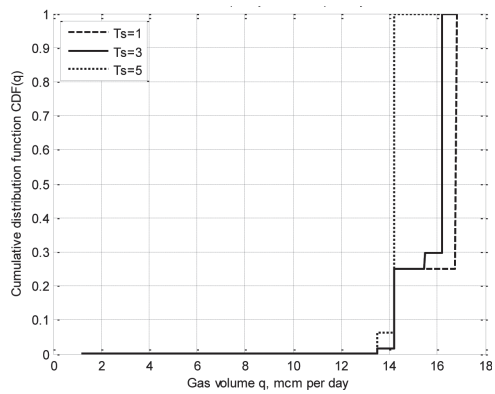

Figure 7. Cumulative distribution function at time steps 1, 3 and 5. Pipeline supply in Node 2 is reduced to 13 mcm per day.

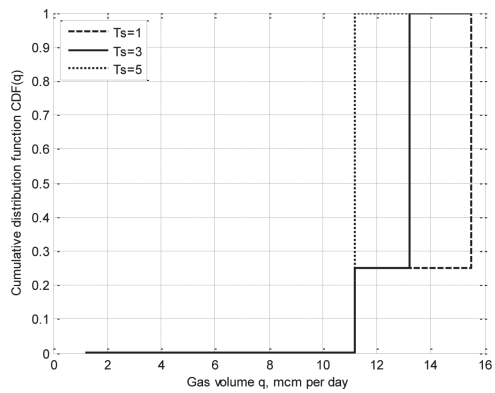

Figure 8. Cumulative distribution function at time steps 1, 3 and 5. Pipeline supply in Node 2 is reduced to 10 mcm per day.

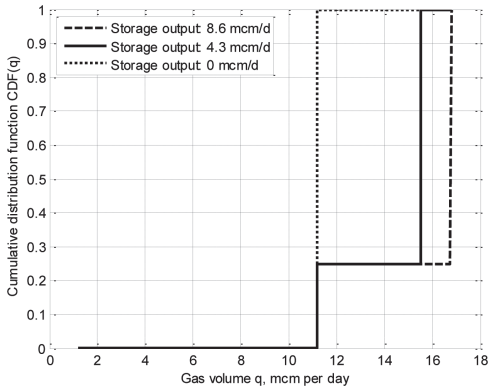

Figure 9. Comparison of the storage effect with double maximum discharge volume.

investigate network response and find optimum configuration. For example, storage maximum discharge volume can be increased and the effect to the network can be quantified.

Figure 9 effectively shows the results of the double maximum storage discharge volume effect on the total gas volume availability in the network. Similar "what-if" type of analysis can be done for any element and parameter in the network in order to effectively plan network modifications and quantify various options in terms of security of supply.

7 CONCLUSIONS AND DISCUSSION

The probabilistic gas network model has been developed and tested on a number of scenarios including time-dependent storage discharge scenario. The testing network is a real one country gas transmission network, but its geographical location is not provided. The model has a number of advantages and limitations that must be considered by interpreting the results. The model at this stage cannot model adequately consequences of failures of compressor stations. Currently, it is assumed that pipeline capacity is reduced by 20% in the nearest section, however this assumption needs to be validated by physical flow computations. Failures of two nearby compressor stations would have severe effect on the network capacity, but this event is not considered in the current version of the probabilistic model.

The model currently computes time-dependent storage discharge in a simplified step-wise manner. These limitations will be eliminated or reduced in the future versions of the model.

Despite the limitations, the model provides an indication of the worst networks nodes in terms of security of supply and provides their numerical ranking. It is recommended to use the results of the model in a qualitative (comparative) way rather than interpret numerical values directly. The model is very powerful to compare and evaluate different supply options, new network development plans and analyse potential crisis situations.

Weekly availability changes of web applications implemented in virtualized environment

T. Walkowiak
Wroclaw University of Technology, Wroclaw, Poland

ABSTRACT: Paper presents a numerical method for determining changes of availability of web applications implemented in virtual environment. It takes into account the reliability and performance aspects of software and hardware elements of the web system. The revenue process model takes into account working hours of administrators and a time of repair (or reconfiguration) for each type of failures. The described method was a basis for the development of a Monte-Carlo simulator that allows calculating variability of web application availability over a week. The paper contains the numerical results for a test case web application implemented in virtualised environment.

1 INTRODUCTION

Over the last decade we observe not only rapidly increase in a number of web page users but also significant amount of new web applications, that became available every day. As modern web applications are complex systems with wide range of features and access to many external services, meeting expectations of nowadays user is a challenging task for websites providers.

The formal service's requirements are defined in a negotiated agreement between a customer and a website provider which is called SLA (service-level agreement). One of the most significant problems that web site providers have to face is how they can provide the QoS (quality-of-service) required by their clients, having in mind that the web traffic is highly dynamic and volatile (Liu et al. 2006). A given web server configuration may meet requirements under some traffic load while under other workload its performance may not be satisfying.

Many aspects like hardware features, software characteristic, a multilayer architecture and network aspects make the problem of analyzing, projecting and reconfiguration of the web service not a trivial one. One of important techniques in implementing web application is virtualization. It supports the backups and rollback feature, which allows recovering virtual machine after security breaches (Hoopes 2009) and performing reconfiguration (Walkowiak & Caban 2014) very fast.

One of quality metrics used for web systems is availability, defined as the probability that a user will be properly serviced by a system at a specific time.

In the paper we propose to analyze the availability of web systems implemented in virtualized environment. The analysis takes into consideration functional aspects (like changes in workload) and reliability aspects of the system on which the application is deployed. The reliability aspects includes virtualization environment, reconfiguration as a method of preserving continuity of services in case of failures (Caban & Walkowiak 2012) and working hours of system administrator (Walkowiak 2014).

The organization of the paper is as follows. We start with short analysis of related works, next virtualization and its reliability aspects are presented. In the section 4 the availability of a web application is defined including reliability and functional aspects. It is followed by a detail model of assessing the web application availability by computer simulation. Finally, a test case system is presented and its availability calculated as it varies in time (over a week). We conclude with a short summary.

2 RELATED WORKS

There are a large number of studies examining the reliability of websites or web applications. However, in most cases the reliability analysis is based on Markov processes (Barlow & Proschan 1996) and the analyzed system is modelled as a simple serial one (Lipinski 2006). The Markov or Semi-Markov approach have significant limitations (Malinowski 2012) which includes the limited distributions (mostly exponential), narrow applicability (only to a special class of systems) and poor compliance with reality. That is why computer simulation (Juan et al. 2012) is used for availability analysis of complex systems.

The administration hour's model presented in the paper aims to create a detail model of repair time. Whereas due to the popularity of the Markov approach the most common assumption done by researches is a usage of exponential distribution for a repair time (Aven & Uve 1999). In fewer cases researches are using other distributions (Jia & Wu 2009) or compose the repair time of two periods: waiting and real repair (Zhang & Wu 2009). The last one approach is related to presented here.

The paper addresses some issues connected with relocating services as a reaction to hardware failures and security incidents, so called reconfiguration. This is a well-documented concept and a review of which is given in (Lent 2012). The analysis of the system availability under reconfiguration could be found in (Walkowiak & Caban 2014).

Methods of availability analysis of web systems that are described in the literature are based on the analytical models (Gokhale & Jijun 2006) on real system monitoring (Banerjee et al. 2010) or computer simulation (Rahmawan & Gondokaryono 2009).

The approach presented in this paper is an extension to work (Walkowiak 2014). The extension includes:

– modelling failure results not only by as an inoperability of a component but also by a degradation of component performance,
– modelling the reconfiguration process as a reaction to failures,
– analysis of web application deployed in virtual environment resulting in a hierarchy of failures (virtual machines and physical servers) and less importance of hardware failures.

3 VIRTUALIZATION

3.1 *Introduction*

IT industry is nowadays affected by virtualization trend. Increasing popularity of virtualization was born since it became clear that virtualization is supposed to help companies to save money on IT costs. Virtualization advantages encourage business owners to invest in it. However, they should also take in consideration the risks, dangers and weaknesses of this technology (Stanclik & Walkowiak 2013).

The term virtualization refers to methodology of dividing the computer (or server) resources (the CPU, memory, disk drives, network interface cards and so forth) in to multiple separate execution environmental achieving by many mechanisms such as hardware partitioning, time-sharing, partial or complete machine simulation, emulation and others. The resulting environments which are called virtual machines should ensure efficiency as high as possible (Smith & Nair 2005).

3.2 *Reliability aspects of virtualization*

Moving business into virtualization brings undoubtedly many benefits. First, server consolidation allows increasing the utilization of physical servers. Many servers use only 10 to 15% of hardware re-sources (Portnoy 2012), thus other resources are wasted. Such a solution is very unprofitable. Virtualization gives the way to better utilization of resources. Moving processing environments to virtual machines decreases the number of physical machines with utilization ratio up to 90% (Portnoy 2012). Fewer servers also reduce the costs of power consumption as well as money spends on hardware maintenance.

Each guest operating system deployed on the server running in isolation manner, which is crucial for a secure and reliable environment. Any guest's fault appearing in the virtual system cannot be spread on the others while virtual machines' operations are separated from each other. This feature keeps virtual environment safer. Additionally to increase security level, during configuration security settings can be assigned to virtual machines rather than to the server. It relates especially to the access privileges. In standard operating system each application in general runs with administrator access. However under virtualization applications can be run on the designated virtual machines, each may be configured with different credentials and different privilege access.

Hardware management is one of the biggest challenges that organizations are faced with. Each failure or hardware upgrade can take hours to restore server operability. Virtualization makes the virtual infra-structure management more convenient and efficient. Since operating systems are independent from the hardware they can be easily moved to another server. This is a key feature when server's memory capacity gets low especially it takes only a few minutes. A storage virtualization gives also better way for data management. Data centralization makes data access much easier when it can be assigned as a single logical entity instead of being separated along several individual physical servers.

To protect business continuity virtualization provides also disaster recovery mechanism. Disaster recovery ensure that when virtualized system crash, it will be restored as quick as possible. With system allows to take snapshots of current state of system each virtual machine can be backup from any time, for example from last week. What is more such mechanism is used for data replication

keeping data consistent and up to date. (Stanclik & Walkowiak 2013)

4 AVAILABILITY OF WEB APPLCIATION

4.1 *Reliability analysis*

The faults occurring in the web based systems can have multiple causes. Hardware faults, most commonly considered in reliability analysis, occur relatively rarely due to the advances in manufacturing technology. However, they require long time to repair. (Walkowiak & Caban 2014)

Most failures in contemporary computer systems are caused by exploitation of software faults, which can have consequences ranging from decreased availability to complete blockage of an application. Intentional attempts at exploitation of software vulnerabilities constitute the most widespread type of threats to a web application. Human mistakes can have effects similar to vulnerability exploitation, even if they are less likely than the intentional attacks. (Caban & Walkowiak 2012)

Whenever a fault manifests itself in a web system, whether it is a hardware failure, a software error or a security attack, an administrator is faced with a difficult problem to maintain the continuity of business services. Isolation of the affected hardware and software is usually the first reaction (to prevent propagation of the problem to yet unaffected parts of the system). It then follows that the most important components of the application have to be moved from the affected hosts/servers to those that are still operational. This process of reconfiguration is easily achieved nowadays in virtualization environment.

Therefore, the web system from the reliability point of view is a repairable system. Faults occur in the system randomly, usually with a predictable distribution. Then the system for some time operates in a degraded state or becomes inoperational in a failure state until maintenance procedures start. It is firstly based on partly restoring the system operability by redeployment of virtual machines so for some time the system operates in degraded state and finally is restored to full operability. The performance of the application is different at each level of degradation. (Walkowiak & Caban 2014)

Summarizing, the application is operating in one of $0...L$ levels of degradation (including normal operations—without any failure). Since the process of changes of degradation levels is ruled by a random distribution let assume, that we could describe each level of degradation be its probability. Let $P(t,l)$ be a probability that the web application is in the l-level of degradation at time t [s], i.e.:

$$P(t,l) = \Pr(S_{l,t}), \tag{1}$$

where $S_{l,t}$ is an event that the application is in the the l-the level of degradation at time t.

4.2 *Availability analysis*

The paper focuses on assessing the availability defined as the probability that a user will be properly serviced by a web application at a specific time, i.e.:

$$A(t) = \Pr(U_t), \tag{2}$$

where U_t is an event that the application provides correct responses. It the previous section we have distinguished a set of levels at which the application is operating. Therefore, taking into consideration the conditional probabilities and Bayes' law the (2) could be calculated as:

$$A(t) = \sum_{l=0}^{L} \Pr(U_t \mid S_{l,t}) P(t,l). \tag{3}$$

It has been proven (Nielsen 1994) that if user will not receive answer for the service in less than 10 seconds he/she will probably resign from active interaction with the service and will be distracted by other ones. Therefore, the user is not properly serviced if there are too long responses of the web application. It could be caused by the system overload or/and the working of the system in the degradation state as a result of some failure. The response time in web systems depends also on the intensity of user request (Goseva-Popstojanova et al. 2010) that is changing in time—$\Lambda(t)$ [1/s]. Let's mark the availability of the web application at the l-level of degradation and under the intensity of user requests Λ as $Af(\Lambda,l)$, so:

$$\Pr(U_t \mid S_{l,t}) = Af(\Lambda(t),l). \tag{4}$$

Therefore, based on (3) and (4), the web application availability could be calculated as the expected value of functional availability over all degradation levels, i.e.:

$$A(t) = \sum_{l=0}^{L} Af\left(\Lambda(t),l\right) P\left(t,l\right). \tag{5}$$

The number of degradation levels could raise technical problems. For example if we assume that

the system consist of n independent components which could be failed and we consider two types of failures (distinguished based on its results) it results in 2^{2n} reliability states. It does not directly define the number of degradation states since several reliability states could be classified to one of L+1 degradation levels. But still L could be quite large and we have to assess the functional availability for each level of degradation.

The problem could be solved in a similar way as presented in (Walkowiak & Michalska 2011) by limiting the sum in (5) to the most probable levels and skipping less probable ones. It could be done by sorting all levels by its cumulative probability (calculated for the analyzed period T) starting with the most probable, and then by selecting N—levels that represent more than 99.99% of cases, i.e.:

$$0.9999 < \sum_{n=1}^{N} \int_{t=0}^{T} P(t,n)dt \tag{6}$$

5 AVAILABILITY ASSESSMENT

5.1 *Reliability model*

As it was stated in the introduction we are analyzing web applications that are deployed in the virtualized environment. Therefore, we could distinguish two groups of components that failure could result in the application inoperability or in the degradation of its performance: virtual machines and physical servers.

Let's assume that one technical service (like databases, web servers, application servers) is deployed on one virtual machine. This is a typical situation in case of virtualization. That is why we don't have to analyze additional levels in the reliability structure (i.e. technical services). A failure of one of servers results in a failure of all virtual machines deployed on that server and therefore of all technical services deployed on affected virtual machines.

The reliability analysis requires to model failures occurrence, their results and the repair time.

Let's assume that component failures could be modelled by a set of independent failures. Each component could fail in two different ways resulting in the component inoperability or in the degradation of its performance. The time to failure is modelled by the exponential distribution like in the Markov approach. The failure result is modelled by assigning each set of virtual machines (the lowest level of the hierarchy of components) failures to one of the degradation levels of the web application (including the level of the inoperability of the whole application). It seems that this is not a simple process. Since it has to take into consideration a large number of possible combination of failures, but, as noticed in section 4.2, it could be simplified by selecting only the most probable combinations. Moreover inoperability of one of virtual machines mostly results in inoperability of the web application. So cases with at least one inoperability failure exists are assigned to one degradation level. This is not true in case of the performance degradation failure.

Next step in the reliability analysis is the repair model. As it was stated in section 4.1 it is a three phase approach since at first the failed component is isolated and moved to other server or other virtual machine instance, secondly the component is repaired and finally the normal operation is restored. We need to describe the process of reconfiguration and to model duration of each phase.

We propose to model the repair time taking into consideration administrator working hours, i.e. a reconfiguration or repair could start only if the administrator is available. We assume that the administration staff works within a given time limit each day (defined by work start and finish hour) as well as on given days (working days) within a week. So the working hours of administration are periodic over a week time.

Let assume that the repair time consists of following phases:

1. time to failure discovery—equal to zero if a failure happens during working hours, in other cases it is a time to next working period;
2. failure analysis time—a time needed to discover a failure reason and to make a decision of how to reconfigure the system, we propose to model it by a random variable with a truncated normal distribution, it is a short period time so we assume that the administrator is finishing it even if it overlaps with a not working period;
3. component replace time—time required to replace a failed hardware component or to reinstall failed software component, it is modelled by a random variable with the truncated normal distribution plus an extra value in case of overlapping with not working hours; in case of hardware failures a repair time starts on the next working day, it models the delivery of a new system component by courier (Walkowiak 2014).

During a time to failure discovery and failure analysis time the web application is working on degraded level of performance defined by a failure type (like discussed above). After the failure analysis time system is reconfigured and the web application is working on degraded level of performance till the end of a repair time, when the application returns to normal operation. We assume that repairs of each component could be done independently

on each other, but degradation levels for each of repair time phases have to be analyzed.

5.2 *Degradation levels probability*

The described reliability model is based on a stochastic state-transition process, in which the states are described by the vectors of operability states of all the components in the system. The transitions between states are caused by incident occurrence and by renewal.

The state-transition model can be analyzed using a number of approaches: as a Markov chains, using semi-Markov processes or using Monte Carlo simulation (Fishman 1996). The applicability of each method depends on the assumptions that can be made regarding faults occurrence and a repair time. In case of the Markov approach, it is necessary to assume that both the faults and renewals occur with constant intensities (i.e. exponential distribution). Also the large number of states makes Markov or semi-Markov method more difficult to use. Presented in the previous section reliability model includes random values with exponential, truncated normal and discrete distributions as well as some periodic relations (staff working time), so it is hard to be solved by analytical methods.

Therefore, authors developed the reliability simulator for calculation of the probability of each degradation level. It was implemented in C++ within the Scalable Simulation Framework (SSF) (Liu 2006). Operation of the simulator is based on repetition of the failure and repair process simulation. Following simulations differ in the values of random variables occurring in the analyzed system. Knowing the distribution of these variables (input data for simulation), one can get information about the behavior of the system in the most probable cases. By observing changes of some metric values, the information about their distributions and any other statistics could be easily gathered. A single simulation last for a fixed length (in the analyzed case a multiplication of a week).

5.3 *Functional analysis*

The availability calculation method defined by (4) requires a way to assess the functional availability, i.e. the probability that a user will be properly serviced within a time less than a limit. It is a function of the degradation level and the intensity of user requests. The functional availability can be determined experimentally by performing load tests of real systems (using tools as: Funkload, Apache JMeter, Rational Performance Tester or Developer Tools from Microsoft), estimated by analytical models (Gokhale & Jijun 2006) or by simulation techniques (Walkowiak 2009). Due to fact that in case of virtualized environment it is easy to modify the system configuration, authors performed tests on the real system using self-developed load test tool. The tests were performed only for the most probable degradation levels (see section 4.2).

6 AVAILABILITY ANALYSIS OF A CASE SYSTEM

6.1 *Testbed overview*

The infrastructure of analyzed web system consists of six servers. From a pool of physical servers six virtual machines are created, on which Windows Servers are installed. All six servers are connected in a VMware cluster, under control of VMware ESXi hypervisor. The purpose of this solution is unbreakable high availability of the system, regardless of the efficiency of each server. The use of such a solution results from VMware policy, which assumes that if all servers are available, is best to keep each virtual machine separate on the server, which delivers high performance. The advantage is that if a server failure occurs, hosted virtual machine is moved up and running on the server that is the least loaded at the time. Servers and virtual machines are managed in fact from another virtual machine, VMware vCenter Server installed on one of hosts (we a copy on each of others).

In case of any failure in the system D2D2T (disk-to-disk-to-tape) backups are generated. It is the most popular backup strategy based on storing of the same data simultaneously on disk array and tape. This type of backup assumes that a backup is stored on the disk, and then stored on a magnetic tape media. As a result two backup copies are created. It is a protection in case something goes wrong during the data restoring. Then a second equivalent of a copy, stored on the tape, can be used.

6.2 *Reliability model parameters*

Since, today's computer devices are characterized by high reliability parameters, the intensity of server failure was set to one per three years. In case of hardware failures (assigned only to servers) the component replace time takes into consideration the time needed to delivery of a new system component by courier. The software components failure (with intensity set to one per year) with probability 0.2 results in the component inoperability, in other cases in the component performance degradation.

The repair model parameters were set as follows:

- mean failure analysis time—15 minutes,
- mean component replacement time—2 hours for inoperability failure, 15 minutes for performance degradation failure,

– working hours of administrator—8 am to 16 pm, Monday to Friday,
– standard deviation of truncated normal distributions—20% of its mean values.

6.3 *Simulation results*

Due to symmetrical structure of the system (identical servers, only one virtual machine per server, only one technical server on each virtual machine) and rule given by formula (6), only five levels of degradation were analyzed. The achieved results for simulating 3,000 weeks 5,000 times are presented in Figure 1. The changes of degradation level probability within a week could be noticed. The lowest value is achieved on Monday morning. It is caused by the fact that the administrator is not working during weekends and failures that occurred during that time are maintained on the next working day (Walkowiak 2014).

As it was stated in section 5.3 the functional availability was assessed by workload test on the real system. The results for analyzed degradation levels are presented in Figure 2.

It is obvious that the intensity of user requests varies in time. It depends on a type of provided service. But usually on weekends, there are fewer users then on weekdays. Also one could notice changes in traffic during a day with a peak load in a middle of day, and minimum load at night. For the analyzed case we have used the variations of intensity of user requests as presented in Figure 3.

And finally the web application availability could be calculated according to (4). The results are presented in Figure 4. It could be noticed that availability varies in time, following changes of user requests intensities and system reliability (due to a fact that the system administrator is not working 24 hours per day).

6.4 *Expected value of not properly serviced requests*

The web application availability plot from Figure 4 shows how the rate of properly serviced requests changes in time.

Since the intensity of users requests is also changing in time a more practical metric should show how many requests are rejected in a given moment of time. We propose to name it as expected intensity of rejected requests and define as:

$$Irr(t) = A(t) \cdot \Lambda(t) = \Lambda(t) \sum_{l=0}^{L} Af\left(\Lambda(t), l\right) P\left(t, l\right) \tag{7}$$

The value of this metric is presented in Figure 5.

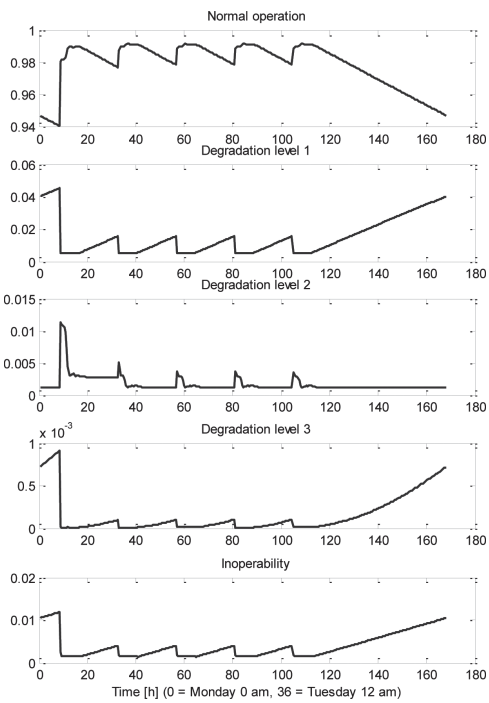

Figure 1. Probability of each degradation level as it varies over a week.

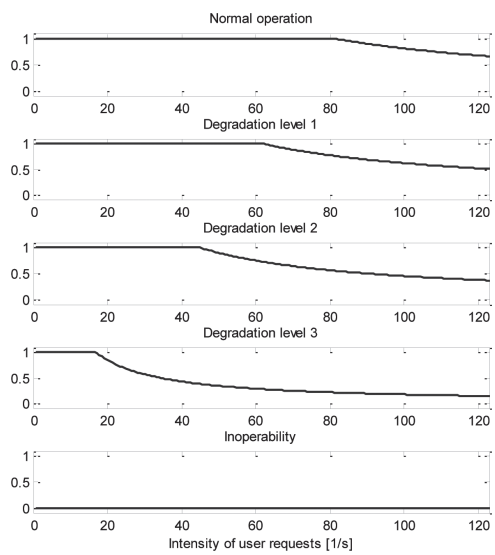

Figure 2. Functional availability for all analyzed level of degradation as a function of user requests intensity.

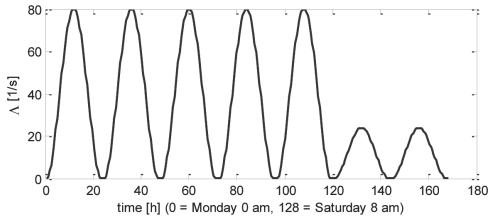

Figure 3. Assumed changes in user request intensity over a week.

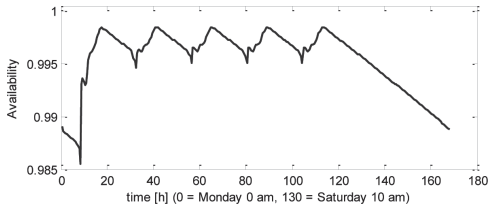

Figure 4. Web application availability changes over a week.

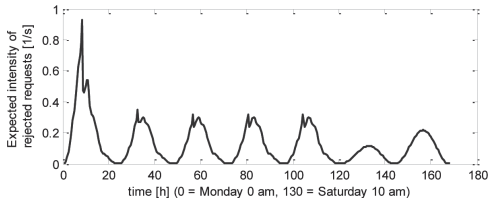

Figure 5. Expected value of not properly serviced requests changes over a week.

7 CONCLUSIONS

We have presented a method for assessing the availability of the web application based on modelling and analysis approach. It allows to:

- analyse the web application deployed in virtual environment
- analyse failures that results in an inoperability of or performance degradation of the system,
- model the reconfiguration process,
- model the repair time by three phases and to take into account working hours of administrators within a week,
- model the changes in user request intensity over a week.

The described method was a basis for the development of a Monte-Carlo simulator that calculates the variability of the web application availability over a week.

The reliability model contains some arbitrary assumptions, such as working hours of administrator. However, the proposed method allows changing the assumptions and thus different maintenance scenarios could be simulated. However, it could require changes in the source code of the simulator.

The presented method and developed tool allow to explore the impact of changes in the system maintenance (such as number of shifts or working hours of administrator) on the web application deployed in virtual environment availability. This is why the proposed solution may become the essential tool for operators of web systems.

Due to a fact that failures occur very rare in modern web systems and that the web system life is relatively short it is almost impossible to establish reliability parameters required to calculate the availability based on historical data. That is why these parameters are fixed based on experts' experience. To model the uncertainty introduced by experts we plan to use fuzzy sets, for example following methodology proposed in (Chongshan 2009), to model the web system availability.

The presented work was supported by the Polish National Science Centre under grant number N N516 475940.

Dynamic approach to modeling MTBF/MTTR in industrial and logistics systems

P. Hoffa & P. Pawlewski
Poznan University of Technology, Poznań, Poland

ABSTRACT: Safety and reliability is very important in every system. Depends on characteristics of system and its specifics different maintenance strategy can be distinguished. Currently, companies seek to reduce operating costs (whether production costs or the provision of services). One of area in which they are looking for savings is maintenance of machines and equipment. That way companies look for suitable strategy. Looking for appropriate way of keeping devices able to work, with a view to lowering costs generated by that economy, can not forget about maintaining an appropriate level of safety and reliability of the study area. In this article authors focus on one aspect, which is simulation modeling of failure of individual elements in an analyzed transport system. Subject of interest of authors is a dynamic method of mapping a failure and damage in a transport system. Authors represent possibilities of modeling aspects of reliability within an area of logistics, which are analyzed, using a variety of approaches to modeling, like using MTBF/MTTR mechanism (MTBF—mean time between next failure, MTTR—mean time to repair) and sending messages by flow item to itself.

1 INTRODUCTION

An article presents results of authors research, relating to a safety and reliability of systems. The general maintenance strategies are shown with their brief characteristics. Attention was drawn to need for selection of an appropriate strategy depending on analyzed system and its specifics. In this paper, authors limited their work to area of logistics—saying more specifically to an issue of maintenance in a field of transport and road infrastructure. Authors focus on one aspect, which is simulation modeling of failure of individual elements in an analyzed transport system. Simulation modeling is a modern method allows a simulation, experimentation, analysis and optimization of an investigated process. Subject of interest of authors is a dynamic method of mapping a failure and damage in a transport system.

Article shows the following aspects:

- a possibility of using, available on a world market, simulation software to analyze a maintenance of a specific area of logistics;
- a need to integrate an approach of Discrete Event Simulation (DES) with simulation based on agent (ABS) in order to modeling a maintenance of an exemplary model of logistics area;
- technique of modeling a disruption/failure of objects, which "are flowing" through a process.

Main purpose of this article is to present possibilities of modeling aspects of reliability within an area of logistics, which are analyzed, using a variety of approaches to modeling.

Main contribution is: the fact that an object is created dynamically, and labels describing the MTBF and MTTR (MTBF—mean time between next failure, MTTR—mean time to repair) definitions are defined when the object is created during a simulation experiment—it make different approach from standard solutions, used in traditional simulation programs.

An article consists of five parts. Section 2 and 3, respectively, contains a description for maintenance issues and a traditional modeling of damage and failure, that is modeling using MTBF/MTTR. A section 4 presents way of modeling failure of selected elements with using agent-based technology. An article ends with conclusions and plans for further work.

2 SYSTEM SAFETY AND RELIABILITY—GENERAL APPROACH

Currently, due to the large availability of any goods or services on the market, the main competitive factors are price and quality of offered goods or services. Companies seek to reduce operating costs (whether production costs or the provision of services), operating costs. One of areas in

which savings are sought is an area of maintenance of machines and equipment. Through look for (define) a suitable method of maintenance for an area of logistics is possible to reduce costs related to a maintenance of equipment and infrastructure (included in a given area) at an appropriate level of action.

Looking for appropriate way of keeping devices able to work, with a view to lowering costs generated by that economy, can not forget about maintaining an appropriate level of safety and reliability of the study area. Neglect of maintain an adequate efficiency levels of machines and devices (related to cuts spending on operations) may involve a complete destruction of the machine or an accident involving humans.

Speaking of issue of safety and reliability of the system, we should pay attention to a very broad aspect of this issue. We can consider production systems, distribution systems, civil infrastructure (such as transportation, water supply, sewers, telecommunications, and electrical and gasnetworks) and the other. In the literature many articles can be found refering to a safety and reliability of various systems (Braglia et al., 2012), (Kim & Kang, 2013), (Zhou et al., 2013), (Barone & Frangopol, 2014), (Aven & Pedersen, 2014). Each system is characterized by specific properties, therefore, for each of them an appropriate method of maintenance should be selected.

Activities related to a maintenance of machinery and equipment at an appropriate level of functionality are considered as unavoidable source of cost. Depending on specifications of the system, these costs range from several to several tens of percent of a total cost. The effect of damage, besides failure of machine for work, can also become a problem with a safety and protection of an environment, which can lead to deterioration of an image of the company (Jasiulewicz-Kaczmarek, 2009a). Therefore, maintenance strategies have a special meaning in the industry (Swanson, 2003); (Vatn & Aven, 2010); (Jia & Cui, 2011); (Tan et al., 2011).

We can distinguish different maintenance strategies (Jasiulewicz-Kaczmarek, 2009b)—two extremes are: preventive maintenance and actions taken only by the occurrence of damage. Costs associated with maintenance depend on a chosen strategy. In that way, companies are looking for solutions to reduce costs while keeping service maintenance on the assumed level.

In the literature we can find many articles about maintenance and strategy of maintenance. Relying on Pawlewski and Jasiulewicz-Kaczmarek (where review of the older, classical methods was presented), several strategies depended on a viewpoint of the goal of a strategy can be distinguished (Pawlewski & Jasiulewicz-Kaczmarek, 2011):

- "Profit oriented strategies; their aim is to plan actions in a profit-maximizing manner, which means, for instance, phasing out technical devices that bring no profit, and reducing investment expenditure to the level that is absolutely essential to sustain economic activity of a company.
- Cost minimization oriented strategies; their aim is to plan actions that will lead to a maximal reduction of costs, e.g. by liquidating supportive departments and the implementation of outsourcing.
- Strategies oriented towards working time maximization; their aim is to maintain technical availability of machinery and technical devices according to the scheduled period of time by means of increasing expenditure on maintaining the efficiency and technical availability of the company's own technological potential, which results from the appointed operational policy." (Jasiulewicz-Kaczmarek, 2009b).

Simulation is one of the methods enable companies to analyze the operation and maintenance services and a financial investment related to this services. New methods for selecting maintenance strategy are created. They are based on use of simulation and optimization experiments. The traditional approach based on the use of a process approach and DES simulation (discrete event simulation). Specificity of maintenance problems, research issues of maintaining system components able to work, mapping failure events and process of their removal also require consideration of other approaches.

The following article focuses on ways of failures and components damages modeling for chosen by authors logistics area. This area includes a supply chain, more specifically a transport of goods from point A to point B. Very often problems of failures of machines and devices involved in the manufacturing process are described. But, to deliver this product to a customer, a transport operation is necessary. Therefore, authors decided to focus on ways of modeling failures and damage components (which are involved in transport)—more specifically on means of transport engaged in the carriage and the other participants in the road.

On the route of goods delivery it can be distinguished a number of possible disruptions. Authors, based on their own experience and observations, distinguished following interferences under this area:

1. Related with means of transport
   - Failures of the means of transport—a failure is random; based on historical data you can predict the probability of such situation; this failure is associated with the time of waiting

for help, and the time required to repair a fault;
- Not providing a vehicle on time (e.g. due to theft)—a disturbance is random; it is necessary to determine the probability of this situation; it results in significant delay in order execution (associated with the search for a replacement car), or failure in order execution;

2. Related with the route
   - Traffic congestion—random factor; based on historical data it is possible to determine the volume of traffic in a changeable geographical/spatial area; it shortens or extends the duration of the transport order;
   - Road traffic accidents (so-called "black spots")—random aspect; based on historical data it is possible to determine the probability of an accident in so-called "Black spots"; vehicle accident without participation of the vehicle executing the transport order: it is associated with a stoppage at the accident site; an accident involving a vehicle performing a transport order: it is associated with longer duration of order execution due to the need to provide roadside assistance, as a result of damages it may impossible to execute the order;
   - Weather conditions (sudden bad weather)—this disturbance is random in nature; based on historical data and weather maps it is possible to determine points of weather breaks; an area of this disturbances will be changeable—depending on strength of this phenomenon; results of this disturbance is time extension of realization order (associated with a lower traveling speed);
   - Toll-collection points on toll roads (in case of toll road)—a time of paying the fee should be determined as a variable (depending on the number of cars waiting to pay the toll and the individual characteristics of particular drivers);
   - Natural disasters (hurricanes, floods, etc.) and other situations that slow down traffic on the road (e.g. strikes)—a disturbance is completely random in nature, it involves a changeable geographical/spatial area affected by the disturbance; it results in significant lengthening of order execution (associated with a slower traveling speed), or failure in order execution;

Authors, later in an article, focus on way of modeling of failure means of transport. They describe in details two ways of modeling a vehicle breakdown, depending on whether we focus on one vehicle or group of vehicles (which creates a traffic on a route).

3 MODELING DAMAGE WITH MTBF/MTTR (DES)

Shown approach to modeling failure of means of transport is presented for simulation model, which use MTBF and MTTR mechanism. The main purpose of this chapter is to show the way of modeling damage with MTBF/MTTR mechanism, not to show exactly a simulation program. MTBF and MTTR mechanism is offered in different simulation softwares. Authors uses Flexsim programme to show this approach. It is possible to define MTBF (time between the occurrence of the next failure) and MTTR (the time required to repair the damage) for almost all objects occurring in the system (Fig. 1). Using this mechanism it is possible to determine an occurrence of any failure of vehicles involved in the analyzed area. In addition, it is possible to model a damage of point on the route—in this way you can map disturbance for exactly a point of road.

Figure 1 presents pre-established times for analyzed operations. Of course it is possible to edit them, depending on user needs. It can be set any statistical distribution with the specified values or other rules of occurrence (Fig. 2).

Presented MTBF/MTTR tool provides a simple and quick way to model a failure of mean of transport or reproduction in some way interference in some points (network in route). However, this approach is limited—allows to modeling failure for static objects, which have been defined at time of creation of model (before performing a simulation experiment) permanently assigned to a model (resources which are not changing position

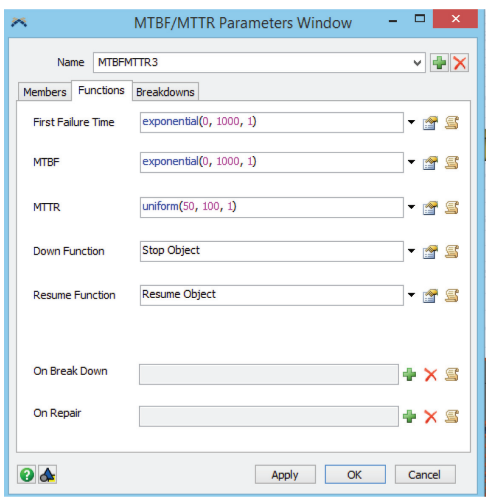

Figure 1. MTBF/MTTR Parameters Window (Source: Flexsim model).

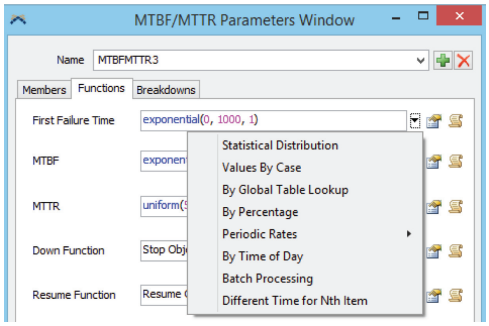

Figure 2. Additional parameters (Source: Flexsim model).

(fixed resource) and resources which are moving (mobile resource)). However, all these elements must be introduced into a model before starting a simulation experiment. This means that in a case of modeling a route with defined traffic volume, these vehicles must be made permanent to a model. They are not generated in a dynamic way. This is a significant limitation. When a situation in which the number of means of transport is unknown, vehicles are dynamically generated during an execution of simulation experiment. In this situation presented approach can not be applied. Authors propose for such cases, a different way of modeling interference/failure, which is described in the next section.

4 FLOW ITEMS DEMAGE MODELING (ABS + MESSAGES)

Authors, in order to model disturbances/failures of objects created dynamically during execution of simulation experiment, suggest use of modeling ABS (called Agent-Based Simulation) with a mechanism for sending messages between objects. To create other transport means in the model in dynamically way, it was decided to map vehicles by using flow items. Flow items are elements flowing through a process. They are not a static resource, they are created and destroyed during the simulation experiment. Creating means an input flow item into the system, manufacturing process, and a destruction means an output flow item of the analyzed system. For these items a failure by MTBF/MTTR can not be modeled. A failure of these components is a random event that affects whole transportation process. Therefore, for flow item authors suggest use an agent-based approach, specifically mechanism of messaging between objects.

To realized such a defined task FlexSim program was used. It is a simulation software, in which tools are both powerful and user-friendly. Analysis and optimization any system in any industry is possible with using FlexSim. Flexsim allows:

– a creation flow items as task executors,
– sending messages between objects.

A simulation based on ABS (Agent-Based Simulation) helps to better understand real-world systems, in which individual entities with their autonomous behavior are presented or modeled. ABS approach is characterized by (Siebers et al., 2010): approach from bottom to top, focus on modeling a behavior of entities and interactions between them, having by entities ability to make decisions and others factors.

These attributes do not describe the manufacturing processes but provide a description of many aspects of management. They can be used to make decisions concerning the choice of maintenance strategy and modeling of failure, repair, preventive maintenance.

Proposed by authors approach is that a flow item is modeled by an object, in which labels describing the two statistical distributions are defined. The first statistical distribution defines MTBF (time between the occurrence of the next failure) and the second MTTR (the time required to repair the damage). These labels are defined and set at the moment of creation of an item flow (entrance to the analyzed system). The fact that an object is created dynamically, and labels describing the MTBF and MTTR definitions are defined when the object is created during a simulation experiment—it make different approach from standard solutions, used in traditional simulation programs.

Figure 3 represents a set labels with MTBF and MTTR.

An essence of modeling an event is sending a message by a flow item object to itself. The first message is sent at time of entry into the system—it is sent with a delay, which is set in accordance with a defined distribution of MTBF. The second message is sent when the first message was received. It is also sent with a delay, which is set in accordance with a defined distribution of MTTR. A cycle can be repeated if a damage is repairable. If it is not, this means the end of a life cycle of an flow item. Figure 4 shows state when object is able to work or not. Depend on ability to work it has state 1 or –1.

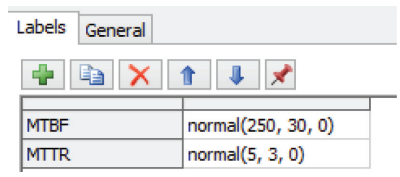

Figure 3. MTBF and MTTR labels (Source: Flexsim model).

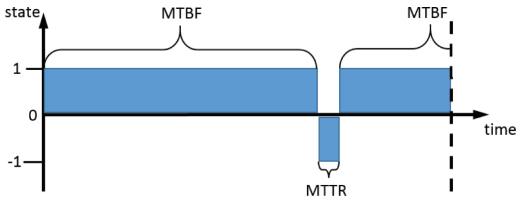

Figure 4. Object states graph (Source: own study based on Braglia et al., 2012).

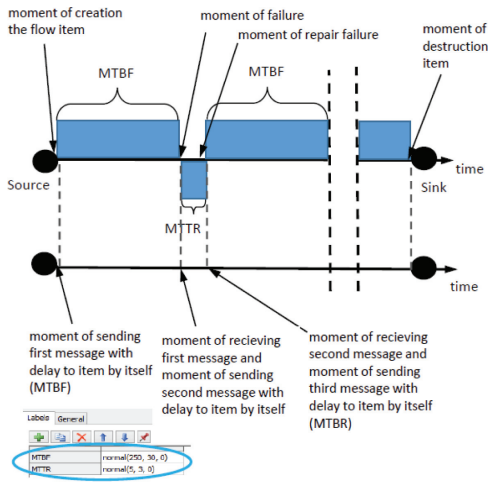

Figure 5. Life cycle of an dynamically created object (Source: own study).

Figure 5 shows a life cycle of an object, which is created dynamically in the model. It shows a general method for modeling dynamic objects and failures of them. It takes into account an occurrence of failure at a certain time and the time required to removing a distortion that has occurred.

It is worth mentioning that in order to make sending and receiving messages by means of transport for himself possible, item flow should be created by using TaskExecuterFlowItem. These elements have additional features compared to the basic, inter alia, Triggers tab, so that it is possible to include receiving messages.

5 CONCLUSIONS

Building flow items using agent-based modeling and messaging element to itself, creates huge opportunities for the modeling of damage elements involved in the analyzed process. This allows a different perspective on the process and modeling of failure of individual 'participants'. In addition, combining it with a built-in mechanism for modeling MTBF/MTTR makes it possible to build a complete model, taking into account the number of failures and damages occurring in the process. With the model, which maps the actual system, it is possible to observe and analyze the behavior of the system depending on the conditions. In addition, simulation of a failure allows for an observation and evaluation of activities undertaken within a selected maintenance strategy.

A new Monte Carlo method for environmental contour estimation

Arne B. Huseby
University of Oslo, Norway

Erik Vanem
DNV—GL, Norway

Bent Natvig
University of Oslo, Norway

ABSTRACT: Environmental contour estimation is an efficient and widely used method for identifying extreme conditions as a basis for e.g., ship design. Monte Carlo simulation is a flexible method for estimating such contours. A main challenge with this approach, however, is that extreme conditions typically correspond to events with low probabilities. Thus, in order to obtain satisfactory estimates, large numbers of simulations are needed. While these simulations can be carried out very fast, the analysis of the resulting data can be very time-consuming. In the present paper we propose a new Monte Carlo method where only the extreme simulation results are stored and analyzed. This method utilizes the fact that an unbiased estimate of an environmental contour does not depend on the exact values of the non-extreme results. It is sufficient to know the number of such results. Probabilistic structural reliability analysis is performed to ensure that mechanical structures can withstand certain design loads. Obtaining precise environmental contours has become an important part of this analysis. The proposed method improves precision and speeds up calculations.

1 INTRODUCTION

Probabilistic structural reliability analysis is performed to ensure that a structure is able to withstand the required design loads. A realistic description of the environmental loads and structural response is a crucial prerequisite for structural reliability analysis of structures exposed to environmental forces. The concept of environmental contours is an efficient method of estimating extreme conditions as basis for design. See (Winterstein et al., 1993) and (Haver & Winterstein 2009). It is widely used in marine structural design. See e.g., (Baarholm et al., 2010), (Fontaine et al., 2013), (Jonathan et al., 2011), (Moan 2009) and (Ditlevsen 2002). The traditional approach is to use the well-known *Rosenblatt transformation* introduced in (Rosenblatt 1952) to transform the environmental variables into independent standard normal variables and identify a sphere with desired radius in the transformed space. Environmental contours are then found by re-transforming the sphere back to the original space. This approach is closely related to the FORM-approximation (First Order Reliability Method), where the failure boundary in the transformed space is approximated by a hyperplane at the design point.

However, a supporting hyperplane in the transformed space will generally not correspond to a supporting hyperplane in the original space, and this may introduce biases in the failure probability estimates in either direction. See (Huseby et al., 2013). To avoid such biases, contours in the original space can be constructed by using Monte Carlo simulations on the joint environmental model. The resulting environmental contours would then have supporting hyperplanes with the desired failure probability. This yields a more straightforward interpretation of the contours. Another advantage of this approach is a more flexible framework for establishing environmental contours, which for example simplifies the inclusion of effects such as future projections of the wave climate related to climatic change. See (Vanem & Bitner-Gregersen 2012).

In Section 2 we review the basic definitions of environmental contours and the fundamental existence theorem proved in (Huseby et al., 2014). Moreover, we show how this contour can be expressed in terms of a certain percentile function. In Section 3 we explain briefly how to estimate the contour using direct Monte Carlo simulations. More details on this are given in (Huseby et al., 2013) and (Huseby et al., 2014). We then

propose a new Monte Carlo method where only the extreme simulation results are stored and analyzed. This method utilizes the fact that an unbiased estimate of an environmental contour does not depend on the exact values of the non-extreme results. Knowing the number of such results is sufficient. An important part of this approach is how to choose the set of non-extreme results which can be discarded. This isssue is discussed in Section 4. Finally the suggested method is demonstrated on a few numerical examples in Section 5.

2 BASIC CONCEPTS AND RESULTS

Environmental contours are defined in various ways in the literature. See e.g., (Leira 2008), (Moan et al., 2005) and (Haver 1987). In this paper, however, we apply the same definition of environmental contours as used in (Huseby et al. 2013). Let $\mathbf{X}$ be a vector of environmental variables with possible values in the set $\mathcal{X} \subseteq \mathbb{R}^n$ and assume that the distribution of $\mathbf{X}$ is absolutely continuous with respect to the Lebesgues measure in $\mathbb{R}^n$. Moreover, let $P_e \in (0,0.5)$ be a given exceedance probability. The objective is to identify a convex set $\mathcal{B} \subset X$ such that for every supporting hyperplane[1] Π of $\mathcal{B}$, we have $P[\mathbf{X} \in \Pi^+] = P_e$, where Π^+ denotes the halfspace bounded by the hyperplane Π and not containing $\mathcal{B}$. We also introduce Π^- which denotes the halfspace complementary to Π^+. Thus, $\mathcal{B} \subseteq \Pi^-$. The resulting environmental contour is the boundary of the set $\mathcal{B}$ and denoted $\partial\mathcal{B}$. Whenever such a set $\mathcal{B}$ can be found, safely designed structures can easily be identified by considering the points in $\partial\mathcal{B}$.

The properties of the set $\mathcal{B}$ depends on the probability distribution of the vector $\mathbf{X}$. If $\mathcal{B}$ has the property mentioned above, we say that $\mathbf{X}$ admits a P_e-contour. From the above definition we see that the construction of $\mathcal{B}$ is strongly linked to hyperplanes Π with the property that $P[\mathbf{X} \in \Pi^+] = P_e$. We will refer to such hyperplanes as P_e-exceedance hyperplanes, and we denote by $\mathcal{P}(P_e)$ the family of all P_e-exceedance hyperplanes. In (Huseby et al., 2014) necessary and sufficient conditions for the existence of P_e-contours are given. In particular it is shown that in the general case $\mathcal{B}$ can be defined as follows:

$$\mathcal{B} = \bigcap_{\Pi \in P(P_e)} \Pi^-. \tag{1}$$

[1] A hyperplane Π is a supporting hyperplane of a convex set B if B is entirely contained in one of the two closed half-spaces determined by Π and B has at least one boundary-point on Π.

Note that all the halfspaces $\Pi^- \in \mathcal{P}(P_e)$ are convex sets. Hence, the definition of $\mathcal{B}$ given in (1) implies that the set $\mathcal{B}$ is indeed a *convex set* as well since it is an intersection of convex sets.

In the remaining part of the paper we consider the two-dimensional case where $\mathbf{X} = (T, H)$. In this case it is convenient to introduce a function $C(\theta)$ defined for $\theta \in [0, 2\pi)$ as:

$$C(\theta) = \inf\{C : P[T\cos(\theta) + H\sin(\theta) > C] = P_e\}. \tag{2}$$

Thus, $C(\theta)$ is the $(1-P_e)$-percentile in the distribution of the random variable $Y(\theta) = T\cos(\theta) + H\sin(\theta)$. We also introduce:

$$\Pi(\theta) = \{(t,h) : t\cos(\theta) + h\sin(\theta) = C(\theta)\}$$
$$\Pi^+(\theta) = \{(t,h) : t\cos(\theta) + h\sin(\theta) > C(\theta)\},$$
$$\Pi^-(\theta) = \{(t,h) : t\cos(\theta) + h\sin(\theta) \le C(\theta)\}.$$

In (Huseby et al., 2014) it is shown that the expression for $\mathcal{B}$ given in (1) can be simplified to:

$$\mathcal{B} = \bigcap_{\theta \in [0,2\pi)} \Pi(\theta)^-. \tag{3}$$

Existence of P_e-contours can then be expressed as a condition on the function C:

Theorem 2.1. $\mathbf{X}$ admits a P_e-contour if and only if for any $\theta \in [0, 2\pi)$ and $\delta \in (0, \pi/2)$, we have:

$$\frac{1}{2}[C(\theta - \delta) + C(\theta + \delta)] > \cos(\delta)C(\theta). \tag{4}$$

We observe that if C is convex in $[\theta - \delta, \theta + \delta]$, then the condition (4) holds for this particular q and δ. If C is everywhere convex, then (4) will be satisfied for every $\theta \in [0, 2\pi)$ and $\delta > 0$. However, since C typically will have the property that $\lim_{\theta \to 2\pi} C(\theta) = C(0)$, C cannot be strictly convex everywhere. Thus, unless C is constant, this function will have parts where it is concave as well. Intuitively, Theorem 2.1 states that C in its concave parts should behave locally like the cosine function around zero. On the other hand, if C has parts with a more dramatically concave shape, the condition (4) may not hold, and in such cases $\mathbf{X}$ does *not* admit a P_e-contour.

The function $C(\theta)$ can be used to identify the boundary of the set $\mathcal{B}$. In order to show this, we assume that $C(\theta)$ is differentiable. For a given angle $\theta \in [0, 2\pi)$ and a small number $\delta > 0$ we consider the intersection between the two P_e-exceedance hyperplanes $\Pi(\theta)$ and $\Pi(\theta + \delta)$. This point can be found by solving the following linear equations:

$$\begin{aligned} t\cos(\theta) + h\sin(\theta) &= C(\theta), \\ t\cos(\theta + \delta) + h\sin(\theta + \delta) &= C(\theta + \delta), \end{aligned} \tag{5}$$

with the solution:

$$t = \frac{\sin(\theta+\delta)C(\theta) - \sin(\theta)C(\theta+\delta)}{\sin(\delta)} \tag{6}$$

$$h = \frac{-\cos(\theta+\delta)C(\theta) + \cos(\theta)C(\theta+\delta)}{\sin(\delta)}$$

As $\delta \to 0$ the intersection point (t,h) will converge to a point in $\Pi(\theta)$ which we denote by $(t(\theta),h(\theta))$. Using l'Hôpital's rule it is easy to see that $(t(\theta),h(\theta))$ is given by:

$$\begin{pmatrix} t(\theta) \\ h(\theta) \end{pmatrix} = \begin{bmatrix} C(\theta) & -C'(\theta)(8) \\ C'(\theta) & C(\theta) \end{bmatrix} \cdot \begin{pmatrix} \cos(\theta)(9) \\ \sin(\theta) \end{pmatrix}, \tag{7}$$

where $C'(\theta)$ denotes the derivative of $C(\theta)$.

As θ runs through all angles in $[0,2\pi)$, the point $(t(\theta),h(\theta))$ will move along the boundary of the set $\mathcal{B}$. Thus, the environmental contour can be expressed as:

$$\partial\mathcal{B} = \{(t(\theta),h(\theta)) : \theta \in [0,2\pi)\}. \tag{8}$$

In the next section we shall see how the function C and hence also the environmental contour $\partial\mathcal{B}$ can be estimated using Monte Carlo simulation.

3 ESTIMATING ENVIRONMENTAL CONTOURS USING MONTE CARLO SIMULATION

In this section we show how to estimate environmental contours using Monte Carlo simulation. More specifically, we use Monte Carlo simulations in order to estimate the set $\mathcal{B}$ introduced in the previous section, and then use its boundary $\partial\mathcal{B}$ as the desired contour. As in the previous section a two-dimensional environmental space is assumed, and we let T and H denote the two environmental variables. Moreover, for any $\theta \in [0,2\pi)$ we introduce the random variable $Y(\theta) = T\cos(\theta) + H\sin(\theta)$ and its cumulative distribution function $F_\theta(y) = P(Y(\theta) \le y)$.

We start out by performing a Monte Carlo simulation on the joint environmental model (or alternatively on an empirical distribution) producing a total of n sample points:

$$(T_1,H_1),\ldots,(T_n,H_n) \tag{9}$$

For a given angle $\theta \in [0,2\pi)$ we calculate the projections of these points onto the unit vector $(\cos(\theta),\sin(\theta))$, i.e.:

$$Y_i(\theta) = T_i\cos(\theta) + H_i\sin(\theta), i = 1,\ldots,n \tag{10}$$

These projections are then sorted in ascending order:

$$Y_{(1)}(\theta) \le Y_{(2)}(\theta) \le \cdots \le Y_{(n)}(\theta). \tag{11}$$

Using the sampled values $Y_1(\theta),\ldots,Y_n(\theta)$ the cumulative distribution function F_θ can be estimated by the well-known empirical cumulative distribution function:

$$\hat{F}_\theta(y) = \frac{1}{n}\sum_{i=1}^{n} I(Y_i(\theta) \le y). \tag{12}$$

Now, for a given exceedance probability P_e, we recall that $C(\theta)$ is the $(1-P_e)$-percentile in the distribution of $Y(\theta)$. Thus, in order to estimate $C(\theta)$, we look for a value y such that $\hat{F}_\theta(y) = (1-P_e)$. We then note that for $k = 1,\ldots,n$ we have $\hat{F}_\theta(Y_{(k)}(\theta)) = k/n$. Hence, we proceed by identifying an integer k such that:

$$\frac{k}{n} \approx 1 - P_e. \tag{13}$$

That is[2], $k \approx n(1-P_e)$. Having determined k, an unbiased estimate for $C(\theta)$ is:

$$\hat{C}(\theta) = Y_{(k)}(\theta). \tag{14}$$

Furthermore, using standard numerical methods we estimate $C'(\theta)$ by $\hat{C}'(\theta)$. Using these estimates in combination with (7) we obtain the contour estimate. Further details and a couple of alternative methods are given in (Huseby et al., 2013).

For moderately small exceedance probabilities this method works very well. However, in many typical applications P_e can be very small, i.e., less than 0.1%. In such cases a large number of simulations are needed in order to obtain stable estimates. At the same time most of the simulations yield results close to the central area of the joint distribution, and thus very few results provide information about the contour area.

While Monte Carlo simulation on a bivariate distribution can be done extremely fast on modern computers, processing the results in order to obtain the contours can be much more time consuming. In fact, even storing a large number of simulation results in the computer memory can represent a challenge.

In order to address these issues, we propose an alternative sampling scheme. Assume that we can

[2] Assuming that $P_e \in (0,1)$ is a *rational number*, we can in fact ensure that $k = n(1-P_e)$ by choosing n sufficiently large.

find a subset e of the set $\mathcal{B}$. Although the set $\mathcal{B}$ is yet to be estimated, finding such a subset is usually not difficult using e.g., a crude preliminary estimate of the set $\mathcal{B}$. We will return to the problem of choosing a suitable set e later. Since e is a subset of $\mathcal{B}$, it follows that for any supporting hyperplane $\Pi(\theta)$ of $\mathcal{B}$ we will have that $\varepsilon \subset \mathcal{B} \subset \Pi^{-}(\theta)$. See Figure 1.

