, we get the system of equations

$$\dot{p}_b = \frac{\pi_b \dot{M}_b}{\sum_{l=1}^{v} \pi_l \dot{M}_l}, b = 1,2, ..., v. \tag{22}$$

After simple transformations the above system takes the form

$$\begin{aligned}
&(\dot{p}_1 - 1)\pi_1 \dot{M}_1 + \dot{p}_1 \pi_2 \dot{M}_2 + ... + \dot{p}_1 \pi_\nu \dot{M}_\nu = 0 \\
&\dot{p}_2 \pi_1 \dot{M}_1 + (\dot{p}_2 - 1)\pi_2 \dot{M}_2 + ... + \dot{p}_2 \pi_\nu \dot{M}_\nu = 0 \\
&... \\
&\dot{p}_\nu \pi_1 \dot{M}_1 + \dot{p}_\nu \pi_2 \dot{M}_2 + ... + (\dot{p}_\nu - 1)\pi_\nu \dot{M}_\nu = 0,
\end{aligned} \tag{23}$$

where $\dot{M}_b$ are unknown variables we want to find, $\dot{p}_b$ are optimal transient probabilities determined by (14) and π_b are steady probabilities determined by (4) given in (Kołowrocki & Soszyńska-Budny 2014).

Since the system of equations (23) is homogeneous and it can be proved that the determinant of its main matrix is equal to zero, then it has nonzero solutions and moreover, these solutions are ambiguous. Thus, if we fix some of the optimal values $\dot{M}_b$ of the mean values M_b of the unconditional sojourn times at the operation states, for instance by arbitrary fixing one or a few of them, we may find the values of the remaining once and this way to get the solution of this equation.

Having this solution, it is also possible to look for the optimal values $\dot{M}_{bl}$ of the mean values M_{bl} of the conditional sojourn times at the operation states using the following system of equations

$$\sum_{l=1}^{v} p_{bl} \dot{M}_{bl} = \dot{M}_b, b = 1,2, ..., v, \tag{24}$$

obtained from (2) given in (Kołowrocki & Soszyńska-Budny 2014) by replacing M_b by $\dot{M}_b$ and M_{bl} by $\dot{M}_{bl}$, were p_{bl} are known probabilities of the system operation process transitions between the operation states z_b i z_l, $b,l = 1,2, ..., v$.

Another very useful and much easier to be applied in practice tool that can help in planning the operation processes of the complex technical systems are the system operation process optimal mean values of the total system operation process sojourn times $\hat{\theta}_b$ at the particular operation states z_b, $b = 1,2, ..., v$, during the fixed system operation time θ, that can be obtain by the replacing in the formula (5) given in (Kołowrocki & Soszyńska-Budny 2014), the transient probabilities p_b at the operation states z_b by their optimal values $\dot{p}_b$ and resulting in the following expession

$$\dot{\hat{M}}_b = \dot{E}[\hat{\theta}_b] = \dot{p}_b \theta, b = 1,2, ..., v. \tag{25}$$

The knowledge of the optimal values $\dot{M}_b$ of the mean values of the unconditional sojourn times and the optimal values $\dot{M}_{bl}$ of the mean values of the conditional sojourn times at the operation states and the optimal mean values $\dot{\hat{M}}_b$ of the total

sojourn times at the particular operation states during the fixed system operation time may by the basis for changing the complex technical systems operation processes in order to ensure these systems operation more reliable.

3 APPLICATION

We consider the port grain transportation system, presented in Figure 1, assigned to handle the clearing of exported and imported grain.

This system reliability structure and its components reliability parameters depend on its changing in time operation states with arbitrarily fixed the number of the system operation process states $\nu = 3$ and their influence on the system reliability indicated in (Kołowrocki & Soszyńska-Budny 2014) where its main reliability characteristics are predicted.

In the case when the system operation time is large enough its unconditional three-state reliability function determined in (Kołowrocki & Soszyńska-Budny 2014) is given by the vector

$$\boldsymbol{R}(t,\cdot)=[1,\boldsymbol{R}(t,1),\boldsymbol{R}(t,2)]\ \ t\geq 0, \tag{26}$$

where according to (14) given in (Kołowrocki & Soszyńska-Budny 2014) and considering the system operation process transient probabilities at the operation states determined by (10) given in (Kołowrocki & Soszyńska-Budny 2014), the vector co-ordinates are given respectively by

$$\begin{aligned}\boldsymbol{R}(t,1) &= p_1[\boldsymbol{R}(t,1)]^{(1)} + p_2[\boldsymbol{R}(t,1)]^{(2)} + p_3[\boldsymbol{R}(t,1)]^{(3)}\\ &= 0.530\cdot[\boldsymbol{R}(t,1)]^{(1)} + 0.109\cdot[\boldsymbol{R}(t,1)]^{(2)}\\ &\quad + 0.361\cdot[\boldsymbol{R}(t,1)]^{(3)} \text{ for } t\geq 0,\\ \boldsymbol{R}(t,2) &= p_1[\boldsymbol{R}(t,2)]^{(1)} + p_2[\boldsymbol{R}(t,2)]^{(2)} + p_3[\boldsymbol{R}(t,2)]^{(3)}\\ &= 0.530\cdot[\boldsymbol{R}(t,2)]^{(1)} + 0.109\cdot[\boldsymbol{R}(t,2)]^{(2)}\\ &\quad + 0.361\cdot[\boldsymbol{R}(t,2)]^{(3)} \text{ for } t\geq 0,\end{aligned} \tag{27}$$

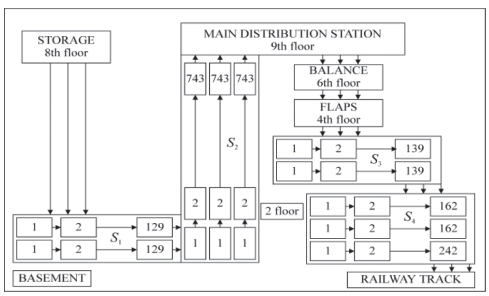

Figure 1. The scheme of the port grain transportation system structure at the operation state z_1.

where the reliability functions $[\boldsymbol{R}(t,1)]^{(1)}$, $[\boldsymbol{R}(t,1)]^{(2)}$, $[\boldsymbol{R}(t,1)]^{(3)}$, $[\boldsymbol{R}(t,2)]^{(1)}$, $[\boldsymbol{R}(t,2)]^{(2)}$, $[\boldsymbol{R}(t,2)]^{(3)}$ are given in (Kołowrocki & Soszyńska-Budny 2014).

The expected value of the system unconditional lifetime in the reliability state subsets $\{1,2\}$, $\{2\}$, calculated in (Kołowrocki & Soszyńska-Budny 2014) from the results given by (26)-(27), are

$$\begin{aligned}\mu(1) &= p_1\mu_1(1) + p_2\mu_2(1) + p_3\mu_3(1)\\ &= 0.530\cdot 0.0813 + 0.109\cdot 0.0861\\ &\quad + 0.361\cdot 0.0607 \cong 0.0744 \text{ year},\\ \mu(2) &= p_1\mu_1(2) + p_2\mu_2(2) + p_3\mu_3(2)\\ &= 0.530\cdot 0.0691 + 0.109\cdot 0.0728\\ &\quad + 0.361\cdot 0.0493 \cong 0.0624 \text{ year}.\end{aligned} \tag{28}$$

To find the optimal values of those system reliability characteristics, we conclude that the objective function defined by (1), in this case, as the system critical state is $r = 1$, according to (28), takes the form

$$\mu(1) = p_1\cdot 0.0813 + p_2\cdot 0.0861 + p_3\cdot 0.0607. \tag{29}$$

The lower $\breve{p}_b$ and upper $\hat{p}_b$ bounds of the unknown optimal values of transient probabilities p_b, $b = 1,2,3$, respectively are:

$$\begin{aligned}&\breve{p}_1 = 0.460, \breve{p}_2 = 0.080, \breve{p}_3 = 0.310;\\ &\hat{p}_1 = 0.600, \hat{p}_2 = 0.140, \hat{p}_3 = 0.410.\end{aligned}$$

Therefore, according to (2)-(3), we assume the following bound constraints

$$\begin{aligned}&0.460 \leq p_1 \leq 0.600,\ 0.080 \leq p_2 \leq 0.140,\\ &0.310 \leq p_3 \leq 0.410,\\ &\sum_{b=1}^{3} p_b = 1.\end{aligned} \tag{30}$$

Now, before we find optimal values $\dot{p}_b$ of the transient probabilities p_b, $b = 1,2,3$, that maximize the objective function (29), w arrange the system conditional lifetime mean values $\mu_b(1)$, $b = 1,2,3$, in non-increasing order

$$\mu_2(1) \geq \mu_1(1) \geq \mu_3(1).$$

Further, according to (4), we substitute

$$x_1 = p_2,\ x_2 = p_1,\ x_3 = p_3, \tag{31}$$

and

$$\begin{aligned}&\breve{x}_1 = \breve{p}_2 = 0.080,\ \breve{x}_2 = \breve{p}_1 = 0.460,\\ &\breve{x}_3 = \breve{p}_3 = 0.310;\end{aligned} \tag{32}$$

$$\begin{aligned}&\hat{x}_1 = \hat{p}_2 = 0.140,\ \hat{x}_2 = \hat{p}_1 = 0.600,\\ &\hat{x}_3 = \hat{p}_3 = 0.410.\end{aligned} \tag{33}$$

and we maximize with respect to x_i, $i=1,2,3$, the linear form (29) that according to (5)–(7) takes the form

$$\mu(1) = x_1 \cdot 0.0873 + x_2 \cdot 0.0812 + x_3 \cdot 0.0605, \tag{34}$$

with the following bound constraints

$$0.080 \le x_1 \le 0.140,\ 0.460 \le x_2 \le 0.600,$$
$$0.310 \le x_3 \le 0.410.$$
$$\sum_{i=1}^{3} x_i = 1. \tag{35}$$

According to (8), we calculate

$$\breve{x} = \sum_{i=1} \breve{x}_i = 0.850,$$
$$\hat{y} = 1 - \breve{x} = 1 - 0.850 = 0.150 \tag{36}$$

and according to (9), we determine

$$\breve{x}^0 = 0,\ \hat{x}^0 = 0,\ \hat{x}^0 - \breve{x}^0 = 0,$$
$$\breve{x}^1 = 0.080,\ \hat{x}^1 = 0.140,\ \hat{x}^1 - \breve{x}^1 = 0.060,$$
$$\breve{x}^2 = 0.540\ \hat{x}^2 = 0.740,\ \hat{x}^2 - \breve{x}^2 = 0.200,$$
$$\breve{x}^3 = 0.850,\ \hat{x}^3 = 1.150,\ \hat{x}^3 - \breve{x}^3 = 0.300. \tag{37}$$

From the above, as according to (36), the inequality (10) takes the form

$$\hat{x}^I - \breve{x}^I < 0.150, \tag{38}$$

it follows that the largest value $I \in \{0,1,2,3\}$ such that this inequality holds is $I = 1$.

Therefore, we fix the optimal solution that maximize linear function (34) according to the rule (12). Namely, we get

$$\dot{x}_1 = \hat{x}_1 = 0.140,$$
$$\dot{x}_2 = \hat{y} - \hat{x}^1 + \breve{x}^1 + \breve{x}_2$$
$$= 0.150 - 0.140 + 0.080 + 0.460 = 0.550,$$
$$\dot{x}_3 = \breve{x}_3 = 0.310. \tag{39}$$

Finally, after making the inverse to (31) substitution, we get the optimal transient probabilities

$$\dot{p}_1 = \dot{x}_2 = 0.550,\ \dot{p}_2 = \dot{x}_1 = 0.140,$$
$$\dot{p}_3 = \dot{x}_3 = 0.310, \tag{40}$$

that maximize the exemplary system mean lifetime $\mu(1)$ in the reliability state subset $\{1,2\}$ expressed by the linear form (29) giving, according to (15) and (40), its optimal value

$$\dot{\mu}(1) = \dot{p}_1 \cdot 0.0813 + \dot{p}_2 \cdot 0.0861 + \dot{p}_3 \cdot 0.0607$$
$$= 0.55 \cdot 0.0813 + 0.14 \cdot 0.0861$$
$$+ 0.31 \cdot 0.0607 = 0.0756\,\text{month}. \tag{41}$$

Substituting the optimal solution (40) into the formula (16), we obtain the optimal solution for the mean values of the exemplary system unconditional lifetimes in the reliability state subset $\{2\}$, that is as follows

$$\dot{\mu}(2) = \dot{p}_1 \cdot 0.0691 + \dot{p}_2 \cdot 0.0728 + \dot{p}_3 \cdot 0.0493$$
$$= 0.55 \cdot 0.0691 + 0.14 \cdot 0.0728$$
$$+ 0.31 \cdot 0.0493 = 0.0635\,\text{month}. \tag{42}$$

and according to (19), the optimal values of the mean values of the system unconditional lifetimes in the particular reliability states 1 and 2, respectively are

$$\dot{\tilde{\mu}}(1) = \dot{\mu}(1) - \dot{\mu}(2) = 0.0121\ \text{month},$$
$$\dot{\tilde{\mu}}(2) = \dot{\mu}(2) = 0.0635\ \text{month}. \tag{43}$$

Moreover, according to (17)-(18), the corresponding optimal unconditional multistate reliability function of the port grain transportation system is of the form

$$\dot{\boldsymbol{R}}(t,\cdot) = [1, \dot{\boldsymbol{R}}(t,1),\ \dot{\boldsymbol{R}}(t,2)],\ t \ge 0, \tag{44}$$

with the coordinates given by

$$\dot{\boldsymbol{R}}(t,1) = 0.55 \cdot [\boldsymbol{R}(t,1)]^{(1)} + 0.14 \cdot [\boldsymbol{R}(t,1)]^{(2)}$$
$$+ 0.31 \cdot [\boldsymbol{R}(t,1)]^{(3)} \text{ for } t \ge 0, \tag{45}$$

$$\dot{\boldsymbol{R}}(t,2) = 0.55 \cdot [\boldsymbol{R}(t,2)]^{(1)} + 0.14 \cdot [\boldsymbol{R}(t,2)]^{(2)}$$
$$+ 0.31 \cdot [\boldsymbol{R}(t,2)]^{(3)} \text{ for } t \ge 0, \tag{46}$$

where $[\boldsymbol{R}(t,1)]^{(b)}$, $[\boldsymbol{R}(t,2)]^{(b)}$, $b = 1,2,3$, are fixed in (Kołowrocki & Soszyńska-Budny 2014).

The graph of the port grain transportation system optimal reliability function $\dot{\boldsymbol{R}}(t,\cdot)$ given by (44)-(46) is presented in Figure 2.

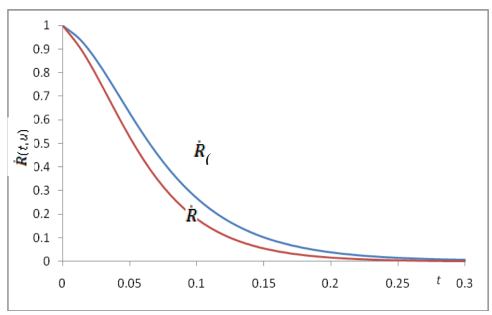

Figure 2. The graph of the port grain transportation system optimal reliability function $\dot{\boldsymbol{R}}(t,\cdot)$ coordinates.

As the critical reliability state is $r = 1$, then the optimal system risk function, according to (20), is given by (Fig. 3)

$$\dot{r}(t) = 1 - \dot{R}(t,1) \text{ for } t \geq 0, \tag{47}$$

where $\dot{R}(t,1)$ is given by (45).

Hence and considering (21), the moment when the optimal system risk function exceeds a permitted level, for instance $\delta = 0.05$, is

$$\dot{\tau} = \dot{r}^{-1}(\delta) \cong 0{,}0114 \text{ month}. \tag{48}$$

Substituting the exemplary operation process optimal transient probabilities at operation states

$$\dot{p}_1 = 0.5,\ \dot{p}_2 = 0.14,\ \dot{p}_3 = 0.31,$$

determined by (40) and the steady probabilities

$$\pi_1 \cong 0.279,\ \pi_2 \cong 0.344,\ \pi_3 \cong 0.377.$$

determined by (9) in (Kołowrocki & Soszyńska-Budny 2014) into (23), we get the following system of equations with the unknown optimal mean values $\hat{M}_b$ of the port grain transportation system operation process unconditional sojourn times at the operation states we are looking for

$$\begin{aligned} &-0.12555\dot{M}_1 + 0.18920\dot{M}_2 + 0.20735\dot{M}_3 = 0 \\ &0.03906\dot{M}_1 - 0.29584\dot{M}_2 + 0.05278\dot{M}_3 = 0 \\ &0.08649\dot{M}_1 + 0.10664\dot{M}_2 - 0.26013\dot{M}_3 = 0. \end{aligned} \tag{49}$$

The determinant of the main matrix of the above homogeneous system of equations is equal to zero and therefore there are non-zero solutions of this system of equations that are ambiguous and dependent on one or more parameters. Thus, we may fix some of them and determine the remaining ones. To show the way of solving this system of equations, we may suppose that we are arbitrarily interested in fixing the value of $\dot{M}_3$ and we put

$$\dot{M}_3 = 0.070.$$

Substituting the above value into the system of equations (49), we get

$$\begin{aligned} &-0.12555\dot{M}_1 + 0.18920\dot{M}_2 = -0.0145145 \\ &0.03906\dot{M}_1 - 0.29584\dot{M}_2 = -0.0036946 \\ &0.08649\dot{M}_1 + 0.10664\dot{M}_2 = 0.0182091. \end{aligned}$$

and we solve it with respect to $\dot{M}_1$ and $\dot{M}_2$, after omitting its last equation. This way obtained solutions that satisfy (49), are

$$\dot{M}_1 \cong 0.1678,\ \dot{M}_2 \cong 0.0346,\ \dot{M}_3 = 0.0700. \tag{50}$$

It can be seen that these solution are different from the values M_1, M_2 and M_3 estimated in (Kołowrocki & Soszyńska-Budny 2014).

Having these solutions, it is also possible to look for the optimal values $\dot{M}_{bl}$ of the mean values M_{bl} of the port grain transportation system operation process conditional sojourn times at operation states. Namely, substituting the values $\dot{M}_b$ instead of M_b, the probabilities

$$[p_{bl}]_{3x3} = \begin{bmatrix} 0 & \frac{1}{3} & \frac{2}{3} \\ \frac{4}{9} & 0 & \frac{5}{9} \\ \frac{1}{3} & \frac{2}{3} & 0 \end{bmatrix}$$

of the port grain transportation system operation process transitions between the operation states given by (6) in (Kołowrocki & Soszyńska-Budny 2014) and replacing M_{bl} by $\dot{M}_{bl}$ in (24), we get the following system of equations

$$\begin{aligned} &\frac{1}{3}\dot{M}_{12} + \frac{2}{3}\dot{M}_{13} = 0.1678 \\ &\frac{4}{9}\dot{M}_{21} + \frac{5}{9}\dot{M}_{23} = 0.0346 \\ &\frac{1}{3}\dot{M}_{31} + \frac{2}{3}\dot{M}_{32} = 0.0700 \end{aligned} \tag{51}$$

with the unknown optimal values $\dot{M}_{bl}$ we want to find.

As the solutions of the above system of equations are ambiguous, then we fix some of them, say that because of practically important reasons, and we find the remaining ones. For instance:

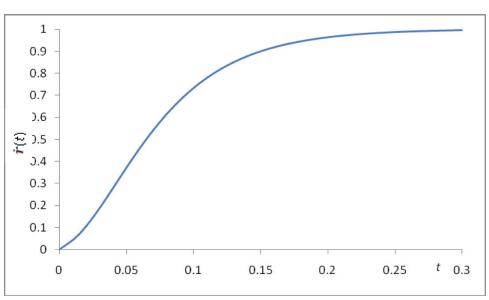

Figure 3. The graph of the port grain transportation system optimal risk function $\dot{r}(t)$.

– we fix in the first equation $\dot{M}_{13} = 0.050$ and we find $\dot{M}_{12} = 0.403$;
– we fix in the second equation $\dot{M}_{23} = 0.010$ and we find $\dot{M}_{21} = 0.065$;
– we fix in the third equation $\dot{M}_{32} = 0.100$ and we find $\dot{M}_{31} = 0.010$. (52)

It can be seen that these solutions differ much from the mean values of the port grain transportation system conditional sojourn times at the particular operation states before its operation process optimization given by (7) in (Kołowrocki & Soszyńska-Budny 2014).

Another very useful and much easier to be applied in practice tool that can help in planning the operation process of the port grain transportation system are the system operation process optimal mean values of the total sojourn times at the particular operation states during the system operation time that by the same assumpion as in (Kołowrocki & Soszyńska-Budny 2014) is equel to $\theta = 1$ year = 365 days. Under this assumption, after aplying (25), we get the optimal values of the exemplary system operation process total sojourn times at the particular operation states during 1 year

$$\dot{\hat{M}}_1 = \dot{E}[\hat{\theta}_1] = \dot{p}_1\theta = 0.55 \cdot 365 \cong 200.75,$$
$$\dot{\hat{M}}_2 = \dot{E}[\hat{\theta}_2] = \dot{p}_2\theta = 0.14 \cdot 365 \cong 51.1,$$
$$\dot{\hat{M}}_3 = \dot{E}[\hat{\theta}_3] = \dot{p}_3\theta = 0.31 \cdot 365 = 113.15, \quad (53)$$

that are different from the values of $\hat{M}_1$, $\hat{M}_2$, $\hat{M}_3$, determined by (8) in (Kołowrocki & Soszyńska-Budny 2014).

In practice, the knowledge of the optimal values of $\dot{M}_b$, $\dot{M}_{bl}$ and $\hat{M}_b$ given respectively by (50), (52), (53), can be very important and helpful for the system operation process planning and improving in order to make the system operation more reliable.

The comparison of the values of the selected port grain transportation system reliability characteristics before the system operation process optimization given in (Kołowrocki & Soszyńska-Budny 2014) by (55)-(56) and (58) with their values after the system operation process optimization respectively given by (41)-(43) and (48) justifies the sensibility of the performed system operation process optimization.

From the analysis of the results of the port grain transportation system operation process optimization it can be suggested to organize the system operation process in the way that causes the replacing (or the approaching/convergence to) the conditional mean sojourn times M_{bl} of the system at the particular operation states before the optimization given by (7) in (Kołowrocki & Soszyńska-Budny 2014) by their optimal values $\dot{M}_{bl}$ after the optimization given by (52). The possibility of fulfilling this suggestion of the operation process parameters changing is not easy and has to be checked in practice.

It seems to be practically a bit easier way, changing the operation process characteristics that results in replacing (or the approaching/convergence to) the unconditional mean sojourn times M_b of the port grain transportation system at the particular operation states before the optimization given by (8) in (Kołowrocki & Soszyńska-Budny 2014) by their optimal values $\dot{M}_b$ after the optimization given by (50).

The easiest way of the system operation process reorganizing is that leading to the replacing (or the approaching/convergence to) the total sojourn times $\hat{M}_b$ of the port grain transportation system operation process at the particular operation states during the operation time $\theta = 1$ year before the optimization given by (11) in (Kołowrocki & Sɒszyńska-Budny 2014) by their optimal values $\dot{\hat{M}}_b$ after the optimization given by (53).

The port grain transportation system operating at the varying in time operation conditions reliability evaluation and prediction are approximate because of non sufficiently exact input data. Therefore, the achieved results may only be considered as an illustration of the possibilities of applications of the proposed methods and procedures to this system operation and reliability analysis, prediction and optimization. However, the obtained evaluation may be a very useful example in other port grain transportation systems and other complex technical systems reliability characteristics prediction, especially during the design and when planning and improving their operation processes effectiveness.

4 CONCLUSIONS

Presented in this paper tool is useful in reliability and operation optimization of a very wide class of real technical systems operating at the varying conditions that have an influence on changing their reliability structures and their components reliability parameters. The results can be interesting for reliability practitioners from various industrial sectors.

Involvement of expert judgement in dynamic model

R. Krikštolaitis, A.E. Lutynska, S. Pečiulytė & I. Žutautaitė
Vytautas Magnus University, Kaunas, Lithuania

ABSTRACT: In many areas models of different processes take into account various factors that are time-dependent and dependent on each other. Thus, it is advisable to construct a dynamic model in order to describe these dependences. In the dynamic model we use indicators. An indicator is a special index, which provides numerical values to important factors for the investigated sector. The values of indicators are obtained from statistical data. Also this dynamic model enables to forecast the dynamics of the indicators according to different new factors. Since the parameters of new factors are not exactly known (got from expert judgement), their influences on indicators are expressed as random variables with known probabilistic distributions. Indicators model based on historic data is adjusted by probabilistic model with the influence of new factors on indicators using a Bayesian method.

1 INTRODUCTION

In many areas models of different processes take into account various factors that are time-dependent and dependent on each other. Thus, it is advisable to construct dynamic model in order to describe these dependences. In dynamic model we use indicators. An indicator is a special index, which provides numerical values to important factors for the investigated sector.

The paper presents a dynamic indicator model, involvement of expert judgement to dynamic model using a Bayesian method and pilot calculations. Pilot calculations of Lithuanian, Latvian and Estonian energy security from technical point of view were presented as an example. The calculations period was chosen from 2007 till 2012. Using the proposed model additional influence of two new energy facilities (LNG and VNPP) was evaluated. Liquefied Natural Gas (LNG) Terminal is one of the most important Lithuania's energy projects that will improve energy security situation in country, create conditions for natural gas market and provide economic boost for many local economies and residents. It is planned that LNG terminal is to be launched from the beginning of 2015. Visaginas Nuclear Power Plant (VNPP) is a new nuclear plant in Visaginas which could be one of the main electricity generating facilities. VNPP construction is still under discussion phase.

2 DYNAMIC INDICATOR MODEL

Let us construct a homogeneous differential equations system, according to the interdependencies between indicators

$$\begin{cases} \dfrac{\mathrm{d}I_1(t)}{dt} = a_{11}I_1(t) + a_{12}I_2(t) + \cdots + a_{1N}I_N(t), \\ \cdots \\ \dfrac{\mathrm{d}I_N(t)}{dt} = a_{N1}I_1(t) + a_{N2}I_2(t) + \cdots + a_{NN}I_N(t), \end{cases} \quad (1)$$

here a_{ij}, $i,j = 1, \ldots, N$ are coefficients, I_i, $i = 1, \ldots, N$—indicators, describing factors of different areas.

Coefficients a_{ij}, $i,j = 1, \ldots, N$ in formula (1) may be calculated using different methods: algebraic, statistical, etc. In (Augutis, Pečiulytė et al, 2012) we proposed to use algebraic method for calculation of these coefficients. This method is quite limited, as we should have square matrices. So, the number of indicators and the number of time moments (when factual values of indicators are observed) must be the same. So, it is better to use Least Square Method (LSM) for calculation of coefficients (Augutis, Krikštolaitis et al, 2013). Let us give the variation for each indicator $\Delta I_i(t) = \left(I_i(t+\Delta t) - I_i(t)\right)/\Delta t$, $i = 1, \ldots, N$ and construct system of algebraic equations

$$\begin{cases} \Delta I_1(t) = a_{11}I_1(t) + a_{12}I_2(t) + \cdots + a_{1N}I_N(t), \\ \cdots \\ \Delta I_N(t) = a_{N1}I_1(t) + a_{N2}I_2(t) + \cdots + a_{NN}I_N(t). \end{cases} \quad (2)$$

We take values of each indicator in time moments t_k, $k = 1, .., n$ and define $I_{ik} = I_i(t_k)$, $i = 1, \ldots, N$, $k = 1, \ldots, n$. So, we have N algebraic systems of N equations with N^2 unknowns

$$\Delta I_{ik} = a_{i1}I_{1k} + a_{i2}I_{2k} + \cdots + a_{iN}I_{Nk}, \quad i = 1, \ldots, N, k = 1, \ldots, n. \quad (3)$$

LSM is applied to calculate estimates of unknown coefficients of equation (3) with assumption that a_{ii}=0, i=1, …, N. For the application of LSM number of observed factual values of indicators $n : n \geq N-1$. In this way all collected statistical data on factual values of indicators may be used.

The expression of the solution of differential equations system (1) depends on eigenvalues λ of system coefficients matrix $\mathrm{A} = \{a_{ij}\}$, $i,j = 1, \ldots, N$. If all eigenvalues are real and different numbers, the solution may be found according to the formula (4) (Golokvosčius, 2000)

$$\left\{ \mathrm{I}(t) = \sum_{j=1}^{N} C_j B_j \mathrm{e}^{\lambda_j t}, \right. \tag{4}$$

here $\mathrm{I}(t) = (I_1(t), I_2(t), \ldots, I_N(t))^{\mathrm{T}}$. If eigenvalues are complex numbers $\lambda_j = \alpha_j + \beta_j \mathrm{i}$, $j = 1,2, ..., N/2$, (N is even number in this case) the solution may be found according to the formula (5)

$$\mathrm{I}(t) = \sum_{j=1}^{N/2} \left(\tilde{C}_{2j-1} B_{2j-1} e^{\alpha_{2j-1} t} \left(\cos\left(\beta_{2j-1} t\right) + \mathrm{i}\sin\left(\beta_{2j-1} t\right) \right) + \tilde{C}_{2j} B_{2j} e^{\alpha_{2j-1} t} \left(\cos\left(\beta_{2j-1} t\right) + \mathrm{i}\sin\left(\beta_{2j-1} t\right) \right) \right), \tag{5}$$

here $B = (b_1, \ldots, b_n)^{\mathrm{T}}$—vector of constants, $\tilde{C}_j = C_j + \mathrm{i}C_j$. Also the solution of differential equations system (1) may be the combination of expressions from formulas (4) and (5).

Aiming to find a particular solution for differential equations system (1), i.e. particular expression of each indicator as on time dependent function, we need to formulate initial conditions for differential equations system. Constants C_i, $i = 1, \ldots, N$ of general solution may be found by solving system of differential equations (1) in time moment t_0

$$I_1(t_0) = I_1^0, ..., I_N(t_0) = I_N^0, \tag{6}$$

here I_i^0, $i = 1, \ldots, N$—normalized factual value of indicator in time moment t_0.

Suppose, that coefficient matrix A of differential equations system (1) is normal, id est $\mathrm{P}^{-1} = \mathrm{P}^*$, here P is a matrix composed from eigenvectors of matrix A, P^*—joint matrix to matrix P. And if $\lambda_1 \leq ... \leq \lambda_k < 0 \leq \lambda_{k+1} \leq ... \leq \lambda_N$ then stability estimate of differential equations system (1) solution is

$$\left\| \mathrm{I}(t) \right\|_2 \leq \mathrm{e}^{|\lambda_1| t} \left\| \mathrm{I}(0) \right\|_2. \tag{7}$$

Created dynamic model will enable us to forecast alternation of different systems factors, such as energy security level according to introducing new objects. In this case we should correct the initial conditions (6) of differential equations system. Since parameters of new objects are not exactly known, these uncertainties should be reflected in the initial conditions. Thus, in such conditions, the values of indicators are random variables.

In mathematical statistics theory it is well known that Bayesian method allows a combination of two kinds of information: prior (for instance, generic statistic data, subjective option of experts) and measurements or observations (Bernardo et al, 2003; Berthold et al, 2003). Bayesian method allows updating estimates of all parameters in the model with a single new obtained observation, i.e. Bayesian method does not require to have new information on the values of all factors involved in the created model.

Bayesian method also allows taking into account the expert's opinion, i.e. when instead of real data we have experts opinion about factors behavior in the future. In our case, the pilot calculations are used for analyzing influence of two energy projects on energy security. One of the projects (LNG terminal) is almost at the completion stage, so the uncertainty due to the start of operation is minimal. The bigger uncertainty is with another project (VNPP). Currently it is not clear whether the project will be implemented. Therefore, the Bayesian method allows to include in the model not only the probable mean value, but also to evaluate the emerging uncertainties.

Also the expert opinion on new object parameters may be involved to dynamic model through initial conditions of differential equations system (6). In this case we should find a new separate solution of differential equations system (1). But there are weaknesses of this method: we need to have expert evaluation of all indicator values without uncertainties and this method does not allow to include more than one new object. So, while calculating the example, we used the Bayesian method for involving expert judgement on new objects, as it is more appropriate.

Expert judgment—probable mean values of indicators time t^*: $I(t^*) = (I_1^*, \ldots, I_N^*)$, with standard deviations σ_i, $i = 1, \ldots, N$, that represent uncertainties. C_i, $i = 1, \ldots, N$, in (4) or (5) solution of differential equations system (1) are independent random variables, with prior probability density functions (pdfs) $p_i(x_i)$, $i = 1, \ldots, N$.

In our case, non-stationary processes are analyzed, i.e. the values of factors depend on time t. Classical application of Bayesian method is not correct in this case, because observations obtained in different time moments represent the other state of the indicators. The modified application of Bayesian method for the calculation estimates of parameters of non-stationary process mathematical models is presented in research papers (Augutis et al, 2012; Žutautaitė-Šeputienė et al, 2010).

3 EXAMPLE OF CALCULATION

For practical demonstration of the proposed method technical blocks of energy security systems in three Baltic States—Lithuania, Latvia and Estonia were chosen. Three generalized indicators describing electricity ($I_1(t)$), gas ($I_2(t)$) and heat (district heat) ($I_3(t)$) were used. These indicators cover various aspects of technical infrastructure, aging of particular infrastructure, etc. The selection of such aggregated indicators was determined by the development of new energy facilities in Lithuania, which mainly influence the condition of technical infrastructure.

Statistical data of 2007–2012 was used for calculation of differential equations system (1) coefficients with least square method in cases of each country (8).

$$\mathrm{A}_{LT} = \begin{pmatrix} 0 & -0.09 & 0.08 \\ 1.74 & 0 & -1.48 \\ 0.52 & -0.48 & 0 \end{pmatrix},$$

$$\mathrm{A}_{LV} = \begin{pmatrix} 0 & -0.4 & 0.66 \\ 0.29 & 0 & -0.3 \\ 0.44 & -0.28 & 0 \end{pmatrix}, \quad (8)$$

$$\mathrm{A}_{EE} = \begin{pmatrix} 0 & 0.08 & -0.12 \\ 0.85 & 0 & -0.8 \\ 0.05 & -0.03 & 0 \end{pmatrix}.$$

All matrices A_{LT}, A_{LV}, and A_{EE} are normal.

As all eigenvalues of matrices (8) are real, so general solutions of (1) differential equations systems with coefficients (8) are constructed using expression of the solution (4):

$$\begin{cases} I_1^{LT}(t) = -0.17C_1\mathrm{e}^{0.77t} - 0.06C_2\mathrm{e}^{-0.76t} + 0.1\mathrm{e}^{-0.01t}, \\ I_2^{LT}(t) = 0.87C_1\mathrm{e}^{0.77t} - 1.05C_2\mathrm{e}^{-0.76t} + 0.11\mathrm{e}^{-0.01t}, \\ I_3^{LT}(t) = -0.65C_1\mathrm{e}^{0.77t} - 0.614C_2\mathrm{e}^{-0.76t} + 0.12\mathrm{e}^{-0.01t}, \end{cases} \quad (9)$$

$$\begin{cases} I_1^{LV}(t) = -0.49C_1\mathrm{e}^{-0.52t} - 0.73C_2\mathrm{e}^{0.51t} + 0.8\mathrm{e}^{0.01t}, \\ I_2^{LV}(t) = 0.77C_1\mathrm{e}^{-0.52t} - 0.06C_2\mathrm{e}^{0.51t} + 1.22\mathrm{e}^{0.01t}, \\ I_3^{LV}(t) = 0.84C_1\mathrm{e}^{-0.52t} - 0.6C_2\mathrm{e}^{0.51t} + 0.74\mathrm{e}^{0.01t}, \end{cases} \quad (10)$$

$$\begin{cases} I_1^{EE}(t) = 0.82C_1\mathrm{e}^{0.004t} + 1.35C_2\mathrm{e}^{0.28t} + 0.87\mathrm{e}^{-0.28t}, \\ I_2^{EE}(t) = 0.77C_1\mathrm{e}^{0.004t} - 0.06C_2\mathrm{e}^{0.28t} + 1.22\mathrm{e}^{-0.28t}, \\ I_3^{EE}(t) = 0.84C_1\mathrm{e}^{0.004t} - 0.6C_2\mathrm{e}^{0.28t} + 0.74\mathrm{e}^{-0.28t}. \end{cases} \quad (11)$$

Using stability estimate of differential equations system solution (7), there was checked up the stability of solutions (9)–(11) taking factual values of indicators in each year from 2007 till 2012 as initial conditions (I(0)) of differential equations systems. As all solutions are stable, constants C_i, $i = 1, 2, 3$ of general solution were chosen in each country case to calculate using normalized factual values of indicators I_i, $i = 1, 2, 3$ in 2012.

In Figures 1–3 are given functions of electricity, gas and heat indicators in each country (Lithuania, Latvia and Estonia) case in 2007–2015.

The decrease of electricity indicator for Lithuania is explainable by the fact that in the end of 2009 the main electricity generation source, Ignalina nuclear power plant, was shut down. The increase of electricity indicator of Latvia is explainable by the reconstruction of two blocks of Riga combined heat and power plant (Fig. 1).

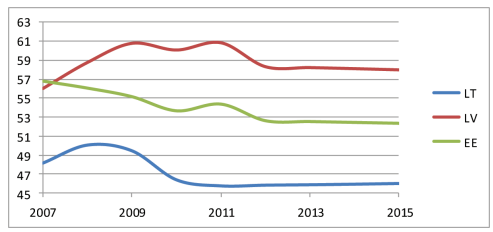

Figure 1. Electricity indicator $I_1(t)$.

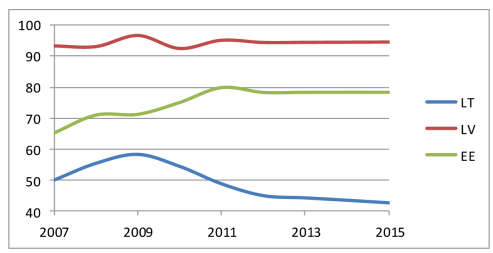

Figure 2. Gas indicator $I_2(t)$.

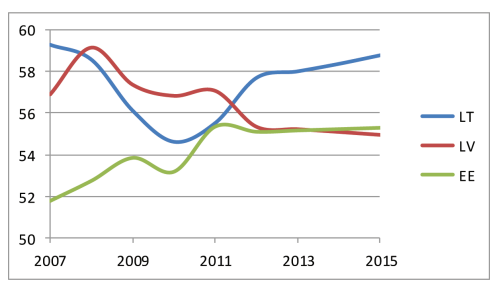

Figure 3. Heat indicator $I_3(t)$.

From 2010, the prevailing resource of electricity production in Lithuania has changed—basic production of electricity was ensured by power plants fuelled with gas. That is why we can see a decrease of gas indicator for Lithuania (Fig. 2).

In Figure 3 heat indicator of Lithuania is presented. This is determined by modernization of heat supply infrastructure.

In order to identify the technical blocks' state in each country, a 100 percent assessment scale is used. The scale is divided into three main parts: normal state (66.67–100 percent), pre-critical state (33.33–66.67 percent) and critical state (0–33.33 percent). These three parts are further subdivided into five equal parts accordingly. The value of each indicator is evaluated by percent during the research year. The state of technical blocks is evaluated using equal weights of all indicators according to the formula

$$TBS = s_1 I_1^p + s_2 I_2^p + s_3 I_3^p, \tag{12}$$

here I_i^p, $i = 1, 2, 3$–value of indicator in percent, s_i, $i = 1, 2, 3$–weight of each indicator (Augutis, Krikštolaitis et al, 2013). Integral characteristic of technical blocks states in Lithuania, Latvia and Estonia are presented in Figure 4. As changes of forecasted indicator values in 2013–2015 are very small, the assessment scale does not accurately reflect them. In order to be more accurate more a detailed scale is needed.

Three scenarios were investigated regarding practical demonstration of the proposed method how to involve expert judgement into a dynamic model:

- scenario 1—neither LNG terminal nor VNPP are constructed,
- scenario 2—LNG plant will start up in 2015,
- scenario 3—VNPP will start up in 2022.

Probable mean values I_i^* of indicators I_i in cases of two different scenarios are presented in Table 1.

Let's assume that at time moment t probability distributions of indicators $I_i(t)$ are normal with

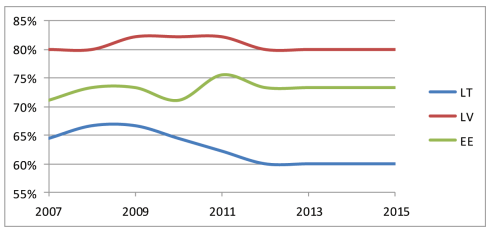

Figure 4. Technical blocks state in Lithuania, Latvia and Estonia.

Table 1. Probable mean values of indicators in cases of two scenarios.

	Indicator		
Scenario	I_1	I_2	I_3
SC2	47.65	63.23	61
SC3	57.5	45	61

means that satisfy equality (9), here C_i ($i = 1, 2, 3$) are independent random variables. C_i can be determined using sum of constants and indicator products (form system of equations (1) with coefficient matrix A_{LT} (8)). In case of normal distributions of indicators, probability distributions of random variables C_i ($i = 1, 2, 3$) are normal as well with means equal to values that are calculated for 2012, i.e. general solution of system of equations (1) with coefficient matrix A_{LT} (8). Denote means are $c_1 = -6.562$, $c_2 = -0.855$, $c_3 = 451.116$ and standard deviations are 10% of its means, i.e. $s_i = 0.1c_i$ ($i = 1, 2, 3$). Multidimensional probability density function (pdf)

$$p(x_1, x_2, x_3) = \prod_{i=1}^{3} \frac{1}{s_i\sqrt{2\pi}} \exp\left(-\frac{1}{2s_i^2}(x_i - c_i)^2\right). \tag{13}$$

BM was applied to obtain posterior pdf

$$p(x_1, x_2, x_3 \mid I_1^*, I_2^*, I_3^*) \propto p(x_1, x_2, x_3) L(I_1^*, I_2^*, I_3^* \mid x_1, x_2, x_3), \tag{14}$$

where $L(\cdot)$—likelihood function

$$L(I_1^*, I_2^*, I_3^* \mid x_1, x_2, x_3) = \prod_{i=1}^{3} \exp\left(-\frac{1}{2\sigma_i^2}\left(I_i^* - \sum_{j=1}^{3} x_j b_{ij} e^{\lambda_j t^*}\right)\right), \tag{15}$$

where σ_i—standard deviation as measure of uncertainty of indicator value forecast (of expert opinion).

The updated point estimates of random variables C_i ($i = 1, 2, 3$) are calculated using posterior pdf

$$\hat{C}_i = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} x_i p(x_1, x_2, x_3 \mid I_1^*, I_2^*, I_3^*) \mathrm{d}x_1 \mathrm{d}x_2 \mathrm{d}x_3, \quad i = 1, 2, 3. \tag{16}$$

Forecasted mean values of indicators calculated with Bayesian method point estimates of random

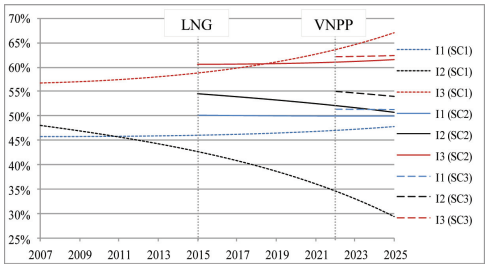

Figure 5. Electricity indicator $I_1(t)$ (blue line), gas indicator $I_2(t)$ (black line), heat indicator $I_3(t)$ (red line); indicators $I_i(t)$ of: SC1 (dot line), SC2 (solid line), SC3 (dash line), $i = 1, 2, 3$.

variables C_i ($i = 1, 2, 3$) was calculated in two scenario cases:

– SC2: LNG in 2015 (I_i^* probable values presented in Table 1, $\sigma_i = 0.5$, $i = 1, 2, 3$);
– SC3: LNG in 2015 (I_i^* probable values presented in Table 1, $\sigma_i = 0.5$, $i = 1, 2, 3$) and VNPP in 2022 (I_i^* probable values presented in Table 1, $\sigma_i = 1$, $i = 1, 2, 3$), i.e. BM was applied twice.

Obtained results presented in Figure 5.

In Figure 5 it is presented that in case business-as-usual (doing nothing) the better results can be expected only in the case of district heat. This can be explained by the fact that LNG terminal may encourage additional use of gas, while preventing the use of biofuel and other renewables for heating. In other cases, new energy objects improve the situation.

In order to be more accurate in long term construction of new facilities it is recommended to recalculate not only separate solution, but also differential equations system (1) coefficients matrix A.

4 CONCLUSIONS

1. The method, based on Bayesian method, explaining how to involve expert judgement as preliminary information with uncertainties on future projects into dynamic different indicator model, is proposed. The solution of this differential indicators system can be used for evaluation of indicators in the future according to the expert opinions.
2. The comparison of energy sector technical block states in three Baltic countries (Lithuania, Latvia and Estonia) was carried out according to the developed methodology. The technical block state is highest in Latvia (approx. 80 percent in 100 percent scale). In Estonia this state is equal to approx. 73 percent, and in Lithuania—approx. 60 percent.
3. The created method of involvement of expert judgement was illustrated by calculating examples for two scenarios—building liquefied natural gas terminal in 2015 and Visaginas nuclear power plant in 2022.

Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: The development of new techniques, technology and the progress of civilization meant that man exploits Technical Objects (TO) offers a set of numerous and interrelated services implemented under different types of systems. In most cases, these are anthropo-technical systems (SA-T) taking into account the essential components of the process of exploitation: man—the operator, the technical object—hardware and software, and the environment—external and internal. Was developed a model of situational awareness SA-T in the implementation of services based on efficient transport of data between the operator and TO (machine, robot) using any interface. The result is a proposal to develop a comprehensive measure to estimate the reliability of SA-T using effectiveness and potentiality trajectories identifying the state of readiness of the system. The paper ends with conclusions of the research and a summary with prospects for further analysis SA-T.

1 INTRODUCTION

1.1 *Technical object*

Nowadays, various types of technical objects are exploited being the result of technology development and civilisation progress. Wide spectrum of properties characterising technical objects of the system nature designed today can be divided into subsets of fundamental discriminates (Laskowski D. 2011):

– people being significant participants of each object exploitation process,
– role of an object as a system component and a participant of system-environment relations,
– complexity of the structure and variety and complexity of functions and tasks.

The evolution of techniques, technology and the progress of civilization have made to society currently offers many services to help existence. The undeniable superiority of these services is the flow of data between sender and receiver. These can be both humans and machines (robots). The substrates for this are the various types of communication systems.

There are many indicators to split the system understood as a Complex Technical System/System (CTS, S). For the purposes of this publication, it is proposed to adopt a criterion in the form of: a man (operator), a technical object (hardware, software) and the environment (the impact of external and internal) operating system. So the system is divided into: classical (ST), anthropo-technical (SA-T) and social engineering (SS-T). These assumptions take into account the essential components of the process operation. Inability states of essential components in systems or destructive interactions of users can cause interruptions in transmission and loose of information. Considerable financial losses, human health or even life, depending on a type and the amount of information lost, can be a consequence of failures. That is why the more and more significant is to take widely understood operating requirements into considerations (particularly related to reliability). The required systems reliability can be achieved at least in two ways. Reliability of a system—it is a nondimensional feature of a system describing its readiness to render services and factors affecting this readiness, e.g.: unimpairability, maintainability and providing maintaining resources. From one hand the tendency should be to create a system with components of high unimpairability.

1.2 *Environment technical object*

Transmission of information between the terminal operator and the machine is connected with the flow of data through interfaces in stationary and mobile, simple and complex architectures CTS (S). This process is accompanied by anomalies related to the time-varying:

1. The state of technical and functional system.
2. Destructive: behavior of people, environmental factors (exposure).

Anomalies are different types of events that could disrupt the transport of data in the form of lost information. The consequences of adverse events are: reducing the number of services (e.g. telecommunications sector), financial loss (e.g. the banking, finance and insurance), human health or life (such as medical services, the transport sector ground, sea and air, uniformed services). Now, the growing importance of continuous—time identification of the state of airworthiness (technical and functional) of man and machine. Safety systems have a tendency to fail, which becomes the subject of a detailed analysis and examination procedure to eliminate such danger in the future. In most situations the direct cause of failure may be damage to the system, its exposure to unexpected load, or fault of the employee (Butlewski. & Sławińska 2014).

These important tasks from the perspective of situational awareness are the perception and understanding of events happening around in relation to time and space. Situation awareness is an essential determinant of operation CTS in which data flow is significant and "bad" decisions can lead to serious consequences. For more information we recommend reading e.g. (Nowakowski & Werbińska 2009), where issues on proper maintenance strategy selection and its influence on dependability state of the system are reviewed, or (Kowalski et al. 2014, 2011), where maintenance problems of complex technical systems are investigated in the context of different solution methodology use (Jasiulewicz-Kaczmarek & Drożyner 2013).

Taking into account the conclusions of the analysis of literature study area (reliability system) was assumed to have not been shown explicitly complex mathematical relationships that could be used to estimate the state of airworthiness man-machine system. There are grounds to conclude that the commonly used commercial solutions and research and implementation for many years used a piecemeal approach to achieve and maintain the declared level of airworthiness technical object (the system and its component) for continuous-time ability to implement services. The attention is focused on the analysis and synthesis of selected aspects of the research problem. Not defining numerical indicators and not taking into account technical and functional capabilities CTS and the effects of the conditions and environmental exposures and human origin. In addition, notes the lack of a clearly definite influence are methods of access to the system, data transport mechanisms and guarantee the level characteristics (i.e., reliability, safety, quality, efficiency, etc.) are important from the point of view of the system and the user who is the recipient of its products. This type of approach, particularly in the structures of the system, is focused on one or a few acquaint criteria,

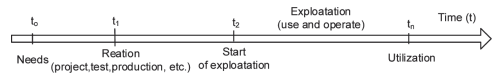

Figure 1. The cycle of existence CTS.

e.g. in the context of the optimization of financial resources, time or space.

It is, therefore definite conclusions from the available publications and the results of scientific research highlight the need for a comprehensive approach, correlating mutual projects in the areas of postulating, design and operational reality in terms of ensuring the proper operation of the OT (Fig. 1).

2 ANTHROPO-TECHNICAL SYSTEMS

2.1 *Model SA-T*

The main predicate research complex technical objects are the concept of "system". Manifested by the existence of a synergistic interaction of its parts was present in (Cempel 2012). The division of the system into components—elements (OTE)—addicted to the study aimed to validate the functionality of the system services. This division is hierarchical, multi-level. In many situations, is one of the initial stages of the development of the formal system description. Assuming assumptions general systems theory stands out, at least a few levels of the existence of systems (Berge 1961). The study adopted the interpretation of "cybernetic system", homeostat based on the transmission and interpretation of data.

In many scenarios, the analysis of the anomaly system is treated as an "or" indivisible. Substantive feature of the system as a whole is that its properties are not trivial functions of the properties of its components. In contrast instantiation is carried out taking into account the relationships between the elements. Become critical in the process of reliability of the item and the need for taking into account external factors (environmental impact). The process of reliability system modeling is a fundamental operation requiring the designer knowledge and technical skills. Supports are mathematical models, system engineering and simulation tools. The final step is to perform simulation studies and locals. For the issue in the article problems OTE collections are: man (operator behaviour), machine (device structures and mechanisms for proper operation) and exposure (resistance to destruction).

In the literature devoted to descriptions of systems you can find many definitions of the term appropriate for the specific situation of research. Therefore, they cannot be used universally for the entire test process system object. The aim of

unifying the nomenclature proposed to adopt a model system of human-machine (Fig. 2).

Depending on the level of detail of the system, its detailed articulation (including definitional) and the articulation of its elements and attributes may be different.

Accordance with the foregoing and publications (Dabrowski 2001), assumes that the measurable properties of a reliability system, respectively interpreted in a certain unit of time (t), are:

1. The potentiality required $(E_{p\text{-}wym}(t))$—determined by the number of services that start and continue the implementation of demanding users of the system.
2. The potential required $(F_{p\text{-}wym}(\Delta T))$—a measure of utility needs addressed at S. This measure to characterize the users' expectations regarding the number and type of services provided over a certain period of time.
3. The potentiality of fit $(E_{p\text{-}dys}(t))$—identified by the number of possible execution services ordered by the user or the probability of an ability condition (properly functioning) for their implementation:

$$E_{p-dys_S}(t,e_i) = f\left[P_{Pf_S}(t,e_i)\right] = \begin{cases} f\left[P_{Pf_ST}(t,e_i)\right] & for \quad ST \\ f\left[P_{Pf_SA-T}(t,e_i)\right] & for \quad SA-T \\ f\left[P_{Pf_SS-T}(t,n,\pi,e_i)\right] & for \quad SS-T \end{cases} \quad (1)$$

where:

– $P_{Pf_S}(t,e_i)$—the probability of an ability condition of the system (ST, SA-T and SS-T) or its components (e_i) taking into account the properties of the inner.

2.2 *Measure of system*

For research purposes, assume that the S classic data transport system (Fig. 3).

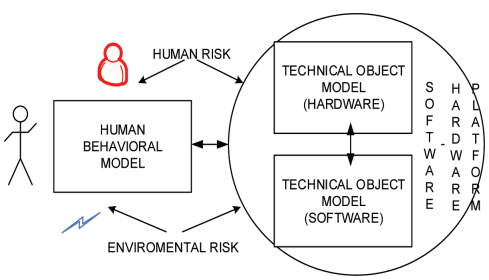

Figure 2. Human-machine system model.

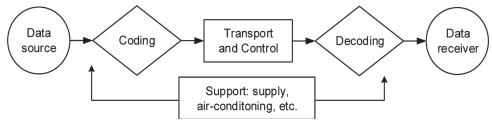

Figure 3. Data transport system model.

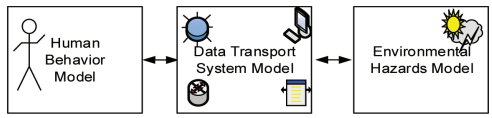

Figure 4. System operator—data transport system—exposure model.

Then it analyzed the system model takes into account the human machine and the environment will contain three elements (Fig. 4).

For the mathematical description of the observed reality in layers (physical, abstract and symbolic) in the S, it is proposed to use the relationship (Cempel 2012, Berge 1961):

$$TO \equiv \langle G, \{Fz\}, \{fk\} \rangle \quad (2)$$

where:

– F_z—attributes and properties,
– f_k—relationships and ties, cooperation,
– G—finite graph of system topology:

$$G = \langle W, K, R \rangle \quad (3)$$

where:

o $W=\{w_l: l=\overline{1, L}\}$, countable set of vertices of the graph (the nodes of the system);
o $K=\{k_m: m=1, M\}$, countable set of branches of the graph (transport channels);
o $R \subset W \otimes^1 K \otimes W$, tripartite relationship of incidence satisfies the condition;
o $B=\{e_i: i=1, I\}$, a size of a system components set is a sum of elements contains:

$$|B| = |W| + |K| \quad and \quad B = \left\{e_i : i = \overline{1, L+M}\right\} \quad (4)$$

In this case the states of system elements can be presented with the vector $\vec{X}^2$ of components $(L+M)$, which take the values *0* or *1*:

$$\vec{X}_{TO} = [\underbrace{x_1, \ldots, x_L}_{L}, \underbrace{x_{L+1} \ldots, x_{L+M}}_{M}] \quad (5)$$

[1]Symbol ⊗ represents the Cartesian product.
[2]Then the operating condition element can be described using the vector.

and components:

$$x_i = x(e_i) = \begin{cases} 1 & when \quad element \quad is \quad able \\ 0 & when \quad element \quad is \quad unable \end{cases} \tag{6}$$

Similarly, the operating states of the system in terms of reliability, it is advisable:
– generalized criterion of suitability of structural:

$$\Phi(S) = \begin{cases} 1 & when \quad system \quad is \quad able \\ 0 & when \quad system \quad is \quad unable \end{cases} \tag{7}$$

– criterion of fitness using the measure (1, 5 ÷ 7) for the system of temporary disablement (Fig. 5):

$$\bigvee_{t \in \Delta t_{zad}} \left[\bigvee_{\substack{E_{p-dys}(t) \in \Delta E_{p-d}(t) \\ E_{p-wym}(t) \in \Delta E_{p-d}(t)}} \left[\begin{array}{l} \left[E_{p-dys}(t) \geq E_{p-wym}(t) \right] \Rightarrow \\ \Rightarrow \left[\Phi(P_{pf_SA-T}, t) \equiv \Phi^{z}(t) \right] \end{array} \right] \right] \tag{8}$$

where:
– t—time, the current while,
– t_z—task time,
– Δt_{zad}—the time interval from the time the task adopted for the start of the task t_0 the moment of the t_z, $\Delta t_{zad} = [t_0, t_z]$,
– $E_{p\text{-}dys}(t)$—potentiality predisposed are value of the interval ($E_{p\text{-}d\text{-}min}(t) \div E_{p\text{-}d\text{-}max}(t)$):[3]

$$E_{p\text{-}dys}(t) \geq E_{p\text{-}wym}(t) \tag{9}$$

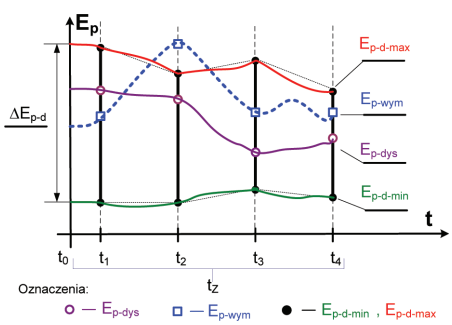

Figure 5. A graphical interpretation of the criterion (8) of an instantaneous system ability state (Dabrowski 2001).

[3]If at a certain time t potentiality predisposed is not less than the potentiality required, the system at time t is fit.

– $E_{p\text{-}wym}(t)$—potentiality required at the time of t,
– $E_{p\text{-}d}$—permissible value of potentiality at the moment t,
– $\Delta E_{p\text{-}d}(t) = [E_{p\text{-}d\text{-}min}(t), E_{p\text{-}d\text{-}max}(t)]$—the range of permissible values of potentiality,[4]
– $\Phi(P_{pf}, t)$—state of the system (P_{pf}—the probability of an airworthiness status),
– $\Phi^{Z}(t)$—the airworthiness status of the system at time t.

If there is even one moment of time t in the interval of the task, in which the potentiality predisposed of the set of potentialities limit is not less than the required potentiality, also belonging to the range of potentiality limit, the state of the system at the moment t is the state of availability (reliability).

The ability criterion is satisfied for the moment t_1, the ability criterion is not satisfied for the moment's t_2, t_3 and t_4. A principal conclusion resulting from the assumptions (6 ÷ 8) and the graphical interpretation of the criterion (Fog 5) of the instantaneous system ability is that, for the system to be able to satisfy functions stated for executing, a value of the required potentiality should at least be equal to a value of the disposed potentiality. In the case of a system it will be the state of executing a service, e.g. viewing electronic mails, viewing WWWs, loading ftp files, and so on.

Basing on accepted initial assumptions related to the criterion of the system ability was proposed to define the SA-T reliability as follows: "Reliability of a anthropo-technical system is defined as the capability to perform a system service for a defined user in conditions influenced by stresses[5], and to adaptation of components owned by the system in order to restore its correctness of operation".

The term "SA-T reliability" can be interpreted also as the ability of an application based on a communication component of a basic system to satisfy ordered critical requirements (e.g. related to security, reliability, real time response and faultlessness) in specified time in spite of unfavourable conditions. An influence range of harmful factors is in general definable, but some situations non-defined earlier should be expected.

Given the multiplicity and complexity of the factors proposed to be grouped into meaningful sets

[4]The range of permissible values of potentiality is determined, inter alia, the properties of the object, type your task, the task conditions, technical requirements, security, economic, administrative—it is, therefore, about the relative width of the interval.

[5]Stresses are sets of natural factors and the ones resulting from human activities, people, other living being and technical equipment presence.

of determinants in the form of intrinsic properties of the system, the properties of the operator and the harmful effects of the environment as a component of the formula for the probability of an ability condition:

$$P_{Pf_S}(t,e_i) \cong f\left(P_{wWi}, P_{pOpi}, P_{zOti}\right) \tag{10}$$

where:
P_{wWi}—probability of proper operation of the TO:

$$P_{wWi}(t,e_i) \cong f\left(K_{gi}, P_{sri}, P_{sni}\right) \tag{11}$$

where:
K_{gi}—unsteady readiness index (taking into account the intensity of damage λ and repair μ):

$$K_{gi}(t,e_i) = \frac{\mu_i}{\lambda_i + \mu_i} + \frac{\lambda_i}{\lambda_i + \mu_i}\ e^{-(\lambda_i+\mu_i)t} \tag{12}$$

P_{sri}—the likelihood of blockages in the ith element taking into account the model of service requests,

P_{sni}—the probability of loss of data in a stream of the ith element functioning as a result of incorrect synchronization (signalization)[6].

P_{pOpi}—the probability of correct operation of the operator TO with regard to knowledge and experience in project implementation time regimes (Fig. 6) determined on the basis of the method of HCR (*Human Cognitive Reliability*, Hannaman *i* in.):

$$P_{bOp_HCR} = \exp\left[-\left(\frac{t}{t_{0,5}} - C_{e,i}\right)C_{g,i}^{-1}\right]^{B_i} \tag{13}$$

where:
C_{ei}, C_{gi}, B_i—coefficients depend on the type of work being done (education, experience, reflexes, rules, etc.),

t—time available to complete the task,

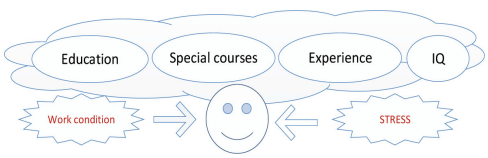

Figure 6. Behavior operator (determinants) model.

[6]Probability value is determined on the basis of technical parameters of the signaling system.

$t_{0,5}$—the average time usually sufficient to complete the task (k_1—experience, k_2—the level of stress, k_3—ergonomic workplace):

$$t_{0,5} = t_{0,5n}\left(1+k_1\right) + \left(1+k_2\right) + \left(1+k_3\right) \tag{14}$$

P_{zOti}—likely to remain CTS able to take into account the suitability of the environment impact:

$$P_{zOt}\left(t, U_k^{\times h}\right) = \left\langle E_{dys}(t) = f\left(P_{e_i}\left(U_k^{\times h}\right)\right)\right\rangle \tag{15}$$

where:
$P_{ei}(U_k^{xh})$—likely to remain in the state of airworthiness e_i after tripping on an object a series of factors U_k of multiplicity h[7]:

$$P_{e_i}\left(U_k^{\times h}\right) = \prod_{k=1}^{h}\left[1 - P_{de_i}^{U_k}\left(r_n^k\right)\right] \tag{16}$$

where:
$P_{de_i}^{U_k}(r_n^k)$—probability of destruction (electric, lower the state of airworthiness) e_i present in the nth (e.g. ring) the effect of factor U_k:

$$P_{de_i}^{U_k}\left(r_n^k, n, \pi, e_i\right) = 1 - \exp\left[-\delta\left(\frac{P\mathrm{r_n}}{P_{ue_i}}\right)^2\right] \tag{17}$$

where:
- δ—parameter of distribution,
- r_n^k—radius of influence of nth exposure of the πth set of types of exposures,
- P_{uei}—probability of damage e_i component systems of nth exposure of the πth-set of types of exposures.

Forms of measure (indicator) of the proper SA-T reliability are:

1) Comprehensive:

$$E_{p-dys_S}(t,e_i) = f\left[P_{Pf_S}(t,e_i)\right] = f\left[P_{wW}(t,e_i), P_{bOp_HCR}(t,e_i), P_{e_i}\left(t,e_i,U_k^{xh}\right)\right] \tag{18}$$

2) Elaborated for:
   - ST (11):

$$E_{p-dys_ST}(t,e_i) = q_1 P_{wWi}(t,e_i) \tag{19}$$

[7]The line may include the harvest Ω,Π factors, some of which may appear multiple times. It is understood that the impact area is divided into zones of different intensities of impact.

– SA–T (11,13):

$$E_{p-dys_SA-T}(t,e_i,U_k^{xh}) = q_1 P_{wW}(t,e_i)\cdot q_2 P_{bOp_HCR}(t,e_i) \quad (20)$$

– SS–T (11,13,16):

$$E_{p-dys_SS-T}(t,e_i,U_k^{xh}) = q_1 P_{wW}(t,e_i) \cdot q_2 P_{bOp_HCR}(t,e_i)\cdot q_3 P_{e_i}(t,e_i,U_k^{xh}) \quad (21)$$

where:
q_i—weight of component probability value depending on a number of components.

Inference on SA-T reliability was based on a statistical estimation fit potentiality based on the output patterns (19 ÷ 21) and the probability distributions. Below the critical value of $E_{p\text{-}dys}$ services will not be realized and OT will be able to unfitness technical and functional well.

3 RESEARCH SA-T

3.1 *Testbed*

Known scientific studies on the issues presented in the article show a diverse and inconsistent methodology of the identification CTS (ie, data transport system, goods or people). A multitude of solutions is closely linked with the selective choice of system characteristics and interests of researchers.

From the analysis of previous publications revealed that this issue is still a research model and design. Due to the ongoing process of analysis and research of the subject area, it was decided here on their own examination of the proposal taking into account the copyright approach to determine the measure of SA-T. These measures include hardware and software properties of the inner components, the proper operation of the operator in the presence of environmental hazards.

For the representative object of research and modeling adopted SA-T reflects the data transfer by classic architecture (Fig. 7). Survey methodology assumes the correctness of construction architecture SA-T in the context of its operation and comes to the implementation of a number of analytical and research work, which is important (Bajda et al. 2011, Laskowski D. 2013):

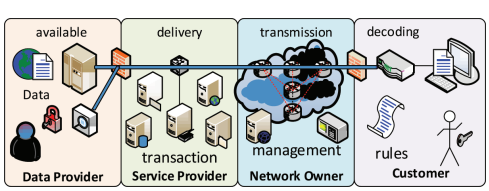

Figure 7. SA-T architecture.

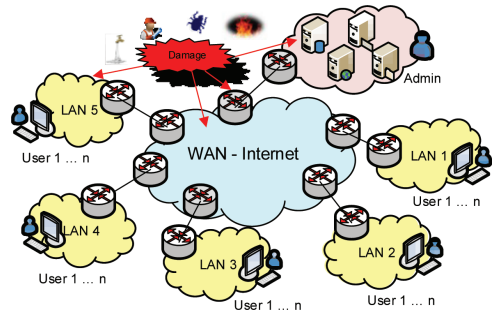

Figure 8. Reference architecture system testbed for research.

1. SA-T is a composition of elements in the chain functional implementation services (e.g. transfers).
2. Elements of SA-T are variable during the fitness of functional and are administered independently.
3. Contracts motor brings the maximum value of static data streams between the areas in SA-T.
4. The test plan included the verification of the suitability of the technical and functional variable traffic volumes and fixed structure research, randomness exposure and damage to components and a change in the level of knowledge of the operator.
5. The reliability of the results was based on the maximum mapping the actual conditions of use SA-T, the cardinality of measurement, reproducibility of results, etc.

This architecture is used in most current system services such as VoIP (Voice over IP), WWW, FTP and database (Lubkowski & Laskowski 2013).

It was therefore decided to extend it for the adopted research purposes (Fig. 8). SA-T contains important elements (testbed system architecture) for the realization of the services necessary to determine the potentiality trajectory.

4 RESULTS

On the basis of simulation studies and tests were obtained extensive collection of local data. Exemplary data is entered in the Table 1 and shown in the drawings (Figs. 9, 10).

Table 1. Example of output data for Group A scenarios.

Lp.	Parameter	Value		
		Minimum [%]	Maximum [%]	Average [%]
Scenario expert knowledge (Fig. 9)

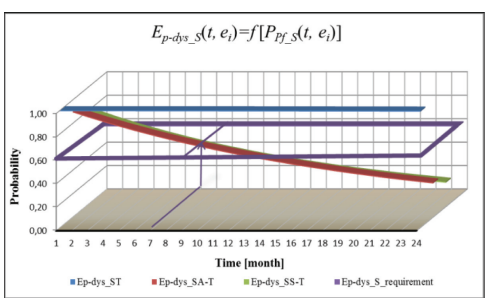

Figure 9. Scenarios 1_the knowledge of the expert.

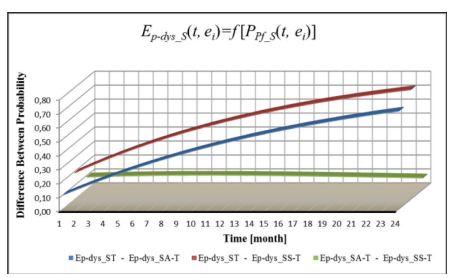

Figure 10. Scenarios A1_the knowledge of the expert difference.

The resulting trajectories of potentiality are taking into account:

1. Determinants:
   – base of stationary relations system and random occurrence of exposure,
   – detailed: change in the level of knowledge.
2. The result, values for charts:
   – Trajectory ST ($E_{p\text{-}dys_ST}$), SA-T ($E_{p\text{-}dys_SA\text{-}T}$) and SS-T ($E_{p\text{-}dys_SS\text{-}T}$) for the knowledge of the Expert (Fig. 9), Advanced (Fig. 11) and Primary (Fig. 13),
   – Differences in the probabilities of trajectories:
     o ST ($E_{p\text{-}dys_ST}$)—SA-T ($E_{p\text{-}dys_SA\text{-}T}$),
     o ST ($E_{p\text{-}dys_ST}$)—SS-T ($E_{p\text{-}dys_SS\text{-}T}$),
     o SA-T ($E_{p\text{-}dys_SA\text{-}T}$)—SS-T ($E_{p\text{-}dys_SS\text{-}T}$)

for the knowledge of the Expert (Fig. 10), Advanced (Fig. 12) and Primary (Fig. 13).

On the trajectory (Fig. 9), depending on the requirements of the operator, determining a required critical value ($E_{p\text{-}dys\text{-}requirment}$), below which it is believed that OT is no longer fit for operation.

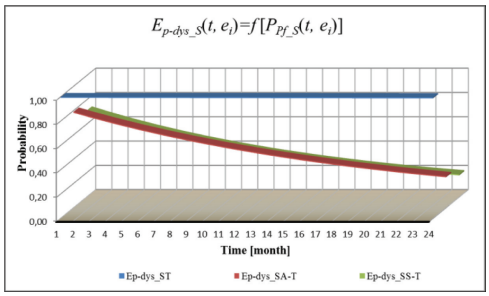

Figure 11. Scenarios A1_advanced knowledge.

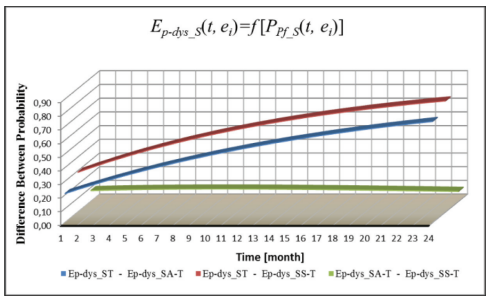

Figure 12. Scenarios A1_advanced knowledge_ difference.

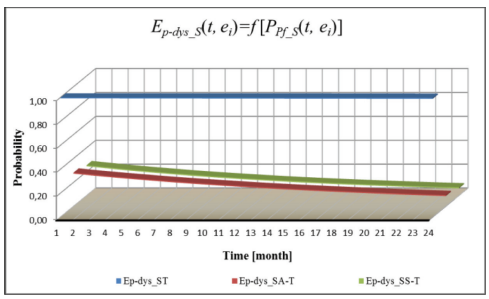

Figure 13. Scenarios A1_primary knowledge.

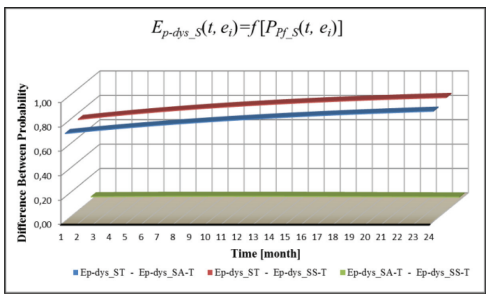

Figure 14. Scenarios A1_primary knowledge_ difference.

For example, the value may be 0.6, and the probability of $E_{p\text{-}dys\text{-}requirment}$ is reached after 7 months.

On the basis of the performed analysis and research projects of local output data were collected and subjected to statistical analysis. Such a procedure has facilitated clarification of observations for the period concerned (24 months), of which the main ones are:

1. Trajectories $E_{p\text{-}dys_ST}$, $E_{p\text{-}dys_SA\text{-}T}$, $E_{p\text{-}dys_SS\text{-}T}$ can be divided into several major collections are characterized by similar shapes depending on:
   – $E_{p\text{-}dys_ST}$—network traffic—"slightly" linearly decreasing (this effect is properly functioning and "high" reliability of hardware and software),
   – $E_{p\text{-}dys_SA\text{-}T}$: knowledge of the operator—"significantly" exponentially decreasing and value of traffic—"significantly" less than the influence of the human factor,
   – $E_{p\text{-}dys_SS\text{-}T}$: knowledge of the operator, environmental hazards and human—"significantly" exponentially decreasing and traffic value are smaller and oscillate at 1%.
2. The variability of the differences between the trajectories $E_{p\text{-}dys_ST}$, $E_{p\text{-}dys_SA\text{-}T}$, $E_{p\text{-}dys_SS\text{-}T}$ can be divided into two basic sets of relationships:
   – $E_{p\text{-}dys_ST}$—$E_{p\text{-}dys_SA\text{-}T}$ and $E_{p\text{-}dys_ST}$—$E_{p\text{-}dys_SS\text{-}T}$—"significantly" logarithmic growing,
   – $E_{p\text{-}dys_SA\text{-}T}$—$E_{p\text{-}dys_SS\text{-}T}$ – close to constant in time.

The data obtained on the basis of the concept developed, confirmed the need to consider many factors component. These factors determine the suitability of the technical SA-T (also ST, SS-T) and the correctness of the implementation of network services.

Used development tools have reduced the time and effort of research, and contributed to the reliability and reproducibility of the data. Also facilitate the removal of the trajectory of potentiality. Reasonable to conclude, that the results will enable the implementation of a synthetic analysis and clarification of observations with regard to the conduct of subsequent studies human-machine systems.

5 CONCLUSIONS

The main findings from the analysis of theories and research results in the field of system reliability during potentiality trajectory ($E_{p\text{-}dys_ST}$, $E_{p\text{-}dys_SA\text{-}T}$ and $E_{p\text{-}dys_SS\text{-}T}$) are:

1. It is possible to designate this kind of value for respectively the exact explicit baseline data identifying properties hardware and software platform, operator and environmental hazards.

2. Accuracy of change and shape of the trajectory depends on multiplicity and diversity of events occurring in the system environment.
3. The impact of the factors considered in the order of their weight (importance) is as follows:
   – environmental exposure and destructive human behavior (random) and knowledge operator hardware and software platform (Expert and Advanced),
   – traffic value (appropriate to the reported demand of the service and exchanged data synchronization) and technical parameters of the hardware and software platform.
4. The method is universal and is used to identify, by estimating selected parameters (i.e. potentiality), current and future technologies and network technologies used in the system (ST, SA-T, SS-T).
5. The components of this method may constitute a separate method to identify the impact of individual factors (ownership, i.e. technical, operator or exposure) environmental airworthiness status of the system or its component.

Potential measures proposed in the form of probabilities of system reliability can be used at any system operational step to restore or increase the SA-T ability state with taking into account stresses possible to occur. Therefore it is also advisable not to confine to design and establish an object rendering services, but to carry a permanent process of monitoring operational status of the network.

Knowledge related to the shape and location of potential trajectories, determined by using values of a reliability indices distribution for a anytime hour period of using, can considerably influence improving management of the operational process. This influence is possible first of all because of using the results of the trajectories synthesis in the formulation process of prognostic conclusions and operating decisions.

It seems reasonable to say that there is a need for further analysis and research undertaken scientific problem to accurately detail the relationship between the various elements of the COT analyzed in a broader spectrum of events anthropo-technical. The developed method can also be applied to other transport systems, and more.

Cost-benefit analysis of surveillance technologies

Pei-Hui Lin & Coen van Gulijk
Safety Science, Technical University of Delft, Delft, The Netherlands

ABSTRACT: There are several types of surveillance devices in the market, each with its own operating characteristics. Since the terrorist attack of 9/11 there has been much focus on preventing or mitigating damages and causalities caused by terrorist activities. A key issue is whether the investment in fighting crime and counter-terrorism devices is well spent in a manner that optimizes public safety in a cost-effective manner. SURVEILLE is a research project funded within the EU Commission FP7 framework where one of the objectives is to assess the benefits and costs of surveillance technology. This paper reports on ongoing work of cost-benefit modelling for security that is performed within in this project.

This paper provides a brief overview of the quantification method for cost-benefit models for security devices. Currently, a straightforward and easy-to-use cost-benefit analysis of surveillance technologies is not available. A cost-benefit model considering probabilistic terrorism risk assessment is developed. The model developed here considers probability of attack, risk reduction, losses, and costs of security devices. However, it is found that a full cost-benefit analysis requires a substantial effort, even for a single surveillance device which may be difficult in operational organizations such as the Police. A brief discussion on mathematical modelling is shown in this paper. But more detail discussion can be found in the SURVEILLE project report that is available through the website[1]. Special attention was given to "cost" modelling of the security device in this paper. The paper ends with discussions of the use of cost modelling in a (semi-)quantitative cost-benefit analysis for surveillance. We are currently performing a case for the remainder of the SURVEILLE project, but cannot disclose the results. These results will be available on the SURVEILLE website later during the project.

1 INTRODUCTION

There are many types of surveillance devices that you can buy today. Since the terrorist attacks of 9/11 there has been much focus, and funding, on preventing or mitigating damage and casualties caused by terrorist activities. However, it is not quite transparent whether anti-terrorist spending's are cost-effective.

SURVEILLE is a research project funded within the EU Commission FP7 framework where one of the objectives is to assess the benefits and costs of surveillance technology. Work towards this objective is done through technology assessment experts operating in constant interaction with lawyers, ethicists and social scientists. Currently, a straightforward and easy-to-use cost-benefit analysis of surveillance technologies is not available. This paper reports on ongoing work of cost-benefit modelling for security that is performed within in this project.

Section 2 provides a brief overview of the quantification method for cost-benefit models for security devices. It is found that a full cost-benefit analysis requires a substantial effort, even for a single surveillance device which may be difficult in operational organizations such as the Police. The discussion on mathematical modelling is briefly summarized in Section 3. But more detail discussion can be found in the SURVEILLE project report that is available through the website[2]. Special attention was given to "cost" modelling of the security device in Section 4. Section 5 discusses the use of cost modelling in a (semi-)quantitative cost-benefit analysis for surveillance.

2 A BRIEF OVERVIEW OF THE QUANTIFICATION METHOD FOR COST-BENEFIT MODELS FOR SECURITY DEVICES

2.1 *Economic analysis*

A number of approaches exist for calculating and comparing the benefits and costs of a government policy. Cost-effectiveness analysis and cost-benefit analysis are among the most commonly used tools for this kind. Cost-benefit analysis compares a programme's benefits to a stakeholder with the costs to that stakeholder. This approach places benefits and costs in comparable terms, usually dollars. Cost-

[1]www.surveille.eu.
[2]www.surveille.eu.

effectiveness analysis determines how much is spent on a programme to produce a particular outcome (or how much of a particular benefit will result from a given expenditure). Unlike cost-benefit analysis, cost-effectiveness analysis only requires that costs be monetized (Dhiri & Brand, 1999; Cohen, 2004).

There are two principle types of formulation of cost-benefit analysis (European Commission, 2004). One is "net value of costs and benefits". This cost-benefit approach uses a net present value formula to make future costs and benefits comparable with present costs and benefits. It measures the benefits versus the costs in a well-defined period.

$$NPV = \sum_{t=0}^{T} \left(\frac{B_t - C_t}{(1+r)^t} \right) - K_o$$

NPV = net present value
B_t = benefits of the project at time t
C_t = operational costs of the project at time t
r = rate of discount
T = lifetime of the project
K_o = initial costs of the project in the base period

The project is considered as financially feasible if the calculated NPV > 0.

Alternatively one may also use a "cost-benefit ratio" formula. In this case a quotient of the net present benefits and the net present costs is calculated. If the ratio is >1 the social benefits outweigh the cost. The bigger the ratio, the better the project.

$$CBR = \frac{\sum_{t=0}^{T} \frac{B_t}{(1+r)^t}}{\sum_{t=0}^{T} \frac{C_t}{(1+r)^t}}$$

However, generally speaking cost-benefit analysis used in law enforcement and crime prevention policies is still rather simple and usually takes only some of the outcomes into account (European Commission, 2004). Moreover, after the terrorist attack of 9/11 there has been much focus on preventing or mitigating damage and causalities caused by terrorist activities. A key issue is whether the investment in counter-terrorism devices is well spent in a manner that optimizes public safety in a cost-effective manner. However, to compare costs and benefits requires the quantification of threat probability. Threat probability is the likelihood that a threat will occur. The formulas mentioned above do not include the issue of risk assessment or address the quantification of security risks (e.g., Stewart et al. 2006; Stewart and Netherton 2008; Dillon et al. 2009; Cox 2009). This is a challenging task, but necessary for probabilistic terrorism risk assessment. In next section, we will discuss the detail formulation of the net benefit of a security measure.

2.2 *Cost-benefit model for a security device*

As stated, a key issue often being raised in investing in security measures is the probability of crime. Considering the risk assessment, the formula of Stewart and Mueller (2011) is particularly useful for our project that is specifically designed for security devices. We can use this formula as a guideline to quantify the net benefit of a security device. A security measure is cost-effective when the benefit of the measure outweighs the costs of the security measure.

The net benefit of a security measure can be expressed as follows:

$$\begin{aligned} Net\,benefit = {} & P(attack) \times C(loss) \\ & \times \Delta R - C(Security) \end{aligned} \quad (1)$$

- P ($attack$): the probability of a successful attack is the likelihood that a successful terrorist attack will take place in the absence of the security measure.
- C ($loss$): the losses in the successful attack. This includes fatalities and damage to the infrastructures, as well as the psychological and political impact.
- ΔR: percentage reduction in risk. This is the degree to which the security measure protects against a terrorist attack. If a security device will foil every threat, then the risk reduction is 100%.
- C (security measure): cost of security measures. This includes public and private economic costs of applying a security device, and infringement of fundamental rights by this device.

The risk reduction ΔR in Stewart and Mueller (2011) is presented as risk percentage achieved by the presence of advanced image technology in airports. The paper by Stewart and Mueller (2011) considers a multidimensional decision problem with many possible interactions between security measures, threat scenarios, threat probabilities, risk reduction and losses. This means that it considers the risk reduction of several security measures. In this research, we will not consider the combination of different control measures, but rather focus on one security device at a time.

In equation (1) the amount of risk reduction is formulated as $P(attack) \times \Delta R$. In this research, we can re-formulate $P(attack) \times \Delta R$ as:

$$\begin{aligned} P(attack) \times \Delta R &= P(attack) \\ &\times P(success\,detect \mid attack) \\ &= P(attack) \times (1 - P(no\,detect \mid attack)) \end{aligned} \quad (2)$$

Thus, equation (1) becomes

$$\begin{aligned} Net\ benefit = {} & C(loss) \times P(attack) \\ & \times (1 - P(no\,detect \mid attack)) \\ & - C(Security\,measure) \end{aligned} \quad (3)$$

P(*no detect*|*attack*) is defined as 'false negative rate' which can be obtained based on the testing and evaluation of a security device. Such testing is normally required before a device can obtain state approval.

3 DISCUSSION ON MATHEMATICAL COST MODELLING

A full cost-benefit analysis requires a substantial effort for a single surveillance device. Each part of the parameters in equation (3) is discussed separately in the SURVEILLE project, but due to the length restriction of the ESREL paper submissions, the discussion on mathematical modelling for each parameter is briefly summarized here.

1. Cost of loss includes direct tangible costs of a terrorist incident, for example, the replacement costs of property damage after a terrorist incident; and intangible costs of terrorism includes, for instance, loss of lives after an attack, fear or social tensions in relation to terrorist activity, etc. When talking about cost-benefit analysis, a big concern in applying such a method to the case of security is that it requires the researcher to monetize the intangible costs of terrorism, such as value of life. It is very difficult, if not outright unethical, to obtain an objective value for a human life. There is now extensive literature on the value of life, which should not be interpreted as the value of any one particular life, but instead, of society's value of saving a "statistical" life.

   Other intangible costs are also legitimate costs to incorporate into cost-benefit analysis. These could be psychological and emotional costs, such as the cost of pain, suffering and loss of quality of life resulting from victimisation (Cohen et al. 2004). Estimation of these costs can be also difficult. However, a number of methods, such as method based on jury award data (Cohen 1988; Cohen 2000; Miller et al. 1996) or willingness to pay (Cohen 2000), have been developed to place monetary estimation on those intangible costs.

   During the development of cost-benefit model in this project, it is controversial if non-economic values are calculated. It can be argued that placing a monetary figure on a person's life is cold and detached; however, the alternative of not recognising this cost is probably also arguable. Currently placing monetary figure in those intangible costs is still arguable in our project. If the decision in the SURVEILLE project is to apply a formal cost-benefit analysis, then the information provided here give us an idea of how to quantify these impacts.
2. *P*(*attack*): The probability of a successful attack is the likelihood that a successful terrorist attack will take place in the absence of the security measure. Often, the data on the probability of attack is scarce and this makes the estimation of likelihood difficult. Due to this reason, Stewart and Mueller (2011) use a practical approach, "break even" cost-benefit analysis that finds the minimum probability of a successful attack required for the benefit of security measures to equal their cost. This means that they set net benefit in equation 1 to be zero and calculated the minimum attack probability necessary for full-body scanners to be cost-effective.

   In the safety domain, we also face the same severe limit on the availability of data to quantify failure probabilities. Expert opinion in the form of subjective probabilities has been a dominant source for failure probabilities in quantifying risk in safety science. Cooke (1991) and Cooke and Goossens (2000) presented a structured expert judgment procedure to combine experts' opinion in a scientifically defensible way. The overall goal of the method developed by these authors is to achieve rational consensus in the resulting assessments, and thus to enable the information of diverse experts or stakeholders to be incorporated into the process by which the results are reached. We have successfully applied this approach in a series of studies in the field of aviation and chemical industry studies (Ale et al. 2009; 2011; 2013) with Bayesian Belief Networks (BBNs) quantification. Although the structure expert judgement is not yet implemented in the security world, the scientific proof of such a method can be implemented in this domain.
3. 1 – *P*(*no detect*|*attack*) is the amount of risk reduction achieved by deploying a single device. This technical feature related to false negative rate often can be obtained based on the testing and evaluation of a security device before a device can obtain state approval. However, in reality, to decrease the false negative rate in the system, a practical solution for homeland security and international security is to choose a set of alternative devices to be combined together, to increase inspection criteria, or to incorporate operators to control risk. Stewart and Mueller (2011) assume the security measures are linear and use reliability block diagram to calculate risk reduction. However, in reality the inspection criteria, operators and security devices are not linear to foil terrorist attacks and there is uncertainty involved in risk reduction. In the SURVEILLE project report[3], Bayesian Belief Net approach

[3]www.surveille.eu.

is proposed to deal with uncertainty of risk reduction in a complex system/scenario.

4. Cost of a security device: as mentioned above in equation (1), the cost of a security device should include the economic costs of applying a security device, and indirect costs associated with using a device (e.g. infringement of fundamental rights as regards the protection of personal data, privacy, and freedom of thought) as defined in the project. It was decided by the project that analysis of cost security device is a precondition for evaluating the impacts of different surveillance systems for the security of the citizens. Therefore, special attention was given to cost modelling of the security device in the SURVEILLE project report. Next section shows the direct economic costs developed in that report.

4 COST MODELLING

4.1 *Literature review of cost models*

A literature review of cost modeling of security devices is conducted in this section. There is no general guideline on the cost modelling of security devices in technical scientific literature. Our literature review produced three topics which have contributed to our study:

- Assessing the impact of CCTV
- Selecting screening technologies for checked baggage inspection systems at airports
- Analyzing crime prevention programs

The first two topics are related to specific security measures. The last topic relates to national strategy on community safety and crime prevention. The purpose of the crime prevention programs studies is to build comprehensive and standard crime prevention measures for various types of programs. The governments of both the United Kingdom and Canada want to facilitate the comparison of cost-benefit analysis, thus building a comprehensive knowledge base in crime prevention programs to support the development of sound policy. The "cost parameters" incorporated in these three topics are particularly interesting for our research in cost modelling for surveillance technologies. As a result of the literature review, Table 1 summarizes all the variables considered in our literature review.

4.2 *Cost modelling of a security device*

The cost modelling of surveillance technology is exhibited as the annual cost of using devices to meet the security demand. The annual cost is based on the variables shown in Table 1. The cost model in our research includes the fixed cost and operational costs and also takes into account the costs associated with resolving false positive alarms.

There are two types of errors that any security device can make. A false positive reading when the device identifies an object (person or thing) as potential hazard when it is not. This is a problem because every such false reading leads to additional steps being taken that causes inconvenience to consumers, delays system operation, and costs money. The impact of this error reading is taken into account in the cost of the security measure that formulated in equation 4. Another type of errors is false negative reading when the hazard is actually present but a single device fails to recognize it. The designers of the system are most concerned with false negative readings, i.e. a situation with a real threat is not detected by the system. The consequence of this error may lead to loss of lives and infrastructure, and disruption of the transportation system. This is the type of error we do not want. The false negative error is incorporated in the cost-benefit equation showed in section 2.2.

Based on the analysis of Table 1, the cost model in this project considers:

- purchase price and installation cost—*P&I*
- space requirement cost—*S*
- human resources cost including any training that is required to operate the security equipment (start-up and in-service)—*H*
- maintenance and sustainability cost (e.g. renewing license, rental cost, and necessary manpower)—*M*
- cost of equipment operation such as power consumption—*O*
- other running costs (e.g. office furniture, transport, insurance, stationery items)—*R*
- false-positive rate—*FA*

The annual cost of a surveillance technology is modelled as follows:

$$C(\textit{security measure}) = \frac{[P\ \&\ I + S + H + M + O + R + FA]}{T_S} \tag{4}$$

- $\boldsymbol{T_S}$ = *desired system service time* (*year*). This is independent from which device is used.
- $\boldsymbol{P}\ \&\ \boldsymbol{I} = C_{p\&i} \times \lceil D_S / R_D \rceil \times \lceil T_S / T_D \rceil$

  $C_{p\&i}$ = purchase and install cost/per device;
  $\boldsymbol{D_S}$ = system operating demand;
  R_D = device processing rate including the waiting time (time/hour); $\lceil D_s / R_D \rceil$ determines the number of devices needed to meet the demand and the standard average waiting time; The processing

Table 1. Variables considered in the reviewed literature.