Hence, for any sampling point $(T_i, H_i) \in \varepsilon$ we have that $Y_i(\theta) \leq C(\theta)$. Thus, in order to estimate $C(\theta)$, we do not need to know the exact values of the sampling points in e. It is sufficient to know the *phnumber of sampling points inside this set.*

In order to explain this idea further, we assume that we have performed another Monte Carlo simulation on the joint environmental model producing a total of n points. However, in this case only the sample points outside of the set e are stored while the sample points inside the set e are discarded. We assume that the number of stored points is d, while the number of discarded points is e, where $d + e = n$. The stored points are denoted:

$$(T_1, H_1), \ldots, (T_d, H_d). \tag{15}$$

As before we also calculate the projections of these points onto the vector $(\cos(\theta), \sin(\theta))$:

$$Y_i(\theta) = T_i \cos(\theta) + H_i \sin(\theta), i = 1, \ldots, d, \tag{16}$$

and sort the projections in ascending order:

$$Y_{(1)}(\theta) \leq Y_{(2)}(\theta) \leq \cdots \leq Y_{(d)}(\theta). \tag{17}$$

Assuming that y is greater than the projections of all the discarded points, we can still estimate the cumulative distribution function $F_\theta(y)$ by $\hat{F}_\theta(y)$ which in this case can be written as:

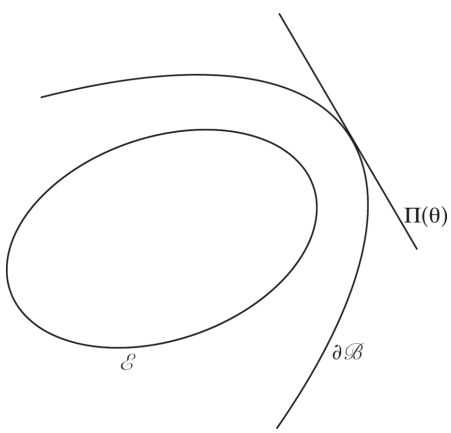

Figure 1. The set ε, part of the environmental contour $\partial\mathcal{B}$ and the supporting hyperplane $\Pi(\theta)$.

$$\hat{F}_\theta(y) = \frac{1}{n} \sum_{i=1}^{d} I(Y_i(\theta) \leq y) + \frac{e}{n}. \tag{18}$$

Again we look for a value y satisfying the following condition $\hat{F}_\theta(y) = (1 - P_e)$. Using (21) it is easy to see that this condition can be expressed as:

$$\tilde{F}_\theta(y) = \frac{1}{d} \sum_{i=1}^{d} I(Y_i(\theta) \leq y) = \frac{n(1 - P_e) - e}{d}, \tag{19}$$

where we have introduced $\tilde{F}_\theta(y)$ denoting the empirical distribution function based on the stored sample points only. Noting that for $k = 1, \ldots, d$ we have $\tilde{F}_\theta(Y_{(k)}(\theta)) = k/d$, we proceed by identifying an integer k such that:

$$\frac{k}{d} \approx \frac{n(1 - P_e) - e}{d}. \tag{20}$$

That is, $k \approx n(1 - P_e) - e$, and an unbiased estimate for $C(\theta)$ is:

$$\tilde{C}(\theta) = Y_{(k)}(\theta). \tag{21}$$

By using the right-hand side of (23) we introduce the following quantity:

$$P'_e = 1 - \frac{n(1 - P_e) - e}{d}. \tag{22}$$

This quantity may be interpreted as an *adjusted* exceedance probability which applies to the reduced sample. When $e > 0$ it is easy to see that we always have $P'_e > P_e$. A consequence of this is that the percentile estimates becomes more stable as the exceedance events occur much more frequent within the reduced sample. Working with this adjusted exceedance probability also has the technical advantage that we may use exactly the same algorithm for the reduced sample as we use for the full sample except that we replace P_e by P'_e as input to the calculations.

Note that if $\tilde{C}(\theta)$ and $\hat{C}(\theta)$ are computed using the same n sample points, the two estimates will in fact be equal. The advantage of $\tilde{C}(\theta)$, however, is that this estimate can be calculated using only a small fraction of the full sample. Hence, we can easily increase the number n substantially without running into memory problems or long processing time.

4 CHOOSING THE SET ε

In this section we return to the problem of choosing the set ε. There are obviously many ways of doing this. In order to explain our approach we

start out by considering a very simple example where the environmental contour can be calculated analytically. This is the case when the environmental variables are independent standard normally distributed. This joint distribution is rotationally symmetric, and the exact environmental contour is a circle centered in the origin. See Figure 2. The radius of this circle can easily be calculated e.g., by considering the supporting hyperplane $\Pi(0)$. In this case the projection of (T,H) is simply:

$$Y(0) = T\cos(0) + H\sin(0) = T. \tag{23}$$

Thus, $Y(0)$ is standard normally distributed, and $C(0)$ is simply the $(1-P_e)$-percentile of this distribution. In fact, due to the rotational symmetry of the joint distribution, $Y(\theta)$ is standard normally distributed for all $\theta \in [0, 2\pi)$. Hence, $C(\theta)$ is constant, which implies that the environmental contour is indeed a circle with radius R equal to the $(1-P_e)$-percentile. Thus, if e.g., $P_e = 0.001$, then $R = 3.09$.

Having found the environmental contour, there is of course no need to perform any simulations in this case. However, it may still be of interest to explore possible choices for the set $\mathcal{E}$. In Figure 2 we have chosen this set to be a circle inside the set $\mathcal{B}$ with radius $r < R$ and centered in the origin. With this choice it is easy to calculate the probability that a sample point is discarded, i.e., $P((T,H) \in \mathcal{E})$. This probability can be expressed as:

$$P((T,H) \in \mathcal{E}) = P(T^2 + H^2 \le r^2). \tag{24}$$

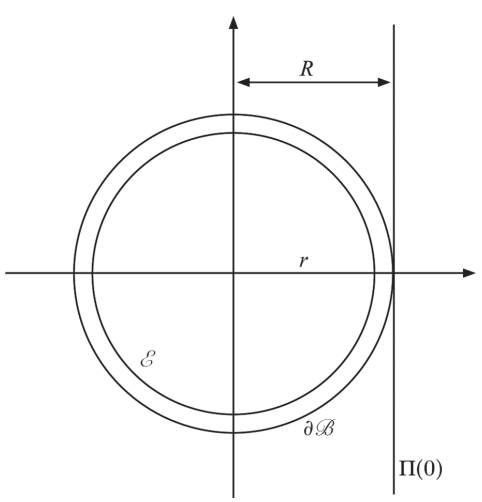

Figure 2. The environmental contour, $\partial\mathcal{B}$, in the case where the variables are independent standard normally distributed.

Furthermore, since T and H are independent standard normally distributed, it follows that $T^2 + H^2$ is χ^2-distributed with 2 degrees of freedom. Hence, it is easy to see that:

$$P((T,H)\mathcal{E}) = 1 - \exp(-r^2/2). \tag{25}$$

Thus, if e.g., $r = 3.0$ we get that $P((T,H) \in \mathcal{E}) = 0.988891$. Hence, if we e.g., perform $n = 1000000$ simulations, then the expected number of stored points is $d = 11109$, while the expected number of discarded points is $e = 988891$. If we plug these numbers along with the exceedance probability $P_e = 0.001$ into (25) we get the following adjusted exceedance probability:

$$P'_e = 1 - \frac{1000000 \cdot (1 - 0.001) - 988891}{11109} = 0.09. \tag{26}$$

We observe that in this case P'_e is as much as 90 times greater than P_e.

We now proceed by extending the methodology to general joint distributions. As mentioned in the introduction it is always possible to transform any pair of random variables into a pair of independent standard normal variables using the Rosenblatt transformation. As before we denote the environmental variables by T and H. The Rosenblatt transformation is a transformation Ψ such that if $(T', H') = \Psi(T,H)$, then T' and H' are independent standard normal variables. As explained above for these transformed variables we can easily find the environmental contour, which we denote $\partial\mathcal{B}'$ and a suitable circular set within the contour, which we denote by $\mathcal{E}'$. Unless the Rosenblatt transformation is linear, which happensonly when (T,H) has a bivariate normal distribution, we cannot simply obtain the environmental contour for T and H by using the inverse Rosenblatt transformation. That is, except for the linear case, we typically have that $\Psi^{-1}(\partial\mathcal{B}') \neq \partial\mathcal{B}$. See (Huseby et al., 2013). However, provided that $\mathcal{E}'$ is not too close to $\partial\mathcal{B}'$, we may still have that $\Psi^{-1}(\mathcal{E}') \subset \mathcal{B}$. Thus, we propose to simply choose $\mathcal{E}$ as $\Psi^{-1}(\mathcal{E}')$. See Figure 3. That is, we let:

$$\mathcal{E} = \{(t,h) : \Psi(t,h) \in \mathcal{E}'\}. \tag{27}$$

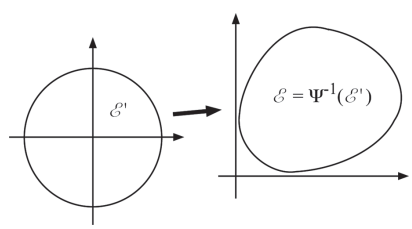

Figure 3. Obtaining the set $\mathcal{E}$ by using the inverse Rosenblatt transformation Ψ^{-1}.

5 NUMERICAL EXAMPLES

In this section we illustrate the proposed method with two numerical examples. In both cases we let $P_e = 0.001$. Moreover, in every plot, the variables T and H are represented by respectively the horizontal and vertical axes.

In the first example we assume that T and H are bivariate lognormally distributed with:

$$\begin{aligned} &\mathrm{E}[\ln(T)] = \mathrm{E}[\ln(H)] = 1.0, \\ &\mathrm{SD}[\ln(T)] = \mathrm{SD}[\ln(H)] = 1.0, \\ &\mathrm{Cov}[\ln(T), \ln(H)] = 0.7. \end{aligned}$$

We start out by running $n = 50000$ simulations where all results are used in the estimation of the environmental contour. The resulting contour is shown in Figure 4. While the overall shape of the contour is fairly well captured, we see some noticable numerical instabilities in the form of loops along the curve. This is a typical phenomenon indicating that the data is insufficient for the exceedance probability.

In Figure 5 the same contour curve is shown along with a scatter representing the simulation results. We see that there are only a few points in the area of the contour. This fact accounts for both numerical and statistical instabilities.

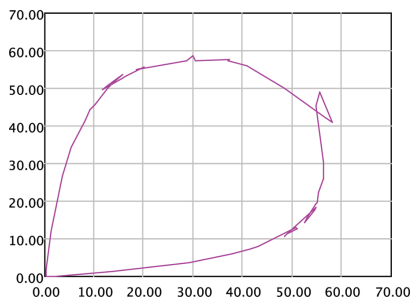

Figure 4. Environmental contour plot obtained using all 50000 points from a simulation run.

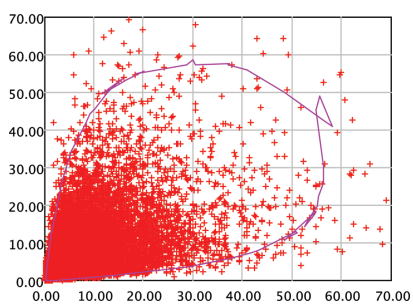

Figure 5. Environmental contour plot and scatter obtained using all 50000 points from a simulation run.

We then proceed by running simulations where a point (t,h) is discarded if $\Psi(t,h) \in \mathcal{E}'$, where the set $\mathcal{E}'$ is a circle with radius 3. This is less than 3.09, which is the $(1-P_e)$-percentile of the normal distribution.

The simulation is run until we end up with $d = 50000$ stored points. The number of discarded points in this case is $e = 4452434$. Thus, the total number of simulations in this case is $n = 4502434$. Since this number is much larger than the total numberof simulations in the case where all results where used, the latter simulation run takes a little bit longer time to finish. However, on a standard PC both runs can be completed in a few seconds anyway. Inserting P_e, n, d and e into (22) we obtain the adjusted exceedance probability $P'_e = 0.09$. Using this as input to the contour plot algorithm we obtain the environmental contour shown in Figure 6.

In this case we get a nice and smooth stable contour. In Figure 7 the same contour is shown along with a scatter representing the simulation results. The area around the contour is now surrounded by a large number of sample points. Thus, with this sampling scheme we get a numerically and statistically stable estimate of the environmental contour.

It is of interest to compare this contour with the corresponding contour obtained by the

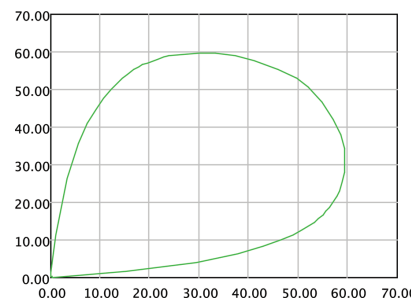

Figure 6. Environmental contour plot obtained using a reduced set of 50000 points from a simulation run.

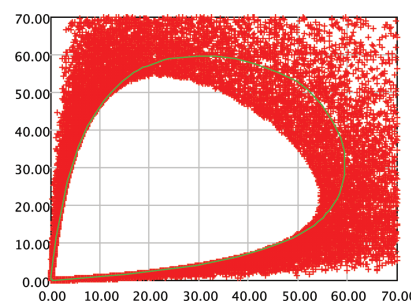

Figure 7. Environmental contour plot and scatter obtained using a reduced set of 50000 points from a simulation run.

transformation method. Denoting as before the contour in the transformed space by $\partial\mathcal{B}'$, the transformed contour is obtained by using the inverse Rosenblatt transformation: $\Psi^{-1}(\partial\mathcal{B}')$. In Figure 8 we have plotted the two curves in the same diagram. We see that the two contours deviate from each other quite noticable due to the bias resulting from the non-linear transformation Ψ^{-1}. In particular in the area around the point $(50,50)$, the transformation method produces a much more optimistic contour than the Monte Carlo method, Thus, in this area the exceedance probability is underestimated if the transformation method is used.

In the second example we again assume that T and H are bivariate lognormally distributed with the same logarithmic means and standard deviations. However, in this case we let $\mathrm{COV}[\ln(T),\ln(H)] = 0.0$.

As in the previous example we start out by running $n = 50000$ simulations where all results are used in the estimation of the environmental contour. The resulting contour is shown in Figure 9. We observe that there are several numerical instabilities in the form of loops along the curve in this case as well.

In Figure 10 the same contour curve is shown along with a scatter representing the simulation results. We see that there are only a few points in the area of the contour. Hence, both numerical and statistical instabilities are to be expected.

As before, we proceed by running simulations where a point (t,h) is discarded if $\Psi(t,h) \in \mathcal{E}$, where the set $\mathcal{E}$ is a circle with radius 3. The resulting contour is shown in Figure 11 and with a scatter in Figure 12.

In this case we also get a very smooth contour. We observe that there is a part of the contour where the scatter is less dense compared to the scatter in the previous example. Still there are more than enough points to obtain satisfactory

results from a statistical perspective. It should also be pointed out that the scatter in fact reaches far outside the area included in the figures. Thus, there are in fact a lot of points being used in the calculations even though they do no show up in the scatter.

We close this section by comparing the environmental curve obtained by Monte Carlo estimation to the corresponding contour obtained by the transformation method. Both contours are shown in Figure 13. For this somewhat more extreme joint distribution we observe that the transformation method does not even produce a convex contour. Thus, this contour does not have the required properties. Moreover, most of the contour is biased in the sense that the exceedance probability is underestimated.

6 CONCLUSIONS

In the present paper we have presented a new Monte Carlo method where only the extreme simulation results are stored and analyzed. In the numerical examples the exceedance probability was chosen to be 0.001, and the condition for discarding sampled points were chosen accordingly. For even smaller exceedance probabilities this condition can easily be adjusted so that we always have sufficient data in the area of the contour. Using this new method it becomes very easy to obtain numerically as well as statistically stable results even for very low exceedance probabilities without having to store and analyze millions of simulation results. Contrary to the transformation method the Monte Carlo method avoids bias resulting from non-linear transformations. As seen from the examples this bias can be substantial.

On multistate technical system operation process influence on its reliability

K. Kołowrocki, E. Kuligowska & J. Soszyńska-Budny
Maritime University of Gdynia, Poland

ABSTRACT: The paper presents analytical and Monte Carlo simulation methods applied to the reliability evaluation of a complex multistate system. A semi-Markov process is applied to construct the multistate model of the system operation process and its main characteristics are determined. Analytical linking of the system operation process model with the system multistate reliability model is proposed to get a general reliability model of the complex system operating at varying in time operation conditions and to find its reliability characteristics. The application of Monte Carlo simulation based on the constructed general reliability model of the complex system is proposed to reliability evaluation of a port grain transportation system and the results of this application are illustrated and compared with the results obtained by analytical method.

1 INTRODUCTION

The reliability analysis of a system subjected to varying in time its operation process very often leads to complicated calculations and therefore it is difficult to implement its analytical modeling, prediction and optimization, especially in the case when we assume the system multistate reliability model and the multistate model of its operation process (Grabski & Jaźwiński 2009, Grabski 2002, Kołowrocki 2014, Kołowrocki, Kuligowska & Soszyńska-Budny 2012, Kołowrocki & Soszyńska-Budny 2011, 2014). On the other hand, the complexity of the systems' operation processes and their influence on changing in time the systems' reliability parameters are very often met in real practice (Kołowrocki & Kuligowska 2013, Kuligowska 2012, Soszyńska 2007, 2010). Thus, the practical importance of an approach linking the system reliability models and the system operation processes models into an integrated general model in reliability assessment of real technical systems is evident. The Monte Carlo simulation method (Kołowrocki & Kuligowska 2013, Kuligowska 2013, Zio & Marseguerra 2002) is a tool that sometimes allows to simplify solving this problem. All cited here publications presents general results obtained under a strong assumption that the system components have exponential conditional reliability functions at different operation states. To omit this assumption that narrows the investigation down and to get wider a Monte Carlo simulation method is proposed to test the possibility of finding more general solutions better convergent to real technical problems. The analytical approach to the reliability analysis of multistate systems subjected to multistate operation processes is presented and next the computer simulation modeling method for such systems reliability assessment is proposed and practically applied.

2 SYSTEM OPERATION PROCESS

We assume that a system during its operation at the fixed moment t, $t\in\langle 0,\infty)$ may be at one of v, $v \geq 2$, operations states z_b, $b = 1,2, \ldots, v$. Consequently, we mark by $Z(t)$, $t\in\langle 0,\infty)$, the system operation process, that is a function of a continuous variable t, taking discrete values at the set $\{z_1,z_2, \ldots, z_v\}$ of the system operation states. We assume a semi-Markov model (Grabski 2002, Kołowrocki 2014) of the system operation process $Z(t)$ and we mark by Θ_{bl} its random conditional sojourn times at the operation states z_b, when its next operation state is z_l, $b,l = 1,2,\ldots, v$, $b\neq l$.

Consequently, the operation process may be described by the following parameters (Kołowrocki & Soszyńska-Budny 2011):

- the vector $[p_b(0)]_{1\times v}$, $b,l = 1,2, \ldots, v$, of the initial probabilities of the system operation process $Z(t)$ staying at the particular operation states at the moment $t = 0$;
- the matrix $[p_{bl}]_{v\times v}$, $b,l = 1,2, \ldots, v$, of the probabilities of the system operation process $Z(t)$ transitions between the operation states z_b and z_l, $b,l = 1,2, \ldots, v$, $b\neq l$;
- the matrix $[H_{bl}(t)]_{v\times v}$, $b,l = 1,2, \ldots, v$, of the conditional distribution functions of the system

operation process $Z(t)$ conditional sojourn times Θ_{bl}, $b,l = 1,2, \ldots, v$, $b \neq l$, at the operation states.

From the formula for total probability, it follows that the unconditional distribution functions of the sojourn times Θ_b, $b = 1,2, \ldots, v$, of the system operation process $Z(t)$ at the operation states z_b, $b = 1,2, \ldots, v$, are given by (Kołowrocki & Soszyńska-Budny 2011).

$$H_b(t) = \sum_{l=1}^{v} p_{bl} H_{bl}(t), \; b = 1,2,\ldots,v. \tag{1}$$

The limit values of the system operation process $Z(t)$ transient probabilities at the particular operation states $p_b(t) = P(Z(t) = z_b)$, $t \in \langle 0,\infty)$ $b = 1,2, \ldots, v$, are given by (Grabski 2002, Kołowrocki & Soszyńska-Budny 2011, Kołowrocki 2006, Soszyńska 2007)

$$p_b = \lim_{t\to\infty} p_b(t) = \frac{\pi_b M_b}{\sum_{l=1}^{v} \pi_l M_l}, \; b = 1,2,\ldots,v, \tag{1}$$

where M_b, $b = 1,2, \ldots, v$, are given in (Kołowrocki & Soszyńska 2011), while the steady probabilities π_b of the vector $[\pi_b]_{1xv}$ satisfy the system of equations

$$\begin{cases} [\pi_b] = [\pi_b][p_{bl}] \\ \sum_{l=1}^{v} \pi_l = 1. \end{cases}$$

3 RELIABILITY OF MULTISTATE SYSTEM

In the multistate reliability analysis to define the system with degrading components, we assume that:

- n is the number of the system components,
- E_i, $i = 1,2, \ldots, n$, are components of a system,
- all components and a system under consideration have the reliability state set $\{0,1, \ldots, z\}$, $z \geq 1$,
- the reliability states are ordered, the reliability state 0 is the worst and the reliability state z is the best,
- $T_i(u)$, $i = 1,2, \ldots, n$, are independent random variables representing the lifetimes of components E_i in the reliability state subset $\{u,u+1, \ldots, z\}$, while they were in the reliability state z at the moment $t = 0$,
- $T(u)$ is a random variable representing the lifetime of a system in the reliability state subset $\{u,u+1, \ldots, z\}$ while it was in the reliability state z at the moment $t = 0$,
- the system states degrades with time t,
- $E_i(t)$ is a component E_i reliability state at the moment t, $t \in \langle 0,\infty)$ given that it was in the reliability state z at the moment $t = 0$,
- $S(t)$ is a system S reliability state at the moment t, $t \in \langle 0,\infty)$ given that it was in the reliability state z at the moment $t = 0$.

Under the above assumptions, we denote the component E_i, $i = 1,2, \ldots, n$, reliability function by the vector

$$R_i(t,\cdot) = [1, R_i(t,1), \ldots, R_i(t,z)],$$

with the coordinates defined by

$$R_i(t,u) = P(T_i(u) > t) \text{ for } t \in \langle 0,\infty), \; u = 1,2, \ldots, z,$$

Similarly, we denote the system reliability function by the vector

$$\boldsymbol{R}(t,\cdot) = [1, \boldsymbol{R}(t,1), \ldots, \boldsymbol{R}(t,z)],$$

with the coordinates defined by

$$\boldsymbol{R}(t,u) = P(T(u) > t) \text{ for } t \in \langle 0,\infty) \; u = 1,2, \ldots, z, \tag{2}$$

Further, we assume that the changes of the operation states of the system operation process $Z(t)$ have an influence on the system multistate components E_i, $i = 1,2, \ldots, n$, reliability and the system reliability structure as well. Consequently, we denote the system multistate component E_i, $i = 1,2, \ldots, n$, conditional lifetime in the reliability state subset $\{u,u+1, \ldots, z\}$ while the system is at the operation state z_b, $b = 1,2, \ldots, v$, by $[T_i(u)]^{(b)}$ and its conditional reliability function by the vector

$$[R_i(t,\cdot)]^{(b)} = [1, [R_i(t,1)]^{(b)}, \ldots, [R_i(t,z)]^{(b)}],$$

with the coordinates defined by

$$[R_i(t,u)]^{(b)} = P(T_i^{(b)}(u) > t | Z(t) = z_b) \text{ for } t \in \langle 0,\infty), \; u = 1,2, \ldots, z, \; b = 1,2, \ldots, v, \tag{3}$$

The reliability function $[R_i(t,u)]^{(b)}$ is the conditional probability that the component E_i lifetime $[T_i(u)]^{(b)}$ in the reliability state subset $\{u,u+1, \ldots, z\}$ is greater than t, while the system operation process $Z(t)$ is at the operation state z_b.

Similarly, we denote the system conditional lifetime in the reliability state subset $\{u,u+1, \ldots, z\}$ while the system is at the operation state z_b, $b = 1,2, \ldots, v$, by $T^{(b)}(u)$ and the conditional reliability function of the system by the vector

$$[\boldsymbol{R}(t,\cdot)]^{(b)} = [1, [\boldsymbol{R}(t,1)]^{(b)}, \ldots, [\boldsymbol{R}(t,z)]^{(b)}],$$

with the coordinates defined by

$$[\boldsymbol{R}(t,u)]^{(b)} = P(T^{(b)}(u) > t | Z(t) = z_b) \text{ for } t \in \langle 0,\infty), \; u = 1,2, \ldots, z, \; b = 1,2, \ldots, v, \tag{4}$$

The reliability function $[\boldsymbol{R}(t,u)]^{(b)}$ is the conditional probability that the system lifetime $T^{(b)}(u)$ in the reliability state subset $\{u,u+1, \ldots, z\}$ is greater than t, while the system operation process $Z(t)$ is at the operation state z_b.

In the case when the system operation time θ is large enough, the coordinates of the unconditional reliability function of the system defined by (2) are given by

$$R(t,u) \cong \sum_{b=1}^{v} p_b [R(t,u)]^{(b)} \ for\, t \in \langle 0,\infty), u = 1,2,\ldots,z, \qquad (5)$$

where $[\boldsymbol{R}(t,u)]^{(b)}$, $u = 1,2, \ldots, z$, $b = 1,2, \ldots, v$, are the coordinates of the system conditional reliability functions defined by (4) and p_b, $b = 1,2, \ldots, v$, are the system operation process limit transient probabilities given by (1).

Hence, the mean value $\mu(u) = E[T(u)]$ of the system unconditional lifetime $T(u)$ in the reliability state subset $\{u,u+1, \ldots, z\}$ is given by (Kołowrocki 2011, 2014)

$$\mu(u) \cong \sum_{b=1}^{v} p_b \mu_b(u), \quad u = 1,2,\ldots,z, \qquad (6)$$

where $\mu_b(u) = E[T^{(b)}(u)]$ are the mean values of the system conditional lifetimes $T^{(b)}(u)$ in the reliability state subset $\{u,u+1, \ldots, z\}$ at the operation state z_b, $b = 1,2, \ldots, v$, given by

$$\mu_b(u) = \int_0^{\infty} [R(t,u)]^{(b)} dt, \quad u = 1,2,\ldots,z, \qquad (7)$$

where $[\boldsymbol{R}(t,u)]^{(b)}$, $u = 1,2, \ldots, z$, $b = 1,2, \ldots, v$, are defined by (4) and p_b are limit probabilities of the system particular operation states given by (1). Since the relationships between the system unconditional lifetimes $\overline{T}(u)$ in the particular reliability states and the system unconditional lifetimes $T(u)$ in the reliability state subsets can be expressed by

$$\overline{T}(u) = T(u) - T(u+1), u = 0,1,\ldots,z-1, \overline{T}(z) = T(z),$$

then we get the following formulae for the mean values of the unconditional lifetimes of the system in particular reliability states

$$\begin{aligned} &\overline{\mu}(u) = \mu(u) - \mu(u+1), u = 0,1,\ldots,z-1, \\ &\overline{\mu}(z) = \mu(z), \end{aligned} \qquad (8)$$

where $\mu(u)$ $u = 0,1, \ldots, z$ are given by (7).

4 MONTE CARLO SIMULATION APPROACH TO RELIABILITY EVALUATION OF MULTI-STATE SYSTEM

4.1 *Generating system operation process*

We denote by $\theta_{bl}^{(i)}$, $b,l = 1,2, \ldots, v$, $i = 1,2, \ldots, n_{bl}$, $b \neq l$, the realizations of the conditional sojourn time θ_{bl} of the system operation process generated from the distribution H_{bl}, where n_{bl} is the number of those sojourn time realizations during the experiment time $\tilde{\theta}$. Those realizations are generated according to the formulae

$$\theta_{bl}^{(i)} = H_{bl}^{-1}(h), b,l = 1,2,\ldots,v,$$

where $H_{bl}^{-1}(h)$ is the inverse function of the distribution function $H_{bl}(t)$ and h is a randomly generated number from the uniform distribution on the interval $\langle 0,1 \rangle$.

Having the realizations of the conditional sojourn times of the system operation process

$$\theta_{bl}^{(1)}, \theta_{bl}^{(2)}, \ldots, \theta_{bl}^{(n_{bl})}, b,l = 1,2,\ldots,v, b \neq 1,$$

it is possible to determine approximately the total sojourn time at the operation state z_b, during the time of the experiment $\tilde{\theta}$ applying the formula

$$\tilde{\theta}_b = \sum_{\substack{l=1 \\ l \neq b}}^{v} \sum_{j=1}^{n_{bl}} \theta_{bl}^{(i)}.$$

Further, the limit transient probabilities $p_b(t)$ can be approximately obtained using the formula

$$p_b = \frac{\tilde{\theta}_b}{\tilde{\theta}},$$

where

$$\tilde{\theta} = \sum_{b=1}^{v} \tilde{\theta}_b, b = 1,2,\ldots,v.$$

4.2 *Generating system reliability state changing process*

The realizations $[t_i(u)]^{(b)}$, of the components E_i, $i = 1,2, \ldots, n$, conditional lifetimes $[T_i(u)]^{(b)}$, $i = 1,2, \ldots, n$, $u = 1,2, \ldots, z$, $b = 1,2, \ldots, v$, are generated according to the distribution (3), i.e. they are generated by the sampling formula

$$[t_i(u)]^{(b)} = \left([F_i(f,u)]^{(b)} \right)^{-1} = \left(1 - [R_i(f,u)]^{(b)} \right)^{-1},$$

where $\left([F_i(f,u)]^{(b)} \right)^{-1}$ is the inverse function of the distribution function

$$[F_i(t,u)]^{(b)} = 1 - [R_i(t,u)]^{(b)}$$

of the component conditional lifetime $[T_i(u)]^{(b)}$ and $[R_i(t,u)]^{(b)}$ is defined by (3) which in the case of exponential distribution takes the following form

$$[F_i(t,u)]^{(b)} = 1 - \exp[-[\lambda_i(u)]^{(b)} t], \quad for\, t \in \langle 0,\infty),$$

$i = 1,2, \ldots, n$, $u = 1,2, \ldots, z$, $b = 1,2, \ldots, v$.

In the case of the above exponential distribution the realizations of the system component conditional lifetimes take the following form

$$[t_i(u)]^{(b)} = -\frac{1}{[\lambda_i(u)]^{(b)}}\ln(1-f),\ i=1,2,\ldots,n,\quad b=1,2,\ldots,v, \tag{9}$$

The realizations $t(u)$, $u = 1,2, \ldots, z$, of the system unconditional lifetime $T(u)$, $u = 1,2, \ldots, z$, in the reliability state subset $\{u,u+1, \ldots, z\}$ depend on the realizations $[t_i(u)]^{(b)}$, $i = 1,2, \ldots, n$, $b = 1,2, \ldots, v$, of the system component conditional lifetimes $[T_i(u)]^{(b)}$, $i = 1,2, \ldots, n$, $u = 1,2, \ldots, z$, $b = 1,2, \ldots, v$, and are calculated from the expression

$$t(u) = t([t_i(u)]^{(b)},\ i = 1,2, \ldots, n,\ b = 1,2, \ldots, v),$$

for $u = 1,2, \ldots, z$,

taking suitable explicit form dependent of the system structure.

The procedure of Monte Carlo simulation is repeated N times. The approximate mean value of the system lifetimes is an arithmetic mean of all system lifetime realizations for N iterations

$$[\mathrm{t}(u)]_k^{(b)},\ k=1,2,\ldots,N,\ b=1,2,\ldots,v,\ u=1,2,\ldots,z,$$

i.e.

$$[\overline{t}(u)]^{(b)} = \frac{1}{N}\sum_{k=1}^{N}[t(u)]_k^{(b)},\ b=1,2,\ldots,v,\ u=1,2,\ldots,z,$$

Using the procedure of Monte Carlo simulation (Kołowrocki & Kuligowska 2013, Kuligowska 2012, 2013), the histogram of the system unconditional lifetime can be found and the empirical mean value of the system unconditional lifetime can be calculated according to the formulae

$$\mu(u) = \frac{1}{N}\sum_{k=1}^{N} t_k(u), \tag{10}$$

on the basis of system unconditional lifetime realizations for N iterations

$$[t(u)]_k,\ k = 1,2, \ldots, N,\ u = 1,2, \ldots, z.$$

5 PORT GRAIN TRANSPORTATION SYSTEM RELIABILITY EVALUATION

5.1 *Port grain transportation system operation process*

We consider the port grain transportation system, presented in Figure 1, assigned to handle the clearing of exported and imported grain.

The port grain transportation system function is loading railway trucks with grain. The railway truck loading is performed in the following successive grain transportation system steps:

- gravitational passing of grain from the storage placed on the 8th elevator floor through 45 hall to horizontal conveyors placed in the elevator basement,
- transport of grain through horizontal conveyors to vertical bucket elevators transporting grain to the main distribution station placed on the 9th floor,
- gravitational dumping of grain through the main distribution station to the balance placed on the 6th floor,
- dumping weighed grain through the complex of flaps placed on the 4th floor to horizontal conveyors placed on the 2nd floor,
- dumping of grain from horizontal conveyors to worm conveyors,
- dumping of grain from worm conveyors to railway trucks.

In loading the railway trucks with grain the following presented in Figures 1–3 transportation subsystems take part:

S_1 – horizontal conveyors of the first type,
S_2 – vertical bucket elevators,
S_3 – horizontal conveyors of the second type,
S_4 – worm conveyors.

Taking into account the operation process of the considered transportation system, described by its operators, we distinguish its following $v = 3$ operation states:

- z_1– the system operation with the largest efficiency when all components of subsystems S_1, S_2, S_3, and S_4 are used (Figure 1),
- z_2– the system operation with less efficiency system when the first conveyor of subsystem S_1, the first and second elevators of subsystem S_2, the first conveyor of subsystem S_3 and the first

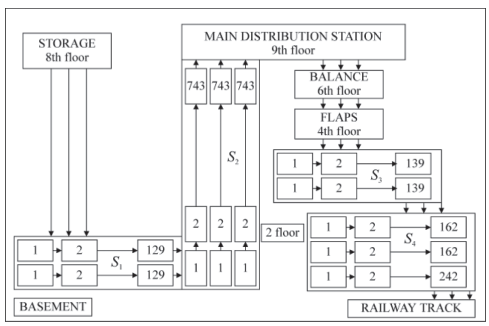

Figure 1. The scheme of the port grain transportation system structure at the operation state z_1.

and second conveyors of subsystem S_4 are used (Figure 2),

– z_3– the system operation with least efficiency when only the first conveyor of subsystem S_1, the first elevator of subsystem S_2, the first conveyor of subsystem S_3 and the first conveyor of subsystem S_4 are used (Figure 3).

At all system operation states, subsystems S_1, S_2, S_3 and S_4 become either non-homogeneous series-parallel systems or non-homogeneous series systems.

This way, the changes of the grain transportation system reliability structure at different operation states are defined.

Considering the system operators opinion, we assume the vector of approximate values of the initial probabilities $p_b(0)$, $b = 1,2,3$,

$$[p_b(0)]_{1x3} = \left[\frac{1}{3}, \frac{1}{3}, \frac{1}{3}\right]$$

of the system operation process staying at the particular states z_b at the time $t = 0$ and the matrix of the probabilities of transitions between the states are given by

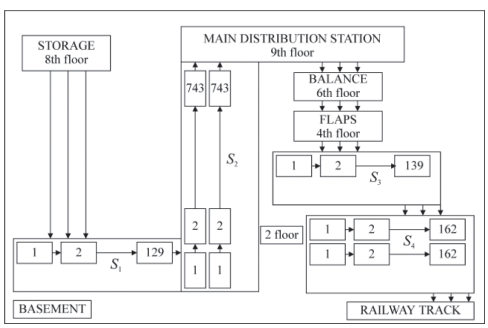

Figure 2. The scheme of the port grain transportation system structure at the operation state z_2.

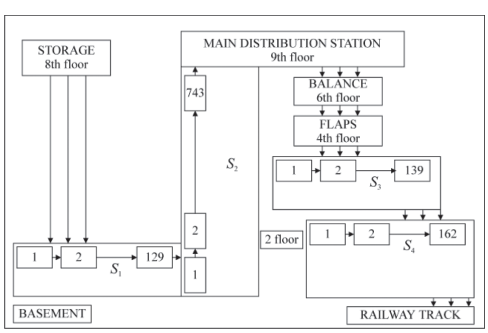

Figure 3. The scheme of the port grain transportation system structure at the operation state z_3.

$$[p_{bl}]_{3x3} = \begin{bmatrix} 0 & \frac{1}{3} & \frac{2}{3} \\ \frac{4}{9} & 0 & \frac{5}{9} \\ \frac{1}{3} & \frac{2}{3} & 0 \end{bmatrix}.$$

Moreover, we assume the following matrix of the conditional distribution functions of the system sojourn times θ_{bl}, $b,l = 1,2,3$,

$$[H_{bl}(t)]_{3x3} = \begin{bmatrix} 0 & 1-e^{-5t} & 1-e^{-10t} \\ 1-e^{-40t} & 0 & 1-e^{-50t} \\ 1-e^{-10t} & 1-e^{-20t} & 0 \end{bmatrix}.$$

In (Kołowrocki & Soszyńska-Budny 2014), after considering the above data and applying (1), the following limit values of the system operation process transient probabilities at the operation states are determined

$$p_1 \cong 0.530,\ p_2 \cong 0.109,\ p_3 \cong 0.361. \tag{11}$$

5.2 *Port grain transportation system reliability parameters*

Taking into account the efficiency of the considered in Section 2 port grain transportation system we distinguish the following three reliability states of the systems and its components:

– state 2—the state ensuring the largest efficiency of the system and its conveyors,
– state 1—the state ensuring less efficiency of the system caused by throwing grain off the system conveyors,
– state 0—the state involving failure of the system.

The considered here transportation system reliability analysis at the constant operation conditions is performed in (Kołowrocki 2014). It is assumed that the system reliability structure and its subsystems and components reliability depend on its changing in time operation states. Considering the assumptions and agreements of these sections, we assume that its subsystems S_υ, $\upsilon = 1,2,3,4$, are composed of three-state, i.e. $z = 3$, components $E_{ij}^{(\upsilon)}$, $\upsilon = 1,2,3,4$, having the conditional lifetimes $[T_{ij}^{(\upsilon)}(1)]^{(b)}$ and $[T_{ij}^{(\upsilon)}(2)]^{(b)}$ in the reliability states $\{1,2\}$ and $\{2\}$ respectively the conditional reliability functions given by the vector

$$[R_{ij}^{(\upsilon)}(t,\cdot)]^{(b)} = [1,[R_{ij}^{(\upsilon)}(t,1)]^{(b)},[R_{ij}^{(\upsilon)}(t,1)]^{(b)}],$$
$$b = 1,2,3,$$

with the exponential coordinates

$$[R_{ij}^{(\upsilon)}(t,1)]^{(b)} = P([T_{ij}^{(\upsilon)}(1)]^{(b)} > t) = \exp[-[\lambda_{ij}^{(\upsilon)}(1)]^{(b)}t],$$

$$[R_{ij}^{(\upsilon)}(t,1)]^{(b)} = P([T_{ij}^{(\upsilon)}(1)]^{(b)} > t) = \exp[-[\lambda_{ij}^{(\upsilon)}(1)]^{(b)}t],$$

different at various operation states z_b, $b = 1,2,3$, and with the intensities of departure from the reliability state subsets {1,2}, {2}, respectively

$$[\lambda_{ij}^{(\upsilon)}(1)]^{(b)}, [\lambda_{ij}^{(\upsilon)}(2)]^{(b)},\ \upsilon = 1,2,3,4,\ i = 1,2,\ldots,[i^{(\upsilon)}]^{(b)},$$

$$j = 1,2,\ldots,[j^{(\upsilon)}]^{(b)},\ b = 1,2,3,$$

given in (Kołowrocki 2014) and presented in Tables 1–3.

At all the operational states, subsystems S_1, S_2, S_3 and S_4 are non-homogeneous regular either series-parallel or series systems. The influence of the system operation states changing on the changes of the system reliability structure and its components reliability functions is presented in Tables 1–3.

5.3 *Port grain transportation system reliability characteristics*

5.3.1 *Analytical evaluation*

Analytical evaluation of the system unconditional three-state reliability function is performed in (Kołowrocki & Soszyńska-Budny 2014) and according to (5), (11) it is given by the vector

Table 1. List of system components and intensities of departure at the operation state z_1.

Sub-system	Components	Intensity of departure	
S_1	2 identical belt conveyors (the 1st type)		
	1 belt	0.0125	0.015
	2 drums	0.0015	0.002
	117 channelled rollers	0.005	0.010
	9 supporting rollers	0.004	0.008
S_2	3 identical vertical bucket elevators		
	1 belt	0.025	0.030
	2 drums	0.0015	0.002
	740 buckets	0.030	0.035
S_3	2 identical belt conveyors (the 2nd type)		
	1 belt	0.0125	0.015
	2 drums	0.0015	0.002
	117 channelled rollers	0.005	0.010
	19 supporting rollers	0.004	0.008
S_4	3 chain worm conveyors		
	2 conveyors of the 1st type		
	2 driving wheels	0.005	0.006
	160 links	0.012	0.014
	1 conveyor of the 2nd type		
	2 driving wheels	0.022	0.024
	240 links	0.034	0.040

Table 2. List of system components and intensities of departure at the operation state z_2.

Sub-system	Components	Intensity of departure	
S_1	1 belt conveyor (the 1st type)		
	1 belt	0.011	0.012
	2 drums	0.001	0.0012
	117 channelled rollers	0.003	0.006
	9 supporting rollers	0.002	0.003
S_2	2 identical vertical bucket elevators		
	1 belt	0.020	0.024
	2 drums	0.0012	0.0014
	740 buckets	0.022	0.025
S_3	1 belt conveyor (the 2nd type)		
	1 belt	0.011	0.012
	2 drums	0.001	0.0012
	117 channelled rollers	0.003	0.006
	19 supporting rollers	0.002	0.003
S_4	2 chain worm conveyors (the 1st type)		
	2 driving wheels	0.002	0.004
	160 links	0.008	0.010

Table 3. List of system components and intensities of departure at the operation state z_3.

Sub-system	Components	Intensity of departure	
S_1	1 belt conveyor (the 1st type)		
	1 belt	0.010	0.0105
	2 drums	0.0009	0.0011
	117 channelled rollers	0.002	0.004
	9 supporting rollers	0.001	0.002
S_2	1 vertical bucket elevator		
	1 belt	0.018	0.022
	2 drums	0.0011	0.0013
	740 buckets	0.020	0.024
S_3	1 belt conveyor (the 2nd type)		
	1 belt	0.010	0.0105
	2 drums	0.0009	0.0011
	117 channelled rollers	0.002	0.004
	19 supporting rollers	0.001	0.002
S_4	1 chain worm conveyor (the 1st type)		
	2 driving wheels	0.001	0.003
	160 links	0.007	0.009

$$\boldsymbol{R}(t,\cdot) = [1, \boldsymbol{R}(t,1), \boldsymbol{R}(t,2)],\ t \in \langle 0,\infty), \tag{12}$$

with the co-ordinates

$$\begin{aligned}\boldsymbol{R}(t,1) &= 0.530[\boldsymbol{R}(t,1)]^{(1)} + 0.109[\boldsymbol{R}(t,1)]^{(2)} \\ &\quad + 0.361\,[\boldsymbol{R}(t,1)]^{(3)},\ \text{for } t \in \langle 0,\infty), \\ \boldsymbol{R}(t,2) &= 0.530[\boldsymbol{R}(t,2)]^{(1)} + 0.109[\boldsymbol{R}(t,2)]^{(2)} \\ &\quad + 0.361\,[\boldsymbol{R}(t,2)]^{(3)},\ \text{for } t \in \langle 0,\infty),\end{aligned} \tag{13}$$

where the reliability functions $[\boldsymbol{R}(t,1)]^{(1)}$, $[\boldsymbol{R}(t,1)]^{(2)}$, $[\boldsymbol{R}(t,1)]^{(3)}$, $[\boldsymbol{R}(t,2)]^{(1)}$, $[\boldsymbol{R}(t,2)]^{(2)}$, $[\boldsymbol{R}(t,2)]^{(3)}$ are given in (Kołowrocki & Soszyńska-Budny 2014).

The expected value of the system unconditional lifetime in the reliability state subsets {1,2}, {2}, calculated according to (6)-(7) from the results given by (12)-(13), are

$$\mu(1) \cong 0.0744 \text{ month}, \ \mu(2) \cong 0.0624 \text{ month}. \quad (14)$$

Further, considering (14) and (8), the mean values of the system unconditional lifetimes in the particular reliability states 1, 2, respectively are:

$$\overline{\mu}(1) \cong 0.0120 \text{ month}, \ \overline{\mu}(2) \cong 0.0624 \text{ month}.$$

5.3.2 *Monte Carlo evaluation*

The realizations of the port grain transportation system components lifetimes $[t_{ij}^{(\upsilon)}(u)]_k^{(b)}$, $k = 1,2,...,N$, $\upsilon = 1,2,3,4$, $u = 1,2$, $b = 1,2,3$, $i = 1,2,...,[i^{(\upsilon)}]^{(b)}$, $j = 1,2,...,[j^{(\upsilon)}]^{(b)}$, are generated from the exponential distribution according to (13) and Tables 1–3. The realizations $[t(u)]_k$, $k = 1,2,...,N$, $u = 1,2$, of the system unconditional lifetime depend on the realizations of the system component conditional lifetimes and are calculated taking suitable explicit form dependent of the system operation process and system structure. Namely:

– at the operation state z_1, we use the formula

$$[t(u)]_k^{(1)} = \min\{\max_{1\le i\le 2}\{\min_{1\le j\le 129}\{[t_{ij}^{(1)}(u)]_k^{(1)}\}\},$$
$$\max_{1\le i\le 3}\{\min_{1\le j\le 743}\{[t_{ij}^{(2)}(u)]_k^{(1)}\}\}, \max_{1\le i\le 2}\{\min_{1\le j\le 139}\{[t_{ij}^{(3)}(u)]_k^{(1)}\}\},$$
$$\max_{1\le i\le 3}\{\min_{1\le j\le 242}\{[t_{ij}^{(4)}(u)]_k^{(1)}\}\}\}, k = 1,2,\ldots,N, u = 1,2;$$

– at the operation state z_2, we use the formula

$$[t(u)]_k^{(2)} = \min\{\min_{1\le j\le 129}\{[t_{ij}^{(1)}(u)]_k^{(2)}\},$$
$$\min_{1\le j\le 139}\{[t_{ij}^{(3)}(u)]_k^{(2)}\}, \max_{1\le i\le 2}\{\min_{1\le j\le 743}\{[t_{ij}^{(2)}(u)]_k^{(2)}\}\},$$
$$\max_{1\le i\le 2}\{\min_{1\le j\le 242}\{[t_{ij}^{(4)}(u)]_k^{(2)}\}\}\}, k = 1,2,\ldots,N, u = 1,2;$$

– at the operation state z_3, we use the formula

$$[t(u)]_k^{(3)} = \min\{\min_{1\le \upsilon\le 4}\{\min_{1\le j\le 129}\{[t_{ij}^{(1)}(u)]_k^{(3)}\},$$
$$\min_{1\le j\le 743}\{[t_{ij}^{(2)}(u)]_k^{(3)}\}, \min_{1\le j\le 139}\{[t_{ij}^{(3)}(u)]_k^{(1)}\},$$
$$\min_{1\le j\le 242}\{[t_{ij}^{(4)}(u)]_k^{(3)}\}\}, k = 1,2,\ldots,N, u = 1,2.$$

The simulation was made with N = 1 000 000 runs. The realizations $[t(u)]_k$, $k = 1,2, \ldots, N$, $u = 1,2$, of the system unconditional lifetimes are illustrated in the form of the histograms in Figure 4.

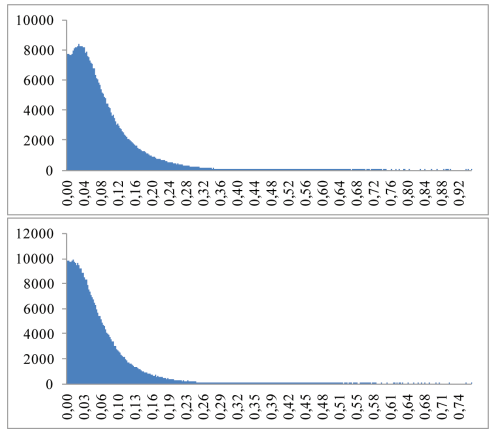

Figure 4. The graph of the histogram of port grain transportation system unconditional lifetime in the reliability state subsets {1,2},{2}.

After analyzing the histograms, we formulate the hypotheses that the system unconditional lifetimes in the reliability state subsets {1,2},{2}, have Weibull distributions. Those hypotheses testing result in the conclusion that the approximate system unconditional reliability function is given by the vector

$$\mathbf{R}(t,\cdot) = [1, \mathbf{R}(t,1), \mathbf{R}(t,2)], \ t \in \langle 0,\infty),$$

with the co-ordinates

$$\boldsymbol{R}(t,1) = \exp[-17.3150 t^{1.1526}],$$
$$\boldsymbol{R}(t,2) = \exp[-23.0851 t^{1.1052}] \text{ for } t \in \langle 0,\infty).$$

Hence, the expected value of the system unconditional lifetime in the reliability state subsets {1,2},{2}, according to (7) are

$$\mu_s(1) \cong 0{,}0801 \text{ month}, \ \mu_s(2) \cong 0.0563 \text{ month}.$$

Consequently, according to (8), the system unconditional lifetimes in the particular reliability states 1, 2, respectively are:

$$\overline{\mu}(1) \cong 0.0238 \text{ month}, \ \overline{\mu}(2) \cong 0.0563 \text{ month}.$$

6 CONCLUSIONS

The Monte Carlo simulation algorithm based on the integrated general model of a complex multistate system reliability, linking its reliability model and its operation process model and considering variable at different operation states its

reliability structure and its components reliability parameters is applied to the reliability evaluation of the port grain transportation system. The predicted reliability characteristics of this system differ not much from those determined for this system by approximate analytical method presented in (Kołowrocki & Soszyńska-Budny 2014). This fact justifies the sensibility of using Monte Carlo simulation approach to reliability evaluation of a very wide class of real complex technical systems changing their reliability structures and reliability parameters at their variable operation processes.

ABSTRACT: Modeling and improving uncertainty during importance sampling is a vital component for effective decision making. In real world and examples, elements may be belong to any groups or uncertain. Unfortunately, most of the random numbers sampling studies suffer from uncertainty analysis. The development of tools and techniques for capturing uncertainty in sampling is ongoing and with the set of given numbers or elements or objects in the statistical approaches we can select the elements in a random way to compute values of many subjects like mean, variance and etc. There are some sampling methods in this way that argued in many publications. In this article, the cross-disciplinary approaches for uncertainty analyses are identified and a modified approach suitable for random number generation is proposed by using fuzzy set theory and cluster sampling. The proposed method is applied to improving the sampling efficiency in the (probabilistic and possibilistic) uncertainties. In argued methods each element just belongs to one category, but in our approach each element include in all groups with one exception that membership values are different. In this paper we introduce new approach base on fuzzy theory combined with sampling methods. The case study results show that the proposed method provides better measure of uncertainty than the existing methods as unlike traditional sampling method.

1 INTRODUCTION

Modeling, improving and handling uncertainty the sampling is a vital component for effective decision making. Uncertainty is insufficiently, explicitly communicated to random sampling methods. The quantification and propagation of uncertainty become essential in precisely those situations where quantitative modeling cannot draw upon extensive historical, statistical or measurement data (Kurowicka and Cooke 2006). Fuzzy logic systems constitute a powerful tool for coping with ubiquitous uncertainty in many engineering applications (Ondrej Linda and Manic 2010). The most important point in assessing uncertainty of gained population via sampling is to recognize that all uncertainties are not quantifiable, and therefore they should be separated from the sampling characteristics (Verdonck, Souren et al. 2007). In sampling methods, if we are willing to give up some features of random sampling, notably serial independence, then variance reduction techniques may be invoked (Kwakernaak 1978). A suitable mathematical model for random variables which assume fuzzy values are so-called fuzzy random variables (L. Zadeh 1978). In standard statistics the combination of observations into an element of the sample space is trivial. But for fuzzy data this is not (Viertl 2011). Since Zadeh first introduced the concept of a fuzzy set (Zadeh 1975), Fuzzy principles have been applied to a huge and diverse range of sciences (Garibaldi and John 2003). Now we want use advantages of fuzzy model to improve sampling and solve the problems that occur in probability sampling. In stratified and cluster sampling it is hard and time-consuming to separate data into categories, however after do this it is not precise. For example one element can be belonging to some categories near to that element (Fig. 2). As a result although these methods have many benefits in sampling versus of other methods, unfortunately category based methods have many problems, because of unsuitable clustering results are not precise. A basic problem, at the present stage of the sampling methods, is how to manage the variance of sample process while taking into account its intrinsic features of uncertainty, including imprecision and vagueness.

2 SAMPLING METHODS

Once a choice is made to use a probability sample design, one must choose the type of probability

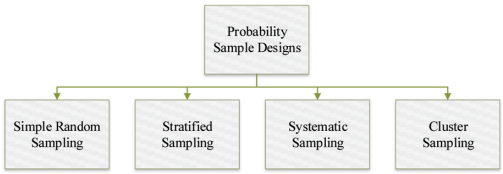

Figure 1. Major types of probability sampling (Levy and Lemeshow 2009).

sampling to use. There are four major types of probability sample designs: simple random sampling, stratified sampling, systematic sampling, and cluster sampling. Simple random sampling is the most recognized probability sampling procedure(Cochran 2007). Stratified sampling offers significant improvement to simple random sampling. Systematic sampling is probably the easiest one to use, and cluster sampling is most practical for large national surveys. Figure 1 shows major types of probability sampling methods (Levy and Lemeshow 2013). These methods have Main weaknesses. For example, simple random sampling requires frame, does not take advantage of knowledge of population, larger errors and less precision, and for widely dispersed population, and data collection costs might be higher. Stratified random sampling requires information that belongs to each stratum, more expensive, time-consuming, complicated, and need to select at least two elements in each stratum. In systematic sampling, combinations of elements have different probabilities of being selected, technically, only the selection of the first element is a probability, principle of independence is violated (selection of first element), and estimating variances is more complex. Cluster sampling may not be as representative, variances tend be much higher, introduces more complexity in analyzing data and interpreting results, and yields larger sampling errors for samples of comparable size than other probability samples.

3 SOURCES OF UNCERTAINTY

The main purpose of most measurements is to enable decisions to be made. The credibility of these decisions depends on knowledge about the uncertainty of the measurement results. Uncertainty in measurement can be defined as being made up of two components: uncertainty derived from sampling a matrix and using those samples to represent the whole sampled mass; and the uncertainty derived from the analytical process. If the uncertainty of measurements is underestimated, for example because the sampling is not taken into account, then erroneous decisions may be made that can have large financial, health and environmental consequences. For this reason it is essential that effective procedures are available for estimating the uncertainties arising from all parts of the measurement process. The uncertainty arises from a variety of sources, and these can be categorized in different ways. The sources of uncertainty from analyses are well studied, but less focus has been upon uncertainty from sampling. In Table 1, some sources of uncertainty in sampling and sample preparation are listed (Grøn, Hansen et al. 2007). Both sampling and analysis contribute to measurement uncertainty. The uncertainty contribution due to physical sample preparation, transport, sample storage etc. is either included in the uncertainty of the sampling or of the analysis. The random part of the uncertainty is described by the standard deviation. The standard deviation of the measurement, $S_{measurement}$, is given by the following equation:

$$S^2_{measurement} = S^2_{sampling} + S^2_{analysis} \quad (1)$$

$$S_{sampling} = \sqrt{S^2_{measurement} - S^2_{analysis}} \quad (2)$$

The cross-disciplinary approaches for uncertainty analyses are identified and a modified approach suitable for random number generation is proposed by using fuzzy set theory and cluster sampling. The proposed method is applied to improving the sampling efficiency in the (Probabilistic and Possibilistic) uncertainties. The relative uncertainty itself can also be used without the subsequent statistical testing particularly if enough is known about the parameter being evaluated. This value of relative uncertainty is given by (Billinton and Allan 1983):

$$Relative\ \ uncertainty = \frac{s}{\overline{x}\sqrt{n}} \quad (3)$$

where
$\overline{x}$ = mean value of parameter
s = standard deviation of parameter
n = number of sample.

In this paper, in order to decrease the uncertainty of sampling, the variance reduction techniques have been used. Variance reduction techniques are methods that attempt to reduce the variance, i.e., the dispersion associated with the variations, of the parameter being evaluated.

Table 1. Some sources of uncertainty in sampling and sample preparation (Grøn, Hansen et al. 2007).

Sampling	Sample preparation
Heterogeneity (or inhomogeneity)	Homogenization and/or sub-sampling effects
Effects of specific sampling strategy (e.g. random, stratified random, proportional etc.)	Milling, drying, dissolution
Physical state of bulk (solid, liquid, gas)	(Pre-)Concentration, dilution errors
Effect of sampling process on composition (e.g. differential adsorption in sampling system).	Control of speciation effects.

4 FUZZY SAMPLING

Now we want use advantages of fuzzy model to improve sampling and solve the problems that occur in probability sampling. In stratified and cluster sampling it is hard and time-consuming to separate data into categories, however after do this it is not precise. For example one element can be belonging to some categories near to that element (see Fig. 2). As a result although these methods have many benefits in sampling versus of other methods, unfortunately category based methods have many problems, because of unsuitable clustering results are not precise. In probability methods there are some problems and weaknesses that we can solve them with our new approach namely fuzzy sampling. Here after review of these methods and their properties, we show that how we can fix their problems with fuzzy approach.

In argued methods each element just belongs to one category, but in our approach each element include in all groups with one exception that membership values are different. For example consider age ranges. (Fig. 3) i.e. a man with 30 years old belongs to five groups by blow membership values:

When we categories such samples with stratified and clustering methods, some errors raised for computing values like variance, mean, etc. in fuzzy approach these types of errors can be eliminated. In fact each element is member of every category with a probability between 0 and 1. Our new approach is a combination of fuzzy and clustering. In this approach we assume that linguistic variables comprised as three parts and modeled in triangular. When we categories such samples with stratified and clustering methods, some errors raised for computing values like variance, mean, etc. in fuzzy approach these types of errors can be eliminated. In fact each element is member of every category with a probability between 0 and 1. Our new approach is a combination of fuzzy and clustering.

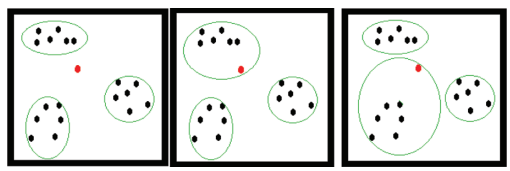

Figure 2. Methods of element categorizing in clusters.

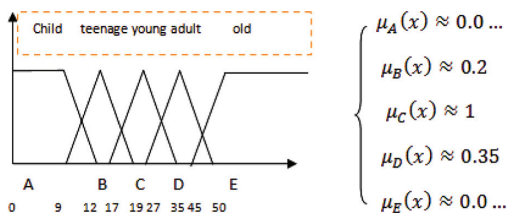

Figure 3. Demonstration of fuzzy membership function for age example.

5 PROPOSED ALGORITHM

Like cluster method we choose some random clusters for sampling, and then we identify the neighborhood of clusters to modeling fuzzy. Let $n_1, n_2 \ldots, n_m$ be the number of elements in each of the m sampled clusters. Let $\bar{X}_1, \bar{X}_2, \ldots, \bar{X}_m$ be the means of the sampled clusters. The relative uncertainty itself can also be used without the subsequent statistical testing particularly if enough is known about the parameter being evaluated. Variance reduction techniques are methods that attempt to reduce the variance, i.e., the dispersion associated with the variations, of the parameter being evaluated. This can result in one of two outcomes. Either the variance is reduced for the same number of sampling or the number of sampling can be reduced for the same variance, the comparison of both being made when no variance reduction techniques are used. This therefore either increases the confidence in the

results or reduces the computational burden. There are many forms of variance reduction techniques and a specialized text should be consulted if full details of all techniques are needed. This algorithm provides reduced variances and standard errors comparison with other traditional methods. Schematic of proposed method is shown in Figure 4. Steps that are used for programming with use of fuzzy-clustering method that are mentioned in below algorithm consist of below classified steps:

1. Select m random clusters
2. Determine neighbors of each selected cluster
3. Calculate membership values for these clusters
4. Calculate mean value, variance, max confidence and min confidence from formulas

Formulations and relations that are used for computing the parameters such as Mean, Variance,

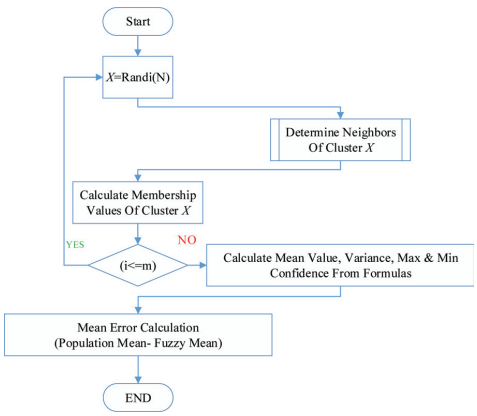

Figure 4. Flowchart of proposed sampling method.

Maximum and Minimum Confidence intervals are the same as cluster sampling formulations, in addition with fuzzy membership functions. Hence, for Mean estimator of this method we have:

$$Mean = \frac{\sum_{i=1}^{m}\left(\bar{X}_i n_i + \mu_{i+1}\bar{X}_{i+1}n_{i+1} + \mu_{i-1}\bar{X}_{i-1}n_{i-1}\right)}{\sum_{i=1}^{m} n_i} \tag{4}$$

where $\bar{X}_i$ and n_i are the mean and the number of elements for ith cluster respectively. And μ_{i+1} and μ_{i-1} are membership values of two neighboring clusters.

An estimator of samples variance is given by:

$$Variance = \frac{M-q}{Mq\bar{n}^2}\frac{\sum_{i=1}^{m} n_i^2\left(\bar{X}_i - mean\right)^2}{q-1} \tag{5}$$

where

$$\bar{n} = \left(\sum_{i=1}^{m} n_i\right)\Big/ q \quad \text{and} \quad q = m^*(\mu_{i+1} + \mu_{i-1}) \tag{6}$$

Using the preceding information, we construct a 95% confidence interval for Mean as follows:

$$\text{Confidence interval} = \text{mean} \pm 1.96\sqrt{variance} \tag{7}$$

For example consider Transport Company that contains trucks is based in N centers (clusters), assume that measure of the weekly average fuel saving for each of the centers is given. We modeled this method, cluster sampling and exhaustive method (real mean and variance) in a system

Table 2. Sampling parameter results.

	No. of iterations	1000	5000	10000
Population (exhaustive)	Run times (s)	0.0156	0.1404	0.2496
	Mean value	15.8781	15.8781	15.8781
	Variance	0.33719	0.33719	0.33719
	Confidence interval	[14.74, 17.016]	[14.74, 17.016]	[14.74, 17.016]
	Error value	0	0	0
Cluster	Run times (s)	0.0624	0.2964	0.5304
	Mean value	15.4939	15.4681	15.4897
	Variance	0.37591	0.3741	0.37508
	Confidence interval	[14.302, 16.685]	[14.276, 16.659]	[14.295, 16.6835]
	Error value	0.63211	0.65154	0.63143
Fuzzy	Run times (s)	0.0156	0.1092	0.234
	Mean value	15.5226	15.4896	15.4914
	Variance	0.29896	0.29754	0.29649
	Confidence interval	[14.461, 16.583]	[14.429, 16.550]	[14.434, 16.5481]
	Error value	0.58528	0.59778	0.59765

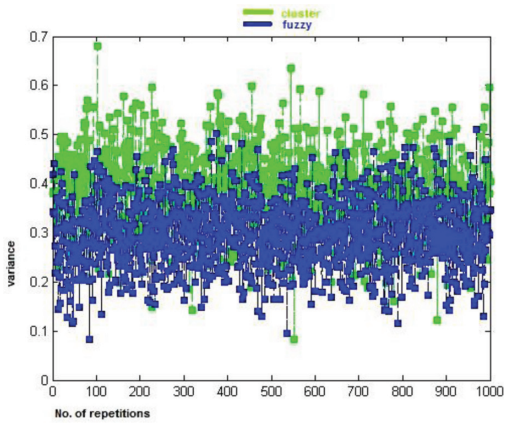

Figure 5. Variance deviations on difference run for fuzzy and cluster sampling.

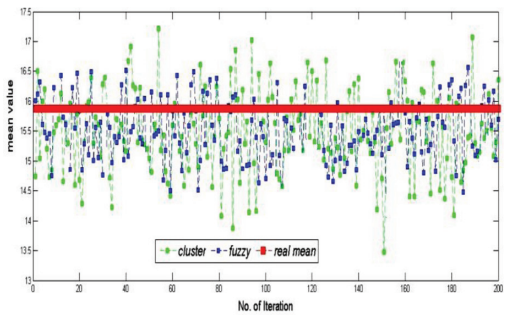

Figure 6. Mean deviations of sampling.

(win 7, mat lab R2010a, 2.30 GHz, 2 GB), and then compared results are given in Table 2.

Results show that significantly error values for fuzzy method is less than clustering and also approximation of mean value for fuzzy is close to population mean. Fuzzy method has less differences variance than cluster method (Fig. 5), as results in statistical approaches we can conclude that this method is an effective way to compute statistical values.

Also, Figure 6 shows the Mean values for exact, cluster sampling, and fuzzy sampling. As obviously, the fuzzy-clustering method has less deviation from the mean exact solution rather than simple clustering method. So, this method shows less error values from the exact solve.

6 CONCLUSION

With the set of given numbers, elements or objects in the statistical approaches we can select the elements in a random way to compute values of many subjects like mean, variance and etc. There are some sampling methods in this way that argued in many publications. In the whole of these methods we assumed that the input data is precise, i.e. each data belongs to a set. For example in stratified sampling we assume that the population of N units may be divided into m groups and the m strata are no overlapping, and then samples select from within each groups. However, in real world, examples and elements may be belong to any groups or not precise. Even in simple random sampling or systematic way we can see some errors lead to equal probabilities of elements. In this paper we introduce new approach base on fuzzy theory combined with sampling methods. The process is to calculate the relative error or uncertainty as the simulation proceeds and, using appropriate statistical tests generally based on the fuzzy theory, calculate the confidence interval after each sampling. This is compared with the pre-specified example. In this paper we introduce new approach base on fuzzy theory combined with sampling methods.

The case study results show that the proposed method provides better measure of uncertainty than the existing methods as unlike traditional sampling method. In this paper, in order to decrease the uncertainty of sampling, the variance reduction techniques have been used. Variance reduction techniques are methods that attempt to reduce the variance, i.e., the dispersion associated with the variations, of the parameter being evaluated. Results show that significantly error values for fuzzy method is less than clustering and also approximation of mean value for fuzzy is close to population mean. Fuzzy method has less differences variance than cluster method (Fig. 5), as results in statistical approaches we can conclude that this method is an effective way to compute statistical values. Also, the fuzzy-clustering method has less deviation from the mean exact solution rather than simple clustering method.

Like cluster method we choose some random clusters for sampling, and then we identify the neighborhood of clusters to modeling fuzzy. Now we want use advantages of fuzzy model to improve sampling and solve the problems that occur in probability sampling.

Conversion of a based risk model into a simulation model for simulation and analysis

K. Negrichi, J.-M. Flaus & M. Di Mascolo
Université Grenoble Alpes, G-SCOP, Grenoble, France
CNRS, G-SCOP, Grenoble, France

ABSTRACT: For production systems, risks may have serious effects that may threaten their performance. Nevertheless, we cannot estimate the degradation that a risk may cause to system performance, since risk analysis methods found in the literature do notallow simulating the behavior of the system in degraded mode. In this paper, we propose a translation method that helps to convert a model based risk analysis framework, which is the Function, Interaction, Structure (FIS) model, into an executable model based on Predicate-Transition, Prioritized, Synchronous (PTPS) Petri Net, which is a new class of Petri Net (PN)s that we defined for simulationpurposes. Using the proposed conversion method, we will be able to obtain a model capable of simulating the behavior of a production system in degraded mode. Furthermore, quantitative indicators can be generated to help risk analyst to quantify the performance degradation. To obtain degraded mode simulation model, we start by performing risk analysis of the system using FIS framework. Then, the obtained model from this risk analysis is translated automatically using algorithms into a PTPS Petri Net model. Finally, using a simulator, the PTPS PN model is executed in order to visualize the behavior of the system in degraded mode.

1 INTRODUCTION

Nowadays production systems are asked to perform their activities in a high uncertainty environment and to guarantee their performance in this environment. Therefore they are asked to master risks, that are part of their daily activities, to maintain the performance which is considered their key success factor.

Risk analysis is the discipline used to identify, assess, and prioritize risks according to the criticality of their effects. Their effects on production system performance may vary from simple perturbation to the total system loss.

Today many risk management methods are available and widely used in order to assist production systems in their process of mastering risks. Among these methods we can find classic methods (Villemeur 1992) such as Preliminary Hazard Analysis (PHA), Failure Mode, Effects and Criticality Analysis (FMECA) and HAZard and OPerability (HAZOP) and model driven methods as FIS (Flaus 2008) and CORAS (Lund, Solhaug, & Stølen 2011). By examining from closer view these methods, we can conclude that their risk ranking methods are based on quantitative indicators that depend only of the perception of the person performing the analysis. This kind of risk ranking method can lead to errors especially for risk causing performance degradation to since no quantitative performance indicators are used.

Based on this observation, we propose in this paper a method enabling to convert a risk analysis model into a simulation model. This simulation model is used to perform simulation in degraded mode in order to obtain quantitative performance indicators that can represent the degradation of the system performance in risk situation.

This paper is structured as follows: The next section deals with the risk model used in our proposed approach. Section 3 gives a presentation of the model used to perform degraded mode simulation. Section 4 presents the set of conversion algorithms used to convert risk model to a simulation model. Section 5 presents some of the performance indicators that can be obtained using the simulation model.

2 PRESENTATION OF THE RISK MODEL USED TO PERFORM THE ANALYSIS

There are several methods that exist to perform risk analysis. These methods can be divided to two types:

- Classical methods as PHA, FMECA and HAZOP
- Model driven methods such as FIS and CORAS.

Classical methods have been used for some time now to perform risk analysis. Generally their results consist in a table in which we

include elements of risk (as Hazard, contact event, failure mode…) and the assessment of the risk severity and the necessary corrective measures.

For simulation purposes, classical methods are not suitable to use. In fact, these methods do not offer a sufficient view of the system to perform simulation. For example, in classical methods there is no indication regarding the material flows in the system, neither indication about the consumed and produced resources of each function. In addition, resources are not treated as in simulation by their number where each instance of the resource is presented.

In this paper we lay on a model driven risk analysis method, FIS, which was published for the first time in 2008 (Flaus 2008). Since then it has been repeatedly used to analyze various systems such as Backup communal plan (Girard, Piatyszek, David, & Flaus 2013), Industrial emergency plans (Karagiannis, Piatyszek, & Flaus 2013) and sterilization services (Negrichi, Di Mascolo, & Flaus 2012) According to FIS (Flaus 2013), a system can be modeled using there different views: Structuro-functional, dysfunctional and evolution view, as detailed below.

2.1 *Structuro-functional view*

Functional view is devoted to describe the structure and the function of the analyzed system. The system is decomposed into functional view composed of *functions* and structural view mainly composed of *resources* (human, technical and organizational resources) (see Fig. 1).

Functions are defined as the role of a group of resources expressed in terms of purpose. According to this definition, a function needs a set of resources called *input resources* to be performed. Then the function creates *output resources*. For their, *support resources* are resource needed by the function to be performed but they are not transformed after the function accomplishment.

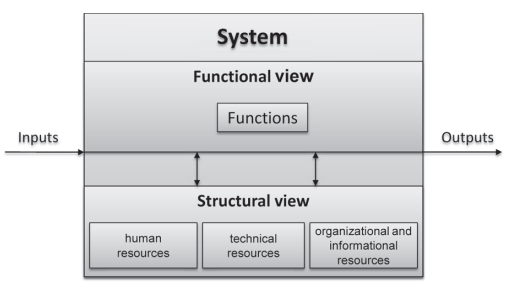

Figure 1. Structuro-functional view of FIS model.

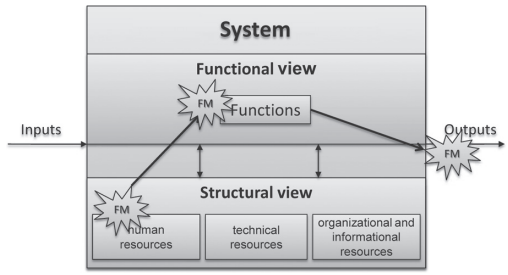

Figure 2. Dysfunctional view of FIS model.

2.2 *Dysfunctional view*

Dysfunctional view represents the failure occurrences in the system and their propagation. First *failure modes* need to be added to the elements defined in the functional view (resources and function see paragraph N 2.1). In a second stage, failure modes propagation relations are added. These propagation relations are causes-effects relations who represent the propagation of failures in a system and are visualized using Fault Trees (see Fig. 2).

2.3 *Evolution view*

The aim of the evolution view is to represent the behavior of the system using the behavior of its functions. FIS gives the possibility to add to each function several behavior modes (see Fig. 3). Each behavior mode is defined by *consumed resources* needed for the function execution (resources selected from the declared input resources of the function (see paragraph 2.1), *produced resources* created of the function execution (resources selected from the declared output resources of the function (see paragraph 2.1), *duration*: the amount of time needed for the function to transform consumed resources to produced resources, *filtering conditions* used to select consumed resources, *input and output actions* that are applied respectively to consumed and produced resources.

During simulation the function can change its behavior according to its state. The state of a function is defined according to the states of its behavior modes. Therefore if a failure mode is activated in the function, this function can change its behavior.

2.4 *Formalization of FIS model*

In order to perform conversion, we need to formalize FIS model. A FIS model M is composed by a set of PR, and a set of systems Sy ($M = \{Sy, PR\}$). Sy is a set of systems ($Sy = \{S_1, S_2, ..., S_n\}$). A system

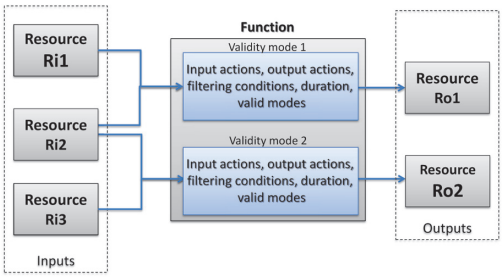

Figure 3. Evolution view of FIS model.

S_i is formally defined as $S_i = \{Fn_i, R_i\}$ (for clarity reasons we will not display the function index (i) in the following) where:

- Fn is a set of functions ($Fn : \{fn_1, fn_2, ..., fn_n\}$)
- R is a set of resources ($R : \{r_1, r_2, ..., r_m\}$).

A function fn_j is formally defined as $fn_j = \{af_j, FM_j, FPR_j, VM_j\}$ (for clarity reasons we will not display the function index (j) in the following) where:

- af is an attribute of the function name
- FM is a set of failure modes associated to the function ($FM : \{fm_1, fm_2, ..., fm_n\}$)
- VM is a set of function behavior modes (($VM : \{vm_1, vm_2, \ldots vm_n\}$). A behavior mode vm_i is definied as $vm_k : \{avm_k, IR_k, OR_k, \theta_k, p_k, IA_k, OA_k, FS_k\}$, where:
  - avm_k is an attribute of behavior mode name
  - IR_k is a set of input resources $\in IR_k$: $\{ir_{k_1}, ir_{k_2}, ..., ir_{k_n}\}$), each input resource ir_{l_m} is defined by $ir_{l_m} : \{irn_{l_m}, irc_{l_m}, RFC_{l_m}\}$, where:
    * irn_{l_m} is the input resource name
    * irc_{l_m} is a number of needed resources
    * RFC_{l_m} is a set of filtering conditions
  - OR_k is a set of output resources, each output resources ($OR_k : \{or_{k_1}, or_{k_2}, ..., or_{k_n}\}$), each output resource or_{l_m} is defined by $or_{l_m} : \{orn_{l_m}, orc_{l_m}\}$, where
    * orn_{l_n} is the output resource name
    * orc_{l_n} is a number of produced resources
  - θ_k is the duration needed to transform input resource to output resources
  - p_k is the priority associated to the behavior mode
  - IA_k is a set of actions applied to input resources ($IA_k : \{ia_{k_1}, ia_{k_2}, ..., ia_{k_n}\}$). Each input action ia_{l_m} defined by $ia_{l_m} : \{iar_{l_m}, iat_{l_m}, IP_{l_m}\}$ where:
    * iar_{l_m} is the input resource name
    * iat_{l_m} is the action type
    * IP_{l_m} is a set of action parameters
  - OA_k is a set of actions applied to output resources ($OA_k : \{oa_{k_1}, oa_{k_2}, ..., oa_{k_n}\}$). Each output action oa_{l_m} defined by $oa_{l_m} : \{oar_{l_m}, oat_{l_m}, OP_{l_m}\}$ where:
    * oar_{l_m} is the output resource name
    * oat_{l_m} is the action type
    * OP_{l_m} is a set of action parameters
  - FS_k is the function state (FS_k: $\{fs_{k_1}, fs_{k_2}, ..., fs_{k_n}\}$) i.e, a set binary constants that represent the state of the function failure modes in a specific date.

A resource r_j is formally defined as $r_j = \{ar_j, RV_j, FM_j, RI_j\}$ (for clarity reasons we will not display the resource index j in the following FIS resource formalization) where:

- ar is an attribute related to the resource name
- RV is a set of resource variables associated to the resource ($RV : \{rv_1, rv_2, ..., rv_m\}$)
- FM is a set of failure modes associated to the resource ($FM : \{fm_1, fm_2, ..., fm_n\}$)
- RI is a set of resource instances ($RI : \{ri_1, ri_2, ri_i\}$), where each resource instance ri_i is defined by a set of constant representing the initial state of the resource variables and failure modes $ri_i = \{IS_1, IS_2, ..., IS_n\}$.

PR is a set of propagation relations ($PR = \{pr_1, pr_2, ..., pr_m\}$). A propagation relation $pr_o = \{Ca_o, Op_o, Ef_o\}$ is composed by a set of causes Ca_o, an operator Op_o and a set of effects Ef_o. Causes and effects are faillure modes associated to FIS functions and resources. Operator is used to describe the relationship between Causes and effects. Propagation Relations (PR) are the formalization of fault trees (see Fig. 10) in the analyzed systems.

3 SIMULATION MODEL

3.1 *Description of the simulation model*

To represent the dynamic behavior of the analyzed system, we need to rely on a simulation model. Several simulation model formalisms exist. Among them we can find PN. PN are a very powerful graphical and mathematical formalism used to representand analyze complex Discrete Event Systems (DES). They were first introduced in 1962 (Petri 1962). They represent a suitable formalism for performance analysis (Ajmone Marsan, Bobbio, & Donatelli 1998). The power of PN relies on their flexibility and their Evolution. In fact many classes of PN were introduced to cope with the increasing complexity of analyzed systems (Reisig, Wolfgang 2013).

According to the requirements of FIS model, we decided to introduce a new class of PN named PTPS PN, which is a class of PN defined using, as its name suggests, Predicate-Transition PN (Genrich & Lautenbach 1981), Prioritized PN (Guan, Yu, & Yang 1998) and Synchronous PN (David & Alla 2010).

3.2 *Formalization of simulation model*

As for FIS model, we need to formalize the PTPS PN in order to perform conversion from risk model into simulation model. Formally, a PTPS PN is is defined by a triplet $< R, A_n, M_0 >$ where:

- R is an ordinay PN, $R = (P, T, F, W)$, where:
  - P is a finite set of places
  - T is a finite set of transitions
  - F is a set of arcs $F(F \subseteq (P \times T) \cup (T \times P))$
  - $W : F \to \mathbb{N}^+$, a set of arc weights
- A_n are the PTPS PN annotations $A_n = < C_{const}, V, E, S, P_r, A_{tc}, A_{ta}, A_c >$ where:
  - C_{const} is a set of constants (belonging to $\mathbb{N}, \{0,1\}, \{a,..,z\}$)
  - V is a formal set of variables, these variables will be substituted by constants during the transitions firing (belonging to $\{a, .., z\}$)
  - E is a set of external events ($E = \{e_1, e_2 \ldots e_n\}$)
  - $S : T \to E \cup \{e\}$ is an application associating to each transition an event, where e is the always occurring event
  - $P_r : T \to N^+$ is an application associating a priority with each transition
  - $A_{tc} : T \to L_c(C_{const}, V)$ is an application associating with each transition a condition using both constants and variables
  - $A_{ta} : T \to L_a(C_{const}, V)$ is an application associating with each transition an action as a result of allocation of the values of formal variables
  - A_c is an application associating with each arc (element of F) a formal set of n-tuples of elements of V. $A_c : F \to V$.

3.3 *Example of PTPS PN*

Figure 4 presents an example of PTPS PN. This simple PTPS PN model consists of three *places* (p_1, p_2, p_3) a *transition* (t_1) and a set of 3 *arcs* $(p_1 - t_1, p_2 - t_1, t_1 - p_3)$. Initially, place p_1 *marking* (M_0) is composed of one *token* that contains two contstants $(t, 31)$, place p_2 marking is composed of two tokens each of them is composed of two constants $(5, true$ and $2, false)$, while place p_3 is empty. All of the three arcs weights are set to one ($W_{p_1 - t_1} = W_{p_2 - t_1} = W_{t_1 - p_3} = 1$). For their, arc functions are present as follows: $A_{c_{(p_1 - t1)}} = \{a, b\}$, $A_{c_{(p_2 - t1)}} = \{c, d\}$, $A_{c_{(t_1 - p3)}} = \{a, b, c, d\}$. Transition t_1 contains only one condition ($A_{tc_{t1}} : d = = false$) and one action ($A_{ta_{t1}} : c = 20$).

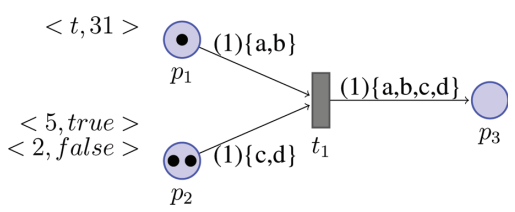

Figure 4. Example of PTPS PN.

Before transition t_1 firing, two tokens need to be reserved, one from place p_1 and one from place p_2 as indicated by the arcs weights ($W_{p_1 - t_1} = W_{p_2 - t_1} = 1$). Then $(p_1 - t_1, p_2 - t_1)$ arcs variables are substituted by reserved tokens constants. This process is called unification. For example, if token $< t, 31 >$ is reserved from the place p_1 and token $2, false$ is reserved from the place $< p_2 >$, unification process will give the following substitution $a = t, b = 31, c = 2, d = false$.

For transition t_1 to be fired, condition $A_{tc_{t1}}$ need to be validated. Therefore among the two present tokens in place p_2, only token $(2, false)$ can be reserved as it is the only token that verifies this condition. After t_1 firing, one token is added to place p_3 as indicated by arc weight ($W_{t_1 - p_3} = 1$). The constants composing this token are calculated from reserved token substituted variables and transitions t_1 action. In this case, t_1 contains one action imposing that c is set to 20. Hence the token added to place p_3 is composed by the following constants: $t, 31, 20, false$.

4 CONVERSION OF FIS MODEL INTO SIMULATION MODEL

In order to convert the FIS model into a simulation model, we implemented a set of conversion algorithms. These algorithms take in input the FIS model and produce a set of two PTPS PNs named function view and resource view. Function view PN is devoted to visualize the state of functions and their evolution over time. For its part, resource view is dedicated to visualize the state of resources and their interactions over time.

4.1 *Functions view conversion*

Algorithm 1 is devoted to obtain the function view from the FIS model. According to this algorithm, every FIS function is converted into a set of two places $(p_{af_i activation}, p_{af_i desactivation})$, two transitions $(t_{af_i activation}, t_{af_i desactivation})$ and four arcs between the created places and transitions. A token is then constitued from the function name (af_i) and the initial state of the function failure modes FM_i. This token is added to the place $p_{af_i activation}$. Finally, for each function failure mode, a set of two transitions are added. The first transition $(t_{fm_i activation})$ includes an action devoted to failure mode activation, while the

Algorithm 1 Function view translation algorithm

for each function fn_i in $Fn, i \in \{1,...,n\}$ **do**
  $P \leftarrow P \cup \{p_{af_i activation}, p_{af_i desactivation}\}$
  $T \leftarrow T \cup \{t_{af_i activation}, t_{af_i desactivation}\}$
  $F_{fn_i} \leftarrow F_{fn_i} \cup \{(p_{af_i desactivation}, t_{af_i activation}),$
    $(t_{af_i activation}, p_{af_i activation}),$
    $(p_{af_i activation}, t_{af_i desactivation}),$
    $(t_{af_i desactivation}, p_{af_i desactivation})\}$
  for each failure mode $fm_j \in FM_i, j \in \{1,...,m\}$ **do**
    $T \leftarrow T \cup \{t_{fm_j activation}, t_{fm_j desactivation}\}$
    $A_{ta}(t_{fm_j activation}) \leftarrow fm_j = true$
    $A_{ta}(t_{fm_j desactivation}) \leftarrow fm_j = false$
  end for
  $W(x,y) = 1 \quad \forall x,y \in F_{fn_i}$
  $A_c(x,y) = V_{fn_i} \quad \forall x,y \in F_{fn_i}$
end for

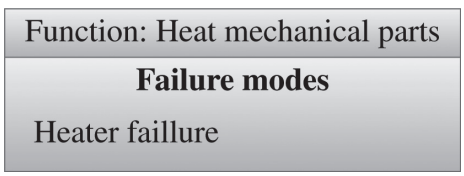

Figure 5. Example of FIS function.

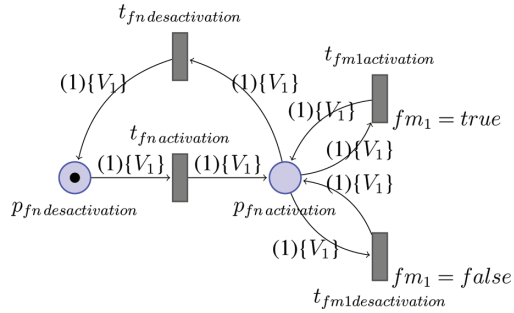

Figure 6. Example of function view conversion.

Algorithm 2 Resource creation and instanciation

for each resource r_i in $R, i \in \{1,...,n\}$ **do**
  $P \leftarrow P \cup \{p_{ari}\}$
  for each resource instance $ri_j \in RI, j \in \{1,...,m\}$ **do**
    for each resource instance state $IS_k \in ri_j, k \in \{1,...,o\}$ **do**
      $to_{ri_j} \leftarrow to_{ri_j} \cup \{IS_k\}$
    end for
    $M_{0_{p_{ari}}} = M_{0_{p_{ari}}} \cup \{to_{ri_j}\}$
  end for
end for

second transition ($t_{fm_i desactivation}$) includes anaction devoted to failure mode desactivation. Finally, an arc functions (composed using another algorithm not presented for space reasons) is associated to all the function view arcs, then all arc weights are initiated to 1. Figure 5 presents an example of FIS function. This function is named *"Heat mechanical parts"*, and is has one faillure mode called *"Heater failure"*. The obtained PTPS PN from the conversion of this function is presented in Figure 6. We can distinguish the places needed for function activation and desactivation ($p_{fndesactivation}, p_{fnactivation}$) the two transitions for function activation and desactivation ($t_{fndesactivation}, t_{fnactivation}$), the two transitions needed for faillure activation and desactivation ($t_{fm_i desactivation}, t_{fm_i activation}$) and the initial marking of place representing the FIS function initial state $p_{fndesactivation}$ is $M_{0pfndesactivation}$ = {< "*Heat mechanical parts", false*>}.

4.2 *Resources view conversion*

To obtain the resource view, we implemented a set of algorithms that are treated in sequence. The first algorithm (see Algorithm 2) is called to convert FIS resources into a set of places and tokens. Then each behavior mode in a FIS function is converted using Algorithm 3. Finally, Algorithm 4 is called to link the obtained resources and behavior modes. For clarity reasons, arc functions, arc weights, transition conditions and transition actions are not presented in the following figures.

Algorithm 2 is the first algorithm to execute. It is devoted to create and instanciate FIS resource. According to this algorithm, each FIS resource is converted into a place named using the resource name attribute (ar_i). Then, each of the resource instance is converted to a token (to_i). This token is composed using the resource instance state variables (Si_j) and then added to the resource place P_{ar_i}.

To illustrate the ressource creation and instanciation, Figure 7 presents an example of FIS resource. According to the example, the presented resource is named *"heater"* and it is parametrized using a binairy variable ("Calibration") and a failure mode ("Heating failure"). This resource has one instance. This instance contains 3 state constantes, one related to the instance identifier (*heater*) and two states constantes representing the initial state of its variable and failure mode (*true*, *false*). The obtained place from this resource conversion is presented in Figure 8. It is a place named using the place of the (p_{heater}). This place containes one token constituted by the resource initial state constants (< "*heater*",*true*, *false* >).

Algorithm 3 Function behavior modes conversion algorithm

for each function behavior mode vm_i in Fn, $i \in \{1,...,n\}$ **do**
  $P \leftarrow P \cup \{p_{avm_i in}, p_{avm_i wat}, p_{avm_i proces}\}$
  $T \leftarrow T \cup \{t_{avm_i in}, t_{avm_i out}, t_{avm_i iowat}, t_{avm_i watio}, t_{watpro}, t_{tprowat}\}$
  $F_{vm_i} \leftarrow F_{vm_i} \cup \{(t_{avm_i in}, p_{avm_i inout}), (p_{avm_i inout}, t_{avm_i out}) (p_{avm_i in}, t_{avm_i iowat}), (t_{avm_i watgio}, p_{avm_i inout}), (t_{avm_i iowat}, p_{avm_i wat}), (p_{avm_i wat}, t_{avm_i watio}), (p_{avm_i wat}, t_{avm_i watpro}), (t_{avm_i prowat}, p_{avm_i wat}), (t_{avm_i watpro}, p_{avm_i proces}), (p_{avm_i proces}, t_{avm_i prowat})\}$
  for each input resources $IR_j \in vm_i$, $j \in \{1,...,m\}$ **do**
    for each resource $r_k \in R, k \in \{1,...,o\}$ **do**
      if $(ar_k == irn_j)$ **then**
        for each failure mode $fm_l \in r_k$, $l \in \{1,...,u\}$ **do**
          $T \leftarrow T \cup \{t_{fm_l}\}$
          $A_{ta}(t_{fm_l}) \leftarrow fm_l = true$
          $A_{ta}(t_{fm_l}) \leftarrow fm_l = true$
          $F_{vm_i} \leftarrow F_{vm_i} \cup \{(t_{fm_l}, p_{avm_i proces}), (p_{avm_i proces}, t_{fm_l})\}$
        end for
        for each propagation relation $rpr_l \in r_k$, $l \in \{1,...,v\}$ **do**
          $T \leftarrow T \cup \{t_{synch_{fm_k}}\}$
          $A_{tc}(t_{synch_{fm_k}}) \leftarrow fm_k == true$
          $F_{vm_i} \leftarrow F_{vm_i} \cup \{(t_{synch_{fm_k}}, p_{avm_i proces}), (p_{avm_i proces}, t_{synch_{fm_k}})\}$
        end for
      end if
    end for
  end for
  $W(x,y) = 1 \quad \forall x,y \in F_{vm_i}$
  $A_c(x,y) = V_{vm_i} \quad \forall x,y \in F_{vm_i}$
end for

After ressource creation and instanciation, the following step is the conversion of FIS function behavior modes. Algorithm 3 is used to convert function behavior mode. According to this algorithm, each behavior mode is converted into a set of places ($(p_{avm_i in}, p_{avm_i wat}, p_{avm_i proces})$), a set of transitions ($t_{avm_i in}$,$t_{avm_i out}$,$t_{avm_i iowat}$,$t_{avm_i watio}$,t_{watpro},$t_{tprowat}$) and a set of arcs between them. In a second stage, each of the input resources failure modes is converted into a transition (t_{tfmi}) which includes an action related to failure activation ($fm_i = true$).

Then each of the propagation relations related to the treated failure is converted to a transition ($t_{synch_{fmi}}$), this transition contains a condition and an action. The condition is used to garantee that the firing of the transition can be performed only if the failure mode is active ($fm_i == true$) while the action presents the propagation relation ($fm_{i_{effect}} = true$).

To illustrate the conversion of FIS function behavior modes, Figure 9 presents an example of FIS beahvior modes. According to this example, we can see that the function *heat mechanical parts* (presented previously in Fig. 5) has 2 behavior modes. The first behavior mode is the *OK mode*.

Algorithm 4 Resources and behavior modes connection algorithm

for each function behavior mode vm_i in Fn, $i \in \{1,...,n\}$ **do**
  for each input resource $IR_j \in vm_i$,$j \in 1,...,m$ **do**
    for each resource $r_k \in R$, $k \in 1,...,o$ **do**
      if $(ar_k == irn_j)$ **then**
        $F \leftarrow F \cup \{(p_{ar_k}, t_{input_{vm_i}})\}$
        $W(p_{ar_k}, t_{input_{vm_i}}) = irc_j$
        $A_{c_{(p_{ar_k}, t_{input_{vm_i}})}} = V_{r_k}$
      end if
    end for
  end for
  for each output resource $OR_j \in vm_i \quad j \in \{1,...,p\}$ **do**
    for each resource $r_k \in Rk \in \{1,...,o\}$ **do**
      if $(ar_k == orn_j)$ **then**
        $F \leftarrow F \cup \{t_{output_{vm_i}}, p_{ar_k}\}$
        $W(t_{output_{vm_i}}, p_{ar_k}) = orc_j$
        $A_{c(t_{output_{vm_i}}, p_{ar_k})} = V_{r_k}$
      end if
    end for
  end for
end for

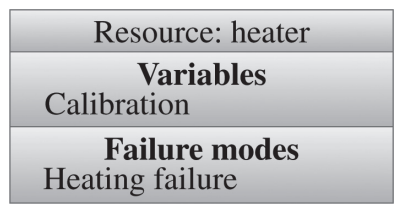

Figure 7. Example of FIS resource.

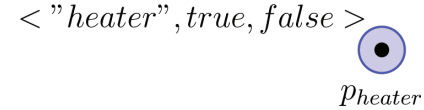

Figure 8. Result of a FIS resource conversion.

To illustrate the conversion of FIS function behavior modes, Figure 9 presents an example of FIS beahvior modes. According to this example, we can see that the function *heat mechanical parts* (presented previously in Fig. 5) has 2 behavior modes. The first behavior mode is the *OK mode*.

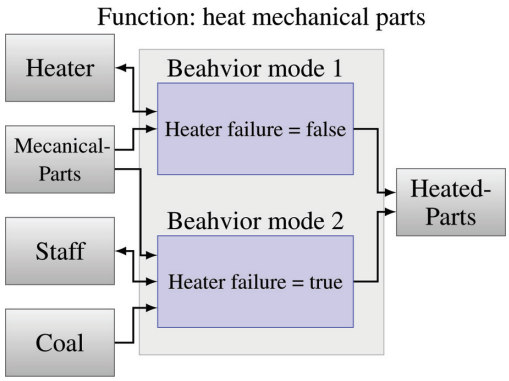

Figure 9. Example of FIS behavior modes.

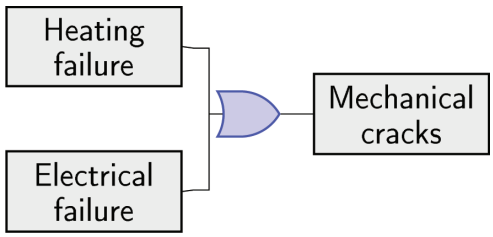

Figure 10. Extract of FIS example fault tree.

It is the mode activated when the failure there is non failure activated on the function (Heater failure = false). In this mode, to perform heating, we need to used *heater* and *mecanical parts* as input and we get as output *heated parts* and the used *heater* (in this case *heater* is a support resource). The second mode is actioned when failure *Heater failure* is activated (Heater failure = true). As we can not use heater due to the failure, to perform heating, we need to used the resources *Staff*, *Coal* and *mecanical parts* as input and in the output we get *heated parts* and *Staff*. Figure 10 presents an extract of the fault tree. According to this fault tree, we can conclude that the failure mode *heating failure* associated to the resource *heater* causes the faillure mode *Mecanicalcracks* on the resource *heatedparts*.

The obtained PTPS PN from the conversion of the *OK mode* is presented in Figure 11. We can see the set of places and transitions related to this *OK mode*. It's important also to highlight that transition $t_{synch_{fm_i}}$ containes a condition $A_{tc}(t_{synch_{fm_i}}) = \{fm_{heatingfailure} == true\}$ and an action $A_{tc}(t_{synch_{fm_i}}) = \{fm_{Mecanicalcracks} = true\}$ which are the conversion of the propagation presented in Figure 10.

After the conversion of the FIS behavior modes, we can see that there in no connexion between the instanciated resources and the converted behavior modes. To complete the conversion process, Algorithm 4 is called to link the created resources and behavior modes.

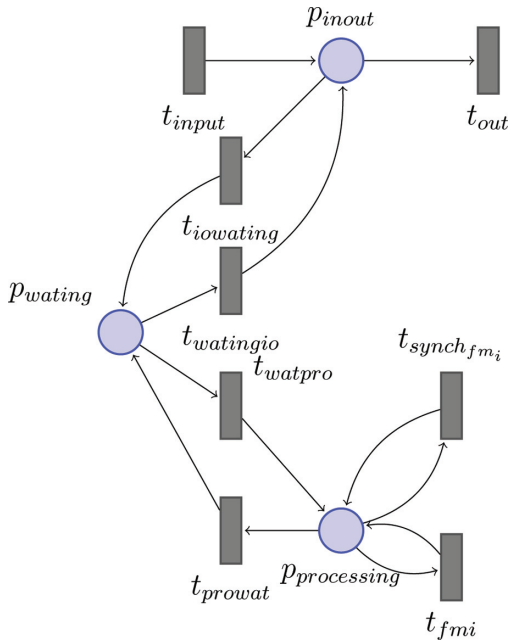

Figure 11. Example of behavior mode conversion.

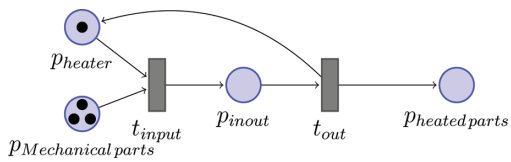

Figure 12. Example of resource and behavior mode connection.

To link FIS behavior modes and instaciated resources, algorithm 12 each function behavior mode. If this behavior mode has an input resource then an arc is created between this resource place and the transition $t_{input_{vmi}}$ of the behavior mode. The created arc weight initiated to the number of required resources and its arc functions is created based on the resource variables and failure modes. If this behavior mode has an output resource then an arc is created between the output transition $t_{output_{vmi}}$ and the resource place. The created arc weight initiated to the number of produced resources and its arc functions is created based on the resource variables and failure modes.

Figure 12 presents the result obtained after applying the Algorithm 4 on the example presented in Figure 9. As *heater* is support resource

(input and output resource in the same time), an arc is created between the place p_{heater} and the mode input transition $t_{input_{vm_i}}$ and an other arc is created between the behavior mode output transition $t_{output_{vm_i}}$ and the heater place p_{heater}. *Mechanicalparts* is an input resource for the mode, so an other arc is created between the place $p_{Mechanicalparts}$ and the transition $t_{input_{vm_i}}$. Similarly an other arc is added between the transiton $t_{output_{vm_i}}$ and the heated parts place $p_{heatedparts}$.

5 SIMULATION RESULTS

Using the two obtained views of the PTPS PN is possible to perform simulation. Simulation alows to observe the dynamic behavior of the modeled system and to generated performance indicators. Performance indicators are quantitave indicators that illustrates the performances of the system in it is different beahvior modes. Among the performance indicators generated by simualtion we can find, the resource rates of use which reflects which of the support resources are over or under used during processing, the mean time spent by resource in each function, the amount of time spent by the function in each beahavior mode and the resources Mean Time Between Failures (MTBF) and Mean Time To Repair (MTTR).

6 CONCLUSIONS

In this paper, we presented a method to convert the FIS risk based model into a simulation model based on PTPS PN. We started our work by presenting FIS model through its differents views (structurofunctional, dysfunctional and evolution view). Then to prepare its conversion, we presented a formalization of the FIS model. Therafter, we defined a new class of PN called PTPS used as simulation model. Finally, we exposed as set of conversion algorithms used to convert the FIS model to a set of two PTPS PN named functions and resource views.

Based on FIS risk model that can be obtained using XRisk[1], our work has shown that we can convert this risk model into a simulation model. This simulation model is capable of representing the dynamic behavior of a system in a risk situation including flow of materials, failure occurrence, failure propagation...

This simulation model is designed as a part of a simulation tool called SIMRISK. SIMRISK is a production systems degaraded modes simulation tool used to assess production systems performances in different situations especially when the system is in a riskcircumstances.

Using this tools, it is possible to simulate and visualize the behavior of the system under different circumstances especially in risk situations. It allows the generations of quantitative indicators that reflect the system performances. Using these indicators, managers can improve reliability of their system by appropriate safety barriers targeting the failures that cause the most significant performance degradation.

ABSTRACT: This paper presents an approach to assess the effects of Common Cause Failures (CCF) on dependability of digital systems. Independent failures of system components and partial or lethal shocks are considered in a global CCF model, the Atwood model. The Coloured Petri Nets (CPN) are used to modelize the digital system and the common cause failures. Based on the CPN, the parameters of Atwood model are estimated analytically and by Monte-Carlo simulation. Thereafter, the Atwood model of CCF is modified in order to represent the dominant failures propagation on some system components in the case of partial shocks. The assessment of system dependability, in the presence of CCF failures, becomes possible. This approach is applied to a representative instrumentation and control system of a nuclear power plant. The system is large with a high level of redundancy.

1 INTRODUCTION

Digital Instrumentation and Control systems (I&C) systems have a major role in the control and protection of nuclear power plants. These systems are characterized by a large size, a high level of redundancy and a complex logic of vote. Although digital systems and their components are more reliable than the analog systems they replace, some characteristics raise specific issues on the modelling and assessment of Common Cause Failures (CCF). A CCF can occur in operational or on demand modes and affect groups of identical or similar redundant components having the same function and operating under comparable conditions.

The β-factor model is the most widely used model for taking into account CCF within all types of systems, like nuclear power plants (US-NRC 1987) and, more generally, in the field of power system (Bricman-Rejc et al. 2013). It involves *thefailure of whole set of components* when a common cause event occurs. This model is used when the system is composed of only a few components. However when the system is composed of dozens of identical or similar components, the assumption of failure of whole set of components, when a CCF occurs, is very conservative.

The concepts of partial and lethal shocks are very well adapted to represent the potential effects of stress factors on electronic hardware. In the next section we introduce the Atwood model of CCF that takes into account independent failures of components and CCF failures due to shocks that affect all or only some components. For dependability assessment, the CCF model must be integrated within a system model. Also, the system model must integrate the dynamic behaviour of the digital I&C systems. The Markov chains or Petri nets are such types of models and the β-factor model has been integrated in Markov chains (Lilleheier 2008) and in the classical Petri Nets (Signoret et al. 2013). The main drawback of these

models is the combinatorial explosion of their size when the modelled system is large. To overcome this drawback, we propose to use the Coloured Petri Nets (CPN) for I&C systems modelling. The section three of this paper develops a CPN model for an I&C system and, also, for the CCF Atwood model. In the same section, firstly, we propose two approaches for parameters estimation of Atwood model and, secondly, we modify this model to represent asymmetry in CCF propagation oriented on some types of components. If for I&C modelled system only the hardware architecture is considered, the oriented propagation of CCF on this architecture takes into account the software and human aspects of functional safety analysis. Section four presents the probabilistic assessment of dependability indicators (PFD, MTTF) or of the impact of the oriented CCF. Finally, some conclusions and future outlook are presented.

2 MODELLING OF COMMON CAUSES FAILURES (CCF)

2.1 *The Atwood model*

The model introduced by Atwood (1980) considers that the system components are subject to two types of failures: independent failures and shock failures. Two kinds of shock failures are defined: lethal shocks and partial (or non-lethal) shocks. In a large redundant systems with N components, a shock is assumed to be non-lethal when it affects k components among N with $1 \leq k \leq N$. A shock is lethal when it affects *all* components. In the case of a non-lethal shock, only the failure of some components is considered. Each component has then a *conditional probability p* of failure. Individual failures, non-lethal and lethal shocks are assumed to follow independent processes. The occurrence frequencies of shocks (denoted μ for non-lethal shocks and ω for lethal shocks) are assumed to be constant.

The failure rate of a specific component in a group of N elements, due to an independent failure or to a non-lethal shock is:

$$\lambda_1^N = \lambda_i + \mu \cdot p \cdot (1-p)^{N-1} \tag{1}$$

The failure rate of a group of k components from N with $1 \leq k \leq N$ due to a non-lethal shock is:

$$\lambda_k^{(N)} = \mu \cdot p^k \cdot (1-p)^{N-k} \tag{2}$$

The failure rate of N components due to a non-lethal and lethal shock is:

$$\lambda_N^N = \mu \cdot p^N + \omega \tag{3}$$

For a specific component in a group of N components, the total failure rate is given by:

$$\lambda_{TOT} = \lambda_{IND} + \omega + \mu \cdot \sum_{k=1}^{N} C_{N-1}^{k-1} p^k \cdot (1-p)^{N-k} \tag{4}$$

The Atwood model is considered representative for the phenomena leading to multiple failures in the large digital I&C systems. It allows to represent CCF affecting only a part of the all components of the system. However, it introduces three parameters to estimate p, μ and ω. The results will be sensitive, of course, to the values used, usually given by expert opinion or by using default values. The default values usually used for these parameters are the following:

- $\alpha = \mu / \lambda_{TOT} = 0.405$: the rate of non-lethal shocks.
- $p = 0.2$ *ou* 0.33 *ou* 0.5: conditional probability of component failure in a non-lethal shock.
- $\beta_{letal} = \omega / \lambda_{TOT} = 5 \cdot 10^{-3}$: the rate of lethal shocks.

Later, in this work, we propose to determine the values of these parameters by two approaches: an analytical one, or a second approach based on results of Monte-Carlo simulations.

2.2 *The Coloured Petri Nets (CPN) model*

In order to asses the impact of CCF in the dependability study of digital I&C systems, it is necessary to have a model of this studied system that is able to take into account the system dynamics. A widely used model in the dependability studies of dynamic systems is represented by the Petri nets (Signoret et al. 2013). Since I&C systems are complex and large, we choose to use the coloured Petri nets (CPN) type. CPN (Jensen & Kristensen 2009, Jensen 1997) is a discrete-event modelling language combining the capabilities of Petri nets with the capabilities of a high-level programming language. The main difference between a classical Petri Net and a CPN is that the CPN tokens can have different *colours* representing data types (*e.g.* Boolean, integer or more complex data structure). The formal definition of CPN is as follows.

A Coloured Petri Net is a 9-uplet $CPN = (P, T, A, \Sigma, V, C, G, E, I)$, where:

1. P is a finite set of **places**.
2. T is a finite set of **transitions**, $P \cap T = \varnothing$.
3. $A \subseteq P \times T \cup T \times P$ is a set of directed **arcs**.
4. Σ is a finite set of non-empty **colour sets**.
5. V is a finite set of **typed variables** such that $Type[v] \in \Sigma$ for all variables $v \in V$.
6. $C : P \rightarrow \Sigma$ is a **colour set function** that assigns a colour set to each place.
7. $G : T \rightarrow EXPR_V$ is a **guard function** that assigns a guard condition to each transition t such that

$Type[G(t)]$ = Bool, bool standing for Boolean data type.

8. $E : A \rightarrow EXPR_V$ is an **arc expression function** that assigns an arc expression to each arc a such that $Type[E(a)] = Type[C(p)]$, where p is the place connected to the arc a.
9. $I : P \rightarrow EXPR_\varnothing$ is an **initialisation function** that assigns an initialisation expression to each place p such that $Type[I(p)] = Type[C(p)]$.

Individual CPN models can be hierarchically related to each other in a formal way, *i.e.* with a well-defined semantics. CPN model hierarchy is realized through *substitution transitions*. The idea is to associate a transition to a more complex CPN (a module), which gives a more precise and detailed description of the activity represented by the substitution transition (represented by a double rectangle, *e.g.* in Fig. 2). The places connected to a substitution transition transmit a given marking from a high level (level of substitution transition) to a low level (level of module) and vice versa. CPN concept of hierarchy allows us to propose a *modular modelling* approach for a complex systems, based on generic modules that can be instantiated as often as needed.

Additionally, the probabilistic dependability assessment requires the time evolution of the system. For this, the CPN must take into account the *time* aspect. In a timed CPN (Jensen & Kristensen 2009, Jensen 1997), the time is given by a global clock. In addition to their colour, the tokens contain a time value, also called a *time stamp*. When a transition is enabled, it is fired and changes the time stamps of tokens which are deposited in its output places. In these places, the tokens remain *frozen* and can not be used to enable other transitions until the current model time (given by the global clock) is smaller than their time stamps. As soon as the time stamp of the tokens is greater than or equal to the current time model, these tokens can enable other transitions which are instantly fired. In other words, the time stamp describes the *earliest* model time from which a token can be used.

The following drawbacks can be cited: the low readability (which can be put into perspective by using hierarchical CPN) and the difficulty in verifying a Petri net model. This last drawback can be offset by using a verification of CPN properties. This properties verification is supported by the *state space method*. The basic idea underlying the state space method is to compute all reachable states and state changes of the CPN model and to represent them as a directed graph, where nodes represent states and arcs represent occurring events. From a constructed state space, it is possible to answer a large set of questions concerning the behaviour of the system, such as absence of deadlocks, a possibility to be able to reach a given state. We have used this formal verification of a CPN to study and validate some specific safety properties of an I&C systems (Pinna et al. 2013), but a Monte-Carlo simulation can be also realized without this type of verification.

In this paper, we propose to integrate the Atwood model into a CPN model of an I&C system. The obtained model allows the assessment of the CCF impact on the system dependability. In order to realize this assessment, in the next section, we introduce a case study coming from a nuclear power plant.

3 CASE-STUDY PRESENTATION AND ITS MODELLING

The studied system is a digital protection system. It is a part of the defence in depth of a nuclear power plant.

3.1 *System architecture*

This protection I&C system contains four divisions, which are strictly identical, see Figure 1. These divisions are physically separated. Each division is composed of five "Acquisition & Processing Units" (APU). The APU 0, 1 and 2 represent the subsystem A (SSA). The APU 3 and 4 represent the subsystem B (SSB). The gathering of APU into subsystems takes into account the allocation of control functions of the I&C system. For the same control function, there is one implementation in an APU of SSA and one implementation in an APU of SSB with different inputs and treatment and their outputs must be identical in the normal operating mode.

Different electronic boards *C1* et *C2* are included in each APU. Each APU contains one *C1* board. The APU 0 and 1 contain four *C2* boards, and the APU 3, 4 and 5 contain three *C2* boards. These electronic boards are used for reception, treatment and emission of signals.

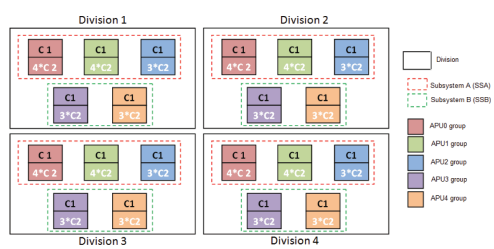

Figure 1. Architecture of the case study I&C system for a nuclear power plant.

A second type of partition is defined: the *groups of APU* (GAPU). A group of APU contains all of the APU i (i [0,4]) of the four divisions.

3.2 *Modelling assumptions*

3.2.1 *Assumptions for the electronic boards modelling*

A constant failure rate is considered for boards.

The *C2* boards of an APU are considered as a series system.

The board failures can be detected by a set of self-tests. When a failure is detected by a self-test (SA), the detection time is considered null. When a failure is not detected by a self-test (NSA), then it is detected offline during a periodical-test. For a given division, these periodical-tests take place at each 18 months. So every quarter of this period, a division is tested during the periodic tests. After the periodic tests, the failed boards are repaired.

According to the supplier of electronic boards, their coverage rate of self-tests (t_c) is 100%, but this value seems to be ambitious. We add to the model the non-detected failures by self-test (NSA failures) in order to take into account the errors due to operation (different parameters or installation of boards from the nominal conditions specified by the provider). Thus the coverage rate is reduced at 85%. The global failure rate of the boards remains identical ($\lambda_{IND} = \lambda_{SA} + \lambda_{NSA}$). The rates of detected failures (λ_{SA}) and non-detected failures(λ_{NSA}) are adjusted by the following equations: $\lambda_{SA} = t_c \cdot \lambda_{IND}$ and $\lambda_{NSA} = (1 - t_c) \cdot \lambda_{IND}$.

3.2.2 *Assumptions for global system modelling*

The hazardous event is represented by the failure of the protection I&C system.

The occurrence of this hazardous event is based on the voting logic of the APU:

- An APU fails when a card *C*1 or *C*2 is failed.
- A group of APU (GAPU) fails when 3 out of 4 APU is failed (3oo4).
- A subsystem (SSA or SSB) fails when a GAPU is failed.
- The I&C system fails when a subsystem is failed (1oo2) *or* when two subsystems are failed (2oo2).

We assume that the mission time of the protection I&C system is ten years. Indeed, this system is retrofitted only during the decennial maintenance operations of the nuclear plant. System unavailability can occur during the ten years. The system changes from unavailable to available state without being as good as new as it is not fully retrofitted on this period of ten years. Some electronic boards may be still failed when the system becomes available.

3.3 *CPN modelling*

We propose to use a modular approach for system modelling. Thus, the CPN model (shown in Fig. 2) is composed by the following modules:

- CCF generating (blue box)
- System representation (red box)
- State system description (green box).