Aviation-checked baggage security system		Crime prevention program		CCTV
(Virta et al. 2003) (Jacobson et al. 2006)	(Blejcharova et al. 2012)	(Legg & Powell, 2000) (Hornick et al. 2000)	(Gill and Spriggs, 2005)	(Hornick et al. 2000)
Purchase and installation cost		Staff cost Recruitment	Personnel	Staff salaries and benefits
Expected annual maintenance costs		Training	Training	Staff training costs
Annual lease expenditure		Premises	Premises	
Operation of baggage screening security device per checked bag inspected		Equipment Purchase & rental costs: electrical appliances, office furniture, telephones, vehicles, fences, gates	Equipment	Equipment Purchase & rental costs (including office space)
		Research cost Publicity cost	Research, advertising and publicity	Advertising
		Running costs: (telephone, post, insurance, stationary items, vehicles, equipment maintenance)	Transport	– Furniture – Telephone, fax, mail, etc. – Office supplies – Utilities (heat, water, electricity) – Insurance (e.g., liability, automotive, property) – Transport
			Other overheads	Client expenses
False clear cost	False clear cost			Volunteer time for partner networks and administration
False alarm cost	False alarm cost			Volunteer time for client services
True clear cost				Victim costs
True alarm cost				In-kind resources (e.g., resources shared from host agency such as space, furniture, computers)

rate is an important factor that affects the number of devices required. For instance, the processing rate for automated x-rays for scanning baggage is 1200–1500 bags/hour. An EDS machine is 150–200 bags/hour. Thus, the annual processing capacity can be estimated by processing rate *operating hours/day*days/year. If the maximum annual requirement is denoted by D_S, the number of devices required is calculated as $\lceil D_s / R_D \rceil$.

$\boldsymbol{T_D}$ = lifetime of a surveillance device(year); $\lceil T_S / T_D \rceil$ determines the number of times that the security devices need to be purchased over a given time period.

- $\boldsymbol{S} = C_s \times \lceil D_s / R_D \rceil$
  C_s = space requirement cost/per device
- $\boldsymbol{H} = \boldsymbol{N}_P \times \lceil D_s / R_D \rceil \times C_P$
  $\boldsymbol{N_P}$ = number of personnel/per device
  C_P = salary/per personnel
- $\boldsymbol{M} = [C_{m1} + C_{m2}] \times \lceil D_s / R_D \rceil$
  C_{m1} = schedule maintenance cost; schedule maintenance is a preventive form of maintenance conducted at pre-set intervals to inspect and ensure that the device works properly;
  C_{m2} = unscheduled maintenance; unscheduled maintenance is needed after any failure event or the discovery of any unexpected technical wear or anomaly.
- $\boldsymbol{O} = C_O \times \lceil D_s / R_D \rceil$
  C_O = equipment operational cost/per device
- $\boldsymbol{FA} = C_{FA} \times P_{FA} \times (1 - P_T) \times D_s$
  False alarm cost, including inconvenience, delay, re-inspection cost of operators, re-

Table 2. Cost factors.

Categories	Cost factors proposed in this research
– Purchase cost	– Purchase price and installation cost – Space requirement cost
– Personnel cost	– Human resources cost including any training that is required to operate the security equipment
– Additional running costs	– Maintenance and sustainability cost (e.g. renewing license, rental cost, and necessary manpower) – Cost of equipment operation such as power consumption – Other running cost (e.g. office furniture, transport, insurance, stationary items) – Cost related to false-positive rate

inspection cost of device. Every false alarm leads to additional procedures being taken that waste money and man-hours, cause comsumer dissatisfaction, and reduce people's confidence in the security system.

Then, according to equation (4) the annual expected cost of a piece of surveillance technology can be calculated as:

$$C(security measure) = \frac{\left[C_{p\&i}\times\left\lceil\frac{D_S}{R_D}\right\rceil\times\left\lceil\frac{T_S}{T_D}\right\rceil + C_s\times\left\lceil\frac{D_s}{R_D}\right\rceil + N_P\times\left\lceil\frac{D_s}{R_D}\right\rceil\times C_P\right]}{T_S\times\left\lceil\frac{D_S}{R_D}\right\rceil} + \frac{[C_{m1}+C_{m2}]\times\left\lceil\frac{D_s}{R_D}\right\rceil + C_O\times\left\lceil\frac{D_s}{R_D}\right\rceil + C_{FA}\times P_{FA}\times(1-P_T)\times D_s}{T_S\times\left\lceil\frac{D_S}{R_D}\right\rceil} \quad (5)$$

5 DISCUSSION AND CONCLUSION

The objective of this paper is to show the ongoing work of cost-benefit modelling for security devices in this EU project. This research discusses the basic formulation of cost-benefit analysis. From there we extend the basic formula of the economic analysis model and develop a relatively straightforward modelling for cost-benefit analysis for security devices. However, as the factors in the model are closely examined, this relatively simple model becomes mathematically challenging, involving questions of uncertainties (e.g. probability of attack, amount of risk reduced) and modelling direct and indirect costs (e.g. loss of lives after an attack, fear or social tensions in relation to terrorist activity, infringement of fundamental rights to privacy).

As a full cost-benefit analysis requires a substantial effort for a single surveillance device, currently it is decided by the SURVEILLE project to utilize a (semi-)quantitative cost-benefit analysis for surveillance technology which includes costs other than financial cost. The multidimensional matrix for technology assessment includes (a) usability, in terms of effectiveness, cost, privacy-by-design features and overall excellence, (b) ethics, and (c) intrusiveness into fundamental legal rights. Significant insight gained in "cost" analysis in this research will contribute to the overall score for usability. Based on the cost factors found in section 4.2, Table 2 summarized three major cost categories that should be covered in SURVEILLE assessment matrix.

A matrix of surveillance technologies that reflects assessments of usability and of the risks of violating both ethical standards and fundamental rights is represented by numerical scores awarded in the usability and fundamental rights assessments and ethics assessment. The main conclusions that in the context of the matrix can be drawn from the combination of usability (technology), fundamental rights (law) and moral risk (ethics) assessments for 14 surveillance technologies.

It should be emphasized that this first version assessment measures the use of specific surveillance technologies and provide a basis for a general, all-things-considered assessment for surveillance technologies.

Integrated estimation of pipeline failure probability

I. Žutautaitė, G. Dundulis, S. Rimkevičius & R. Janulionis
Lithuanian Energy Institute, Kaunas, Lithuania

ABSTRACT: The estimation of pipeline failure probability based on the results of integrated deterministic-probabilistic structural integrity analysis and pipeline failure data analysis is presented in the paper. Deterministic-probabilistic structural integrity analysis evaluates the uncertainties associated with loads, material properties, and geometrical parameters. The application of Bayesian method allows us to update estimate of pipeline failure probability (obtained in deterministic-probabilistic structural integrity analysis) with regard to district heating network operation data. The developed methodology is applicable for district heating, gas and oil supply networks. Integrated failure analysis was performed for the selected part of Kaunas (Lithuania) district heating network to illustrate implementation of the proposed method.

1 INTRODUCTION

Piping networks as District Heating (DH) networks, natural gas transmission network or oil pipelines are very important elements of infrastructure of country energy system. District heating networks provide and distribute heat, generated in a heating source, for heating buildings and industry enterprises, heating water and technological needs. The consequences of loss of heating accidents are especially dangerous during the winter season in countries with harsh winters (for instance, in 2006 in Lithuania, Telšiai, an accident at –26.5 °C in the district heating system led to the loss of heat supply for thousands of people for almost a week). Natural gas and oil belong to the main energy resources which are needed for industry and public. The consequences of loss of gas supply could be catastrophic (for instance, loss of gas supply from Russia to Europe in 2009); therefore, the reliability of these networks is an issue of high concern. The reliability of all these systems depends on the degradation mechanisms and structural integrity of pipes. In this paper more attention is focused on the failure analysis of the district heating system. But all proposed methods are suitable for any piping network. In bigger cities of Lithuania and other Baltic countries the district heating systems were designed and installed more than 30 years ago. The degradation mechanisms and phenomena influence the ageing behavior of piping. The bigger part of piping and its components (valves, muffs, connections, etc.) are near at the end of their lifetime.

The methodology for the assessment of reliability of piping networks, presented in our previous work (Rimkevičius et al, 2012), was taken into account in this paper. This methodology includes the estimation of failure probability of each separate part of district heating systems.

There are research works devoted for assessment of piping system reliability based on statistical data (Suna et al, 2009; Gerbec, 2010). Other studies investigate piping degradation mechanisms (Filippov et al, 2006; Maesa et al, 2008) or present structural integrity analysis, which is performed using analytical formulas (Amirat et al, 2007; Davis et al, 2007) or finite element method (Chang et al, 2007).

In this paper authors present the method for the estimation of pipeline failure probability based on:

1. deterministic-probabilistic structural integrity analysis (taking into account loads, material properties, geometrical and boundaries parameters of pipes, defected zone thickness);
2. the application of Bayesian method (pipeline failure probability obtained by deterministic-probabilistic structural integrity analysis is updated with regard to network operation data (failure data)).

The estimate of failure probability of selected part of Kaunas (Lithuania) district heating (DH) network was calculated to illustrate implementation of the proposed method. The estimate of failure probability of selected part of DH network (with the highest failure rate) obtained by probabilistic structural integrity analysis using Bayesian method will be adjusted to other parts of DH network taking into account specific data of these parts. The estimate of failure probability will be used performing reliability and risk analysis of this network.

2 STATISTICAL DATA ANALYSIS AND DH NETWORK AGEING PROCESS ANALYSIS

2.1 *Operation data*

The following data were collected for the statistical failure analysis of district heating network:

1. general information about piping: diameters of pipes, material, piping laying technique, length, operating time;
2. information about failures (ruptures) of piping: identification of piping failure place, diameter of pipe, piping laying technique, groundwater levels, causes of the failures, repair time.

For the calculation example information of Kaunas (the second biggest city of Lithuania) district heating network of last three years was analyzed. Kaunas district heating network is one of the most complicated and oldest one in Lithuania, this system well represents other systems installed in bigger cities of Lithuanian.

2.2 *Statistical data analysis*

Practically all pipes failures are the final point of corrosion process. Approximately 3% of pipe failures are related to external effects. Performed initial statistical analysis shows failure rate dependence on pipeline laying technique and technical properties of pipes. Comparative reliability characteristic λ_i (failure rate per km per year) was calculated for the separate parts of district heating network. According performed calculations three parts of DH network were identified with higher failure rate (5K, 5T and 3Z, notation as it uses "Kaunas Energy" AB—the district heating supplier in Kaunas city).

5K pipeline failure data t_j, $j = 1, 2, \ldots, 28$, t_j—piping operation time till rupture (years), at 5 Bar pressure (normal operation condition).

In reliability theory the most common probability distributions for the modelling time to failure (Lewis, 1994, Zio, 2007): exponential $Exp(\lambda)$ (in case of constant failure rate); Weibull $W(k, \eta)$; log-normal $Log\text{-}N(\mu, \sigma^2)$; gamma $\Gamma(\alpha, \beta)$, etc.

The probability distribution of operation time T to failure is obtained by applying any of goodness of fit tests. Performed Kolmogorov-Smirnov and Anderson-Darling goodness of fit tests showed Weibull distribution is appropriate to model operation time to failure ($p\text{-value}_{(K\text{-}S)} = 0.7028$; $p\text{-value}_{(A\text{-}D)} = 0.6012$). Piping failure data histogram and obtained Weibull probability density function are presented in Figure 1.

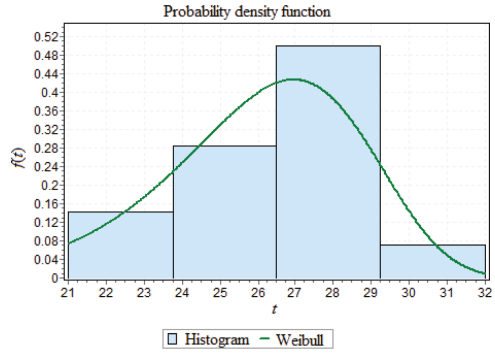

Figure 1. Histogram of failure data and probability density function (of Weibull distribution).

2.3 *The design and ageing mechanisms of DH network*

DH network are mainly built in underground channels. Pipes are supported by movable and immovable supports. To reduce the stresses caused by thermal loading movable supports are used which allow pipes to move in horizontal direction. The pipe elongation is compensated by loop compensators, stuffing boxes and by pipeline geometry itself. According to the specialists of Kaunas DH network operation organization the highest number of pipeline failures occurs at place of movable support. The schematic view of movable support is shown in Figure 2. Support is made of sheet metal bent to U shape beam with the stiffness plate and it is welded directly to the pipe as it is shown in Figure 2.

Movable supports are built each 8.5 to 10 meters depending on the diameter of the pipe. The deadweight load of 8.5–10 meter pipe with insulation and heating water is supported at two thin sheet metal edges welded to the pipe. The problem is that high stress fields are located at the welding zone where pipe material is weakened due to high temperatures during welding process. It is also known that corrosion rates are higher at higher stress fields. All these condition make the movable support as the weakest point of DH pipeline.

Kaunas district heating network is one of the oldest in Lithuania. The oldest pipelines were built in 1963. As it is up to 50 years old the main reason of pipeline failure is ageing mechanisms. And corrosion is the leading ageing mechanism. It is estimated that metal corrosion rate in the heating water vary from 0.05–0.2 mm/year ("Ekotermijos" service, 2007; Table 1 in section 4).

In this paper deterministic-probabilistic structural integrity analysis will be made for the pipe section with the movable support. As the movable support has unfavorable conditions for corrosion resistance high corrosion rates will be used in this paper. To select pipe section with movable support the statistical analysis of pipe failures and structural integrity analysis of pipelines were made. According to the statistical analysis results, three main pipelines 5K, 3Z and 5T were determined as

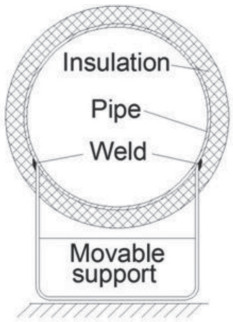

Figure 2. DH pipe movable support.

Table 1. Criteria for the assessment of corrosion rate ("Ekotermijos" service, 2007).

Assessment	Corrosion rate mm/year
No corrosion	0–0.02
Low	0.02–0.04
Allowable	0.04–0.05
High	0.05–0.2
Accident	>0.2

pipelines characterized by the highest failure rates. Pipeline 5K has the worst conditions in structural integrity analysis point of view. It has the highest stress level comparing to the other two. For deterministic-probabilistic structural integrity analysis the most loaded pipe section with movable support from pipeline 5K was selected.

The finite element model preparation requires a lot of human effort and deterministic-probabilistic structural integrity analysis is time consuming. Therefore conservatively it was assumed that all pipe sections with movable supports has the same failure probability as the most loaded pipe section with movable support from pipeline 5K.

3 PROBABILISTIC FAILURE ANALYSIS

In his section will be discussed probabilistic failure analysis made for previously selected pipe section with movable support. Probabilistic failure analysis combines deterministic and probabilistic analysis. Finite element method was used as deterministic method while the Monte Carlo Simulation and the combined Monte Carlo Simulation and Response Surface methods were used for the probabilistic analyses.

The FE software NEPTUNE (Dundulis et al, 2010; Kulak & Fiala, 1988) was used for deterministic calculations and ProFES software (Cesare & Sues, 1999) was used for probabilistic analysis.

During operation of DH pipelines due to various reasons (start and stop of the system, change of heat source, accidents in pipeline, etc.) the pressure in the pipeline can vary from its nominal value (5 bar), material properties are changing due to ageing and degradation mechanisms and also the pipe wall thickness at support and pipe welding zone due to corrosion can fluctuate from through-wall crack to un-defected pipe. Therefore probabilistic failure analysis was done using loads, material properties and defected zone thickness as random variables. As limit state the strength analysis of pipe wall in welding zone was selected. The calculated stresses in pipe welding zone were compared with allowable stresses (114.3 MPa), i.e. if the stresses in the pipe reach the allowable stress level the pipe failure can occur.

The failure dependence from wall thick-ness of defected zone of the movable support was defined in structural reliability analysis. "Response Surface/ Monte-Carlo simulation" method was used for determination of defected zone thickness probability functions. Rupture limit state dependence wall thickness and material properties is presented in equation (1)

$$\begin{aligned} y = \; & 7\cdot 10^{7} - 9.4P - 10.3P_a + 0.00023E_1 \\ & - 2.25\cdot 10^{9} b + 21.5P_b - 13.7P_c - 37.5P_d \\ & - 18672t - 1.3^{-5} E_1 - 0.044\sigma_{y1} \\ & - 2.4\cdot 10^{-5} E_2 - 0.009\sigma_{y2} - 6.4\cdot 10^{-5} E_3 \\ & - 0.04\sigma_{y3} + 3.7\cdot 10^{-5} E_4 - 0.02\sigma_{y4} \\ & + 8.2\cdot 10^{-6} E_5 - 0.02\sigma_{y5}, \end{aligned} \quad (1)$$

where y—limit state response variable; P, P_a, P_b, P_c and P_d—pressure inside the pipe, Pa; b—defected zone thickness, mm; t—temperature inside the pipe, °C; E_1, E_2, E_3, E_4 and E_5—elastic modulus of steel St3 at temperatures 20, 50, 100, 120 and 150 °C, Pa; σ_{y1}, σ_{y2}, σ_{y3}, σ_{y4} ir σ_{y5}—yield strength of steel St3 at temperatures 20, 50, 100, 120 and 150 °C, Pa.

The equation (1) was used as inner response function calculating rupture probabilities using "Monte-Carlo simulations" methods. It allows to define pipe rupture at movable support section dependence defected zone thickness were defined.

Described analysis was done for one selected movable support. The analysis results are presented in Figure 3.

It was defined that failure probability is $2.08\cdot 10^{-4}$ when pressure is 5 bars and when defected zone thickness is 1 mm.

4 RUPTURE PROBABILITY DEPENDENCE ON TIME

According to the research study ("Ekotermijos" service, 2007) for the estimation of metal corrosion

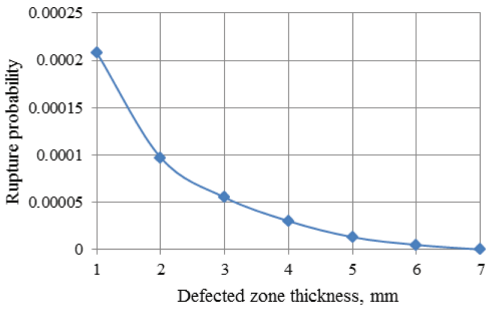

Figure 3. Pipe rupture probability (per year) dependence on defected zone thickness at pressure of 5 bars.

rate in heating water corrosion rates are classified (see Table 1).

Defected zone thickness (mm) dependence on operating time t (years) with regard to corrosion rate r (mm/year) is

$$b = 7 - rt, \tag{2}$$

where t—pipe operating time (years), new pipe are of 7 mm thickness of the wall.

The result of the deterministic-probabilistic structural integrity analysis is the estimates q_i, $i = 1, \ldots, 8$, of pipe rupture (failure) probability with in case of different defected zone thickness $b = \{ 0.1, 0.5, 1, 2, 3, 4, 5, 6\}$, mm (presented in Fig. 3). Rupture probability (per year) dependence on piping operating time t was calculated using corrosion rate $r = 0.2$ mm/year, conservatively (the worst case): $(q_i, b_i) \Rightarrow (q_i, t_i)$, $i = 1, \ldots, 8$.

5 BAYESIAN METHOD FOR FAILURE PROBABILITY ESTIMATE

5.1 *Bayesian method for the estimation of model parameters*

In general, according to the results of pipe Deterministic-Probabilistic Structural Integrity Analysis (DPSIA) (with regard to properties of materials, pressures, temperatures, etc.), failure probability function is known $F(t) = F(t, \theta_1, \ldots, \theta_m)$, the estimates of parameters $\theta_1, \ldots, \theta_m$ are known as well. Considered failure probability function can be updated by taking into account the statistical data about registered failures of operating pipelines. Updating is based on application of Bayesian method.

The parameters $\theta_1, \ldots, \theta_m$ are assumed as random variables with known prior probability density functions (pdfs) $p_l(x_l)$, $l = 1, \ldots, m$, with mean values equal to its estimates (of DPSIA). With respect to available failure data the posterior (updated) pdf of random parameters is obtained by Bayesian Method (BM):

$$p(x_1, \ldots, x_m \mid t_1, \ldots, t_n) = \frac{\prod_{l=1}^{s} p_l(x_l) \cdot L(t_1, \ldots, t_n, x_1, \ldots, x_m)}{\int_{D_1} \ldots \int_{D_m} \prod_{l=1}^{m} p_l(u_l) \cdot L(t_1, \ldots, t_n, u_1, \ldots, u_m) \mathrm{d}u_1 \ldots \mathrm{d}u_m} \tag{3}$$

where t_j—piping operation time till failure (years), $j = 1, 2, \ldots, n$, $L(\cdot)$—likelihood function (with regard to operation time till failure T distribution), D_l—range of parameter θ_l, $l = 1, \ldots, m$, values.

Usually in reliability theory (of technical system) probability distributions of random variable T (time-to-failure) are exponential $Exp(\lambda)$ (in case of constant failure rate), Weibull $W(k, \eta)$ (with appropriate choice of parameters a variety of failure rate behaviors can be modeled), lognormal $Log\text{-}N(\mu, \sigma^2)$, gamma $\Gamma(\alpha, \beta)$, etc. (Lewis, 1994, Zio, 2007).

Bayesian point estimate of parameter θ_l is an expected value calculated using posterior pdf

$$\hat{\theta}_l = \int_{D_1} \ldots \int_{D_m} x_l p(x_1, \ldots, x_m \mid t_1, \ldots, t_n) \mathrm{d}u_1 \ldots \mathrm{d}u_m, \tag{4}$$

where $l = 1, \ldots, m$.

The updated failure probability function is

$$F(t, \hat{\theta}_1, \ldots, \hat{\theta}_m). \tag{5}$$

If the pipe is required to have design-life reliability of p_r, design-life t_{DL} is the solution of equation

$$R(t_{DL}, \hat{\theta}_1, \ldots, \hat{\theta}_m) = p_r, \tag{6}$$

where reliability function

$$R(t, \hat{\theta}_1, \ldots, \hat{\theta}_m) = 1 - F(t, \hat{\theta}_1, \ldots, \hat{\theta}_m). \tag{7}$$

5.2 *Selected district heating network pipeline analysis*

For the implementation of the presented method application one part of district heating network was selected: 5K pipeline of 8,62 km length. 1 km DH pipeline has approximately 95 movable supports. Conservatively it was assumed that failure of pipe can occur at any movable support. Therefore ProFES analysis results (pipe failure probability) determined for one pipe section of movable

support was recalculated to pipe failure probability per 1 km per year or failure probability of 5K pipeline (per year). 5K pipeline is constructed of approximately 819 movable supports.

Failure probability (per year) of analyzed part of DH is calculated

$$q_{(5K),i} = 1-(1-q_i)^{819}, \quad i = 1, \ldots, 8. \tag{8}$$

Failure probability (per year) function $F(t)$ obtained using pipe failure probability dependence on the defected zone thickness (Fig. 3) is

$$F(t,k^*,\eta^*) = 1-\mathrm{e}^{-\left(\frac{t}{\eta^*}\right)^{k^*}}, \tag{9}$$

with shape parameter $k^* = 4.366$ and scale parameter $\eta^* = 44.65$ (cumulative distribution function of Weibull distribution). Loss function is defined

$$S(k,\eta) = \sum_{i=1}^{8} \left| q_{(5K),i} - F(t_i,k,\eta) \right|, \tag{10}$$

where $q_{(5\,\mathrm{K}),i}$—the estimate of failure probability at the time t_i., $i = 1, \ldots, 8$.

$$(k^*, \eta^*)^T := \arg\min_{k,\eta\,>\,0} S(k,\eta), \tag{11}$$

in analysed case $S(k^*, \eta^*) = 0.0559$.

Function $F(t)$ obtained using pipe rupture probability dependence on operation the defected zone thickness (Fig. 3) is presented in Figure 4 (dot line).

Statistical data analysis of operation time till failure shows that operation time till failure T as random variable follows Weibull distribution (according to performed goodness of fit tests). The parameters k and η are assumed as independent random variables with prior probability density functions: $p_1(x)$—gamma pdf with mean value equals to prior (DPSIA) estimate of k^* and variance—10% of estimate value, $p_2(y)$—inverse gamma (as conjugate prior (Bernardo et al, 2003; Berthold et al, 2003)) pdf with mean value equals to prior (DPSIA) estimate of η^* and variance—10% of estimate value. Failure data t_j, $j = 1, 2, \ldots, 28$. Thus, likelihood function is

$$L(t_1, \ldots, t_n \mid x, y) = \prod_{j=1}^{n} \left(\frac{x}{y}\right)\left(\frac{t_j}{y}\right)^{y-1} \mathrm{e}^{-\left(\frac{t_j}{y}\right)^{x}}. \tag{12}$$

BM was applied to calculate posterior probability density functions of the parameters of Weibull distribution (formula (3)), Bayesian point estimates of parameters are calculated using formula (4) as well

$$\hat{k} = 4.92,$$
$$\hat{\eta} = 34.85.$$

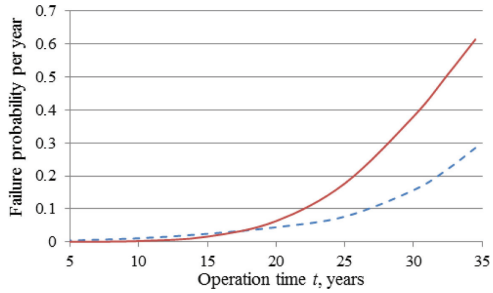

Figure 4. Failure probability $F(t)$ per year of 5 K pipeline (of 8,62 km length, at 5 Bar pressure): failure probability obtained by DPSIA (dot line), updated failure probability by BM (solid line).

Updated failure probability $F(t, 4.92, 34.85)$ (per year) of 5K pipeline (8.62 km length) is presented in Figure 4 (solid line).

Comparative measure as failure probability per 1 km per year was calculated

$$F_{(1km)}(t,\hat{k}',\hat{\eta}') = 1-\mathrm{e}^{-\left(\frac{t}{\hat{\eta}'}\right)^{\hat{k}'}}, \tag{13}$$

where $\hat{k}' = \hat{k}$, $\hat{\eta}' = \hat{\eta}\left(\frac{819}{95}\right)^{\frac{1}{\hat{k}}} = 53.995$.

Failure probability $F_{(1\mathrm{km})}(t,\ 4.92,\ 53.995)$ (per 1 km per year) is presented in Figure 5 ("solid line").

In analyzed case the design-life (solution of equation (6)) of 5K pipeline and 1 km of pipeline with reliability $p_r = 0.9$ are

$$t_{DL} = \hat{\eta}\left(-\ln p_r\right)^{\frac{1}{\hat{k}}} = 22.01 \text{ years}, \tag{14}$$

$$t_{(1km)DL} = \hat{\eta}\left(-\frac{819}{95}\ln p_r\right)^{\frac{1}{\hat{k}}} = 34.18 \text{ years}. \tag{15}$$

The updated failure probability function (Figs. 4 or 5) is significantly increasing when operation time is over 30 years. The renovation of pipeline is recommended. The results of analyzed case show (Figs. 4 and 5) that failures in piping of considered part of district heating main network occur more frequently than it was forecasted with failure probability obtained in deterministic-probabilistic structural integrity analysis. More frequent failures

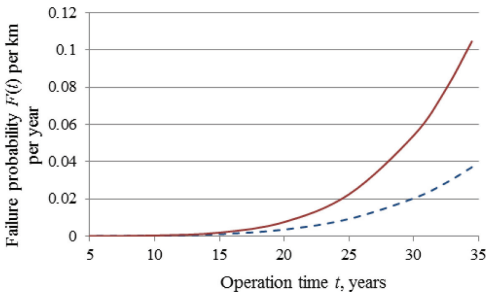

Figure 5. Failure probability $F(t)$ per km per year (at 5 bar pressure): failure probability obtained by DPSIA (dot line), updated failure probability by BM (solid line).

in district heating main network can be related to higher corrosion rate, groundwater, inappropriate drainage, etc.

The estimate of failure probability of selected part of DH network (with the highest failure rate) obtained by probabilistic structural integrity analysis using Bayesian method will be adjusted to other parts of DH network taking into account specific data of these parts. The estimate of failure probability will be used performing reliability and risk analysis of this network.

6 CONCLUSIONS

The estimation of pipeline failure probability based on the results of integrated deterministic-probabilistic structural integrity analysis and pipeline failure data analysis is presented in the paper.

The pipe rupture probability dependence on the defected zone thickness and loading was calculated using deterministic-probabilistic structural integrity analysis. Deterministic-probabilistic structural integrity analysis evaluates the uncertainties associated with loads, material properties, and geometrical parameters as well.

The obtained estimate of pipeline failure probability was updated with regard to network operation data (failure data)) by application of Bayesian method.

The implementation of the proposed method was presented by method application to obtain failure probability estimates of one part of Kaunas (Lithuania) district heating network.

The developed methodology is applicable for district heating, gas and oil supply networks.

Reliability engineering interactions in aerospace products

E.N. Çetin & A.Ş. Temiz
TAI, Turkish Aerospace Industries Inc., Ankara, Turkey

ABSTRACT: Reliability is an engineering discipline that mainly deals with the systems' or equipment's failures. Therefore, data produced by the reliability engineers becomes very essential for the design team and the rest of the specialty engineering professionals. When the concerned product is a complex one like an aircraft, the data transfer between the specialty engineering disciplines become more and more important. In this paper reliability engineering analysis [like modeling, allocation, prediction and Failure Mode Effects and Criticality Analysis (FMECA)] and relations with the other specialty engineering disciplines during the design of different aerospace products will be discussed in terms of input and output data. And the lessons learned that is gained about the reliability process and the management of the different subcontractors, during the development of Training Aircraft and different avionics modernization products of Turkish Aerospace Industries, Inc. (TAI), will be shared.

1 INTRODUCTION

Reliability is a discipline concerned with ensuring that system performs its mission successfully. It aims at finding potential failures; determine their causes and probabilities in order to ensure more robust products. Reliability is an important attribute of final product. For this reason; the manufacturer must ensure that reliability is considered during the design phase.

Specialty engineering disciplines include analysis of specific features of a system that requires special skills to identify requirements and assess their impact on the system life cycle. Reliability, testability, maintainability, safety, availability, electromagnetic compatibility and human systems integration disciplines are specialty engineering areas.

Specialty engineering disciplines management is becoming more important as the systems are becoming more complex. Complex systems, which are composed of many subsystems, require more people dealing with those specialty engineering disciplines, and sometimes under different groups of the organization. And also it becomes necessary to work with different subcontractors. Different subcontractors have a different way of managing those disciplines; and sometimes no knowledge of how to do.

Reliability is one of the main disciplines of specialty engineering which provides both qualitative and quantitative data to the rest of the specialty engineering disciplines. System safety, testability, maintainability and logistics all require reliability data in order to proceed.

Therefore, in an organization it is very important to establish the relations between these disciplines in order to complete the projects in a timely and cost effective manner.

2 RELIABILITY PROCESS

The data produced by reliability engineering are used by the rest of the specialty engineering disciplines and most of the time those data are the pre—requisite as the starting point. (Dikbaş 2011).

There are four main reliability engineering processes that are carried over at the very early phases of a design project and updated during the development phase of the project. Those are modeling, allocation, prediction and Failure Modes Effects and Criticality Analysis (FMECA). MIL-STD-785B can be used as a reference for conducting a reliability program. (Department of Defense 1980, Aydın & Çetin 2009, Demirel & Çetin 2010).

2.1 *Reliability modeling and allocation*

A Reliability Model presents a clear picture of the interdependencies within a system. A Reliability Block Diagram (RBD) is very helpful for evaluating complex redundant systems by showing all series and parallel relationships of the system. MIL-HDBK-338B well defines the types of RBDs as serial, active-parallel, standby-parallel and complex mixed serial-parallel types. (Department of Defense 2007) A complex system will require a large number of RBDs; so it should be started by drawing a top level RBD and then the next down level RBDs. An example of RBD reflecting the

fuel system of an aircraft for levels I and II is given in Figures 1 and 2 respectively. Level I contain all series blocks; whereas level II is made up of both parallel and series string of blocks.

Hardware reliability models can be used for making numerical allocations and showing redundancies. While a reliability engineer is drawing RBDs showing the system architecture and making some allocations, in the meanwhile maintainability engineers need those RBDs for the maintainability budgeting, like repair times. And also a RBD showing the system structure is also used by the logistics engineers who are in charge with the spare parts planning.

Once a system RBD is drawn; there are several different techniques for the allocation of the reliability goals to the subsystem/equipment levels. Those include "equal apportionment technique", "ARINC apportionment technique" and "feasibility of objectives technique", which are defined in detail in MIL-HDBK-338B. (Department of Defense 2007) However, experience coming from the similar projects will be the best way for making allocations.

RBDs are most effective for easy identification of single point failures and this can be achieved by drawing functional RBDs. When a reliability engineer is drawing the RBD of any subsystem of a complex system, he/she should always be keep in touch with his/her collogue who is dealing with the RBD of the other subsystem. What I mean, the reliability engineer dealing with the landing gears of an aircraft, should keep in touch with his/her friend who is dealing with the hydraulics. Functional RBDs require all the systems' interactions and should be evaluated together. Functional RBDs are good tools for the prediction of mission reliability. While preparing RBDs for mission success, alternative modes of operation shall be modelled parallel as well as redundant equipment. An example RBD is provided in Figure 3 about "video recording" function.

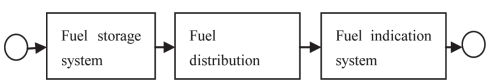

Figure 1. Level I RBD of fuel system.

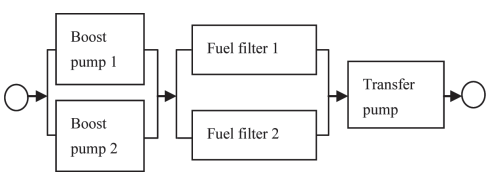

Figure 2. Level II RBD of fuel system. This RBD reflects the "fuel distribution system" portion of the fuel system.

2.2 *Reliability prediction*

Reliability prediction is performed for estimation of the system's ability to meet the specified reliability goals. Basic reliability prediction estimates the ability of a system to perform its function failure free without demand on the support system. (Reliability Information Analysis Center 2005) That is why basic reliability is also called as logistic reliability. At the operational phase, failure rates can be obtained by test data or by field operation data evaluation. At the design phase, different reliability prediction techniques can be used depending on the depth of the knowledge of the system design. At the very early phases, "parts count method" and then as the design progresses "parts stress method" is used; details of which are defined in MIL-HDBK-217F. (Department of Defense 1995) In common sense, part failure rates are predicted by using "parts stress method" during detailed design phase. However, it is a common practice to calculate equipment Mean-Time-Between-Failures (MTBF) by using "parts count method" in order to save time and effort. Furthermore reliability data banks like NPRD and EPRD can be also used for easy gathering of part failure rates. By using the predicted MTBF data it is checked whether the system level and aircraft level reliability goals are met or not. Predicted MTBF data is also used to estimate the demand for maintenance and logistic support in case of an item's unreliability. As the maintainability engineers have the MTBF data in their hand they start to estimate the Mean-Time-To-Repair (MTTR) data of the system. Also, logistics engineers start to make the spare parts planning.

Mission reliability prediction estimates the probability that the system is operable and capable of performing its required function for stated mission

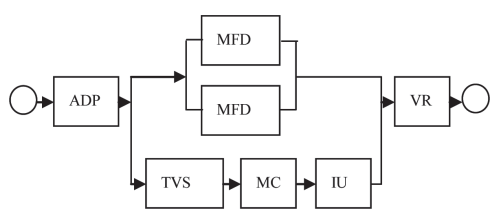

Figure 3. RBD for "video recording" function; where ADP stands for Avionics-Distribution-Panel, MFD stands for Multi-Function-Display, TVS stands for Television-Sensor, MC stands for Mission-Computer, IU stands for Interface-Unit, VR stands for Video-Recorder.

duration. Mission reliability is predicted by using the functional RBDs with the associated mathematical model and predicted reliability figures of the system equipment with the applicable time of the mission. Mission reliability is increased by redundancy; however always keep in mind that increasing redundancy decreases basic reliability figures. While the MTBF data is used to calculate inherent availability of the equipment, mission reliability data is an essential input for the system availability studies.

Therefore, while the reliability engineer is performing predictions in order to check if the specified reliability goal is met; those data should be shared at the same time with the maintainability and logistic engineers. Meanwhile they will perform predictions in order to estimate the repair times, demand for maintenance, demand for logistic support and whether the availability goals are met or not.

2.3 *Failure Modes Effects and Criticality Analysis (FMECA)*

A very important and powerful reliability analysis tool is the FMECA. FMECA identifies all potential weaknesses of a system by systematically identifying all the potential failure modes, their causes, failure frequencies, effects of the failure modes to the item, system and aircraft, severities of those effects, detection method of the failures and finally possible compensating provisions of the failures. There are several different standards and guidelines available which outlines how a FMECA can be performed and documented. For the aircraft programs MIL-STD-1629 A can be used as a reference and can be tailored in accordance with the program needs. (Department of Defense 1998) Steps to be followed while performing a FMECA, is shown in Figure 4.

A generic FMECA worksheet includes the following columns;

- Identification number: which is a unique number defining the each failure mode,
- Function: defines the functions that the related item is supposed to perform,
- Failure mode: defines all the failure modes of the item,
- Failure cause: defines possible causes of the failure modes,
- Failure rate: defines the failure rate of each failure mode,
- Failure effect: the consequence(s) of a failure mode on the function, operation or status of the item being analyzed is evaluated at the equipment, system and aircraft level,
- Failure detection method: the means or methods by which a failure is discovered by the operator during operation or by the maintenance people by some diagnostics.
- Severity: severity classification is given in accordance with the effects of the failure on the system,
- Compensating provisions: includes the actions that are available or can be taken to negate or mitigate the effects of failure.

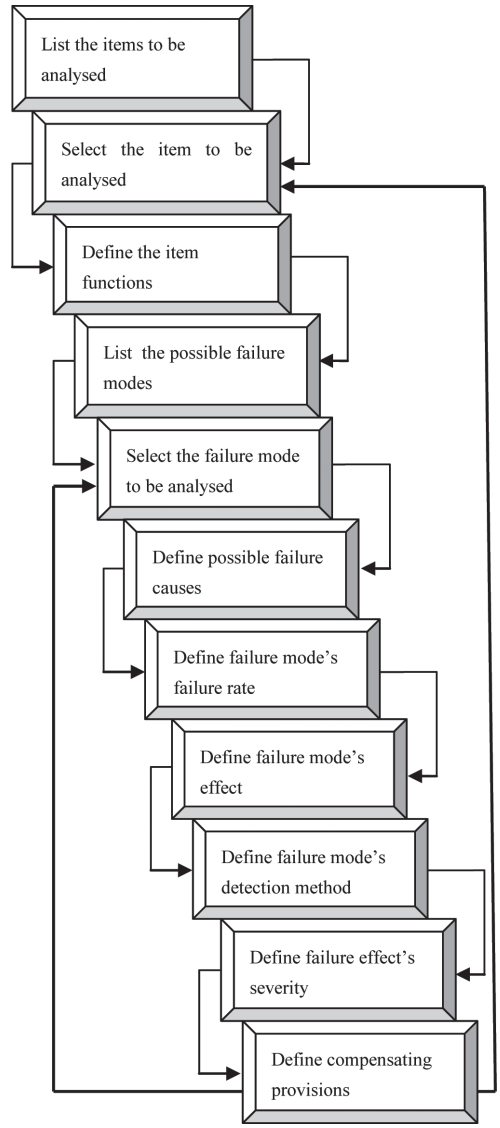

Figure 4. FMECA steps.

An example of FMECA worksheet covering some of the failure modes of "fuel distribution system boost pump" is given in Figure 5.

Item Function	Boost Pump Supply fuel flow		
ID	Failure Mode	Failure Cause	Failure Rate
28.01.01	Open circuit of electric motor	Stator winding	0,004
28.01.02	Rubbing rotor	Bearings wiring/ binding/ sticking	1,023
28.01.03	Cracks in pump housing	Mechanical damage	0,001

Local Effect	Next Effect	End Effect	Detection Method
Motor inoperative	Loss of boosted fuel supply	Mission degradation	Pressure switch signal
Motor speed falls	Reduced fuel supply	Mission degradation	Pressure monitoring
Leakage	External leakage	Mission cancels	Fuel quantity indicators/ Visual

Severity	Compensating provisions
Marginal	The other boost pump is used
Marginal	
Marginal	Pre/ Post Flight check required

Figure 5. FMECA worksheet example.

A well-studied FMECA Report is a very comprehensive report and has many customers in the design team;

- System designers require FMECA in order to see single point failures with their severity. System designers try to eliminate the single point failure cases in an acceptable level.
- Testability engineers require FMECA in order to calculate the FDR (Fault Detection Rate) and FIR (Fault Isolation Rate) of the system,
- Maintainability engineers require FMECA in order to perform the scheduled maintenance analysis like Maintenance Steering Group-3 (MSG-3) or Reliability Centered Maintenance (RCM) analysis,
- System safety engineers require FMECA in order to complete the FTA (Fault Tree Analysis) of the system and use the FR (Failure Rate) data,
- Logistic engineers require FMECA in order to prepare the troubleshooting procedures.
- If the FMECA is for mechanical systems; structural design and analyst engineers use FMECA in order to decide on the items which require further analysis or tests,
- Also, assembly planning engineers use FMECA in order to decide on the inspection points during assembly, if FMECA is performed for mechanical items.

Therefore, after completion of a FMECA of an aircraft's subsystem it is not enough to distribute the resulting report to the whole design team; but also to;

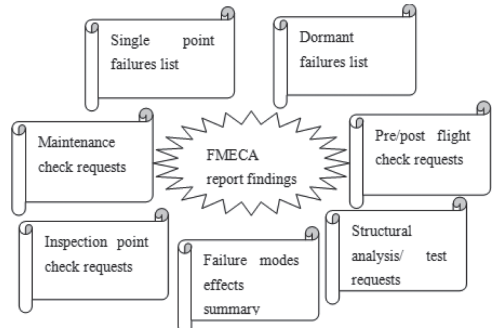

Figure 6. FMECA report findings.

- list the failure modes effects summary and pass to system safety engineers,
- list all the single points leading to "catastrophic" and "hazardous" effects and pass to the system safety engineers and to system design engineers,
- list the dormant failures and pass to maintainability and testability engineers,
- list the failure modes that can be compensated by pre-flight or post-flight check and pass to logistic engineers
- list the periodic check/maintenance requests and pass to maintenance engineers
- list the structural analysis or test requests and pass to the structural design and analyst engineers
- list the inspection points requests and pass to the production planning engineers

FMECA Report findings are shown in Figure 6.

3 INTERACTIONS WITH THE SPECIALTY ENGINEERING DISCIPLINES

3.1 *Reliability interfaces with system safety*

System safety is a discipline which identifies potential hazards and provides controls and certain counter measures by applying several safety assessment methods. System safety requires equipment MTBF data and FMECA Report findings in order to complete the Fault Tree Analysis (FTA)s and System Safety Assessments (SSA)s. A FMECA may be used to supplement the FTA by providing a complementary list of failure effects from the bottom up.

The SSA uses the quantitative values obtained from the Failure Modes and Effects Summary (FMES). The FMES is a summary of failures identified by the FMECA(s) which are grouped together on the basis of their failure effects. (Society of Automotive Engineers 1996).

The FTA Basic Events get their failure rates from the FMECAs and/or FMESs. The SSA should verify that all significant effects identified in the FMES are considered for inclusion as primary events in the FTA. Equipment MTBF data are provided to system safety groups via reliability reports; and reliability reports are revised as the design progresses. Single point failures list and dormant failures list, which is the part of FMECA report is used by the system safety group while performing SSAs. FMECA report findings (FMES, single point failures list, dormant failures list) are distributed to the system safety groups by engineering coordination memos as well as FMECA reports.

3.2 *Reliability interfaces with testability*

Testability is defined as the design characteristic which allows the status (operable, inoperable, or degraded) of an item to be determined and the isolation of faults within the item to be performed in a timely manner. From this definition it is obvious that testability includes both the detection and isolation of faults within a system. Testability engineers do the necessary trade-offs for designing an easily testable and cost effective system.

In order to configure optimum testable design solution and assign the degree of self-test capability, reliability prediction and FMECA are used as input. Reliability predictions must be performed so that high failure rate items can be identified. In conjunction with the prediction, a Failure Mode, Effects and Criticality Analysis (FMECA) should be done to ensure that malfunctions will not adversely affect other units and to determine the exact level of BIT (Build in Test) achieved. (Raytheon Company 1991).

FMECA is a good tool to assess the testability parameters of a system. Dormant failures list with severity information is provided to testability engineers via engineering coordination memos as well as FMECA reports. Testability engineers use "failure detection method" and "failure rate" columns of FMECA in order to calculate Fault Detection Rate (FDR) and Fault Isolation Rate (FIR) of a system. And also perform necessary revisions in order to lessen the number of dormant failures by taking into account the failure severities.

3.3 *Reliability interfaces with maintainability*

Maintainability is defined as the ability of an item to be retained in, or restored to, a specified condition when maintenance is performed by personnel having specified skill levels, using prescribed procedures and resources. Maintainability is concerned with the relative ease and economy of preventing or correcting failures by the use of maintenance actions.

Maintainability is considered to be complementary to reliability. RBDs are used in order to allocate and predict numerical maintainability parameters. Numerical maintainability requirements are allocated from system level to sub-system levels by the use of RBDs and MTBF data. Main sources for performing preventive/scheduled maintenance analysis are the FMECA and system safety assessment. Failure modes considered in FMECA are used to determine preventive/scheduled maintenance tasks and intervals in MSG-3 analysis or RCM analysis. MTBF data of the equipment is used while planning the Qualitative Maintainability Analysis (QMA) of a system and performing MTTR predictions. MTTR predictions are used to estimate the maintainability of the system and to make a determination of whether or not the required maintainability could be achieved with the proposed design.

Maintainability engineers are one of the main customers of reliability reports and FMECA reports. Maintenance check requests list is also provided to the maintainability engineers by engineering coordination memos.

3.4 *Reliability interfaces with logistics*

Logistics is the degree to which system design characteristics and planned logistics resources like diagnostic equipment, spares and technical data etc. allow meeting system availability. Logistics engineers perform Logistics Support Analysis (LSA) in order to include supportability during the design process. LSA is based on a Data Element Definition (DED) list and MTBF data is one of the many data required by the standard. For each LSA candidate FMECA gives the necessary potential failure modes, failure effects on equipment, subsystem and product operation with severities. FMECA also describes the means by which the occurrence of a specific failure mode is detected and localized by the operator and the maintenance person. Any applicable warning device, Built-In-Test (BIT) indication or any other indication that make evident that an item has failed or malfunctioned is clearly identified in the FMECA; so that FMECA is well used while preparation of the troubleshoot check lists. Reliability reports and FMECA reports are distributed to the Logistics group with an engineering coordination memo including the pre/post flight check requests list.

3.5 *Reliability interfaces with environmental qualification studies*

During development and installation of airborne equipment and systems, the anticipated external

and internal airplane environmental conditions should be considered.

For environmental qualification studies, the airplane is divided into zones and environmental characteristics of each zone are defined. Equipment's are selected and installed considering these environmental condition requirements.

While performing reliability models and predictions, the environmental conditions of the equipment is taken into account. A Reliability Prediction frequently needs to be revised or updated because the equipment is operated in an environment different than what the original prediction assumed. (Marvin & Willie 2006).

4 LESSONS LEARNED

Below some of the lessons learned are listed in groups about the reliability process during modernization programs of C-130 and CN-235 transport aircrafts and T-38 trainer aircraft;

4.1 *Reliability management*

- Giving trainings at the beginning of a project and repeating for the integrated design teams increases the reliability awareness within the project team.
- Working side by side all the specialty engineering groups is very useful for the quick communication and easy management.
- It is more powerful to distribute the FMECA findings in the form of lists by some engineering coordination memos or by the use of a software tool for the attention of the related FMECA customer for quick action and traceability.
- Using software tools for FMECA is useful for easy management of design changes.
- FMECA and FTA are complementary safety tools. Using a common software tool is time saving while establishing links between the FTA events and FMECA failure modes.
- Using the Bill-Of-Material (BOM) printed out from a centralized system will ensure that all the items in a system are analyzed by the use of FMECA.

4.2 *Sub-contractor management*

- Detailed guidelines for the preparation of reliability reports and FMECA reports are very useful when the subcontractors have no or limited experience of the reliability process. Just referring the standards in the contracts is not enough, because generally standards tell what to do but not how to do.
- Requesting FMECA sheets from subcontractors in soft form and in terms of the applicable project template will lessen the workload while incorporating to the total system FMECA.
- While requesting reliability reports from the subcontractors always give the environmental and temperature factors and reliability prediction methods; and request the reliability data sources.
- When working with the equipment suppliers always query the availability of the reliability data, otherwise it will be very difficult to incorporate the equipment with no reliability data into the system design.

4.3 *Reliability process*

- Using reliability allocation models defined in military standards is an appropriate way when there is no existing data in hand; but always update the data with the ones acquired from the subcontractors or as the system designs starts to shape; and use the previous projects data as the starting point if any available.
- It is more meaningful to give reliability requirements to the system functions rather than system equipment.
- While performing system FMECA it is useful to take into consideration the FHA events as system effects so as to easily harmonize FMECA and FHA in the next step.

5 CONCLUSIONS

Reliability is an engineering discipline concerning with the systems/equipment performance for completing their mission successfully. Reliability improves the design of the product and reduces the life cycle cost by finding potential failures of the design and determining their causes and probabilities. Reliability process approach of TAI Aircraft Group is briefly described in this study. Reliability analysis methods are defined with reference to the standards.

Interfaces with the other specialty engineering disciplines are explained by the data flow between each other. Lessons learned during several design projects are shared. With a well-planned specialty engineering organization, it will be easier to design a user friendly and maintainable system by reducing the life cycle cost.

ACKNOWLEDGMENT

This study has been prepared with the permission and support of TAI Aircraft Group. The authors

wish to express their deepest gratitude to all their managers for support.

An influence of the lifetime assessment in aviation technology

K. Kustroń
Faculty of Power and Aeronautical Engineering, Institute of Aeronautics and Applied Mechanics, Warsaw University of Technology, Poland

J. Lewitowicz
Air Force Institute of Technology, Poland

ABSTRACT: There are many properties correlated with maintenance costs. Due to minimize the maintenance costs we should recognize them and assess the level of influence and choose them of which the mitigation is the most cost effective. One of the most important property is lifetime which is assessed using statistical methods during accelerated tests. And may be improved based on real data. The parametric and non-parametric statistics could be applied to assessment the lifetime of aviation items. In the paper their advantages and disadvantages were recognized.

1 INTRODUCTION

Effective methods to reduce costs of servicing aircraft are welcome. The servicing costs include operation as well as maintenance costs. In the paper we are focused on cutting the maintenance costs. Optimization of maintenance programs directly affects the cost of aircraft maintenance and it is a key factor in air carrier's profitability. Due to improving aircraft maintenance solutions which directly cut servicing costs we must recognize all factors affected both safety and costs, assess them and their uncertainty. It is sure that in commercial aviation the downtime for maintenance double costs because of spending money for different activities connected with sustaining the airworthiness and losses of no operation. In military aviation the longer downtime reduced readiness and there is desirable to shorten it.

One of the ways to increase the efficiency of servicing is finding the best suitable model of lifetime, taken in this paper. The most suitable lifetime model with the acquisition of operating data decrease uncertainty and better assess the prevention activities reduced them to only the needed based on more real behavior of fleet in comparison to the initial assumptions which are assessed by manufacturer in accelerated tests. In (Nelson 2003) are recommends greater use of available advances in accelerating tests that are not yet being fully utilized in practice. Also, it suggests advances that need to be developed. Aircraft maintenance activities ensure security and the continued airworthiness of the fleet as well as on-time performance. Aircraft maintenance is based on pre-established programs and during servicing should be improve.

The high reliable systems undergo Reliability Centered Maintenance (RCM) strategy that is implemented to optimize the maintenance program. In aviation the strategy based on RCM for assessment maintenance tasks was developed and is involving as MSG-3 which implement the newest research achievements.

Second problem is the classification aircraft items into Significant Structural Item (SSI) influenced safety when damaged and have to be prevent and other which may be servicing to failure and then replace as correction maintenance or could be replace according to assessed life-time. This is very important classification and generate the maintenance costs and influence on safety. Mentioned above problems of the activities before or after failure based on statistical assessments of the accelerated tests data.

Third problem, which has to be implemented to maintenance improvement process, is using appropriate statistics to number of sample.

Presented in (Kustroń et al. 2012) study is an introduction to research in the field of process automation to optimize aircraft maintenance programs using expert systems in the form of available software. The analysis indicates that the best distribution of the random variable T for the failure rate data collected by non-renewable component of the aircraft due to the maximization of technical readiness, a log-normal distribution, for which the time interval preventive replacement component is 103 hours. In order to assess the accuracy of the analysis determined time intervals under

consideration component for gamma distribution, Weibull and normal. Intervals for these distributions differed for the benefit of the log-normal distribution, was chosen as best for the accumulation of data on a non-revolving component failure rate about five hours for the gamma distribution, about 16 hours for the Weibull distribution, and up to 29 hours for a normal distribution. The benefits of proper selection of random variable distribution of correct non-revolving facility is fundamentally due to the costs generated by double-under-the real component durability and losses as a result of the fault and the ground plane at the time of exchange. This work constitutes a development of the subject to identify appropriate methods of statistical analysis-nonparametric and statements for and against in the analysis of lifetime.

2 THE LIFETIME ASSESSMENT AND MANAGEMENT

The lifetime is created by appropriate requirements set by regulations managed by Aviation Authorities as relatives to States' constitutional rights to ensure the safety of its citizens, including the safety and security of transport means including air transport. Although the safety is a priority the ICAO's Annex 19 safety management was established in November last year. This Annex ensures safety of flight and will be implemented in the near future.

Lifetime of aircraft is created in design process according to Annex 8 and during accelerated tests have to be assessed. In manufacturing process the lifetime is materialized with appropriate quality. During the process of servicing the lifetime have to be sustain. All these processes creates maintenance costs which air carriers spend on ensuring safety.

The lifetime of an aircraft is recognized by longtime servicing with required safety. To ensure the safety we can used method of prevention the failures influenced the safety. To prevent failure we can assess risk of occurrence damages with an influence on safety. Additional we should have appropriate diagnostic system to assess health of the structure. The health assessment is the base of classification the aircraft to airworthy or non-airworthy stage. For commercial aircraft the strategy to list checks is ATA MSG-3. According to this strategy checks are the periodic routine and detailed inspections that have to be done in the set periods of time or usage. Commercial operators of large or turbine-powered aircraft are obligated for continuous inspection programs approved by national aviation authorities e.g. the European Aviation Safety Agency (EASA), Federal Aviation Administration (FAA) in the United States, Transport Canada. Each operator prepares a continuous airworthiness maintenance program under its operations specifications. The continuous airworthiness maintenance program includes: A, B, C, and D checks. A and B checks are lighter checks, while C and D are considered heavier checks. The checks are set in accelerated tests using statistical calculation. The maintenance cost could be reduced by appropriate statistic method of failures rates which correspond with real data. Due to this the maintenance program have to be improve while servicing aircraft.

3 PARAMETRIC VS. NONPARAMETRIC STATISTICS

The parametric and nonparametric statistics could be applied to assessment the lifetime of aviation items.

Both for parametric and nonparametric statistics have to be set assumptions. For parametric are:

- the observations must be independent,
- the observations must be drawn from normally distributed populations,
- these populations must have the same variances,
- the means of these normal and homoscedastic populations must be linear combinations of effects due to columns and/or rows;

And for nonparametric:

- observations are independent and
- variable under study has underlying continuity.

There is at least one nonparametric test equivalent to a parametric test.

Power of the test can be measured as statistical power and it is the probability of rejecting the null hypothesis when it is in fact false and should be rejected. Power of parametric tests is calculated from formula, tables, and graphs based on their underlying distribution. Power of nonparametric tests is less straightforward and can be calculated using Monte Carlo simulation methods (Mumby 2002).

The statistical methods based on assumption that the lifetime were drawn from known distributed populations such as normal etc., and below there are techniques that do not make such assumptions. The methods are recognized as distribution-free statistics or nonparametric statistics. In situations where the known assumption holds, the nonparametric tests are less efficient than parametric methods.

There are used many models in nonparametric statistics. Nonparametric models differ from parametric ones in that the model structure is not specified a priori but is instead determined from data. The term nonparametric means that the number and nature of the parameters are flexible and not

fixed in advance. A simple nonparametric estimate of a probability distribution is a histogram. Kernel density estimation provides better estimates of the density than histograms. There are too nonparametric regression and semi-parametric regresion and data envelopment analysis provides efficiency coefficients.

The tests which we can use to assess lifetime are: Wilcoxon Rank Sum Test or Mann-Whitney U Test, Wilcoxon Signed Rank Test and Kruskal-Wallis test.

Wilcoxon Rank Sum Test or Mann-Whitney U Test is the technique tests whether the medians of two populations are the same, when the two samples are independent of each other. This test is comparable to the parametric t-test on the difference between two means that we considered previously. Technique is followed merge and rank the observations and find the sum of the ranks R_1 and R_2 for each of the two samples. Compute the T_1 statistic (based on the smaller of the two samples, or either sample if same sizes) and its mean μ_{T_1} and standard deviation σ_{T_1} is written as:

$$T_1 = n_1 n_2 + \frac{n_1(n_1+1)}{2} - R_1$$

$$\mu_{T_1} = \frac{n_1 n_2}{2}$$

$$\sigma_{T_1} = \sqrt{\frac{n_1 n_2 (n_1 + n_2 + 1)}{12}}$$

If the two sample sizes are each greater than 10, then U is approximately normal and we can standardize to get:

$$Z = (T_1 - \mu_{T1})/\sigma_{T1}$$

Then if Z is statistically different from zero, we conclude that the medians are not the same.

Wilcoxon Signed Rank Test is the technique tests whether the medians of two populations are the same, when the samples are not independent of each other. This test is comparable to the parametric matched-pairs test that we considered previously. Technique follows calculate the differences between the two sample values for each pair of observations, drop the zero values, of the n non-zero values, rank the absolute values of the differences and sum the ranks of the positive and negative differences separately. Let W be the sum of the positive ranks.

The mean and standard deviation of W are:

$$\mu_W = \frac{n(n+1)}{4}$$

$$\sigma_W = \sqrt{\frac{n(n+1)(2n+1)}{24}}$$

If the number of non-zero differences is at least 20, then W is approximately normal and we can standardize to get:

$$Z = \frac{W - \mu_W}{\sigma_W}$$

If Z is statistically different from zero, we conclude that the medians are not the same.

Kruskal-Wallis test is the technique tests the null hypothesis that several populations have the same median. It is the nonparametric equivalent of the one-factor ANOVA. The test statistic is:

$$K = \frac{12}{n(n+1)}\left(\sum \frac{R_j^2}{n_j}\right) - 3(n+1)$$

where n_j is the number of observations in the j-th sample, n is the total number of observations, and R_j is the sum of the ranks for the jth sample. If each n_j is at least 5 and the null hypothesis is true, then the distribution of K is χ^2 with $c-1$ degrees of freedom, where c is the number of sample groups. If testing at the level α and K is in the α-tail, then we conclude that the medians are not the same. In the case of ties, a corrected statistic K_c should be computed:

$$K_c = \frac{K}{1 - \left[\frac{\Sigma(t_j^3 - t_j)}{n^3 - n}\right]}$$

where t_j is the number of ties in the jth sample.

The nonparametric tests have plenty of advantages but some criticisms too. The nonparametric tests advantages are:

- probability statements obtained from most nonparametric statistics are exact probabilities, regardless of the shape of the population distribution from which the random sample was drawn,
- if sample sizes as small as N = 6 are used, there is no alternative to using a nonparametric test,
- treat samples made up of observations from several different populations,
- can treat data which are inherently in ranks as well as data whose seemingly numerical scores have the strength in ranks,
- available to treat data which are classificatory,
- easier to learn and apply than parametric tests (Hebel 2002).

Criticisms of nonparametric procedures are losing precision/wasteful of data, low power, false sense of security, lack of software, testing distributions only and higher-ordered interactions not dealt with.

Table 1. Summary the statistical methods according to analysis type.

Analysis type	Parametric test Nonparametric test
Differences between independent groups. Compare means of two independent groups	Independent sample t-test Wilcoxon Rank Sum Test Wald-Wolfowitz runs test Kolmogorov-Smirnov two sample test
Differences between independent groups. Compare means of the same group at two time points	Paired sample t-test Wilcoxon Signed Rank Test
Differences between independent groups. Compare means between three or more independent groups	Analysis of variance (ANOVA/MANOVA) Kruskal-Wallis analysis of rank Median Test
Differences between dependent groups. Compare two variables measured in the same sample	T-test for dependent sample Sgh test Wilcoxon's patched pair test
Differences between dependent groups	Related measures ANOVA Friedman's two way analysis of variance Cochran Q
Relationship between variables. Estimate degree of association	Spearman's Product Moment Correlation coefficient Spearman's Rank Correlation Kendall Tau Coefficient gamma Chi square Phi coefficient Fisher exact test Kendall coefficient of concordance

4 CONCLUSIONS

This paper is next step to improvement maintenance program. Here were presented comparison to potential implementation parametric and nonparametric statistics to assess lifetime in design stage as well as manage it during servicing aircraft.

Both groups of statistics method will be used in expert system improving maintenance of aircraft in Air Carrier's fleet.

How managers should think about risk—a case study from the oil and gas industry

T. Bjerga & T. Aven
University of Stavanger, Norway

ABSTRACT: We discuss how managers should think about risk when facing challenging decision-making situations with large uncertainties and high values at stake. The paper is based on the thesis that managers are well qualified for the proper understanding and management of such risk and uncertainties, but that there has been a lack of suitable conceptual frameworks available. We argue that the key to success in this respect is to be open to broader risk perspectives than the common damage-probability view. Risk also has to reflect uncertainties and knowledge, and potential surprises relative to this knowledge. A case taken from the oil and gas industry is used to illustrate the discussion. The main aim of the paper is to guide managers and analysts on the conceptualization of risk and on which principles to adopt in order to understand, assess, manage and communicate risk in relation to situations of large uncertainties and high values at stake.

1 INTRODUCTION

Back in 2003 the Board of Directors of the Norwegian oil company Statoil made a decision to acquire 50% of BP's interest in the In Amenas project in Algeria (STO 2013). Statoil's global footprint and experience base at the time was rather limited, and this acquisition represented a major move subject to high risk and a new type of risk events. The major operational risk identified and discussed in the time prior to the decision was the security risk for personnel, both at the gas facility and in transit between the gas facility and the airport. Algeria had just come out of a decade of unrest, and terrorist kidnapping for ransom was a quite common phenomenon. Reassured by having BP and Algerian Sonatrach as partners with global and local experience, and by relying strongly on the Algerian military for protection, the decision to invest was made. The security was found to be satisfactory. In other words the risk of terrorist attacks was found to be within company standard and conduct—assuming the army would protect the facility and the workers from terror. This assumption was considered to be solid, as the government was heavily reliant on the income from the oil and gas industry. The strong track record for the Algerian army demonstrated this. The assumption failed, as a surprising attack materialized in the early morning hours of January 16th, 2013. It became one of the largest terrorist attacks in the history of the industry with 69 casualties (including 29 killed terrorists) (STO 2013).

In the aftermath it seems obvious that the assumption and background knowledge should have been better analyzed and given weight to in some way, as it turned out to be a major source of the surprising attack. The current paper is based on the thesis that managers are well qualified for understanding and managing risk and uncertainties, but that there has been a lack of suitable conceptual frameworks available that adequately address the knowledge dimension. It is for instance common to consider risk to contain a combination of consequences (loss) and probabilities (Lowrence 1976, Kaplan & Garrick 1981, Ale 2002), which pays little attention to the knowledge base, including the assumptions, underpinning the numbers. Deviations in the knowledge base can lead to quite different numbers. The risk, uncertainty and potential for surprises associated with this knowledge base need to be addressed and given weight to in some way. Giving weight to risk, uncertainties and potential surprises, in synthesis and balance with other concerns, is primarily the responsibility of the managers, though risk analysts need to contribute to the analysis part, informing the managers. The aim of the paper is to guide managers and analysts on how to conceptualize risk—giving due attention to the knowledge dimension—and on what principles to use in order to understand, assess, manage and communicate risk in relation to situations of large uncertainties and high values at stake.

The remainder of the paper is organized as follows. In Section 2 we will introduce a conceptual

framework of risk, giving attention to the knowledge and surprise dimensions. Section 3 applies the framework to the In Amenas case introduced above. Section 4 discusses the findings, and Section 5 concludes.

2 RISK, KNOWLEDGE AND BLACK SWANS

The general setting is this. We are at the present time interested in the future outcomes of an activity. The activity can be ongoing or in the planning stage. The aim is to avoid negative outcomes and nurture positive ones in the period considered. In this setting: Risk is defined as (C, U), where C is the consequences of the activity, and U is the associated uncertainty (what will C be) (Aven 2012). Sometimes (A, C, U) is used to account for initiating events A. The consequences C are relative to something that humans value (health, environment, assets).

Under this definition, risk is described generally as (C′, Q, K) (or (A′, C′, Q, K)), where C′ represents some specific consequences, Q is a measure of uncertainty like subjective probability P, and K represents the background knowledge on which C′ and Q are based.

2.1 *Knowledge in risk analysis and risk descriptions*

What we mean by knowledge needs to be clarified. There are numerous definitions, classifications and theories to explain knowledge. See for instance the many definitions and categories in Alavi and Leidner (2001). One common categorization is to distinguish between three types of knowledge: as know-how (skill), know-that of propositional knowledge, and acquaintance knowledge (Lemos 2007). "Knowing how to ride a bicycle" is an example of know-how, and the statement "I know that Algiers is the capital of Algeria" is an example of propositional knowledge, while "I know John" is an instance of acquaintance knowledge. In relation to risk analysis and risk descriptions, we are primarily dealing with propositional knowledge. A traditional perspective on (propositional) knowledge, often credited to the Greek philosopher Plato, is that knowledge is justified true beliefs. However, the propositions made in risk analysis are typically in the form of assumptions and phenomenological understanding—perhaps shaped by history and present, but which concerns the future. It implies that we cannot talk about something being a "true belief". For example, we cannot say today that it is an absolute true belief that "Algiers will be the capital of Algeria in 10 years." No one can! The way we will understand knowledge is as justified beliefs. Some comments are in order. Firstly, in practice beliefs are in degrees. This means that we can for instance have a strong belief about something: "I strongly believe that Algiers will be the capital of Algeria in 10 years." The degree of belief can even be quantified using for example subjective probabilities. Secondly, it is necessary that the belief is justified. This means that it is not sufficient to proclaim, "I strongly believe …." Justification must be provided in addition to *why* you strongly believe (or have a low belief if that is the case). A belief is someone's belief, i.e. it is subjective, and it is not of much value in risk analysis unless it can be justified. At the very least it should be informed when justification cannot be provided. As for the statement above, one could argue that Algiers is the current capital, and has been for nearly 200 years, and nothing on the horizon appears to be capable of changing that. This would provide fairly strong justification. However, in risk analysis there are many cases where (strong) justification cannot be provided, i.e. it is just a belief, or a belief with varying degrees of justification. The degree of justification—the strength of the knowledge—can also be assessed, for example using a scoring system as described in Appendix A.

2.2 *Black swans in a risk context*

Knowledge, in a risk context, being justified beliefs for a future time period implies that knowledge is not an absolute and objective truth, and sometimes surprises can emerge relative to the justified beliefs. A black swan in a risk analysis context is here understood as a surprising extreme event relative to current knowledge/beliefs (Aven 2013b). Black swans are relative to the knowledge of the risk analysts, reflected by the risk description (A′, C′, Q, K). Three types are used:

- Unknown unknown – strictly unknown to all (at least in the scientific community). This means an actual event A that was not captured by the list A′ in the risk description.
- Unknown known – known to someone, not to all (in the scientific community). The event A is not on the list A′ of the current analyst, but might have been on someone else's list.
- Events judged not to occur because of negligible probability.

3 HOW MANAGERS SHOULD THINK ABOUT RISK

Let us start again with the case introduced in Section 1, turn back in time to 2003 and take the stand of a manager. Assume an investment

opportunity—the In Amenas project—has been presented. At first glance it seems like a good fit for the company's strategic ambitions. The decision problem is whether to invest here or in other alternatives including waiting for a better option, but also if controlling actions should be taken in case an investment is made. The investment prospect will ordinarily only be chosen if it represents a good/best mean to achieve the strategic objectives of the company, including to maximize profits and ensure security for the personnel.

The In Amenas is located far away from home, not only geographically speaking. Algeria has had unrest lasting for a decade that has just come to an end, but terrorist groups are still active. Undoubtedly, there are opportunities that may pay off very well for those who dare, but there are uncertainties, and there may be large negative surprises hidden in the future. There is risk; and an analysis of risk is in place. To provide support with this task is the job of the risk analysts, and their services are requested.

3.1 *The request for a risk analysis focusing on knowledge and surprises*

Now, giving attention to knowledge and uncertainties starts already with the request for a risk analysis. The first thing a manager needs to do is to reflect on what information the analysts should provide. What is it important and useful to know in order to make the decision? Financial risk obviously, but security risk is also important in this case given the presence of terrorist groups and the recent political unrest. Other aspects are also important, but we focus only on these two to illustrate our points. Secondly, and most importantly, attention must be devoted to uncertainty, knowledge and potential black swans in relation to these two: finance and security. A manager and leader should motivate, facilitate and request this from the risk analysts. One way to do this for financial risk, focusing on the cost side, is to request expected values and best estimates, but the use of uncertainty intervals may also be applied. In this case, say that the In Amenas project cost is estimated at $750 m, but a 90% uncertainty interval within which the analyst believes the "true" cost will lie, say $[600, 1,500] m, can also be informative. It is equally important to request an accompanying assessment of the strength of the knowledge underpinning all these numbers. This can be done by using a crude scale and scoring criteria like the one in Appendix A. Next, all key assumptions must be made visible for scrutiny about their importance. One way to do this is by assessing the assumption-deviation-risk (Aven 2013a), i.e. analyzing what deviations from the assumptions could occur and what consequences such deviation would have on the cost. See Appendix A for more details. In addition, evaluations of black swans types ii) and iii) should be requested. Assessment and judgments should be made for:

1. Potential thematic knowledge not possessed by the risk analyst group. In search for potential black swans type ii).
2. Evaluation of events judged negligible due to low probability—black swans type iii). This can include looking into historical events and experts not following the dominant way of thinking.
3. Evaluations of weaknesses and gaps in the underpinning knowledge K.

For the case of security, the request should not only cover scenarios, probabilities and expected consequences given an attack or quantities like Individual Risk (IR), Fatal Accident Rate (FAR), Potential Loss of Life (PLL), f-n curves etc., but also, and equally importantly, that the background knowledge underpinning these numbers and potential black swans is assessed in the same way as for financial risk. Take for example the assumption that the military will prevent terror—what if it fails? What could be the consequences? An assessment of the assumption deviation risk needs to be requested.

Table 1 summarizes the request. The request can cover alternatives other than to invest in the In Amenas, also the alternative of not investing at all. A comparison can then be made between the alternatives, which focuses knowledge, uncertainties and black swans.

In search for black swans, i.e. large surprises relative to the existing knowledge, it is essential that the existing knowledge is scrutinized and other sources of knowledge accessed. In practice this means that not only self-evaluation is mandatory. It is also essential that people with other competences be brought in to have a critical and independent view of the risk analysis. They could act as a "red team", taking the side of an opposing view, and for example argue for the occurrence of rare events (black swans type iii)), look for holes in the knowledge (black swans type ii)), and check how precursors and warnings have been dealt with. Constraints on time and resources may hamper such evaluations, yet they are necessary. Good planning and routines are keys to success in this respect.

In this case it might also be interesting to consider protecting measures to reduce the risk, for instance in case the Algerian military forces fail to prevent terrorist attacks. It is common to use cost-benefit type of analysis based on the Expected Net Present Value formula (E[NPV]), to say something about Implied Cost Per Averted Fatality (ICAF)

Table 1. Summary of the risk analysis request, covering different aspects and alternatives.

	Alternative		
Attribute	1: Invest in In Amenas	2: Second alternative	n: nth alternative
Cost	(Best) estimates		
	90% uncertainty intervals*		
	Strength of knowledge assessment		
	Key assumptions		
	Assumption deviation risk assessment		
	Evaluations to reveal potential unknown knowns (black swans type ii)), i.e. knowledge about the topic not possessed by the group, but which others may possess		
	Evaluations of events judged to not occur due to negligible probability (black swans type iii))		
	Evaluations to reveal potential weaknesses and gaps in the knowledge underpinning the risk analysis		
Security	Scenarios/consequences		
	Probabilities		
	Strength of knowledge assessment		
	Key assumptions		
	Assumption-deviation-risk assessment		
	Evaluations to reveal potential unknown knowns (black swans type ii)), i.e. knowledge about the topic not possessed by the group, but which others may possess		
	Evaluations of events judged to not occur due to negligible probability (black swans type iii))		
	Evaluations to reveal potential weaknesses and gaps in the knowledge underpinning the risk analysis		
…			

*An x% uncertainty interval is an interval that the assessor is x% confident will contain the "true" number. For example, 10% confident is comparable with drawing 1 favorable ball out of an urn containing 10 balls (Lindley 2000).

in such cases. Again the uncertainties, strength of knowledge, and potential surprises must be assessed in a similar manner as above, since expected values and probabilities are not a good way to reflect risk.

The risk analysts will then perform the analysis, and return a risk description. The risk description covers requested information and knowledge in relation to the risk, assessed through the eyes of the risk analyst and experts.

3.2 *Managerial review and judgment focusing on knowledge and surprises*

Eventually the risk analyst hands over the risk description of the aspects and alternatives requested. At this point, there is a very important question that needs to be reflected upon by the manager, preferably even before reading the report. Should the risk description be indiscriminately accepted and assimilated as the manager's own? Informal arguments in favor could be that risk analysts are professional experts paid to do the job and it could be difficult to challenge that from a manager's "ignorant" position. Say too that something surprising and bad should occur in the future; then one can always say that one did what the experts advised. However, from the point of view of what a black swan is, this cannot be defended. Remember, black swans are surprises relative to present knowledge/beliefs. This means that if a black swan were to occur in the future it would be a surprise relative to the knowledge/beliefs of the risk analysts—explicitly engraved in the risk description. A manager constitutes a different knowledge source and a different set of lenses with which to view the risk description, which can be useful to reveal potential black swans. The role of a manager is to be a critical and independent reviewer of the risk description; a similar approach as that of the "red team" introduced above—taking an opposing view. The same bullet points 1) through 3) need to be evaluated by the manager: What if the military turn their guns? What would weaken the incentives the government has to protect the facility? What would strengthen them? What about an invasion by neighboring countries? What if large terrorist groups should reach the facility? The knowledge needs to be scrutinized and critical questions asked. In many

real cases, there may not be time and resources to employ a full-scale, independent, "red team", as recommended in Section 3.1. More important is the manager's review as a last "filter" to reveal potential black swans before an action is taken. Requesting an assessment of the knowledge and potential black swans, as in Section 3.1, is certainly useful and a step in the right direction, but a manager has the responsibility for carrying out evaluations and scrutiny of the work performed by the risk analyst for him/herself before accepting it. Ultimately the manager and decision maker is also the top risk analyst.

A related topic is also that the risk analysts themselves might be "biased". For instance, could the risk analysts have personal interests for a decision to enter In Amenas, or a particular security technology? This issue is often seen in political decisions. Administrative staff performs the analysis, prepares the case and advises the elected officials on a decision. Of course the administrators try to be objective in their assessment, but they too have political or financial interests of their own which may influence the analysis and advice. The manager must also take similar concerns into account when presented with a risk description, as such "biases" could lead to unpleasant surprises.

Also relevant is the fact that the risk analysis with its qualitative flaws and weaknesses is only one contribution of many. The risk description is limited and targets only some aspects and events. In this case only finance and security risk is considered. What about technical challenges? Or third party risk? Or the environment? The manager also has to bring these elements to the table.

A decision is risk informed, not risk based (Apostolakis 2004). The risk description will only target some aspects and events, and has weaknesses and limitations both in its quality and scope.

In the end, the foundation for the decision will constitute the risk description covering elements of risk, knowledge, uncertainty and black swans placed in a greater context which takes into account 1) limitations and weaknesses of the risk description, and 2) other concerns and inputs (analysis). Now, judging how to give weight to all of these elements and inputs, and use them in order to reach a choice—a decision—is the job of the manager.

3.3 *Giving weight to uncertainties and black swans in the decision*

At the point when the risk description is judged eligible to be input to the decision, and all elements are on the table, the next role of the manager begins: to give weight to consequences and surprises, uncertainties and knowledge in balance and synthesis with other concerns. Many principles are applicable to that end.

Giving weight to uncertainty is giving weight to principles like the cautionary and precautionary principles. The cautionary principle says that when uncertainty is present caution is advised (Aven & Vinnem 2007). An example of its use is found on the Norwegian continental shelf, where it is mandatory to have a firewall protecting the living quarters on platforms in case a fire occurs in the production zone. The precautionary principle can be considered a special case of the cautionary principle and applies when scientific uncertainties are present (Aven 2011). This means situations in which the phenomena and processes are poorly understood by the scientists, and reliable models are lacking. In the In Amenas case here discussed, there are large uncertainties and poor knowledge, and both principles can apply. This could mean that the investment is not made, or that further measures to reduce risk and uncertainty are taken. Some potential candidates to reduce the risk for terrorist attacks would be to hire more security personnel, arm the security personnel, invest in intruder safe shelters, put more efforts into training in case of emergencies, and surveillance. How much caution is taken needs to be balanced against attributes like cost, and they all come with security risks of their own. For instance, armor given to security personnel can potentially also be used against the personnel they are supposed to protect.

In line with cautionary thinking and the case when the question is whether or not to implement an identified mitigating measure, like armored shelters designed to withstand a terrorist attack, the ALARP principle might be used. It says that risk should be as low as reasonably practicable. In the way that risk is understood here, it means that the (C′, Q, K) should be as low as reasonably practicable, where 'reasonably practicable' needs to be seen in relation to other costs and benefits. The ALARP principle means a reversed burden of proof, i.e. identified reducing measures shall be implemented unless gross disproportion between cost and benefits can be demonstrated. It is common to use a cost-benefit type of analysis as mentioned in Section 3.1 for such demonstration. However, when giving attention to uncertainties and surprises, a decision cannot be made based on the expected numbers alone. This especially concerns the cases when the cost is high, and the cost-benefit analysis demonstrates gross disproportion. Still, the measure should be considered implemented if the strength of knowledge is poor, provided it can strengthen knowledge, or the measure will reduce the risk of surprises and black swans.

It is also common to use risk acceptance criterion. If the risk is below a predefined limit, then the risk should be accepted. Giving weight to knowledge, uncertainty and black swans means

that the acceptance criteria cannot be defined solely on probability except in the case of strong background knowledge and small potential for black swans. In cases of poor knowledge and/or large risk for black swans, the risk may not be accepted regardless of the probability. This could have been the case for the In Amenas investment prospect, as it was accepted back in 2003, without introducing further measures.

Another way to give weight to surprises is by giving weight to resilience, i.e. the ability to prepare and cope with consequences and uncertainty given the occurrence of any type of event including new types (Hollnagel et al. 2006, Steen & Aven 2011), for instance various attack scenarios. In practice, there is always a trade-off between resilience and efficiency, i.e. how much weight and resources the manager is willing to give resilience.

4 DISCUSSION

How the manager should think about risk when large uncertainties are present and high values are at stake has been elaborated in Section 3. At the very center is the conceptualization of risk and the associated request/description summarized in Table 1. This request/description can be generalized into three primary elements. The first element contains the specified consequences C' and the measures of uncertainty Q, which are both conditioned on the background knowledge K. We refer to this pair as element Z, hence $Z = (C', Q)$. The second element is a description of the knowledge K including a judgment of the strength of this knowledge, and the third element is an assessment of surprises S relative to the knowledge and beliefs as expressed by (Z, K). We can combine these three elements in a triplet, (Z, K, S). There are various tools and measures applicable for carrying out the evaluations of these elements. In our case for security, scenarios, probabilities and expected consequences were requested, while for finance best estimates and uncertainty intervals were requested. Other measures like imprecise probabilities could also apply. From a practical point of view, it may be preferable to use the same way of measuring aspects, for all alternatives, as this would make comparison fairly straightforward. Equally important are the qualitative aspects linked to the knowledge K, and surprises S. Without these knowledge assessments there is no expression of the level of justification of the beliefs Z, and relevant comparisons and the decision-making can accordingly lack basis.

Concerning surprises and black swans, the careful reader may have noticed that we primarily have been addressing black swans of types ii) and iii). These can be addressed at the current time of the analysis, and be dealt with to some degree by means of scrutiny and knowledge sharing/transfer. The knowledge exists; it is just a matter of finding it, or using it the right way. That is what one would do when employing a red team, or hiring specialists. It is also the same thing a manager would do when using his/her knowledge to review the work done. Black swans of type i), however, are by definition very hard to do something about at the current time (unknown to the entire scientific community). Fortunately, knowledge is changing and growing with time, so that what is unknown at the current time may not be unknown at a future point in time. Research and development can reveal potential unknown unknowns. In addition, there are often signals and warnings, also for this type of events. Paté-Cornell (2012) recommends a mix of alertness, quick detection and early response to cope with type i) black swans, but this also applies to types ii) and iii). The thinking is in line with collective mindfulness principles linked to High Reliability Organizations (HROs) (Weick & Sutcliffe 2007, Aven & Krohn 2014), as well as ideas of resilience engineering (Hollnagel et al. 2006). Take the HRO principle of sensitivity to operations, i.e. sensing what is happening and taking the necessary action. It addresses (rapidly) changing knowledge in an operational setting.

Lastly, we would like to highlight the use of the cautionary principle. The ideas highlighted in the present paper acknowledge the importance of uncertainty in risk descriptions and characterizations, and the need for management to be aware of these uncertainties and give them proper weight in the decision-making when balancing different concerns, such as safety/security and costs. Common decision-making practice is often risk-based (Aven & Vinnem 2007), where the uncertainties are concealed. In accordance with the proposed methods presented above, the proper management regime is risk-informed where due consideration is given to the uncertainties, and the cautionary principle is seen as an integrated part.

5 CONCLUSION

This paper has primarily been concerned with how managers should think about risk and what principles they should apply in related decision-making. The work is based on the thesis that there has been a lack of suitable conceptual frameworks to account for the knowledge and surprise dimensions of risk. A decision process case from the oil and gas industry has been used to exemplify various aspects of how to account for these dimensions. At the very center is the way risk is understood, and the request/

description of risk it leads to, which addresses specified consequences and measures of uncertainty, assessments of underpinning knowledge, and surprises relative to the knowledge. It is argued that the cautionary principle needs to play an important role in the decision making, to give proper weight to the uncertainty component of risk. The management task is to balance different concerns, such as security/safety and costs, but in order to do this in a meaningful way, the full spectrum of the uncertainty dimension must be reflected. The present paper has pointed to some key aspects to consider, which extend beyond current practice.

APPENDIX A—KNOWLEDGE ASSESSMENTS

The knowledge K in the risk description includes assumptions and phenomenological/contextual understanding. One way to assess the strength of the knowledge is by using a scoring system based on Flage and Aven (2009). The strength of knowledge is poor if one or more of the following conditions are met:

- The assumptions made represent strong simplifications.
- Data is not available, or is unreliable.
- There is a lack of agreement/consensus among experts.
- The phenomena involved are not well understood; models are non-existent or known/believed to give poor predictions.

The strength of knowledge is strong if all of the following conditions are met:

- The assumptions made are seen as very reasonable.
- Much reliable data is available.
- There is broad agreement/consensus among experts.
- The phenomena involved are well understood; the models used are known/believed to give poor predictions.

The strength of knowledge is graded medium in cases in between.

More detailed analysis of assumption-deviation-risk (Aven 2013a) can be performed by considering 1) the magnitude of a potential assumption deviation, 2) how likely the deviation is (the probability), 3) the consequences given a deviation, and 4) a strength of knowledge assessment of preceding points 1)–3).

Balancing safety and performance through QRA and RAM analyses

Victor Borges & Colin Hickey
DNV GL Software, London, UK

ABSTRACT: Improving safety through risk management and improving economic viability through asset management are crucial elements of sustainable business success. However, what if the needs of these initiatives conflict? The impact of risk management on asset performance and the impact of asset management on risk can be assessed and thus an iterative analysis begins. Loss prevention tools and methods can be summarised under two main headings: Risk management and asset management. In using these approaches, operators ensure that assets are running optimally with a known and managed level of risk. We find that sometimes the methods to assure safety and asset management methodologies may at times conflict; changes recommended from risk management work can directly impact the performance of a system- and vice-versa.

1 INTRODUCTION

This paper presents a case study where a conflict in risk management and asset management is found and a balance sought. Managing assets encompasses different techniques to ensure that a system is running at optimum capacity in a safe manner. Loss prevention contains a range of methodologies—some integrated, some not—under one business' management system or systems.

Two management methods that are vital to ensure optimum performance and safe operations are risk management and asset management.

1.1 *Risk management*

Risk management is a process used in many industries. Very plainly it is the process of identifying what might go wrong in terms of consequence and likelihood, and using this factored view of the incident to inform us when deciding which steps we will take prevent or protect against the incident. Risk management is a powerful method to—in some cases—quantify or at least qualify the intangible wealth of possible futures of an activity. The process of risk management therefore contains an ever evolving array of tools and methods such as HAZOP, a systematic procedure for imagining all undesirable behaviour from the process flow diagrams of a process plant, to cutting edge experiments used to look at how newly popular materials such as Hydrogen and CO2 behave when they escape from containment. These methods—and everything in between—offer the safety engineer, or risk analyst and design and process engineers the tools required to build and run safe plant.

1.2 *Asset management*

Asset management is the process used to maintain production in a wide range of industries. In its application in the process industry, asset management is used to ensure the optimum performance of a process plant by balancing design configurations, maintenance strategies and operational bottlenecks with capital investments. By considering each of the factors involved in asset management in a strategic manner the "asset manager" can define and aim for the enterprise's optimum.

Asset management contains an array of complex range of tools and methods. From data management and storage systems used for handling vast quantities of information related to inspection and maintenance to the advanced technology of remotely operated vehicles used for inspection of subsea equipment.

This paper presents a case study of a separation unit where a conflict arises between advice given by risk management and asset management techniques and a balance is sought.

2 LOSS PREVENTION TECHNIQUES

The loss prevention pyramid, as shown in Figure 1, provides a description of the array of tools and

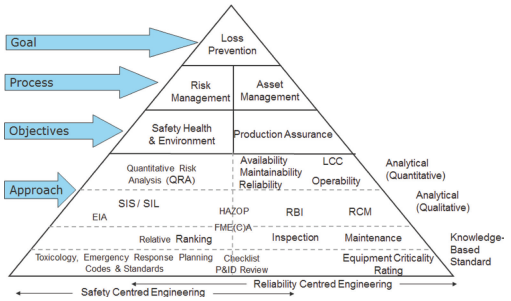

Figure 1. Loss prevention pyramid.

methods within risk management and asset management and how they can be combined to create an available and safe system.

The main goal of the activities in the pyramid is to prevent loss. From the risk management point of view, loss prevention refers to preventing loss of lives and property and avoiding environmental impact. From the asset management point of view, loss prevention refers to assuring production by ensuring that a system is available to perform its intended function.

As the pyramid describes, both domains are supported by qualitative and quantitative analyses, simulation techniques, management processes and standards.

Two well established and advanced methodologies that are widely used by the process industry to assess risk and performance are Quantitative Risk Analysis (QRA) and Reliability, Availability and Maintainability (RAM) Analysis.

2.1 *Quantitative risk analysis*

QRA is a method for systematically analyzing major accident hazards within an operation. QRA methods have been well documented and the approach is now ubiquitous within the process industry, with regulatory demand for it in some countries. Examples of guidance are the CCPS guide book (CCPS, 1989) and the Dutch BEVI guidelines (RIVM, 2009). The general approach is to take the following steps:

1. Identify hazards
2. Qualitatively assess the consequence and likelihood of the hazards and postulate major accident hazards
3. Quantify the extent of consequences
4. Quantify the extent of likelihood
5. Sum the risks
6. Compare the risks against some criteria

The quantification and assessment of risks is a powerful tool which can help you identify a risk profile. Knowing which hazards pose the most harm in a relative context can inform many factors of loss prevention such as plant design, building siting, emergency preparedness, and can inform cost benefit decisions on all manner of risk management activities. In general QRA will point to the core, common sense approach of "what you don't have can't leak" and other inherent safety approaches. The QRA can be conducted throughout all stages of the lifecycle of the asset; from the conceptual design through to decommissioning. Importantly, changes in design and operation may have significant impact on the total risk and the risk profile across the plant. Quantity of, physical and hazardous properties of products, location and vulnerability of population and location of ignition sources all have a relation to the risk. Presence of sources of loss of containment, potential for loss of containment from operational activities and their preventive and protective barriers form the root hazards across the site. For this reason, information relating to all of these factors must be considered as accurately as possible.

Typical outputs of a risk analysis are risk contours, FN curves and risk ranking measures. These are used in a variety of ways, for example to direct application of resources when considering layers of protection or for providing details required for emergency response planning.

2.2 *RAM analysis*

RAM analysis is a methodology (Smith, 2011) used to predict the performance of a system and is made possible through evaluating three factors:

- Reliability; typically expressed as the mean time between failures under given operating conditions.
- Maintainability; typically expressed as the mean time needed to return failed or shutdown equipment back to normal service. Influencing factors are the equipment's design, working conditions, organisation of work, procedures, and the location and availability of people and spare equipment.
- Availability; typically expressed as the fraction of time the equipment is able to perform its intended function under given operating conditions. Availability is a function of reliability and maintainability.

The main output of the analysis is an availability value, which is the fraction of the time where the system is available.

This methodology has been applied to a wide range of industries and throughout all stages of asset lifecycle from early design to decommissioning.