3.3.1 *CCF generating using Atwood model*

Non-lethal CCF are modelled by the CPN sub-net shown in Figure 3. It corresponds to the substitution transition *DCC_non_letale* of the Figure 2. The place *Nb-carte* contains the number of electronic boards *N* in the system. The firing of transition *Save* maintains the number of electronic boards *N* of the system in the place *SNb_carte* and set *N* tokens in the place nb_carteu. The transition *proba* is fired N times. Thefunction *defdcc*() draws a random value using an uniform distribution law of probabilities in the interval [0, 1]. If the

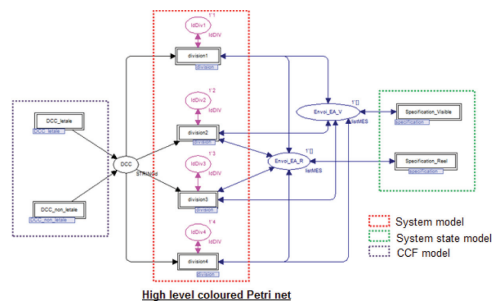

Figure 2. High level coloured Petri net of the I&C system.

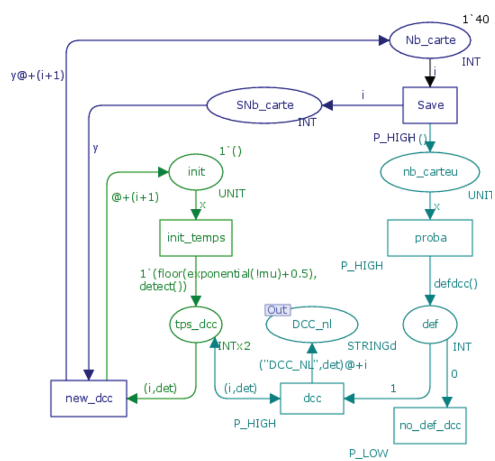

Figure 3. CPN sub-net modelling the *non-lethal CCF*.

drawn value is lower than conditional probability p the considered board will be shock sensitive. The returned value will be 1, otherwise 0.

The firing of *init_temps* transition allows to determine the occurrence time of the non-lethal shock using the function *floor*(*exponential*(*!mu*)+0.5) and, in the same time, to specify if it is detected or not by a self-test. This is done using the function *detect*(). This function draws a random value using an uniform distribution law of probabilities in the interval [0, 1]. If the value is lower than coverage rate of self-tests (t_c), the non-lethal shock is detected. In this case the function return the value *1*, otherwise *0*. The firing of the transition *dcc* assigns the occurrence time of CCF and the variable of failure detection at each token of the system that is shock sensitive. The transition *no_def_dcc* allows to remove the tokens representing boards that are not shock sensitive. The transition *new_dcc* allows to generate the next occurrence time of the non-lethal shock and to redefine the number of boards, which are shock sensitive.

Lethal CCF are modelled by the CPN sub-net shown in Figure 4. It corresponds to the substitution transition *DCC_letale* of the Figure 2. The firing of the transition *gene_dcc_l* allows to determine the occurrence time of the lethal shock using the function *floor*(*exponential*(*!omega*)+0.5). A lethal CCF affects all the components (electronic boards) of the system and is always detected online. Thus, there are issued N temporized tokens with a color ph('DCC-NL',1) (1 for detection). The next occurrence time for a new lethal CCF is calculated since the previous is realized.

The Atwood model introduces three parameters to estimate: p, μ and ω. Two approaches, analytic or by simulation, can be used for doing their estimation.

Analytical approach for estimation of CCF model parameters. From the expressions of α, β_{letal} and λ_{TOT}, we obtain the following equations system:

$$\left(1-\alpha\sum_{k=1}^{N}p^k(1-p)^{N-k}\right)\mu+\alpha\omega=\alpha\lambda_{IND} \tag{5}$$

$$\left(-\beta\sum_{k=1}^{N}p^k(1-p)^{N-k}\right)\mu+(1-\beta)\omega=\beta\lambda_{IND} \tag{6}$$

The value of conditional probability p is considered known (e.g. at classical default values 0.2, 0.33 or 0.5). The independent failure rate for an electronic board is $\lambda_{IND}=2.35\,10^{-6}h^{-1}$. The equations (5) and (6) give the values of occurrence frequencies of non-lethal shocks μ and of lethal shocks ω. The obtained results are presented in Table 1.

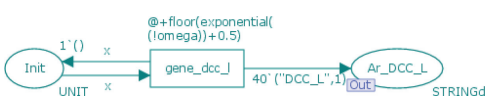

Figure 4. CPN sub-net modelling the *lethal CCF*.

Monte-Carlo simulation approach for estimation of CCF model parameters. We introduce the ratio between the occurrence rate of independent failures λ_{IND} and the total failure rate λ_{TOT} of a component (an electronic board):

$$\gamma=\frac{\lambda_{IND}}{\lambda_{TOT}}=1-\alpha\cdot\sum_{k=1}^{N}C_{N-1}^{k-1}p^k\cdot(1-p)^{N-k}-\beta_{letal} \tag{7}$$

$$\gamma=1-\alpha\cdot p-\beta_{letal} \tag{8}$$

We introduce also E_i that represents the number of independent failure events realized in 10 years of simulations. This number is obtained by simulating only the independent failures in Petri net model and their occurrences are counted. It allows to obtain from the equation 9, the average independent failure rate λ_{IND} for a board in the system. The different rates can be estimated from the following equations:

$$\lambda_{IND}=\frac{E_i}{10ans*N} \tag{9}$$

$$\mu=\frac{\alpha\cdot\lambda_{IND}}{\gamma} \tag{10}$$

$$\omega=\frac{\beta_{letal}\cdot\lambda_{IND}}{\gamma} \tag{11}$$

The expected value of E_i is equal to 8.28 and the value obtained for independent failures rate is: $\lambda_{IND}=2{,}36E^{-6}h^{-1}$. The results obtained by applying this approach are presented in Table 2.

The occurrence frequencies μ and ω for non-lethal and lethal shocks obtained by applying these approaches (analytical and simulation approaches) are almost identical. This result allows, firstly, to validate the proposed CPN modelling approach for the Atwood shock model. Secondly, the Monte-Carlo simulation approach could be used to revisit

Table 1. The values of occurrence frequencies μ and ω for non-lethal and lethal shocks as a function of p using analytical approach.

p	μ in h^{-1}	ω in h^{-1}
0.2	$9.52\,10^{-7}$	$1.18\,10^{-8}$
0.33	$9.52\,10^{-7}$	$1.18\,10^{-8}$
0.5	$9.52\,10^{-7}$	$1.18\,10^{-8}$

Table 2. The values of occurrence frequencies μ and ω for non-lethal and lethal shocks as a function of p using Monte-Carlo simulation approach.

p	γ	λ_{TOT}	μ	ω
0.2	0.995	$2.37\ 10^{-6}$	$9.62\ 10^{-7}$	$1.18\ 10^{-8}$
0.33	0.995	$2.37\ 10^{-6}$	$9.62\ 10^{-7}$	$1.18\ 10^{-8}$
0.5	0.995	$2.37\ 10^{-6}$	$9.62\ 10^{-7}$	$1.18\ 10^{-8}$

some assumptions supporting the Binomial Failure Rate model underlying the Atwood shock model, especially in the case of digital I&C systems including software.

Introduction of asymmetry in CCF propagation. For a realistic modelling of Common Causes Failures (CCF) and of their impact on the systems dependability, it is interesting to assume that some non-lethal shocks predominantly affect some k components among the all N components of the system, with $1 \leq k \leq N$ (e.g. only some types of electronic boards belonging to the I&C systems). We propose to modify the generation of non-lethal CCF for simulating the asymmetries in their propagation, in other words considering "oriented" CCF.

In a system with N components, a non-lethal shock affects the boards with a conditional probability p. The expected number of affected components is $N * p$. The set of N components can be divided in two sub-sets A (SSA) and B (SSB), containing respectively a et b components, such as $a + b = N$. Let be x (respectively y) the probability that a component of SSA (respectively SSB) is affected by a non-lethal shock. From reasoning on mathematical expectation, we have:

$$ax + by = Np \tag{12}$$

To determine x and y we choose how a CCF will affect the SSA (p_1) and SSB (p_2), such as $p_1 + p_2 = 1$. Thus, we obtain:

$$x = \frac{N \cdot p \cdot p_1}{a} \tag{13}$$

$$y = \frac{N \cdot p \cdot p_2}{b} \tag{14}$$

The solutions of these equations, x and y, are the probabilities of non-lethal shock for the CPN tokens that represent respectively the SSA and SSB components.

3.3.2 *System modelling by CPN*

The hierarchical and modular aspects of Coloured Petri nets are exploited to develop the CPN model of I&C system. Thus, each of its divisions is modelled by means of a substitution transition at the high level of the system, in the Figure 2. A division includes five APU, each of them includes the correct number of electronic boards C1 and C2. The CCF are transmitted to the APU and to the boards by means of CPN places (socket places). The state of an APU is determined by the state of its boards (available or unavailable). Once the state of a board changes, the new state of APU is sent to the specification that determines the state of the whole I&C system.

An electronic board represented in the Figure 5 has three possible tangibles states: operational ("Marche" place), failed and non-detected ("detection" place) and in reparation ("reparation" place). When the board is operational, it can change its state if one of the following four events occurs:

- independent failure detected online by a self-test (modelled by the purple Petri sub-net on the right side of the model)
- independent failure detected offline in periodical-tests (modelled by the purple sub-Petri net on the left side of the model)
- non-lethal CCF detected online and lethal CCF (modelled by the tokens received by "AR_DCC" place from the CCF models of the Figures 3 and 4)
- non-lethal CCF detected offline in periodical-tests (modelled also by the tokens received by "AR_DCC" place from the CCF model of the Fig. 3).

If the failures are detected during the periodic tests, the "rep" transition is fired and the board changes its state to the reparation state. If the failures are detected online, the board changes its state immediately from the operational to the repair state. The repair time is calculated using the function *floor*(*exponential*(1/!MTTR) + 1.0). As soon as the board is repaired, its state changes immediately to the operational state. The next occurrence times of the independent failures detected onlineand offline are also calculated.

This CPN model of electronic boards are generic. For all boards, only the numerical values of parameters (failure and repair rates) are different.

3.3.3 *System state modelling by CPN*

Using the information about the state (available/unavailable) of the APU i ($i \in [0,4]$ of the division j ($j \in [1,4]$)), it is possible to determine the state of the I&C system during the Monte-Carlo simulation using the CPN of Figure 6. The system state is represented by a token whose colour is composed of five booleans, each of them representing the state of one APU. The different configurations on the transitions' guards allow to define the conditions of availability/unavailability of the system.

The entire CPN model obtained for the I&C system has 685 transitions and 504 places. Even if the

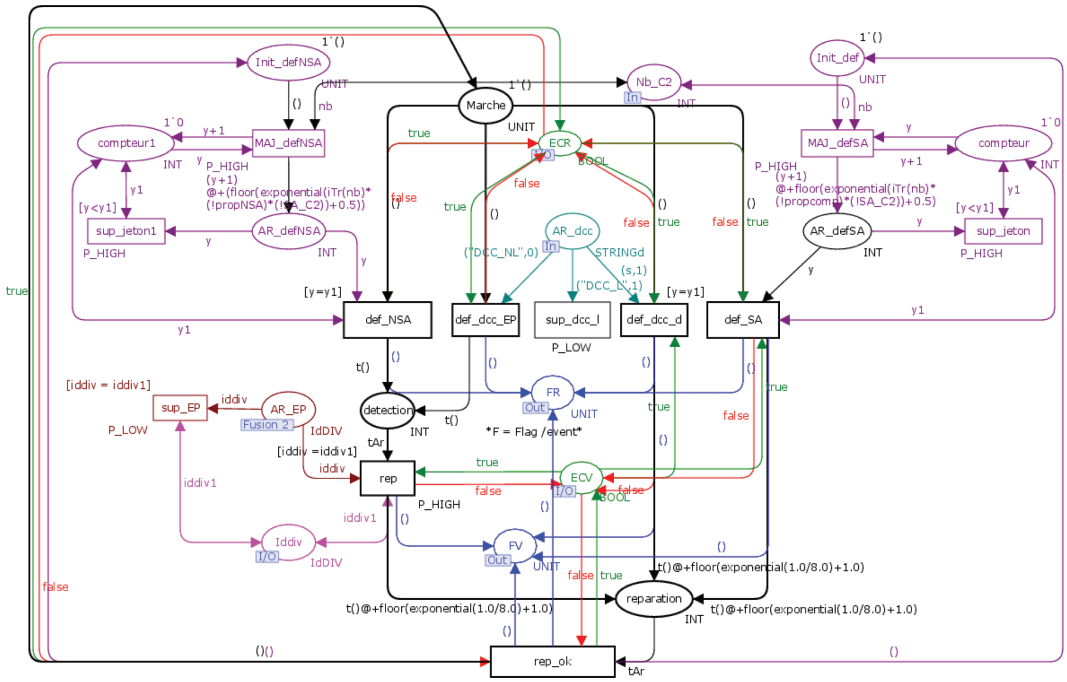

Figure 5. CPN sub-net of an *electronic board*.

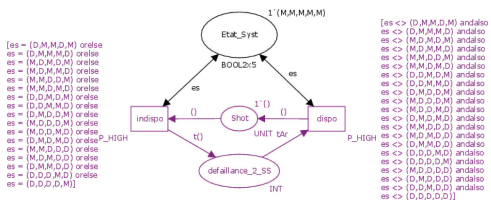

Figure 6. CPN sub-net to determine the state of the whole I&C system (available or unavailable).

model size is large enough, the use of hierarchy and colours concepts have resulted in a modular and readable model obtained through the instantiation of generic templates. We can note, that an equivalent classical Petri net model for the same I&C system should have several thousands places and transitions. The obtained CPN model allows the probabilistic dependability assessment of the system.

4 PROBABILISTIC DEPENDABILITY ASSESSMENT

4.1 *Probability of failure on demand*

Since the I&C system is a protection system (its mission is to protect the nuclear power plant), we are interested to asses only the *Probability of Failure on Demand* (PFD). This is in accordance with the IEC-61508 (2010) standard and its declination IEC-61513 (2011) that address the functional safety of digital systems. We define two kinds of PFD:

- the *real* PFD that represents the I&C system unavailability starting with the moment where the electronic boards are not anymore in their operational state;
- the *visible* PFD that represents the system unavailability only starting with the moment where the boards failure is detected. The time between the occurrence of non-detected failures and their detection by a periodical-test is not considered.

The definition of the two kinds of PFD allows to estimate the difference between the real state of the system and the state observed by plant operators during operation.

The PFD is estimate using Monte-Carlo simulation by the following equation:

$$\mathrm{PFD} = \frac{\text{System unavailability time}}{\text{Mission time}} \tag{15}$$

The results presented in the Table 3 are obtained after 10,000 histories during 10 years. The 95%

Table 3. Real and visible PFD of the protection I&C system for different values of p.

Indicators	p	Average
Real PFD	0.2	$2.5\ 10^{-5}$
Visible PFD	0.2	$<10^{-6}$
Real PFD	0.33	$2.73\ 10^{-4}$
Visible PFD	0.33	$1.0\ 10^{-6}$
Real PFD	0.5	$5.4\ 10^{-4}$
Visible PFD	0.5	$4.0\ 10^{-6}$

Table 4. Combinations of failed boards leading to the system downtime depending on p_1 and p_2.

CCF orientation			
p_1 SSA	0.1	0.2	0.3
p_2 SSB	0.9	0.8	0.7
Only CCF	9404	9723	9787
Indep. SA failures	3	0	1
Indep. NA failures	21	9	9
Indep. SA and NSA	77	46	42
CCF & indep. SA failures	8	6	1
CCF & indep. NSA failures	487	216	160
MTTFF (in h)	49586	28921	22056

confidence interval for all of the results presented in Table 3 is also estimated and its value is $<10^{-6}$.

According to IEC-61513 (2011) "there is not an equivalent scheme to the reliability/risk reduction SIL levels proposed in IEC 61508 in common use in the nuclear sector". Consequently, we do not associate a SIL level for the system under study.

If the conditional probability of failure of one component in a non-lethal shock p increases, there will be more components affected by a shock and the PFD also increases. The difference between the real PFD and the visible PFD is about 10 to 100.

4.2 *Influence of the oriented non-lethal CCF*

To asses the impact of asymmetric propagation of non-lethal CCF, we consider the orientation of CCF on the two sub-systems SSA and SSB, using the approach presented in section 3.3.1.

The conditional probability of failure of one component in a non-lethal shock is $p = 0.2$. The frequency of non-lethal shocks is arbitrary fixed at one shock per year, i.e. $\mu = 1.1410^{-1}h^{-1}$. The lethal shocks are not represented. 10,000 trajectories during 10 years are also realized and the occurrence of system failure ends the trajectory simulation. Table 4 shows the results. The sum of failures' combinations (columns) is equal with the total number of histories (10,000) for a fixed CCF orientation.

We can observe that the more a sub-system is preferred (according to p_1 and p_2), the more the MTTFF increases. The logic vote explains this phenomenon. We observe also that independent failures combinations without CCF rarely leads to system failure, due to the high level of redundancy. Independent failures detected offline lead more easily to system failure than the ones detected online. This aspect can be improved by increasing the frequency of periodic tests or the coverage rate of self-tests.

5 CONCLUSIONS

The coloured Petri nets allow to represent the digital I&C systems and to assess the dependability indicators considering CCF. The shock Atwood model has been transposed in Petri net. It allows to take in account the independent failures, the lethal CCF,but also the non-lethal CCF. An extension of this model was proposed to represent the asymmetric propagation of non-lethal CCF on privileged axes. This allows to relax the assumption of the random repartition of non-lethal shocks on the all components and to represent the effects of diversity. The proposed approach has been applied to a representative case of I&C system of a nuclear power plant.

The extremely low volume of operating experience related to the protection I&C systems makes it difficult to estimate the α factors representing the conditional probability of failures on demand of the k components in a group of N components when a CCF occurs. This CPN model could be used to simulate operating experience for obtaining more data, which make a more accurate estimation of these factors.

Another interesting axis concerns the estimation of the three parameters of the Atwood model. The proposed Monte-Carlo simulation approach for the estimation of these parameters has been validated by an analytical approach. This Monte-Carlo simulation approach could be used to revisit the assumptions supporting the Binomial Failure Rate model underlying the Atwood model.

Propagation of aleatory and epistemic uncertainties in quantification of systems failure probabilities or safety margins

M. Marquès
CEA, DEN, DER, Saint-Paul-lez-Durance, France

ABSTRACT: Epistemic uncertainties may be taken into account in the probabilistic assessment of complex systems, by a Second Order Probabilistic (SOP) analysis, based on a separate propagation of the aleatory and epistemic uncertainties in two nested-loops. This SOP analysis enables to obtain a confidence interval on the system failure probability or on the safety margin, which takes into account the lack of knowledge. In this approach, a probabilistic description may characterize both random uncertainty and epistemic uncertainty. However, if the probabilistic framework has solid mathematical bases for modeling and processing aleatory uncertainties, its use shows limits in the case of epistemic uncertainty and it seems more appropriate to rely on an adapted framework for representing the imprecisions on the failure probabilities or on the safety margins. Among several alternative modeling frameworks, two approaches: interval analysis and Dempster-Shafer Theory of Evidence (DSTE) have been tested and compared on an example of risk analysis of complex systems. Additionally, thinking has been initiated on the idea to jointly use the DSTE and the probabilistic analysis in order to deal separately with the aleatory and the epistemic uncertainties in the "Best-Estimate Plus Uncertainty" (BEPU) approach. A range of cumulative functions will result from this separate treatment, for the quantile $R_{95,95}$ of the classical BEPU approach. Through this proposed methodology, uncertainties due to a lack of knowledge, and in particular modeling uncertainties, will be coherently integrated into an Extended BEPU approach. However, this proposal may pose some problems related to decision making, which are discussed in the paper.

1 INTRODUCTION

The treatment of uncertainties in the analysis of complex system is essential for determining possible ranges on responses of interest such as safety margins or probabilities of exceeding failure criteria. The input uncertainties may be characterized as either aleatory uncertainties, which represent the intrinsic randomness of a phenomenon, irreducible in nature, or epistemic uncertainties, which are reducible uncertainties resulting from a lack of knowledge (Der Kiuregan 2007, Helton 2011, Swiler et al., 2009). For aleatory uncertainties, sufficient data is generally available enabling the definition of input probability distributions and the use of probabilistic methods. By cons, for epistemic uncertainties, data is generally too sparse to enable precise probabilistic descriptions and consequently the uncertainties are often modeled by variation intervals deduced from expert judgment. In this case, the intervals are assimilated to uniform distributions, which enable a probabilistic treatment of epistemic uncertainties. However, several alternative mathematical structures for the representation of epistemic uncertainty, that we will name extra-probabilistic approaches, such as interval analysis, possibility theory, fuzzy set theory or Dempster-Shafer evidence theory, have been developed in the last decades (Demster 1967, Shafer 1976, Zadeh 1978). When both aleatory and epistemic uncertainties are present in the analysis of a complex system, it is often desirable to maintain segregation between these both types of uncertainties. A common approach to quantifying the effects of mixed aleatory and epistemic uncertainties is to perform what is sometimes called a Second-Order Probability (SOP) analysis (Eldred et al., 2011). The idea of SOP is to treat separately the aleatory variables and the epistemic variables and to perform a two-stage Monte Carlo simulation, typically by sampling the epistemic variables on the outer loop, then by sampling the aleatory variables on the inner loop. If the result of the inner loop is an empirical distribution of the response of interest, the SOP process yields a family of distributions. Then relevant statistics, such as mean or percentiles, may be computed based on this ensemble and the intervals obtained on the statistics can be interpreted as possible ranges for the statistics given the epistemic uncertainties. In the SOP analysis, the aleatory variables are treated generally by probabilistic methods and the epistemic variables

may be considered either by probabilistic methods or by extra-probabilistic methods depending on the assumptions taken for these epistemic variables. The objective of this paper is to show the interest of using extra-probabilistic method for the treatment of the epistemic variables within the framework of the quantification of system failure probabilities or safety margins. In Section 2, two extra-probabilistic approaches, interval analysis and Dempster-Shafer theory of evidence, are presented insisting on two points: the decision taking and their interest in expert elicitation. Section 3 presents an example of application of SOP analysis with extra-probabilistic or probabilistic treatment of epistemic variables. Finally in Section 4, a proposal is made to use SOP analysis with extra-probabilistic treatment of epistemic variables within the framework of the called « Best-Estimate Plus Uncertainty » (BEPU) approach for safety analysis.

2 TREATMENT OF EPISTEMIC VARIABLES WITHIN AN EXTRA-PROBABILITIC FRAMEWORK

The probabilistic framework is usually used for modeling aleatory and epistemic uncertainties. However, although it remains the framework for the representation of random uncertainty, it is not considered best able to properly handle the different concepts associated with epistemic uncertainty (Shafer 1976, Fallet-Fidry 2012). Besides the fact that it does not allow to represent incompleteness (in the probabilistic framework, the space of possibilities is exhaustive and therefore all possible hypotheses are identified and defined), its use for the representation of ignorance implies the choice of a single arbitrary probability distribution and the risk is to not represent faithfully the available knowledge and to distort the results of the analysis. The arbitrary choice of a probability distribution to model ignorance is likely to cause errors in the propagation of uncertainties and to provide inaccurate or inconsistent result with regard to the available knowledge, which may have a very significant impact on the assessment results and therefore in the decisions that may arise. It should then not constrain the expression of knowledge to comply with the probabilistic framework but rather to provide a framework to represent, in a more coherent and flexible way, the different types of knowledge. The need for a consistent modeling of epistemic uncertainties is now widely accepted, especially when analyses generate important decisions as is the case for risk analysis (Der Kiuriegan 2007, Helton 2008 and 2011). Bayesian approach may be suitable to express epistemic uncertainty if prior information, subjectively obtained by expert elicitation, may be updated by objective knowledge coming from measurement for instance. But in the case where no additional information is available, extra-probabilistic approach is used to model epistemic uncertainty. This extra-probabilistic framework consists in modeling the epistemic uncertainty around a not well known value by an interval between two bounds containing the true value. This modeling is based on the general concept of imprecise probabilities, which may be defined as an interval of a probability measure between upper and lower bounds:

$$\underline{P} < P < \overline{P} \tag{1}$$

where the range between the bounds represents the uncertainty around the sought true value. The main extra-probabilistic approaches are:

- Interval analysis.
- P-box modeling.
- Possibility theory.
- Dempster-Shafer theory of evidence.

In the following, the principle of interval analysis and Dempster-Shafer theory are reminded.

2.1 *Interval analysis*

In interval analysis, it is assumed that nothing is known about the uncertain input variables except that they lie within certain intervals. The problem of uncertainty propagation then becomes an interval analysis problem: given inputs that are defined within intervals, what is the corresponding interval on the outputs? Although interval analysis is conceptually simple, in practice it may require a prohibitively large number of function evaluations to determine the maximum and minimum values of the response of interest, especially if the relation between the response and the epistemic variables if very nonlinear, if it exhibits discontinuities or if the epistemic variables have strong interactions. It consists in solving two related bound-constrained problems (Eldred et al., 2011):

– minimize $R(s)$
– subject to $s_L \leq s \leq s_U$
– maximize $R(s)$
– subject to $s_L \leq s \leq s_U$

where $R(s)$ is a response of interest and s the vector of epistemic variables.

This optimization problem can be solved using either direct evaluation function of the response (computer code) or by using a surrogate model (polynomial, neural network, Gaussian processes …) approximating the evaluation function and allowing cheaper simulations. In both cases,

two types of approaches are possible to solve this interval analysis: by sampling or by optimization.

2.2 *Dempster-Shafer Theory of Evidence (DSTE)*

In the DSTE, epistemic variables are represented by one or more intervals (called focal intervals) as shown in Figure 1. A belief mass m_i is associated to each focal interval i, indicating the likelihood that the variable belongs to the corresponding uncertain interval. The sum of the belief masses of all focal intervals must be equal to 1.

From this definition of mass belief, are derived belief and plausibility functions respectively noted, *Bel* and *Pl*. The plausibility (respectively the belief) may be interpreted as the upper bound (respectively the lower bound) of the probability induced by a family of probability distribution. Thus, the interval $[Bel(B),\ Pl(B)]$ may be seen as an interval surrounding a not well known probability $P(B)$:

$$Bel(B) \leq P(B) \leq Pl(B) \tag{2}$$

The difference between $Pl(B)$ and $Bel(B)$ measures the ignorance relative to B.

2.2.1 *Propagation of epistemic uncertainties*

All intervals of all epistemic variables are then propagated in order to calculate the focal intervals of the response of interest and deduce the belief and plausibility functions of the response, which are the upper and lower bounds of its probability function. This interval propagation can be very time consuming as all combinations of intervals must be evaluated. As for interval analysis, it is also possible to implement optimization methods (local or global) to find the limits of each interval of the response.

2.2.2 *Decision making by pignistic transformation*

Decision making from the belief and plausibility functions of the response of interest is a problem difficult to solve in the DSTE approach to make it robust to the process of uncertainty treatment (Dubois, 2011). Several transformations have been proposed to transfer the belief model toward the probabilistic model. We opt for "the pignistic transformation" introduced by Smets (2005).

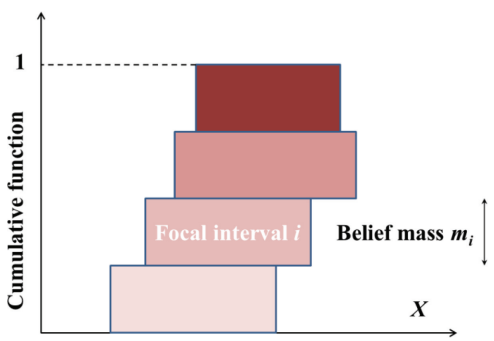

Figure 1. Modeling epistemic variable by DSTE.

2.2.3 *Interest of DSTE for modeling expert opinion*

As stated above, epistemic uncertainties correspond to a lack of knowledge and their modeling can only rely on expert judgment. The DSTE approach consisting in modeling epistemic variables by focal intervals is interesting because it allows to take into account the opinion of one or more experts. The expert must provide at least an interval of variation and in this case, the epistemic variable will be defined by a single focal interval, but he can also provide the median of the variable (two focal intervals in this case) and possibly other quantiles. This approach is also interesting because it allows the aggregation of opinions from several experts (dissenting expert opinions). Different types of aggregation (weighting, envelop…) are possible (Ferson 2003).

3 APPLICATION EXAMPLE TO THE SAFETY ANALYSIS OF AN INDUSTRIAL COMPONENT

Interval analysis and DSTE, for the modeling of epistemic variables, have been compared with classical probabilistic approach on a realistic example concerning the failure risk of an industrial component during an accidental loading.

3.1 *Description of the example*

The purpose of the analysis is to evaluate the failure probability of a component when it is subject to a severe situation. The failure occurs when the loading L applied to the component exceed the strength S of its composing materials. L and S are estimated by a chain of complex thermal-hydraulics and mechanics calculations. In the deterministic assessment, a margin factor (MF), which is equal to the ratio S/L, must exceed a safety factor equal to *1.2*. The deterministic rule to be complied with is thus: $MF > 1.2$. The failure probability is therefore defined as:

$$Pf = P(MF \leq 1{,}2) \tag{3}$$

Segregation of uncertain parameters into two groups (epistemic and aleatory uncertainties) has given:

– 4 aleatory variables: strength of material (modeled by a 3 parameters Weibull distribution, each

parameter being a function of the temperature), depth of an hypothetical flaw (2 parameters Weibull distribution), ratio between depth and length of the hypothetical flaw and effect of irradiation (Gaussian distributions).
– 8 epistemic variables: 6 coefficients of the functions of the temperature for the parameters of the strength distribution (modeled in the probabilistic approach by 6 correlated Gaussian distributions) and 2 parameters of the Weibull distribution of flaw depth (modeled in the probabilistic approach by independent Gaussian distributions).

The failure probability *Pf* is evaluated by Monte Carlo simulation in the inner loop of the SOP analysis and the range of variation of *Pf* is obtained by interval analysis or DSTE (see Figure 2). For the present application, a surrogate model giving accurate estimations of L and S has been used instead of the complex calculation chain.

3.2 *Results of interval analysis*

Two different hypotheses have been taken for the interval of the epistemic variables, based on their previous probabilistic definition (with μ and σ respectively the mean and the standard deviation of the variable):

1. 95% intervals: $[\mu - 1.96\ \sigma, \mu + 1.96\ \sigma]$
2. 99,8% intervals: $[\mu - 3\ \sigma, \mu + 3\ \sigma]$

The bounds of the failure probability have been determined by sampling (1000 simulations) or by optimization in using the global optimization algorithm EGO of DAKOTA software (DAKOTA 2011). Table 1 gives in both case and for the two hypotheses on the intervals, the upper bounds of the failure probability P_f (probabilities are multiplied by 100 in the Table). These values are compared to an analytical solution obtained with the surrogate model. By optimization with EGO algorithm, 10 simulations are sufficient to obtain a value very close to this global maximum in dimension 8. With 1000 simulations, sampling underestimates the upper bound of P_f by about 12% in both cases.

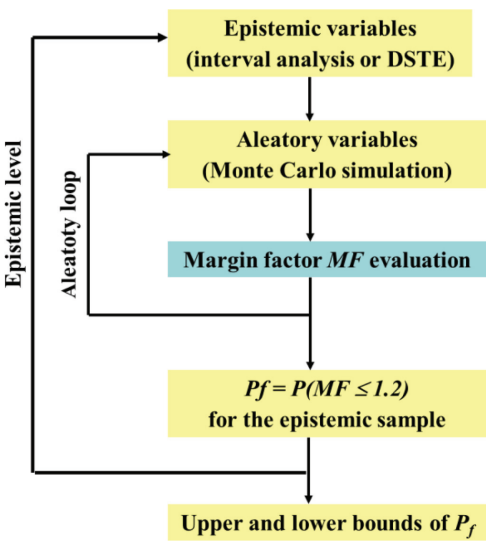

Figure 2. Scheme of the SOP analysis on the example.

3.3 *Results of DSTE*

By way of illustration, different modeling of the epistemic variables have been considered:

A. Each epistemic variable is represented by its median E_{med} and a range $[E_{min}, E_{max}]$.

We have supposed that the true and unknown distributions of the epistemic variables are Gaussian. The results will depend in the capacity of the expert to give quantiles and interval close to the actual values. We have supposed first that the expert gives the true median and the true 95% interval for the epistemic variables (Figure 3). Belief and plausibility functions of the response *Pf* are described here by 256 focal intervals; indeed, the 8 epistemic variables are each described by two intervals, that means 2^8 (= 256) hypercubes to be evaluated in the space of epistemic variables. For each hypercube, the evaluation of the minimum and maximum values of the response P_f provides the corresponding

Table 1. Upper bounds of failure probability P_f (multiplied by 100) obtained by interval analysis.

	Analytical	Sampling	Optimization
95% interval	6.91	6.08	6.89
99.8% interval	9.17	7.88	9.08

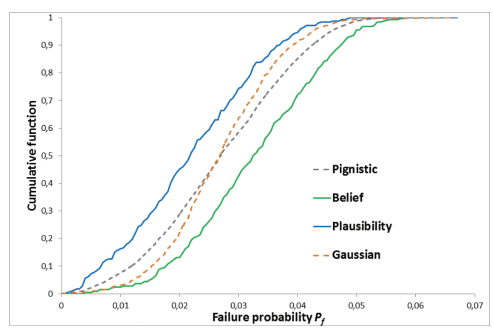

Figure 3. DSTE analysis. Case: true medians and 95% intervals. Belief, plausibility and pignistic function of the response P_f.

focal range. Logically, one finds that the pignistic function and Gaussian reference are equal at the bounds of the 95% interval and at the median of P_f, since these values are correctly evaluated by the expert. By cons, the lack of knowledge outside of these quantiles, results in an overestimation of P_f by the pignistic function beyond the median and an underestimation below.

We have now considered that the expert gives the thrue 95% interval but a median shifted in an unfavorable direction. Accordingly (Figure 4), we see that the belief and plausibility functions as well as the pignistic function deviate significantly from the Gaussian reference in an unfavorable direction, resulting in an overestimation of the failure probability.

B. Each epistemic variable is represented by two quantile ($E_{20\%}$ and $E_{80\%}$) and a range [E_{min}, E_{max}].

In this case, each epistemic variable is described by three intervals with belief masses equal to 20%, 60% and 20%. The response P_f is described here by 3^8 (= 6561) focal intervals. It is seen in Figure 5, that the pignistic function becomes very close to

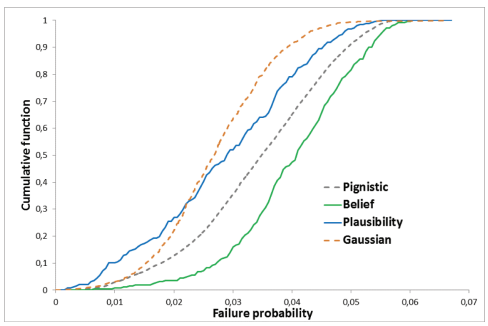

Figure 4. DSTE analysis. Case: true 95% intervals and median unfavorably shifted. Belief, plausibility and pignistic function of the response P_f.

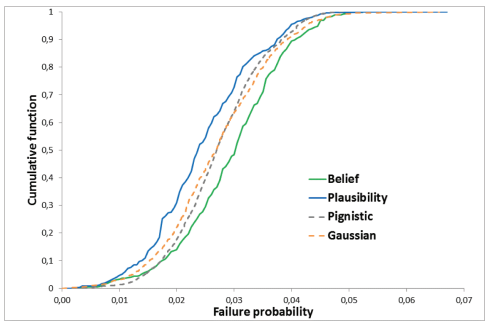

Figure 5. DSTE analysis. Case: true 95% intervals and 20% and 80% quantiles. Belief, plausibility and pignistic function of the response P_f.

the Gaussian reference and the gap between belief functions and plausibility function is tighter. We notice that a description of the epistemic variables by three intervals correctly evaluated enables to obtain results very close to a description by a probability density function.

Table 2 summarizes the results obtained on the upper bound of the failure probability P_f (the upper bound considered is the 95% quantile, except for the interval analysis where it is the upper bound of the interval). The various methods are listed from top to bottom on an increased level of knowledge:

- Case without consideration of epistemic uncertainties: the total lack of knowledge about the epistemic uncertainty variables is expressed here by a single result obtained for the nominal values of the epistemic variables.
- Conservative calculation: epistemic variables are equal to their most unfavorable value.
- Interval analysis: the upper bound obtained by optimization is selected.
- DSTE with different descriptions of epistemic variables: 95% quantile of P_f are evaluated on the pignistic function and on the belief function (pessimistic assumption, between brackets in Table 2).
- SOP analysis: epistemic variable modeled by probability function and 95% quantile of P_f taken on the empirical distribution of the response.

We notice that:

- Interval analysis gives the most penalizing result. The fact that the value obtained is greater than the conservative result indicates that there is a combination of epistemic variable more penalizing that the choice a priori conservative.
- DSTE approach gives results less penalizing even if the 95% quantile is taken on the belief function and not on the pignistic function.

Table 2. Upper bound of failure probability (multiplied by 100) depending on the level of knowledge.

	95% intervals	99.8% intervals
No epistemic uncertainty	2.7	
Conservative calculation	5.5	7.0
Interval analysis	6.9	9.1
DSTE true medians & intervals	4.6 (5)	5.6
DSTE true intervals & favorably shifted medians	4.0	5.0
DSTE true intervals & unfavorably shifted medians	5.2 (5.6)	6.2
DSTE true intervals & 20% and 80% quantiles	4.1 (4.5)	4.3
SOP	4.2	

– DSTE results, which depend on the description of the epistemic variables by the expert, give the upper limit of the results of the SOP analysis.

These results show the interest of DSTE, which enables to take into account the lack of knowledge on certain variables without being as conservative as interval analysis and without requiring a complet probabilistic description of the epistemic variables. In the context of risk analysis of complex systems, we recommend using DSTE for modeling and propagating of epistemic uncertainty in addition to the probabilistic approach which, in turn, treat the random uncertainties.

4 PARTICULAR CONSIDERATION OF EPISTEMIC VARIABLES WITHIN THE FRAMEWORK OF THE BEPU APPROACH

In this section, we will use this extra-probabilistic formalism for taking into account the epistemic uncertainties in the BEPU approach

4.1 *Principle of the BEPU analysis*

The Best Estimate Plus Uncertainties (BEPU) analysis is recommended by IAEA in addition or alternatively to the deterministic approach in the safety analysis of nuclear components and systems (IAEA 2009). The aim of the BEPU analysis is to determine a quantile of an output measure of interest (noted R in the following) with a certain level of confidence (usually the 95% quantile obtained with a 95% confidence, denoted $R_{95,95}$) and to verify that this quantile is below an acceptable limit (acceptance criteria). In order to obtain this quantile, the uncertainty space of input parameters is sampled at random according to their combined probability distribution and a code calculation is performed for each sampled set of parameters. The number of code calculations is determined by the requirement to estimate a tolerance and confidence interval for the quantity of interest. Wilks' formula (Wilks 1941) (or Wald' formula (Wald 1943) when several criteria must be respected simultaneously) is used to determine the number of calculations to obtain the uncertainty bands and the associated quantile with a given confidence level. In classical BEPU analysis, there is no separation between the aleatory variables and the epistemic variables; the epistemic variables, which are often model uncertainties, are generally modeled by uniform probability distributions within intervals provided by expert opinion and propagated in the same way that the aleatory variables by Monte Carlo simulation.

4.2 *Proposal for a separate treatment of epistemic variables in BEPU approach*

We here propose to perform a separate treatment of epistemic and random variables identical to that presented previously in the context of the evaluation of failure probability. This separate processing, through an interval analysis or a DSTE approach will result in, an interval of the quantile $R_{95,95}$ in the case of the interval analysis or two envelops (upper and lower) of its cumulative function in the case of the DSTE. Unlike conventional BEPU analysis where the method consists in comparing the quantile $R_{95,95}$ to an acceptance criteria, we will have here to compare an interval to this acceptance criteria. If the criteria is outside the interval, there will be no difficulty in deciding whether the criteria is met or not; by cons if the acceptance threshold is within the interval, there will be a problem of decision making. One solution to this problem is to try to reduce the uncertainty of the epistemic variables in order to reduce the interval on the response of interest.

4.2.1 *Reduction of epistemic uncertainty*

Reducing the epistemic uncertainty on the response of interest R requires identifying the contributors to this uncertainty. In other words, it is to identify among the input epistemic variables, those whose uncertainty contributes most to the epistemic uncertainty of R. In the case of the two levels analysis proposed in this study, a solution is to perform a global sensitivity analysis of the response uncertainty to the input epistemic uncertainties. Conventionally, an analysis based on the decomposition of the variance of the response is used: that means, calculate the standard regression coefficients in the case of a fairly linear relationship between the inputs epistemic variables and the response or Sobol indices in the general case (Saltelli et al., 2000). Then, the objective will be to reduce the uncertainty of the epistemic variable, which is the largest contributor to the response variance. If the uncertainty of this epistemic variable has been already minimized, the second largest contributor will be concerned by the reduction, etc.

4.2.2 *Decision taking*

Once uncertainty on the response of interest has been reduced and/or shifted at maximum with regard to the available knowledge, two situations are possible: either the uncertainty is small enough to make a decision (i.e. the acceptance criteria is now outside the interval of uncertainty) or the residual uncertainty does not enable easily to make a decision. If the first case does not pose a problem, in the second case the analyst has the

choice between one of two following alternatives (Fallet-Fidry 2012):

1. The analyst is taking no chances and considers that in the present state of available knowledge, the constraint to be satisfied is not met.
2. The analyst decides to interpret the uncertainty in the response of interest according to its risk aversion and then makes a decision to accept or reject.

In the presence of uncertain results, three main behaviors of the analyst for decision making may be distinguished, which depend mainly on the measure on which rely the decision making (Ramasso 2008):

– Pessimistic behavior: the analyst bases its decision on the choice of the belief measure (*Bel*) because it corresponds to the minimum value of belief that he is certain to obtain. This behavior is also called conservatism.
– Optimistic behavior: the analyst relies on the choice of the plausibility measure (*Pl*) because it corresponds to the maximum value that could be been reached if further information reduced the uncertainty.
– Rational behavior: the analyst transforms the distribution of masses in a distribution of probabilities in order to maximize expected utility (i.e. pignistic transformation).

We propose to integrate into an Extended BEPU approach the additional dimension of the inclusion of epistemic variables: that will result, within the framework of DSTE, by obtaining a range of cumulative functions of the 95% quantile $R_{95,95}$ of classic BEPU approach. The decision will therefore be based on:

1. The choice of a confidence level *N%* on the part of uncertainty due to lack of knowledge: we will take, for example, the median (reasonable approach) or the 95% quantile (pessimistic approach); then we will determine the quantile $R_{95,95,N}$, with $N = 50\%$ or 95% following the chosen approach.
2. The comparison between the acceptance criteria and the interval obtained by DSTE for the quantile $R_{95,95,N}$,; so there is the problem of decision previously mentioned. If the acceptance criteria is outside the range, the decision is obvious; if the criteria is within the range, we will try at first, after having performed a global sensitivity analysis, to improve the knowledge (if possible) on the most important epistemic variables and secondly, if the criteria remains in the interval, to make a decision by evaluating the quantile $R_{95,95,N}$ either on the belief function (pessimistic behavior), or on the plausibility function (optimistic behavior) or on the pignistic function (rational behavior). Once the function has been chosen, the decision is simple since it is based on the comparison between the resulting value of $R_{95,95,N}$ and the acceptance criteria. For the Extended BEPU approach taking into account the epistemic variables, it seems reasonable to use as indicator of risk the quantile $R_{95,95,50}$ (thus taking a confidence level of 50% sharing uncertainty due to lack of knowledge) but favoring a pessimistic decision on this quantile, that is to say, in taking its upper bound.

4.3 *Application to the example of industrial component*

In this example, the verification consists in comparing a sufficient low value of the margin factor *MF* (for example, the 5% quantile) to the safety factor.

4.3.1 *Application of the classic BEPU analysis*

We seek the 5% quantile of *MF* obtained with 95% confidence (then for this application the estimated quantile is denoted $MF_{5,95}$). For that, we perform 59 simulations (Wilks's theorem applied at 1st order) in drawing randomly samples of the aleatory variables (epistemic variables are fixed at their nominal values) and in taking the smallest value of *MF*, obtained among the 59 results, as the $MF_{5,95}$. The value obtained is 1.225 and this value is greater than the safety factor (1.2), we can conclude that the rule on the integrity of the component is respected in case of an accidental loading belonging to the 4th category.

4.3.2 *Application of the Extended BEPU analysis with separate treatment of epistemic uncertainty*

As previously proposed, a separate treatment of epistemic and aleatory variables is performed, with a probabilistic treatment of aleatory variables and DSTE for epistemic variables. So this consists in adding an extra loop for the treatment of the epistemic variables (Figure 6).

Epistemic variables are modeled with 95% intervals and medians known. The results obtained on the epistemic uncertainty of the quantile $MF_{5,95}$ are shown in Figure 7. The risk indicator proposed ($MF_{5,95,50}$) is equal to 1.19 on the plausibility function, 1.22 on the pignistic function and 1.26 on the belief function.

We notice that, in this case, the pessimistic choice that we propose will lead to the conclusion of non-compliance with the rule in 4th category, since the indicator proposed ($FM_{5,\ 95.50}$) risk equal

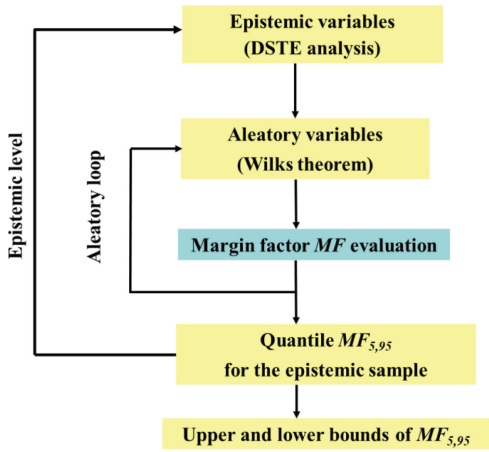

Figure 6. Proposal of a separated treatment of aleatory and epistemic variables in an extended BEPU approach.

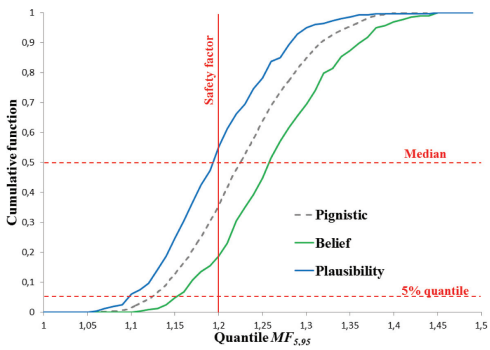

Figure 7. Belief, plausibility and pignistic function of quantile $MF_{5,95}$ obtained by DSTE.

to 1.19 on the lower envelope (envelop to be taken for *MF*).

5 CONCLUSION

In the safety analysis of complex systems, the treatment of uncertainty must distinguish the aleatory uncertainties, which represent the intrinsic randomness of the phenomena, from the epistemic uncertainties resulting from a lack of knowledge. This separation has to be done through a two-level uncertainty propagation: the internal level concerning the aleatory variables and the external level the epistemic variables. For the propagation of epistemic uncertainties, it appears more appropriate to use extra-probabilistic approaches such as interval analysis or Dempter-Shafer Theory of Evidence (DSTE).

The results show the interest of the DSTE, which additionally enables to easily formalize the expert opinion or to aggregate the opinion of several experts. This two-level propagation will provide an interval on the response of interest (failure probability or safety margin), which will be compared to the acceptance criteria. We raised the problems posed by the comparison between a value and an interval within the context of the decision making and attempted to provide some solutions.

Finally, we have proposed an improved Best Estimate Plus Uncertainty (BEPU) approach taking into account the epistemic uncertainties. The main principles of this extended BEPU approach are:

1. Separate treatment of aleatory and epistemic uncertainties by a two-level analysis.
2. Treatment of the aleatory uncertainties within a probabilistic framework (i.e. Monte Carlo simulation) and treatment of the epistemic uncertainty within an extra-probabilistic framework (i.e. DSTE).
3. Interval evaluation of a risk indicator, which is the quantile of the classic BEPU approach (i.e. $R_{95,\ 95}$) but obtained with a 50% confidence level on the part uncertainty due lack of knowledge.
4. Pessimistic decision making on this risk indicator taking the upper or the lower bound of the interval.

The choices of a 50% confidence level in the 3rd step and of a pessimistic decision in the 4th step, are only proposals and will need to be explored more deeply by discussion and application examples.

Safe level of redundancy in Discrete Transportation Systems

D. Caban & T. Walkowiak
Wrocław University of Technology, Poland

ABSTRACT: Discrete transportation systems are designed to operate with minimal resources that guarantee the fulfillment of their transportation tasks. Some redundancy is needed to reduce the risk of not meeting the requirements. This is particularly important, if the system operates in critical regime and cannot reject excessive transportation demand. Safe level of redundancy should ensure operation with acceptable risk, considering both the likelihood of adverse events and their consequences. The level of redundancy should consider normal system operation and occasional faults of the resources, but it should also address catastrophic risks and limiting their impact. We provide a uniform approach to finding the acceptable redundancy level in all these situations. The solution is based on standard stochastic approach, modified by injecting artificially some unlikely events into the system model. This avoids the limitations of Monte Carlo simulation—numerical hardness of analyzing events with a very low probability of occurrence.

1 INTRODUCTION

The logistics of discrete transportation systems DTS are well understood and analyzed in literature. When designing such systems, the main goal is to ensure proper functioning with minimal expenses. Thus, the costly resources (vehicles and employed drivers) are minimized.

In the paper, we address the situations where a level of redundancy of the resources is required. In Chapter 2, we demonstrate that the level of resources based on global throughput analysis can be significantly under-estimated. Simulation results show that there is a level of functional redundancy required to ensure proper quality of service.

In Chapter 3, we consider the reliability aspects of DTS and their impact on the required level of redundancy. The reliability analysis lets us determine the level of redundancy that ensures continuity of service at an economically justified level of assurance. There are a lot of techniques that support this type of analysis (Avizienis et al. 2000, Jarnicki et al. 2008, Walkowiak & Mazurkiewicz 2010, Zio 2007).

In Chapter 4, we analyze the unlikely catastrophic faults and how their consequences can be mitigated by introducing redundant resources. The dependability analysis tends to underemphasize the events that are very improbable. Such situations are addressed by the techniques of risk analysis which consider the probability of risk occurrence and their effects (Flyvbjerg 2006, Kahneman & Tversky 1979, Kaplan & Garrick 1981, Walkowiak & Mazurkiewicz 2009).

2 SIMULATION OF DISCRETE TRANSPORTATION SYSTEMS

2.1 *Monte Carlo simulation*

There are various approaches to the analysis of discrete transportation systems (Gartner et al. 1998). Probably the most versatile is to use simulation. In the simulation approach, the first step is to formulate an adequately detailed model of the system. Then, the model is used to build a program that reflects the model responses to the various events occurring in the system. These responses generate changes to the internal model state and further events that have to be handled.

Monte Carlo simulation is used when the model responses are described stochastically, i.e. some of them are not deterministic, rather they are described by random distributions. In this situation the simulation has to be run repeatedly to obtain several independent realizations of the same process. These are used to build the probabilistic distribution of the results, especially the average measures.

We use a custom designed discrete event simulator, based on the publicly available SSF simulation engine. The engine provides all the required simulation primitives and frameworks, as well as a convenient modeling language DML (Liu 2006) for inputting all the system model parameters. The simulator does not support the models specific to transportation systems, though. These are custom developed. Furthermore, the use of open-source engine and the custom models provide sufficient

flexibility to experiment with the code. This provides a better understanding of its limitations, and allows experimentation with new techniques.

2.2 *DTS model*

The discrete transportation systems (DTS) can significantly differ depending on their type and application. It is very difficult to formulate a general model, applicable to all the various classes of DTS. Still, in all cases, the models distinguish the following resources: the set of terminal nodes, the set of available routes between these nodes, the set of vehicles, the set of vehicle drivers, the fixed or dynamically modified travel schedules, and the set of transportation tasks or assignments, that the system is required to perform.

We consider in this paper a fairly wide class of DTS models, though all the numerical experiments are performed on a test case based on mail delivery system presented by us in (Walkowiak & Mazurkiewicz 2010, Caban & Walkowiak 2012).

It is assumed that the considered class of systems must conform to the following stipulations:

- System is required to perform time critical deliveries, i.e. its quality is characterized by the number of deliveries realized on time.
- System is liable to random faults that affect its operation and should have capabilities to tolerate them.
- System operates in the critical services regime, i.e. it has to accept all the incoming assignments and cannot reject excessive service demand.

The model considers transportation of goods between terminal nodes along specified routes. Assignments determine the entry nodes, at which the goods arrive at specified time, and the exit nodes, where they have to be transported to. Deadline for delivery is also specified. The assignments are generated randomly to model the real demand on services.

The routes represent connections between the nodes. They are characterized by the distance that the vehicles must travel. Taking into account the average travelling speed of vehicles, this fixes the latency connected with moving from one node to another, distorted by the travel delays caused by the traffic congestion.

Vehicles and their drivers constitute the system components directly responsible for realizing the assignments. The DST model assumes a fixed number of vehicles and a fixed number of drivers. At any moment in time a vehicle is either en route realizing assignments, waiting for goods at a node or stopped due to unavailability of a driver or due to regulatory rest period of its driver.

The vehicles are characterized by their capacity (expressed as the number of standard containers) and by the average cruising speed (determining the route latency). It may be realizing multiple assignments at the same time. It is fully loaded with goods if the pending assignments allow it. If there are insufficient assignments for nodes towards which the vehicle is destined, then it may be partially loaded or even travelling empty. It collects goods en route if there are pending assignments in the visited nodes.

A driver must be associated with a vehicle, whenever it is assigned to realize a job. Any unallocated driver can be associated with any vehicle. Only one driver at a time is associated with a vehicle (we do not consider long distance routes with standby drivers). The working time of vehicle operators is regulated by local and EU law. The daily working hours are limited (to 8 hours), there are also compulsory rest breaks while driving. At any time the driver can be either: driving, resting (between work shifts), pausing (i.e. having a compulsory break while driving) or waiting to be assigned a job.

The parameters describing the driver model include the daily working hours limit, maximum uninterrupted driving period, minimum break duration.

Vehicles are travelling in accordance to fixed travel schedules. Each schedule determines a sequence of nodes that must be visited by the vehicle as well as the times of these visits. It describes the daily work of the associated vehicle, independent of the actual needs as determined by the incoming assignments. Vehicles are loaded to their capacity (if there are sufficient assignments) on starting a travel schedule. On reaching each consecutive node, the goods destined to it are unloaded and the goods waiting there are loaded in their place. The time used for unloading and loading is taken into account. If there are other vehicles in the node, then they are queued and the period of loading/unloading is extended commensurately. When a vehicle reaches the end node, it is completely unloaded. It can then be associated with another schedule or it may be pooled, waiting to be associated.

The schedules are not directly associated with vehicles or drivers. Instead, any available vehicle and operator is allocated when needed. If there are no vehicles or drivers available, then the schedule cannot be realized.

2.3 *Level of redundancy ensuring functionality*

The goal of system simulation is to ensure that it is capable to deliver service at the required level of confidence. The proposed DTS model is probabilistic (due to the random nature of assignments input and travel times). For this reason some level

of redundancy in its throughput is required to achieve this confidence.

The measure of the system functionality is derived by monitoring the delays in realizing the assignments. As already mentioned, each assignment has a deadline for goods delivery. The proposed measure of acceptance ratio is defined as the proportion of assignments that are delivered on time to the total number of assignments in the system during a fixed time period. A 24 hour reporting period is assumed for determining this ratio.

The time instances (t_0, t_1, …, t_n) fix the boundaries of the consecutive days, for which the ratio is considered. $N_d(t_i)$ denotes the number of assignments completed in period (t_i, t_{i+1}), while $N_{pd}(t_i)$ denotes the part of them completed on time. The average ratio A_r of on-time deliveries, computed over the multiple runs of the simulator and over all the period (t_i, t_{i+1}) is defined as:

$$A_r = \underset{i}{E}\left[E\left(\frac{N_{pd}(t_i)}{N_d(t_i)+1} \right) \right]. \quad (1)$$

The addition of 1 in the above equation is noteworthy. It does not have any analytical justification. In normal operation, the number of completed assignments is significantly greater than 1 and adding this value does not change the ratio. On the other hand, if the system is down for more than a day, then the constant prevents division by 0.

It is possible to assess the acceptance ratio analytically, assuming average number of assignments and average cruise times. The results of such assessment for the testcase DTS system mentioned in 2.2 is presented in Figure 1. This can be taken as a baseline for system operation without any redundancy to accommodate the random behaviour.

The results of the same system analysis using simulation (with random distributions of assignments and cruise times) are presented in Figure 2.

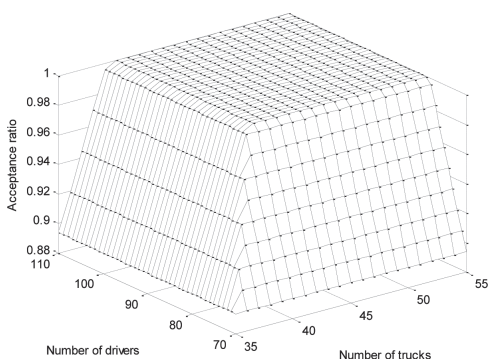

Figure 1. Analytical model of acceptance ratio—the value of 42 vehicles and 84 drivers ensures perfect operation.