RAM analysis helps in the decision making process as it highlights areas which will cause system downtime or which will require continuous effort and resource to keep the system in a serviceable state. With the information that RAM analysis can provide, decisions can be made with regard to design and maintenance strategies, optimising production and reducing maintenance resources usage and cost.

In order to obtain a complete picture of the performance, we must not only evaluate the uptime of the system from generic reliability of hardware and the general 'time it takes to fix or replace things', but also the effects on performance from operations. For example, upon failure of a piece of equipment used to process gas leaving a 2-phase separator, can we bypass the failed equipment and flare the gas so that we can keep the liquid fraction of the product flowing? This is particularly important for oil and gas developments where systems are complex, time dependant and interrelated. To extend the traditional RAM analysis approach and account for operability factors a combined method utilising traditional RAM analysis with flow assessment is used.

By adding flow assessment, another dimension is introduced—the production rate. This enables the methodology to account for a range of results containing:

- Flaring operations
- Export requirements
- Recovery Mechanisms
- Buffer and Tank management
- Logistics and transportation
- Ramping time

3 CASE STUDY: SEPARATION SYSTEM

3.1 *Process description*

The process serves to remove unwanted liquids from a high pressure and low pressure gas lines providing fuel gas to a downstream utility plant. The arrangement of equipment is shown in the process flow diagram of Figure 2.

The process takes high pressure and low pressure gas feeds, which pass through separators used to remove liquids. Each of the two separators has a liquid outlet on the bottom. Each of the separators has a gas outlet on the top, which send the gas to be compressed and used as fuel. The low pressure system takes the liquids removed from the high pressure separator vessel, after the low pressure separator the liquids are removed from the system. The gas lines all have a connection to a flare line through pressure relief valves.

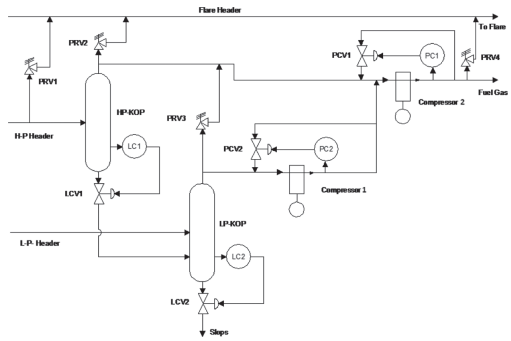

Figure 2. Process flow diagram of separation unit.

3.1.1 *The safety and operational performance analyses*

The performance will be evaluated by running a RAM study and the risk assessment will be performed using QRA.

The base case must fulfil safety and performance requirements. If the system does not meet the safety and performance requirement, changes must be suggested satisfying both risk and asset performance criteria. The principles adopted for this case study are that base case risks must be proven to be as low as reasonably practicable, by adopting economically viable risk reduction measures on the primary risk contributors. The RAM analysis will aim to establish the base case production efficiency and then further analysis will determine what changes should be made to the design to achieve a more reliable and maintainable selection and arrangement of equipment resulting in an improved production efficiency which more than pays for itself.

3.2 *QRA model*

3.2.1 *Description of QRA analysis case study*

A hazard and operability study was used to identify hazardous scenarios arising from the process. These were qualitatively assessed and a risk ranking was established. With knowledge of the operational procedures and intended layout of the plant, the key potential accidents identified in the HAZOP have been rationalised for the purposes of the case study to:

1. Rupture of HP-KOP
2. Ignition of relief from HP-KOP
3. Line Rupture at gas outlet of HP-KOP
4. Leak from Compressor 2 kick-back loop
5. Ignition of relief from LP-KOP
6. Line Rupture of gas outlet of LP-KOP
7. Leak from Compressor 1 kick-back loop

The domain of loss prevention is helpfully supported by an array of tools and techniques with

which to identify and manage risks from hazardous activities, and each of the above accidental events would be investigated further using techniques such as Layer of Protection Analysis, Bow-Tie analysis so as to determine the presence and effectiveness of barriers to prevent and protect against their failures. In this case study, QRA is used to support and enhance the qualitative risk ranking of the above scenarios by using best available science to estimate the extent of harm from each scenario.

A plot plan, shown in Figure 3 is used in the QRA tool. QRA software is used to simulate the range of flammable hazards including fireballs, jet fires, flash fires and explosions. There are no toxics present. As can be seen in Figure 3, there are congested regions around the compressor units. Ignition in these regions would give rise to overpressures. Also shown in Figure 3 is a risk ranking point; this is a geographical location of interest representing a point which if impacted would give rise to an escalation event. Following QRA calculations for the accidental scenarios and their predicted outcomes, Location Specific Individual Risk contours (LSIR) are developed, as shown in Figure 4.

The spikes in the risk contours are generated from elongated jet fire radiation zones. The risk ranking point is in an area which appears to be impacted by various outcomes. This can be confirmed by looking to the individual risk ranking results for the point. These are shown in Table 1.

The risk ranking results of Table 1 show us that the majority of escalation risk comes from jet fires resulting from leaks from the two compressors. The percentage risk shows the relative contribution to risk at the risk ranking point from each source.

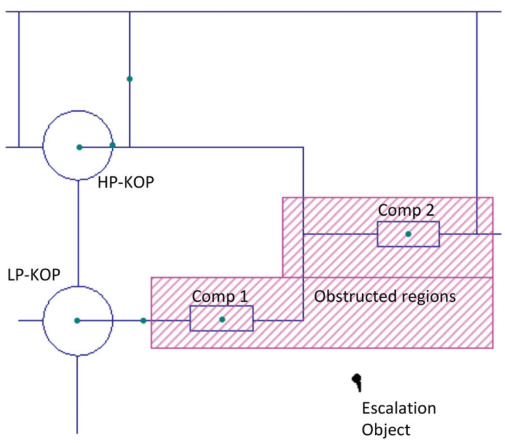

Figure 3. Plot plan with obstructed regions and risk ranking point.

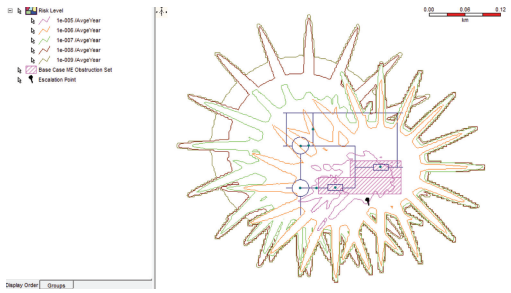

Figure 4. Risk contours for the base case.

Table 1. Ranking of risk contributions at escalation location.

Model name	Risk (/yr)	% risk
7 Leak from Compressor 1 kick-back	8.11E-7	47.37
Jet Fire	8.11E-7	47.37
4 Leak from Compressor 2 kick-back	8.11E-7	47.37
Jet Fire	8.11E-7	47.37
3 Line Rupture at gas outlet of HP-KOP	8.92E-8	5.21
Flash Fire	5.35E-8	3.13
Explosion	3.57E-8	2.09
1 rupture HP-KOP	6.98E-10	0.04
Fireball	6.98E-10	0.04
TOTAL	1.71E-6	

3.3 *RAM model*

The RAM study was performed to calculate the production efficiency of the base case design and identify the critical items impacting the production of fuel gas.

3.3.1 *Study boundary*

Boundary plays an important role in this study. The separation system might be assumed to be part of pool of utilities systems. Utilities systems refer to any essential services required by a process plant. For example, water supply, compressed air, gas, electricity, steam, nitrogen etc.

Loss of utility supplies can cause substantial disruptions to process operations for example, loss of compressed air, steam for heating, water for cooling or electricity for running pumps. In the case of this separation system, failures will have direct impact to any unit that requires fuel gas to operate. Fuel gas can be used for a wide range of application from power generation to heating products.

A total failure of this system may lead to a complete or partial shutdown of the processing

facilities upstream and downstream. Additionally, in certain conditions to safely shut down the plant, chemical may be routed to flare systems and burnt in order to reduce the potential safety hazard on the process plant.

This case study aims at calculating the availability and production efficiency of the separation system but it could be extended if needed.

3.3.2 *Flow network and flow rates*

The most important and thought provoking step in RAM analysis is to formulate a logic network which will reflect the functionality of the system and interdependence of the elements. In order to produce a flow network, it is necessary to decide from the outset which primary function of the system is to be monitored and then create a flow network mimicking that operation.

For this case study, the primary function of the system is to produce fuel gas. Armed with this information, the logic flow network is constructed as shown Figure 5.

The flow network in Figure 5 imposes that failures on the LP or HP separation will partially shut down the system. Failures at the compression system will prevent the system from exporting fuel gas and cause a full shut down of the system.

The overall flow exported from this system is 100 mmscf per day. The high and low pressure gas systems are assumed to have equal contribution to the end product quantity exported: 50% LP Gas and 50% HP Gas.

3.3.3 *Reliability block diagram*

One level below the flow network, the analyst must define the Reliability Block Diagrams. Reliability Block Diagrams (RBD) are similar to logic flow networks and describe the interdependency between equipment items. Two configurations are to be defined: blocks in series or blocks in parallel. Equipment items in series are required to be operational at all times to keep the system available. Equipment items in parallel, also known as being in redundancy, require more information to be properly defined. Apart from the number of trains, the definition includes flow rates available in each train as well as its mode of operation, active or stand-by. Depending on the combination of the elements defined above, the impact of losing each one of the trains can be assessed.

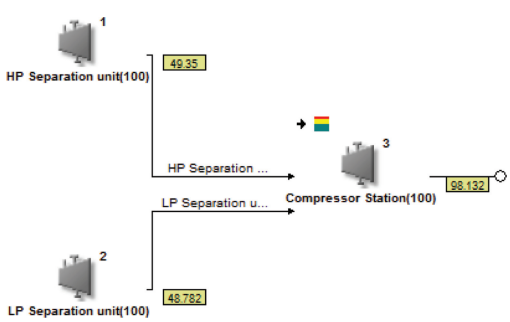

Figure 5. Separation plant flow network.

This process flow diagram does not show any redundancy at the equipment level. Hence, losing any equipment item will impose a production loss to the system.

Figure 6 shows the RBD for the HP Compression system and Figure 7 shows the RBD for the HP Separation system.

3.3.4 *Failure events and impact*

The failure of different systems will cause different impacts on the system. For example, different types of failures of the *Process Control Valve 1* will produce different losses. If the *Process Control Valve 1*:

- Fails open—half of the fuel gas production is lost because the flow is split between the recycle flow and the export pipe flow
- Fails close—full shut down of production to protect units downstream to the separation system

An evaluation of each of the possible failure modes must be carried out for all equipment items.

3.3.5 *Failure data*

The reliability data for this study is a modified version of OREDA's data (Det Norske Veritas AS, 2002). OREDA is a database of reliability data used for the offshore industry. As this system is operating onshore, the failure data and repair data is factored to more accurately represent the plant.

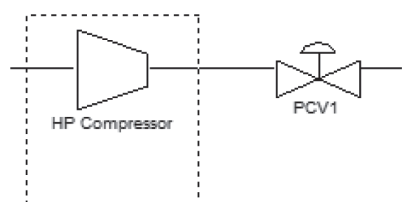

Figure 6. RBD Representation of the HP compression System.

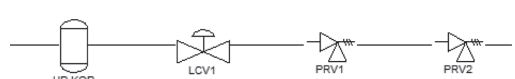

Figure 7. RBD representation of the HP separation system.

Table 2. Failure rates of equipment items.

Subsystem	Equipment	MTTF (years)	MTTR (hours)
HP compressor	HP compressor	0.106	24
	PCV1	7.189	17.28
HP separation	HP-KOP	7.189	17.28
	LCV1	2.327	22.08
	PRV1	7.189	17.28
	PRV2	7.189	17.28
LP compressor	LP compressor	0.106	24
	PCV2	7.189	17.28
LP separation	LP-KOP	7.189	17.28
	LCV2	2.327	22.08
	PRV3	7.189	17.28

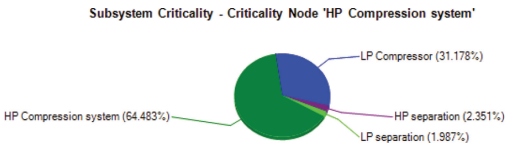

Figure 8. Criticality ranking of equipment contribution to unavailability.

All equipment items use statistical distributions which use a constant repair time and a constant failure rate.

3.3.6 *Maintenance strategy*

In this case study maintenance resources are assumed to be available at all times to perform repairs upon failure. It is important to bear in mind that maintenance strategies could impose delays to repair and increase the unavailability of the system.

3.3.7 *Performance results*

For the base design configuration the overall production efficiency of the system is 96.05%. The criticality ranking is shown in Figure 8 and tells us that the compression systems contribute the majority of production losses. The HP compression system causes 64% of losses and the LP compression system causes 31% of losses.

4 IMPROVEMENT CASE 1—IMPLEMENT WARM RUNNING REDUNDANCY TO COMPRESSORS

4.1 *RAM analysis*

The compression system including parallel redundancy for the HP compressor is shown in Figure 9.

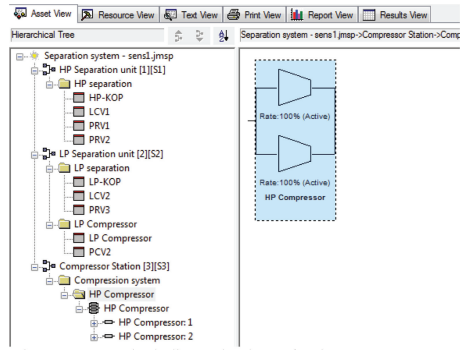

Figure 9. RBD including redundancy for the HP compressors.

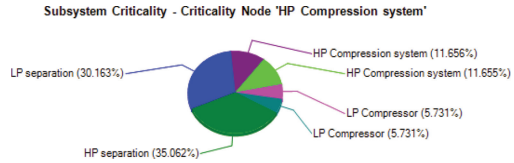

Figure 10. New criticality ranking of equipment contribution to unavailability.

Warm running parallel redundancy is a selected option for investigation as it offers instant switchover without ramping of the equipment should the operating compressors fail or be taken out for scheduled maintenance.

The improvement in availability and production flow from introduction of parallel redundancy to the compressors is of 3.7% resulting in 99.7% production efficiency.

4.2 *QRA analysis*

By adding parallel compressors which are running warm, so as to ensure instant switch over capability we are introducing two new parallel compressors. The plot plan of the suggested design is shown in Figure 11.

Following HAZOP of this modified design it was found that additional failure cases were present at the new compressors. Due to the need for immediate switchover to the parallel compressors, the equipment items would be at process conditions and therefore pose identical hazards as the operational compressors. In the QRA duplicate failure cases are used to represent loss of containment from the kick-back loops around each compressor. As this is a simplified case study no other changes were made to the QRA.

The LSIR contours resulting from analysis of this case are shown in Figure 12.

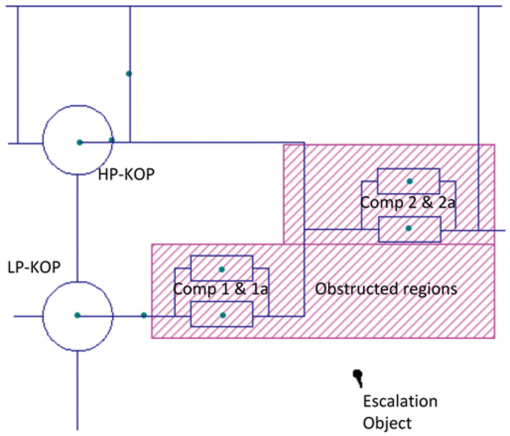

Figure 11. Plot plan of separation plant with parallel redundancy compressors.

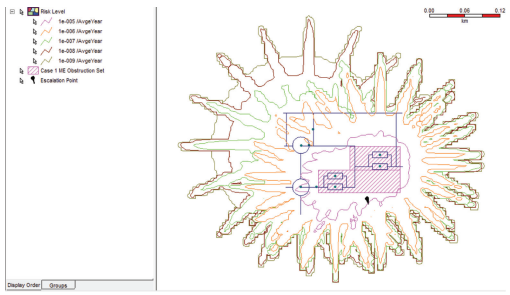

Figure 12. Risk contours for case with parallel compressors.

The risk contours indicate several changes to the risk results. The increase in size of the obstructed regions appears to have increased the size of the 1E-5/yr risk contour, which largely follows the shape of the obstructed regions. Larger congested and confined volumes will increase the flammable mass, flame path length and possibly turbulence patterns and thus increase the blast extents. Compounding the additional equipment is the increase in the number of failure sources. This of course increases the number of and thus frequency of hazardous outcomes. The risk ranking results in Table 3 for the escalation location tells us more.

The total location specific individual risk, as shown in Table 3 has increased by 30% to 2.21E-06/yr compared to the base case. Interestingly, the increased risk does not come from the new release location as the source term. Instead, the risk comes from expansion of the congested volume and its effect on the extent of blast potential on the escalation point. The increased risk from introducing the parallel compressors must now be assessed against the benefits derived.

Table 3. Risk ranking at escalation location after introduction of parallel compressors.

Model name	Risk (/yr)	Pct. risk
7 Leak from Compressor 1 kick-back	1.28E-06	58.07
Jet Fire	8.11E-07	36.67
Explosion	4.73E-07	21.40
4 Leak from Compressor 2 kick-back	8.11E-07	36.67
Jet Fire	8.11E-07	36.67
3 Line Rupture at gas outlet of HP-KOP	8.92E-08	4.04
Flash Fire	5.35E-08	2.42
Explosion	3.57E-08	1.61
7a Leak from Compressor 1a kick-back	2.63E-08	1.19
Jet Fire	2.63E-08	1.19
1 Rupture HP-KOP	6.98E-10	0.03
Fireball	6.98E-10	0.03
TOTAL	2.21E-06	

5 DISCUSSION

Clearly the increase in production availability has caused an increase in risk. The method used to increase availability from to 96.05% to 99.7% has increased individual risk at the escalation location from 1.71E-6/yr to 2.21E-6/yr.

The decision of whether this is tolerable must take into account a range of factors:

- local regulations for individual risk criteria
- corporate risk tolerance criteria
- the nature of the escalation location
- the increased value of the production efficiency gain from introducing improved availability
- the lifecycle cost of the improved availability initiative

5.1 *What other options do we have?*

Engineers are pragmatic and creative. Armed with analysis tools such as those used above for QRA and RAM we can perform sensitivity analyses to check the risk and production performance of a range of other ideas. Ideas we could adopt include but are not limited to:

- Offer standby (cold) redundancy, so as to reduce the potential for full pressure leaks from the parallel compressors—this would have an adverse but tolerable effect on the production efficiency

– Move the object that poses as the risk ranking point location. This might be a control room, an expensive or safety critical piece of equipment. Given that fuel gas production has increased we may have further funding available to invest in making a change to the site layout.
– Do nothing—perhaps the production efficiency gains outweigh the increase in risk

This case study highlights the benefits of having a unified asset data system that can be called upon by QRA and RAM analyses. By taking instances of the base case and making changes we can efficiently analyse a range of options. Each option will have production efficiency, risk and cost impact. Using quantified measures of production efficiency and risk we can make informed decisions about plant design and operation and take a holistic view of Loss Prevention.

6 CONCLUSIONS

In conclusion this case study has highlighted the benefits of the quantified analyses within the domain of Loss Prevention. By using QRA and RAM we are able to assess the design of a plant from a safety and performance perspective. The values of Risk and Production Efficiency and by performing sensitivity analyses we are able to make informed decisions about the impact of changes to design over a base case.

In this study we saw that a plant modification involving introduction of parallel redundancy to gas compressors provided a 3.5% increase in production efficiency, but a 30% increase in individual risk to a sensitive location.

Using quantified analysis allows us to check what other options we may have and to compare the pros and cons of each in an informed and numerate manner.

This holistic approach to the safety and asset management sides of Loss Prevention would be more accessible and improved if a repository of plant asset data were available on which to perform the analyses. QRA and RAM analysis are multi-faceted techniques which themselves require an underlying appreciable platform of good information. QRA requires thorough hazard identification and failure frequencies and RAM requires sound reliability data and well thought out flow networks and reliability block diagrams. The approaches in this case study made use of QRA and RAM analysis software tools. It is the opinion of the authors that such tools are crucial for freeing up the analyst to spend time working on the most important factor in these analyses: the information input to and output from the analyses.

Public risk perception towards chemical process industry: Comprehension and response planning

D. Botheju & K. Abeysinghe
Agility Group AS, Sandefjord, Norway

ABSTRACT: The chemical process industry is a vastly diversified entity which effectively involved in every facet of human life. Public perception of risks associated with chemical process industry is not necessarily aligned with the risk evaluation methods used by safety professionals. The risk perception by public is a subjective, emotional, and contextual process. This article is an attempt to elucidate this phenomenon in relation to chemical process industry and to provide a general guide for safety managers and decision makers to formulate responsive actions.

Several contextual factors which influence the public risk perception are identified and their impacts are described. The necessity of two way risk communication is emphasized as a mean of avoiding public concerns escalating into outrage. A case example is provided in this regard. Correct understanding of social dimensions of the concept of risk and timely engagement with the public are recognized as crucial aspects of modern day safety management in chemical process industry.

1 INTRODUCTION

1.1 *General*

The chemical process industry is a vastly diversified entity which effectively involved in every facet of human life. The essential life requirements like medications, foods, energy; as well as day-to-day use chemicals like detergents, fragrances, agrochemicals; and also the basic ingredients of modern high tech products (e.g. semiconductors, polymers) are all among the products of chemical process industry.

Chemical process industry involves many risk elements as all other human activities. However, it has been widely observed that public (including media) perception of risks associated with chemical process industry is being highly amplified in a distorted way. It is clearly noted that public is willing to accept far more dangerous events from other sectors (such as construction industry, transport, foods and healthcare, etc.) compared to probabilistically less risky activities emanating from chemical process industry.

Quite different to the way risks are quantified by safety professionals having associated scientific and engineering knowledge, the public risk perception is heavily affected by various emotional and contextual aspects. Laypersons often gauge risks mostly by the associated hazard which generates the risk, and also based on a number of other factors including various emotional states (Byrd, 2005).

It is seriously important for decision and policy makers within the industry and for other stakeholders to understand this phenomenon and accordingly plan their responsive activities to minimize negative repercussions arising from this distorted public risk pictures towards chemical process industry.

Also, the future progress of many technologies such as nuclear and genetic technologies (Huang et al., 2013) heavily depends on the social acceptability, other than any other factor. Therefore high attention on public risk pictures associated with the process industry is more crucial than ever.

1.2 *Objectives*

One objective of this paper is to discuss the above mentioned public risk perception scenarios associated with chemical process industry and to explain why this distortion is happening. The article provides a common understanding and recognizes a few key aspects which can be used to understand the basis of public risk perception towards chemical process industry.

The paper also suggests several strategies of communication that can be adopted by safety and risk management systems and by regulative authorities to correctly respond to the recognized public risk perception scenarios.

Table 1. Relative safety of chemical process industry (data adopted from Sanders, 2005).

	Risk related to chemical process industry	Comparison
Estimated loss of life expectancy (no. of "days")	Dangerous job (in general): 300	Cigarette smoking (male): 2250; Being overweight (30%): 1300; Vehicle accident: 207; Average job: 74
Relative occupational risk in US (1995)	Chemical and allied products industry: 0.6	Fishermen: 21.3, Timber cutter: 0.6, Taxi driver: 9.5, Average job: 1 Finance sector: 0.4
Fatal accident rate in UK (1987–90)	Chemical and allied industry: 1.2	Deep sea fishing: 42; Construction: 5; Agriculture 3.7; All manufacturing industries: 1.2.

1.3 *Relative safety in chemical process industry*

Despite the common misperception of chemical process industry being dangerous to occupants and surrounding communities, which is promoted by isolated case histories, such as the Bhopal tragedy, regular statistics show a very different picture. According to the data presented by Sanders (2005) the relative risk index of workplace accidents in chemical and allied products industry (value of 0.6) is about 20 times less than the relative risk faced by Fishermen (index of 21.3) and Timber cutters (index of 20.6). It is even less than the relative risk of an average job (index of 1.0). This fact is further emphasized when it comes to the fatal accidents and death. The relative risk index is a method of expressing workplace risk and it gives the ratio of the rate of quantified risk (such as the rate of fatal accidents) for a particular group of workers against the rate for the total number of workers (Bureau of Labor Statistics, 1997).

Table 1 indicates several other statistical figures related to chemical process industry compared against other occupations. If the comparison is made against other potential risks faced in life (other than occupation), the figures become even more intriguing. It can be underlined that doing a dangerous job (in broad perspective) carries only a 13% of risk compared to smoking habit (Table 1).

2 PUBLIC RISK PERCEPTION

2.1 *Risk*

Let us first indicate how the term "risk" is understood by its usual meaning, and by the typical definitions given in scientific literature (Table 2).

Except for the first 2 dictionary references, the rest of the definitions reflect the standard way "risk" is "defined" by scientific community, or by the "experts" opinion.

Table 2. Different definitions of "risk".

Definition	Source
A situation involving exposure to danger.	Oxford dictionary
Possibility of loss or injury.	Merriam Webster dictionary
Probability of an unwanted event that results in negative consequences.	Ostrom & Wilhelmsen (2012)
A measure of economic loss, human injury, or environmental damage in terms of both the incident likelihood and the magnitude of the loss, injury, or damage.	Bollinger et al. (1996)
The combination of the expected frequency (events/year) and severity (effects/event) of a single incident or a group of incidents.	Center for chemical process safety (2008)
Mathematical probability of a specified undesired event occurring, in specified circumstances or within a specified period	Mannan, 2014
Combination of the probability of occurrence of harm and the severity of that harm	NORSOK Z-013 Standard
Combination of the probability of an event and the consequences of the event	ISO 17776 Standard

But when it comes to the domain of public or the "laypersons", the way they perceive "risk" may not necessarily bounded by any of the above definitions. That is when one needs to consider the concept of risk perception.

2.2 *Risk perception*

It is understood that public's risk perception or relative risk ranking is affected by a number of qualitative factors or modifiers; hence they do not restrict themselves by the rational judgments

presented by experts regarding the quantitative likelihood of a specified risk. In other words, inexpert people may carry drastic biases when they come to judge the acceptability of a certain risk. This means, two similar risk events can be judged very differently by the public if the associated "context" is different, while experts' opinion may put both risks at the same threshold number. Note that the "perception" is subjective and will vary while the "actual risk" is constant.

In the following sections several factors recognized as important when analyzing the public risk perception phenomena related to chemical process industry are described. Note that some of these factors can be interrelated.

2.2.1 *Familiarity*

Risks posed by familiar establishments or events are seen as more acceptable compared to completely strange and new events. The communities living close to an old process plant may see a less and less risk when time goes by due to their experience that nothing dangerous has ever happened during previous years of their experience. However, in the eyes of experts, the risk of that process plant might be increasing when the plant nears its operational life time with aging equipment and older safety systems.

2.2.2 *Complexity*

The public can perceive a higher risk with the industrial processes and plants that seem hard to be understood. They feel a certain degree of mystery surrounding such facilities, but in most of the cases people have never even had a chance to see inside of such facilities.

For example: A community living nearby a water dam might face a statistically higher risk of dam failure compared to any risk posed by a nearby process plants. Still, public will "see" a higher risk with the plant than that "simple dam" which they can easily comprehend its arrangement and the purpose.

This implies that, in association with risk communication, it might sometimes be a good idea to let people come and visit a process facility and get them explained the processes happening there.

2.2.3 *Media*

Media can significantly influence public opinion on risks related to industrial activities. Media coverage most of the time leads to accelerate the risk perception, i.e.: amplification of perceived risk than what the risk really is. When it comes to chemical process industry, media coverage can be inherently biased. This is due to a characteristic nature of public media. The commercial media is usually based on popular incidents (for obvious reasons) rather than true scientific reporting. Hence, media tend to report "sudden, dreadful, sellable" incidents with a heavy weight rather than any news about "a peaceful operation of a chemical plant for a long time". This deposits an idea in public mind resembling chemical process industry to all-time "Bhopal gas tragedy", "Piper Alpha accident", or "Deepwater Horizon disaster". This should however be seen in the context that public media is always more interested in "disturbed, dangerous, and unsteady" occurrences rather than "steady, safe, slow phase" situations. That is where the "news" exists. Thus, this should be understood as the ground reality rather than a reason to blame the media. An industry should always try to maintain good relations with public media despite any past encounters with bad publicity.

Analysts suggest that the effect of media is more prominent among the less educated sectors of the public. Similarly if the targeted public is less experienced or knowledgeable regarding the particular hazard, then they can be more rigorously mediated by media coverage (Williamson & Weyman, 2005).

However some studies suggest that the relationship between media coverage and the public risk perception is not directly proportional as one might expect (Williamson & Weyman, 2005). Authors believe this may be due to the interrelated complexity between different demographic and other factors (modifiers) affecting risk perception, such as level of education, familiarity to the specific hazard, etc.

2.2.4 *Previous fatal experience*

If the community of concern has had a previous fatal encounter with similar risk, they would have a high intolerance for the same risk despite of the fact that reoccurrence of the same incident is statistically highly unlikely. This is especially relevant for highly dreadful incidents (Williamson & Weyman, 2005) Looking at an example of a natural event; 2004 tsunami which hit the eastern and southern coastlines of Sri Lanka claimed a casualty rate of about 15–20% of population lived within 1 km distance from the coast (Fehr, et al., 2006). After experiencing such a deadly event, people developed a high fear level of the risk of reoccurring tsunamis. There were several occurrences that coastline populations were scared themselves off and self-evacuated by false alarms. Meanwhile the "expert" opinion is that it will take another 300–400 years before any significant risk of a similar mega thrust seismic event can surface (NGI, 2006).

2.2.5 *Equity*

Public accepts more of the risks which are fairly distributed compared to the ones those are specifically

affecting a sector or an isolated community (Sinisi, 2004).

2.2.6 *Benefits*
Sometimes risks are perceived based on their relative benefits. A risk with high benefits to the local community might be perceived as less risky than it really is, and vice versa. Example: Some expressway road construction projects are opposed by some farming communities in Sri Lanka, because they do not gain much from the expressways which only serves rapid transit between big cities while these roads claim parts of their agricultural land.

As discussed for the case study in Section 4, this vital aspect is neglected by the controversial Rathupaswala latex factory (name of the locality in Sri Lanka) by deciding (unofficially) not to employ personnel from the nearby community.

2.2.7 *Cultural values and social norms*
Some industries are repulsed by the communities simply based on their cultural values. For example: poultry industry and associated meat processing facilities such as slaughter houses are highly repulsive to the rural communities in Sri Lanka where common public disapproves animal farming for meat production. The slightest of the emergence of any risk, such as an untreated effluent release, may be aggressively protested. In that case the protest may weigh way beyond the expected harm. In that example case, the design of the effluent treatment facility should include this dimension of public risk perception, and might need to invest for additional treatment stages.

Risk tolerance can heavily depend on the social norms of a particular society at a particular era. For example: Extremely high fatality rates of coal mine labors were an acceptable norm in Europe about a century ago.

2.2.8 *Voluntariness and control*
People give less weight to the risks that they are voluntarily subjected to (Sanders, 2005). Similarly they feel less risk in activities that they have control over (Sinisi, 2004). Meanwhile they might fiercely oppose an industrial activity that might have a very low risk compared to their day today activities (such as driving, sports, air travel, etc.) but in which they do not have "a say". This is where risk communication can play a major role in diffusing such amplified risk perceptions, by giving the public a chance to express their say and being listened.

2.2.9 *Artificiality*
Compared to natural disasters, people have a less acceptability to risks posed by manmade events such as a process plant explosion, or a chemical release. This is key perception modifier regarding chemical process industry. People have a general fear of all sorts of chemicals (perhaps except for water!) which in turn results in an amplified risk perception towards chemical process industry. Risk managements in chemical industry need to bear this additional weight compared to their colleagues in other industries, e.g civil engineering constructions, or electrical manufacturing. For example; Sanders (2005) pointed out that a particular dam collapse occurred in 1979 might have killed more people in India than the fatality count in Bhopal tragedy. The failure of Machchhu dam on August 11, 1979, in Rajkot district of Gujarat might have killed 1800–25 000 people (exact count is disputed). Yet, seemingly everyone has forgotten that dam collapse accident, but still a lot of talk is going on Bhopal tragedy that occurred five years later on 3rd December 1984. The official death toll was given as 3787 (the worst of the estimates put it at 16 000). The killing agent of the dam incident is water which is naturally familiar to people; while Bhopal tragedy involves methyl isocyanate (CH_3NCO), an artificial gaseous agent unknown to the public.

In risk communication, communicators must bear in mind the fact that repeated comparison of a chemical process plant risk to risks faced by natural events might make public angry and agitated; because they simply do not see the connection. (e.g. comparing the risk of industrial effluent release incident to a tsunami event).

2.2.10 *Permanency*
Risks leading to irreversible or long term persisting consequences are likely to be resisted extensively by the public, in comparison with risks leading to short term and recoverable consequences. In this context, a nuclear power plant which may have low statistical risk of fatality can be highly resisted by the public, while high fatality risk caused by flooding of the nearby river is easily forgotten.

2.2.11 *Dreadfulness*
There is a tendency that the public and media give overweight to highly dreadful incidents (Sanders, 2005) such as Bhopal tragedy or Piper Alpha accident; and they remember such events for a long time. But in reality the likelihood of such events can be quite low by modern day industrial safety practice. That means the "risk" (experts' risk) is low, but the "perceived risk" by the public is still high. The basic reason for this is that people are scared of violent scary ways of danger (such as an explosion) despite their low probability (hence the low risk) compared to slowly occurring (but perhaps more frequent and hence high risky) events such as disease caused by unhealthy life habits (e.g. smoking).

For example; public often react negatively to nuclear power generation, despite its statistically low fatality rate compared to other power generation means. This may associate with a couple of past incidents with catastrophic outcomes, including use of nuclear energy as a weapon.

2.2.12 *Phase of consequences*

When the consequences are readily observable, people react more negatively. Some risks emerge in so slow phase that people do not notice them for a long time. In an incident at Rathupaswala (Sri Lanka) where ground water acidification occurred (as explained in the Case Study, Section 4) reaction of the surrounding community was rapid. Meanwhile in an another region in Sri Lanka, where the heavy use of agricultural herbicides might have led to heavy metal contamination of ground water and associated widespread kidney decease, no public outcry was observed for decades, until recently the widespread danger is eventually surfaced. Higher risks with slow consequences are likely to be forgotten while smaller risks with rapidly observable consequences get largely magnified public reactions.

2.2.13 *Demographic factors*

Various studies suggest the influence of demographic factors on public risk perception. Factors such as education level, ethnicity, gender, age, income, occupation, etc, can have bearing on the risk perception. Investigating on such demographic effects on the public risk acceptability based on survey results conducted covering three provinces in China, Huang et al. (2013) observed that men had a higher risk acceptance to chemical industry compared women; younger people were more likely to accept chemical industry risks compared over 50 age people; farmers, retired persons, and house wives had less risk acceptability compared to other occupations. The same study by Huang et al. (2013) further suggested that highly educated people were more likely to accept chemical industry risks compared to the people with lower education. They further observed that people in the middle income category were highly resistive to chemical industry risks, compared to lower or higher income categories. This might be due to the fact that high income people are better shielded from risk elements, while the lower income category considers the potential benefits from the local industry. Such demographic factors must be given proper consideration by the industrial decision makers when they evaluate investments on new plants or when modifying existing plants.

Sometimes certain ethnic groups are more disturbed by new industries arriving at their localities. An example case: In an attempt to build a coal based power generation plant in Sri Lanka, strong opposition had been initiated by a certain minor religious group who were residing close to the suggested location. The location was chosen based on strategic considerations with the aim of minimized environmental effects, and was perhaps among the best locations for such plant. However, the perceived environmental risk by that local ethnic group was highly exaggerated which could be related to their perception that might have its roots in being a minor ethnic group.

This shows that industrial decision makers need to consider a very wide spectrum of social phenomena before they dare to invest in new projects which can trigger sensitive demographic factors.

2.2.14 *Trust*

Public's trust (or distrust) of the authorities and of the personnel responsible for handling any disaster aftermath and the experts who are advising public, is among the most critical elements which affect industrial risk acceptance by public.

A strong trust can overcome many other factors such as media influence, lack of knowledge, uncertainty, complex technologies, etc. Trust can be seen as a kind of compensation factor (Huang et al., 2013) that people can use to overcome other influential perception modifiers (Williamson & Weyman, 2005).

The trust can be based on four key aspects, i.e. impartiality, competence, openness, and past track records. If the concerned party is known to have high vested interests in other things than public safety, people may not trust them considering them as prejudice. This is very applicable for regulative and government authorities, perhaps for the whole political structure of a government. Trust can also be easily broken when a management or a particular expert is exposed by lack of knowledge or incompetence or negligence to carry out a particular task. Openness in sharing accurate details and presenting the whole picture increases the public trust. Managements and individuals with poor track records of safety and competence may need additional efforts to build public trust again.

What this means is that "trust" is one of the best assets an industry can build to defend themselves against unfavorable public risk perceptions. A community or the general public may after all accept a perceived high risk from a trusted company management, that they would not have accepted from a suspicious management which is known to have made past mistakes or have not kept their promises to the public (or to their employees). This point is further emphasized in the case study mentioned in Sec. 4.

The most critical aspect of public trust is that it takes a long time to build while it can be quite easily broken within a very short duration.

For example: A soft drink manufacturer might have been building public reputation for many decades while it takes one single news article in one day to break the whole trust, if it mentions that "an item" has been found inside one of their drink bottles.

3 RESPONSE PLANNING

3.1 *Policy decisions*

In decision making regarding safety, it is essential that regulators or industrial safety managers base their decisions not only on the expert opinion but they should seriously evaluate also the public perception of the associated risks. One might argue that publics' opinion is habitually inaccurate, unscientific, irrational, or biased. However, often the ground reality is that industry has to deal with public *en masse*, other than a bunch of safety experts; also to remember that it is the public who shapes the political arena which eventually takes higher-up policy decisions. In other words, the industry has to address this *perceived risk*, even if the experts' risk picture is quite different.

This expert verses layperson debate has its roots in two different world views. One school of thought is that the reality can only be scientifically explained and hence the decisions must be made based on tangible scientific evidence (such as the statistical probability of an event).

However, there exists an entirely different school of thoughts suggesting that there is no such thing as absolute reality, and the reality is relative to the perception of an observer. Hence the concept of risk itself is relative and the "real risk" is the one that is perceived by the majority of a society that represents cultural values and demographic factors. In this view point, opinion of the public may carry a similar or even higher validity than the experts' opinion. Williamson & Weyman (2005) indicated that even the experts can sometimes be culturally biased, making their opinions based on perception too, rather than founded on hard science and mathematics.

This effectively suggests that the concept of "risk" has a scientific dimension as well as a social dimension. Authors believe that "safety" shall not only be physically guaranteed but it shall be "felt" by the individuals who are being protected. One example of this concept: There is an elevated water storage tank situated in one of the large public hospitals in Sri Lanka where the water tank is purposefully constructed with a unique structural design. The massive concrete tank lies on an apparently narrow beam of straighten up single concrete column. Although the structural design is unique, extremely "safe" and showcases the skills of its designers, many patients coming to the hospital have expressed their worry about the "risky position" of the water tank. In this context, even though the tank is "safe" the public sees a "risk" in it. This may not be a good "and safe" design for a hospital after all (perhaps very good for a structural engineering faculty of a university). A good engineering designer must be able to combine both scientific and social dimensions into their designs.

Hence it is essential that modern-day chemical process facilities affectively engage the public, and also even more importantly the local communities, in a continuous dialogue throughout all life cycle phases of a process plant (i.e. from concept studies to operation, modifications and eventually until decommissioning). The safety policies and associated decisions must reflect, at least to a reasonable extent, that the public has been heard and their views are respected.

3.2 *Redefining risk*

The conventional formulation of the concept of risk is based on the extent of negative consequences of predefined events and the frequencies or probabilities of the occurrence of the defined events (Table 1). This definition of risk may be modified to include social dimensions as shown in (Formula 1), where risk (R) is defined as a function of threat events (e), consequences (c), probabilities (p) and social perceptions (s)

$$R = f(e,c,p,s) \tag{1}$$

Any eventual true formula based on Eq. 1 can be very complex and hard to estimate, since some of the associated social contexts can be extremely complicated and of varying nature. However, Eq. 1 can be a useful mean of emphasizing the impact of social dimensions in risk based decisions.

3.3 *Risk communication*

Risk communication is an integral part of modern day industrial safety management. Risk communication involves exchange of information related to the nature, magnitude, expected effects, and control of associated risks. The communication can happen between different stakeholders, such as safety management, the general public, media, investors, pressure groups, local communities, etc. In many situations, two way dialogues are essentially emphasized rather than unidirectional communications (Ng and Hamby, 1997).

Understanding of the nature of public risk perception towards a particular industrial activity is critical for the communicators to plan and execute proper communication strategies. Risk communication has become a vital topic among modern day process industries, instigated by new national and

international legislations mandating the obligatory requirements of industries producing or using hazardous chemicals or materials to inform general public regarding type, quantities, and other details related to their use of hazardous materials. In addition, "right to know" principal is now a widely accepted principle throughout the world.

In many process industry related cases, timely engagement with the public through constructive dialogues can prevent public opinion from escalating into public uproars and outrage. Note that if the matters are escalated into the higher levels, different pressure groups such as environmental groups (Sheppard et al., 2012) and media may involve and then the communication can be significantly complicated and difficult. This has been noted in the Rathupaswala latex industry incident which is mentioned under the case study in Section 4.

Communications related to risk details should be carefully planned based on public risk perception factors. Following guidelines must be paid with due attention in this regard.

3.3.1 *Key guidelines for risk communication*

Give a full picture of the involved risk: Even though it is likely to suggest that common lay people may not be able to comprehend complex concepts involving technology and physics, a number of studies has indicated that if the facts are properly presented common public is able to understand quite complicated information (Williamson & Weyman, 2005; other references). Hence, it is important to present the risk picture without withholding critical information. If the public get to know later that the company has withheld such info, it can totally ruin the trust between the communicating parties. Sinisi (2004) indicated several categories of key information that should be included in risk communications.

Public must be heard: The outcomes resulting from the engagement processes should not be disregarded eventually. This means that the dialogues with the public shall not be used as a mere face-saving mean. The public must be able to see that their viewpoints has been appreciated and taken care of. In some situations, full implementation of public opinions might not be feasible, but that should not result in total disregard of their voices.

Do not over-impose scientific opinion: Communicators must well understand the complexity of public risk perception factors and hence should be open to receive diverse opinions. Public must feel that their perspectives have been respected. Any attempt from communicator's side to overemphasize scientific opinion while downplaying the public views can lead to the collapse of any constructive dialog. Public may be expressing their true feelings and hence their view points are equally legitimate, whatever extent they might be distant from scientific reality.

Targeted communications if necessary: Sometimes it may be necessary to carry out targeted risk communication. E.g. certain ethnic groups in the area, or certain well respected community leaders in the area.

Communicators must have necessary knowledge and trust: Communicators shall not be only skillful in public communication but they should also have enough knowledge to present correct facts, figures and data. They must be able to answer questions raised by the public. It is to remember that there can indeed be technology experts among general public. If the public to see that communicators become speechless in certain questions raised, they will immediately loose the trust on the communicators. If such situations are likely, the management should use additional technical experts in the communication team to back the communicators up.

Do education campaigns if needed: In some situations, it will indeed need to do certain education of the public. Public seminars, handbills, electronic media, newspapers, or any such suitable mean can be used.

Maintain good relations with media: In many industrial risk scenarios media publicity can escalate public perception; at least that will be the apparent view point from industry's side. But it is truly important for the management to maintain good relations with public media. Be open to them and provide necessary information upon demand. Hostile attitudes towards media will always worsen the situation. Fighting with media is unwinnable and can be interpreted as fighting an invincible enemy. On the other hand, bad media publicity can be counteracted through industry's own media campaigns. Such campaigns should not however look like advertisements or blowing your own trumpet, but should carry some impartiality and deliver correct information.

4 CASE STUDY

4.1 *Rathupaswala (Sri Lanka) incident*

In 2013 there was a huge outrage related to a latex manufacturing facility in Sri Lanka, which was then known as Rathupaswala incident (Rathupaswala is the area name of the locality). The local manufacturing company which is known to be a global entity in latex industry, for supplying almost 5% of the world demand of rubber gloves (non-medical), was accused of polluting the ground water resource which is used by local community for drinking and other.

The company rejected downright the accusation telling that they had nothing to do with ground water acidification issue and had a proper wastewater treatment facility and all their activities were under the environmental license.

But the local community did not accept the claims and went ahead to continuous public demonstrations, picketing, hunger strikes and some violence. Media were covering the incident with 24 hr. broadcasts and cameras permanently located at the industrial facility, making it a public relations nightmare for the company. The government and the judicial had to involve as an urgent matter and the company was ordered to stop the production immediately. Eventually the large scale latex manufacturer was ordered to close down the facility and asked to move out of the area and relocate itself in a designated industrial zone.

Later research done by several independent research institution, public safety authorities, and local universities, indicated perhaps the accused industry might have nothing to do with the ground water acidification issue. Analysis and groundwater infiltration simulations suggested that other natural reasons may have led to the generally observed low pH of the ground water.

The important lesson here is that the company management did not maintain a public trust and credibility at the time of this incident occurred. They did not have a proper risk communication or public engagement strategy. They have had a number of past shaky deals related to effluent treatment. In the past, they were accused of ground infiltrating latex wash water (known to be acidic) which were stored in deep wells. After those past confrontations with the local community the factory did seem to resort to retorting actions like not to employ any one from the surrounding community. Also they did not seem to have trustworthy relations with media. This antagonist approach escalated the public risk perception and distrust among the surrounding communities that eventually led to a huge outrage.