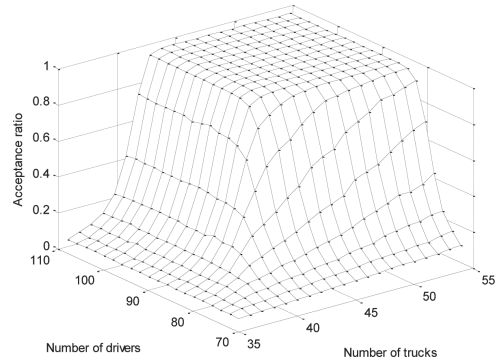

Figure 2. Simulation results for the DTS example—required 45 vehicles and 90 drivers.

It should be noted that the system with 42 vehicles and 84 drivers, analytically determined from Figure 1, ensures average acceptance ratio at the level of approximately 0.2 in Figure 2. Clearly, there is need for some redundancy to ensure that the random fluctuations in system operation do not have excessively adverse impact on its operation. This redundancy is further referred to as the "redundancy ensuring functionality". As further demonstrated even greater redundancy is needed if we aim to achieve a level of fault tolerance, i.e. if we need to preserve the DTS quality in the presence of vehicle or human faults.

3 DTS RELIABILITY ANALYSIS

3.1 *System faults*

The DTS system is prone to be disrupted due to the occurrence of faults in its operation. These faults can affect the system's ability to realize assignments on time.

We consider three types of operational faults. All are temporary. The faults are as follows:

– vehicle breakdowns,
– driver absence at work (e.g. due to illness),
– traffic congestion, causing excessive delays in the vehicles cruise time.

Broken down vehicles are repaired, drivers get well and return to work after a period of absence, traffic gets back to normal in time. In consequence, the system is fully repairable and there is no long term degradation.

The vehicles are assumed to break down occasionally, in accordance to their reliability parameters (failure rates). They stop operation and wait for a maintenance team. On being repaired (after

a random repair time), the vehicles continue the work they were realizing before breakdown.

The model does not distinguish any specific parameters of the maintenance teams, just their number. Each maintenance team repairs only one vehicle at a time. If all the maintenance teams are currently occupied, then the vehicle repair is delayed until one becomes available.

Drivers get ill or otherwise temporarily unavailable. There are multiple causes for absence in the work, all characterized by different frequencies of occurrence. Statistical data published by the Central Statistical Office gives an indication of the likelihood of the various periods of absenteeism. We use a simplified stochastic model of absenteeism (Walkowiak & Mazurkiewicz 2010):

– short sickness (1 to 3 days),
– typical illness (7 to 10 days),
– protracted disability (10 to 300 days).

In the model the three types of disabilities are treated independently. In each case the actual period of absence is randomly chosen from the appropriate range.

3.2 *Level of redundancy ensuring fault tolerance*

The simulation approach, proposed in 2.1 and 2.3, can also be applied to the analysis of the DTS system liable to fault occurrence. The simulation model needs to be extended by the fault occurrence and repair processes.

The results of simulation of the system with likely faults are presented in Figure 3. There is no significant difference in the shape and properties of the obtained acceptance ratio characteristic. It should be noted, though, that the slopes of the surface are shifted towards greater numbers of drivers and vehicles. This indicates that the required level of redundancy ensuring fault tolerance is greater that in case of the functional redundancy.

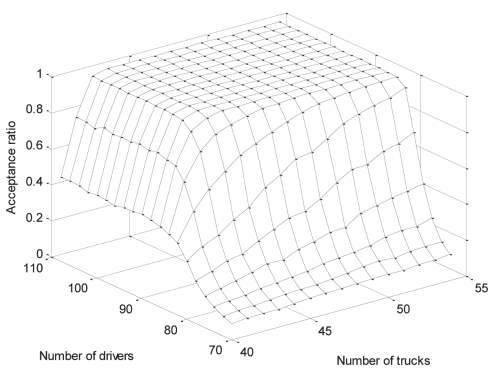

Figure 3. Simulation results for the DTS example with faults hazard—required increased redundancy.

4 ANALYSIS OF UNLIKELY FAULTS

4.1 *Unlikely faults*

Transportation systems are prone to hazards that are very unlikely, i.e. their probability of occurrence is so small that they are not considered in the reliability analysis. This does not mean that they cannot occur, though. If they cause extensive damage to the system, then they still need to be taken into account in contingency risk planning.

The following risks are identified in case of the DTS model:

– Complete stoppage of the DTS system, caused by all the drivers going on strike, sabotage of vehicles, natural disasters disrupting the vehicle fleet or the road infrastructure. As a result the system becomes inoperable for a fixed period of time (a few days).
– Periodic rapid increase in the service demand, e.g. due to unexpected seasonal changes or connected with failures of other, competitive transportation systems operating in the same region. It manifests itself by a much higher rate of assignments arriving in all the nodes. In effect there is a sudden influx of assignments that the system cannot handle.
– Unforeseeable unavailability of a significant proportion of drivers, caused by strikes or an epidemic illness, such as flu or virus infection. As a result, a significant proportion of the drivers may be simultaneously absent from work. This is a generalized version of the periodic stoppage risk, where some parts of the system can still operate.
– Unforeseeable reduction in the number of available vehicles, connected with disrupted supply chains, shortage of fuel or vehicle replacement parts. As a result, some vehicles cannot be kept operational (as if they all failed simultaneously).

4.2 *Assessment of risk of unlikely faults*

Risk assessment plays the key role in any management activity. There are various alternative approaches to risk assessment (Kaplan & Garrick 1981, Zio 2007). Most popular is the qualitative approach, based on expert opinions (Flyvbjerg 2006). The basis of this analysis is to classify the identified risks in accordance to the likelihood of their occurrence and the gravity of their consequences.

The likelihood of any risk occurrence is assessed as either: low, medium, or high. Likewise, the gravity of its consequences is assessed as: insignificant, low impact, or serious. Qualitative risk assessment is based on these two. Obviously, if we regard an

event to be very improbable and its consequences insignificant, then the associated risk is very low. On the other hand, a likely event with serious consequences is associated with very high risk.

The likelihood of the events discussed in 4.1 is low to medium. On the other hand, the consequences cannot be predicted just by expert knowledge. It is proposed to use the simulation technique for this purpose.

4.3 *Modified simulation approach*

As discussed in 2.1, Monte Carlo simulation has to be run repeatedly to obtain several independent realizations of the same process. The results differ, since the model is not deterministic. The number of runs has to be sufficiently high, so the probabilistic distribution of the results captures all the possible situations. The lower the probability of an event, the higher is the required number of runs.

For this reason, the approach is inadequate to analyze the effect of unlikely faults on the DTS system. The number of runs would have to be huge to capture even single occurrences of these events. The simulator had to be modified to enable this analysis.

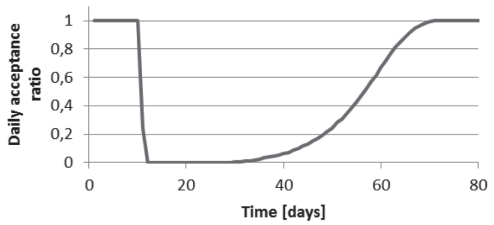

Figure 4. Daily acceptance ratio with complete DTS stoppage from day 10 to 15—consequences observed until day 70.

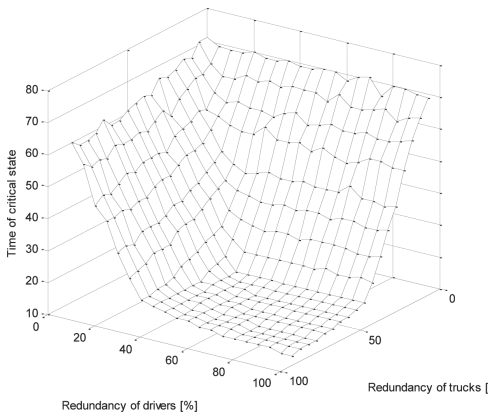

Figure 5. Critical state of operation measured for DTS systems with various level of vehicles/drivers redundancy.

The occurrence of the unlikely faults mentioned in 4.1 can be predetermined manually in the simulator. Then, the simulator can be used to predict their effects on the rate of on-time deliveries. The system is analyzed against its ability to resume normal operation after a disruption of service, i.e. it is used to assess the gravity of consequences (instead of likelihood of occurrence).

The measure of the acceptance ratio, defined by equation (2), is not adequate in this case—it assumes the same distribution in all the time periods (t_i, t_{i+1}), i.e. the stationary property of the stochastic process. Instead, we consider the daily acceptance ratio a_{ri}:

$$a_{ri} = E\left(\frac{N_{pd}(t_i)}{N_d(t_i)+1} \right). \tag{2}$$

In this case, the average is taken only on the same time periods (t_i, t_{i+1}) of the various simulation runs.

Figure 4 presents an example of the simulation results obtained in this approach. The time from the occurrence of the unlikely event (day 10 in the Figure) until its diverse effects are mitigated is called the "time of critical state of operation". In this case, it is about 2 months!

4.4 *Level of redundancy limiting the risk of unlikely faults*

The length of time of the critical state of operation depends on the redundancy in the system resources. Simply speaking, the greater this redundancy, the faster is recovery from an unlikely fault. The results of simulation given in Figure 5 support this intuition.

It should be noted that there is a level of redundancy, above which the impact on limiting the time of critical operation becomes small. This level of redundancy (about 25% in this example) is the obvious choice to limit the risk of unlikely faults.

5 CONCLUSIONS

We have analyzed three different phenomena that lead to the necessity of introducing redundancy in the resources of a discrete transportation system:

– redundancy ensuring proper functionality,
– redundancy ensuring fault tolerance,
– redundancy limiting the risk of unlikely faults.

In each case, the level of required redundancy is different. As expected, the least redundancy is required to ensure functionality and the greatest

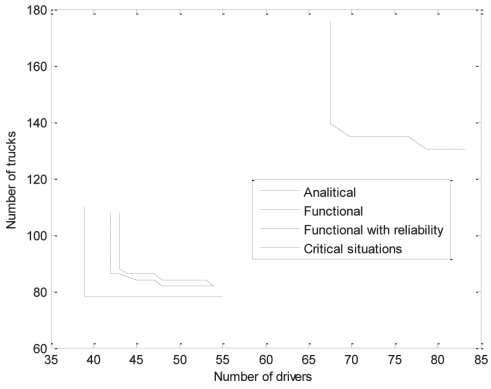

Figure 6. Minimal number of resources (vehicles and drivers) required for the various types of redundancy.

redundancy occurs when limiting the risk of unlikely faults. This is presented in Figure 6.

It should be noted that, unlike the functional and reliability redundancies, the redundancy for limiting the risk of catastrophic faults does not need to be available at all time. It is only used when the system is in the state of disorder after a catastrophic fault. This can be the basis of a number of different risk mitigation strategies. Some interesting approaches to dealing with this are:

– subcontracting some transportation tasks to external systems,
– moving resources between DTS subsystems (this is analyzed in (Caban & Walkowiak 2013),
– centralizing of the redundant resources in a multiple subsystems DTS.

Using Petri-Net analysis for advanced reliability analysis of polymer electrolyte membrane fuel cells

M. Whiteley, J. Leigh, A. Fly, L.M. Jackson & S.J. Dunnett
Aeronautical and Automotive Engineering Department, Risk and Reliability Research Group, Loughborough University, Loughborough, UK

ABSTRACT: With the ever increasing concerns of anthropogenic climate change in recent years, the scientific community has been tasked with developing low-zero carbon technologies to mitigate climate change. One of the most promising technologies to answer to the concerns is the hydrogen fuel cell, particularly when integrated into an automotive context. Hydrogen fuel cells are an electro-chemical, zero-emission energy conversion and power generation device. They use hydrogen and oxygen gas to produce electricity, with their only by-products of heat and water vapour.

Reliability issues with fuel cells have held back the commercialisation of this promising technology, and as such are required to be studied further. The international fuel cell community has set reliability standards to require an automotive fuel cell to last more than 5000 hours. These standards are difficult meet; therefore in depth reliability analysis can help allude towards the key areas of improvement in fuel cell technology to meet these standards.

Previous failure mode and effect analysis and fault tree analysis work by the authors has shown that the inherently complex system of a PEMFC assembly can harbor dependencies between multiple failure modes. Therefore in this presented work, Petri-Net simulation has been adopted to develop a more accurate degradation model. Operational parameters such as water content, temperature and current density's effects on the occurrence of failure modes can be modelled through this technique. This work will improve previous fuel cell reliability studies by taking into consideration; operating parameters (water content, temperature), ambient weather and fuel cell voltage demand (drive cycles).

1 INTRODUCTION

1.1 *Hydrogen fuel cells*

Climate change worries and sustainability issues have become a poignant talking point in recent years, since it has become impossible to ignore the anthropogenic source of climate change (Solomon, et al. 2007). Man-made pollution contributes towards climate change due to Greenhouse Gas (GHG) emissions, including; Carbon Dioxide (CO_2), Methane (CH_4) and Nitrous Oxide (N_2O) amongst others.

In 2011, the United Kingdom emitted 549.3 million tons of CO_2 equivalent ($MtCO_2e$) (DECC, 2011), with 122.2 $MtCO_2e$ being down to the transport industry. Cars, taxis and busses accounted for 74% of this figure, which is a startling contribution (DfT, 2010).

Not only are GHG emissions affecting the atmosphere in a negative way, energy prices are predicted to increase at ever increasing rates (BERR, 2006), which could potentially lead to disruption in the UK's energy system.

Due to the aforementioned climate and energy issues, the UK's GHG contributions needs to be dramatically reduced.

Hydrogen fuel cells could potentially be the answer (or a part of the answer) to climate change and sustainable energy issues. A hydrogen fuel cell is a zero-emission energy conversion and power generation device. They combine Hydrogen (H_2) and atmospheric Oxygen (O_2) to create Water (H_2O), a little heat, and electricity. If the H_2 can be sourced from renewable means (such using as wind and solar energy electrolysis of water), the whole process of using a fuel cell is zero emissions in use. With all of these factors considered, the hydrogen fuel cell could be used in an automotive context to replace the fossil fuel powered Internal Combustion Engine (ICE).

1.2 *The Polymer Electrolyte Membrane Fuel Cell*

Out of the five main sub-categories of fuel cell, the Polymer Electrolyte Membrane Fuel Cell (PEMFC) has been underlined as the most feasible

to be integrated into an automotive application. This is due to its low operating temperature and rapid start-up time. The main components of a PEMFC are shown in Figure 1.

Currently, there are three main hurdles to the commercialization of PEMFCs; Cost, Infrastructure and Reliability:

Cost—PEMFCs use Platinum (Pt) catalysts, which is inherently expensive. Pt loadings for PEMFCs are coming down year after year with more development.
Infrastructure—For a successful commercial uptake of PEMFCs, there must be an adequate network of filling stations to service PEMFC vehicles.
Reliability—Reliability is the largest stumbling block for PEMFC uptake as the technology stands. Cost and infrastructure can be overcome via investment and policy, whereas reliability requires an in-depth analysis.

PEMFCs in an automotive application need to meet targets set out by the United States (US) Department of Energy (DoE) of; a lifetime of more than 5000 hours with a performance drop of no more than 5% over that period. The Japanese New Energy and Industrial Technology Development Organisation (NEDO) and the European Hydrogen and Fuel Technology Platform (HFP) targets mirror that of the US DoE with a 5000 hour lifetime goal in an automotive application (Borup, et al. 2007).

However, modern day PEMFC systems cannot quite reach these targets due to unforeseen degradation of the membrane, Catalyst Layer (CL), Gas Diffusion Layer (GDL) and Bipolar Plate (BIP) components, leading to a drop in performance of the PEMFC, or even catastrophic failure.

1.3 *PEMFC degradation*

There are three main failure mechanism categories that could affect the operating lifetime of a PEMFC; chemical, thermal and mechanical degradation. These overarching failure categories can contain numerous individual failure modes that a PEMFC can experience.

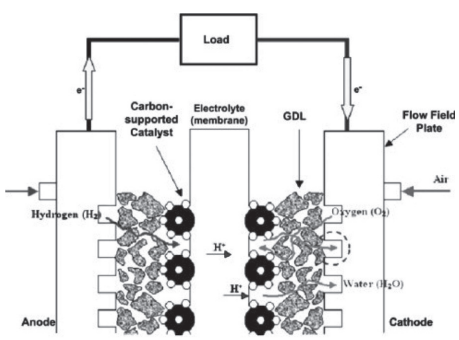

Figure 1. Components of a PEMFC (Kandlikar & Lu, 2009).

To illustrate a chemical degradation mechanism, out of the many chemical degradation events that degrade a PEMFC, Hydrogen Peroxide (H_2O_2) and radical attack (namely Hydroxyl (OH) and Hydroperoxy (OOH)) are of the most prominent.

OH and OOH radicals are formed through the chemical reactions surrounding H_2O_2 production. The membrane of a PEMFC is inherently thin to try to increase performance, however this means that there is always a small amount of gas cross-over between the anode and cathode. The H_2O_2 formation and radical propagation can lead on to a chemical attack of the Polytetrafluoroethylene (PTFE) based membrane and areas of the CL and GDL.

As platinum (Pt) is used as a catalyst in a PEMFC, it can be a catalyst for the formation of H_2O_2 and OOH radicals as described by LaConti, et al. (2003). Another method of H_2O_2 and radical production can be via the presence of foreign metal cations.

Peroxide and radical attack damage the PEMFC via chemical dissolution of the PTFE based membrane material, and even parts of the CL and GDL. Chain scission and end-group unzipping is the process of chemical degradation where the membrane wastes away and loses mass due to peroxide and radical contamination. This can be observed by a presence on fluorine in the exhaust gas stream, where the PTFE based membrane is being pulled apart and is leaving the cell.

2 RELIABILITY ANALYSIS OF PEMFCS

2.1 *Work in the literature*

Reliability analysis of PEMFCs is still in its infancy and needs to be further developed to advance the lifetime of PEMFCs and understanding of degradation mechanisms.

Previous work includes a Failure Mode Identification (FMEA) and fault Tree Analysis (FTA) of a general PEMFC by Rama, et al. (2008). Additionally, a more recent FTA work was presented by Placca. L & Kouta. R (2011), looking at the failure modes that could cause PEMFC degradation, yielding a more detailed fault tree of fuel cell degradation.

Work by Whiteley, et al. (2013a & 2013b), identified areas for improvement in these former works, improving the FMEA and FTA and furthering the reliability and degradation field of PEMFC research. Results from these studies identified the dependent nature of some degradation mechanisms, thus this latest research focusses on the

Petri-Net technique due to its ability to take into account relationships and dependencies between failure modes.

2.2 *Petri-Net analysis*

Petri-Net simulation is based upon a graphical process of representing component relationships, conditions and events. It can be used to model and analyse dynamic behaviors of systems taking into account relationships and dependencies which FTA cannot.

Petri-Nets are comprised of two main symbols; P (places) and T (transitions). Places indicate the state of the system being modelled, and can therefore contain information such as health of a component. Transitions contain the relevant data to facilitate the changeover from one place to another. They can contain data such as probability or timings.

These two nodes are connected by arrows known as 'Arcs' A, which show the direction of flow of 'tokens'. Tokens are used to describe the state of the system, and are used to mark/enable a place as in Figure 2.

Figure 2 shows a basic Petri-Net model that has place one enabled (*P1* containing a token) denoting a system state. The transition (*T1*) will fire based on criteria that could range from time intervals to probability. If the pre-set conditions are met, the transition will take the one token from *P1* and place it into *P2*, representing a new state of the system.

P, *T* and *A* can be defined as per Liu & Chiou (1997):

$$P = \{P_i \mid P_i \text{ is a place, } 1 \le i \le I\},$$

where *i* is a positive integer

$$T = \{T_i \mid T_i \text{ is a transition, } 1 \le i \le I\},$$

$$A \subseteq (P \times T)\ U\ (T \times P).$$

2.3 *Literature on Petri-Net analysis of PEMFCs*

In the literature, there is currently only one example of Petri-Net use for reliability analysis of PEMFCs from Wieland, et al. (2009),

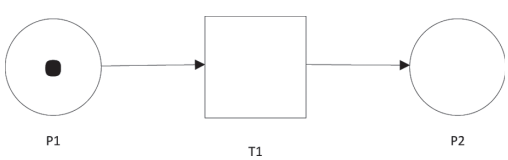

Figure 2. Example Petri-Net.

This work has a basic overall Petri-Net. At the centre of this net, there is an initial place which denotes the operational state of a PEMFC. The model can fire through five main transitions; Degradation, Spontaneous event, Reversible event, Repair and Breakdown. The way in which the transitions fire is based upon degradation rates taken from the literature, or the authors' own assumptions. The degradation rates are selected utilising the normal distribution based upon mean, lower and upper limits, assumed by the authors.

The output of the model is an estimated voltage degradation based upon a simple linear model. Additionally, it was found that (due to their simulation) 'Natural Aging' was the most prominent failure mode in the system.

2.3.1 *Limitations with the modelling*

The limitations found by the authors are acknowledged as a lot of simplification of the model (i.e. with reference to spontaneous events); use of the normal distribution; and time of year effects.

Review has shown that along with these factors, not only would time of year affect fuel cell operation, but load cycle and other operating variables could be considered. A PEMFC will change temperature, gas flow rates and other parameters based upon load demand. Therefore incorporation of a drive cycle such as the New European Drive Cycle (NEDC) would put the fuel cell under differing loads, and thus differing operating parameters.

The authors adopted the normal distribution method to model the degradation rate, which is a potential drawback. Components in a PEMFC don't share features with the normal distribution probability theory. In fact, components aging in a PEMFC system share characteristics with the Weibull distribution and the 'bathtub curve'. Here, the Weibull shape parameter 'β' is indicative of the phase of the component in its lifetime. This shape parameter (alongside the location parameter 'γ') can be changed dependent upon the failure mode in question. That is to say that an early life failure mode such as 'creep' in the initial stages would have a shape parameter of less than one, whereas 'Relative Humidity Cycling' (taking a long time to have an affect) would use a parameter of more than one. Any failure modes experienced throughout the useful life phase would use a shape parameter of one.

The work presented is a good start to develop reliability analysis in this field. However, the model could in addition be further developed to accurately represent all of the previously identified failure modes from FMEA and FTA work presented by Whiteley, et al. (2013a & 2013b).

3 PROPOSED MODEL

As previously discussed in section 2, the reliability analysis of PEMFCs, and more specifically Petri-Net analysis, needs to be evolved. This work attempts to enhance the capabilities of the Petri-Net approach towards PEMFC degradation modelling. The proposed work looks at the inherent complexity of degradation within a PEMFC and therefore can accommodate the interdependencies of failure mode groups, which would change the overall degradation of the cell. Additionally, this work can account for degradation due to operating conditions, such as high temperature or low relative humidity operation of the cell. These changes of input operating conditions will have an effect on the degradation as previously found in (Whiteley, et al. 2013a & 2013b).

The overall 'global' Petri-Net for the PEMFC simulation is presented in Figure 3.

There are two global states 'Operating State' and 'Failed State', The 'Operating State' is initially set to represent 100% health of the PEMFC and fires through the 'Degradation' transition on every time-step of the simulation. Contained within the degradation transition, are individual, separate Petri-Nets. Each failure mode has a relationship Petri-Net to explain its logic, and how it interacts with other failure value to be ascertained for each failure mode, and also its interaction with other individual Petri-Nets to be included in the simulation.

The 'Failure' transition will be fired based upon the criteria of unacceptable system performance. This is set at a lifetime of less than 5000 hours with more than a 5% drop in cell performance over that time as per the US DoE target discussed in section 1.2. If this target threshold is exceeded, the transition will fire into the 'Failed' state and end the simulation run.

3.1 *Degradation modules*

A total of 21 Petri-Net modules have been created, with two being discussed to illustrate the module development. The two failure modes described are 'H_2O_2 Degradation' and 'Radical Attack', which are intrinsically linked.

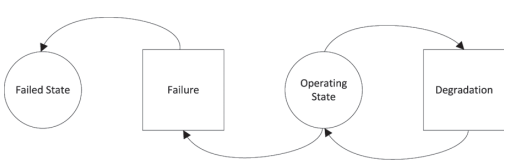

Figure 3. 'Global' Petri-Net of PEMFC.

3.2 *H_2O_2 degradation Petri-Net*

Figure 4 shows the example Petri-Net for 'H_2O_2 Degradation', *P1* is enabled with a token on the first running of the model. It is indicative of a healthy PEMFC, with no H_2O_2 degradation. *T1* can only fire when there is a token in *P2* and *P1* at the same time. *P2* is used to indicate a state of H_2O_2 degradation, agglomerating the lower level transitions. This is for the integrity of the transition logic.

The firing of this transition would enable *P8*, indicating a state of H_2O_2 degradation, and would have an output affecting the performance of the PEMFC and potentially linking into another Petri-Net module. There are a number of contributors to *P2*, stemming from places *P3* 'Pt dissolution/redistribution 'Pt Band'', *P4* 'Low rate of gas crossover', *P5* 'BIP corrosion & release of metal ions' and *P6* 'High rate of gas crossover'. *P3* is enabled by an interaction from a separate Petri-Net module, and indicates the presence of Pt which acts as a catalyst for H_2O_2 formation. Therefore for *T2* to fire, *P3* and *P4* need to be enabled. This would show that there is gas crossover and a free Pt presence to cause a rate of formation of H_2O_2 over and above normal gas crossover formation.

H_2O_2 can form from the crossover of the reactant gasses through the membrane. Thus for a given rate of gas crossover, a corresponding rate of H_2O_2 formation is attributed. This enables the Petri-Net modelling of *T3* and *T5* firing and a corresponding degradation of PEMFC overall performance. Consequently if *P6* is enabled, *T5* will fire, placing a token in *P2*, and if *P4* is enabled, *T3* will fire a token into *P2*.

Pozio, et al. (2003) also showed that the presence of Fe^{2+} and Cu^{2+} (Iron and Copper ions) released from BIP corrosion greatly accelerate the degradation due to H_2O_2 formation when there is gas cross-over. Therefore a separate rate is associated with *T4*.

P7 is an inhibitor and serves to prevent the transition of *T2*, *T3*, *T4* & *T5*. Due to the information in the literature, Borup, et al. (2007), who state that the potential for H_2O_2 formation (E^o H_2O_2) is equal to 0.695 V, and that any potential greater than this would inhibit the formation of H_2O_2 in the PEMFC. Therefore in Figure 4 the inhibitor *P7* is used to reflect this fact.

H. Tang, et al. (2007) show that H_2O_2 degradation reduced the OCV value of a PEMFC over time (Fig. 5). Therefore the degradation rate attributed to H_2O_2 degradation is set at 0.0065 Vh^{-1}. This degradation rate is a contributor towards the overall voltage degradation agglomerated from each individual module's outcome.

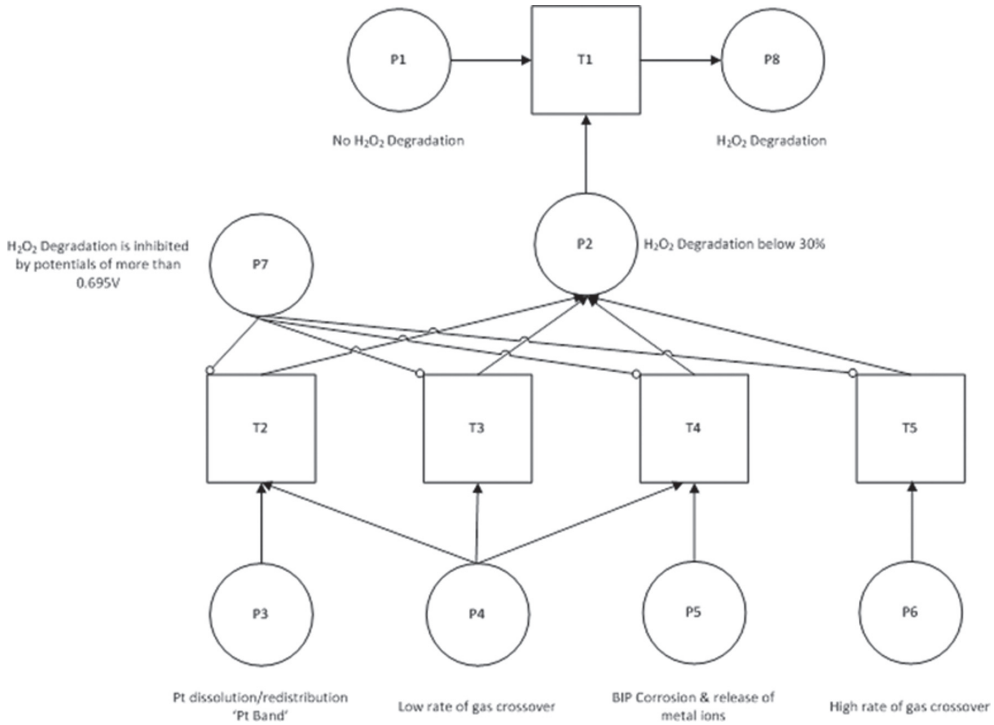

Figure 4. Example of H_2O_2 degradation module Petri-Net.

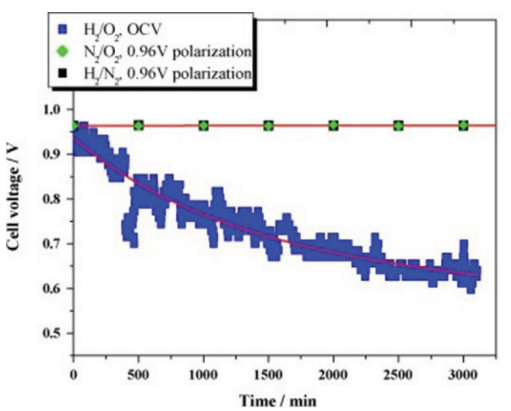

Figure 5. H_2O_2 performance degradation at OCV (Tang, et al, 2007).

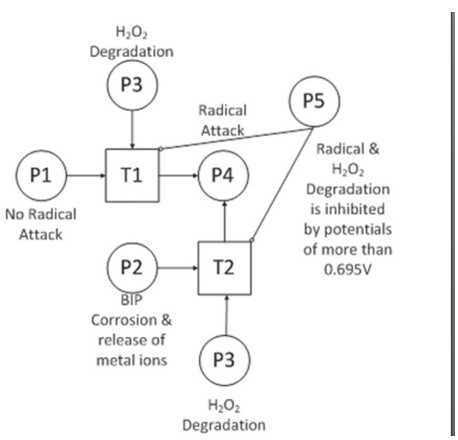

Figure 6. Example of radical attack module Petri-Net.

3.2.1 *Radical attack Petri-Net*

Due to the inherent chemical relationship between H_2O_2 and OH/OOH radical attack, both of these degradation Petri-Nets need to interact to form an accurate degradation model. The Petri net module developed for radical attack is shown in Figure 6.

P1 (in Fig. 6) is indicative of a state of no degradation. *T1* requires *P1* and *P3* to be enabled to fire, and will fire automatically with no delay. *P5* serves as an inhibitor using the same logic as for *P7* in Figure 4. If *P5* is disabled and there are tokens contained within *P3* and *P1*, *P4* would be enabled indicating a state of 'Radical Attack'.

P2 will become enabled via the result of the BIP degradation Petri-Net module. If *P2* is enabled, and *P3* is also, *T2* will fire automatically (as long as *P5* is not enabled), placing a token in *P4*. This will denote the state of 'Radical Attack'.

P3 in Figure 6 is the same place as *P8* in Figure 4 showing the interaction between the 2 modules. Borup, et al. (2007) suggest that radical attack greatly accelerates the membrane degradation rate. As there is no degradation rate available in the literature for radical attack, one can only assume a rate and attribute this to *P4* of Figure 5. An order of magnitude is therefore applied to the H_2O_2 degradation rate of 0.0065 Vh^{-1}, resulting in a degradation rate of 0.065 Vh^{-1} for radical attack.

3.3 *Petri-Net firing mechanism*

The firing of the Petri-Net uses the following equation:

$$M_n = M_0 + A^T \sum \tag{1}$$

where M_n is the final marking, M_0 is the initial marking, A^T is the incidence matrix for the module, and ∑ is the transition firing count vector. The relationship between A^T and ∑ is summarised in Equation 2:

$$A^T \sum = \Delta M = M_n - M_0 \tag{2}$$

For each individual Petri-Net module contained within the 'Degradation' transition of the global Petri-Net, there is a corresponding incidence matrix as in Equation 11 for radical attack degradation.

The logic behind each transition from place to place is noted in each A^T matrix for each module. A—1 indicates the taking of a token from a place, and a 1 indicates the placing of a token into that place.

3.4 *Summary of the model*

The Petri-Net degradation model developed in this work is a comprehensive model of the interactions between the previously identified failure modes in a PEMFC of standard construction. The standard construction is such that there is a PTFE based membrane, Carbon/Pt catalyst, steel BIP and carbon GDL. The individual 'degradation' modules range from relatively simple relationships with 2–3 places and a low number of transitions, to larger modules with 8 places and 8 transitions. It contains 21 separate modules that interact to both; deliver a voltage degradation value, and further interact with other failure modes.

Transition timings for the examples in Figure 4 and Figure 6 are instant, but for others could be timed or based upon enabling criteria.

4 RESULTS

The Petri-Net model was programmed in MATLAB on a desktop PC running a dual core 3.10GHz processor. The simulation model is outlined in Figure 7. The computer script is activated and the initial variables set which include operating temperature, relative humidity, number of Startup/Shutdown Cycles (SSC)s and simulation end time. This data is implicit in placing tokens in the relevant initial places, and inhibitor gates. A dynamic range of inputs can be added to have a varying input (such as temperature) over time.

The incident matrix for the Global Petri net shown in Figure 3 is then generated. This global net is then run for a preset time. The degradation transition fires on every time step initiating the

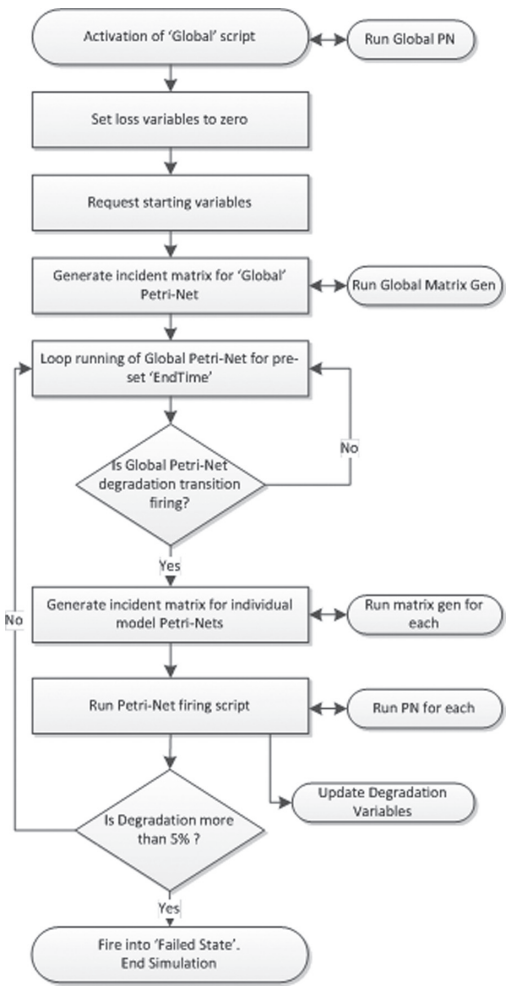

Figure 7. Flow chart of simulation running.

individual Petri Net modules for each failure mode. The incident matrices for each failure mode net are generated and run and the overall voltage degradation value is updated. For all of the individual Petri-Net models, an A^T matrix was constructed with a corresponding transition 'firing' script to use the A^T matrix information.

For each Petri-Net that has an output for which a reduction in performance is noted, a voltage drop count variable is used to store the total amount of degradation in performance due to the failure relationships. Therefore for each output place in a degradation module Petri-Net, a voltage drop figure is added to the overall voltage drop count.

Reversible events will refer back to the initial states of no degradation, and irreversible events will remain in their product states after first firing.

$$A^T = \begin{matrix} P_1 \\ P_2 \\ P_3 \\ P_4 \\ P_5 \end{matrix} \begin{pmatrix} T_1 & T_2 \\ -1 & 0 \\ 0 & -1 \\ -1 & -1 \\ 1 & 1 \\ 0 & 0 \end{pmatrix} \tag{3}$$

A check is made to determine if that degradation has exceeded the threshold of 5% as required by the US DoE. If that threshold has been exceeded then the simulation is terminated and run time logged. If it is not the degradation transition cycle continues.

4.1 *Verification of model*

SSC was chosen as a failure mode to verify initially, as this Petri-Net interaction is relatively simple, and easy to analyse for effective modelling. SSC degradation was considered through a review of the literature in this area. Hong Kim, et al. (2010) conducted extensive experimentation to reveal the relationship between SSC and degradation of fuel cell performance. Their results show that after 1500 instances of SSC, a drop in performance of 0.08 V was observed (Fig. 8). Therefore per cycle it can be considered that SSC causes a drop in performance of 5.333×10^{-5} V.

The degradation rate was programmed to take affect per SSC, through the transition T1 in Figure 9. Therefore, for each time there is an instance of SSC, a degradation rate of 5.333×10^{-5} V is applied to a voltage drop count variable.

The results of the Petri-Net model using a SSC degradation module was tested using a polarisation curve model as in Figure 8. The model shows a good replication of the polarisation curve drop observed by Hong Kim, et al. (2010) in Figure 8.

With the same logic being carried through the entirety of the Petri-Net model. Each failure mode interaction has a voltage degradation value assigned to it, with some acting reversibly dependent upon the state of the system, and some acting as a counter (irreversible).

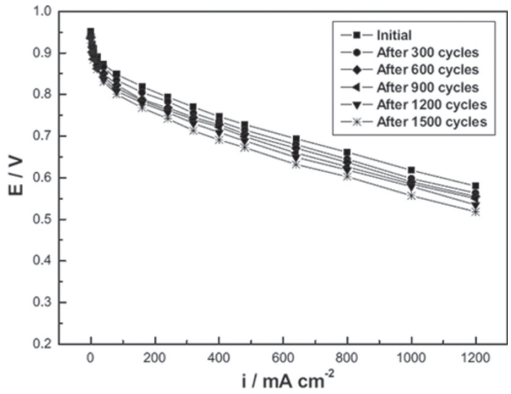

Figure 8. Startup/shutdown cycling tests (Hong Kim, et al. 2010).

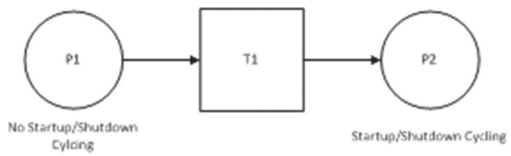

Figure 9. Startup/shutdown cycling Petri-Net.

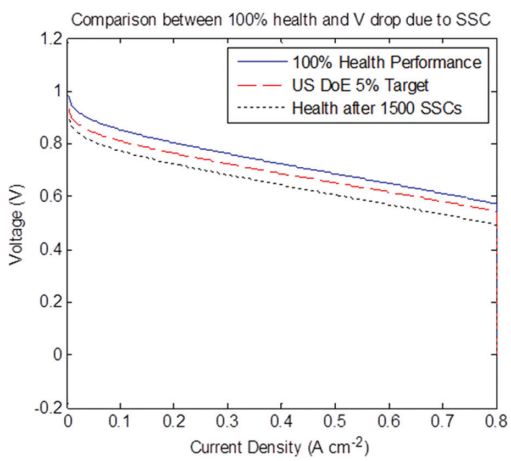

Figure 10. Result of startup/shutdown cycling 1500 cycles.

5 CONCLUSIONS AND FUTURE WORK

The presented work is a step forward in degradation and reliability modelling of PEMFCs.

The previous work by the authors leading to this has ensured that the Petri-Net model proposed, is reliably constructed based upon an in-depth, and up-to-date review of PEMFC failure phenomena. The failure logic is sound based upon current literature. However, if further interactions or modules are discovered that need to be added, the Petri-Net model can easily facilitate this occurrence, with a simple addition to the script files.

A lumped parameter PEMFC model is used to validate voltage degradation predictions against observed degradation from the literature. Additionally it can be used to integrate the degradation model and therefore have a more accurate relationship between degradation and operational performance. As can be seen in Figure 8 & 10, the initial activation range of the polarisation curve does not match up correctly.

Due to the fuel cell model developed, this area can be modified due to SSC and take into account degradation in different regions of the polarization curve through an integration the two models. The result would be capable of plotting polarisation data from key operational inputs of the polarization model, fed into the degradation model.

Currently the degradation model needs operating data in the form of initial inputs from the user. That is to say that operating voltage is set from the outset. Integration into a PEMFC performance model will allow the performance model to output operational data into the degradation Petri-Net model for its inputs. Then after running the Petri-Net model, the outputs would feed back into the performance model. As the process continues, degradation, and its effect on the performance of the cell can be accurately ascertained. Not only does integration with a PEMFC performance model mean more accurate degradation modelling, it also means that PEMFC operational load levels (such as drive cycles) can be preset, and the degradation due to the fluctuation in load (and therefore temperature etc.) can be considered.

ABSTRACT: Aiming to find out the navigation method and voyage patterns of ships in the Wuhan Yangtze River Bridge Waterway, and to provide a theoretical basis for vessel traffic flow evolution and safety risk assessment in bridge waterway, ship navigation behaviors need to be analyzed to assist in the authority supervising. The waterway around the Wuhan Yangtze River Bridge is selected, in which the ships' information is received and stored by three AIS based stations to analysis the ship navigation behaviors when passing the bridge. The characteristics of navigation behaviors are statistically analyzed with the collected AIS data, and the distribution function models for ship's behaviors are built as well as a hypothesis testing. In the meanwhile, the basic traffic trajectory of ship could be simulated to pass this bridge clearly.

1 INTRODUCTION

The inland waterway combines the inland area, coastal ports and other major cities together as a transport network (Tak and Ligteringen 2010). With the development of the waterway transport and the increasing number and carrying capacity of ships, the navigation conditions have been changed dramatically (Pan 2010). In the meanwhile, ship accidents occur frequently because of intensive traffic flow and narrow waterways (Dai 2003, Qu 2011). In China, the Yangtze River connects the eastern, the central and the western regions, and plays an irreplaceable role in supporting economic and social development along the river (Tao 2013). However, in the past decades, large areas of shoals with deposition in the Wuhan section of the Yangtze River waterway leads the central channel of the Wuhan Port to become narrower, which affects the navigable holes, worsens the navigation conditions and minifies the area of navigable channel (Ingo 2000). The Wuhan Maritime Safety Administration adjusted the bridge opening mark (lights), pillar lights and other identifiers of the Wuhan Yangtze River Bridge (Figure1) to keep navigation safety. Besides, some other factors have led the bridge to be bottlenecks in the middle reaches of the Yangtze River. The analysis of inland navigable accidents, traffic trend and traffic distribution is based on AIS information, which receives real time navigation information from AIS base stations. And it provides advice for the safety

Figure 1. The Wuhan Yangtze River Bridge.

of ship navigation in the bridge waterway (Yan 2010, Li 2007, Jin 2012, Xiao 2012).

The basic data, received from AIS stations, has been processed effectively to determine the four possible ship steering regions near the Wuhan Yangtze River Bridge. In this paper, the distribution function model for each ship steering region is built with a hypothesis testing based on the analysis of the regions.

2 DATA COLLECTING AND PROCESSING

2.1 *Data collecting*

To receive the real-time information of ships that passing the Wuhan Yangtze River Bridge, three AIS base stations (Figure 2) were installed near the waterway of the bridge.

In this paper, the data was collected during the flood period in July 2012. Due to the influence of uncertain factors in the process of transmission and reception, some information of ships were lost. Consequently, the information of 672 ships was collected, 423 of them was actually available.

2.2 *Data categorization*

From the beginning in May 2012, the water level of Hankou kept rising, the Wuhan Maritime Safety Administration adjusted the navigable holes of the bridge in order to ensure the navigation safety of ships in the waterway near the Wuhan Yangtze River Bridge. After that, the 4th navigable hole replaced the 5th for the upstream ship, while the 6th navigable hole remained the same. At the same time, the 2nd navigable hole was opened for ferries, and also the culverts standards (lights), pillar lights were adjusted accordingly.

Figure 2. AIS base station.

Depending on the different navigable holes for ship navigation, itineraries are divided into three categories: the 2nd navigable hole for upstream ferries, the 4th navigable hole for normally upstream ships and the 6th navigable hole for downstream ships. The ratio of them is shown in Figure 3.

As can be seen, the ratio of the first kind of ship itinerary is 8.75%, the second is 46.81%, and the third is 44.44%. That is, a few ships navigate through the 2nd navigable hole to pass the bridge. Therefore, the 2nd navigable hole is not taken into account.

In Wuhan section, the course angle of the downstream ship is in [0°, 90°], while that of the upstream ship is in [180°, 270°]. Combing with latitudinal and longitudinal location where the ship is, the itinerary has been identified. The 423 ships available are selected to study, and 235 of them are upstream ships, 188 of them are downstream ships. The distribution of ship itineraries is shown in Figure 4.

As is shown, the ship itineraries are almost straightly when passing the 2nd and the 6th, while the ship itineraries of the 4th have been changed obviously. As a result, curvilinear itineraries are

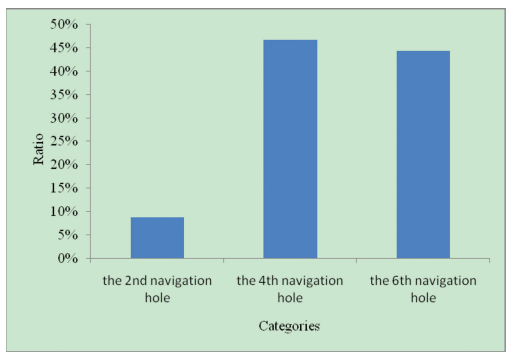

Figure 3. Ratio of three categories.

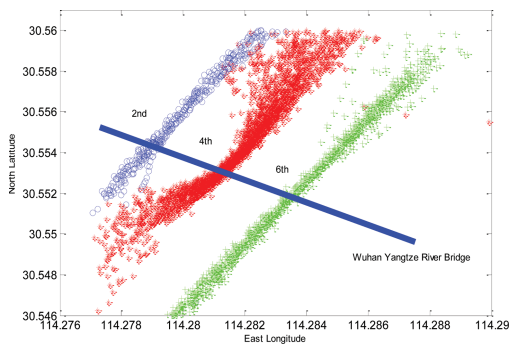

Figure 4. Ship itineraries distribution of the selected data.

formed because of ship navigation behaviors. Therefore, this paper mainly deals with the information of ships that go through the 4th navigable hole to pass the bridge.

2.3 *The first selection of data*

As is shown in Figure 5, the upstream ship that through the 4th navigable hole is generally sailing in tranquil flow at edge of the fairway before region A. After getting closed to the navigable hole, the ship's position will be adjusted gradually because of the navigation behaviors in region A during a period of time. When the ship navigates into region B, the first positional adjustment has been completed, and ship will be back to keep straightly navigating into region C for passing the bridge. Then the position will be adjusted again and approaching to the region D. Finally, the ship returns to navigate normally.

It is possible for the upstream ship to steering within region A, B, C and D. When a ship navigates through the bridge, the curvilinear itinerary will be formed because of the ship's navigation behaviors within A, B, C and D four regions. According to the pattern of ship's navigation, the points within region A, B, C and D will be selected. Taking region A as an example, when a ship navigates straightly before region A, and it will navigate into region A next, the slope of ship trajectory will be changed significantly, and it can be calculated as follow.

$$k = \frac{\Delta_{lat}}{\Delta_{lon}} \tag{1}$$

where Δ_{lat} = latitudinal variation value; and Δ_{lon} = longitudinal variation value.

To judge the ship is navigating normally when the slope changed significantly, a constraint is added as follow.

$$\Delta_1 \times \Delta_2 > 0 \tag{2}$$

The constraint is used to ensure that the direction of changed slope of ship itinerary keeps consistent when ship is navigating, and also delete abnormal points caused by position drift.

$$\begin{cases} \Delta_1 = k_{i+1} - k_i \\ \Delta_2 = k_{i+2} - k_{i+1} \end{cases} \tag{3}$$

Where k_i = the rate of slope in i-th ship's position.

2.4 *The second selection of data*

The emergence of redundant points is inevitable, though we have done our best to reduce that. The positional points within A, B, C, and D four regions are selected roughly by using the first selection method. Consequently, the result is not accurate for our study. Hence, the data should be selected for the second time. As is shown in Figure 5, the slopes of region A, B, C and D have been changed significantly during a period of time when a ship navigates into the waterway. Then the first point of the slope is regarded as available, thus deleting other points which are accordance with the first selection method. Similarly, the points within region B, C and D are selected. Putting the positional points into 8 independent regions to analyze the navigating behaviors of ship.

3 DISTRIBUTION OF SHIP POSITON

3.1 *Distribution function model and hypothesis testing*

After completing data classification, distribution models are built through analyzing frequency histogram of each region, and verified through the t-test. The result is shown as follows.

The longitudinal distribution of region A is shown in Figure 6.

The longitudinal distribution of region A obeys the normal distribution. Through t-test, the

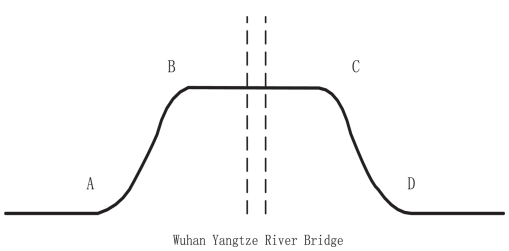

Figure 5. Ship trajectory in special region.

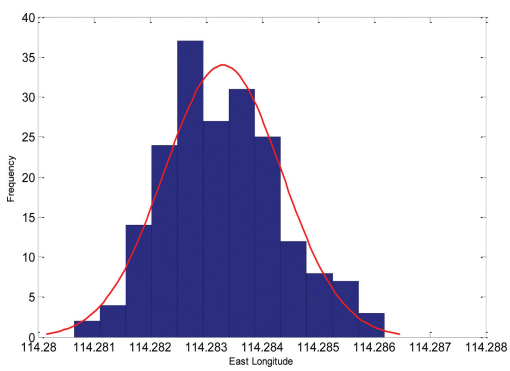

Figure 6. Longitudinal distribution of region A.

value of expectation μ = 114.2833, "the variance σ = 0.0011" the confidence coefficient above 95% is [114.2832; 114.2835]

The latitudinal distribution of region A is shown in Figure 7.

The latitudinal distribution does not obey the normal distribution in region A. On the basis of observation, the linear equation is fitted by using the method of linear least squares.

$$y = 0.0505312 \times 10^5 \times x - 1.5438476 \times 10^5 \quad (4)$$

Where x = the latitudinal average of region A in a range of frequency, and y = the frequency accordingly.

The longitudinal distribution of region B is shown in Figure 8.

The longitudinal distribution of region B obeys the normal distribution. Through t-test, the value of expectation μ = 114.2822, the variance σ = 0.00091, the confidence coefficient above 95% is [114.2821; 114.2823].

The latitudinal distribution of region B is shown in Figure 9.

The latitudinal distribution of region B obeys the normal distribution. Through t-test, the value of expectation μ = 30.5547, the variance σ = 0.0014, the confidence coefficient above 95% is [30.5545, 30.5549].

The longitudinal distribution of region C is shown in Figure 10.

The longitudinal distribution of the ship when it navigates into region C obeys the normal distribution. Through t-test, the value of expectation μ = 114.2811, the variance σ = 0.00096, the confidence coefficient above 95% is [114.2810, 114.2813].

The latitudinal distribution of region C is shown in Figure 11.

The latitudinal distribution of region C obeys the normal distribution. Through t-test, the value of expectation μ = 30.5531, the variance σ = 0.0012, the confidence coefficient above 95% is [30.5529, 30.5533].

The longitudinal distribution of region C is shown in Figure 12.

The longitudinal distribution of the ship when it navigates into region D obeys the normal distribution. Through t-test, the value of expectation μ = 114.2798, the variance σ = 0.0012, the confidence coefficient above 95% is [114.2796, 114.2799].

The latitudinal distribution of region C is shown in Figure 13

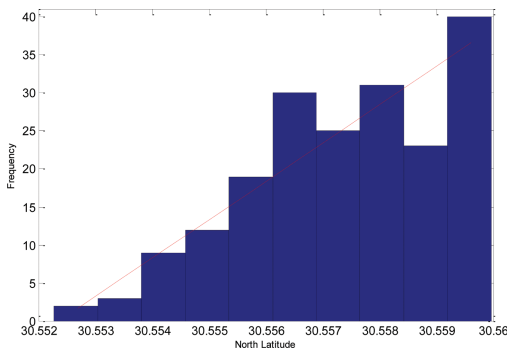

Figure 7. Latitudinal distribution of region A.

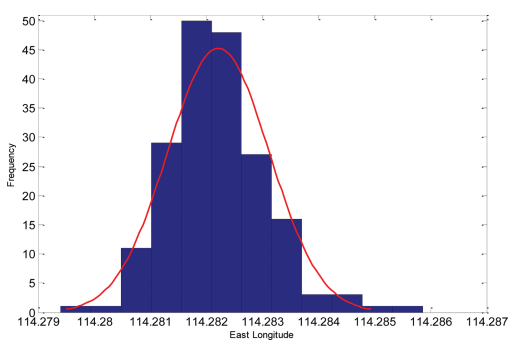

Figure 8. Longitudinal distribution of region B.

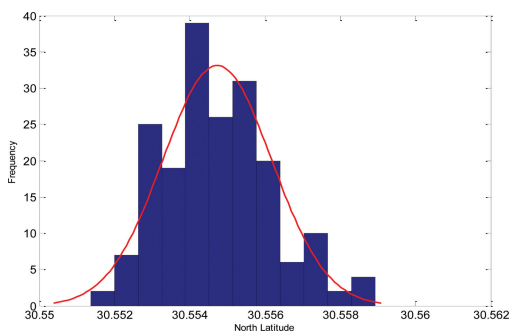

Figure 9. Latitudinal distribution of region B.

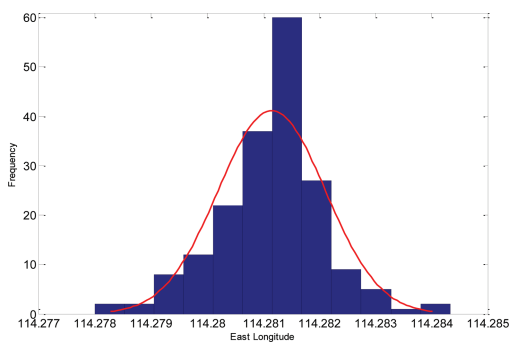

Figure 10. Longitudinal distribution of region C.

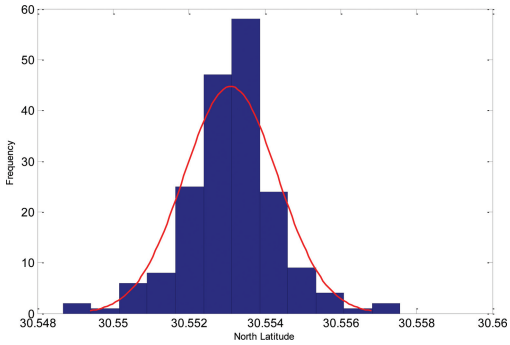

Figure 11. Latitudinal distribution of region C.

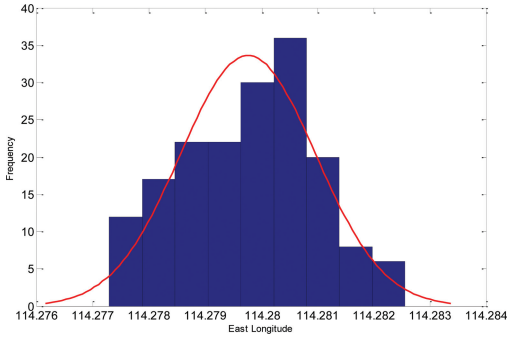

Figure 12. Longitudinal distribution of region D.

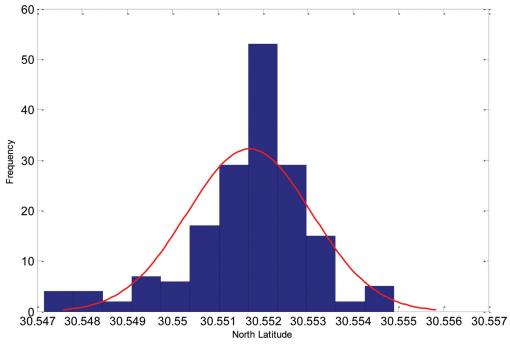

Figure 13. Latitudinal distribution of region D.

The latitudinal distribution of region D obeys the normal distribution. Through t-test, the value of expectation $\mu = 30.5517$, the variance $\sigma = 0.0014$, the confidence coefficient above 95% is [30.5515, 30.5519].

3.2 *A ship-bridge behavioral simulation case*

The simulation data is generated from the longitudinal and latitudinal distribution models, and the result is shown in Figure 14.

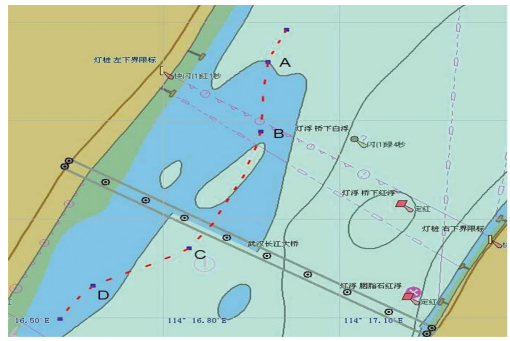

Figure 14. A simulation example.

As is shown, the trajectory is in accordance with the positions of ship steering regions as well as the special location distribution of ship navigation behaviors.