If the factory management had had a constructive discussion (before the incidents) and had resort to effective risk communication techniques, this eventuality could have been avoided which almost ruined the company both by economically by enormous relocation and rebuilding cost, and by losing its reputation.

5 CONCLUSIONS

Social dimensions of the concept of risk is emphasized and explained in differentiation with typically accepted view point of statistical risk.

Different factors influencing the amplification and attenuation of public risk perception and tolerance in relation to chemical process industry have been documented.

Importance of timely risk communication has been pointed out and a general guide for managing risk communication is provided.

Risk assessment system for verifying the safety guards system based on the HAZOP analysis information

A. Nakai, K. Isshiki & K. Suzuki
Okayama University, Okayama, Japan

ABSTRACT: In recent years, serious accidents in chemical plants occurred frequently in Japan. Also in order to prevent deserters/accidents caused by natural disasters, it is needed to re-evaluate risks which consider reliability of existed safety guards system in chemical plants. In order to identify hazards in chemical plants, HAZOP (Hazard and Operability Study) is used as one of effective measures. In this paper, we propose the method to calculate the probability of occurrence of hazards in chemical plants by considering of existed safety guards system. The method is based on the HAZOP information and reliability of safety equipment arrangement.

1 INTRODUCTION

In past few years, serious accidents in chemical plants occurred frequently in Japan. Large-scale and complexity of chemical plants are growing. After the severe accident of Fukushima Daiichi nuclear power plants due to the Great East Japan Earthquake and Tsunami, the safety management of large industrial facilities has taken on increasing importance. Since then most Japanese people feel anxiety about not only nuclear engineering but also chemical engineering. In other words, our society required to build up a believable safety and reliability of chemical plants. As well-known many kinds of hazardous materials are under controlled in facilities. If a severe accident occurs, there is a possibility of a serious damage to employees and also local residents in the community. Therefore "risk assessment" is more important to identify the cause of the accident. Before an accident occurs, we should calculate the risk based on the frequency and scale of the damage of industrial facilities (Isshiki et al. 2013). This paper shows how to re-evaluate risks in chemical plants by considering reliability of existed safety guards system in plants.

2 PURPOSE AND APPROACH

In order to identify hazards in chemical plants, HAZOP (Hazard and Operability Study) is used as one of effective measures (Klets, T.A. 1992). When the risk assessment is performed, there is a problem whether the current measures are sufficient enough to evaluate the hazard. Therefore various methods are proposed to solve this problem. For example the system used in the risk assessment to create a statistical model based on the accident database (Meel et al. 2007). In chemical plants, the safety guards system is installed to prevent the accidents and the damage from spreading. The control system and the safety instrumented system perform in order to operate safely the existing chemical plant as the safety guards system. In this paper, we have proposed the method to calculate the probability of occurrence of hazards in chemical plants by considering of existed safety guards system. It is based on the HAZOP information and reliability of safety equipment arrangement. In this study, function for synthesis scenario trees is introduced HAZOP analysis system. Figure 1 shows overview the proposed system. After hazards are identified by HAZOP analysis system, the fault propagation scenarios are created automatically.

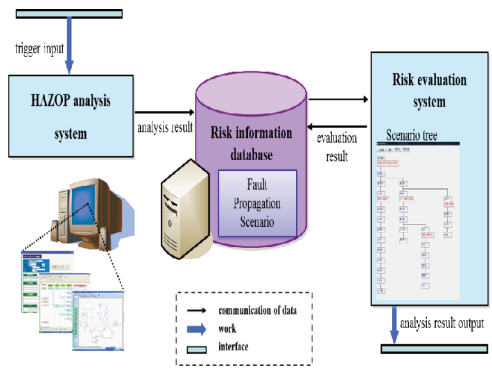

Figure 1. Outline of proposed system.

In this step, the information of abnormal states with the safety measures in IPL (Independent Protection Layer) is added to fault propagation scenarios. The system that we developed creates a scenario tree using fault propagation scenarios. Two or more causes are shown to one hazard in the created scenario tree.

We can calculate the probability of hazard using the information by HAZOP analysis system and layout of safety equipment in the fault propagation scenario. The probability of hazard is cut down by the suitable safety measures for the fault propagation scenario. The system can calculates likelihood of fault propagation scenario and evaluate of the risks which consider reliability of existed safety guards system in chemical plants. Based on this information, it is possible to verify and design safety guards system in plants to prevent accidents/disasters. The results can be used to assess risk of the chemical plant according to this method. When adding a safety measures after risk assessment, prepared method can determine a valid location to stop the fault propagation.

3 PROPOSED SYSTEM

3.1 *Add function to HAZOP system*

HAZOP analysis is a technique to identify hazard by using 'deviation' from the design intent. HAZOP used in the preliminary safety assessment of new plant or modification to existing ones. HazopNavi was developed to clarify the operation, behavior of the chemical plant (Kawamura et al. 2008).

Deviation is expressed 'guide word' and 'process parameter'. Guide word is a keyword used in analysis. Process parameters are flow, pressure, temperature and etc. In analysis, deviation is applied the pipe that is a part of process and propagated next equipment. Fault propagation is process that deviation is propagated. Fault propagation is used to identify hazards and to assess safety measures in HAZOP (Isshiki et al. 2013). Figure 2 shows the model expressing HAZOP analysis. This proposed system analysis is based on the HAZOP information and safety guards system arrangement. When hazards in plant are identified, at the same time, it can be recognized the location that safety measures work.

The instruments and equipment are arranged in the process for control to operate. If the deviation is propagated, the change and the propagation of the deviation are defined by each of the internal function of the equipment. Then the fault propagation consist of the deviation that perform safety guards system, the data is stored in the system database.

The following shows these procedures.

1. "Deviation" is defined
2. "Deviation" is converted into electrical signal
3. It performs control equipment, "Deviation" propagate safety measures
4. Parameter indicating by instrument is controlled.
5. The information of HAZOP analysis is stored in the risk information data base.

Using result by HAZOP system, the fault propagation scenario is created. The information of propagation is stored to the data base in the system. The analysis result shows the cause of propagation and identifies the hazards by the database. From this data base, it can remove the necessary information to create scenario tree. The proposed system creates the scenario tree of fault propagation automatically. This scenario tree system is developed to calculate automatically the accident frequency quantitatively. The model of the fault propagation scenario is created from many results of HAZOP system. It is shown in Figure 3. Ei0 is

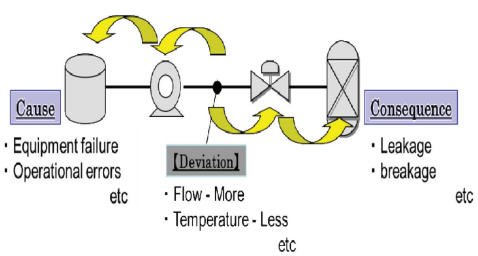

Figure 2. HAZOP analysis.

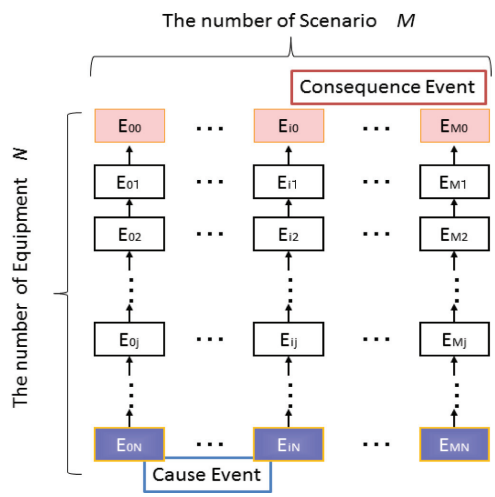

Figure 3. The model of fault propagation scenario.

the consequence event and EiN is the cause event in the fault propagation scenario. In this scenario tree system, it is possible to create a scenario tree indicating the cause of multiple hazards using fault propagation scenarios. Figure 4 shows scenario tree created from the propagation scenario. First the branch conditions are determined. When the system is generating the scenario tree, the scenario with the same consequence event is detected from the database.

To search information of hazards in the database is repeated. It is retrieved in the same way about branch condition. A search with some conditions perform on all equipment in the fault propagation scenario. By using the fault propagation scenarios, it is cleared that there are multiple causes for one consequence event. To visualize the position of the equipment that causes the fault propagation in chemical plant is very important. Since effect of fault propagation involved in the equipment becomes clear, it is possible to determine where to add new safety equipment by this technique. The safety equipment that located in a higher place from a branch point in the scenario tree can reduces the probability of hazard to two or more scenarios.

3.2 *Calculating the probability of consequence event*

3.2.1 *One cause event in the scenario*

There is one consequence event and one cause event in the fault propagation scenario. In this case, the probability of consequence event is as equal to the probability of cause event. This is the unavailability of the equipment causing failure. The unavailability of the cause equipment is given by $\overline{A}$. The probability of consequence event is expressed by (1) when the safety measure is not installed in the scenario.

λ = Failure rate of the cause equipment,

μ = Repair rate of the cause equipment,

MTTR = mean time to repair

P = the probability of occurrence of the consequence event

$$P = \overline{A}$$

$$\overline{A} = \lambda \times MTTR = \frac{\lambda}{\mu}$$

$$P = \lambda / \mu \tag{1}$$

There are more than one cause event in the scenario tree. The probability of occurrence of consequence event is equal to the sum of the probability of occurrence of each cause event as expressed in (2).

$$P = \sum_{i=1}^{n} (\lambda_i / \mu_i) \tag{2}$$

3.2.2 *One cause event and one safety measure in the scenario*

The probability of occurrence of hazards depends on the allocation of the safety measures in fault propagation scenario. By calculating likelihood of fault propagation scenario, the proposed system conduct evaluation of the risks which consider reliability of existed safety guards system in chemical plants.

In order to calculate probability safety measures, the PFD (Probability of Failure on Demand) is installed to calculate. The PFD means the probability that the equipment does not work properly when it is required (CCPS 2001). The PFD used on this system reference to "Guidelines for Process Equipment Reliability Data with Data Tables" (CCPS 1989). The Probability of consequence events caused by equipment failure can be calculated by equation (3).

λ = Failure rate of the cause equipment,

μ = Repair rate of the cause equipment,

P = the probability of occurrence of the consequence event

$$P = (\lambda / \mu) \times a \cdot 10^{-3} \tag{3}$$

3.2.3 *One cause event and more than one safety measures in the scenario*

In the scenario tree, there is one consequence event and one cause event. Safety measures placed more than one in the fault propagation scenario. And they work effectively. The probability of occurrence of consequence event is given by equation (4).

N = the number of safety equipment placed in the scenario tree

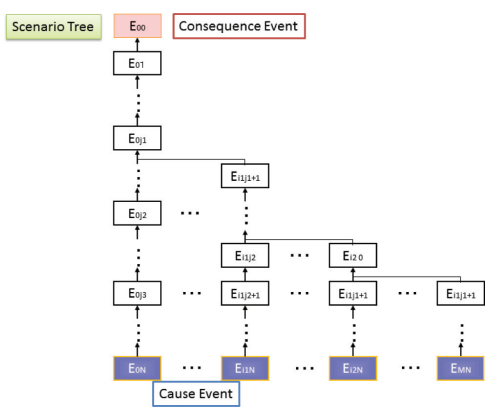

Figure 4. Scenario tree created from fault propagation scenario.

When the safety equipment does not exist, i.e., n = 0, PFD0 = 1

$$P = (\lambda / \mu) \times \prod_{i=0}^{n} PFD_i \tag{4}$$

3.2.4 *More than one cause event and safety measures in the scenario*

The safety equipment is placed appropriately in the fault propagation scenario. At this time, it will be expressed in the same tree that the same equipment causes failure in the scenario. There are more than one cause event and safety measures. Then the formula that calculates the probability of consequence event is generalized by (5).

$$P = \sum_{i=0}^{M} \left\{ \left(\lambda_{in_i} / \mu_{in_i} \right) \times \prod_{j=0}^{L_i} PFD_{ij} \right\} \tag{5}$$

3.3 *Changes in the probability of occurrence*

Therefore the system can calculate the probability of the effect of reducing the hazard by arranging the safety equipment. When the safety equipment is installed to control "deviation" in fault propagation scenario, the probability of occurrence of hazard of that scenario is reduced. The probability of occurrence of hazard varies depending on the placement of the safety equipment for the branch of the scenario tree. When safety measures are located on the side of the cause event branch, it works for only one scenario to reduce the probability of occurrence hazard. When safety equipment is located on the side of the consequence event, it works for more than one scenario to reduce the probability of occurrence hazard. When safety measures are placed to work effectively to the fault propagation, they can reduce the risk of hazard.

4 CASE STUDY

4.1 *Analysis range*

This method is supposed to the ethylene production plant. Analysis range is shown in Figure 5.

Prerequisite at this time is as follows.

1. Chemical plant analyzed by this system is a continuous operation plant.
2. The safety measures and the control system are analyzed in this investigation. (For example, safety valve and transmitter, instrument, control cable, and control valve)
3. All sensors are in order.

Safety measures are defined not to prevent hazard identification. Safety valve function linked parameter "pressure-more".

After the HAZOP analysis including safety measures, the information of a safety measures

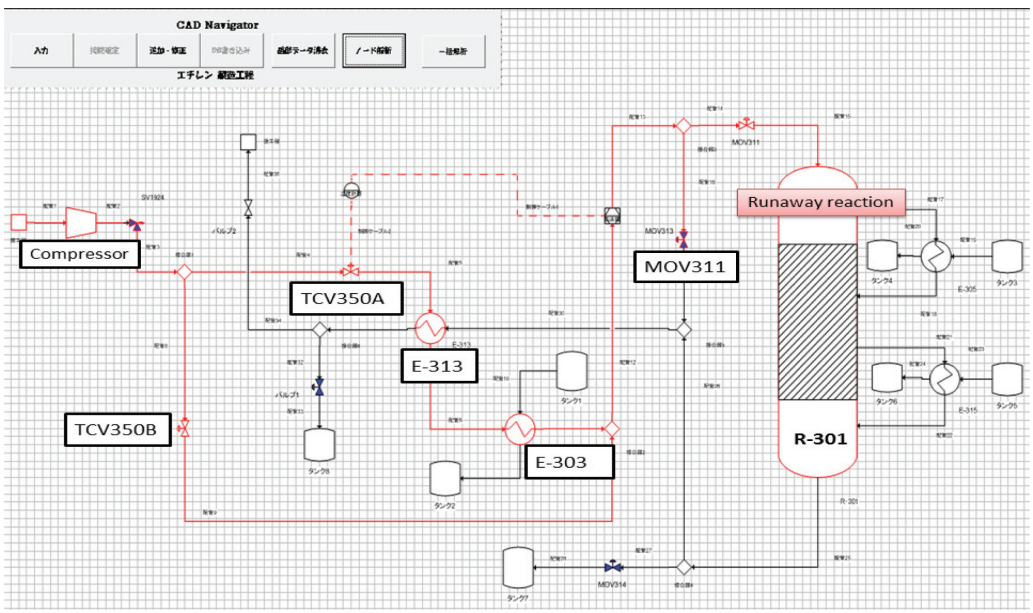

Figure 5. Analysis range in the ethylene production plant.

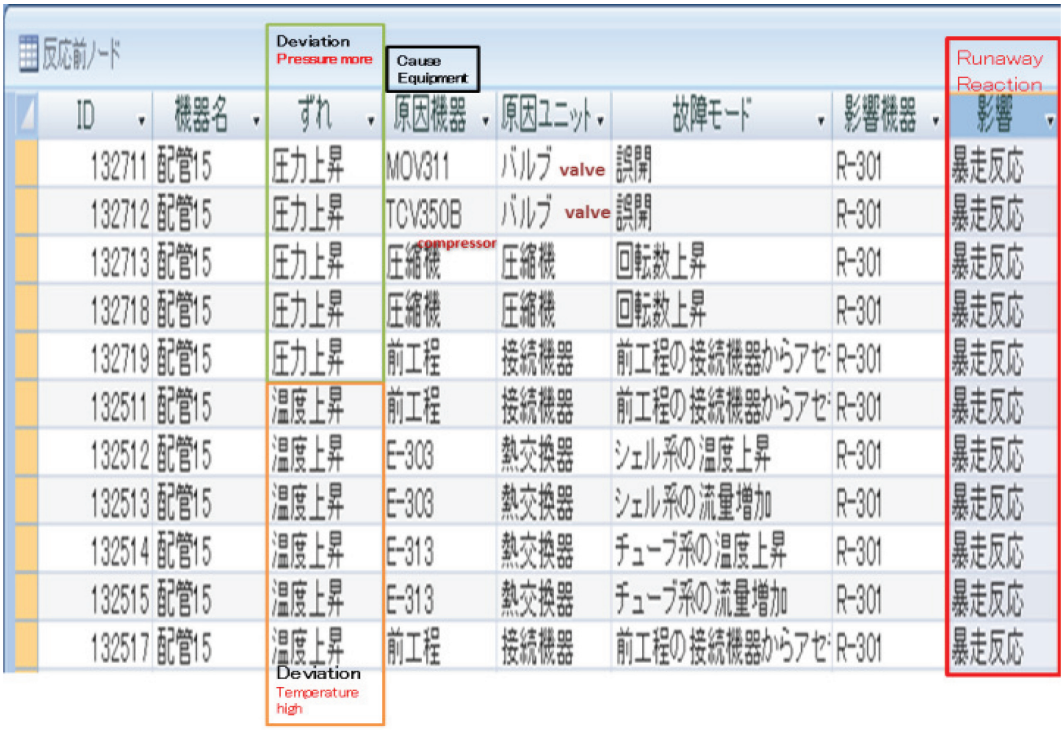

Figure 6. Fault propagation scenario.

is stored as a result. Repeat HAZOP analysis in the analysis range, the fault propagation scenario that has a top influence event in the reaction vessel of "runaway reaction" is created. The scenarios created are shown in Figure 6. By using the fault propagation scenario, the scenario tree including the safeguards equipment is created. This system can calculate the probability of the consequence event.

Figure 7 shows the scenario tree.

The probability of consequence event in the scenario tree is calculated according to equation (5). The probability of consequence events is obtained by summing the probability each scenario including the safety measures. Two deviations propagate in the scenario tree in Figure 7. The deviations are "temperature high" and "pressure more". There are seven cause events in the analysis range in Figure 7.

The probability of consequence event in the scenario tree is calculated according to equation (5). The probability of consequence events is obtained by summing the probability each scenario including the safety measures. Two deviations propagate in the scenario tree in Figure 7. The deviations are

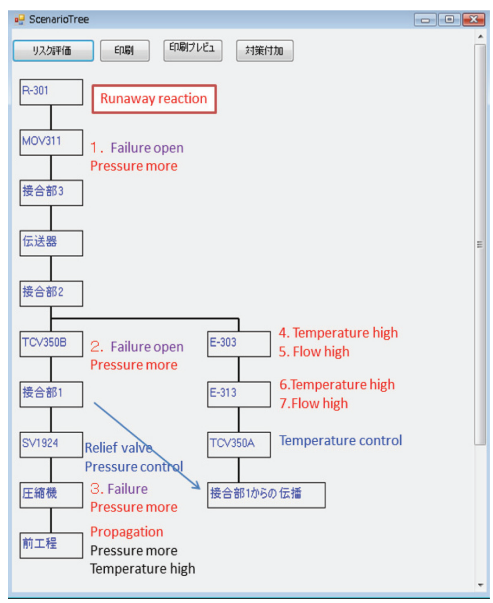

Figure 7. Scenario tree of the ethylene production plant.

"temperature high" and "pressure more". There are seven cause events in the analysis range in Figure 7.

The probability of occurrence of a runaway reaction in the reactor R-301 is calculated as follows.

1. MOV311: $P_1 = (\lambda_1/\mu_1) \times \mathrm{PFD}_0$
2. TCV350B: $P_2 = (\lambda_2/\mu_2) \times \mathrm{PFD}_0$
3. Compressor: $P_3 = (\lambda_3/\mu_3) \times \mathrm{PFD}_1$
4. E-303: $P_4 = (\lambda_4/\mu_4) \times \mathrm{PFD}_0$
5. E-303: $P_5 = (\lambda_5/\mu_5) \times \mathrm{PFD}_0$
6. E-313: $P_6 = (\lambda_6/\mu_6) \times \mathrm{PFD}_0$
7. E-313: $P_7 = (\lambda_7/\mu_7) \times \mathrm{PFD}_0$

$$P = \sum_{i=1}^{7} P_i = 0.00072 / \mathrm{year}$$

Therefore the probability of occurrence of the top event of this scenario tree is 0.00072 per year.

This result can be used for risk assessment in risk management.

5 CONCLUSION

In this study, we have proposed the risk assessment system for verifying the safety guards system based on the HAZOP analysis information. The system is developed to identify hazard and to calculate the probability of occurrence of consequence event. Safety guards system is installed in the existing chemical plants in operation. The effect of safety guards system is evaluated explicitly by using our system. This paper can clearly explain elucidated the linkage between the fault propagation and safety measures. It becomes possible to add information of the arrangement of the safety measures in fault propagation scenario without interfering hazard identified by them. The method included here can create a scenario tree based on the fault propagation scenario automatically. The scenario tree shows the placement of the equipment of the plant with safety measures. As a result of the analysis by the method included in this paper will become possible to consider the best placement of safety measures. Result of calculation by this method is the occurrence probability of the hazard based on the information of safety measures placement. This proposed method can re-evaluate the risk of chemical plants currently in operation. If an accident occurs, emergency shutdown is required rapidly. Furthermore, accident prevention is necessary not only for chemical plant and but also other industrial facilities. But still there exists the possibility that unexpected accident could occur in chemical plants. Therefore risk management is required to recognize and to examine all the angles of the situation in the plant. It is expected that the proposed method will become valid for this purpose and present useful information to support for plant operation.

Development of the Safety Requirements Specification (SRS) in oil and gas industry

E.H. Park, K.P. Chang & S.T. Kim
Advanced Technology Institute, Hyundai Heavy Industries, Yongin-si, Gyeonggi-do, Korea

ABSTRACT: This paper presents the technical interpretations for Safety Requirements Specification (SRS) preparations in oil and gas industries based on international standards such as IEC 61508, 61511, and OLF 070. Development of SRS is an important activity to design the Safety Instrumented System (SIS). Some difficulties are explained to reflect international standards and fulfill all requirements of the standards in SRS during design phase of oil and gas plant. A new approach suggests a feasible systematic approach for SRS preparation to satisfy the safety requirement clauses by using case study. Also, an example of SRS based on above methodology is provided.

1 INTRODUCTION

The importance of safety systems has been gradually increasing in oil and gas industry. In general, safety systems, which are different and independent from each other, are considered to provide multiple protection layers. The typical multiple protection layers installed in oil and gas facilities are BPCS (Basic Process Control System), SIS (Safety Instrumented System) and Physical Mitigation System.

BPCS is a system which handles process control and monitoring for oil and gas facilities. SIS is a system composed of sensors, logic solvers and final elements to keep "people", "environment", "assets" in safe conditions during operation periods often oil and gas facility. Physical mitigation system is a system which consists of active fire protection and fire/blast walls. Among the various multiple protection layers, SIS is the most important and critical protection layer to prevent or reduce the risk of abnormal process condition which may be hazardous. A variety of SISs are installed in the oil and gas plants such as fire & gas system, emergency shutdown system and process shutdown system. SIS is the next layer of protection following BPCS and alarm/operator intervention.

In accordance with IEC 61508/61511, the overall required safety management and proper technical activities relates with all documentation for SIS are summarized in safety life cycle. The purpose of analysis phase is to identify hazards and assess safety requirements of SIS. Safety Requirements Specification (SRS) of SIS should contain critical information which includes functional description of each System Instrumented Function (SIF), target SIL, mitigated hazards, process parameters, maintenance requirements, response time, etc. Next phase of safety life cycle is the realization of SIS based on SRS results. All performance targets and functional requirements defined in SRS are the key information for design, installation and operation of SIS. The development of the SRS is one of the most important activities during the design of SISs. If important information regarding safety protection is missing, the design of the SIS may not be performed in a safe way.

According to the study by Health and Safety Executive (HSE) in the United Kingdom, improper SRSs are classified as the most significant cause of accident relating to control systems including SIS. Therefore, demands for well-prepared SRS are increasing in oil and gas industry.

However, there is lack of practical guidelines or systematic approaches to prepare SRS based on the technical interpretations of standards such as IEC 61508/61511 and OLF 070. For example, most standards just give a requirement description and the list with general level. On the other hand, more detail and quantitative information should be prepared and involved in SRS. Therefore, there are always technical gaps between detail SRS preparation and general guidance summarized in the standards during practical oil and gas projects.

So, the objective of this paper is to provide effective way to prepare SRS which can save cost and time. It is expected that this new approach reduces difficulties to prepare the SRS, and make the procedure of safety documentation simple. An example of SRS preparation is provided briefly.

2 SRS GUIDANCE REQUIREMENT REVIEWS

2.1 *Review of safety standards for SRS*

The general contents of SRS are based on standards such as IEC 61508, IEC61511 and OLF 070. The definition of SRS is given in the IEC 61508 (2010), "specification that contains all the requirements of the safety instrumented functions that have to be performed by the safety instrumented systems." Also, the objective of SRS preparation is stated in the IEC 61511 (2003), "The SRS shall specify all requirements of safety instrumented systems, SIS, needed for detailed engineering and process safety information purposes." According to these standards, it is important that the documentation covers all safety aspects to be addressed during the safety lifecycle. In OLF 070 (2004), the SRS contents are the same as IEC 61511 (2003). Typically, the SRS of a SIS includes requirements for design, reliability, availability, installation, testing, maintenance, hardware specification, software development, and so on. The requirement is quite clear in the IEC 61511-1 (2003), chapter 10.

The SRS are divided in two components such as general parts and specific parts. The input information and general requirements are applicable to all SIFs implemented by SISs. Each SIF must fulfill specified functional requirements and integrity requirements.

The specific requirements for SIF are divided in three parts: requirements of function, safety integrity and software safety. Therefore, main content of SRS for SIF should involve quantitative safety integrity requirements as well as functional ones. The SRS input requirement documentation is used to give detailed information regarding functional requirements. These functional requirements consist of safe state, response time, reset function, trip point, output actions, etc. The integrity requirements for the SRS include assigned SIL, reliability requirements, demand mode, proof testing, environmental stress, and so on. The application software safety requirements are specified in IEC 61511-1 (2003), chapter 10.3.1. Several critical requirements such as common cause failure, spurious trip rate, response time and so on are discussed in Appendix A. The specification should be sufficiently detailed to allow the design and implementation to achieve the required safety integrity and the assessment of functional safety.

2.2 *Safety requirements in IEC 61511-1*

SRS contains three types of requirements such as functional requirements, integrity requirements and software safety requirements. The description of the requirements in IEC 61511-1 (2003) is presented in Table 1. The following contents consist of 27 requirements and include general/specific requirements.

The safety requirements specification is followed by SIL assignments in the safety lifecycle. In order to fulfill a complete SRS, the required safety input information should be accessible. A typical set of input information includes process conditions, existing hazards, required SISs, required SIFs,

Table 1. Description of the requirements (ref. IEC 61511-1).

	Description of Requirements (IEC 61511-1)
SRS-1	Description of all the SIFs
SRS-2	Identify common cause failure
SRS-3	Definition of the safe state of the process (each SIF)
SRS-4	Definition of any individually safe process state (create a separate hazard)
SRS-5	Assumed sources of demand and demand rate
SRS-6	Requirements for proof-test interval
SRS-7	Response time requirements
SRS-8	The SIL and mode of operation for each SIF
SRS-9	Description of SIS process measurements and their trip points
SRS-10	Description of SIS process output action and criteria for successful operation
SRS-11	The functional relationship between process inputs and outputs
SRS-12	Requirements for manual shutdown
SRS-13	Requirements relating to energize or de-energize to trip
SRS-14	Requirements for resetting the SIS after a shutdown
SRS-15	Maximum allowable spurious trip rate
SRS-16	Failure modes and desired response of the SIS
SRS-17	Any specific requirements for starting up and restarting the SIS
SRS-18	All interfaces between the SIS and any other system
SRS-19	Description of the modes of operation and identification of the SIFs required to operate within each mode
SRS-20	The application software safety requirements
SRS-21	Requirements for overrides/inhibits/bypass
SRS-22	The specification of any action necessary to achieve or maintain a safe state
SRS-23	The mean time to repair
SRS-24	Identification of the dangerous combination of output states
SRS-25	The extremes of all environmental conditions
SRS-26	Identification to normal and abnormal modes and individual plant operational procedure
SRS-27	Definition of the requirements for any SIF necessary to survive a major accident event

target SILs, common cause failures, and so on. This input information is taken in various documents such as P&ID, HAZID/HAZOP report, C&E charts, logic diagrams, etc.

2.3 *SRS documentation*

The SRS is prepared before hazard and risk analysis and the allocation of safety function to protective layers in the safety lifecycle according to IEC 61511-1 (2003). It is important that the documentation covers all SIFs to be addressed during the safety lifecycle. After completing the risk analysis and SIL allocation, the SRS is created and updated according to the procedure in Figure 1. Revision process of SRS is needed in each phase according to the safety lifecycle. The average number of revisions is commonly more than 5 times.

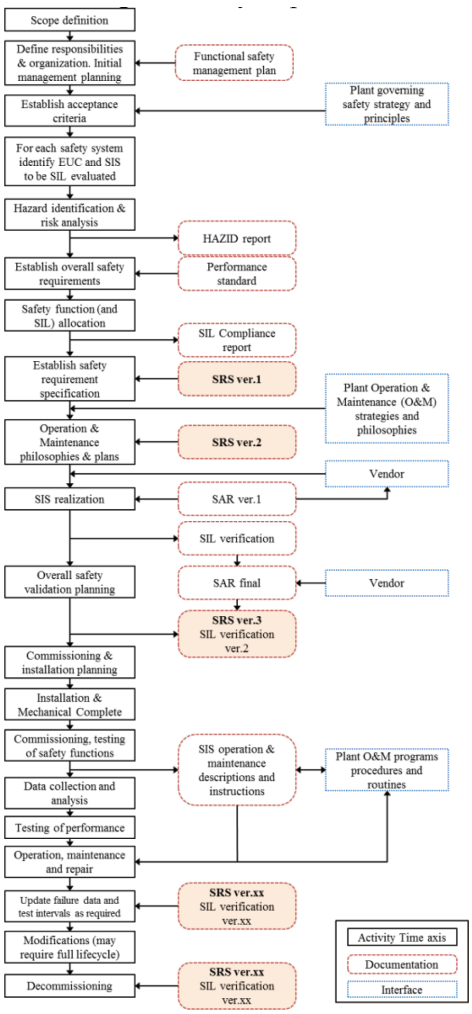

Figure 1. Procedure of SRS documentation (OLF 070 2004).

Generally, the SRS contains the relevant information to specify and operate the instrumented safety functions and provides the basis for design. The required information for the SRS is normally included in previous documents such as HAZID report, SIL compliance report, and so on. Most of the required contents of the SRS would not be available during early project phases because the actual data is not reflected on these documents. The SRS document is subject to follow-up and updating by vendor data through all lifecycle phases of the SIS.

Also, the SRS is an important document for the validation process. The SRS must cover all safety aspects for the actual SIS. During the validation phase, the SRS is served as the reference to check where the safety requirements are implemented in the SIS.

3 SUGGESTION OF MODIFIED FORMAT FOR THE SRS

3.1 *Problems of conventional SRS format—Comparison between IEC 61511 and practical projects*

The elements of SRS described in IEC 61511 are selectively involved based on characteristics of projects with respect of practicality. All requirements are not always engaged in practical projects during preparation of SRS documentation.

There is information of practical projects in Table 2. SRSs containing different contents are summarized in Table 3. If the requirement agrees with IEC 61511, circle is marked. And if the requirements have differences, it is X. The triangle is shown when the requirement is matched with a part of the IEC 61511. As shown in Table 3, requirements for SRS documentation differ from each project. For instance, although all 27 requirements can be mentioned in SRS documentation

Table 2. Details about 3 practical projects.

	Project A	Project B	Project C
Onshore/ offshore	Offshore	Onshore	Onshore
Site	Norway	United Arab Emirates	Saudi Arabia
Division	Oil & Gas production facilities	Gas processing plants	Refineries

Table 3. Comparison of requirements between IEC 61511 and practical projects.

IEC 61511	Project A	Project B	Project C
SRS-1	O	O	O
SRS-2	O	O	Δ
SRS-3	O	O	O
SRS-4	O	Δ	X
SRS-5	O	O	O
SRS-6	O	O	O
SRS-7	O	O	O
SRS-8	O	O	Δ
SRS-9	O	O	O
SRS-10	O	O	Δ
SRS-11	O	O	O
SRS-12	O	O	O
SRS-13	O	O	O
SRS-14	O	O	O
SRS-15	O	O	O
SRS-16	O	X	O
SRS-17	O	O	X
SRS-18	O	O	X
SRS-19	O	O	O
SRS-20	O	O	X
SRS-21	O	O	Δ
SRS-22	O	X	X
SRS-23	O	O	Δ
SRS-24	O	O	X
SRS-25	O	O	X
SRS-26	O	X	X
SRS-27	O	X	X

like project A, some requirements may be omitted in SRS documentation like project B or C. Also, some requirements are added to the SRS contents in project C.

Some contents which are related to SIF, safe state, proof test interval, response time, manual shutdown, and etc. are commonly included as main requirements in all projects. However, safe process state, additional action, normal/abnormal mode and major accident event are sometimes dropped. There are some occasions that new requirements are often added to SRS such as design intent, consequence of failure and so on.

Therefore, if all of the requirements in IEC 61511 are used as the format for SRS, there are a few difficulties. Although most of functional requirements for SRS can be handled, there are still concerns to miss some elements relating to integrity requirements. These include diagnostic coverage, maintenance requirements, concrete proof testing and reliability requirements, which may lack on the conventional SRS format as described in Table 4. Therefore, SRS format would be modified to include any necessary elements for integrity requirements which can be used in SIL verification followed by SRS documentation.

If input information for SRS is not available, the requirement must assume the empirical values with approximation. These assumptions may induce uncertainties of the elements.

Some requirements covering similar topics exist in IEC 61511. These are composed of several categorized items with similar subject. However, information on the requirements is redundant. This redundancy is unreasonable in terms of waste

Table 4. Suggested requirements for the SRS.

No.	IEC 61511	Suggested requirements
1	SRS-1, 10, 11, 24	Description of all the SIFs (Initiator, logic solver, final element)
2	SRS-2	Identify common cause failure
3	SRS-3, 4, 22	Specification of the safe state of the process and any action to achieve or maintain a safe state
4	SRS-5	Assumed sources of demand and demand rate
5	SRS-6	Requirements for proof testing(Interval, Coverage)
6	SRS-7	Response time requirements
7	SRS-8, 19	The SIL and mode of operation for each SIF
8	SRS-9	Description of SIS process measurements and their trip points
9	SRS-12	Requirements for manual shutdown
10	SRS-13	Requirements relating to energize or de-energize to trip
11	SRS-14	Requirements for resetting the SIS after a shutdown
12	SRS-15	Maximum allowable spurious trip rate
13	SRS-16	Failure modes and desired response of the SIS
14	SRS-17	Any specific requirements for starting up and restarting the SIS
15	SRS-18	All interfaces between the SIS and any other systems
16	SRS-20	The application software safety requirements
17	SRS-21	Requirements for overrides/inhibits/ bypass
18	SRS-23	The mean time to repair
19	SRS-25	The extremes of all environmental conditions
20	SRS-26	Identification to normal and abnormal modes and individual plant operational procedure
21	SRS-27	Definition of the requirements for any SIF necessary to survive a major accident event
22	-	Requirements for partial stroke testing (Interval, Coverage)

of time and cost consumption. Duplication of information should be avoided for managing the safety lifecycle as efficient ways. Therefore, process of integration to combine the redundant elements into one is needed.

3.2 *Suggestion of modified format*

It is necessary to define SRS elements thoroughly because there is no specified format in filling with the SRS. The duplicated requirements are removed and the necessary requirements are supplemented through the analysis in IEC 61511.

Incomplete elements that have deficiencies in existing format are eliminated by adding others which can reflect integrity requirements. Furthermore required data for the following phase is SIL verification, is added. Partial stroke testing and proof test coverage, for example, are supplemented in order to relieve the problem of insufficient integrity requirements.

Proof Test Coverage (PTC) is conditional probability that a DU fault will be detected by proof tests, given that the fault is present when initiating the proof test. PTC can also be expressed as the percentage of DU faults which will be detected by proof test among all the DU faults which are present when the proof test is initiated.

Partial Stroke Testing (PST) is sometimes used as a supplement to full proof testing of safety valves.

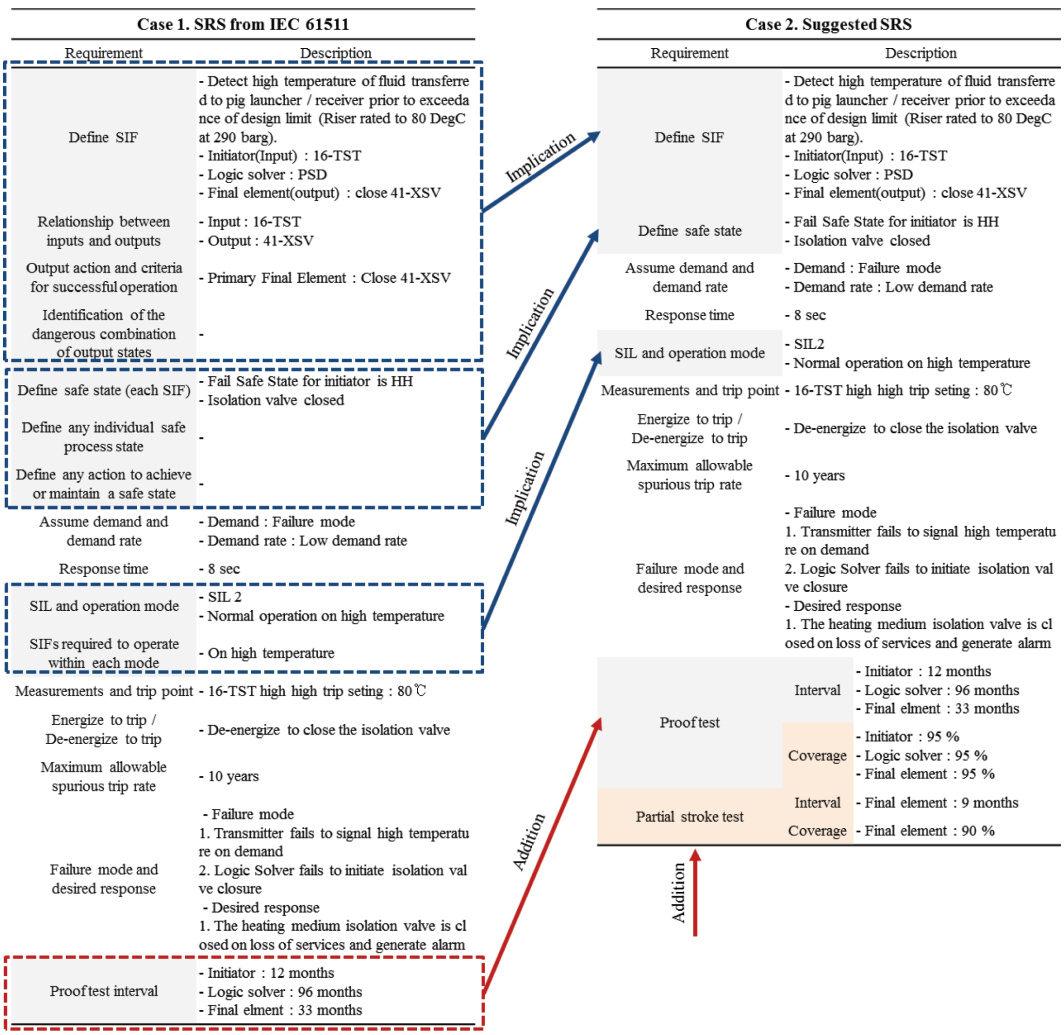

Figure 2. Case study for comparison with IEC 61511 and suggested SRS.

PST is performed by partially opening or closing a valve and returning the valve to the initial position. Assumptions related to PST coverage should be made for plant specific application rather than for an average valve performance in ISA-TR-84.00.03. The PST coverage is typically in the range of 60% to 70% (Summers & Zachary, 2000).

The requirements related to duplication topics are integrated into a single requirement as follows to prevent duplication of contents.

For instance, the similar requirements (SRS-4, SRS-10, SRS-11, SRS-19, SRS-22, SRS-24) are deleted according to the previous analysis. The value of input is described in the SRS-5 and the description of the output is SRS-10. The contents of SRS-5 and SRS-10 have the same contents as SRS-11's. Also, SRS-10 and SRS-24 describe SIS process output actions. SRS-3 and SRS-4 are definitions of the safe state of the process and SRS-22 is the specification of any necessary action to achieve or maintain a safe state. These requirements are similar to each other. Moreover SRS-8 explains SIL and mode of operation and SRS-19 does the latter. Thus, SRS-4, SRS-10, SRS-11, SRS-19, SRS-22 and SRS-24 can be omitted.

3.3 *Advantages of modified format*

All requirements for the SRS in IEC 61511 are difficult to fulfill. The conventional format has some problems regarding incompleteness, uncertainty and duplication. This paper proposes a modified format of the requirements to solve these problems.

Figure 2 shows case study for comparison with IEC 61511 and suggested SRS. The case study is carried out to compare specific requirements for the same SIF. Some requirements combine several similar requirements into one in the suggested SRS format. The requirements related to proof test and partial stroke test are added to the SRS, respectively. Therefore, the list of suggested requirements has simpler form than the conventional one.

Also, the brief list of the requirements can be bigger profit in time and cost when the number of SIF and revision of the SRS is great. Table 5 shows that there is acquirable profit by modifying the SRS. Total saving cost has been calculated by *(Total saving costs) = (Average number of SIFs) X (Reduced analysis time) X (Average number of revision) X (Daily rate)*. If the number of revisions increases, the saving cost will also increase.

Also, the new requirements, proof test coverage and partial stroke testing, are added to the original requirements. They are usefully available value in SIL verification phase.

The suggested requirement format keeps it simple while holding more contents. Management for safety lifecycle can be more convenient and time to prepare and update the SRS can be reduced by the change of format.

Table 5. Suggested requirements for the SRS.

Cost item	Value
Average number of SIFs	200
Reduced requirements	5
Reduced analysis time for each SIF (day)	0.03
Average number of revisions in the safety management plan	5
Daily rate for SRS (USD) (These daily rates are based on 8 hours per day)	2000
Total saving cost (USD)	60,000

4 CONCLUSIONS

SRS should be developed to cover all Safety Instrumented Functions (SIFs). The SRS, based on the contents from standards, has been set but the format has not yet been decided. This paper notes that some difficulties, such as incompleteness, uncertainty and duplication of the requirements in the standard, can be revealed through the analysis for the requirements of SRS. The modified format for the SRS is suggested in order to improve the problems. Multiple requirements dealing with similar topics are integrated and simplified. Moreover, systematic data management can be performed by adding other necessary elements for SIL verification. The suggested requirement format is simpler than the conventional one while holding more contents and management for safety lifecycle can be more convenient. Additional advantage by the change of proposed format is that time to prepare and update the SRS can be reduced.

Analyses in this study are performed to develop the format for the SRS. Some methodologies are suggested to obtain the values for several critical requirements such as common cause failure and spurious trip. However, the approach method for all of the requirements could not be described in more detail because there is no prescribe way for each requirement. A methodology which minimizes the incompleteness and uncertainty between practical data and assumed requirement should be developed. The development of the methodology for each requirement will be discussed in the further study.

Development of functional safety standards for civil engineering

E. Nachtigall
Quantum Brandschutz GmbH, Basel, Switzerland

V. Shcherbina
WASCS Research Center, Moscow, Russia

ABSTRACT: Functional safety, as well as other topics related to safety, usually considered in each industry and also on the level of different standalone systems separately. Thus, each developer considering, basically, only their systems without take account adequately the relationship with other safety systems in buildings. Current standards for safety systems in buildings also do not include a comprehensive approach to safety systems. The aims of the paper are to present why functional safety methods are necessary for development of safety-related systems in civil engineering. Moreover, such methods are to develop in order to manage the increasing complexity of safety-related systems in modern buildings. The paper presents recent developments in the Russian Federation and describes ready to use, GOST R 53195 and interrelated standards focused on functional safety of safety-related systems in buildings.

1 INTRODUCTION

The approach to standardization of functional safety of systems as properties of those systems to fulfill the safety functions in an environment during an interval of time with the established probability (safety integrity) appeared at the very end of the XX century (Smith & Simpson 2004 and Börcsök 2007). A milestone in this approach was the development of IEC 61508 series for functional safety of the electric/electronic/programmable electronic safety-related systems (IEC 2010). This approach began to develop rapidly.

Now there are about 200 standards in more than 40 sectors of standardization of ISO and IEC in this field e.g. IEC (2000, 2005, 2007, 2008, 2012). The key features of standards are: implementation of an iterative process of the analysis of dangers and risks, the general assessment of risk and taking measures to decrease the risks to an acceptable level (according to ISO/IEC Guide 51 on safety aspects), and also the possibility of ensuring management of risk by repeating regular processes at all stages of the life cycle of systems and their components (Rolle 2013a).

Many procedures of risk management have been implemented in different areas after development of ISO Guide 73, ISO 31000 and ISO 31010 ISO (2009, 2011), Hasofer & et al. (2007). Also the acceptance of risk management methods given in those standards, which are related to standards of functional safety, has increased. In IEC according to Administrative Circular AC/7/2004 and Administrative Circular AC/33/2013 steps for transition from standardization of separate units of production to standardization of systems in which separate units of production (components) are structurally and functionally interconnected to work in the common uniform system for ensuring requirement are taken.

Thus, now there are all prerequisites for standardization and sustainable development of complex sociotechnical systems with use methods and means of risk management for safety.

The international standardization in the construction branch develops more slowly, than in other branches. Perhaps it generated a certain conservatism of thinking because of centuries-old traditions in one of the most ancient and, general successful activity of the people. In civil-engineering branch standards are traditionally developed in groups, whose interests often coincide, and members of the group are often from the same industry.

For example, developers and the technical committees of developing standards of automatic fire alarm systems, as a rule, for several reasons don't consider existing functional safety approaches described in IEC 61508 or other standards, claiming that sufficient reliability of systems is completely ensured with their compliance to national norms and standards of the branch ISO/IEC (2009), Rausand & Hoyland (2004).

Thus, each developer of standards and the producer of systems consider, generally only their systems without adequately taking into account

the relation with other safety-related systems in buildings. We know from the general theory of systems, that the properties of system cannot be completely defined by the sum of properties of its components (Ropohl 2012). Therefore there is no possibility to evaluate the level of functional safety or life and fire safety in the building without considering multiple interconnections of the fire alarm system with other systems, such as a fire extinguishing system, smoke extraction systems, security systems etc. (Nachtigall 2013b).

2 COMPLEX APPROACH TO FUNCTIONAL SAFETY IN CIVIL ENGINEERING

Systematic, comprehensive approach to functional safety, systems safety and security of buildings and structures can be seen in a series of national Russian basic standard GOST R 53195 "Functional safety of building/erection safety-related systems" (Shcherbina, Puzyrevskaya, Lubimov, & Matveev 2011, Nachtigall 2013a). The series consists of seven parts, five of which are already in place, and two additional parts are planned for development. Below the seven interrelated parts of the standard are listed.

- Part 1: General
- Part 2: General requirements
- Part 3: Requirements for systems
- Part 4: Software requirements
- Part 5: Techniques and measures on risk reduction, estimation methods
- Part 6: External resources for risk reduction, monitoring systems
- Part 7: Application requirements, sample calculations.

In parts 1 and 2, both first developed in 2008 general definitions and requirements of the standard are given. Parts 3 and 4 define requirements for hard- and software of safety-related systems used in buildings and constructions. In part 5 techniques and measures on risk reduction for those systems are presented. Parts 6 and 7 are in development. The focus of those parts is on methods for risk reduction and monitoring of systems as well as on application requirements and sample calculations.

The basis of GOST R 53195 laid down the basic definitions, philosophy, approaches and methods in accordance to IEC 61508 series, the requirements for quality assurance according to ISO 9000, safety aspects according to ISO Guide/IEC 51 (ISO 1999), with respect to the specificity and demands of civil engineering. During development of GOST R 53195 since the year 2008, current standards as e.g. ISO/IEC 14762 (ISO/IEC 2009) as well as experiences of applications from standards IEC (2000, 2005, 2007, 2008) were taken into account in the development process.

Standards focus on specifications providing improvements of safety to people and properties. They provide methods for analysis of hazards, risks and quantifying the safety of technical means to ensure the safety of buildings and erection or structures in order to achieve an acceptable level of safety, and provide a systematic approach to the facilities in civil engineering. Technical and safety related subsystems used in facilities of civil engineering are considered as systems of system. Also a holistic view of the entire system is given in Shcherbina, Lubimov, Puzyrevskaya & Matveev (2012).

3 TWO TYPES OF APPROACHES TO SAFETY AND RISK REDUCTION AS APPLICATION OF GOST R 53195

Production as a result of activity differs in industrial and construction branches. In Figure 1 the lifecycle of production of industrial manufacturing is shown.

Goods of industrial production are usually created in the design office and made at the factory. Those goods can be tested for compliance to be used in any situation and places according to its specifications.

Such goods, usually of mass production, can be stored in a warehouse, transported and delivered to the consumer, including with crossing of customs borders (Meyna & Pauli 2010).

In contrast to the life cycle of goods of industrial production in civil engineering the lifecycle of goods differs. In Figure 2 a simplified lifecycle of production in civil engineering is shown.

Typically, the lifecycle in civil engineering for most stakeholders begins with some engineering surveys followed by the process of design. After the examination of the project the construction work follows. At the end of this phase installation

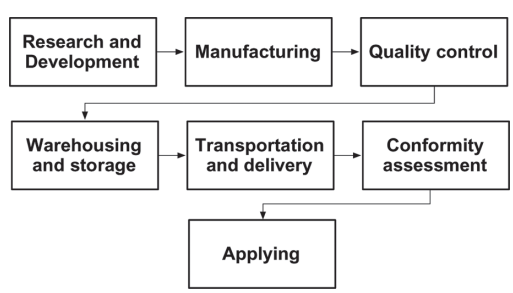

Figure 1. Life cycle of production of industrial manufacturing (after Ryan & Faulconbridge 2014).

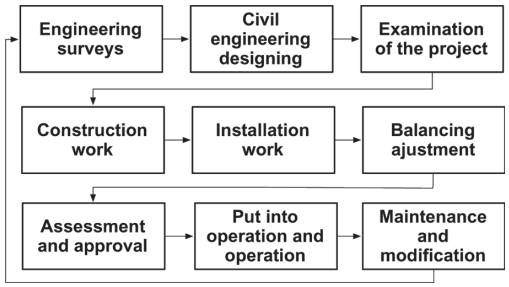

Figure 2. Life cycle of production in civil engineering (compare Mumovic & Santamouris 2009).

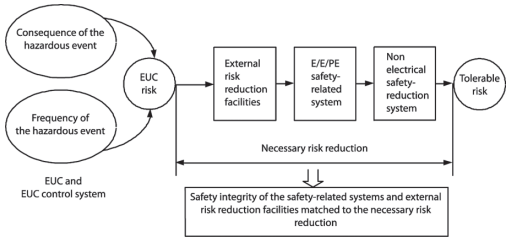

Figure 3. General approach to decrease risk (after DIN 1994, Börcsök 2007).

of technical systems is performed. This is followed by phases of adjustment, assessment and approval. Finally phases of put into operation, operation, maintenance and modifications start.

Due to different life cycles in industrial manufacturing and in civil engineering the approach to functional safety and risk reduction should take into account these differences.

In Figure 3 the general approach to decrease risk is shown.

In general, the risk is the result of a combination of consequence of the hazardous event and the probability of occurrence of these hazardous events. This combination influences the equipment under control risk. If this risk is higher than the tolerable risk, than necessary risk reduction measures are to apply to reach the tolerable risk level. To reach the tolerable risk level external risk reduction measures, the implementation of safety-related systems and the application of non electrical safety reduction systems are to be considered.

With a combination of measures and systems the risk level achieved is usually even lesser than the tolerable risk. In Figure 4 the relationships of risk and safety integrity are shown.

The actual risk reduction should usually be greater than the necessary. By judicious selection of shown modules the risk reduction achieved by all the safety-related systems and external risk

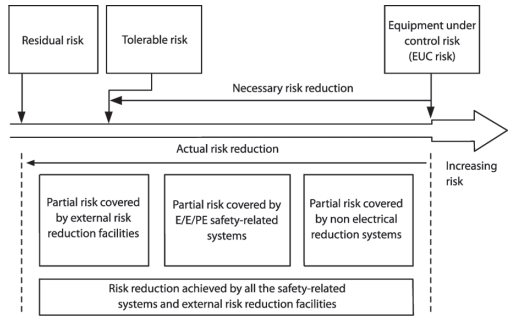

Figure 4. Risk and safety integrity (compare Börcsök 2007).

reduction facilities can be optimized especially for the needs of civil engineering.

During the process of evaluation of different risks not only the safety-related systems are to be considered. This is because in modern buildings many very complex and interrelated systems are usually used (Novak 2008). Therefore for different scenarios different initially non-safety or security-related systems can become crucial for safety or security. This results from the complexity of modern high performance systems in civil engineering. To take this into account GOST R 53195 provides methods and show examples of interrelated systems to consider different safety- and security-related scenarios and systems.

First practical applications of standard show positive experiences in modern and complex buildings. It is reported by the practical users that the use of standards real-world problems can be solved. Furthermore, it is reported that using the standards the safety can be significantly improved as a whole. Since the standards are new and still largely unknown, so far the application was limited to large objects that have an outstanding importance for national safety in Russia.

4 FURTHER DEVELOPMENT OF STANDARDIZATION

Along with independent application of the GOST R 53195 this standards created a basis for development of new standards for functional safety for special buildings and constructions.

Within National association of builders of Russia (NOSTROY), which itself is part of 270 self-regulating organizations uniting over 100.000 enterprises of the construction branch of Russia, the STO NOSTROY 2.35.73-2012 “Engineering networks of high-rise buildings. Systems of complex safety of high-rise buildings

and constructions." was developed and approved (NOSTROY 2014). Both authors of the presented paper are involved in the development and implementation of GOST R 53195 and STO NOSTROY 2.35.73-2012 in Russia and abroad. One of the authors is the coordinator of GOST R 53195.

The STO NOSTROY 2.35.73-2012 standard is applicable on safety- and security-related and other systems installed in high-rise buildings or constructions. Because of the importance of this type of buildings the engineering networks and other boundary conditions play a very important role to ensure the safety needs.

As features and factors influencing safety especially in high-rise buildings following examples can be listed:

- Difficult infrastructure of the building or construction and high saturation power-intensive engineering systems which may contain large volumes of harmful substances
- Large number vertically and horizontally directed supply channels which can be ways of fire propagation
- Vertical layout and natural updraft of air
- Large number of people in the high-rise building
- Limited possibility of safe evacuation of people from the building in emergency situations
- Lack of the effective technical means, allowing to organize rescue of people from high-rise buildings
- Attractiveness to carry out terrorist acts and actions of a criminal nature
- Possible considerable weight of consequences at realization of events doing harm.

5 PECULIAR PROPERTIES OF NOSTROY 2.35.73-2012

The standard establishes the main requirements to functional safety of safety- and security related systems according to GOST R 53195 and IEC 61508, and also considers the systems interrelated to engineering life support systems. Other engineering systems that are initially non-safety or security-related such as comfort maintenance systems according to the IEC 61511series are considered, too (IEC 2003).

It contains requirements for functional safety of about 28 types of safety- and security related systems, including complex system of safety. The standard establishes requirements for actions and procedures, which have to be executed in stages of the life cycle of these systems for achievement and maintenance of their functional and complex safety and antiterrorist and ant-criminal security of the high-rise buildings as a whole. The standard enables planning a control center to manage crisis situations and of evacuation of people. It contains requirements to elevators and their controls for safe evacuation of people, including the evacuation during a fire.

In the standard as well as in GOST R 53195 a systemic process approach is used (Meyers 2009, Ropohl 2012). Lifecycle of system or building is a process, which breaks into subprocesses, etc. Each of them has an input (e.g. information, energy or materials), an output (e.g. information, energy or goods) and functionality (actions in transformation of in- to outputs). A process can have some in- and outputs. The outputs of the previous process are used as inputs of the subsequent processes. Processes can also branch and unite.

In the standard besides requirements to systems also requirements for responsible persons influencing safety at each stage of the life cycle of systems, subsystems and complex systems or safety systems, and to their actions for reduction of influence of a subjective factor are established.

On the basis of presented standards similar standards for different types of construction objects in civil-engineering branch can be developed. Currently the possibility of development of standards for safety-related systems for underground objects is discussed in NOSTROY.

6 ADVANTAGES AND DISADVANTAGES OF FUNCTIONAL SAFETY APPROACH IN CIVIL ENGINEERING

As shown in the examples of the development of functional safety in civil engineering in the Russian Federation the role of functional safety approach is becoming more important.

Below some advantages and disadvantages of the approach of functional safety in civil engineering are listed.

Advantages:

- The society's needs for safety and security can be better achieved
- Civil engineering industry can learn from other industries (compare Rolle 2013b)
- Civil engineering industry can adopt and use best practice processes from other industries (e.g. IEC 2003, 2012)
- Civil engineering industry can use certified and reliable hardware and software from other industries
- Quality of safety and safety-related systems can be improved in the civil engineering industry
- Achieved safety level can be quantified.

Disadvantages:

- The adoption of standards and processes in the civil engineering industry can take long time
- The adoption of hardware and software can, in some cases, be expensive
- Expertise is necessary
- Certificate processes are to develop.

In spite of the disadvantages the advantages of the shown approach predominate from the point of view of the authors.

7 WORLDWIDE DEVELOPMENT OF FUNCTIONAL SAFETY IN CIVIL ENGINEERING

The importance of functional safety has grown steadily in recent years. This, on the one side, is because no other adequate solution to challenges in areas of safety, security and complexity can be observed. And on the other side for fast growing complexity of safety systems e.g. as for fire protection systems a solution to this problem has to be found rapidly as shown in Nachtigall & Klingsch (2011).

In Germany the standard VDI 6010 Part 4 "Safety Technology-Application of SIL classifications in the technical building equipment" is planned. The development of this standard by the Association of German Engineers begins in 2014 and will build on existing parts of the standard VDI 6010 parts 1–3 (VDI 2005). Also other commissions in Germany e.g. in German Commission for Electrical, Electronic & Information Technologies of DIN and VDE develop new standards in functional safety for the special needs of electrical engineering in the civil engineering industry.

Besides the identified national developments and discussed Russian standards the letter are planned to launch to international standards.

8 CONCLUSIONS

The paper shows clear and global trends and needs for safety in civil engineering. Furthermore the need to handle the growing complexity in civil engineering, and the need for new approaches to handle safety and complexity in this area are identified.

With presented and discussed current and interesting developments and ready to use standards a way to deal with growing complexity in civil engineering by implement and use special functional safety developments and standards is shown. First positive experiences of application of presented approach and standards in modern and complex buildings are available.

The discussed functional safety approach can be understood as the beginning of a new era of functional safety in civil engineering. Furthermore, the conclusion can be drawn that it is necessary to consider systems theory approach in functional safety to address the complexity in modern buildings.

Further development of standards will show whether the functional safety approach can solve the presented challenges of modern civil engineering industry. In addition, the development of standards will show whether they can give a new fresh impetus to the improvement of safety and security in civil engineering.

Mechanism design for risk allocation and benefit sharing in the development of a Geological Disposal Facility for nuclear radioactive waste

Oscar Nieto-Cerezo, Edoardo Patelli, Jan Wenzelburger & Michael Beer
Institute of Risk and Uncertainty, The Quadrangle, University of Liverpool, Liverpool, UK

ABSTRACT: In this research, we analyse a mathematical model using principal-agent theory where NDA delegates the implementation of a GDF to site licenced companies through the take-it-or-leave-it offer of a contract. A risk sharing incentive mechanism is designed to overcome the moral hazard problem when agents hide information on the level of risk, in order to accomplish the highest level of economic, environmental and social performance. An application to a simplified model will show the potential of the proposed approach. This paper will be of interest to academic and consultants concerned with the design of incentive contracts in the nuclear industry.

1 INTRODUCTION

Atomic power plays an important role in the mix of energy in the UK supplying 18% of the electricity consumed (World Nuclear Association 2014).

Since the first world's reactor started operating for commercial purposes in Sellafield, the UK has accumulated around 1,000 cubic meters of High Level radioactive Waste (HLW) which represents 95% radioactivity in radioactive waste (NDA 2010).

The viability of the development of the new generation of nuclear plants announced by the government in 2013 is subject to the effective management of radioactive waste.

The proposed solution to manage HLW is the development of a Geological Disposal Facility (GDF) where HLW is placed in a deep rock environment which is stable and unaffected by environmental change for hundred thousands of years. Under this condition radioactive waste which is protected from underground water by a geological, concrete and metallic barrier undertakes a natural process of radiation reduction called radioactive decay (NDA 2010).

The primary risks associated with nuclear activities arise from the radiation released by radioactive materials in the reactor and during the disposal. Nuclear risk can be interpreted from two perspectives, as the probability of death as a result of nuclear explosion, which in the UK is about 1 in 100 million or the probability of death as a result of long time exposure to radiation (HSE 2001).

GDF is an example of a complex project comprising a large number of interrelated risks affecting every-thing from technical feasibility to cost as well as large number of stakeholders including Government, Parent Body Organizations, Site Licensed Companies and financial institution.

This complexity requires a sophisticated multidisciplinary approach to secure a robust balance among all parties in view of sharing risk and benefits. Benefits and risks associated with large energy projects have to be considered from an economic, environmental, engineering and societal point of view.

It is obvious that an optimal solution is often not achieved such as the UK public rejection to GDF and the Fukushima nuclear accident have shown. Fukushima Daiichi reactor accident is an example

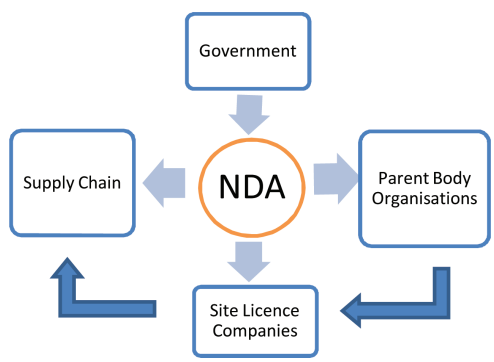

Figure 1. Structural NDA contracts (NDA 2010).

of benefit and risk sharing failure due to the moral hazard problem. As a result of underestimating the level of risk associated with tsunamis, Tokyo Electric Power Company (Tepco) took the decision of cutting down the original 35 meters cliff of the island and replaced it with a shorter concrete seawall to facilitate the access to docked ships. This decision brought some initial savings to the overall project cost but quite tragic consequences (Japan Nuclear Institute 2011).

The contribution of this paper is the introduction of an incentive mechanism to overcome the moral hazard problem when SLC's hide information on the level of risk under asymmetric information. When economic actors make profit—maximizing but inefficient decisions because they are able to avoid the cost associated with the conduct, the incentive mechanism will encourage stakeholders to reveal their private information on risk to accomplish the highest level of economic, environmental and social performance.

2 PRINCIPAL AND AGENT FRAMEWORK

Classical risk management approaches take the perspective of a single player for which the risk analysis is being carried out. Nevertheless, a game theoretical approach can be regarded as a decision making tool to model and predict the outcome of the strategic interactions between principal and agent. This enables managers to take the most efficient action in a given scenario. Strategic interactions comprising government and a consortium of companies to implement energy projects can be model in the framework of principal and multiagents. Principal–agent theory is concerned with the design of incentives by the principal when the principal and agents conflict in their personal objectives and exits asymmetric information between them (Laffont & Martimort 2001). In this setting, the presence of a consortium of site licensed companies requires the coordination of their efforts for joint a team production. The agents' problem is to decide, given a contract, whether to contribute to a public good when costly contribution is unobservable by the principal (Whitford 2002). In this paper, we model the coordination problem between agents in the framework of prisoner's dilemma.

Several authors have attempted to address efficient risk sharing allocations in the framework of principal and agent. Shavel states that a Pareto optimal payment fee by a principal to his agents is subject to the attitudes towards risk of the principal and the agent. The most appropriate payment fee (incentive) to a risk neutral agent is the outcome minus a constant, the principal share. On the other hand, if the agents are risk averse will not accept to bear all risk if an intolerable risk scenario is realized (Shavell 1979).

3 FORMULATION OF THE MECHANISM

NDA as the principal delegates the implementation of the geological disposal facility to the winner of a competitive tendering—PBO's and SLC's.

The asymmetric information of the strategic interaction between NDA and SLC's makes NDA unable to observe the actions taken by SLC's to complete the task. This prevents an efficient resolution of players' conflict of interest. This is known as the moral hazard problem (Laffont & Martimort 2001).

In this context, SLC's are rational companies in a game theoretical sense presented with the dilemma of how many financial resources should be invested in risk reduction when profit-maximizing is the objective.

The level of investment in risk reduction can affect the feasibility of the project as well as NDA and SLC's payoffs.

To this end, NDA faces two questions:

a. How to design an incentive mechanism so that efficient investment in risk reduction is desirable for SLC's
b. How the cost of risk should be shared in relation to possible scenarios

These questions can be answered by defining a game in the principal and agent framework.

3.1 *The game—interaction between SLC's*

Risks of different nature in complex systems are interrelated causing propagation phenomena such as reaction chains and loops (Fang et al. 2012). Thus, risk management in large energy projects requires the cooperation of site license companies as well as the parent body organizations to reduce risks to acceptable levels.

3.1.1 *Notation*

π_i	Payoff function of the Site Licenced Companies.
α	Revenue share allocated to each SLC's.
δ	Percentage of electricity trade-off revenue transferred to SLC's.
$E(\tau_{C_P})$	Expected monetary transfer from NDA to SLC's as a function of the cost of implementing risk mitigation actions.
P	Price of a KWh of electricity generated by nuclear power plants in the UK.
Q	Quantity of KWh of electricity generated by Nuclear Power Plants in the UK.
C_P	Total cost of electricity generation including the cost associated with construction,

maintenance, dismantling of the power plant and managing radioactive waste through a geological disposal facility.

θ Risk associated with nuclear waste; environmental damage (e.g.: contamination of soil, pollution of water bodies) and health effects of radiation (e.g.: cancer).

C_r Cost per unit of risk. When the cost is higher than 0 an investment in risk mitigation has been made. When the cost is equal to 0, companies maintain the status quo.

P_r Probability of a natural hazard.

N Monetary loss when a hazard occurs.

3.1.2 *Payoff function of site licensed companies*

The generation of electricity from nuclear sources has an associated economic revenue from trading off in the energy market as well as some cost related to the construction, maintenance, running and decommissioning of the nuclear plant.

The payoff of SLC's is subject to the outcome realized. Consequently, SLCs' payoff can be represented as follow:

$$\pi_i = \alpha(\delta(E(t_{C_{r>0}}))) - (\theta * C_{r>0}) \quad (1)$$

where α the revenue share to each SLC, δ is the fixed payment agreed between NDA and SLC's $E(t_{Cr})$ δ is the expected monetary transfer from NDA to the SLC's as a function of the level of investment in risk reduction. Risk (θ) is defined as the multiplication of the probability of a hazard to occur times the consequences in monetary loss. C_r is the cost associated with implementing risk mitigation to reduce the current levels of risks.

$$\theta = P_R * N \quad (2)$$

The investment required will depend on the level of risk. Thus, the outcome of the project is a function of the level of risk and the risk mitigation investment.

The consequence of risk in this study is taken as the number of fatalities resulting from nuclear accidents or exposure to high radioactivity levels.

The cost per unit public risk reduction (C_r) can be derived from the compensation for fatalities. (Zhao, et al 2012).

In the UK, 1,000,000 GB pounds (2001) is presented as the Value of Preventing a Fatality (VPF) related to a reduction in risk of one in a hundred thousand (HSE 2001).

3.1.3 *Analysis of the game*

This game setting can be viewed as a prisoners' dilemma paradigm which illustrates the conflict between social incentives to cooperate or private incentives to defect (Auman 1987) as shown in Table 1.

In this setting, Site Licensed Companies strategically interact and take decisions on whether or not to invest in risk reduction or maintain the status quo.

The Nuclear Decommissioning Authority intervenes by offering a contract which includes a payment transfer that encourages companies to jointly contribute to risk reduction.

This payment transfer should satisfy two constraints

a. The incentive constraint

$$\alpha\left(\delta\left(E(t_{C_{r=0}})\right)\right) < \alpha\left(\delta\left(E(t_{C_{r>0}})\right)\right) - (\theta * C_r) \quad (3)$$

Higher levels of investment yields higher revenue to SLC's

b. The participation constraint.

$$p\left(\alpha\left(\delta(E(t_{C_{r=0}}))\right)\right) + (1-p)\left(\alpha\left(\delta\left(E(t_{C_{r>0}})\right)\right) - (\theta * C_r)\right) \geq reservation\ price \quad (4)$$

The expected utility of the payment transfer minus the risk investment should be at least as great as joining another alternative project.

In this study, we assume that NDA and SLC's have a risk neutral behavior.

However, in many real scenarios, it has been observed that SLC's are risk averse with a strictly concave utility function. Equation 5. This is due to NDA being less sensitive to risk and SLC's

Table 1. Site licensed companies' payoff matrix.

Actions	Maintain levels of risk $C_r = 0$	Reduce risk to acceptable levels $C_r > 0$
Maintain levels of risk $C_r = 0$	$\pi_1 = \alpha(\delta(E(t_{C_r} = 0))$ $\pi_2 = (1-\alpha)(\delta(E(t_{C_r=0})))$	$\pi_1 = \alpha(\delta(E(t_{C_r>0})))$ $\pi_2 = (1-\alpha)(\delta(E(t_{C_r>0}) - (\theta * C_{r>0})))$
Reduce levels risk $C_r > 0$	$\pi_1 = \alpha(\delta(E(t_{C_r>0}) - (\theta * C_{r>0})))$ $\pi_2 = (1-\alpha)(\delta(E(t_{C_r>0})))$	$\pi_1 = \alpha(\delta(E(t_{C_r>0}) - (\theta * C_{r>0})))$ $\pi_2 = (1-\alpha)(\delta(E(t_{C_r>0}) - (\theta * C_{r>0})))$

having limited liability. (Laffont & Martimort 2001)

$$p\left(\alpha\left(\delta\left(\sqrt{E(t_{C_{r=0}})}\right)\right)\right) + (1-p)(\alpha(\delta(\sqrt{E(t_{C_{r>0}})}) - (\theta^* C_r))) \geq C_r \quad (5)$$

The best outcome for the companies is that both companies cooperate. Nevertheless, each player has an incentive to be a "free rider". In other words, those companies which do not contribute will still benefit from the additional input of the other companies to risk reduction obtaining even a higher payoff than those companies which invested capital. And finally, if neither of the companies contributes to risk reduction will receive a payoff lower than contributing but higher than contributing if the other company does not.

The game has a unique Nash equilibrium (Maintain, Maintain) as whatever one company does, the other prefers maintain to reduce. Table 1.

As companies are rational and driven by profit maximization, it will be in their best interest to underestimate their level of risk to increase their benefit. This behavior causes uncertainty about the payoffs of the game and information asymmetry between NDA and SLC's (Neuman & Morgenstern 1944). Under these circumstances, a Bayesian game is induced where each company has some beliefs about the level of risk hold by the other companies by assigning a continuous probability distribution over the interval of the level of risk. This distribution is common knowledge. In this paper, we assume that the companies' interval type is the same for both companies (low levels of risk $\underline{\theta}$, high levels of risk $\overline{\theta}$). Each type profile induces a state of the game with different payoffs. Table 1.

Companies will choose a strategy that maximizes their expected payoff in each state of the game. The solution to this game is a Bayesian Nash Equilibrium.

Underestimating the level of risk will decrease the probability of achieving a desirable outcome. In light with this, it is necessary the implementation of an incentive mechanism by NDA to enforce companies to reveal their actual levels of risk.

3.1.4 *The principal and agent model—NDA and SLC'S*

Current practice of risk management allocates all project risks to government (NDA) being passed onto customers as a result. Thus, customers become vulnerable to the consequences of accidents and disruptions of energy services. In line with this, it is necessary the introduction of a risk sharing scheme.

3.1.5 *Tolerability of risk*

The Office for Nuclear Regulation (ONR), regulator for the civil nuclear industry in the UK, has proposed a framework of social risk tolerability which has been established as a benchmark to assess how optimal and desirable each potential outcome is.

The regulation nuclear risk is defined by the introduction of boundaries for each outcome with regards to the risk of death or serious injury (HSE 1988)

a. When risk levels are higher than 1 in 10^4 per annum to any member of the public, the outcome is regarded as intolerable and should be rejected. (HSE 1988)
b. When risk levels are lower than 1 in 10^6 per annum to any member of the public, the outcome is regarded as acceptable and no further precaution is necessary (HSE 1988)
c. When risk levels falls between 1 in 10^4 and 1 in 10^6, the outcome is regarded as tolerable and a cost-benefit analysis can be performed to evaluate if risks levels are as low as reasonable possible (ALARP) (HSE 1988).

3.1.6 *NDA's payoff*

In the principal and agent framework, the revenue of the project depends on the Site Licensed Companies' investment in risk.

$$\sum_{s_i \in s} p(S \mid C_r) * ((P * Q) - C_p + R_b - t_{C_r}) \quad (6)$$

The project revenue is the expected payoff of each possible scenario given the level of investment in risk reduction by Site Licensed Companies. Equation 6. The conditional probability distribution increases from scenario 1 to scenario 3 when high risk investments have been made whereas decreases when lower investments of risk

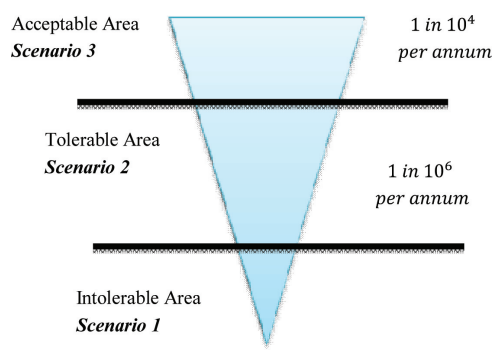

Figure 2. Acceptable, tolerable, intolerable risk scenario and criteria (HSE 1988).

Table 2. Project revenue at different scenario.

	Scenario 1 Socially intolerable level of risk Risk >1 in 10^4 per annum	Scenario 2 Socially tolerable level of risk 1 in $10^4 \geq$ Risk > 1 in 10^6 per annum	Scenario 3 Socially acceptable level of risk Risk ≤ 1 in 10^6 per annum	Expected payoff
$C_r = 0$	$p\,(S1\|C_r = 0) * ((P * Q) - C_p - t_{C_r}$	$p\,(S2\|C_r = 0) * ((P * Q) - C_p + R_b - t_{C_r})$	$p\,(S3\|C_r = 0) * ((P * Q) - C_p + R_b - t_{C_r})$	$\sum_{S_i \in S} p(S\|C_r = 0) * ((P * Q) - C_p + R_b - t_{C_r})$
$C_r > 0$	$p\,(S1\|C_r > 0) * ((P * Q) - C_p - t_{C_r}))$	$p\,(S2\|C_r > 0) * ((P * Q) - C_p + R_b - t_{C_r}))$	$p\,(S3\|C_r > 0) * ((P * Q) - C_p + R_b - t_{C_r}))$	$\sum_{S_i \in S} p(S\|C_r > 0) * ((P * Q) - C_p + R_b - t_{C_r})$

Table 3. Project revenue at different scenarios.

	NDA's revenue	Risk cost sharing and payment transfer
Scenario 1	$((P * Q) - C_p - t_{C_r}) - \sum_{S_i \in S} p(S\|h) * u(S)$	$((P * Q) - C_p - t_{C_r}) - \sum_{S_i \in S} p(S\|h) * u(S) + \pi_i$
Scenario 2	$((P * Q) - C_p - t_{C_r} + R_b) - \sum_{S_i \in S} p(S\|h) * u(S)$	$((P * Q) - C_p - t_{C_r} + R_b) - \sum_{S_i \in S} p(S\|h) * u(S) + \pi_i$
Scenario 3	$((P * Q) - C_p - t_{C_r} + R_b) - \sum_{S_i \in S} p(S\|h) * u(S)$	$((P * Q) - C_p - t_{C_r} + R_b) - \sum_{S_i \in S} p(S\|h) * u(S) + \pi_i$

have been realized. R_b is the economic benefit of improving the environmental and social performance of the project through risk reduction and t_{C_r} is the monetary transfer to SLC's. Table 2. Cost and benefit analysis needs to be perform to convert non-marketable environmental and social benefits into monetary values.

The NDA designs a contract with a variable share of the production depending on the outcome realized. The Site Licensed Companies will decide whether to accept NDA's offer based on the expected payment and the cost associated with performing that action.

$$\left((P * Q) - C_p + R_b - t_{C_r}\right) - \sum_{s_i \in s} p(S \mid h) * u(S) + \pi_i \quad (7)$$

The risk sharing incentive mechanism takes the form of the utility function in equation 7.

If the payoff of the scenario realised under a level of risk reduction is lower (negative) than the expected payoff an equivalent payment transfer will be discounted from the SLC's payoff and transferred to NDA. If, on the contrary, the payoff of the scenario realised under a level of risk reduction is higher a payment is added to SLC's expected payoff.

3.1.7 *Analysis of the principal and agent model*

The contract between NDA and SLC's consists of NDA offering a fixed shared of the production realized. Such a sharing rule should satisfy the participation constraint and be at least as great as the reservation price. However, this payment does not guarantee the effective management of risk by SLC's.

In order to overcome the moral hazard problem with respect to the investment in risk reduction made by SLC's, an incentive mechanism is designed to reduce the degree of information asymmetry in the form of profit sharing scheme. If the revenue of the scenario realized is less than the expected revenue at a given risk investment, SLC's will make an equivalent payment to NDA minus her own share of the expected utility. If the revenue of the scenario realized is higher than the expected revenue at a given risk investment, SLC's will receive an equivalent payment by NDA. As principal and agents have different goals, the non-observability of the agent's action may prevent an efficient resolution of the conflict of interest. Incentive schemes that satisfies incentive constraint and participation constraint, restores efficiency by inducing a higher level of risk investment (Shavell 1979).

4 CONCLUSION

We have built a model of principal—agent theory on the assumption that the NDA and Site Licensed Companies are risk neutral. It has been shown that under this setting, the cost of risk related when an adverse social and environmental outcome is realized, is fully borne by the SLC's. The optimal investment in risk reduction maximizes the payoff of the NDA and SLC's preventing inefficiency associated with asymmetric information.

We also state the necessity of internalizing externalities in risk sharing mechanisms by allocating a monetary value to benefits associated with

an improvement of social and environmental performance through a cost and benefit analysis.

The authors have identified some limitations in the game. For simplicity, it has been assumed that the two players in the game are risk neutral and that the payoffs of the SLC's includes revenue from electricity generation. Further study will be focused on refining the game with more than two risk averse companies and the introduction of a cost and benefit analysis in each project risk scenario to investigate payment transfers when electricity revenue cannot be distributed.

Optimization of the drinking water coagulation and filtration system as a result of reliability analysis and Life Cycle Costing

J. Szymik-Gralewska & I. Zimoch
Institute of Water and Sewage Engineering, Silesian University of Technology, Gliwice, Poland

ABSTRACT: Application of reliability theory allows an evaluation of technical and technological operation of all technical systems including water provision systems. Many other industrial branches like transport or energetics expanded the analysis on existing systems by including costs factors. Authors of this paper propose to implement this approach and develop new model of combined reliability and economic theory dedicated for water systems. Proposed model would include determination of reliability factor and economical part would be represented by Life Cycle Costing which allows to establish all incoming and outgoing of cash for each element and structure.

In this paper, basing on real exploitation data (collected 2005–2012) authors presented an innovation approach of application of reliability and Life Cycle Cost theories.

1 INTRODUCTION

In many scientific articles and presentations the authors present results of reliability analyses undertaken for various types of technical installations, devices and equipment (Möller & Hansson 2008, Zio 2009, Tchorzewska—Cieslak 2008). For a number of decades the reliability theory has been widely applied for drinking water systems and with the development of this field of knowledge today's operators of water systems are able to optimize their technical inspection programmes without the risk of any reduction in the level of reliability. The operator is also able to identify objects/subsystem with high performance risks and/or compare reliability of different devices & systems.

The reliability of a device is not the only factor taken into consideration when the operator plans to buy or build a new installation or system. The capital and upkeep costs also plays a major role in the process. The operator also has to consider the cost and reliability when deciding on the future usage of already operating devices.

After analysis of accounting papers it can be noticed that one of the cost accounting concepts—product Life Cycle Costing (LCC) is particularly applicable in cost management (Sierpinska & Niedbala 2003, Sobczyk 1997). The basic of LCC is to establish future costs, based on the adopted model. Polish norm P*N-EN 60300-3-3* defines LCC as "*the total cost incurred during the life cycle of the product*."

Researchers have determined that the Product Life Cycle Costing can be applied for technical systems such as the transport, power engineering etc. (Aggarwal 1977, Asiedu & Gu 1998, Barringer & Weber 1996, Nizinski & Zoltowski 2002, Li Du, Wang & Huang H. 2010, Selech & Kurczewski 2012).

For the last 20 years researchers have been applying Life Cycle Costing to optimize the operation of pumping units (Jedral 2007). The Hydraulic Institute, and Europump, created a program to allow for efficient energy management based on LCC analysis. Costing analysis requires a combination of economic and technical approaches when considering the projected operating time. The main aim of the research on pumps is to find an optimal system with low energy consumption. The analysis proved that the design process gives the greatest opportunity to optimize the total value of LCC; even though that the higher costs usually occur in the final phases of a pump's life.

Authors of this paper propose to implement the LCC methodology to analyze every device/object of a Drinking Water Treatment Plant (DWTP) (Zimoch & Szymik-Gralewska 2013, 2014).

This approach will allow a full economic efficiency analysis which is especially important when the Operator has to plan future utilization or modernization of any devices.

The authors decided use the approach to combined reliability and economic research based on the existing coagulation and filtration system at one of the largest DWTP in Poland. The coagulation and filtration system includes the following processes; rapid water and coagulant mixing, slow

mixing (Flocculation), sedimentation in Sedimentation Tanks and filtration by Sand Filters.

2 AIM AND SCOPE OF THE RESEARCH

The purpose of this study is to evaluate the existing coagulation and filtration system and to propose future optimization. In this paper "optimized utilization" means usage of a system which can be described with reliability factors higher than required and which also generate associated lower operational costs.

The scope of research includes the calculation of basic reliability factors, recognition of all operational and capital costs and the application of a new index—"indicator of operational readiness" (R), describing the probability of economic readiness of operation.

All of these factors are based on real data i.e. all included data related to any technical events that influence the reliability factors were provided by the operator. Furthermore all cash flows related to the operation of the system were investigated and taken into consideration.

3 METHODOLOGY

3.1 *Reliability model*

During the research the authors identified all operational events which occurred between 01 January 2005 and 30 June 2012. In case of the Sedimentation Tank's rapid and slow mixing subsystems the most common was the failures of the mixers. For the actual Sedimentation Tanks the cleaning of the tanks was only event which influences the ability to operate a Tank. In the case of the Filters some failures took place but the main factor which determines the reliability factor is the backwash procedure. Due account was taken of the time required for backwashing and rearranging the sand beds. During the backwashing the Filter is not able to treat the water, however this results not from a failure but from normal technological/operational activities.

As mentioned above reliability theory has been used in the drinking water sector for a number of years (Wieczysty & others 2001). According to common used formulas (Wieczysty & others 2001, Zimoch & Szymik-Gralewska 2014), and based on two-parametric methods and using operational data, the following indicators for each object (Mixing Chamber, Sedimentation Tank, Filter) were calculated:

- T_p—average operating time between failures—hr
- T_o—average renewal time—hr
- μ—renewal intensity—1/hr
- λ—damage intensity—1/hr
- f—frequency of damage—1/hr
- "K"—readiness index—dimensionless.

In using reliability theory the authors divided the complete system into groups based on their technological role. Taking into account the connections between technical elements all possible reliability structures (parallel or serial) were found. In order to fully describe all parallel structures, basing on actual water production, the authors of this paper calculated reliability characteristic "n of M" where "n" represent the number of operating objects and "M" is represents the number of all existing objects of each type. The reliability indicators (T_p, T_o, μ, λ, f, K) for each structure were calculated, however due to the limited form of this article only values of T_p, T_o, "K" are presented.

For this research, indicator "K" plays a major role in the evaluation of an object/structures. The definition of "K" means that it describes the possibility of future correct operation basing on past events. "Correct operation" is understood as the production of water with the required quality and volume at any time.

3.1.1 *Required reliability level*

To allow the estimation of the operation of each structure, the associated "K" indicator will be calculated and compared to a required value. Based on research conducted on the Polish water supply systems for over 30 years, suitable reliability standards were established (Wieczysty 2001). Depending on the size of the supplied city relevant values of "K" were described. In the case of the Drinking Water Plant considered by the authors the number of water consumer is higher than 500 000 people, therefore the required "K" indicator for whole Water Supply System (WSS) equates to 0,9827329 (Wieczysty 2001).

Taking into account all parallel and serial connections between subsystems and groups of elements, each required value was established (Wieczysty 2001, Zimoch & Szymik-Gralewska 2014). The authors assumed in parallel the reliability of the water production (DWTP) subsystem and the distribution (water pipe network) subsystem.

During the calculations each of the technological processes were divided into groups (Fig. 1):

1. I step of water purification includes initial ozonation, coagulation, filtration (serial structures),
2. I step of water purification is carried out in two technological lines (parallel structure),
3. Coagulation involves mixing (coagulant with water) and flocculation (serial structures),
4. Coagulation and sedimentation are technical groups which create a serial system,

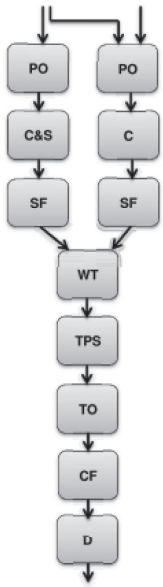

Figure 1. DWTP flow diagram.
PO—Pre-ozonation chambers; C&S—Coagulation and sedimentation; SF—Sand Filters; C—Coagulations (Pulsators); WT—Water Tank; TPS—Transitional pumping station; TO—Transitional ozonation chambers; CF—Carbon filters; D—Disinfection.

5. II step of water purification includes pumping, middle ozonation, sorption on activated carbon & disinfection (serial structure).

The conducted calculations show that the rate of K readiness for the analyzed groups should be as follows:

– for Coagulation K required = 0.9966290;
– for Sedimentation K required = 0.9966290;
– for Filtration K required = 0.9799436.

3.2 *Costing model*

To determinate which model of cost analysis is the most adequate for the DWTP system, different types of analysis were taken into consideration. As combined reliability and economic research in water supply systems is a novel approach the authors reviewed literature from other sectors (Dziaduch 2011). It was assumed that the concept of Life Cycle Costing (LCC) is most applicable. LCC analysis involves specifying the total cost incurred during the life cycle of an object and it can be described with the following equation:

$$LCC = CF_d + CF_b + CF_u + CF_{di} \quad (1)$$

where symbols stand for:
CF_d—cash flows of design phase
CF_b—cash flows of construction phase
CF_u—cash flows of usage phase
CF_{di}—cash flows of disposal phase

Mentioned costs of design, construction and disposal are relatively easy to define, however costs related to the usage phase is much more complicated. To describe all cash flows occurring in that phase Activity Based Costing (ABC) was applied (Sierpinska & Niedbala 2003). This method assigns indirect overhead costs and activity costs to the objects, facilities, systems & devices, and uses "cause—effect" relations between factors that generate costs and activities. In other words the ABC concept allows the grouping of the costs by actions i.e. causes of cost.

In the case of the water supply systems, the type of actions which cause costs are; maintenance works, replacement of failed equipment, & technological activities (filter backwashing). To find the total cost of the operational phase, costs related to materials (spare parts, water for backwashing), labour and energy was calculated.

Another aspect of Life Cycle Costing is the fact that it must allow for the change of money value over time. For this reason all cash flows must be "discounted" and the equation below shows the connection between the future and present value of money:

$$PV = \frac{FV}{(1+r)^t} \quad (2)$$

where:
PV—present value e.g. of a cash flow—PLN,
FV—future value—PLN,
r—the discount rate—dimensionless,
t—the time of the cash flow (here 30 years)—dimensionless.

According to "*Guide to Cost-Benefit Analysis of Major Projects in the context of EC Regional Policy*" by European Commission "r" factor for Poland is 0,05.

It should also be stated, that from an economic point of view, by referring to Cash Flows (CF) we mean the incoming and outgoing of cash, representing the operating activities of a water supply company (Sierpinska & Niedbala 2003). Cash flows can be divided into cash outlays e.g. for design, construction or modernization, costs generated during the operation of an object and cash income e.g. savings from lower energy consumption.

With reference to the above, it can be concluded that during the design and construction phases only cash outlays occur, while during the usage phase costs for maintenance cash outlays for moderniza-

tion and possible income can be observed. During the disposal phase costs related to the demolition, and income from selling the debris can appear. The total value of each life phase is a balance of all the cash flows, and for this reason outlay costs are given a minus signs (as these are expenses) and income is given a plus sign. It can however be seen that the majority of the considered CF has a negative sign i.e. it is an outgoing cost/money In order to facilitate the calculations in this paper, minus signs will be omitted.

Taking all of the above into consideration, the discounted balance of cash flow—Present Value of Cash Flow (PVCF) related to each life phase is presented by the following formula:

$$PVCF = \sum_{t=0}^{n} \frac{CF_t}{(1+r)^n} \tag{3}$$

where:
PVCF—Present Value of Cash Flows—PLN,
CF_t—the net cash flow at time t—PLN,
N—following periods—years.

3.2.1 *Identified costs*
A significant part of the research was to identify and specify all Cash Flows related to each group of elements. Basing on water company records, documentation of analogical DWTP and the author's calculations, the incoming and outgoing of cash was determined. Results are shown in Tables 1–4.