4 CONCLUSION

Upstream and downstream ships go though the Wuhan Yangtze River Bridge from three navigable holes. In order to analyze the navigation method and voyage patterns of ship, AIS information is received from three AIS base stations to analyze the ship navigation behaviors. The paper statistically analyzes the AIS data of ships which go through the Wuhan Yangtze River Bridge, and find out four possible regions for the ship navigation safety. The distribution function models are built and verified by using the t-test. The result shows that only the latitudinal distribution of region A obeys the least squares linear distribution, while the longitudinal and latitudinal distribution of other regions obeys the normal distribution. Finally, simulation is based on the distribution models to verify the models for ship navigation behaviors, which provides a kind of navigational route for the crews to ensure the navigation safety in this waterway.

ABSTRACT: The methodology for availability assessment of complex systems accounting for load sharing configurations with overcapacity and flexible work levels, allow the possibility that all the equipment have different failure behavior. This methodology is based on event space method, considering the matrix modeling for multistate and dynamic impact evaluation, and the result is expressed as an equivalent availability. At the literature there are models that develop the overcapacity problem, but only for identical equipment and without the multistate work level; others allow the modeling of multistate characteristic but avoid the overcapacity evaluation. This situation is commonly present in continuous process industries with important transportation systems, like mining, steel, paper and wood. The case study based on mining trucks availability modeling to optimize the fleet sizing, show the benefits and summarizes the application, obtaining relevant results to develop a expedite decision making process over reliability and availability indicators. The usage of the simulation model, as a bench tool, validated the proposed methodology.

1 INTRODUCTION

In last years, the process flexibility and productivity is a goal to improve the process efficiency and the overall company results. In this context, the dynamic systems have reached a great level of importance for the productive process modelling.

The dynamic systems are those which change in time. In the case of components and its configuration in a system, dependencies, redundancies and the load they bear, which can be shared, varies in time, that is to say, its dependency relations can change with the environment or change its ability to function in different scenarios. The modelling methods like Reliability Block Diagram (RBD) (Barlow 1996, Birolini 2004) and Failure Tree (FT) (Birolini 2004) have different limits to represent these systems, in the case of RBD it presents restrictions with respect to the dependencies and the large complex systems (Macchi 2009).

For the representation of the dynamic systems, different methodologies will be shown below.

Macchi et al. (Macchi 2014) presents a special analysis for buffer (RBD) showing the possibility to make flexible the structure for a dynamic system. Although some of these restrictions are treated by the method of Dynamic Fault Tree (DFT), particularly the shared load case is not modelled through the FT neither through the DFT[5], although have appeared tools that have enriched them, they are not represented appropriately.

A new named model dynamic reliability block diagram (DRBD), is presented by two publications, S. Distefano, L. Xing (Distafano 2006) and by Xu, L. Xing and R. Robidoux 2009 (Xu 2009) both of

them present two ways of applying and schematize the DRBD, though in both is L. Xing, the last one presents a simpler way than the first work.

S. Distefano, L. Xing (Distefano 2006), introduce some features that may be of special interest, as three patterns of state stand-by and three types of dependency. If one component depends on various other components it can produce an attendance conflict which is solved by a discrimination manner due to a hierarchical level of priorities.

For the analysis of one DRBD there are various alternatives within the literature (Manian 2006, Trivedi 1996, Trivedi 1996, Trivedi 1996):

1. Markov Chains: Where the limit are the few reliability distributions that can be analyzed.
2. Petri nets: Where the redundancies and shared load are tailored.
3. Simulations: Where any distribution can be tailored, Montecarlo technique is one of the most ex-plored.

The other way to present DRBD is one introduced by H.Xu, L. Xing and R.Robidoux 2009 (Xu 2009) previously worked only by the first ones in 2007 (Haiping 2007) where show the DRBD as a system that tailor and catch the dynamic relations between components as dependence states as well as redundancy state, they suggest a simple way and tailor a particular case. For checking, it is transferred to a Petri net model colored by a software support which certifies the correct design of the DRBD.

With respect to works related with resolutions of systems availability of shared load, solved by Mar-kov chains, we can find Shendao et al. (Shengdao 2005), where though there are variable failure rates in time, we find again the explosion state-space. It is calculated the availability of a charge load system with variable failure rates solving different equations, however it is required algebraic operations that depend of the size of the system, since for large systems it becomes a huge problem.

Akthar (Akthar 1994) also contributes respect to this same resolution method, although he considers identical equipment, he adds a new feature, cover the failure in an imperfect manner (that is to say there are failures that are impossible to repair).

Due to the inexistence of description of divided systems, it will be used as basis the system k-out-of-N:G/Load Sharing described in the bibliography and that will have the divided load characteristic.

One of the advances in the model system with DRBD and its validation it is made by Distefano and Puliafito (Distefano 2009) where they analyze three study cases, however, although they make great advances, these must be translated to the OPENSesame system to be validated, where some features cannot be introduced and there appears the lack of a special software.

Similar to the above is what considers Scheuer (Scheuer 1988), who studies the reliability for a k-out-of-n:G system where he holds that in basis to previous studies made by Kapur and Lamberson (Karpur 1997) that when there is a component failure, then there is a higher failure in the surviving ones, however it is for identical components with constant failure rates, similar to made by Shao & Lamberson (Shao 1991) where it is also used identical components but with an imperfect switching and it is used for few components due to it is carried out in Markov chains basis.

Jenab y Dhillon (Jenab 2006) grant a form to analyze not only the reliability and availability of a k-out-of-n system but also for reversible multistate systems, that is to say they can change from state i to i+1 in addition it gives the suggestion that all the compo-nents are identical and independent. Something at a short rate but similar to the former study is made by Hasset, Dietrich and Szidarovsky (Hessett 1995) who investigated the reliability and availability of systems 1 of 2 reparable, both components statistically identical with variable failure rate.

On the other hand, Liu (Liu 1998) introduces a pattern to calculate the reliability of shared load systems k-out-of-n, with non-identical components and general distributions (Weibull, Gaussian, lognormal and Gamma), something similar to intended to do, however due to complex scenario and suggested solution, is not possible the resolution for n> = 5 and with k n-3, however taking these elements, is probable to have some results for higher n.

Amari et al. (Amari 2007) develop a solution through Markov chains where it is indicated that the maximum of the components must be 16, nevertheless they analyze a problem of maximum three components, although tips are given to increase the efficiency of the computational resolution. It applies for exponential distributions and for general distributions, is possible to indicate the suggestion that all failure rates are the same when these vary with t time when elements j fails. Nevertheless this choice can be viable with respect to the problem set up, it considers that the load is delivered in the same way on the surviving elements, something that is not sure to happen due to the capacity of each one and though certain rules of the shared load could relax, we can indicate that when the components are not identical each sequence of failure must be analyzed separately and yet this must be studied for the general case.

2 PROBLEM STATEMENT

Transport systems are characterized usually for its flexibility, huge quantity of equipment and application. In effect the feature of load sharing, allows obtaining the required capacity on the basis of the sum of the available equipment even operating in a lower load than required. The case of overcapacity is characterized by having more capacity installed than required, by which there exists a series of combinations that allow satisfy the required capacity. The above condition requires that the equipment can operate at different work levels. As a conclusion of this problem, we can set up that the impact of each component is variable and depends on its required load as well as its reliability and maintainability behavior, as so also of the characteristics of each one of the equipment that constitutes the system. For the previously situation mentioned above, the availability assessment is a complex system to carry out and follow up it is proposed a methodology for its validation.

3 PROPOSITION FOR METHODOLOGY

Here is present the proposed methodology together with defined variables

i. Variables and Nomenclature
ii. Modeling

Assumption 1:

All equipment in the systems has two possible operating states, (1) operating, (0) unavailable. Under the assumption 1, the first step is to obtain all the possible combinations of operating states,

Table 1. Glossary.

Id	Description
E	set of equipment
nE	$\|E\|$ total number of equipment
i	index of equipment $\in \{1, \ldots, n_E\}$
S	set of operating states of the system
nS	$\|S\|$ total number of possible operating states of the system
j	index of operating states $\in \{1, \ldots, n_S\}$
A	Availability
C_S^R	system required capacity
C^{Max}	maximum capacity
C^A	Available capacity
C^O	Operating capacity
P^A	Availability-based probability
I	Impact
δ	Matrix of possible combinations of operating states
n_{zeros}	Number of zeros $\in \{1, \ldots, n_E\}$

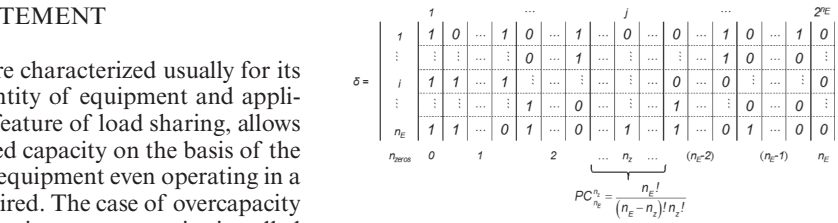

Figure 1. Possible combinations of operating states.

given the total number of equipment in the system. As the operating states are binary, the total number of operating states of the system is 2^{nE}.

Considering one operating state combination $j \in \{1, \ldots, 2^{nE}\}$ of the system, the corresponding binary variables to visualize the individual operating state of each equipment are defined as follows:

$$\delta_{ij} = \begin{cases} 1 & \text{if equipment i is in operating state} \\ 0 & \text{if equipment i is unavailable} \end{cases} \quad \forall i \in \{1, \ldots, n_E\} \tag{1}$$

From the matrix δ, we obtain the available capacity for each operating state combination:

$$C^A{}_j = \sum_{i=1}^{n_E} \delta_{ij} \times C^{\max}{}_i \quad \forall j \in \left\{1, \ldots, 2^{n_E}\right\} \tag{2}$$

Assumption 2:

Given a systemic operating state j, the proportion between the operating capacities of the corresponding equipment $C^O{}_{ij}$ and the maximum equipment capacity $C^{\max}{}_i$ must be the same for all equipment.

To determine the final impact of each equipment, we need to identify the systemic operating states j for which the available capacity of the equipment is less or equal than the required capacity of the system (otherwise the impact is defined *0* since the system is able to satisfy the requirement of capacity).

Then, we define the binary variable ω_j as follows,

$$\omega_j = \begin{cases} 1 & C^A{}_j \geq C^R{}_S \\ 0 & Otherwise \end{cases} \quad \forall j \in \left\{1, \ldots, 2^{n_E}\right\} \tag{3}$$

Then, the operating capacities of the equipment $C^O{}_{ij}$ are:

$$C^O{}_{ij} = \frac{\left(\omega_j \times C_S{}^R + \left(1 - \omega_j\right) \times C^A{}_j\right) \times \delta_{ij} \times C_i^{\max}}{C_i^{\max} + \sum_{k=1 \wedge k \neq i}^{n_E} \delta_{kj} \times C^{\max}{}_k} \quad \begin{array}{l} \forall i \in \{1, \ldots, n_E\}, \\ j \in \left\{1, \ldots, 2^{n_E}\right\} \end{array} \tag{4}$$

When the calculation of the impacts is applicable ($C^R{}_S > C^A{}_j$), the systemic operating state $j = 1$ for which all the equipment are in operating state is considered as the state of reference. The objective is to determine the loss of capacity that the unavailable equipment produces over the system as a function of the operating capacity if that equipment were operating. The formulation of the impact is:

$$I_{ij} = \begin{cases} \dfrac{\left(C^R{}_S - C^A{}_j\right) \times \left(1 - \delta_{ij}\right) \times C^O{}_{i1}}{C^R{}_S \times \sum_{k=1}^{n_E} \left(1 - \delta_{kj}\right) \times C^O{}_{k1}} & C^R{}_S > C^A{}_j \quad \forall i \in \{2,...,n_E\}, \\ & \qquad j \in \{2,...,2^{n_E}\} \\ 0 & Otherwise \end{cases} \tag{5}$$

Assumption 3:

Under systemic operating state $j = 1$ the required capacity is always satisfied.

Then, the availability-based probability of each systemic operating state is defined as follows:

$$P_j{}^A = \prod_{i=1}^{n_E} A^{\delta_{ij}}{}_i \times \left(1 - A_j\right)^{\left(1-\delta_{ij}\right)} \quad j \in \left\{1,...,2^{n_E}\right\} \tag{6}$$

Finally, the weighed impact for each equipment, considering all the possible combinations for the system operating state is:

$$I_i^W = \sum_{j=1}^{2^{n_E}} P_j{}^A \times I_{ij} \quad i \in \{1,...,n_E\} \tag{7}$$

4 CASE STUDY

A company of the great copper mining in Chile requires a transport of an average of 5,200 tons each hour (C_S^R), from the mine to the concentrated plant. This material has between 0.5–1.1% of copper. The transportation system is composed by 20 trucks, of 4 different models, for capacity, manufacturer and antiquity. For each truck, in an independent way, it has obtained its reliability and maintenance data, calculating its main maintenance indexes like: MTBF (Mean Time Between Failure) and MTTR (Mean and Time to repair) respectively.

The expected Availability (A_i) is calculated as shown on equation 8. (Sharma 2008):

$$A_i = \frac{MTBF_i}{MTBF_i + MTTR_i} \tag{8}$$

The Table 2 summarizes the information obtained for each truck and includes the analysis of the individual availability.

As deducted from the information presented, the maximum capacity of the system C^{max} is of 5.590 tons, corresponding to the addition of each individual capacity, which indicates that there is a load sharing system with overcapacity. Additionally, checking the reliability information we can establish that all the equipment has different data and its capacity is in relation with the type classification.

As mentioned above, it can be validated that we are in presence of a load sharing system, overcapacity and flexible work level.

To P_{system}^A (Availability-based probability) determination will use the methodology proposed on point 3.

As first step, the total number of operating states is 1,048,576 states. For example, the state number 96,800 is characterized by 12 available trucks (1, 2, 3, 4, 5, 7, 9, 11, 13, 15, 17, 19), that appears with "1"; and 8 unavailable trucks (6, 8, 10, 12, 14, 16, 18) that appears with "0". In this step, the available capacity is 3,380 tons, that represents an P_j^A equal to 0.6047, as the system has an availability of 60.47% of the time, but this state has only a 3,428E-09 of occurrence probability.

Consolidating the results of each of the 1,048,576 states, the global results obtained indicates an P_{system}^A equal to 0.8955, as the system in each impact over P_{system}^A.

Scenario1: Base case has an equivalent availability of 89.55%.

2.1 *Sensibilization analysis*

- To evaluate and sensibilize the results of the base case, 4 scenarios of improvement will design through the acquirement of new equipment, evaluating
- Scenario 2: Acquisition of 2 new Trucks-Type A (the data given is of the best of the type, which is N°4)
- Scenario 3: Acquisition of 2 new trucks Type B (the data given is of the best of the type which is N°7)
- Scenario 4: Acquisition of 3 new trucks type C (the data given is one of the best of the type, which is N°17)
- Scenario 5: Acquisition of 3 new trucks Type D (the data given is one of the best of the type which is N°20).

The results obtained are shown as follows:

The analysis of the results is very interesting, it is established that the only important is not the number of trucks and the C^{MAX} for the increasing of P_{system}^A, but also the specific values of the A_i of the added equipment, have a relevant impact over the system indicator.

Table 2. Reliability and availability data.

Truck	Type	Capacity (tons)	MTBF	MTTR	Ai
1	A	300	156,4	23,2	0,8708
2	A	300	173,2	26,4	0,8677
3	A	300	168,4	22,5	0,8821
4	A	300	177,3	19,8	0,8995
5	B	350	116,3	27,3	0,8099
6	B	350	125,9	24,1	0,8393
7	B	350	148,7	26,5	0,8487
8	B	350	112,6	30,8	0,7852
9	B	350	151,8	28,5	0,8419
10	B	350	127,3	34,1	0,7887
11	C	220	188,4	14,3	0,9295
12	C	220	178,3	17,5	0,9106
13	C	220	182,9	12,6	0,9355
14	C	220	167,2	11,6	0,9351
15	C	220	159,3	18,4	0,8965
16	C	220	174,2	15,9	0,9164
17	C	220	183,3	9,6	0,9502
18	D	250	203,6	14,6	0,9331
19	D	250	208,5	17,4	0,9230
20	D	250	210,6	13,7	0,9389

Table 3. Scenarios results for the indicator P^{A}_{system}.

Id	Esc 1	Esc 2	Esc 3	Esc 4	Esc 5
C^{R}_{S}	5,200	5,200	5,200	5,200	5,200
C^{MAX}	5,590	6,190	6,290	6,250	6,340
P^{A}_{system}	0.8955	0.9247	0.9220	0.9336	0.9408

To validate the results obtained for the P^{A}_{system}, it was developed a simulation method Montecarlo in order to calculate the availability (Khan 1995). The base for simulations is the states that equipment can take, as described in the Modeling Assumption 1. For this effect, simulations with 100,000; 200,000; and 300,000 iterations are developed with the objective of evaluate the impact of each model over the analytic resolution.

As we can appreciate in the Fig. 2 the deviations obtained respect to the analytic value are extremely low, the maximum deviation is for the Scenario 1 with the model of 100.000 iterations achieving only 0.067% which indicates a high grade of precision of the availability values P^{A}_{system}

To evaluate each one of the models in a more precise way, it is developed the analysis of the absolute deviation, in this case the mean values are:

As we can appreciate in the Fig. 3, increasing the number of iterations the MAD decreases, which implies that the proposed value for P^{A}_{system} as also its methodology of calculus have been validated.

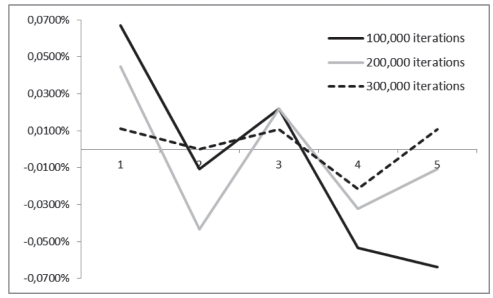

Figure 2. Bench tool deviation from analytical system availability.

Table 4. MAD evaluation for simulation.

Test	Mean Absolute Deviation MAD
100,000 iterations	0.043%
200,000 iterations	0.031%
300,000 iterations	0.011%

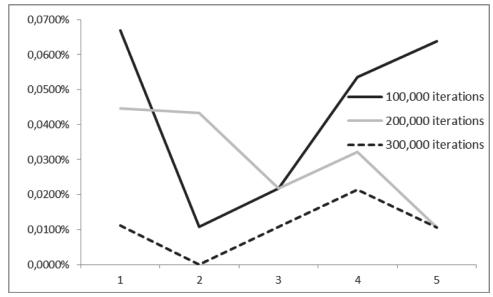

Figure 3. Bench tool absolute deviation from analytical system availability.

5 CONCLUSIONS AND DISCUSSION

It was effectively generated a methodology for the availability assessment of complex systems accounting for load sharing configurations with overcapacity and flexible work levels, presenting its understanding and proving its application in a practical case obtaining positive results in both cases.

In order to implement and compare the results it was developed the analytic application of the methodology with a sensible analysis and with improvement scenarios.

As a result of the earlier, we can establish that the proposed methodology has been validated through the comparison with simulation model such as bench tool since the detected differences between both models exceed a MAD 0.011% for the model with 300.000 iterations.

The case study through the evaluation of the five scenarios (basis case and four of improvements) permits the evaluation of the real impact of rising up the quantity of trucks for the process. The comparison between the scenario 2 and scenario 3 shows that not always the increasing of capacity obtains results in the availability assessment of the system.

In that case there is more impact about the quality of improvement, associated to the availability of the trucks, than the quantity associated to the capacity of the trucks.

Indubitably, we can conclude that the methodology developed is a contribution to model the availability of systems of transport, suggesting an analysis of the evaluation of her, flexible and precise.

As a future step, is thought the possibility to incorporate economic variables to evaluate the scenarios and in this way to determine the profits in the OPEX through the improvement of the availability, versus the costs included in the CAPEX in order to finance these projects.

Life distribution and P-S-N curve analysis of TC21 titanium alloy joint with Electron Beam Welding in ultra-high cycle fatigue regime

Z. Zhiteng, D. Shu, Z. Liang & X. Danjun
China Academy of Aerospace Standardization and Product Assurance, Beijing, China

ABSTRACT: In this paper, ultrasonic fatigue life of TC21 titanium alloy joints with Electron Beam Welding (EBW) was tested at 10^6~10^9 cycles and the life distribution and P-S-N curve of the fatigue life were analyzed based on the study of crack initiation sites. The results show that fatigue failures of the welding joints still take place after 10^7 cycles. SEM observation of fracture surface indicates that the crack initiation sites abruptly shift from surface to interior welding defects of the specimen with decreasing the stress amplitude. Kolmogorov criterion indicates that the fatigue life at a certain stress level submits log-normal distribution and the dispersity for internal crack initiation fatigue life is much smaller. Maximum likelihood fitting method is used to analyze P-S-N curve at 10^6~10^9 cycles of the EBW joints considering fatigue life distribution, having important significance for life prediction and reliability design of engineering welding parts with very long life.

1 INTRODUCTION

TC21 is a kind of titanium alloy with high strength and good mechanical properties, mainly applied on aerospace structures as well as bearing components for high strength and durability requirements. Due to high energy density, small welding deformation, flexible processing parameters, vacuum welding environments and other advantages, Electron Beam Welding (EBW) is widely used in aviation, aerospace and industrial manufacturing. In welding structures, fatigue failure modes account for 70% to 80% of structural metal failure accidents. During the longtime service of space structures, some components are subjected to fluctuating and cyclic load, and the service lives are even greater than 10^7 cycles. Recent studies using ultrasonic test systems have shown that many materials including some steels and titanium alloys exhibit a sharp decrease in fatigue strength between fatigue lives of 10^7 and 10^9 cycles, which is in contrast to the classical concept of fatigue limit. It is clear that a large decrease in fatigue strength in the Ultra-High Cycle Fatigue (UHCF) regime could have great impact on spacecrafts design. So traditional fatigue design is incorrect and even unsafe, which can't satisfy the long life and high reliability requirements of welding structures. However, the fatigue tests with weld joints of titanium alloy in the ultra-high cycle fatigue region (10^7~10^9) are rarely reported, so it is necessary to study the ultra-high cycle fatigue properties of weld joints. In this paper, ultrasonic fatigue life of TC21 titanium alloy joints with EBW was tested at 10^6~10^9 cycles and reliability of the fatigue life was analyzed based on the study of crack initiation sites.

2 MATERIALS AND EXPERIMENT

The titanium alloy investigated in this study, has a nominal chemical composition (by wt %) of 6.26Al, 2.13Zr, 2.38Mo, 0.96Cr, 1.84Nb, 1.87Sn and balance Ti. The static tensile properties of TC21 alloy and weld joint are shown in Table 1. The base metal microstructures were obtained by two thermal treatment procedures. The thickness of TC21 plate used for EBW is 10 mm and the weld width is 5~8 mm. The parameters of EBW are as follows, accelerating voltage 150 kV, focusing current 2100 mA, electron beam current 90 mA, welding speed 300 mm/min. Figure 1 shows the microstructures of the weld joint. As is shown in the microstructure, the weld joint consists of Fusion Zone (FZ), Heat Affected Zone (HAZ) and Base Metal (BM). Further details of the heat treatments and

Table 1. The tensile property of TC21 sheet and weld zone.

Material	Tensile strength (MPa)	Yield strength (MPa)
TC21 sheet (BM)	1220	1100
Weld zone of EBW	1280	1120

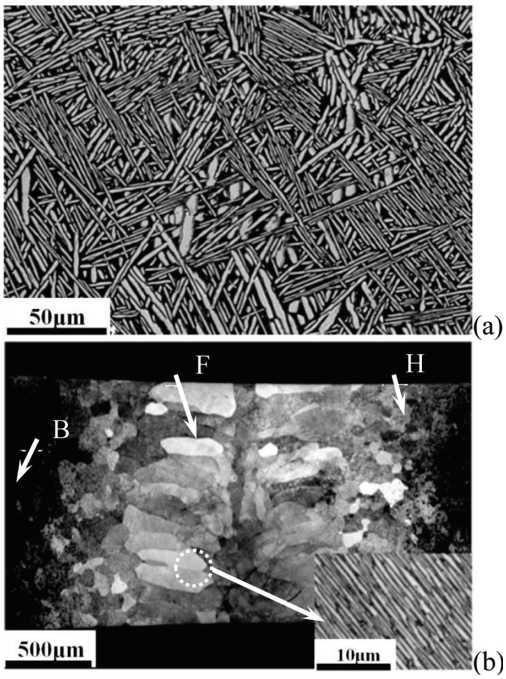

Figure 1. Microstructures of TC21 joint (a) base metal and (b) weld zone.

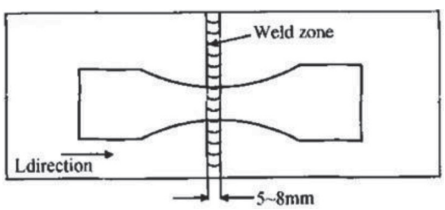

Figure 2. Sampling schematic of TC21 weld plate.

descriptions of microstructure can be found in the references. Fusion zone is the weakest part of the weld joint because of metallurgical defects, and the fatigue crack initiates from this site easily.

The way for fatigue specimens interception as shown in Figure 2 is perpendicular to the weld direction. And the shape and dimension of the specimens for ultra-high cycle fatigue testing is shown in Figure 3. The specimens were fine ground and polished after machining.

Fatigue testing was conducted on Shimadzu USF-2000 testing system with the resonance frequency of 20 kHz, resonance interval of 200 ms, stress ratio of R = −1 and at room temperature in air. During fatigue testing, the specimens were cooled by compressive air. The pause load and compressive air were chosen such that heating of

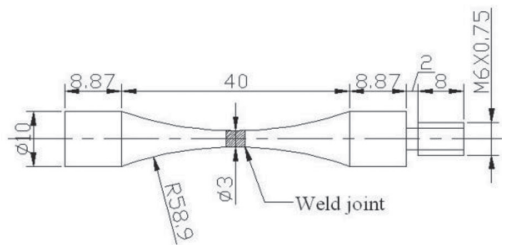

Figure 3. Size and shape of specimen for ultra-high cycle fatigue.

the specimen by internal friction was avoided or much reduced. Details of the ultrasonic fatigue testing procedure and system are described in elsewhere. Scanning Electronic Microscopy (SEM) observation was performed to study the fatigued fracture surface and to determine the fatigue crack initiation sites.

3 RESULTS AND DISCUSSION

3.1 *Characteristics of S-N curve and fatigue crack initiation*

As is shown in Figure 4, the S-N curve decreases continuously and turns less sharply at about 5×10^7 cycles, therefore no horizontal asymptote exits and the fatigue limit is not able to be determined. The fatigue strengths determined using staircase method are 256 ± 10 MPa for the weld joints.

In the fatigue damage stage, cyclic stress attacks both surface and internal defects, and it is considered that the site which is selected for main crack initiation is always competitive and depends on the size of the potential sites and the stress level. SEM investigations show that there is a transition of crack initiation from surface to interior welding defects at the stress 350 MPa, as shown in Figure 4. At high stress level, the fatigue crack occurs on the surface of specimen. However, at lower stress amplitude, internal fatigue cracks were observed. Figure 5 shows examples of surface and internal crack initiation in specimens.

3.2 *Probability distribution of fatigue life in ultra-high cycle fatigue regime*

A large number of experiments show that fatigue life in high cycle regime (10^4~10^6) submits the log-normal distribution, but less research on probability distribution of fatigue life in ultra-high cycle regime. In order to make the fitting of P-S-N curve with TC21 titanium weld joints more logical, generally, we assume that the fatigue life submits the

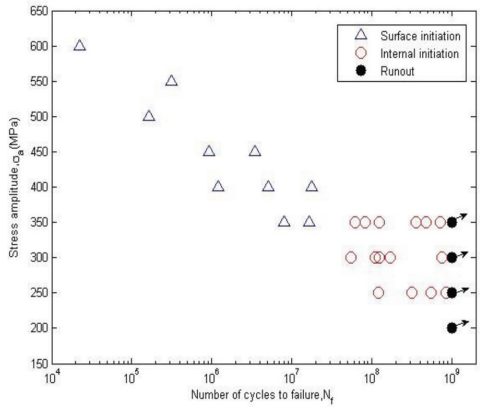

Figure 4. S-N curve for TC21 weld joints.

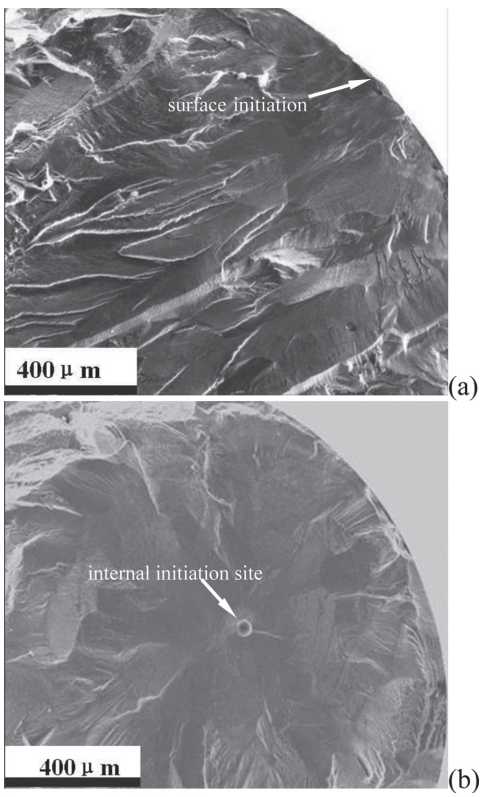

Figure 5. SEM images of fatigue crack initiation sites (a) surface and (b) internal pore.

lognormal distribution, otherwise many work can't be continued. Therefore, lognormal distribution hypothesis testing should be used to test fatigue life distribution under certain stress level in ultra-high cycle regime. Since the purpose of the study is to verify whether the life population submits the lognormal distribution, we start the work from parameter estimation and then the fitting goodness test. And Kolmogorov criterion has the highest sensitivity in a variety of fitting goodness test methods, which is accordingly used to test ultrasonic fatigue life distribution under certain stress level. Due to the apparent difference of fatigue properties under different crack initiation conditions, fatigue life distributions in two kinds of circumstances (surface and interior) are discussed separately, to make the P-S-N curve suitable for fatigue design for engineering components.

3.3 *Fatigue life distribution at stress amplitude 350 MPa*

The fatigue life data obtained at stress amplitude 350 MPa are as follows ($\times 10^7$): 0.802, 1.661, 6.278, 8.324, 12.55, 35.62, 48.43, 72.34, 100 (runout), as for 0.802×10^7 and 1.661×10^7, the fatigue cracks initiate from specimens surface, the rest from interior.

Firstly, we process two kinds of crack initiation site data uniformly. In order to test the probability distribution of fatigue life, we assume that the fatigue life submits the lognormal distribution. To make the runout data ($>10^9$) available (if there is such data), maximum likelihood estimation method with curtailed time data can be used to estimate the mean and standard deviation. If n specimens are tested at a certain stress level, the curtailed time is T, the number of failure specimens is r and their lives are:

$$N_1 \le N_2 \le \ldots N_r \le T \tag{1}$$

Make $t_i = \ln N_i$ (i = 1, 2 … r), $t_T = \ln T$, then the maximum likelihood estimation model is:

$$L = \left[\prod_{i=1}^{r} \frac{1}{\sqrt{2\pi}\sigma} e^{\frac{(t_i-\mu)^2}{2\sigma^2}}\right]\left[1-\int_{-\infty}^{t_T} \frac{1}{\sqrt{2\pi}\sigma} e^{\frac{(t-\mu)^2}{2\sigma^2}} dx\right]^{n-r} \tag{2}$$

Generally, likelihood function is given by the form of natural logarithm, and the value of μ and σ can be obtained from the solution of

$$\begin{cases} \dfrac{\partial \ln L}{\partial \mu} = 0 \\ \dfrac{\partial \ln T}{\partial \sigma} = 0 \end{cases} \tag{3}$$

Then maximum likelihood estimators obtained by calculation are $\hat{\mu} = 18.7952$ and $\hat{\sigma} = 2.1090$.

Through the Kolmogorov criterion method, we can test the life data whether submits lognormal distribution or not. The Kolmogorov criterion statistic with curtailed time test is:

$$T_0 = \sup_{t \le t_T} \left| F_n(t) - F(t) \right| \tag{4}$$

where $F_n(t)$ is empirical distribution function of the sample, for sample $t_{(1)} \le t_{(2)} \le \ldots \le t_{(r)}$, the empirical distribution function is:

$$F_n(t) = \begin{cases} 0, t < t_{(1)} \\ i/n, t_{(i)} \le t < t_{(i+1)} \\ 1, t \ge t_{(n)} \end{cases} \tag{5}$$

and $F(t)$ is the theory distribution function of population.

If the significance level is α, the critical value of $T_{n,\alpha}$ satisfying the relationship $P[T_0 > T_{n,\alpha}] = \alpha$ can be calculated by the table look-up results according to test curtailed time and the number of samples.

Take the significance level as 0.1, then the calculated critical value $T_{n,\alpha}$ is 0.4444. The calculation process is shown in Table 2.

Then $T_0 = 0.1327 < T_{n,\alpha} = 0.4444$, so we can't refuse the assumption that the fatigue life submits the lognormal distribution. Therefore, the fatigue life ignoring initiation sites submits the lognormal distribution at 350 MPa.

Secondly, since there are two cases of fatigue crack initiation at 350 MPa, and most initiate from interior, so we try to make logarithmic normal distribution hypothesis test for internal initiation data independently including the runout data.

Similarly, the estimators of the mean and standard deviation using maximum likelihood estimation method for curtailed time data is $\hat{\mu} = 19.4409$ and $\hat{\sigma} = 1.3110$. And the critical value $T_{n,\alpha}$ is 0.5714 when significance level takes 0.1. The calculation process is also shown in Table 3.

Table 2. Test statistic calculation process at 350 MPa (the whole data).

No.	t_i	$F(t)$	$F_n(t)$	$\lvert F_n(t) - F(t) \rvert$
1	15.89745	0.0466	0.1111	0.0645
2	16.62491	0.1503	0.2222	0.0719
3	17.95387	0.3066	0.3333	0.0267
4	18.23676	0.3949	0.4444	0.0495
5	18.64382	0.5414	0.5556	0.0142
6	19.69044	0.6023	0.6667	0.0644
7	19.99763	0.6901	0.7778	0.0877
8	20.39892	0.7562	0.8889	0.1327

Table 3. Test statistic calculation process at 350 MPa (internal initiation data).

No.	t_i	$F(t)$	$F_n(t)$	$\lvert F_n(t) - F(t) \rvert$
1	17.95387	0.0668	0.1429	0.0761
2	18.23676	0.2352	0.2857	0.0505
3	18.64382	0.3998	0.4286	0.0288
4	19.69044	0.4901	0.5714	0.0813
5	19.99763	0.6291	0.7143	0.0852
6	20.39892	0.6425	0.7571	0.1146

Because $T_0 = 0.1146 < T_{n,\alpha} = 0.5714$, so we can't refuse the assumption that the internal initiation fatigue life submits the lognormal distribution as well. What needs to be emphasized is that the coefficient of variation ($\hat{\sigma}/\hat{\mu}$) is 0.0674 for internal initiation and 0.1122 for the case of ignorance of initiation sites. That is to say, the data dispersity for two kinds of initiation conditions is larger than single initiation mechanism.

After the distribution analysis of fatigue life in two circumstances, the following conclusions can be obtained: when the fatigue crack initiation sites are in two cases, the fatigue life at a certain stress level necessarily submits lognormal distribution, but the stationarity for internal crack initiation fatigue life is much better. Therefore, when analyzing the P-S-N curve, the crack initiation sites should be distinguished then the fitting curve can be more reasonable.

3.4 *P-S-N curve fitting using maximum likelihood estimation method*

Since the number of fatigue test data is relatively small, only with a group of life data at 350 MPa, conventional method for P-S-N curve fitting can't be used here. In this paper, we use the maximum likelihood estimation fitting method on condition that the following assumption is correct:

1. The fatigue cracks initiate from interior only for tested specimens with very long life;
2. The fatigue life submits logarithmic normal distribution for each stress level;
3. Both the mean and standard deviation of normal population have linear relationship with the corresponding stress level.

Then the mean value and standard deviation of parent population can be written as

$$\mu_i = a_1 + a_2 \lg S_i \tag{6}$$

$$\sigma_i = a_3 + a_4 \lg S_i \tag{7}$$

By the assumption (2), the likelihood function can be written as

$$L(\theta)=\prod_{i=1}^{n}\left[\frac{1}{\sqrt{2\pi}\sigma_i(S_i)}e^{-\frac{\left[X_i-\mu_i(S_i)\right]^2}{2\sigma_i^2(S_i)}}\right] \tag{8}$$

Then the parameters a_1, a_2, a_3 and a_4 can be calculated by the likelihood function.

According to Basquin equation, the P-S-N curve satisfies the relationship:

$$S^{m_P}N_p=C_p \tag{9}$$

where m_p and C_p represent the parameters when the reliability is P, N_p is the lifetime corresponding to the stress amplitude S and reliability P. Then the natural logarithm formation is

$$\ln N_p=\ln C_p-m_p\ln S \tag{10}$$

Assume $X_p=lnN_p$, When $P=0.5$, $\mu=X_{0.5}=lnX_{0.5}$,
then

$$\mu(S)=\ln N_{0.5}=\ln C-m\ln S \tag{11}$$

Since the fatigue life submits the lognormal distribution, then

$$X_p=\mu(S)+u_p\sigma(S) \tag{12}$$

and

$$\sigma(S)=\frac{\ln N_p-\mu(S)}{u_p}=\frac{1}{u_p}\left(\ln\frac{C_p}{C}-m_p\ln S+m\ln S\right) \tag{13}$$

If a group of life test data is got at stress amplitude S_r, then the estimators of the mean value μ_r and standard deviation σ_r for the logarithmic fatigue life are

$$\mu_r=\ln C-m\ln S_r \tag{14}$$

$$\sigma_r=\frac{1}{u_p}\left(\ln\frac{C_p}{C}-m_p\ln S_r+m\ln S_r\right) \tag{15}$$

By formula (9)~(14), the following equation can be obtained:

$$\mu(S)=\mu_r+m\ln\frac{S_r}{S} \tag{16}$$

$$\sigma(S)=\sigma_r+\frac{m}{u_p}\ln\frac{S}{S_r}+\frac{m_p}{u_p}\ln\frac{S_r}{S} \tag{17}$$

When $u_p=-1$, $p=84.1\%$, make $m_{0.841}=m_{-1}$, then

$$\sigma(S)=\sigma_r-\mathrm{m}\ln\frac{S}{S_r}-\mathrm{m}_{-1}\ln\frac{S_r}{S} \tag{18}$$

By formula (15), (17) and (7) the maximum likelihood function parameters m and m_{-1} can be obtained. According to formula (11) the fatigue life under different stress levels in any survival rate can be calculated properly.

According to the shape of stress-life curve with general metal materials the following relationship can be obtained:

$$m>0,\ m_{-1}<50,\ m\geq m_{-1} \tag{19}$$

According to $\sigma(s)>0$, we can get the formula

$$m-m_{-1}<\frac{\sigma_r}{\ln S_{\max}-\ln S_r} \tag{20}$$

We use the Matlab software to calculate the value of m and m_{-1} according to the constraint condition (19). By using Matlab optimization toolbox to find the value of m and m_{-1} through maximum likelihood function. The calculation results are

$m=22.3776$, $m_{-1}=21.3352$

Finally, the P-S-N curve can be got as is shown in Figure 5, and the probability formulas for

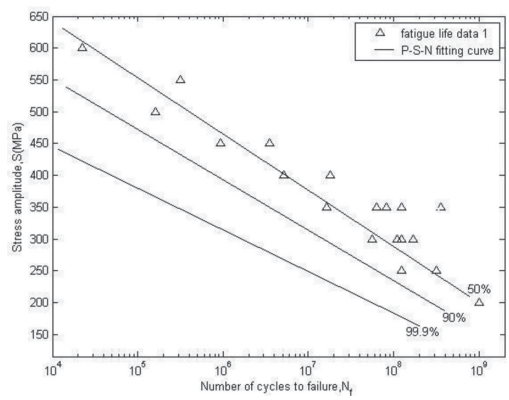

Figure 5. The two parameter P-S-N curve in maximum likelihood method.

stress-life when the reliability is 50%, 90% and 99.9% separately are as follows:

$$P = 50\% \quad lnN = 7.1047 - 0.0722 lnS \tag{21}$$
$$P = 90\% \quad lnN = 6.8821 - 0.07012 lnS \tag{22}$$
$$P = 99.9\% \quad lnN = 5.4867 - 0.06145 lnS \tag{23}$$

4 CONCLUSION

Based on the fatigue life data of TC21 titanium with EBW in ultra-high cycle fatigue regime, the probability distribution of fatigue life at certain stress level is discussed in Kolmogorov criterion method and the P-S-N curve is obtained by maximum likelihood estimation method, the conclusions are as follows:

1. When the fatigue crack initiation sites are in two cases, the fatigue life at a certain stress level necessarily submits lognormal distribution, but the dispersity for internal crack initiation fatigue life is much smaller. Therefore, when analyzing the P-S-N curve for very long life, the crack initiation sites should be distinguished and the fitting curve will be more reasonable.
2. When using the maximum likelihood estimation method to fit long life P-S-N curve of the ultrasonic fatigue life data according to the Basquin equation, we can calculate the value of the relevant parameters according to the relationship equation between probability stress and life for general metals. The P-S-N curve fitting considering fatigue life distribution and cracking initiation sites, which can be used for fatigue design of TC21 titanium EBW engineering components with very long lifetime.

ABSTRACT: Solar energy represents a clean, natural and sustainable source of energy. Solar photovoltaic panels can be installed on roofs of structures or in the ground. This contribution focusses on ground-mounted systems, which are presently widely implemented. At present limited guidelines on the design of solar ground-mounted structures are available. Usually standards for the design of normal buildings are applied. However, the design of ground-mounted structures significantly differs from common structural design by: a) a lower design lifetime (20–25 years) is accepted; b) failure is not associated with the loss of human life; c) resistance uncertainties need due attention; d) uplift wind forces dominating structural reliability are associated with a large scatter. That is why the reliability analysis and optimal design of ground-mounted solar systems is investigated herein. The failure costs and especially their ratio to the initial costs are analyzed considering the data provided from the industry. Probabilistic reliability analyses are carried out and optimum design levels are computed for representative cost ratios. The optimal target reliability depends on the ratio between failure and initial costs; reliability index of 3.5 corresponds to a reasonable cost ratio of 10.

1 INTRODUCTION

Current codes focus on traditional structures such as bridges, civil or industrial buildings. The last years have seen an increase of new types of structures, such as geodesic domes, tensile structures or solar panel structures that have some characteristics different from the traditional ones, not explicitly considered in the codes. In particular they can have different design lifetime and different failure consequences not directly included in the European standards such as EN 1990 (2002).

The most common design procedure, the partial factor method, is a semi-probabilistic method based on a design value which is a function of a characteristic value and of a partial factor. The partial factors depend mainly on relevant uncertainties in resistances and load effects, and on the class of failure consequences (reflected by a target reliability level). Designing new types of structures without specific guidelines, using partial factors that do not fit the characteristics of the structure can lead to an uneconomic (non-optimal) design.

Solar energy is a clean natural and sustainable source of energy. Considerable public investments have thus been made worldwide during the last years leading to an enormous increase in the annual world production of solar energy, from 2.2 GW in 2002 to the global production of 100 GW in 2012 as illustrated by Figure 1, REN21 (2013).

This paper focusses on the risk-based optimal design of ground-mounted photovoltaic

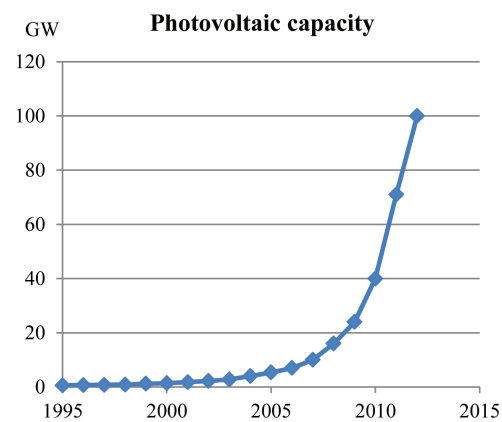

Figure 1. Annual world production of solar energy according to REN21 (2013).

structures. These systems are usually part of a solar production farm and are composed of simple components which can be analyzed based on a probabilistic approach combined with economic optimization. The applied procedure is:

- Flexible to take into account variables that are not considered by the codes,
- Able to consider different variability for the involved stochastic parameters and
- Cost-effective since an optimum design is provided as a function of the failure consequences.

The procedure is illustrated by a case study.

2 PARTIAL FACTOR METHOD

Structural design in current codes is based on the partial factor method. The structural member is reliable if a limit state is not exceeded:

$$r_d > e_d \tag{1}$$

where r_d and e_d = design values for resistance and action effects, respectively.

Design values are calculated trough a representative value (called characteristic value) and a set of partial factors. Through partial factors the designer assigns a certain level of reliability to the structure. The partial factors are fixed values, calibrated using probabilistic methods.

In some circumstances, the aforementioned parameters may vary; for instance uncertainties in soil properties may be reduced based on site investigations; the design working life and the consequence class can be different from those usually considered for the design of traditional structures. In those cases it is possible to apply probabilistic methods in order to recalibrate the partial factors, or directly verify structural reliability.

3 PROBABILISTIC METHOD

3.1 *General framework*

Probabilistic methods, introduced in international standards, are based on the assumption that the reliability of a structure can be measured through the probability of failure. Failure means 'failure to satisfy a limit state criterion' rather than a failure in the sense of a dramatic physical event, Ditlevsen (1997). As a consequence of this, the probability of failure p_f can be expressed in the following way:

$$p_f = \mathrm{P}(R < E) \tag{2}$$

where P = probability; R = random resistance; and E = random load effect. The probability of failure is related to the reliability index β (see also Table 1):

Table 1. Relationship between the failure probability p_f and the reliability index β, EN 1990 (2002).

p_f	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}
β	1.28	2.32	3.09	3.72	4.27	4.78	5.20

$$\beta = -\Phi^{-1}(p_f) \tag{3}$$

where Φ^{-1} = inverse cumulative distribution function of the standardized normal distribution.

It should be emphasized that the probability of failure p_f and the reliability index β provide limited information about the actual frequency of failures, they rather serve as a measure of structural reliability in order to perform structural verification, EN 1990 (2002).

A structural component is considered as reliable if during a reference period T_r a limit state is not exceeded, thus the following verification format is considered:

$$\beta \geq \beta_t \tag{4}$$

where β = computed reliability index; and β_t = target reliability level usually recommended by the codes.

Probabilistic methods are not commonly used in design practice despite calculation procedures and software products already enable a direct verification of structural reliability. Detailed guidance is provided by the Joint Committee on Structural Safety Probabilistic Model Code, JCSS (2014).

3.2 *Target reliability level*

The definition of target reliability levels for a considered limit state depends on the physical consequence (and, thus, the socio-economical consequence) of structural malfunction. This leads directly to the rationale of cost-benefit analysis, Ditlevsen (1997). Recommendations concerning the target reliability are provided in several international standards, as a result of experience, calibration and economical optimization, Vrouwenvelder (2002).

In EN 1990 (2002) the recommended values of reliability indexes are given for two reference periods T_r, i.e. 1 year and 50 years, and for different failure consequences (Table 2). It is important here to remember that the reference period is understood as a chosen period of time used as a basis for statistically assessing time-variable basic random variables of loads and the corresponding probability of failure. The reference period is therefore

fundamentally different from the design working life, that is the assumed period of time for which a structure is to be used for its intended purpose without any major repair being necessary, Holicky (2012).

A more detailed recommendation is given in ISO 2394 (1998) where the target reliability indexes are indicated for the whole design working life and related not only to the consequences of failure but also to the relative costs of safety measures (see Table 3).

Similar recommendations are provided in JCSS (2001) and JCSS (2014), where the recommended target reliability indexes are also related to both the consequences and the relative costs of safety measures for the reference period of 1 year (Table 4). The values proposed by the aforementioned documents are based also on calibrations to previous practice.

Table 2. Reliability classification in accordance with EN 1990 (2002).

Reliability classes	Failure Conseq.	Reliability $T_r = 1$ y.	ind. 50 y.	Examples
RC3—high	High	5.2	4.3	Grandstands, public build
RC2—norm	Medium	4.7	3.8	Residences, offices
RC1—low	Low	4.2	3.3	Agricultural buildings

Table 3. Target reliability index (life-time, examples) in accordance with ISO 2394 (1998).

Relative costs of safety measures	Consequences of failure			
	Small	Some	Moderate	Great
High	0	1.5	2.3	3.1
Moderate	1.3	2.3	3.1	3.8
Low	2.3	3.1	3.8	4.3

Table 4. Tentative target reliability indexes β related to a 1-year reference period and ultimate limit states in JCSS (2001) and JCSS (2014).

Relative costs of safety measures	Consequences of failure		
	Minor	Moderate	Large
Large	3.1	3.3	3.7
Normal	3.7	4.2	4.4
Small	4.2	4.4	4.7

4 COST OPTIMIZATION

Codes usually establish a relationship between the target reliability and the reference period; however a clear link between the target reliability and the design working life is missing. Thus, it is not clear which target reliability index should be used for a shorter design working life, Holicky (2012). In general both economic arguments and limits for human safety play a main role in the definition of target reliability for different periods of design working life, Steenbergen & Vrouwenvelder (2010).

ISO 2394 (1998) indicates a possibility to specify the target reliability levels for existing structures by optimization of the total cost related to a reference period. This approach has been recognized to be convenient for structures in which failures lead to economic consequences and human safety is not endangered. Background information for a consequence analysis is provided by Faber et al. (2004), Imam & Chryssanthopoulos (2012), Janssens et al. (2012), JCSS (2001), Kanda & Shah (1997).

The main aim of this contribution is to provide guidance for the specification of the target reliability level for solar structures. A shorter design working life of 25 years is considered according to current practice. The basic assumption is that solar structures have limited consequences compared to usual building structures and that failure is not associated to the loss of human life. Consequently a lower reliability level can be considered. The assumption is supported by the implementation of an optimization procedure, taking into consideration different values of the cost ratios between failure and initial costs.

ISO 2394 (1998) indicates that the target level of reliability should depend on a balance between the consequences of failure and the costs of safety measures. From an economic point of view the objective is to minimize the total working-life cost.

Based on previous studies the expected total costs C_{tot} may be generally considered as the sum of the expected initial costs, costs of inspections, maintenance, and failure consequences. The decision parameter x to be optimized in the assessment may influence resistance, serviceability, durability, maintenance, inspections upgrade strategies etc. In the present study the decision parameter is assumed to concern the initial costs only while the other costs (inspections, maintenance, future repair etc.) are independent of x (and excluded from the optimization). Moreover the benefits related to use of the structure that in general should be considered in the optimization are not affected by value of the decision parameter. These are reasonable assumptions in case of solar panels.

The key aim of the economic optimization is to achieve reduction of risks (by decreasing failure probability) by reasonable initial investments (increasing structural reliability). The optimization procedure proposed by Holicky (2012) is adopted in this case. The total cost is expressed as follows:

$$C_{tot}(x,q,n) = C_f \sum_i P_f(x,i)\ Q(q,i) + C_0 + C_1 x \qquad (5)$$

where q = annual discount rate; n = number of years (reference period); $P_f(x,i) = p(x)(1 - p(x))^{i-1}$ is the failure probability in year i ($i = 1 \ldots n$) obtained from the annual probability of failure $p(x)$; C_f = failure consequences; $Q(q,i)$ = time factor dependent on q and the numbers of years i; C_0 = initial cost independent of the decision parameter x; and C_1 = unit cost of the decision parameter x.

The total cost in equation (5) is standardized κ_{tot} as proposed by Holicky (2012):

$$\kappa_{tot} = p(x)PQ(x,q,n)\ C_f / C_1 + x \qquad (6)$$

where $PQ(x,q,n)$ = time factor evaluated as:

$$PQ(x,q,n) = 1-[(1-p(x))/(1+q)]^n/[1-(1-p(x))/(1+q)] \qquad (7)$$

The optimum solution x_{opt} corresponds to the minimal standardized costs; optimal reliability index is then $\beta_{opt}(x_{opt})$.

5 CASE STUDY: GROUND-MOUNTED SOLAR SYSTEMS

5.1 *Development of solar structures*

The last years have seen a large increase in utilization of solar panels as renewable energy systems (Figure 1). Photovoltaic systems can be divided into two groups:

- Solar structures on roofs;
- Grounded solar structures.

The proposed procedure is applied in the case study of the optimum design of a solar ground-mounted structure (Figure 2). Such a structure can have different types of foundations: spread footing foundation, drilled piles, micro piles or screw piles.

Due to flexibility of installation and to the ability of reuse, screw piles are commonly used as foundations of light structures such as those for solar panels (Figure 3).

5.2 *Cost aspects*

As input to the optimization procedure cost parameters need to be analyzed. Failure consequences and particularly their ratio to the initial costs C_f/C_1 accepted here are based on the data obtained for a photovoltaic farm of 1.4 MW located in Tuscany, Italy.

An optimized parameter is the length of the screw pile subjected to wind uplift forces. The unit cost of the decision parameter is $C_1 = 80$ €/m.

Estimate of the failure consequences C_f is based on the following assumptions:

- Replacement costs are of the order of $1.2C_1$,
- Failure of the system leads to a production loss of 20 days,
- The expected revenue per day per a solar panel is obtained by averaging expected revenues over 2013–2038 (25 years) obtained from a business plan of the farm,
- 100 solar panels in the farm are considered.

The cost ratio becomes $C_f / C_1 \approx 2.3$. To account also for indirect consequences a reasonable cost ratio may range from 5 to 10. The indirect consequences may include production loss and inspections of solar panels connected with a failed panel, loss of credibility as a supplier and subsequent losses of contracts etc. Note that the ratio C_f / C_1 depends on structure-specific conditions and no general guidance for its estimation is available.

Figure 2. Ground-mounted photovoltaic structure.

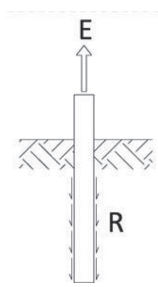

Figure 3. Effect of the wind action on a single pile E and friction resistance of the pile R.

5.3 *Reliability analysis*

Photovoltaic systems are due to their large surface of panels and their light weight mainly affected by the wind uplift action (Figure 3). The resistance of the foundation is the frictional resistance between the pile and the soil, dependent on the soil parameters and the pile geometry.

Initially the partial factor method according to Eurocodes (in particular EN 1997-1 (2004)) is applied to determine design length of the pile. The limit state function reads:

$$R_d = R_k / \gamma_R = [\alpha (C_{u,k} / \gamma_{Cu}) A_l / \xi_3] / \gamma_R \geq \gamma_Q Q_k \quad (8)$$

Characteristic values and partial factors of the basic variables and notation are provided in Table 5. Soil parameters are based on a geotechnical survey (five tests); characteristic value of the wind action effect is obtained from a National Annex to EN 1991-1-4 (2005). The most unfavorable results are obtained using Design Approach 1—Combination 2, EN 1997-1 (2004).

As the structure is very light, the self-weight is negligible and is not considered in the limit state. More details are provided by Boccara (2014).

The design length of the pile is $l_{EC} = 1.60$ m.

In the probabilistic reliability analysis the limit state function accounts for the uncertainties in resistance model θ_R:

$$\theta_R \alpha \cdot C_u \cdot A_l(l) \cdot - Q = 0 \quad (9)$$

Probabilistic models of non-deterministic basic variables are given in Table 6; deterministic basic variables include the diameter and length of the pile, lateral area of friction and adhesion coefficient ($\mu_X / X_k = 1$). The probabilistic models are based on recommendations provided by Huber (2013), JCSS (2014) and Rackwitz (2000). The model uncertainty θ_R is assumed to account for imprecision of the implemented resistance model including the effects covered by the correlation factor (influences of a limited number of piles tested and of profiles of tests).

Reliability of the pile is analyzed considering the pile length l as a study parameter. A sensitivity analysis investigates effects of the coefficients of variation of C_u, θ_R and Q on the reliability index β.

Detailed results are provided by Boccara (2014). Representative results of the analysis are plotted in Figure 4 that shows the reliability index β as a function of the length l for different values of V_{Cu} (0.2, 0.3, 0.4) with fixed $V_{\theta R} = 0.3$ and $V_Q = 0.3$; the vertical dash-point line indicates l_{EC}. Note that for simplicity of computations the mean values of C_u and Q given in Table 6 are kept independent of the relevant coefficients of variation. This approximation has a minor effect on the results of economic optimization.

Table 5. Characteristic values and partial factors of the basic variables applied in the design by the partial factor method.

Basic variable	Sym.	Unit	X_k*	γ_X**
Diameter of pile	ϕ	m	0.159	–
Length of pile	l	m	parameter	–
Lateral area of friction	A_l	m²	$\pi \phi l$	–
Adhesion coefficient	α	–	0.87	–
Unconfined cohesive strength	C_u	kN/m²	50	1.4
Correlation factor	ξ_3***	–	1.31	–
Friction. resist. pile—soil	R	kN	Eq. (8)	1.6
Wind load effect	Q	kN	9.33	1.3

*Characteristic value; **partial factors according to Annex A to EN 1997-1 (2004); ***correlation factor to derive the pile resistance from ground investigation results, not being pile load tests.

Table 6. Probabilistic models of the basic variables.

Basic variable	Sym.	Distrib.	μ_X/X_k*	V_X**
Unconfined cohesive strength	C_u	lognormal	1.4***	0.2–0.5
Uncertainty in resist. model	θ_R	lognormal	1	0.2–0.5
Annual maxima of wind load effect including model uncertainties	Q	Gumbel	0.66****	0.2–0.5

*Mean to characteristic value; **coefficient of variation; ***assuming the characteristic value being a 5% fractile and $V_{Cu} = 0.2$; ***assuming the characteristic value being a 98% fractile of annual maxima and $V_Q = 0.2$.

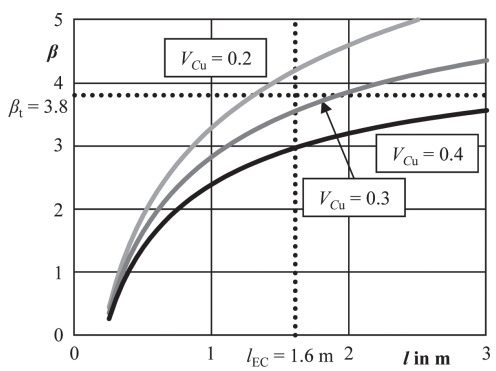

Figure 4. Reliability index β as a function of the length l and V_{Cu} ($V_{\theta R} = 0.3$ and $V_Q = 0.3$).

The following observations follow from Figure 4:

– The reliability level inherent in the design according to Eurocodes for different values of the coefficient of variation of the unconfined cohesive strength ($\beta \sim 3.0$–4.2; for instance $\beta = 3.5$ for $V_{Cu} = 0.3$);
– The pile length needed to reach a specific target reliability level β_t (e.g. $l = 1.9$ m to reach $\beta_t = 3.8$ for $V_{Cu} = 0.3$).

The cost optimization is based on equation (6). The total standardized cost function κ_{tot} is evaluated as a function of the length l of the pile for different values of the cost ratio C_f / C_1 that is a dominating parameter in the optimization.

Figure 5 shows the trend of κ_{tot} with the length l for representative values $C_f / C_1 = 1$, 10, 100 and 1000 (for $V_{Cu} = 0.3$, $V_{\theta R} = 0.2$, $V_Q = 0.3$, $q = 0.03$ and $n = 25$ years). It appears that the target reliability decreases with a decreasing ratio C_f / C_1 as can be expected. For $C_f / C_1 = 10$ the annual target reliability is approximately 3.5. If the cost ratio is around 100, the optimum length approaches that obtained by the partial factor method.

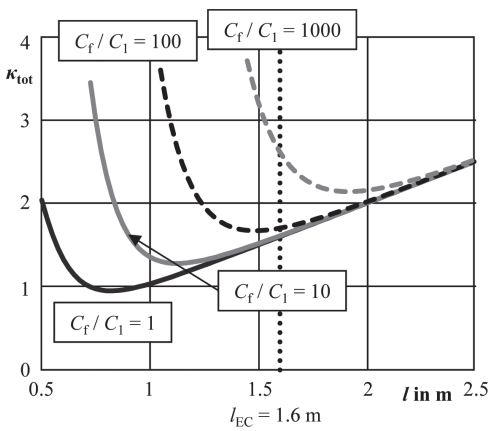

Figure 5. Total standardized cost κ_{tot} as a function of the length l for $C_f / C_1 = 1$, 10, 100 and 1000 (for $V_{Cu} = 0.3$, $V_{\theta R} = 0.2$, $V_Q = 0.3$, $q = 0.03$ and $n = 25$ years).

Table 7. Optimal lengths l_{opt} and corresponding annual β for different C_f / C_1.

Cost Ratio	l_{opt} in m	β
1	0.80	2.85
10	1.10	3.47
100	1.50	4.06
1000	1.90	4.50

Table 7 provides the main results of the economic optimization—optimal lengths l_{opt} and corresponding annual reliability indices β for different cost ratios C_f / C_1.

Note that the discount rate may be greater particularly for private investors; for instance de La Tour et al. (2013) indicated the range $q = 0.05$–0.1.

6 CONCLUSIONS

The present study leads to the following general conclusions concerning the design of ground-mounted solar systems:

– The partial factor method leads to conservative design solutions, desired improvements can be obtained by applications of probabilistic methods;
– The parameters significantly affecting the reliability index include the unconfined cohesive strength of soil, uncertainties in resistance model and effect of wind action;
– Due to considerable variability of soil properties, it is recommended to establish probabilistic models of resistance parameters on the basis of test results;
– The annual target reliability β depends on the ratio between failure and initial costs (for a reasonable ratio 10 $\beta \approx 3.5$ is obtained; this value is lower compared to a value recommended in EN 1990 (2002) for the lowest reliability class).

Further investigations are necessary to in order to propose pre-normative recommendations. In particular uncertainties in the resistance models for geotechnical structures should be improved.

Approximate quantification of the robustness index of concrete beams subjected to deterioration

W. Botte, R. Caspeele & L. Taerwe
Department of Structural Engineering, Ghent University, Ghent, Belgium

ABSTRACT: Deterioration of existing structures due to corrosion of reinforcement has been a growing concern in the last decades since the associated reduction of the steel results in a decrease of the structural reliability. Apart from deterioration, also the assessment of structural robustness has been of particular interest. One way to quantify robustness is through a reliability-based robustness index based on the reliability index of the damaged and undamaged system. Determination of these reliability indices requires the selection of probabilistic and physical models and the estimation of the associated parameters. This introduces uncertainties in the probabilistic models, the reliability indices and hence in the robustness index. These uncertainties are usually not considered. In this contribution, an approximate quantification method is derived in order to assess the influence of uncertainties on the robustness index of deteriorated concrete beams. As an example, a reinforced concrete beam subjected to corrosion is analyzed to demonstrate the influence of uncertainties on the robustness index.

1 INTRODUCTION

In the last decades, deterioration of existing structures has been a growing concern. Deterioration due to corrosion of reinforcement steel has been of particular interest since the associated reduction of the steel section results in a decrease of the structural safety. An other topic which has been the subject of many publications is the assessment of the structural robustness. Different approaches have been proposed in order to quantify this structural robustness through robustness indicators (Sørensen et al. 2012). The robustness indicator based on the reliability index of the undamaged and the damaged system, is the reliability-based robustness index.

Both hot topics are combined in this contribution: the quantification of the structural robustness of reinforced concrete beams subjected to chloride-induced corrosion is discussed. Further, since corrosion is a time-variant process, the associated robustness index will be time-dependent.

In order to assess the structural reliability and robustness with respect to deterioration, it is required to select appropriate models which describe the deterioration process. The parameters associated with these models have to be estimated through statistical inference, which introduces uncertainties in parameter estimates. The reliability index which takes into account these uncertainties is the predictive reliability index (Der Kiureghian 2008). As the structural reliability indices which are incorporated in the reliability-based robustness index can be considered as random variable, this robustness index itself will be a random variable as well. In this contribution, the aforementioned predictive reliability index is used to derive measures of uncertainty in the robustness index with respect to deteriorated structures. To illustrate the proposed concept, the influence of parameter uncertainties on the robustness index of a reinforced concrete beam subjected to chloride-induced corrosion is analyzed.

2 DETERIORATION DUE TO CHLORIDE-INDUCED CORROSION

2.1 *General*

A common deterioration mechanism in reinforced concrete is corrosion of the reinforcement steel. Corrosion affects the steel as well as the concrete by (Rodriguez et al. 1997):

- Reduction of the bar section;
- Reduction of the mechanical properties of the steel;
- Cracking and spalling of the concrete due to the expansion of corrosion products;
- Bond deterioration between the steel and the surrounding concrete.

Because of these phenomena, the safety of deteriorated concrete structures is reduced. According to the Model Code for Service Life Design

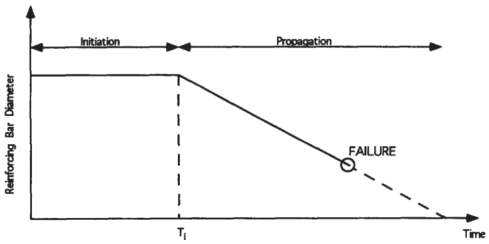

Figure 1. Deterioration process for loss of reinforcing steel (Stewart & Rosowsky 1998).

(fib 2006), the process of corrosion of the reinforcement can be divided roughly into two time periods: the initiation period and the propagation period (Fig. 1). The first phase is defined as the time until the reinforcement becomes depassivated, either by chloride ingress or by carbonatation. During the second phase, the reinforcement itself is affected: the cross-section is reduced. Both phases are governed by different stochastic parameters and can be described by mathematical models, which are presented in the next sections.

2.2 *Initiation period*

Initially, reinforcement steel in concrete is protected by the high alkalinity of the concrete and no corrosion occurs (Val & Melchers 1997). However, in case of chloride-induced corrosion, the diffusion of chlorides through the protective concrete cover results in the depassivation of the concrete. As soon as a critical chloride concentration C_{cr} is reached, the corrosion process starts. Models for the depassivation of concrete can be found in Stewart & Rosowsky (1998) and Vu & Stewart (2000). Generally, the length of the initiation period depends on the concrete cover, the diffusion coefficient, the critical chloride content, the initial chloride concentration in the concrete and the chloride concentration at the surface of the concrete element.

Further in this contribution, the time to corrosion initiation T_i and the associated uncertainties are not considered. For the sake of simplicity, it is assumed that $T_i = 0$. Hence, a possible reduction of the structural safety level during the initiation phase is not considered in this contribution.

2.3 *Propagation period*

Once corrosion is initiated, the corrosion rate is determined by equation (1), as proposed by Vu & Stewart (2000) and Stewart & Suo (2009):

$$i_{corr}(t_p) = i_{corr}(0) \cdot 0.85\, t_p^{-0.29} \quad (1)$$

where $i_{corr}(t_p)$ [μA/cm²] is the corrosion rate at time t_p, t_p [years] is the time since corrosion initiation and $i_{corr}(0)$ [μA/cm²] is the corrosion rate at the start of corrosion propagation. The latter can be calculated from:

$$i_{corr}(0) = \frac{2.70(1 - w/c)^{-1.64}}{a} \quad (2)$$

where w/c [–] is the water cement ratio and a [cm] is the concrete cover. It follows from equation (1) that the corrosion rate decreases in time, which is due to the formation of rust products on the steel surface, obstructing the diffusion of the iron ions away from the steel surface (Vu & Stewart 2000).

Equation (1) is only valid when no spalling occurs, which is assumed in this paper. In case spalling does occur, the corrosion rate can be assumed to be constant (Papadopoulos et al. 2011).

As suggested by Stewart & Rosowsky (1998), the reduction in bar diameter of the reinforcement steel can be derived from the corrosion rate (since 1 μA/cm² = 0.0116 mm/year):

$$Ø(t_p) = Ø_0 - 2 \cdot 0.0116 \int_0^{t_p} i_{corr}(t)dt \quad (3)$$

where $Ø(t_p)$ [mm] is the reinforcement diameter t_p years after corrosion initiation and $Ø_0$ [mm] is the initial diameter.

3 PREDICTIVE RELIABILITY INDEX

The verification of a structure with respect to a certain limit state requires the definition of a limit state function g(.). The theoretical failure probability P_f for that specific limit state is then defined by:

$$P_f = \int_{g(x)<0} f_X(x)dx \quad (4)$$

where $f_{\mathbf{X}}(\mathbf{x})$ is the n-dimensional Probability Density Function (PDF) of the n basic variables X_i (i = 1 … n) and $g(\mathbf{x})$ is the limit state function, defined so that $g(\mathbf{x}) < 0$ corresponds to failure. The n basic variables represent uncertain quantities such as material properties, actions (loads), geometrical properties and model uncertainties.

As stated by Der Kiureghian (2008) the aforementioned formulation is the theoretical formulation of the structural reliability problem, since in practice neither the joint PDF $f_{\mathbf{X}}(\mathbf{x})$ nor the limit state function $g(\mathbf{x})$ are precisely known. Hence, one has to select appropriate probabilistic or physical models and the associated parameters have to be

estimated through statistical inference of experimental data and observations. The model for $f_{\mathbf{X}}(\mathbf{x})$ in which the parameters $\boldsymbol{\Theta}$ are estimated, is designated $\hat{f}_{\boldsymbol{X}}(\boldsymbol{x}\,|\,\Theta)$.

Since the model parameters are uncertain, it follows from (4) that also the failure probability P_f and the reliability index β are uncertain. Hence, the random variables $P = P_f(\boldsymbol{\Theta})$ and $B = \beta(\boldsymbol{\Theta})$ can be introduced. As random variables, P and B have probability density functions, namely $f_P(P_f)$ and $f_B(\beta)$ respectively, and characteristics, such as a mean (μ_P and μ_B) and a variance (σ_P^2 and σ_B^2). The latter expresses the uncertainty of the estimate of the failure probability or reliability index, originating from the parameter uncertainties. Since parameter uncertainties can be reduced by gathering additional information, these variances can also be reduced.

In (Der Kiureghian 2008) the predictive failure probability, denoted as $\tilde{p}$, is defined as the expectation of P over the outcome space of the uncertain parameters $\boldsymbol{\Theta}$:

$$\tilde{p} = \int_{\theta} P_f(\boldsymbol{\theta}) f_{\Theta}(\boldsymbol{\theta}) d\boldsymbol{\theta} \tag{5}$$

where $f_{\boldsymbol{\Theta}}(\boldsymbol{\theta})$ is the posterior joint distribution function for the set of estimated parameters $\boldsymbol{\theta}$. The predictive failure probability is equal to the mean of $f_P(P_f)$.

Consequently, the predictive reliability index is calculated from equation (6):

$$\tilde{\beta} = \Phi^{-1}(1 - \tilde{p}) \tag{6}$$

where $\Phi^{-1}(.)$ is the inverse of the standard normal cumulative distribution function.

Der Kiureghian (2008) provides different methods for calculating the predictive failure probability, predictive reliability index and their measures of uncertainty. One of these methods yields a very simple approximation formula for the predictive reliability index $\tilde{\beta}$:

$$\tilde{\beta} \cong \frac{\mu_B}{\sqrt{1 + \sigma_B^2}} \tag{7}$$

Note that the latter is not equal to the mean of the probability function $f_B(\beta)$.

The only approximation used to obtain equation (7) is the assumption that the reliability index follows a normal distribution, which is in many cases an acceptable assumption (Der Kiureghian 2008).

The calculation of the predictive reliability index according to equation (7) requires the mean and variance of the random variable B. These can be calculated by making use of a first-order approximation of the function $B = \beta(\boldsymbol{\Theta})$. This yields:

$$\mu_B \cong \beta(\mathbf{M}_{\boldsymbol{\Theta}}) \tag{8}$$

$$\sigma_B^2 \cong (\nabla_{\boldsymbol{\Theta}}\beta)^T_{\boldsymbol{\Theta}=\mathbf{M}_{\boldsymbol{\Theta}}} \Sigma_{\boldsymbol{\Theta}\boldsymbol{\Theta}} (\nabla_{\boldsymbol{\Theta}}\beta)_{\boldsymbol{\Theta}=\mathbf{M}_{\boldsymbol{\Theta}}} \tag{9}$$

with $\mathbf{M}_{\boldsymbol{\Theta}}$ the posterior mean vector of $\boldsymbol{\Theta}$, $\boldsymbol{\Sigma}_{\boldsymbol{\Theta}\boldsymbol{\Theta}}$ the posterior covariance matrix of $\boldsymbol{\Theta}$ and $(\boldsymbol{\nabla}_{\boldsymbol{\Theta}}\beta)_{\Theta\,=\,\mathbf{M}\boldsymbol{\Theta}}$ the sensitivity vector of the conditional reliability index with respect to the parameters $\boldsymbol{\Theta}$, evaluated at the posterior mean values. The sensitivity vector in equation (9) is given by:

$$\boldsymbol{\nabla}_{\boldsymbol{\Theta}}\beta = \left(\frac{\partial\beta}{\partial\theta_1}, \frac{\partial\beta}{\partial\theta_2}, \ldots, \frac{\partial\beta}{\partial\theta_n} \right) \tag{10}$$

where:

$$\frac{\partial\beta}{\partial\theta_i} = \boldsymbol{\alpha}^T \left(\frac{\partial\mathbf{u}}{\partial\theta_i} \right)_{\mathbf{u}=\mathbf{y}} \tag{11}$$

and $\boldsymbol{\alpha}$ the sensitivity vector, $\mathbf{u}$ the vector of normalized basic variables, $\mathbf{y}$ the design point in standard normal space and $\beta = \boldsymbol{\alpha}^T\mathbf{y}$.

As an example, consider n independent, normal random variables $\mathbf{X}$ with unknown means and standard deviations. Hence the unknown parameter vector $\boldsymbol{\Theta} = (\mathbf{M}, \boldsymbol{\Sigma}) = (M_1, \Sigma_1, M_2, \Sigma_2 \ldots M_n, \Sigma_n)$. The unknown mean M_i has a mean value $\overline{x_i}$ and standard deviation σ_{Mi}; the unknown standard deviation Σ_i has a mean σ_i and a standard deviation $\sigma_{\Sigma i}$. From equation (11) it follows, in case $\theta_i = M_i$:

$$\frac{\partial\beta}{\partial\theta_i} = \frac{\partial\beta}{\partial M_i} = \alpha_i \frac{\partial}{\partial M_i} \left(\frac{x_i - M_i}{\Sigma_i} \right)_{M_i=\overline{x}_i;\Sigma_i=\sigma_i} = -\frac{\alpha_i}{\sigma_i} \tag{12}$$

And in case $\theta_i = \Sigma_i$:

$$\frac{\partial\beta}{\partial\theta_i} = \frac{\partial\beta}{\partial\Sigma_i} = \alpha_i \frac{\partial}{\partial\Sigma_i} \left(\frac{x_i - M_i}{\Sigma_i} \right)_{M_i=\overline{x}_i;\Sigma_i=\sigma_i} = +\frac{\alpha_i^2\beta}{\sigma_i} \tag{13}$$

With (9), (10), (12) and (13) the variance of the reliability index becomes:

$$\sigma_B^2 \cong \sum_{i=1}^{n} \frac{\alpha_i^2}{\sigma_i^2} \sigma_{M_i}^2 + \sum_{i=1}^{n} \frac{\alpha_i^4\beta^2}{\sigma_i^2} \sigma_{\Sigma_i}^2 \tag{14}$$

The first term represents the contribution of the uncertainty of the mean value of the estimated parameters, while the second term represents the contribution of the uncertainty on the standard deviation.

Equations (8) and (9) show that it is sufficient to perform one single calculation of the reliability index along with the parameter sensitivities in order to determine the mean and variance of the reliability index and the predictive reliability index (equation (6)). This calculation is performed using the mean values of the parameters.

4 QUANTIFICATION OF ROBUSTNESS

4.1 *Structural robustness quantification*

The failure of several structures, such as the Ronan Point Building in 1968, stressed the importance of the robustness of a building. Structural robustness assessment focuses on two states of a building: the undamaged and the damaged state. As stated by Yao (1985) and Frangopol & Curley (1987), 'damaged' may refer to any strength deficiency introduced during the design or construction phase of the structure as well as any deterioration of strength caused by external loading (e.g. sudden column loss) and/or environmental conditions (e.g. corrosion) during the lifetime of the structure.

Different approaches to quantify structural robustness have been proposed by several authors (Sørensen et al. 2012). These approaches can be divided into the following levels, with increasing complexity:

- A deterministic approach based on structural measures (e.g. pushover method on the damaged and undamaged system);
- A probabilistic approach based on the probability of failure of the undamaged and the damaged system;
- A risk-based approach based on a complete risk analysis in which consequences are divided into direct and indirect consequences.

The last approach is the most general one, but, as stated before, also the most complex one. Therefore, in this contribution, a probabilistic approach is used.

4.2 *Reliability-based robustness assessment*

A probabilistic measure of robustness is the redundancy index RI, defined by (Fu & Frangopol 1990):

$$\mathrm{RI} = \frac{P_{f,\mathrm{damaged}} - P_{f,\mathrm{intact}}}{P_{f,\mathrm{intact}}} \tag{15}$$

where $P_{f,\mathrm{damaged}}$ is the probability of failure of the damaged system and $P_{f,\mathrm{intact}}$ is the probability of failure of the undamaged system. This redundancy index takes values between infinity, for structures that are not robust, and zero, for structures that are very robust.

Alternatively, also the redundancy factor β_R defined by (Frangopol & Curley 1987) can be considered:

$$\beta_R = \frac{\beta_i}{\beta_i - \beta_d} \tag{16}$$

where β_i is the reliability index of the intact system and β_d is the reliability index of the damaged system. The redundancy factor takes values between 0 (i.e. $\beta_d = -\infty$), for structures that are not robust, and infinity (i.e. $\beta_d = \beta_i$), for very robust structures.

The redundancy index RI and the redundancy factor β_R are nonlinearly related, since:

$$\beta_R = \frac{\Phi^{-1}(1 - P_{f,\mathrm{intact}})}{\Phi^{-1}(1 - P_{f,\mathrm{intact}}) - \Phi^{-1}(1 - P_{f,\mathrm{damaged}})} \tag{17}$$

Note that the reliability-based robustness index does not require the description of external consequences, unlike risk-based robustness indices, which simplifies the calculations.

4.3 *Approximate quantification of robustness*

As mentioned in paragraph 3, the reliability index is, in practice, never precisely known because of the estimation of parameters. Hence the reliability indices β_i and β_d are not precisely known and the random variables $B_i = \beta_i(\boldsymbol{\Theta})$ and $B_d = \beta_d(\boldsymbol{\Theta})$ are introduced. Based on formulas (8) and (9), the mean (μ_{Bi} and μ_{Bd}) and variance (σ_{Bi}^2 and σ_{Bd}^2) of these random variables can be determined.

Since the reliability index of the undamaged and the damaged system are not precisely known, also the redundancy index, as defined by (16), is not precisely known. Hence, the random variable $B_R = \beta_R(\beta_i(\boldsymbol{\Theta}), \beta_d(\boldsymbol{\Theta}))$ is introduced. As a random variable, B_R has a PDF $f_{BR}(B_R)$ and characteristics such as a mean μ_{BR} and a standard deviation σ_{BR}.

The mean and standard deviation of the redundancy index can be derived by means of Taylor approximations. This yields the following:

$$\mu_{B_R} = \frac{\mu_{B_i}}{\mu_{B_i} - \mu_{B_d}} + \left(\frac{\mu_{B_i}\sigma_{Bd}^2 + \mu_{B_d}\sigma_{B_i}^2}{\left(\mu_{B_i} - \mu_{B_d}\right)^3} \right) \tag{18}$$

$$\sigma_{B_R} = \frac{\mu_{B_d}^2\sigma_{B_i}^2 + \mu_{B_i}^2\sigma_{B_d}^2}{\left(\mu_{B_i} - \mu_{B_d}\right)^4} + (\ldots) \tag{19}$$

The terms between (…) in equations (18) and (19) are higher order approximations. These might

be necessary in case the difference between the reliability index of the undamaged and the damaged system is small. In that case, the second term of the approximation is not negligible.

No assumptions have been made to derive the expressions for the mean and standard deviation (18) and (19). However, one can also find an analytical solution for these characteristics, by assuming a distribution for the reliability indices. For example, one can assume that the uncertain reliability index B follows a lognormal distribution. This enables to find an approximate distribution for the robustness index. In order to do so, the robustness index (16) is rewritten as follows:

$$B_R = \frac{B_i}{\Delta B} \tag{20}$$

where B_i follows a lognormal distribution with mean μ_{Bi} and standard deviation σ_{Bi}; and ΔB also follows a lognormal distribution with mean and standard deviation obtained from Taylor approximations: $\mu_{\Delta B} \approx \mu_{Bi} - \mu_{Bd}$ and $\sigma_{\Delta B} \approx (\sigma_{Bi}^2 + \sigma_{Bd}^2)^{1/2}$. As such, the robustness index B_R also follows a lognormal distribution, with mean and variance calculated from:

$$\mu_{\ln B_R} = \mu_{\ln B_i} - \mu_{\ln \Delta B} \tag{21}$$

$$\sigma^2_{\ln B_R} = \sigma^2_{\ln B_i} - \sigma^2_{\ln \Delta B} \tag{22}$$

and:

$$\mu_{B_R} = \exp\left(\mu_{\ln B_r} + \sigma^2_{\ln B_R}/2\right) \tag{23}$$

$$\sigma^2_{B_R} = \mu^2_{B_R}\left[\exp\left(\sigma^2_{\ln B_R}\right) - 1\right] \tag{24}$$

Hence, assuming that B_i and ΔB follow a lognormal distribution, B_R follows a lognormal distribution with parameters μ_{BR} and σ_{BR}.

Comparable to σ_B^2, σ_{BR}^2 expresses the uncertainty of the estimate of the robustness index, originating from the parameter uncertainties. The uncertainty of the estimate of the robustness index can be reduced by gathering additional information, since parameters uncertainties can be reduced.

5 EXAMPLE

To illustrate the concepts elaborated above, a reinforced concrete beam subjected to chloride-induced corrosion is considered.

5.1 *Characteristics*

The limit state equation with respect to bending, for the most heavily loaded cross-section is expressed as follows:

$$g(x) = A_s \cdot f_y \cdot \left(d - \frac{0.5 A_s f_y}{f_c b}\right) - M_E \tag{25}$$

where A_s [mm²] is the cross-section of the reinforcement, f_y [N/mm²] is the yield strength of the reinforcement, d [mm] is the effective depth of the cross-section, f_c [N/mm²] is the compressive strength of the concrete, b [mm] is the width of the cross-section and M_E [Nmm] is the bending moment acting on the critical cross-section. The characteristics of the beam are summarized in Table 1 (N: normal distribution; LN: lognormal distribution; DET: deterministic). The values for the standard deviations are based on the Probabilistic Model Code (JCSS 2001).

As described in section 2 the cross-section of the reinforcement decreases in time. The reduction of the diameter of the cross-section follows equation (3). Considering this equation and the characteristics in Table 1, the mean reinforcement area as a function of time is shown in Figure 2. Note that the coefficient of variation is constant in time since w/c and a are constant. The cross-section of the reinforcement is reduced from 804 mm² to 670 mm² after 50 years.

Table 1. Characteristics of the reinforced concrete beam.

	Distribution	μ	σ
d [mm]	N	400	10
f_c [MPa]	LN	30	4.25
M_E [kNm]	N	40	18
f_y [MPa]	N	420	30
$Ø_0$ [mm]	N	16	0.16
n* [–]	DET	4	–
b [mm]	DET	200	–
w/c [–]	DET	0.4	–
a [mm]	DET	20	–

* The number of reinforcement bars.

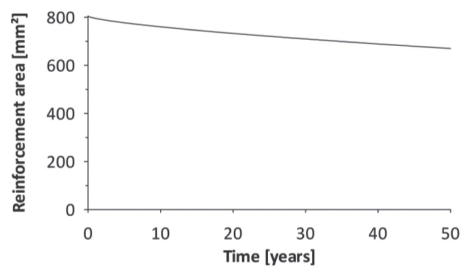

Figure 2. Reinforcement area as a function of time.

5.2 *Predictive reliability index*

Since the cross-section of the reinforcement is a function of time, also the reliability index is a function of time. Moreover, assuming that we have estimated the resistance parameters (i.e. d, f_c, f_y and $Ø_0$) from test data, this reliability index is not precisely known, as explained in section 3. The mean and standard deviation of the estimated parameters are summarized in Table 2. The standard deviation of the mean value $\overline{x}_i$ is calculated from $\sigma_i/\sqrt{(n)}$, where n is the number of samples (here assumed to be equal to 5). The coefficient of variation of the standard deviations Σ_i is assumed to be equal to 0.2 for all basic variables. It should be noted that the cross-section of the reinforcement is the only parameter that changes in time.

Using the characteristics mentioned above, we can calculate the mean and variance of β according to equation (8) and (9), by performing one single calculation of the reliability index and the parameter sensitivities, using the mean values of the parameters. The results of the FORM calculation with mean values of the parameters, as indicated in Table 2, is shown in Figure 3.

Initially, the mean reliability index μ_B is 4.2, which corresponds to a failure probability of 10^{-5}. After 50 years, the mean reliability index has decreased to 3.4, which corresponds to a failure probability of 3×10^{-4}. Hence the failure probability has increased with a factor 10.

Figure 4 shows the sensitivity factors for the basic variables as a function of time. The graph shows that the influence of the basic variables remains more or less constant in time.

Using the sensitivity factors from Figure 4 and the characteristics from Table 2, the standard deviation of the reliability index can be calculated according to equations (9) and (14). To illustrate the results, the dotted lines in Figure 3 show the interval $[\mu_B - \sigma_B; \mu_B + \sigma_B]$. This interval contains approximately 70% probability. As the sensitivity factors remain approximately constant in time, also the width of this confidence interval remains approximately constant. The coefficient of variation σ_B/μ_B varies from 0.110 at t = 0 to 0.108 at t = 50.

Finally, the predictive reliability index can be calculated using equation (7), since the mean and standard deviation of the reliability index are known. The result is shown in Figure 3 as a dashed line. The predictive reliability index decreases from initially 3.84 to 3.15 after 50 years. It is situated in the 70% probability interval.

5.3 *Robustness index*

Now that the mean value and the standard deviation of the reliability index are known, we can calculate an approximate value for the robustness index, as defined in section 4.3. β_i is the reliability index at t = 0 years and β_d is reliability index after a certain time period. The results of this calculation are shown in Figure 5. It shows the evolution in time of the mean value of the robustness index, obtained in different ways. The robustness index takes very high values short after corrosion initiation. This is the result of the small difference between the initial reliability index and the reliability index short after corrosion initiation. Further, the necessity

Table 2. Characteristics of the uncertain parameters.

	Mean M_i		Standard deviation Σ_i	
	$\overline{x}_i$	σ_{Mi}	σ_i	$\sigma_{\Sigma i}$
d	400	4.47	10	2
f_c	30	1.90	4.25	0.85
f_y	420	13.42	30	6
$Ø_0$	16	0.07	0.16	0.032

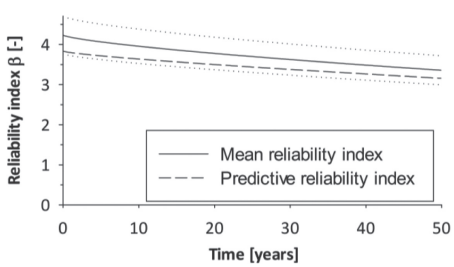

Figure 3. Mean reliability index and predictive reliability index as a function of time.

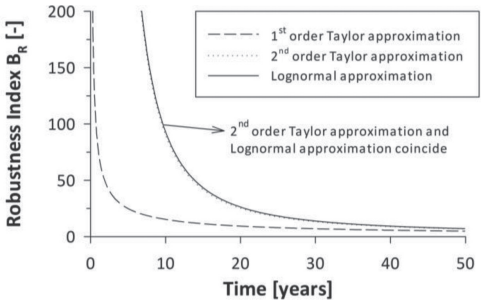

Figure 5. Mean value of the robustness index as function of the time.

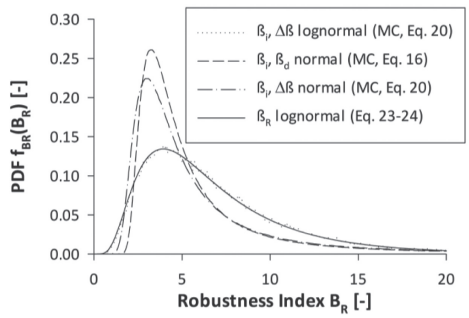

Figure 6. PDF of the robustness index.

of the use of higher-order Taylor approximations becomes clear when calculating the mean value of the robustness index in the first years: there is a big difference between the first order approximation and the second order approximation due to the non-negligible higher-order term. On the other hand, a very good agreement is found between the mean value of the robustness index calculated with a second-order Taylor approximation and the mean value calculated by assuming a lognormal distribution. This indicates that the lognormal approximation as proposed in section 4.3 is acceptable.

In order to compare the influence of the assumptions for the distribution of the reliability index, Monte-Carlo (MC) simulations were performed. Figure 6 shows the results. The curve for 'β_i, $\Delta\beta$ lognormal (MC, Eq. 20)' was obtained by generating 100,000 samples for B_i and ΔB, both following a lognormal distribution. Consequently, the robustness index was calculated according to equation (20). The curve for 'β_i, β_d normal (MC, Eq. 16)' was obtained by generating 10^7 samples for B_i and B_d, both following a normal distribution. The robustness index was calculated according to equation (16). The curve for 'β_i, $\Delta\beta$ normal (MC, Eq. 20)' was obtained by generating 10^7 samples for B_i and ΔB, both following a normal distribution. The robustness index was calculated according to equation (20). More simulations were necessary when using a normal distribution than when using a lognormal distribution, due to a slower convergence. The curve for 'β_R lognormal' represents the theoretical lognormal PDF, with its parameters calculated using equations (23) and (24).

The mode of the different PDF appears, more or less, at the same value for the different MC simulations.

The mean and standard deviations obtained by the MC simulations are summarized in Table 3. Considering the uncertainties, the mean of the robustness index predicted by the different methods is more or less the same. However, the normal approximations yield a higher standard deviation due to the heavy tail of the simulations using normal distributions.

Finally, the influence of parameter uncertainties on the characteristics of the robustness index is investigated. As an example, consider the robustness index at t = 50 years and its characteristics calculated with the lognormal approximation. The results are shown in Figure 7 and Figure 8, where the coefficient of variation or the number of samples for all variables is changed proportionally.

Table 3. Mean and standard deviation of the robustness index, obtained theoretically and by Monte-Carlo simulations.

	μ [–]	σ [–]
2nd order approximation	6.25	2.48
Lognormal approximation	6.44	3.78
MC—β_i, $\Delta\beta$ Lognormal	6.45	3.78
MC—β_i, β_d Normal	6.41	5.89
MC—β_i, $\Delta\beta$ Normal	6.51	6.30

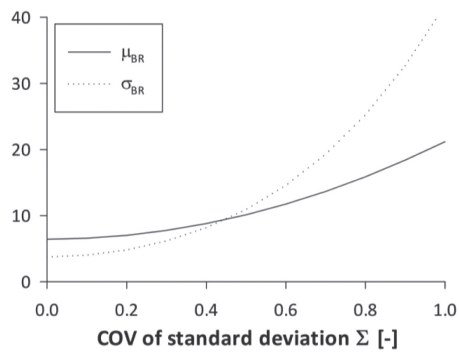

Figure 7. Influence of COV of Σ_i on the characteristics of the robustness index.

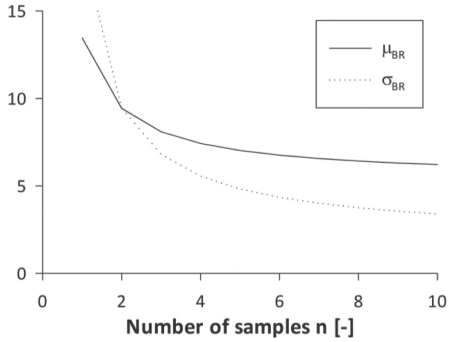

Figure 8. Influence of the number of samples for M_i on the characteristics of the robustness index.

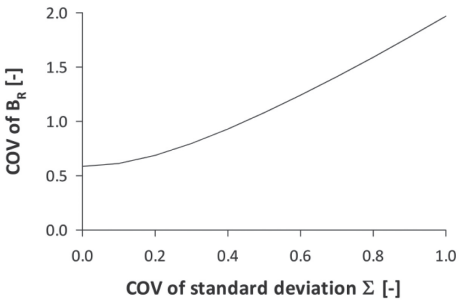

Figure 9. Influence of COV of Σ on the COV of B_R.

Figure 7 shows the influence of the coefficient of variation of the standard deviation of the influencing variables on the mean and standard deviation of the robustness index (the number of samples n remains constant). The graph indicates that both statistics increase significantly as soon as the coefficient of variation is higher than 0.2. The standard deviation increases more than the mean value.

Figure 8 shows the influence of the number of samples n on the characteristics of the robustness index (the coefficient of variation of the standard deviation remains constant). As the number of samples increases, the mean and standard deviation decrease significantly. When the number of samples is higher than five, the value of the characteristics becomes more or less constant.

Figure 9 and 10 summarize these results by showing the coefficient of variation of the robustness index as a function of the coefficient of variation of the standard deviation and the number of samples used to determine the mean value. The influence of the parameter uncertainties is significant: the coefficient of variation of the robustness index increases by a factor of three as the coefficient of variation of the standard deviation increases from

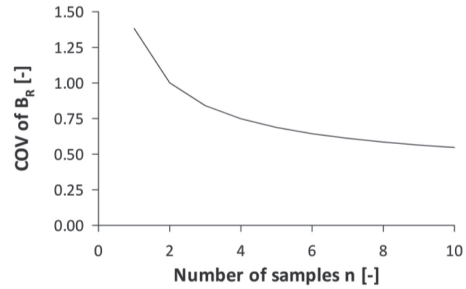

Figure 10. Influence of number of samples on the COV of B_R.

zero to one; and it decreases by a factor of 2.5 when the number of samples in increased from one to ten.

6 CONCLUSIONS

The quantification of the structural robustness under parameter uncertainties was investigated. Therefore, the framework, as developed by Der Kiureghian (2008) for the reliability index under parameter uncertainties, was extended for the reliability-based robustness index. The approximate calculation of the mean and standard deviation of the robustness index, assuming a lognormal distribution for the reliability index, agrees very good with the results from the calculation of these statistics through second-order Taylor approximations. Hence, the lognormal distribution can be considered as a good approximation for the distribution of the robustness index. Finally, the developed framework was applied on a reinforced concrete beam, subjected to chloride-induced corrosion. This showed that parameter uncertainties have a significant influence on the value and uncertainty of the robustness index.

ABSTRACT: In this paper, we want to promote a new approach for modeling the degradation of infrastructures for maintenance purposes. This approach is an intermediate between physical models, that can be complex to apply in a reliability context, and pure probabilistic models, that fail to reflect the physical degradation and therefore suffer from lack of acceptability by the Civil engineering community. We will propose here a new data-driven meta-model. The construction of the state-dependent degradation model will be discussed within an application of the cracking of a submerged concrete structure subject to corrosion. Numerical experiments will be conducted for identifying preliminary properties of our model in terms of statistical inference and reliability concerns.

The consequences of lack or bad maintenance of these infrastructures can be dangerous on human lives and impact the economy, i.e. the Storstrøm Bridge in Denmark built in 1937. In October–November 2011 all train traffic was cancelled immediately after an inspection finding damages. The main plan was to repair everything, but there are doubts on the ability of the bridge to handle the future freight traffic. The cost of a new bridge would be more than 3 billion DKK (400 M€). In August 2012 the Danish government allocated funds for the construction of a new bridge.

The world became aware of the importance of reliability and maintenance, especially after a wave of bridge failing in the USA in these last two decades, i.e. I-35 W Mississippi River Bridge built in 1967 and collapsed in 2007 killing thirteen people.

In Europe, a large number of the infrastructures are built after the Second World War, therefore it is very frequent to find infrastructures built 50 years ago and more. A third of the steel structures in the Atlantic area were built more than 100 years ago.

Hence, many structures require repair and rehabilitation. Some repaired structures exhibit poor repair performance and needs to be assessed and given a reliable safety level.

Furthermore, the growing demand for energy, motivated research to develop new means of production as well as new locations for this production. One of the most targeted sites is clearly coastal areas.

Currently we see more research focusing on the exploitation of offshore wind farms: these farms are located in a very aggressive environment for materials and for inspections to be carried out easily. In addition, the investment cost of these means of production makes the costs of exploitation of this energy not profitable compared to the cost of nuclear energy, for example.

Even thou the repairing and inspection techniques, especially non destructive techniques, are well developed and the mathematical models are highly complex, the ability to use the two of them for one maintenance problem remains extremely hard for both mathematicians and for engineers.

Maintenance decisions are a complex problem since they are a function of many uncertain factors such as material properties, costs, influenced-environment factors (behavior and impacts on the structure), imperfect inspections, manpower and risk expressed with the degradation level. In this study, we deal with the latter one.

A literature review of degradation models of structures and infrastructure in a reliability and maintenance optimization context shows two major trends, on one hand we have rich models based on the explanation of the physical degradation and on the other hand we have probabilistic models based on statistical quantities (Frangopol et al. 2004). In maintenance optimization, the quality of a model is no longer limited to its ability of modeling the pathology and its fit to the data

and available knowledge, but also for its quality to predict the future performance of the structure, its ability to integrate new observations, particularly from Non-Destructive Techniques (NDT) as well as its ease of implementation in a more complex decision optimization criteria.

Since the end of the 1990s degradation models grew to become more and more complex, incorporating physic-chemical and mechanical couplings, leading to an explosion in the number of parameters: i.e. it is common nowadays a 10-parameters propagation deterministic model of chloride ions while Type 90s model included 2. The use of these approaches in a reliability-context raises several problems: how "to randomize" models whose parameters are usually correlated random variables having no prior information on them and how to perform sensitivity studies in the absence of these trends? An alternative for the model's calibration is to associate the integration of expertise in the models and the multiplication of the associated experiments, which grows in number as a function of the parameter number. In addition to this, health-monitoring data usually coming from NDT is not directly linked to these physic-based models and their associated parameters.

One approach seems promising for maintenance optimization in Civil engineering is the construction of meta-models based on stochastic processes such as the gamma process (Van Noortwijk, 2009). It allows modeling the evolution of the degradation using observations via non-destructive techniques while maintaining the most critical aspects of the degradation mechanism in the model for the decision and an ease of integration in a more complex maintenance decision criteria. We may further highlight modeling difficulties when the selected pathologies have non-stationary behavior over time (acceleration or deceleration effects of degradation). Extensions called conditional or state-dependent models (Vatn 2012) and (Zouch et al. 2011) are used to model these non-stationary effects based solely on levels of degradation. However, it may be noted in the construction of their model that they fail to find a robust procedure for the identification of input parameters as well as a lack of application procedure, limitations making them difficult to appropriate and validate in an operating context (Riahi et al. 2010).

The main objective of this article is to promote the approach of meta-models or integrated-degradation models for the decision in the context of optimization of condition-based maintenance of structures and infrastructures. The construction of the state-dependent degradation model will be discussed within an application of the cracking of a submerged concrete structure subject to corrosion. Numerical experiments will be conducted for identifying preliminary properties and advantages of our model in terms of statistical inference and reliability concerns.

We find an advantage in using Meta-Models when addressing two main stakes:

- First, the ageing model description with a physical meaning of the main probabilistic trends and couplings of the inputs (NDT assessment) and outputs (decision parameter). With this approach, we tackle a key issue: the scourge between more and more complex physical models and the increasing complexity of NDT results modeling and assessment (decoupling, fusion …) with heterogeneous developments between these two scientific fields;
- Second, in a condition-based maintenance context, the simple description, flexibility, calibration and statistical calculation make this model easy to implement and beneficial to utilize in a risk management framework. The evaluation of these meta-models is done through state-dependent stochastic processes using information issued from non destructive techniques. The idea is to facilitate the transfer between available information and model.

This paper can be seen as an extension of the preliminary work presented in El Hajj et al. (2014).

This work is a part of the SI3M project (2012–2016 Identification of Meta-Model for Maintenance Strategies) by *Region Pays de la Loire* (*France*).

1 PROBLEM STATEMENT

One of the main risks for a submerged concrete structure is its rupture due to cracking. Several techniques are devoted to measure and monitor the evolution of cracks in concrete. In the case of a reinforced concrete structure, the steel frame has indeed strengthened the material property, but can also be a cause of new cracks because of its own corrosion.

The cracking process of a reinforced concrete structure can be divided into three phases: the diffusion of the aggressive agent (chlorides in this case), the corrosion of the reinforcement steel and the crack propagation from the reinforcement steel towards the surface. The first phase is characterized by the diffusion of chlorides in the concrete. When the chloride concentration on the surface of the reinforcement steel exceeds a threshold concentration, we have steel depassivation followed by the initiation of the corrosion. The second phase is dominated by the expansion of corrosion products in which they slowly fill the pores surrounding the reinforcement steel. Finally, the propagation phase

lies in the accumulation of corrosion which generates tensile stress and results in an excessive crack propagation of concrete cover till rupture. These three phases are shown in the graph in Figure 1. In this study propagation is assumed to result from the corrosion and not from fatigue.

We limit this study to the third phase, crack propagation. Within the context of this phase, the parameters of importance are the corrosion rate and the width of the crack (Li et al. 2006).

The corrosion rate, V_{corr}, represents the volumetric loss of metal per unit of area and unit of time (mm year^{-1}), can be obtained non-destructively from the corrosion current density, i_{corr} (uA/cm^2) through Faraday's law and the density of the metal. i_{corr} is an instantaneous rate of corrosion measured using a nondestructive technique, highly sensitive to external conditions (temperature, humidity …). Thus, it is important to note that for modeling and decision support calibration curves depending on the environmental conditions must be available or that inspections must always be carried out under identical conditions. We assume the second condition is verified, the first one has not been established generally (Breysse et al. 2009). Figure 2 represents the variation of the corrosion rate on all three phases of the cracking.

The crack is considered accessible by its width which is easily measured (Gauge block or image analysis). In Figure 3, Vu et al. (2006) draw the

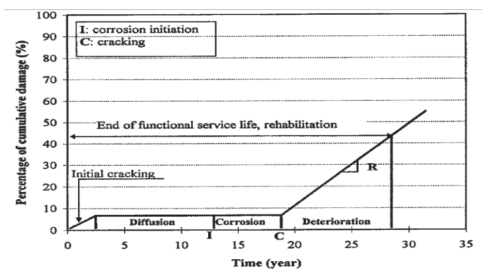

Figure 1. Degradation by corrosion of reinforced concrete (50 mm cover) by (Youping Liu, 1996).

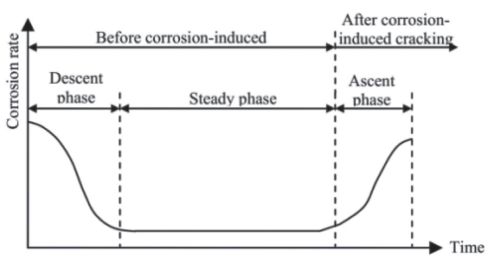

Figure 2. Variation of corrosion rate (Yuan et al. 2009).

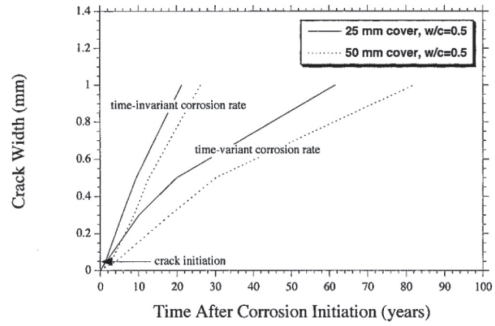

Figure 3. Variation of the width of crack—Phase 3 (Vu et al., 2006).

shape of the variation of the width of a crack versus time for two cases of corrosion rate (invariant or time-varying) and two coatings. The importance of modeling the corrosion rate by a cumulative process is clear. The hypothesis of an invariant corrosion rate is not conservative: in 20 years, it leads to an overestimation of 50% of the crack width.

As far as we know, no work has been published for studying the mutual dependencies of the two processes. One main reason can be attributed to the need of a high number of experiments that is not available for this particular phase; another good reason is that it's virtually impossible to integrate the mutual dependencies in the available physics-based models. However, the idea of modeling the degradation using two processes can be very rewarding in terms of maintenance and inspection optimization. First of all basing the maintenance decision on information coming from two sources of inspections can be more reliable than information coming from one (paragraph 3.2). Secondly, this can be appealing to inspection optimization in a sense that the decision maker can combine the information given by the two inspection modes.

Moreover, the time dependence of the two processes is non-stationary and the patterns can be considered as state-dependent (the evolution laws depend on the level of the current degradation). Finally, these two variables form a bivariate cumulative process where the two sub-processes are mutually dependent.

We propose here to define the bivariate process $(\rho_t, \theta_t)_{\forall t \geq 0}$ as a state dependent stochastic process similar to the one presented in Zouch et al. (2011). The evolution of degradation over a period of time τ is given by positive increments for the degradation processes respectively $(\Delta\rho, \Delta\theta)$ which are continuous random variables. A suitable candidate for these laws of distribution of each increment of the structure's degradation (Van Noortwijk, 2009) is the gamma distribution with two parameters (and

β where: (is the shape parameter and β is the scale parameter. In the described bivariate state-dependent case, we will consider that the shape parameter is a function of the current state.

In summary, the bivariate model is based on the two variables of interest: the size of the crack (maximum size of one structural component) and the rate of corrosion. As a result, the propagation of a crack is controlled by the combination of two state-dependent gamma processes:

– $(\rho_t)_{\forall t \geq 0}$ modeling the width of the crack « a » (mm)
– $(\theta_t)_{\forall t \geq 0}$ modeling the corrosion rate « i_c » (µA/cm^2).

It is essential to describe the relationship between the two sub-processes. To this aim, a choice was made based on a mechanical reason; there is a cause-effect relationship between the corrosion rate and the width of the crack. When the corrosion accelerates (corrosion rate increases), the crack undergoes more stress, which will translate in an acceleration of the cracking.

The correlation will be modeled in terms of mutual acceleration effects directly in each of the shape parameters of the gamma distributions. This model is sequential in the sense that in a first step we seek to characterize the evolution in terms of changes in the corrosion rate (Eq. 1) before doing so for the cracking itself (Eq. 2).

Finally, the advantage of a state dependent approach is that it transforms the process into a stationary one (with respect to time). We can then write, $\forall(\rho,\theta) > 0$:

$$\Delta\theta(\tau:\rho,\theta) \sim gamma(\alpha_\theta(\rho,\theta)\cdot\tau,\beta_\theta) \quad (1)$$

$$\Delta\rho(\tau:\rho,\theta,\Delta\theta) \sim gamma(\alpha_\rho(\rho,\theta,\Delta\theta)\cdot\tau,\beta_\rho) \quad (2)$$

Note.—To simplify the identification process, we consider that the state dependence is exclusive to the shape functions: the scale functions β_θ and β_ρ are considered constant throughout the life cycle. Therefore, we have to define the shape functions α_θ and α_ρ.

The choice for each shape function is based on the evolution of its process in time. In this case, it was found convenient to propose the following shape functions, $\forall(\rho,\theta) > 0$:

$$\alpha_\theta(\rho,\theta) = (a_3\cdot\rho + a_4)\cdot e^{\frac{-(\theta-a_1)^2}{a_2}} \quad (3)$$

$$\alpha_\rho(\rho,\theta,\Delta\theta) = \left(a_6\cdot\left(\theta+\frac{\Delta\theta}{2}\right)+a_7\right)\cdot e^{-a_5\cdot\rho} \quad (4)$$

The definitions of the parameters are presented in the Table 1.

Table 1. Definition of parameters.

Parameter	Definition
β_θ, β_ρ	Proportionality factors common to different structures (materials, …)
a_1	Abscissa of the inflection point of the realizations of corrosion rate
a_2	Reflects the dispersion around the inflection point
a_3, a_6	Acceleration coefficients
a_4	Corrosion rate speed at the origin
a_5	Reflects the kinetics of the process ρ
a_7	Crack growth rate at the origin

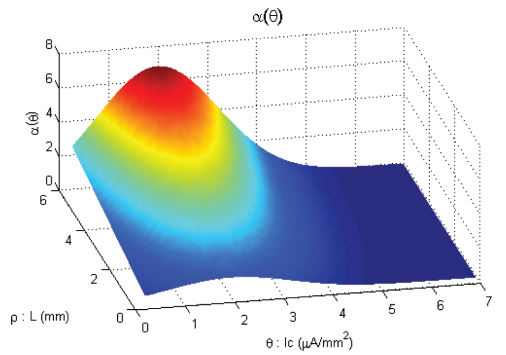

Figure 4. Shape function of the θ process—$\alpha_\theta(\rho,\theta)$.

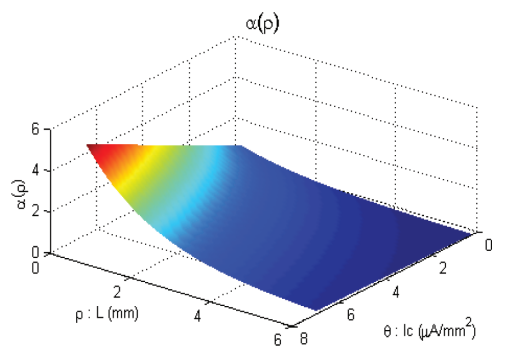

Figure 5. Shape function of the ρ process for constant $\Delta\theta - \alpha_\rho(\rho,\theta,\Delta\theta)$.

Figure 4, 5 illustrate the respective ρ and θ shape functions for given parameters.

The estimation of the parameters is carried using the method of the maximum like-hood on the database. We assume the existence of a database formed by successive perfect measurements of the crack width and the rate of corrosion of n structures denoted $\left\{\left(\rho_t^{(j)},\theta_t^{(j)}\right), t \geq 0,\ j \in [\![1,n]\!]\right\}$.

2 STATISTICAL PERFORMANCE ANALYSIS

In this section, we propose to conduct a set of numerical analyzes to highlight the statistical inference of the model properties.

2.1 *Convergence of the estimation procedure*

We propose an iterative Maximum Likelihood Estimator heuristic for the estimation of the parameters. The objective of this study is to analyze the convergence of our algorithm as a function of the sample size of the database. The Mean Squared Error is used as the performance criteria. We consider that the database is constructed from periodic inspections at a fixed time step τ on independent but identical structures. Two values define the size of the database N: the number of inspected structures n and the number of inspections carried out on each one of these structures T.

To illustrate the performance of our model and its convergence, we propose to evaluate the Mean Squared Error (MSE), Eq. 5, of the estimated parameter vector $\hat{\Theta}$ given the true parameter values Θ^*:

$$MSE = trace\{E\{(\hat{\Theta} - \Theta^*)(\hat{\Theta} - \Theta^*)^T\}\} \quad (5)$$

Table 2 summarizes the MSEs estimations for each one of the 9 parameters, for the total MSE per process, MSE_θ and MSE_ρ, and for the process MSE_t.

These results illustrate the convergence of the approach and more specifically the effects of the number of inspected structures and the number of inspections per structure.

We wanted to investigate the quality of the estimation based on the number of structures to monitor n and on the observation time per structure $T * \tau$.

Before going into the details of the analysis, we can emphasize that the number of data needed to obtain a good estimate may appear important. However, we recall here that we are interested in estimating laws on the entire life cycle of a structure in which the number of parameters, however, remain quite significant.

We can note a variety of behaviors depending on the parameters. We principally retain that the procedure favors the estimation of scale parameters and the parameters of the shape functions directly related to the level of cracking. This is mainly observed for samples of very small size. This can be explained by the fact that the corrosion rate level at $t = 0$ at the in-itiation of the crack is a random variable varying within a given range while the value at the origin of ρ is fixed. It is therefore difficult to calibrate the tails of the distributions when the only observations are concentrated in the early life cycle ($T = 5$) with a small number of structures ($n = 5$). To conclude this section, one can measure the compromise between extending the observation period and increasing the number of structures to monitor (we then take for a sample size $n * T$ with different n and T and we compare the MSE_t). In our experimentation, we can see a very fast compensation when adding new structures. This point is particularly interesting in the sense that it is often easier to find analogous structures than wait for the next inspection.

2.2 *Application to Eurocode 2*

Given the lack of models and data for the cracking propagation phase it is difficult to compare our approach with the literature. We propose here to highlight the benefits, in terms of quality of prediction and propagation of uncertainty for a given

Table 2. Mean Squared Error (MSE).

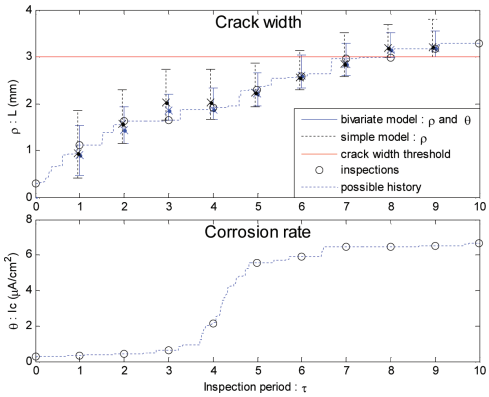

Figure 6. A tracking simulation of a structure and indicators on the quality of prediction of the cracking with and without taking into account the rate of corrosion.

structure, of the introduction of the θ-process in the overall cracking process.

In Figure 6, the dotted lines correspond to one possible history of the cracking structure extracted from the generic database. According to Table 7. N from Eurocode2, for an exposure class XS2 (Corrosion of the reinforcement induced by chlorides from sea water) the performance of the reinforced concrete structure are assumed modified when the width of a crack is greater than or equal to 3 mm.

For each period, τ, an inspection is conducted and the observed values are noted (black circles). For each observation, the expected value of degradation is estimated for the next inspection as well as its confidence interval of 90% when taking into account all the information (ρ and θ), blue lines, or just ρ (green lines). These quantities are obtained using stochastic simulations.

The advantage of our method is clearly illustrated in the decrease of the confidence interval. This illustration provides a better integration of the Eurocode 2 in the reliability decision of structures by adding the corrosion factor; the failure can be then defined as a level of risk related to changes in the performance of the structure for a given interval of time.

3 APPLICATION TO RISK MANAGEMENT

The aim of this section is to illustrate an application of the model in a risk management context. A structure is said to be safe if the probability of failure P_f at any time is lower than a given threshold. Such a safety requirement is given in Eurocode 2 by a failure cracking threshold L as a function of the characteristic of the structure and its environmental conditions.

In case of inspection, the decision criterion becomes the probability of having a failure before the next inspection should be lower than P_f.

The probability of a failure in the next inspection denoted $P_f(\rho_i, \theta_i)$ is a function of the current observation (ρ_i, θ_i) and given by the following equation:

$$P_f(\rho_i, \theta_i) = P(\Delta\rho + \rho_i > L \mid \rho = \rho_i, \theta = \theta_i) \tag{6}$$

For a selected range for ρ ($0 < \rho < L = 3$ mm) and θ, simulations were done for estimating the probability of failure for every possible combination (ρ, θ), Figure 7.

The use of such a curve in risk management could be in a classical way where the P_f threshold defines the acceptance and critical areas (in Figure 8, e.g. the system is said to be safe for any (ρ, θ) in the acceptance area under the iso-curve for a $P_f = 0.05$).

It is also easy to define a safety area with two thresholds and a specific attention or preventive action could be done to reduce the current risk level.

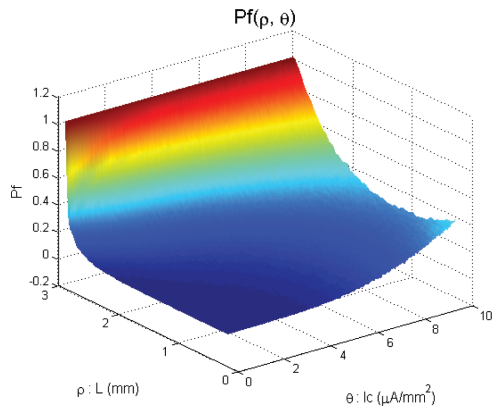

Figure 7. Probability of failure based on degradation level.

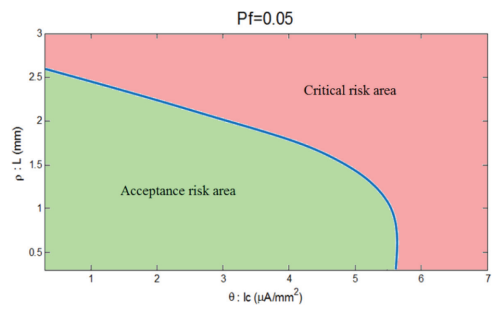

Figure 8. Smoothed iso-curve of the degradation levels for a given probability of failure equals to 0.05.

One major advantage of the proposed approach in risk management is that the decision can be modulated according to additional observation, given that θ can be seen as an acceleration factor of the cracking.

4 CONCLUSION

In this article the Meta-Model approach (El Hajj et al. 2014) is applied and discussed within an application to the cracking of a submerged concrete structure subject to corrosion. The degradation model is based on two correlated processes constructed by NDT data. Expert knowledge is introduced to reflect the main useful degradation properties that the model should tackle for decision-making. This allows both to simplify the construction and the fitness of the model to the data and to overcome some limits in the current practices in Civil Engineering (here the correlation between the crack width and the corrosion rate). We are aware that the construction of the model and, of course, the performance study is not based on field data, but we are confident in the philosophy of the approach and hope that it will help in the future data collection.

This work can also be seen as a preliminary work in the sense that we restrict the cracking phase to the propagation of a crack onto the surface of the structure. From a maintenance optimization perspective, it should be important to have a complete degradation model for the whole lifecycle. The meta-model construction approach will integrate the identification of the different processes in each phase of the cracking and the transition from one phase to the other.

Another perspective could be in modeling the actualization of the degradation model after a new inspection is done. Bayesian updating could be of interest since the bivariate aspect of the degradation process and the state-dependent degradation laws can make the modeling harder.

V. Bures
Faculty of Art and Architecture, Technical University of Liberec, Czech Republic

ABSTRACT: The reliability methods provided in ISO 13822 are applied for the reliability assessment of heritage structures. For practical application, the actual characteristics of existing materials are needed. The material properties can be updated using material tests of inspected structures. The behaviour of an existing structure and the previous load history should be considered when deciding about its further use and rehabilitation. As it is shown, the probabilistic methods may be effectively applied for reliability verifications and decisions about the intervention of cast-iron columns in an industrial heritage building.

1 INTRODUCTION

A number of factories, textile mills, warehouses and other industrial buildings, built from about 19th century up to beginning of 20th century in the Czech Republic, have been registered as industrial heritage monuments. Such structures are mostly of significant architectural, historic, technological or social value. They often form part of the urban landscape and provide the cityscape with visual historical landmarks, Beran et al. (2007).

When they are put out of service, the heritage buildings often degrade and turn into ruins. Reuse and adaptation of such buildings allows the integration of industrial heritage buildings into a modern urban lifestyle and also helps to protect cultural heritage. The buildings are often rebuilt to hotels, museums, residential buildings, commercial centres etc.

2 ASSESSMENT OF HERITAGE STRUCTURES

The assessment of existing structures including heritage ones differs in many aspects from the procedures taken during the design of new structures and may require the application of sophisticated methods, in many cases beyond the scope of common standards for structural design. The prescriptive documents used for the design or verification of new structures cannot be directly applied to the assessment, as the actual state of the structure and its materials must be considered. Moreover, the current standards have often more severe requirements than the standards that were applied at the time when the structure was originally designed. Although some existing structures appear to have a lower reliability level than is presently required for new structures, they may continue to fulfil their functions for many years.

This situation leads to the question of how to specify a suitable reliability level for existing structures when they are planned to be repaired or upgraded. For the optimal decision on structural rehabilitation, the principles of the theory of structural reliability and probabilistic optimisation may be effectively applied, Markova et al. (2013).

General requirements and procedures for the assessment of existing structures based on the theory of structural reliability are provided in the international standard ISO 13822 (2010) including new Annex I on heritage structures.

For practical applications, information on the properties of various construction materials is given in the set of Czech National Annexes to ISO 13822 (2010) which was developed within the new national standard CSN 73 0038 (2014).

One important requirement should be considered during the assessment of existing structures, though it is not explicitly given in ISO 13822 (2010): how to preserve the appearance and materials of heritage structures. Sustainability considerations are more important for the assessment of existing structures than for the design of new structures. Most important differences in the evaluation of functional criteria on structural reliability of new and existing structures are indicated in Table 1. The heritage value of a historic structure resides in the authenticity and integrity of its character-defining elements. To retain its authenticity and integrity, the structure should be preserved, as far as possible,

Table 1. Different viewpoints concerning functional criteria.

Considerations	Existing structures	New structures
Economic	Usually significant incremental costs for reliability enhancement	Usually lower incremental costs for reliability enhancement
Social	May be significant in the case of restriction or exclusion of exploitation and preservation of cultural heritage	Usually less significant than for existing structures
Sustainability	Preferably, existing building materials would be used (leading to reduction of waste materials)	Mostly new materials are used

with its original materials and structural concept intact. However, in some cases the verification of material properties may represent rather a difficult problem. This is particularly true for existing cast-iron columns having significantly different material properties from current structural steels.

An example of the assessment and successful reconversion of an existing industrial building is shown below.

3 ANALYSED INDUSTRIAL BUILDING

A spinning factory was built in the centre of the city of Liberec in North Bohemia in the year 1868. The factory served its purpose up to 1930. Then the building was out of use until 1990, when it was converted to a gallery with a coffee bar, later to a warehouse. Finally it was closed down, an act which led to its gradual degradation.

Recently, it was decided to include the building in the list of regional monuments and to carry out its rehabilitation. The existing industrial heritage building is intended to be used for residential purposes and as a coffee bar. One of the main concerns during the rehabilitation is to preserve the historical character of the building, including heritage structures with old cast-iron columns.

The building with its ornamental façade, just before its rehabilitation is shown in Figure 1.

Figure 1. Industrial heritage building.

Figure 2. A load bearing structure with cast-iron columns.

4 INSPECTION OF EXISTING STRUCTURES

The building made of fired solid bricks consists of three timber floors supported by cast-iron columns with ornamental heads (Fig. 2) carrying timber beams and timber floors. The wood was in some parts attacked by insects or dry rot.

It should be noted that the cast-iron columns were used in various industrial and public buildings erected in the Czech Republic during the 19th and early 20th centuries.

Visual inspection revealed that the masonry structures and cast-iron columns were without any significant damage of a static character. The geometry of all the cast-iron columns including their thickness were measured in the heights of 1 and 2 m above the floor level. The average values for selected columns are illustrated in Table 2.

The actual thickness of all the columns varied along their height and was surprisingly reduced in all the columns on the second floor. It should be noted that it was very difficult to obtain reliable information about the actual external and internal geometrical imperfections of the cast-iron columns.

Grey cast-iron is characterized by a high compressive strength and significantly reduced tensile

Table 2. Thickness of selected columns in mm.

Floor No.	Height of measurement	Thickness t of column No.		
		1	2	3
1st	1 m	21	22	21.5
	2 m	17.5	18	18.3
2nd	1 m	16	15.8	14.6
	2 m	14.7	15.5	14.4
3rd	1 m	17.4	17.2	16.4
	2 m	17.1	16.8	16.1

strength caused by the relative high carbon content between 2 and 5%. The behaviour of the material is ductile in compression and brittle in tension.

Non-destructive tests of the material hardness of the columns were made by the hardness tester TH 130 and then converted by means of a standardised relationship to the ultimate strength in compression. The results indicated that the ultimate strength of the cast-iron varies in a rather broad range from 665 to 800 MPa.

The material hardness was tested at two levels (1 and 2 m) in different parts of each column, and then converted to ultimate strength. The characteristic value of ultimate strength is estimated on the basis of EN 1990 (2002), Annex D. For example, for the selected column, the mean $m = 702$ MPa and the sample standard deviation $s = 50$ MPa are statistically evaluated for six measurements ($n = 6$) and the coefficient $k_n = 2.18$ (assuming lognormal distribution). The characteristic value of ultimate strength of cast-iron is estimated as

$$f_{u,k} = m - k_n s = 702 - 2.18 \times 50 = 593 \text{ MPa} \qquad (1)$$

The design value of ultimate strength $f_{u,d}$ may be roughly estimated for the column from expression (1), considering here the coefficient $k_n = 6.36$. Therefore, it leads to the estimation of the design value of yield strength $f_{yd} = 385$ MPa.

In case the validity of the ratio $f_u/f_y = 2$ between the ultimate compressive strength f_u and yield strength f_y (0.2% proof stress) could be considered, Rondal & Rasmussen (2004), then the characteristic value of yield strength is $f_{yk} \sim 300$ MPa and the design value may be estimated as 190 MPa. It is known that the tensile strength may be considered about one third of the compressive strength (about 60 MPa).

Due to the demands of preservationists not to damage the heritage structures, the results of the non-destructive tests were not calibrated by destructive tensile tests on the samples. Therefore, only a small sample of the material was extracted for a small punching test and the microscopic

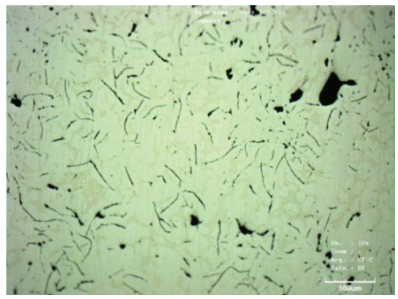

Figure 3. Microscopic analysis of the composition of cast-iron.

analysis of the column material was made (Fig. 3). The prepared material samples were analysed by means of a confocal laser microscope, which confirmed the type of cast iron. Black smudges formed by lamellar graphite are characteristic of gray cast iron. This graphite forms voids or cracks within the iron matrix and leads to considerably reduced tensile strength.

CSN 73 0038 (2014) contains a set of National Annexes to ISO 13822 (2010) and recommends material characteristics of cast-iron which may be applied for the verification of columns when further information is not available. The design value of yield strength under compression, and also compression strength in combination with bending is estimated in CSN ISO 13822 (2010) to 100 MPa (assumed to be a conservative estimate) and modulus of elasticity $E = 100$ GPa.

5 VERIFICATION OF A COLUMN

5.1 *Partial safety method*

Firstly the partial factor method representing the basic method given in EN 1990 (2002) is applied.

For the specification of the load-bearing capacity of the columns on each floor of the heritage building, actions due to self-weight, permanent actions, imposed loads and snow loads are considered. The column on the first floor is furthermore loaded by the masonry vault. Imposed loads for residential areas (category A) and two alternatives of a bearing floor structure are considered (alt. I—reinforced concrete slabs, alt. II—composite timber concrete slabs). Snow is determined according to the Czech snow map given in the nationally implemented EN 1991-1-3 (2003). The characteristic value of snow action in the site location is $s_k = 1.5$ kN/m^2.

Selected results of the analysis of internal forces and using up capacity (in%) are presented in Table 3 for specified material characteristics

Table 3. Reliability assessment of a column for the design strength f_{yd} = 190 MPa.

Alternative	Floor No.	N_{Ed} (kN)	N_{Rd} (kN)	Capacity (%)
I	3rd	350	405	86
	2nd	627	317	198
	1st	985	799	123
II	3rd	199	405	49
	2nd	328	317	104
	1st	530	799	66

Table 4. Reliability assessment of columns for the design strength f_{yd} = 100 MPa.

Alternative No.	Floor No.	N_{Ed} (kN)	N_{Rd} (kN)	Capacity (%)
I	3rd	350	225	155
	2nd	627	176	356
	1st	985	444	222
II	3rd	199	225	89
	2nd	328	176	187
	1st	530	444	119

of the in situ material testing, and in Table 4 for characteristics of the cast iron recommended in CSN 73 0038 (2014).

The results revealed that when the composite, lightweight timber-concrete floor would be designed (alt. II), and for material strengths based on measurements, the columns need not to be further strengthened.

In the cases when heavier floor structures (alt. I) or material characteristics given in ČSN 73 0038 (2014) are considered, most existing columns need to be strengthened, as they do not satisfy the basic reliability condition $R > E$.

Strengthening the columns by concreting their holes may be considered as a common method for which the basis of EN 1994-1-1 (2004) may be applied.

However, the efficacy of such a strengthening in the case of historic materials like cast iron differs from modern steels, and depends considerably on mutual interaction between the cast-iron and the concrete. Therefore, some further guidance is needed than that presently provided in Eurocodes, see e.g. Heider & Geisler (2007).

It should be mentioned that other methods of strengthening might also be applied, e.g. using strips of FRP polymers, see EN 1998–3 (2005).

However, each method of strengthening brings some advantages but also disadvantages which should be taken into account including simplicity of execution, fire resistance and the economic aspects.

5.2 *Probabilistic methods*

Probabilistic methods can be used for the verification of existing structures, or for the assessment of their residual lifetime, when appropriate probabilistic models of the basic variables are known. General guidance for the probabilistic verification of structures including the models of basic variables is given in the JCSS Probabilistic Model Code (2001).

For the probabilistic assessment of existing structures, the limit state function g($\boldsymbol{X}$) should be specified for the vector $\boldsymbol{X}$ of the basic variables. The variables entering the limit state function are random variables. Their characteristics may be described by means of probability theory and mathematical statistics. It is assumed that the structure is reliable for the inequality g($\boldsymbol{X}$) > 0. The reliability indicator, failure probability P_f is given as

$$P_f = \int_{g(X)<0} \varphi_X(x)\,dx \tag{2}$$

where $\varphi_X(\boldsymbol{x})$ is the joint probability density for the realisation of vector $\boldsymbol{x}$. Another reliability indicator is the generalized reliability index $\beta = -\Phi^{-1}(P_f)$ defined on the basis of failure probability P_f where Φ is the standardised normal distribution function.

Reliability analysis is based here on the limit state function g($\boldsymbol{X}$) corresponding to the load effect E and resistance R of the column

$$g(K_E\boldsymbol{E}, K_R\boldsymbol{R}) = K_R\,\boldsymbol{R} - K_E\,\boldsymbol{E} \tag{3}$$

Here $\boldsymbol{X}$ denotes the vector of basic variables (random variables entering the right hand side of this equation), K_R denotes the factor expressing the uncertainty of the resistance model and K_E the factor expressing the uncertainty of action effect model.

Models of basic variables are given in Table 5 (r denotes a column radius). The mean μ_X and the

Table 5. Models of basic variables.

Symbol	Distribution	Mean μ_X	Standard dev. σ_X
f_c	LN	$f_{ck} + 2\,\sigma$	0.10μ
f_y	LN	$1.45 f_{yk}$	0.15μ
r	N	r	$0.05\,\mu$
t	N	t	0.02
K_R	N	1	0.15
K_E	N	1	0.05
G	N	G	0.1G
Q_{Imp}	GUM	$0.6\,Q_{\mathrm{Imp}}$	$0.35 Q_{\mathrm{Imp}}$
Q_{Sn}	GUM	$0.35 Q_{\mathrm{Sn}}$	$0.7 Q_{\mathrm{Sn}}$

standard deviation σ_X of each variable are related to the characteristic value X_k used in the design calculations. For the reliability analysis of the column, the imposed load is considered here as a leading variable action and snow as an accompanying action (combination of 50 year maximum Q_{Imp} and an annual Q_{Sn}).

The results of the probabilistic analysis of a cast-iron columns indicate that when a reinforced concrete slab is applied and material properties of columns updated by testing are considered then the reliability index β is around $\beta \sim 3.5$ which is a little lower than the target value indicated in ISO 13822 (2010) for common types of structures in the consequence class CC2. In case the material properties recommended in the CSN 73 0038 (2014) need to be considered then the resulting reliability is very low ($\beta = 1.5$ only).

In case a lightweight composite timber concrete slab is applied in building rehabilitation then the reliability index $\beta = 4$ is determined for updated material properties, while $\beta = 2.4$ is determined only in case that the default material characteristics recommended for cast-iron columns in CSN 73 0038 (2014) are considered.

It appears that it is unnecessary to strengthen the cast-iron columns in case the updated material properties of the column are considered. However, when material property given in CSN 73 0038 (2014) is used in the analysis and no further information is known then the reliability of the columns is rather low and the columns should be strengthened.

Various uncertainties may exist about the real material properties and geometric imperfections of the cast-iron columns of the industrial heritage building. However, there is a clear evidence that the heritage structure of the spinning factory withstood for more than one hundred years considerably greater imposed loads than presently required for residential purposes.

Therefore, taking into account results of the reliability analyses and the previous good behaviour of a structure it could be recommended to leave the existing columns without any intervention.

6 CONCLUDING REMARKS

General requirements and procedures for the assessment of existing structures based on the theory of structural reliability are provided in the recently revised international standard ISO 13822. Additional guidance on heritage structures is given in the recently developed Annex I to this standard.

The partial factor method and also probabilistic methods are applied for the reliability assessment of a regional industrial heritage building. When the default material properties given in the national codes are applied only, it appears that the historic structures should be commonly strengthened. It is shown that when the actual geometry and material properties based on experimental data are applied, the reliability of the cast-iron columns is acceptable and no intervention is needed.

It is shown that the previous long-term satisfactory performance of the existing cast-iron columns could also be taken into account.

It appears that the characteristics of historic cast—iron materials should be further analysed and a supplementary guidance given in the National Annexes to ISO 13822.

Reliability of structures in national codes to Eurocodes

J. Marková & M. Holicky
Klokner Institute, Czech Technical University in Prague, Prague, Czech Republic

ABSTRACT: Alternative procedures for combination of actions together with reliability elements (partial and reduction factors) recommended in the national annexes to Eurocodes in some CEN member states, are investigated using probability-based reliability methods. Presented reliability analyses of structural members indicate that reliability level of some members might be in some cases lower than the required target reliability level and should be further calibrated.

1 INTRODUCTION

Presently the second generation of the Eurocodes for structural design is foreseen to be developed on the basis of document M/515 (2013) and financial support of European Commission. Recently various Working Groups (WGs) of the Committee CEN/TC 250 have been established including WG7 which is responsible for the evolution of the fundamental Eurocode EN 1990 (2002) for the basis of design. Several new topics are foreseen to be developed including provisions for non-linear structural analyses and fatigue. Annexes A1 and A2 for buildings and bridges will be improved and Annexes A3 to A5 for cranes and machinery, silos and tanks and towers and masts will be transferred to EN 1990 (2002) from appropriate parts of EN 1991 and EN 1993. Moreover, Annex B of EN 1990 (2002) on the management of structural reliability for construction works is intended to be further developed considering execution quality management. The revised Annex C will give information about reliability methods and also basis for the calibration of partial factors for actions and material properties. Chambers of civil engineers, construction and design companies and other users working in construction in various CEN Member States require simplification of Eurocodes and reduction of the current number of parameters NDPs (National Determined Parameters).

However, it appears that for further harmonization of Eurocodes the nationally selected NDPs should be verified including reliability elements as partial factors for actions and material properties, and also combination factors. Present activities of various associations in some CEN Member States including the Czech Republic are focused on the reduction of alternative load combinations and verification of partial factors for permanent and variable loads taking also into account original national standards. The technical subcommittees SC2 and SC3 for design of concrete and steel structures of CEN/TC 250 issued a resolution requesting examination and recalibration of the partial factors for permanent loads and for materials.

Such a recalibration of reliability elements should also take into account national decision given in the National Annexes to Eurocodes. Presently the CEN Member States are requested to upload their NDPs to the database of JRC for further statistical and theoretical analyses. It is expected that information on NDPs should also be available for the project teams facilitating analyses of reliability elements, see Resolution CEN BT (2013). About 2/3 of countries are uploading their NDPs to the JRC database.

Presently available information indicates that most European countries have adopted the values of partial factors and other reliability elements recommended in Eurocode EN 1990 (2002) for the basis of structural design. About half of the countries are applying an exp. (6.10) for verification of structures for the Ultimate Limit States (ULS) and other countries exps. (6.10a,b). Both alternatives (6.10) or (6.10a,b) are allowed to be use in some CEN countries including the Czech Republic (limitations in some countries for application of (6.10a,b) are given). Modified exps. ($6.10a_{mod}$,b) are applied in few countries where in the first expression the permanent actions are considered only. Some countries which preferred exps. (6.10a,b) increased the value of reduction factor ξ for permanent actions from the recommended value 0.85 up to 0.93 diminishing the difference in application of both alternative load combinations. Therefore, the reliability of structures designed according to the nationally implemented Eurocodes may differ from country to country (allowed by EC as a matter of their national safety).

It is expected that the feedback of practicing civil engineers and other users obtained during the application of Eurocodes will be used for the preparation of background materials facilitating further development of EN Eurocodes and will lead to their required harmonization. Presently the National annexes include recommendations concerning alternative procedures provided in EN 1990 (2002) for the fundamental combination of actions and selection of partial factors γ_G and γ_Q for permanent and variable actions. It was shown e.g. in Holicky & Markova (2005, 2010) that choice of the reliability elements significantly affects the resulting reliability level of construction works.

Submitted paper analyses nationally selected parameters of various CEN Member States including proposals for modification of material factors for concrete, reinforcement and steel. Structural members exposed to permanent and variable loads designed according to the recommendations of National Annexes to Eurocodes are analysed using probabilistic methods of structural reliability.

2 FUNDAMENTAL LOAD COMBINATIONS

EN 1990 (2002) introduces for the fundamental combination of actions in permanent and transient design situations (ULS of type STR) three alternative procedures, denoted here as A, B and C. Considering for simplicity one permanent action G and two variable actions Q (e.g. imposed loads) and W (wind actions), the exp. (6.10) of the combination rule A is given in EN 1990 for the design value of action effect E_d as

$$E_d = \gamma_G G_k + \gamma_Q Q_k + \gamma_W \psi_W W_k \quad (1)$$

An alternative procedure B is provided in EN 1990 by exps. (6.10a) and (6.10b) given as

$$E_d = \gamma_G G_k + \gamma_Q \psi_Q Q_k + \gamma_W \psi_W W_k \quad (2)$$

$$E_d = \xi \gamma_G G_k + \gamma_Q Q_k + \gamma_W \psi_W W_k \quad (3)$$

The less favourable action effect from (2) and (3) should be considered.

In addition, EN 1990 (2002) allows further modification of alternative B, simplifying equation (2) by considering permanent loads only (alternative C), denoted here as ($6.10a_{mod}$), thus the load effect is then

$$E_d = \gamma_G G_k \quad (4)$$

The less favourable action effect resulting from (3) and (4) is then considered.

If the leading action is wind W, then in equations (1) and (3) instead of reducing the wind action W by factor ψ_W, the imposed load Q should be reduced by appropriate factor ψ_Q. Factors γ_G, γ_Q and γ_W denote the partial factors of actions G, Q and W.

To investigate resulting load effects under various intensities of variable actions, the characteristic values of actions G_k, Q_k and W_k are related using quantity χ given as the ratio of variable actions Q_k+W_k to total load $G_k+Q_k+W_k$, and ratio k of accompanying action W_k to the main action Q_k as

$$\chi = (Q_k+W_k)/(G_k+Q_k+W_k),\ k = W_k/Q_k \quad (5)$$

The parameter χ may be commonly expected within a range from 0 to 0.6 for common buildings, however sometimes approaching to 1, e.g. in case of snow loads on light-weight steel roofs of industrial halls.

For a given design value of the load effect E_d, the characteristic values of individual actions G_k, Q_k, W_k can be expressed using variables χ and k as follows

$$G_k = \frac{E_d}{(\xi)\gamma_G + \dfrac{((\psi_Q)\gamma_Q + k(\psi_W)\gamma_W)\chi}{(1+k)(1-\chi)}}$$

$$\chi = (Q_k+W_k)/(G_k+Q_k+W_k),\ k = W_k/Q_k \quad (6)$$

The factors ξ, γ and ψ indicated in the first relationship of (6) in brackets are applied in the same way (either yes or no) as in equations (1), (3) for appropriate combination rules.

3 PROBABILISTIC ANALYSIS

EN 1990 (2002) allows a design directly based on the probabilistic methods. In accordance with the principles of these methods the basic variables are considered as random variables with appropriate distributions. It is verified that a limit state of a member is exceeded with a probability lower than the target value p_t given as

$$P(g(\boldsymbol{X}) < 0) < p_t \quad (7)$$

Here $g(\boldsymbol{X})$ denotes the limit state function, for which the inequality $g(\boldsymbol{X}) < 0$ indicates that the limit state is exceeded. The condition (7) may be replaced by the inequality $\beta > \beta_t$, where β denotes the reliability index. EN 1990 (2002) recommends the target probability $p_t = 7.24 \times 10^{-5}$ for ULS of common buildings corresponding to the reliability index $\beta_t = 3.8$ for 50 year design working life.

Reliability analysis is based on the limit state function $g(\boldsymbol{X})$ corresponding to load effect given e.g. by equation (1) and resistance R of a generic structural member

$$g(\boldsymbol{X}) = \theta_R R - \theta_E (G + Q + W) \quad (8)$$

Table 1. Probabilistic models of basic variables.

Basic variable	Distr.	Units	Char.	μ_X	σ_X
Permanent	N	MN/m²	G_k	G_k	0.1 μ_X
Imposed (5 y.)	GUM	MN/m²	Q_k	0.25Q_k	1.1 μ_X
Imposed (50 y.)	GUM	MN/m²	Q_k	0.6Q_k	0.35 μ_X
Wind (1 y.)	GUM	MN/m²	W_k	0.25 W_k	1.1 μ_X
Wind (50 y.)	GUM	MN/m²	W_k	0.6 W_k	0.35 μ_X
Concrete resistance	LN	MPa	R_k	R_k+2σ_X	0.15
Steel resistance	LN	MPa	R_k	R_k+2σ_X	0.08
Load uncertainty	LN	–	θ_E	1.0	0.10
Resist. uncertainty	LN	–	θ_R	1.0	0.05

Here $\boldsymbol{X}$ denotes the vector of basic variables (random variables entering the right hand side of this equation), θ_R denotes the factor expressing the uncertainty of the resistance model and θ_E the factor expressing the uncertainty of the action effect model.

An important step in any reliability analysis is the specification of probabilistic models for the basic variables. The limit state function, equation (8), has six basic variables that describe the actions G, Q and W, the resistance R and the model uncertainties θ_R and θ_E.

The probabilistic models of actions are related to their characteristic values used for the determination of the design values of actions (see Table 1). The permanent action is described by normal distribution (N), variable actions by Gumbel distribution (GUM) and material strength by log-normal distribution (LN). These models are primarily intended as "conventional models" in time invariant reliability analysis of structural members using Turkstra's combination rule, see e.g. Holicky (2013).

4 RESULTS OF ANALYSIS

Selected results of reliability analyses of some concrete and steel structural members are shown in Figures 1 to 8.

An effect of alternative load combination rules of a reinforced concrete beam is illustrated in Figure 1 for common structures in consequence class CC2 considering EN 1992-1-1 (2004).

Obviously the combination B given by exps. (6.10a,b) leads to a better balanced reliability than the combination rule A, exp. (6.10). Combination C (6.10a$_{mod}$,b) with parameters NDPs selected in some CEN countries where the values of partial factor for permanent load are γ_G = 1.2 in exp. (6.10a$_{mod}$) and γ_G = 1.0 in exp. (6.10b), for variable loads γ_Q = 1.5, for concrete γ_c = 1.45 and for reinforcement γ_s = 1.2 leads to a rather low reliability

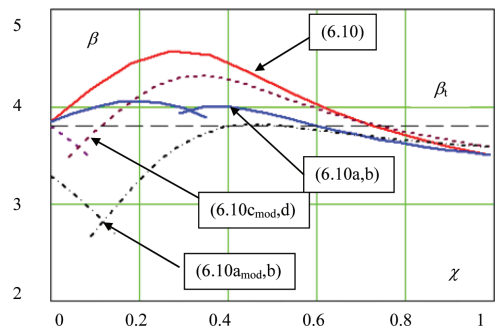

Figure 1. Variation of the reliability index β of the reinforced concrete beam with the load ratio χ (ρ = 0.8%), for the load combinations A to C.

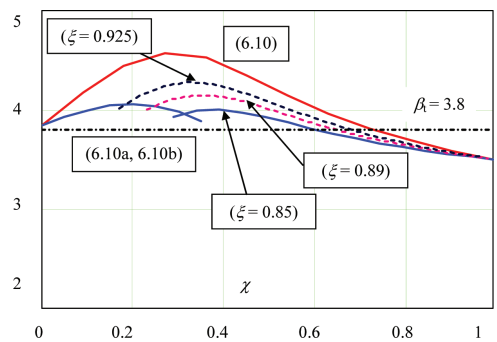

Figure 2. Variation of the reliability index β of the beam with the load ratio χ for the exp. (6.10) and exps. (6.10a,b) considering ξ = 0.85, 0.89 and 0.925.

level of the beam. It should be noted here that the target reliability accepted by these countries for the reliability class RC2 has been modified in comparison to EN 1990 (2002). Figure 1 illustrates also combination (6.10c$_{mod}$,d) where γ_G = 1.3 in exp. (6.10c$_{mod}$) and γ_G = 1,2 in exp. (6.10d) are applied leading to more balanced reliability level.

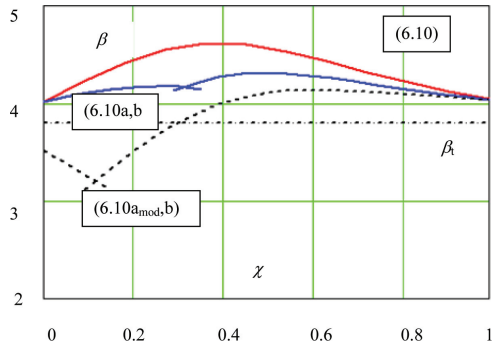

Figure 3. Variation of the reliability index β of the short column with the load ratio χ ($\rho = 1\%$), for the load combinations.

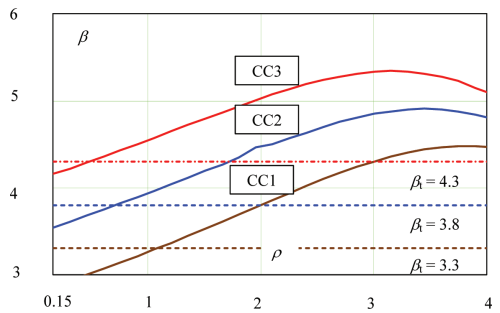

Figure 4. Variation of the reliability index β of the beam with the reinforcement ratio ρ for three consequence classes and load combination (6.10a,b).

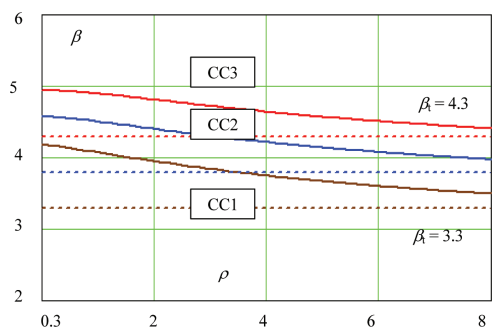

Figure 5. Variation of the reliability index β of the column with the reinforcement ratio ρ for three consequence classes and the load combination (6.10a,b).

Figure 2 shows the significance of national decision concerning the value of reduction factor ξ for permanent actions in alternative B, exp. (6.10b), on the reliability of the concrete beam which is then approaching the alternative A, exp. (6.10).

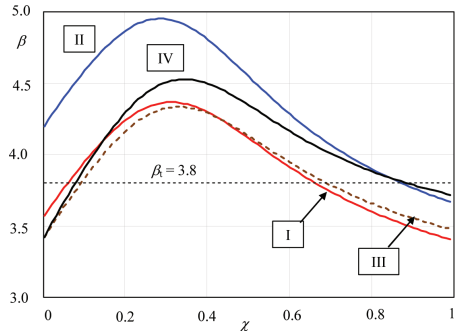

Figure 6. Variation of the reliability index β with the load ratio χ for $k = 0$, the load combination based on exp. (6.10) in EN 1990 and four sets of partial factors.

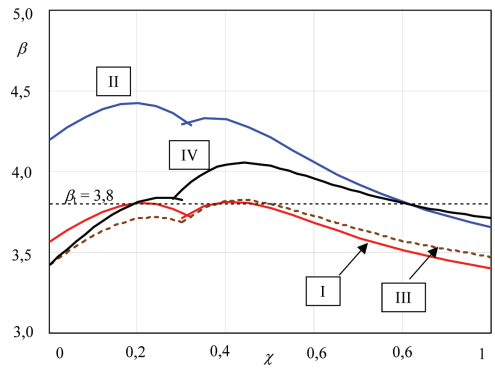

Figure 7. Variation of the reliability index β with the load ratio χ for $k = 0$, the load combination based on exps. (6.10a) and (6.10b) in EN 1990 and four sets of partial factors.

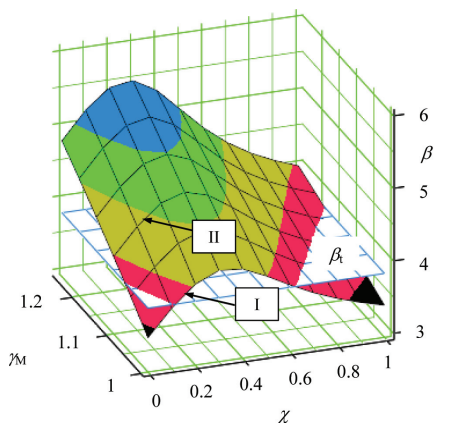

Figure 8. Variation of the reliability index β with the load ratio χ and partial factor γ_M for the load combination based on exp. (6.10) in EN 1990, the study cases I and II are indicated.

The reliability analysis of a short concrete column (axially loaded only, 1% of reinforcement ratio) designed according to Eurocodes, considering the recommended set of partial factors given in EN 1990 (2002), indicates that the reliability index β is greater than the target value β_t (3.8) for the alternative exp. (6.10) and exps. (6.10a,b), see Figure 3. However, for case C (exps. $6.10a_{mod}$,b) the reliability of the column is not meeting requirements.

Figure 4 indicates the favourable effect of increasing reinforcement ratio ρ (for load ratio $\chi = 0.3$) on the reliability level of a reinforced concrete beam for a considered combination B with recommended values of partial factors for variable actions for three reliability classes RC1 to RC3.

Figure 5 indicates the effect of reinforcement ratio on the reliability level of a column for a considered combination B and three reliability classes RC1 to RC3 where with the increasing reinforcement ratio the reliability of column is decreasing.

Next analyses are given for a steel member where presently the material factor $\gamma_M = 1$ is recommended in EN 1993-1-1 (2005) and nationally modified in some Member countries. Following four cases (denoted here by I to IV) characterized by different partial factors for actions and material properties are investigated, see Table 2.

The first two sets of partial factors (I, II) indicated in Table 2 are based on the recommendations of EN 1990 (2002) and EN 1993-1-1 (2003) (or ENV Eurocodes). The third set of γ-factors (III) was recommended in some National application documents of ENV Eurocodes and at present it is also selected as a set of NDPs in some countries. The fourth case (IV) describes a set of γ-factors where importance of material factor is increased and significance of partial factors for actions is reduced.

Figures 6 and 7 illustrate the reliability index β as a function of the load ratio χ assuming the probabilistic models of the basic variables given in Table 1. Further it is considered that the imposed load Q is leading and wind action W is accompanying. The following figures show results for the factor $k = 0$ (one variable action acting only). The reliability level $\beta_t = 3.8$, recommended by EN 1990 (2002) for the fifty year period of design life is indicated by the horizontal dashed line.

Table 2. Sets of partial factors for steel and actions.

No.	γ_M	γ_G	γ_Q
I	1.0	1.35	1.5
II	1.1	1.35	1.5
III	1.1	1.2	1.4
IV	1.2	1.1	1.4

It follows from Figure 6 that the set I of partial factors provides considerably lower reliability level of a steel member than the set II, however still acceptable for the load ratio χ within the common range from 0.1 to 0.6 for combination A. Comparing reliability indexes obtained for the first two cases I and II, it appears that the decrease of γ_M from 1.1 to 1 leads to the considerable decrease in reliability index β (by about 0.6).

Figure 6 (results for the load combination A based on expression (6.10)) and Figure 7 (combination B based on expressions (6.10a,b)) clearly indicate that the partial factor $\gamma_M = 1$ could be applied only in the load combinations based on expression (6.10) and not in the load combinations based on exps. (6.10a,b). It appears that the set of partial factors III may be used in the load combinations A, the set IV in the combinations B provided that the partial factor $\gamma_M > 1$.

It follows from Figure 8 that the set I of partial factors provides considerably lower reliability level of a steel member than the set II, however still acceptable for the common values of load ratio χ.

5 CONCLUSIONS

Submitted analysis of parameters NDPs which were nationally selected by some CEN Member States confirms results of the previous investigations that the reliability of structures, designed according to the alternative combination rules provided in EN 1990 by exps. (6.10) and (6.10a,b) may considerably vary. Exp. (6.10) (combination A) leads to the most reliable but most likely uneconomical structures. Exps. (6.10a,b) (combination B) yield a lower but a more uniform and satisfactory reliability level. It appears that recalibration of partial factors and other safety elements may minimize the deviation of the reliability from its recommended level (given by the reliability index β or probability of failure p_f). Some countries have selected the alternative ($6.10a_{mod}$,b) which leads to a rather low reliability level of structural members.

It is shown that the reliability of the steel members is significantly affected by the material partial factor γ_M. Obviously, any decrease in the factor γ_M leads to a decrease in the reliability level of the member. It appears that for the recommended partial factors γ_G, γ_Q for actions, the partial factor $\gamma_M = 1$ for steel recommended for the strength in EN 1993-1-1 leads to a considerably lower reliability level than previously used value $\gamma_M = 1.1$ in ENV Eurocodes. It appears that $\gamma_M = 1$ should not be used in the combinations based on exps. (6.10a,b) or their modification ($6.10a_{mod}$,b) and could

be used only in the combinations based on exp. (6.10).

ACKNOWLEDGEMENT

This is the partial outcome of the projects LG14012 International co-operation in reliability and risk assessment of structural systems supported by the Ministry of Education and P105/12/0589 Probabilistic optimisation of the target structural reliability supported by the National grant agency.

On climatic actions combinations for probabilistic calibrations

Z. Sadovský
Institute of Construction and Architecture, Slovak Academy of Sciences, Bratislava, Slovakia

ABSTRACT: The contribution addresses combination of time-variant actions, particularly snow and wind loads on a variety of structural design situations. The simplified Turkstra's rule commonly used for probabilistic calibration of standardized design procedures is compared with a an approach employing a direct inclusion of joint action effect. The study is carried out for three representative frames of low-rise industrial buildings designed such that both snow or wind loads could be relevant. For each frame three levels of permanent load realized as light, medium and heavy weight roofs are considered. The frames are designed to the lifetime of 50 years and reliability index $\beta_t = 3.8$ by FORM. The comparison of the values of the resulting design variable—the nominal plastic moment is presented.

1 INTRODUCTION

For the probabilistic assessment of a structure exposed to time-variant loads, the modeling of the maxima of their joint load effect is crucial. Since the load effect varies with the geometry of a structure, the calibration of standardized design approaches derives from simplified combinations of time-variant loads. A basic combination rule was proposed by Turkstra, which assumes that for the combination of two independent time-variant loads, the maximum effect of the combination occurs when one of the loads is at its maximum during the reference period and the other is at an "arbitrary point-in-time value". Another basic combination model is that of Ferry Borghes–Castanheta, see Melchers (2001). Focusing on exceedance probabilities, the rules were checked by pulse processes representations of loads by Wen (1990) and Sýkora & Holický (2011) with outcome appreciating performance of Turkstra's rule for calibration studies.

Adequate probabilistic models of climatic actions and their combinations heavily depend on detailed measurement records of sufficient durations. Such data is available for wind actions, e.g. hourly values of wind speed/pressure. The direct measurements of Snow Water Equivalent values (SWE) (if any) are performed, e.g. in weekly or monthly periods. Daily values have to be recalculated from other meteorological data on various levels of approximation. Consequently, as a starting point for the development of a probabilistic model often only annual or/and monthly snow load maxima with percentage of month with snowfalls (in transitional climates) are available. This allows determination of the annual maxima distribution function used by definition for the assessment of the characteristic value of the action; however combination with wind action then has to be restricted to the basic combination rules.

The present paper utilises database of daily values of snow and wind loads at Bratislava Koliba (BA Koliba) meteorological station. The data allow assessments of both snow and wind load maxima distributions as well as the distribution of maximum action effects on considered frame structures. Three geometries—A, B, C of the frames follow the paper of Schleich et al. (2002) reflecting the cases of dominant snow, wind and combined actions. For each frame three cases of light to heavy weight roofs are considered Sadovský & Páleš (2008) (Sadovský & Sýkora, 2013). The nine design situations provide reasonably broad variety of climatic action effects.

A probabilistic design of the frames for the lifetime of 50 years and the target reliability index $\beta_t = 3.8$ is carried out by FORM. The nominal plastic moments $M_{pl,nom}$ (the design variable) are calculated adopting climatic loads combinations by Turkstra's rule as well as using distribution functions of maxima of their joint action effects developed for each design situation.

The aim of the study is to illustrate differences in design variable values when the simplified combination rule of Turkstra is applied in comparison to a direct inclusion of a joint action effect oriented approach.

The design situations are described in Section 2. The results of probabilistic design are shown in Section 3. Finally short Conclusions Section is given.

2 DESIGN SITUATIONS

2.1 *Basic description*

The dimensions of considered frames are shown in Figure 1 (Schleich et al., 2002). The corresponding limit-state functions Z are given in Eq. (1)

$$Z = M_{pl} - m_{1G}G - m_{1S}S - m_{1W}W, \quad (1)$$

where m_{1G}, m_{1S}, m_{1W} are maximum bending moments found at the leeward corner corresponding to the unit permanent G, wind W and snow load S, Table 1. The products in Eq. (1) represent the load effects of the permanent, snow and wind loads.

The probabilistic model of plastic bending capacity M_{pl} is described by a log-normal distribution. The statistical parameters are expressed in terms of the nominal capacity $M_{pl,nom}$ (Table 2), which is the design variable.

Sadovský and Páleš (2008) extended the number of design situations considering low, medium and high levels of the permanent load. For this purpose, the parameter χ introduced in SAKO (1999) as the ratio of characteristic climatic load effects to the sum of the characteristic climatic and permanent load effects was used

$$\chi = \frac{(m_{1S}S_k + m_{1W}W_k)}{(m_{1G}G_k + m_{1S}S_k + m_{1W}W_k)}. \quad (2)$$

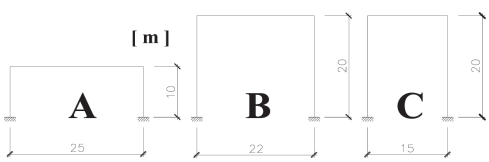

Figure 1. Dimensions of frames.

Table 1. Coefficients of the limit-state functions Eq. (1) (Schleich et al., 2002).

	m_{1G}	m_{1S}	m_{1W}
Frame A	43.37	34.70	7.50
Frame B	27.72	22.18	38.20
Frame C	11.25	9.00	78.03

Table 2. Statistical parameters of the plastic bending capacity (Schleich et al., 2002).

	Mean [kNm]	St. Deviation [kNm]
M_{pl}	1.18 $M_{pl,nom}$	0.08 $M_{pl,nom}$

The values χ = 0.8, 0.5, 0.2 represent light, medium and heavy weight roofs.

Equation (2) allows defining the characteristic value of the permanent load G_k by the characteristic values of snow S_k, wind W_k and χ. The permanent load G is normally distributed with the mean value equal to the characteristic value. The coefficient of variation $V_G = 0.05$ is adopted for the light and medium weight roofs; for the heavy weight roofs $V_G = 0.1$ is considered.

Note that the loads are introduced as uniformly distributed over the unit bay width (1 m). Due to linearity of the limit state function (1), the results obtained can be applied to other bay widths just by multiplication.

2.2 *Probabilistic model of wind and snow action*

The data for the assessment of daily snow and wind loads were collected since the beginning of 1951 up to the half of the year 2006 at Bratislava Koliba (BA Koliba) meteorological station. For snow load with available weekly measurements of SWE the daily values were recalculated from other meteorological data and than fitted to the measurements, Sadovský et al. (2007). SWE are recorded in millimetres; a formal division of the SWE value by 100 is used to obtain the snow load in kN/m^2. The data on wind loads are obtained as transformed daily wind speed maxima of three regular measurements at 7 a.m., 2 p.m. and 7 p.m.

For snow and wind actions the distributions of seasonal and monthly maxima were adjusted from the measurements. Since the minimum size of a sample is 56, which well suites for approximation of the mean value and standard deviation by the sample average and standard deviation, the Gumbel distribution adjusted to these parameters (a, b) was adopted.

Figure 2 shows the approximation of the sample probability of seasonal SWE maxima on the ground. A help line at the 98% probability corresponds to the level of the characteristic value of a climatic action (Eurocode EN 1990: 2002). The cdf of monthly SWE maxima for months with snowfalls are in Figure 3. Including the months without snowfalls, altogether 408 out of 666, a spike probability $1 - p_S$, p_S = (666-408)/666 at zero is added to the cdf from Figure 3 ($F_Y(y)$), which is further correspondingly adjusted and trimmed to $F_{Y,mix}(y)$ Eq. (3), (Fig. 4).

$$F_{Y,mix}(y) = (1 - p_S + p_S F_Y(0))1_{0\le y} + p_S[F_Y(y) - F_Y(0)]_{0\le y} \quad (3)$$

Figures 5, 6 show the sample probability distribution of seasonal and monthly wind pressure maxima measured at the height of 10 m above an

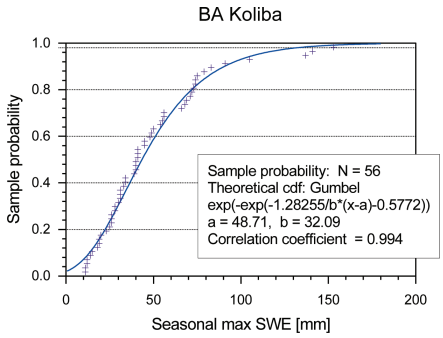

Figure 2. Sample and Gumbel cdf of SWE seasonal maxima.

open terrain. The stepwise values of wind pressure relate to wind speed measurements in whole numbers of meters per second.

Note that the monthly and seasonal maxima provide parameters which do not relate to each other according to Gumbel distribution. For the assessment of a life-time cdf (T = 50 years) the seasonal cdf is employed. The rationale stems from possible dependences in monthly maxima related to occurrences of snow cover durations of more than one month, cf. Coles (2001), Reiss and Thomas (2007).

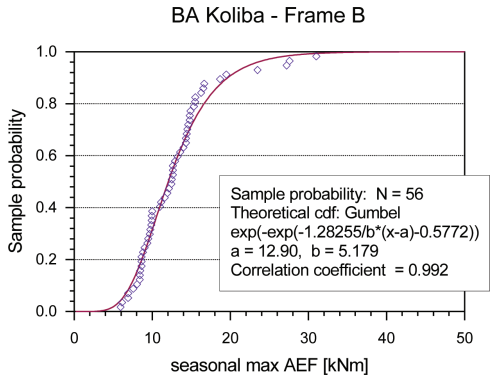

Figure 8. Sample and Gumbel cdf of seasonal maxima of joint climatic actions effect, Frame B.

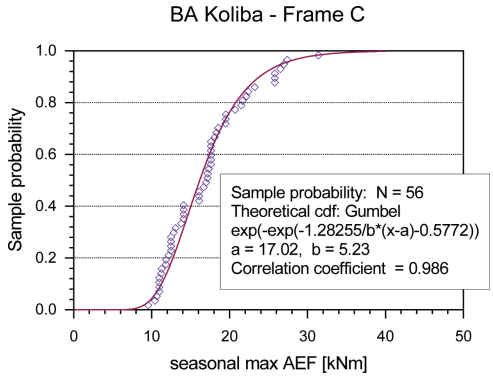

Figure 9. Sample and Gumbel cdf of seasonal maxima of joint climatic actions effect, Frame C.

2.3 *Probabilistic models of joint climatic actions effect*

The sample and approximating Gumbel probability distributions of seasonal maxima of joint climatic actions effect (max AEF) are shown for Frames A, B, C in Figures 7–9. It is obvious that the Frame A is exposed to the occurrence of the highest climatic actions effects.

3 PROBABILISTIC DESIGN OF FRAMES

A probabilistic design of the representative frames is carried out assuming the lifetime of 50 years and the corresponding target reliability index $\beta_t = 3.8$ (EN 1990: 2002). The nominal bending resistance of a cross-section (the design variable) is determined to reach the target reliability in each design situation. An efficient FORM iteration algorithm is applied, Sadovský (2000).

For combinations of snow and wind load by Turkstra's rule the cdf of the lifetime maximum of a dominant load is derived from the cdf of the seasonal maxima. For the accompanying snow action the mixed distribution $F_{Y,mix}(y)$ Eq. (3), (Fig. 4) of the monthly maxima is applied, while for the accompanying wind action the cdf of monthly maxima, Figure 6, is used. The decisive load combination is the one yielding a higher value of the design variable.

The lifetime cdf of maxima of joint action effects is derived from the cdf of seasonal maxima for each frame type, Figures 7–9.

The snow load on the ground should be transformed to the roof by an appropriate shape factor. In conformity to EN 1991-1-3: 2003 the shape factor 0.8 is applied assuming that the thermal and exposure factors are unity.

Nominal plastic moments $M_{pl,nom}$ (the design variable) are compared in Figures 10–12. The notation max AEF relates to the maxima of action effects, while max S_W to Turkstra's rule of time-variant load combinations.

Note that applying for accompanying snow load the monthly maxima cdf without spike (Fig. 3) the

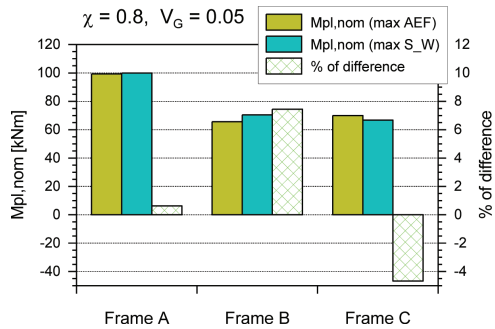

Figure 10. Nominal plastic moments, light weight roofs.

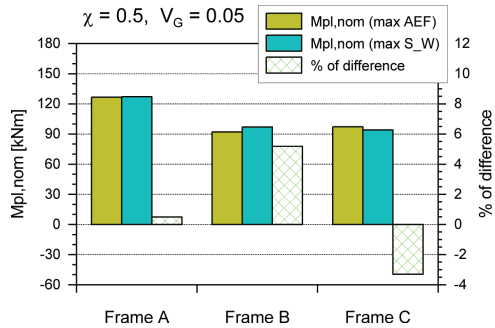

Figure 11. Nominal plastic moments, medium weight roofs.

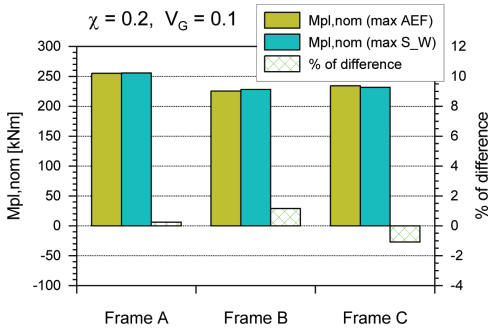

Figure 12. Nominal plastic moments, heavy weight roofs.

differences in the values of design variable shown for Frame C (Figs. 10–12) would be approximately halved.

4 CONCLUSIONS

The in calibration studies of structural design used Turkstra's rule for combination of time-variant loads is checked employing a direct inclusion of joint action effect. Particularly, the combination of climatic actions—snow and wind loads is addressed. The study is carried out for three representative frames of low-rise industrial buildings designed such that both snow or wind loads could be relevant. For each frame three levels of permanent load realized as light, medium and heavy weight roofs are studied.

A probabilistic design of the frames is carried out by FORM considering the lifetime of 50 years and reliability index $\beta_t = 3.8$. Both approaches are compared by the value of the design variable—the nominal plastic moment $M_{pl,nom}$. The results show that Turkstra's rule provides reasonable accurate results. This is in agreement with previous studies employing for time-variant loads pulse processes Wen (1990) and Sýkora & Holický (2011). Nevertheless, an extension of the study to other locations, i.e. to different levels and proportions of the climatic loads is foreseen.

In-plane buckling behaviors of shear-deformable columns with variable cross sections

Lijuan Su & Mario M. Attard
School of Civil and Environmental Engineering, The University of New South Wales, Sydney, NSW, Australia

ABSTRACT: A finite strain elastic in-plane buckling analysis is presented for shear deformable Timoshenko–type columns with variable cross-section. The constitutive relationship for stresses and finite strains is defined adopting a consistent hyperelastic constitutive model. Tensor notation is introduced to establish the physical relationships with simplicity in a curvilinear coordinate reference system. The generalized equilibrium equations are derived considering the shear deformations in addition to the bending deformations. The differential buckling equations are derived for tapered cantilever columns under compressive loads. The critical loads are obtained from the differential buckling equations using the Galerkin method. ANSYS software simulation modeling is also carried out to investigate the buckling problem of tapered columns and show close agreement with the results of numerical analysis. The in-plane buckling behaviors of tapered columns agree well with the published results in classic literature which validates the accuracy of the in-plane buckling formulation developed in this paper.

1 INTRODUCTION

The application of variable cross-sectional beams has increased in the engineering industry due to their unique advantage of the combination of efficiency, economy and aesthetics ((Billington 1985)). Tapered columns are common in all kinds of engineering application. Stability analysis of non-uniform columns is a fundamental component in structural design and had been extensively studied in the past few decades ((Coskun & Atay 2009), (Siginer 1992), (Smith 1988), (O'Rourke & Zebrowski 1977), (Serna et al., 2011)).

In the paper, the constitutive relationship for physical Lagrangian stresses and strains is defined based on consistent hyperelastic formulation to investigate the in-plane buckling behavior of variable cross-sectional columns under finite strain. The shear deformations are incorporated in the buckling formulation based on the Timoshenko beam hypothesis. The generalized equilibrium equations are derived from the virtual work equation. Applying the variational method to the equilibrium equations, the differential buckling equations are developed to for tapered cantilever column under compressive loading. In the numerical analysis, the representative elastic-to-shear rigidity ratios of the taper columns equal 3, 25 and 100 respectively, the critical loads are obtained from the differential buckling equations using the Galerkin method. The buckling problem of tapered columns is also investigated using the ANSYS software simulation. Critical buckling loads obtained from ANSYS model agree well with the results of numerical method analysis. The in-plane buckling behaviors of tapered columns are in good agreement with the results in the published classic literature. The obtained curves of behaviors of normalized buckling loads against slenderness are in good agreement with the results of existing literature (Timoshenko & Gere 1961).

2 KINEMATICS

Consider a structural member made from isotropic hyperelastic material with variable cross-section. The material lines follow the pattern of the continuum boundaries as depicted in Figure 1. In the initial configuration the position vector $\mathbf{P}$ of an arbitrary point on a general material line s with respect to the right-handed rectangular Cartesian coordinate system is given by:

$$\mathbf{P} = x\mathbf{i_1} + y(x)\mathbf{i_2} \tag{1}$$

$\mathbf{i}_1$ and $\mathbf{i}_2$ denote the unit base vectors in the x-axis and y-axis directions respectively.

A general curvilinear coordinate system is introduced. The profile coordinate s defines the material line, and a second coordinate t is perpendicular to the tangential length of the reference axis s_o.

The position vector of point $\mathbf{P_o}$ on the reference axis material line s_o is:

$$\mathbf{P_o} = x_o\mathbf{i_1} + y_o(x)\mathbf{i_2} \tag{2}$$