3.2.1.1 *Mixing chamber*
For the Mixing Chamber the authors determined the following costs (divided into life phases):

Design phase
According to Polish legislation acts for investor's costing, it was assumed that design costs equal 5% of the construction costs. This phase included costs related to the provision of executive design, all necessary expertise surveys, land surveys and obtaining all required permits.

Construction phase
Based on cost documentation of analogical chamber built in other DTWP, construction phase was established. The authors took into consideration the value of construction and assembly works, the value of direct used materials and direct labor costs.

Usage phase
Due to fact, that the Mixing Chamber is a reinforced concrete structure which is not equipped with any machinery, concrete repair is the only associated cost. According to *Guide to cost-benefit analysis of investment projects* by the European Commission, concrete structure durability is normally 50 years. Based on the author's experience, and using data obtained from professional contractors, it was assumed that the concrete surface will require repairs once every 20 years with an average costs of 30% of construction.

Disposal phase
Normally the cost of this phase is mainly the cost of dismantling works and associated disposal.

As the Mixing Chamber is the widening of the water channel it is impossible to demolish this element. Consequently the costs related to the disposal phase equal 0.

3.2.1.2 *Flocculation chamber*
The authors have carried out an investigation of the costs of the Flocculation Chamber and the following costs have been determined:

Design phase
Similar to the Mixing Chamber, in accordance with Polish legislation it was assumed that design phase costs equal 5% of construction costs.

Construction phase
Basing on a cost estimation carried out in accordance with Polish legislation, and using average costs from the first quarter 2014, cash flows for the construction phase were established. The following particular aspect were taken under considera-

Table 1. Summary of required values of indictor K for each groups.

Type	Symbol	Elements no.	Function	Value of K indicator
Serial structure of water production and the subsystem	Wa	2	$\sqrt[2]{K_{WSS}}$	0.9827329
Serial structure of I and II step of water purification	Wb	5	$\sqrt[5]{K_{W_a}}$	0.9965225
Parallel structure of two technological lines of I step of water purification	Wc	2	$1-\sqrt{1-K_{wb}}$	0.9410295
Serial structure of technological system which build one of line of I step of water purification	Wd	3	$\sqrt[3]{K_{W_c}}$	0.9799436
Serial structure of technological groups which build technological system	We	2	$\sqrt[2]{K_{W_d}}$	0.9966290

Table 4. LCC for coagulation subsystem.

LCC of element	Cash flows (net value) PLN
Mixing chamber (2 elements)	2 454 898.47
Flocculation chamber (4 elements)	9 945 168.57
LCC	7 364 695.40

tion; direct costs associated with the purchase and installation of materials and equipment, the cost of construction and assembly/installation works, the cost of installed equipment, the cost of direct used materials and direct labor costs.

Usage phase
As stated for the Mixing Chamber, according to *Guide to cost-benefit analysis of investment projects* by the European Commission, concrete structure durability is normally 50 years. Based on the author's experience, and using data obtained from professional contractors, it was assumed that the concrete surface will require repairs once every 20 years with an average costs of 30% of construction.

To provide a correct flocculation process, Slow Mixers are installed in the chamber. According to *Guide to cost-benefit analysis of investment projects* by the European Commission equipment durability is up to 30 years. For that reason the analysis assumes Mixer replacement after 30 years.

In accordance with the ABC concept costs are being generated during technical activities. Each chamber is cleaned once a year and this action results in costs (labor, material, overheads).

The cost of possible repairs can be illustrated by an average renewal time T_o. For this study the highest T_o was taken into account.

Disposal phase
Cost of this phase is mainly associated with dismantling works and waste disposal. The Flocculation Chamber is a reinforced structure which is a part of the Coagulation Building and for this reason demolition works were not taken into consideration.

Costs related to Mixer demolition was established basing on average costs in the first quarter of 2014.

Profit from the sale of dismantled scrap metal is negligible.

3.2.1.3 *Sedimentation tank*
For the Sedimentation Tank the following costs were found:

Design phase
Similarly to the other analyzed concrete structures, the design phase costs were assumed to be 5% of the construction costs.

Construction phase
For the Sedimentation Tank, the authors carried out a cost estimate based on the average costs in the first quarter 2014. The following aspect were taken under consideration; the value of construction and assembly works, the value of direct used materials & direct labor costs.

Usage phase
The design life of the tank is assumed to be 50 years. As the tank is reinforced hydro concrete the authors assumed that the repairing of the concrete surface once every 20 years would be required and that the repairs have an average costs 30% of construction. This is based on information obtained from the operator.

In accordance with the ABC cost model cash outflows are generated during technical activities; i.e. the cleaning process which takes place once a year.

Disposal phase
Cost of this phase is mainly associated with dismantling works and waste disposal. The authors carried out a cost estimate based on average costs in the first quarter 2014, and the following aspects were taken into consideration; the value of demolition construction and dismantling works, the value of direct used materials, direct labor and the cost of debris removal & disposal.

3.2.1.4 *Sand filter*
Based on a cost estimate provided by a potential contractor for the renewal of the Sand Filters, the following costs were indicated (Zimoch & Szymik-Gralewska 2014):

Design phase
This phase included costs related to the provision of the executive design, all necessary "expertise" surveys and land surveys together with obtaining all required permits.

In contrast to the other analyzed elements, the costs related to the design phase for the Sand Filter were assumed to be real contractor's costs.

Construction phase
The costs of this phase consist of; direct costs associated with the purchase and installation of materials & equipment, the value of construction & assembly works, the value of installed machinery & equipment, the value of direct used materials, direct labor costs, fees & charges related to required permits and the costs of preparing the construction site.

Usage phase
In the life cycle of the Sand Filter the backwash time plays the major role. In the analyzed case the backwash time equals 0.25 hr, and in accordance with the ABC concept costs are being generated during this 0.25 hr period. Rising process results in the following costs; wages of employees directly involved in this process, consumed energy of the pump units (pumps provide purified water to the tower tank) & cost of used backwash water.

The cost of possible repairs can be illustrated by an average renewal time T_o. For this study the highest T_o was taken into account.

What is more, during the data analysis it was noted that on an average of once every 10 years, a Filter must be renovated, i.e. the anthracite bed must be replaced. This operation requires the emptying of the Filter Chamber, removal of the filter bed, disposal of sand and provision of new filter bed material.

For this research, it was assumed that the Sand Filter has an operational life of 30 years.

Disposal
The cost of this phase is mainly the cost of dismantling works and associated disposal. As the Filter Chambers are part of Filters Building, the authors assumed that the structure will be not demolished.

Costs occurred in this phase relate to refer to demolition works, the value of direct used materials, direct labor costs, cost of scrap metal and the cost of used sand disposal.

4 DESCRIPTION OF COAGULATION AND FILTRATION SYSTEM

The Coagulation and Filtration System is part of the DWTP which purifies surface water. The DWTP with other ten local Plants provides water to more than 3 million Silesian citizen. Its design capacity is 500 000 m^3/d and average production equals 213 800 m^3/d. The examined system is one of two parallel coagulation and filtration subsystems (Fig. 1).

During the observed time the average capacity was 37% of the design capacity (150 000 m^3/d) and it equals 55 500 m^3/d. The maximum capacity in this period was 97 700 m^3/d.

The system includes; rapid water and coagulant mixing, slow mixing (flocculation), sedimentation in Sedimentation Tanks and filtration by sand Filters (Fig. 2).

There are three parallel coagulation lines in which water is purified with a coagulant (aluminum sulfate) dosed into the three supply pipes (DN 800) serving the Coagulation Building.

Coagulant is dissolved to an appropriate concentration in 4 concrete tank each with 13.5 m^3 capacity. The coagulant solution is then transferred to tanks by membrane dosing pumps. Each coagulation line has 2 labyrinth Mixing Chambers (MC) and each reinforced concrete MC has five inclined baffles which create turbulent flow. The retention time of Mixing Chambers is 3 minutes.

After the mixing process the water divides into four Flocculation Chambers (FC). Each FC is equipped with two mixers and the capacity of one FC is 67.67 m^2. The maximum design water level in the Flocculation Chamber is 4.1 m and the minimum is 3.8 m. The retention time depends on rate of the water flow, and at the maximum fulfilment and with twelve chambers in operation, the retention time is 27 minutes and with a min fulfilment and 12 chambers in operation—it is 23 minutes.

Further water by three pipelines DN 1200 is transported to the Division Chamber and then to three horizontal post-coagulation Sedimentation Tanks (S). These are roofed reinforced concrete buildings, located below ground level. Each tank is divided into three chambers connected with overflows. The design retention time is 1 hr

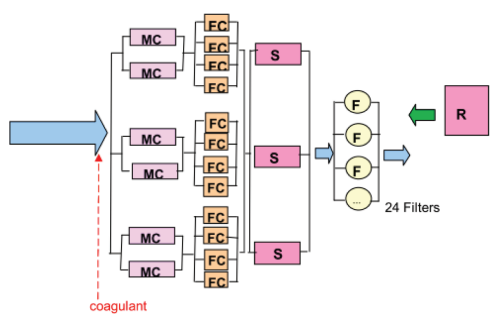

Figure 2. Coagulation and filtration flow diagram (Symbols as in text).

45 min but due to current production levels the actual retention time is a few hours. The capacity of the Sedimentation Tank equals 21 500 m^3.

The clarified water is forwarded to the Filtration Building. The filtration system consists of 24 identical reinforced concrete Filter chambers (F) filled with an anthracite bed. The filtration area equals 46 m^2 and the chamber volume is 115 m^3.

Each Filter bed is provided with a 55 cm layer of sand and a 35-centimeter support layer. The base of the Filter chamber is covered by plates with mushroom shape drainage nozzles. The Filters are backwashed gravitationally with water from the Retention Tank (R).

5 OBTAINED RESULTS

5.1 *LCC calculation*

Based on the assumptions described in point 3.2 and on formulas (1), (2), (3) the Life Cycle Costs for each element were calculated. Due to the limited form of this article only final results are presented.

It can be seen, that two Mixing Chambers are connected only to specific four Flocculation Chambers (Fig. 2). And this means that when the operator decides to stop operating one MC the second MC and related four FC cannot be operated.

For this reason elements arrangement "2MC+ 4FC" should be consider as one Coagulation Subsystem. LCC for Coagulation Subsystem is a sum of LCC for the Mixing and Flocculation Chamber (Table 4).

Regardless to which configuration of the chambers is adopted the water can be provided to any of the Sedimentation Tanks. Therefore the Sedimentation Tanks can be consider as a separate Sedimentation Subsystem.

Similarly the Sedimentation Filtration is a separate subsystem and the following LCC was calculated.

Table 5. LCC for sedimentation tank.

Phase of sedimentation tank's life cycle	Cash flows (net value) PLN
Design	224 759.04
Production	4 495 180.89
Usage	5 439 724.15
Disposal	10 008 017.82
LCC	20 167 681.90

Table 6. LCC for filter.

Phase of Filter's life cycle	Cash flows (net value) PLN
Design	300 000.00
Production	1 277 000.00
Usage	2 769 946.46
Disposal	19 898.46
LCC	4 366 844.92

5.2 *Reliability index calculation*

5.2.1 *Objects*

Based on the assumption of reliability theory described in point 3.1 on this paper, the reliability indicators were established as in Table 7.

At the end of study period only 18 Filters were in operation. The remaining 6 were out of operation due to drainage plate failure.

Table 7. Reliability indicators for elements.

Object	Tp hr	To hr	K dimensionless
Mixing chamber	32 844.00	0.00	1.0000000
Flocc. chamber no. 1 with mixers	222.60	17.15	0.9284552
Flocc. chamber no. 2 with mixers	438.43	5.78	0.9869821
Flocc. chamber no. 3 with mixers	5 051.76	4.69	0.9990717
Sedimentation tank no. 1	5 460.08	15.18	0.9972272
Sedimentation tank no. 2	3 844.65	20.56	0.9946801
Sedimentation tank no. 3	4 093.63	12.67	0.9969153
Filter no. 1	31.64	0.25	0.9921599
Filter no. 2	31.58	15.25	0.6744530
Filter no. 3	31.64	0.25	0.9921599
Filter no. 5	31.64	0.25	0.9921599
Filter no. 8	31.64	0.25	0.9921599
Filter no. 9	31.64	0.25	0.9921599
Filter no. 10	31.64	0.25	0.9921599
Filter no. 11	26.87	9.05	0.7481501
Filter no. 12	31.64	0.25	0.9921599
Filter no. 13	31.64	0.25	0.9921599
Filter no. 14	31.60	18.03	0.6367376
Filter no. 15	31.64	0.25	0.9921599
Filter no. 16	31.64	0.25	0.9921599
Filter no. 17	31.61	18.32	0.6331126
Filter no. 19	31.64	0.25	0.9921599
Filter no. 21	31.64	0.25	0.9921599
Filter no. 22	31.62	9.75	0.7644022
Filter no. 23	31.64	0.25	0.9921599
Filter no. 24	31.64	0.25	0.9921599

Filters no. 4, 6, 7, 18, 20 were unexploited throughout the study period and the drainage plate to Filter no. 22 was damaged during the course of the study.

It can be seen that T_o for the Mixing Chamber equals 0,00. This is a result of the fact that from 2005–2012 maintenance works were executed. As the chamber has no mechanical equipment no failure was recorded.

In case of the Sedimentation Tanks a very long average renewal time (T_o) is observed as the water production rate is considerably lower than the design value (two Tanks can provide the max water capacity) and consequently the Operator does not endeavour to optimise the cleaning period.

Calculations for the Flocculation Chamber with Mixers were calculated based of the Flocculation Chamber (structure) and the associated four mixers being considered as a serial structure. In Chamber no 1, Mixers no 1, 2, 11 & 12 are in operation, in Chamber no 2 there are Mixers no 3, 4, 9 & 10 and in Chamber nr 3—Mixers no 5, 6, 7 & 8. Reliability indicators for each Flocculation element are given in the Table 8.

5.2.2 *Structures*

In order to provide full reliability evaluation, indicators for all technical structures were calculated. Each subsystem being separately analysed.

In this study all subsystems were analysed on the basis of the average water production. It was established that to provide the optimal filtration velocity (6.5 m/h), 8 Filters must be in operation at any one time. For this reason the analyses for the Filtration Subsystem begin with 8 Filters.

The analysis shows that 8 of 18, 9 of 18, 10 of 11, 12 of 18 and 13 of 18 are described with very long average operating times between failures and high K index. This is a result of the fact that the Filters are very rarely subject failure and what is even more important these structures have high reserve i.e. only few of elements in subsystem must be working.

Table 8. Reliability indicators for flocculation elements.

Object	Tp hr	To hr	K dimensionless

6 COMBINED TECHNICAL RELIABILITY AND ECONOMICAL ANALYSIS

An analysis of the obtained results of reliability calculations indicates that for the required values of "K" indicator the following minimum structures satisfy the condition: $K_n > K$ required.

Table 12. Required K values for each subsystem.

Subsystem	K required	Required structure	Value of K for required structure
Coagulation	0.9966290	2 of 3	0.9989919
Sedimentation	0.9966290	2 of 3	0.9999604
Filtration	0.9799436	14 of 18	0.9983213

Table 13. Values of operational readiness rate (R),

Subsystem	R
Coagulation	0.5005041
Sedimentation	0.5000198
Filtration	0.5723895

During the observation period the maximum capacity of the System was 97 700 m^3/d. Taking into consideration the current trend of decreasing water consumption and the fact that the probability of a sudden increase is extremely small, it was assumed that the maximum required capacity of the system be defined as 97 700 m^3/d rather than the design value (150 000 m^3/d).

As previously stated in this paper all subsystems were analysed regarding the average and maximum observed water production.

Currently literature does not define the index linking both reliability and cost factors. The authors of this study propose to introduce the indicator of operational readiness (R), describing the probability of economic readiness of operation (Zimoch & Szymik-Gralewska 2014).

$$R = \frac{K_0 \cdot CF_0}{K_m \cdot CF_m} \tag{4}$$

where:

K_o—probability of proper operation of structure "x of y" where "x" is the number of elements necessary for average water production rate and "y" is the number of all elements necessary for max production rate,

CF_o—total cash flow related to the number of elements necessary for average water production rate,

K_m—probability of proper operation of the structure "x of y" where "x" is the number of elements necessary for max water production rate and "y" is a number of all existing elements necessary for max production rate,

CF_m—total cash flow related to the number of elements necessary for the maximum water production rate,

7 SUMMARY AND CONCLUSIONS

Most of Polish Water Companies face problems related to necessity for optimizing plants. The reason for this situation is the fact that the water demand tends to be less than the design capacity of almost all the DWTPs. Based on professional literature and minding of current trends in water management, problem of effective water supply system optimization was identified. This paper is a continuation of authors study on a new approach to reliability and LCC analysis for DWTPs and can be used as a support tool in the Operator's decision making process.

In this study a new index—operational readiness rate (R) was introduced. The index can be assumed as a first step of optimization process. The closer the value of the indicator is to 1.00, then the higher is the level of system utilization. It can be seen that all analyzed subsystems are not fully utilized. Therefore another steps of optimizing calculation should be conducted.

ACKNOWLEDGEMENT

The paper presented has been realized in frame of the research project co-financed by the European Union from the European Regional Development Fund, Sub-measure 1.3.1. "Development Projects"; project title: "IT system supporting the optimization and planning of production and distribution of water intended for human consumption in the sub-region of the central and western province of Silesia"; project ref no POIG.01.03.01-14-034/12.

Authors would like to thank dr. Ewa Szypulska and Mr. Gary Simpson for all valuable comments.

Methods of visualizing the risk of lack of water supply

I. Piegdoń & B. Tchórzewska-Cieślak
Department of Water Supply and Sewage Systems, Rzeszow University of Technology, Rzeszow, Poland

ABSTRACT: In the era of informatization databases and information systems are an essential source of risk analysis and risk assessment of collective water supply systems. The functioning of the water distribution system is associated with the risk of occurrence of undesirable events. The result of these events may be deterioration of the water quality parameters, reduction of water pressure in the water network or total lack of water.

The aim of the study is to present the application example of applying Geographical Information Systems (GIS), database and selected information systems helpful in mapping the risk of lack of water supply to the consumers. The study also presents the idea of the European Directive INSPIRE, which is a key in risk analyzes in the water supply.

1 INTRODUCTION

The functioning of every Water Distribution Subsystem (WDS) is related to the risk which is associated with the possibility of the occurrence of undesirable events, which may result in deterioration of water quality, lack of water, as well as reduction of water pressure in the water network. Risk associated with the operation of the entire WDS should be continuously monitored to ensure adequate safety level for water consumers. In the environmental engineering a basic definition of risk is applied. That definition presents risk as a multiplication of the probability of undesirable events occurrence, losses as a consequences of these undesirable events and the degree of system vulnerability to undesirable events (Kaplan & Garrick 1981, Rak 2009, Tchórzewska-Cieślak 2011):

$$r = P \cdot C \cdot V \tag{1}$$

where:
P—a measure of probability (frequency) of undesirable events occurrence in WDS, which can be directly felt by water consumers,
C—determines the size of losses associated with undesirable events occurrence (e.g. purchase of bottled water, medical costs after consuming poor quality water, immeasurable losses, such as loss of life or health),
V—the degree of vulnerability to undesirable events.

Risk in every technical systems belonging to the critical infrastructures is inseparably associated with risk management (Babiarz 2006, Kołowrocki 2001, Kotowski & Kaźmierczak 2013, Mays 1989, Rak 2009, Tchórzewska-Cieślak 2011).

Risk management can be defined as socio-economic decision-making process (Rak 2009). It is obvious that it is impossible to eliminate risk, but system operator can take any action to minimize it. Decision-making is the responsibility of the operator of the WDS. Therefore, to avoid the negative consequences of making wrong decisions regarding WDS operation, the operator must learn how to assess risk, inform others of its size, and know what action must be taken in critical situations (Zio 2006).

Risk analysis is a research method relying on decomposing all components creating a problem or issue and analyzing that problem. One of the methods using to minimize risk of undesirable events occurrence is the visualization of all the components that can cause risk growth using the risk maps. In this case the map of risk is understood as a graphic presentation of the areas directly exposed to the negative consequences of failures in WDS. To create the risk maps it is necessary to have a set of operational data about system, as well as detailed statistical data relating to the emergency situations. These data should also allow to identify the analyzed object, undesirable events and to make a cause-effect analysis. The complete and detailed data determine the correct risk analysis and assessment, and thus the process of risk management. Very often the problem is in information interpretation, lack of continuous recording and processing of operational data. There are many sources of operational data.

An important element in risk analysis and assessment is the possibility to use different types

of software that have significant impact on a degree of detailed calculations (Piegdoń et al. 2014, Tchórzewska-Cieślak et al. 2013).

Geographic information systems describes the spatial characteristics of the environment, underground infrastructure which is part of the critical infrastructure. GIS models and simulates the processes of the based on databases. Is developed to collect, process and display spatial data. Is applicable in many areas of life. It is used in water and sewage networks management of by water companies, in struggling with the elements of nature or in spatial, urban planning (Bahr & Vogtle 1999, Baz et al. 2009, Bernhardsen 1992, Ghinoi & Chung 2005, Rao et al. 2000, Sholten & Stillwell 1990, Williams & Shah 2000, Zeng et al. 2007).

The study presents legal regulations relating to the implementation of the directive Infrastructure for Spatial Information in the European Community (INSPIRE) (Directive 2007/2/EC 2007).

The aim of the study is to present the possibility of applying GIS and database in the process of analyzing and assessing undesirable events which may occur in WDS, and to show how determine the areas vulnerable to the negative consequences of these events.

In the example application the risk of lack of water supply using the matrix method, due to the possibility of the occurrence of the accident on the distribution network was determined. The one asset of risk—lack of water—was considered with respect to a water consumer as the main water recipient.

2 THE INSPIRE DIRECTIVE IN THE CONTEXT OF RISK ANALYSIS

In order to identify threats that accompany the WDS operation and which have a negative impact on water consumers, it has become necessary to base on the largest possible amount of data. Currently, the most popular method of data collecting became GIS applications (Filipkowski et al. 2006, Gromiec 2006, Kwietniewski 2008, Piegdoń & Tchórzewska-Cieślak 2013, Tchórzewska-Cieślak et al. 2013, Zimoch & Paciej 2013). These systems allow to collect different geo-information about topographic objects, undesirable events and processes that have significant influence on every critical infrastructure.

However, in many cases making a thorough risk analysis is not possible due to lack of complete operational database. The main reason is that searching for interesting data is a time-consuming and costly operation. In addition, there is always a need to check whether the data are current. The European Union came out to meet all these requirements establishing on March 14th 2007 the INSPIRE Directive. The INSPIRE directive aims to create the European Union (EU) spatial data infrastructure. This will enable the sharing of environmental spatial information among public sector organizations and better facilitate public access to spatial information across Europe. A European Spatial Data Infrastructure will assist in policy-making across boundaries. Therefore the spatial information considered under the directive is extensive and includes a great variety of topical and technical themes.

The main purpose of the Directive is to support Member States in the field of environmental protection and to support the activities having direct impact on environment condition. These activities are related to (inspire.ec.europa.eu):

- collecting data and keeping them where they can be maintained most effectively,
- possibility to combine seamless spatial information from different sources across Europe and sharing it with many users,
- geographic information needed for good governance at all levels should be readily and transparently available,
- easiness in finding what geographic information is available, how it can be used to meet a particular need and under which conditions it can be acquired and used.

For example, water supply companies can post information about failures of water pipes, planned renovations of the network, as well as water quality, or specific parameter values (physico-chemical, bacteriological and organoleptic) on the geoportal. Such communication between supplier and water consumer will affect their relationship as well as increase consumer trust.

3 TYPES AND SOURCES OF DATA IN RISK ANALYSIS

The availability of relevant data is the basis for reliable results obtained from the analysis of risk. These data are needed to describe the system, to identify and assess the undesirable events and mainly to minimize the potential risk. To make an analysis it is necessary to base on data with varying degrees of accuracy. The variety of databases can be considered in three categories (Hokstad et al. 2007, Hokstad et al. 2009)

- general data—data from external sources. The data may relate to the efficiency of Water Treatment Plant (WTP).
- data about system—data characterize the WDS. The data relate to the number of water consumers and local factors affecting the general knowledge about the failure of water pipes.

Table 1. Data in risk analysis.

Type of data	Data source
General data	
– data about effect of various doses of pollutants on human health.	– websites, – website of the World Health Organization (WHO), – websites of State Sanitary Inspectorates,
Data about system	
– geographic data, – possible risks in the catchment area, in water sources and water distribution subsystem, – GIS data regarding the dangers, – data about environment, – data about technology of water treatment, – data about water pipes condition, – number of water consumers, – water consumption during the day.	– maps, – water supply company, – technical drawings, – documented data, – water network exploitation, – employees knowledge, – current controls.
Event data	
– data about failures of all the subsystems forming an integral collective water supply system, – erroneous data arising from human fault, – events that had an impact on water pollution, – operational data relating to preventive and corrective measures.	– database available in water supply company about failures of water network, – active and constant exploitation of water network, – reports about undesirable events that happened in the past, – employees knowledge.

– event data—recorded and documented data about the undesirable events, system failures that occurred in the past.

Table 1 presents the data and their sources for the purposes of risk analysis.

Properly selected and prepared database can be used for many exploitation operations, such as preparing preventive schedule, renovation of critical infrastructure networks, the location of leakages from the network, in water resources management and many other tasks related to the functioning and exploitation of network systems (Applying GIS … 2000, Geographic … 1992, Glasbrook 1994, Heinonen 2000, Iglesias et al. 1997, Kane & Gough 1996, Longley et al. 1999, Lyon 2003, Otero et al. 1997, Schroeiber & Grossman 1997, Wu et al. 1997).

4 RISK AS A MEASURE OF SAFETY

4.1 *Basic concepts*

Safety in water supply is defined as a state of water management that enables to cover the current and future water demand, in a technically and economically justified way, by the requirements of environmental protection (Berg et al. 2010, Ezell et al. 2000, Kołowrocki 2001, Li et al. 2009, Mays 1989, Rak 2009, Tchórzewska-Cieślak 2011, Tchórzewska-Cieślak 2011 et al. 2012). The basic and primary entity to which the water safety concept is directed is water consumer. The secondary is water supplier—water manufacturer. That is why risk can be considered as a consumer risk and supplier risk (Rak 2009, Tchórzewska-Cieślak 2011).

Water supplier risk can be associated with the functioning of the WDS. The risk map in this aspect can be realized on the basis of:

– material of water pipes, their unreliability, age (in the sense of operating time) and pipes provided for renovation.

Figure 1 shows the options of creating the risk maps with respect to water supplier.

The second aspect is to consider risk with respect to a consumer as a major recipient. In this case the maps of risk can be created based on:

– the number of inhabitants exposed to the lack of water supply due to the undesirable events,
– the number of inhabitants exposed to consume poor quality water,
– the designation of areas vulnerable to the undesirable events occurrence.

Figure 2 shows the options of creating the risk maps with respect to a water consumer.

Risk of water supplier and water consumer should be considered separately. In the application example the risk of lack of water supply due to failure of distribution pipes in relation to the consumer of water was made.

4.2 *Research methodology*

One of the methods used for risk analysis is three parametric matrix for risk assessment

Figure 1. Possibilities of risk maps with respect to water supplier.

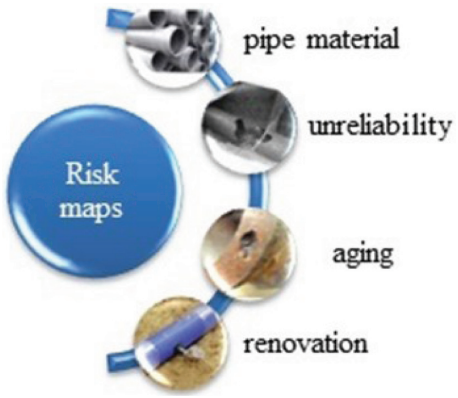

Figure 2. Possibilities of risk maps with respect to water consumer.

(Kołowrocki & Soszyńska-Budny 2012, Rak & Tchórzewska-Cieślak 2006, Tchórzewska-Cieślak & Piegdoń 2012). Risk matrix shows the dependence of the probability of the occurrence of threat from its consequences, which in the WDS are the loss of water, reduction in the level of supply reliability and consumers safety which are equivalent to the loss of water consumers health or life.

In quantitative matrix methods for all parameters of risk a point weight is assigned. In this way it is possible to make an analysis for various undesirable events.

The process of risk assessment consists of determining (estimation) its numerical value and comparing it with the accepted criteria values. The criteria values for the individual levels of scale depend on many factors, expert assessments, as well as accepted method of risk assessment, e.g. 2, 3, 4, or 5 parametric matrix method.

Using the product of the particular risk parameters according to (1) the risk matrix was obtained with numerical values within the range from 1 to 27. Three parametric risk matrix was shown in Table 2.

In quantitative matrix methods all the risk parameters have the relevant point weight assigned (depending on the adopted scale). To estimate the level of risk of the undesirable event occurrence, the criteria for the parameter showing the probability of the undesirable events occurrence (failure of water pipes) depending on the determined level of failure rate indexes, were proposed in Table 3. In Table 4 the values for parameter of losses caused by the undesirable event, depending on the value of the loss factor for the loss of water consumers safety, were proposed. The point scale and the criteria for the parameter V (vulnerability of the system to the undesirable event occurrence) were adopted according to the criteria available in the literature (Tchórzewska-Cieślak 2011).

In Table 5 the loss factor combining the type of water pipes with the degree of loss of water

Table 2. Three parametric risk matrix.

	P								
	1	2	3	1	2	3	1	2	3
C	**V** = 1			**V** = 2			**V** = 3		
1	1	2	3	2	4	6	3	6	9
2	2	4	6	4	8	12	6	12	18
3	3	6	9	6	12	18	9	18	27

Table 3. Criteria for the point scale for the probability parameter with respect to the failure rate index for distribution pipes.

	Distribution pipes
P	λ [failure/km · year]
1	≤0,7
2	0,7 ÷ 1,0
3	>1,0

Table 4. Criteria for the point scale for the parameter of losses caused by the undesirable event, depending on the value of the loss factor, with respect to the loss of water consumers safety.

	Distribution pipes
C	The value of the loss factor, %, f(i)
1	20
2	60
3	80

Table 5. The values of the loss factor combing the pipe type with the degree of the loss of water consumers safety.

Type of pipe	Range of values for the failure rate index, [failure./km · year]	Calculated average value of the failure rate index, $\lambda_{śr}$ [failure./km · year]	The value of the loss factor, % f(i)
Distribution	≤0,7	0,26	20
	0,7 ÷ 1,0		60
	>1,0		85

Table 6. The three-stage scale of risk levels.

Levels of risk	Interval
Tolerable risk	$1,0 \le r \le 8,0$
Controlled risk	$9,0 \le r \le 12,0$
Unacceptable risk	$18,0 \le r \le 27$

consumers safety, was proposed. The values of the loss factor were adopted, depending on the pipe type and the values of the failure rate index.

Based on the values listed in the Tables 2–4 and according to (1), a set of possible risk values can be presented as a matrix:

$$r = \begin{bmatrix} r_{1\cdot1\cdot1} & r_{2\cdot1\cdot1} & r_{3\cdot1\cdot1} \\ r_{1\cdot2\cdot1} & r_{2\cdot2\cdot1} & r_{3\cdot2\cdot1} \\ r_{1\cdot3\cdot1} & r_{2\cdot3\cdot1} & r_{3\cdot3\cdot1} \\ r_{1\cdot1\cdot2} & r_{2\cdot1\cdot2} & r_{3\cdot1\cdot2} \\ r_{1\cdot2\cdot2} & r_{2\cdot2\cdot2} & r_{3\cdot2\cdot2} \\ r_{1\cdot3\cdot2} & r_{2\cdot3\cdot2} & r_{3\cdot3\cdot2} \\ r_{1\cdot1\cdot3} & r_{2\cdot1\cdot3} & r_{3\cdot1\cdot3} \\ r_{1\cdot2\cdot3} & r_{2\cdot2\cdot3} & r_{3\cdot2\cdot3} \\ r_{1\cdot3\cdot3} & r_{2\cdot3\cdot3} & r_{3\cdot3\cdot3} \end{bmatrix} = \begin{bmatrix} 1 & 2 & 3 \\ 2 & 4 & 6 \\ 3 & 6 & 9 \\ 2 & 4 & 6 \\ 4 & 8 & 12 \\ 6 & 12 & 18 \\ 3 & 6 & 9 \\ 6 & 12 & 18 \\ 9 & 18 & 27 \end{bmatrix}$$

The calculation procedure presented above concerns a general characteristics of matrix methods used for risk assessment (Rak & Tchórzewska-Cieślak 2006).

The most commonly encountered scale of risk levels is a three-stage scale: tolerated, controlled and unacceptable risk (Aven 2009, Aven 2010, Boryczko & Tchórzewska-Cieślak 2012, Ezell et al. 2000, Rak 2009, Tchórzewska-Cieślak 2011, Zio 2006).

The scale of the level of risk of lack of water is summarized in Table 6.

5 APPLICATION EXAMPLE

5.1 *Characteristics of the WDS*

Inhabitants of the city are supplied with water by boundary-chamber water intake with a capacity of 84000 m³/d. The total length of the water supply system is 894,1 km (data from 2013). The main network, 49,8 km long, is made of iron and steel pipes. The distribution pipes are made of cast iron, steel, PE and PVC, with a total length of 520,5 kilometres. The water supply connections, with a length of 323,8 km, are mainly made of steel, cast iron, PE and PVC. The water supply system in 80% is a closed system. There are two teams of water storage tanks, ZBI and ZBII, with a total capacity of 33100 m³.

Figure 3 presents water network scheme for analysed city.

5.2 *Analysis of water network failure*

For the WDS an analysis and assessment of the risk of the undesirable event occurrence (the failure of water pipes), has been made. An assessment of the failure of water pipes was made with basic characteristic, statistical parameters. The risk analysis in WDS was based on the proposed three parametric risk matrix, according to formula (1). The analysis includes an assessment of the risk for main network and distribution pipes.

In order to analyse the risk of lack of water supply in the aspect of water consumer, caused by the failures on distribution network in the first instance the analysis of the intensity of distribution network was made. In the failure analysis and assessment the failure rate index, λ, for water pipes, was used. The values of the failure rate index for distribution pipes λ_R were determined on the basis of the formulas available in the literature (Rak 2009, Tchórzewska-Cieślak 2011) and operational data. The results of the analysis and failure assessment for years 2005 to 2012 were presented in Table 7 and Figure 4.

5.3 *Results of analysis and risk assessment*

A calculation example was performed for the distribution pipes. In order to determine the risk of lack of water supply due to failure of distribution pipes the parameter values were assumed:

– parameter P (the probability of the undesirable event) was assumed to be 1 because according to Table 5 λ average ≤ 0.7 failure./km · year,

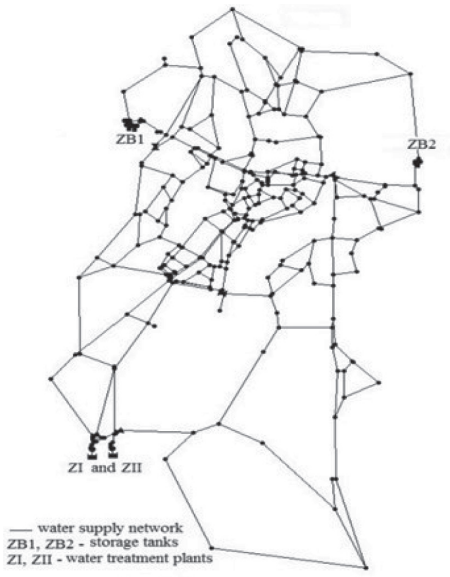

Figure 3. The scheme of water network.

Table 7. The failure rate index for the water supply network, over the years 2005–2012.

	Type of pipe		
	Distribution		
Year	length [km]	Failure	λ_R [failure./km · year]
2005	350,5	108	0,31
2006	384,4	136	0,35
2007	443,5	114	0,26
2008	447,7	106	0,24
2009	468	114	0,24
2010	490,5	114	0,23
2011	504,1	113	0,22
2012	520,5	109	0,21

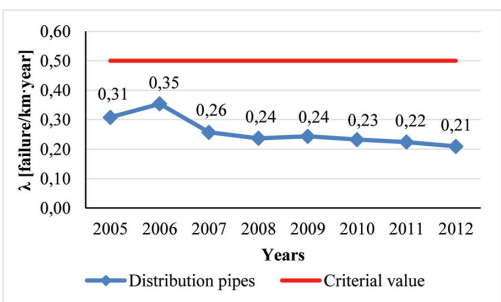

Figure 4. Failure rate indexes for water pipes over the years 2005–2012.

– parameter C (loss caused by the undesirable event) was assumed to be 1 because according to Tables 6 and 7 the undesirable event results in 20% loss of water consumer safety,
– parameter V (the degree of vulnerability to the undesirable events) was assumed to be 1 because 80% of water supply network is a closed system, with the possibility to cut-off the damaged section using gates (in order to repair the network), the network monitoring covers the whole water supply area, water supply company has the comprehensive system of warning and response in crisis situations with the full ability to use the alternative water sources.

Table 8 presents the values of P, C, and V for the risk, associated with the risk of lack of water supply with respect to water consumer and depending on the type of water pipe.

Creating a product of parameters according to the formula (1) and using the scale point for each risk parameter the value of risk of lack of water supply due to failure of distribution pipes on a tolerable level was obtained. The results were shown in Table 9.

5.4 *Risk map*

Intensive development of GIS software extends the capabilities of rational management in water distribution subsystem. An example of this phenomenon is the use of GIS as a spatial database in integrated system management for water companies. Effects of using GIS can be seen for over ten years (Applying GIS 2000, Geographic … 1992, Glasbrook 1994, Iglesias et al. 1997, Reynaert et al. 2004, Shamsi 2005, Scholten & Stillwell 1990, Seidenstat et al. 2005) and since few years also in Poland (Kotowski et al. 2007, Kwietniewski & Kłoss-Trębaczkiewicz 2007,

Table 8. Values of parameters associated with the risk of lack of water supply with respect to water consumer.

Parameter	Distribution pipes
P	1
C	1
V	1

Table 9. Value of the risk caused by failure in the distribution network.

Risk of lack of water supply	Distribution pipes
r	1
Level of risk	Tolerable

Kwietniewski et al. 2007, Kwietniewski 2008, Piechurski & Lampart 2005, Zimoch 2006). In water supply companies GIS applications are very convenient tool used in risk analysis. Using data visualization it is possible to create the risk maps based on the failure of water supply system, the age of pipes and current conditions of pipes with respect to the water supplier, taking also into account the impact of failure with respect to the water consumer. ArcMap software created by ESRI can be an important element in the process of decision making in WDS and risk analysis. ArcMap is the main tool for viewing, editing, and analysing data in a geodatabase. Is highly customizable, and it allows you to save your customization, as well as layers of data, to maps. The software has functions of acquiring and processing the data about the failure in water supply network and allows their spatial visualization.

The risk map of lack of water supply can be made taking into account the operational data, statistical analysis, and analysis of the failure rate indexes. By analysing water supply pipeline which is characterized by the highest failure rate it is possible to make for this pipeline the map of risk of lack of water supply showing the areas and buildings exposed to the long-term lack of water.

To present the results of the analysis using ArcMap it is possible to use two methods: the first method is the question about the attribute belonging to the select operation, e.g. "show water pipes with the failure rate higher than 0.2". The result of this type of analysis is to leave by the program only those sections that meet the above question. More advanced methods are buffering operations which are classified as analytical operations, e.g. "show areas being 20 m away from pipes with the failure rate higher than 0,35". The result of such an analysis are, for example, buffer areas marked above. Figure 5 presents the possibility of presenting data using the risk maps in ArcMap application.

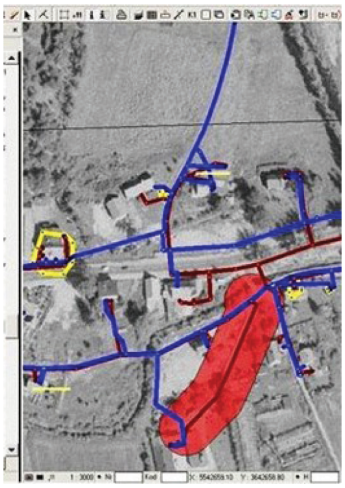

Figure 5. Graphical presentation of the results of analysis.

The map of risk of lack of water supply can be created for all types of water pipes on the basis of available data. Generated maps can be enriched by reports and charts that will clearly show the results to the water consumer. The maps in the application can be browse, edit and it is possible to analyse all kinds of data. There is also the ability to integrate data from different sources such as shape files (.shp), information layers, tables, CAD files, raster images and numerical terrain models. It is possible to browse and search interesting data and identify relationships between localized objects.

6 CONCLUSIONS

- Accurate and complete database systems are a base to perform more or less complicated risk analysis with respect to the lack of water supply to customers. Constantly updated data serve as a foundation in GIS applications. The programs allow to create GIS maps of risk due to the occurrence of undesirable events.
- The diversity of the use of simulation software enables to visualize risk analysis using models and diagrams. They can be used as a tool in decision-making process at planning a renovation of the network. The presented examples of ArcGIS application can be adapted for each water distribution subsystem, its parts or components.
- Nowadays, computer programs available on the market make it possible to fully visualize the various components of the critical infrastructure and track factors affecting the increase in risk.
- In the application example the risk of lack of water supply using matrix methods, due to failure of distribution pipes in relation to the consumer of water was made. This method allows also to determine the risk of lack of water with respect to water supplier considering all assets.
- The proposed method of determining the risk is a graphical presentation of data which clearly allows to present the analyses of conducted projects not only to the decision making body of the company but also to the general public.
- Using the risk maps it is possible to classify the pipes that have to be to replaced or renovated, taking into account the areas and buildings exposed to long-term lack of water.
- Generated risk maps can be used to increase the safety of the WDS in the context of water producer and water consumer.

– If it is not possible to obtain complete data for operational risk analysis an expert knowledge should be used. Database created in this way can be considered as a basis for risk modelling by means of fuzzy methods.
– In further work in this area with detailed simulation of the operation of water distribution subsystem should be carried out (using hydraulic network models), which is the next stage of the authors' research.

Concept for development of safety-related filters

O. Krini, J. Krini & J. Börcsök
Department of Computer Architecture and System Programming, Kassel, Germany

ABSTRACT: The safety standard IEC 61508 defines the requirements for safety systems in the plant safety independently of application. It is intended the basis of all safety related electrical, electronic and programmable electronic systems, in order to apply it in safety critical applications. The purpose of this paper is to describe the design and development of safety digital filters. The digital filter will be implemented on a FPGA structure. The goal of this project is to implement a safety filter which has the characteristic of a low pass filter second order. The safety concept ensures that the filter work with the predefined characteristics. In this documentation a low level safety concept will be discuss. At first an analog signals with different frequencies will be transform in the digital area to make digital signal processing on the signals. The reason of the digital signal processing is to let only some signals with certain frequencies to cross over the System. Which signals can cross over the system will be given over the transfer function of the digital filter.

1 INTRODUCTION

The reliability is one very important parameter of applications software. Hard- and Software reliability is the probability that given hard- and software will be functioning without failure in a given environment during a specified period of time. Hence, hard- and software reliability is a key factor in development process and quality. The state of the art is, that reliability models exclusively consider avoidable faults that could lead to critical failure. Furthermore, there is no possibility to predict the residual number of critical faults, since very few failure data came from the testing.

Digital filters are Systems which are changed the input signals. The changing can be happen of different modes like to steaming signals, to amplify signals or to suppress the input signals. The determining of the characteristic of the digital filter will be done with mathematical models. These mathematical models are the fundamental of the system theory. However where are here the different between the analog filters and digital filters? The different are only in the implementation. While analog filters are designed with passive components like resistors and capacitors or active components like amplifiers, the digital filters are developed with logical components. Digital filters takes an important role in this world which are most controlled by electronics. The application area of these Systems is really huge.

Like in medical technology it is important that a digital filter works with a high reliability. Information's which are converting in the medical technique can be associated with a life-threatening situation. For this reason a digital filter must be implemented safety. In this documentation will be given an abtract about the functional safety, which based on IEC 61508 and also described how a digital filter will be implemented of a FPGA structure. In addition a safety concept will be presented which can let work the filter with a higher reliability.

2 STOCHASTIC BASICS

The modeling of reliabilities, probability calculation plays a central role for the reliability and risk assessment of hardware and software systems.

The probability calculation is one of those areas of mathematics, where the connection between the real world and its mathematical description is particularly evident. However, this particular area of mathematics is one of those, in which logical thinking is so in demand than in virtually any other areas. For the assessment of reliability in software systems, it is necessary to know some basic concepts and calculations of probability theory.

The most known and must favorite probability model for the reliability analysis of safety systems is the exponential distribution. With this distribution it is possible to represent the time dependent

failure probabilities F(t) of components. For the determination of the probability of failure one needs a data of the failure frequency, number of built in components and operational time of the components. The failure probability is defined as

$$F(t) = 1 - e^{-\lambda \cdot t} \tag{1}$$

The density function is calculated from

$$f(t) = \frac{dF(t)}{dt} = \lambda \cdot e^{-\lambda \cdot t}. \tag{2}$$

The Binomial distribution, also known as Bernoulli distribution, belongs to the discrete distribution. The specific feature of the binomial distribution is that it can accept only 2 values. This means that a component failure is present $x = 0$ or is not present $X = 1$. The probability of exactly x successes is given by this formula:

$$P(X = x) = \binom{n}{x} p^x \cdot q^{n-x}, \tag{3}$$

where n is the number of experiments. The binomial distribution can be graphed as following:
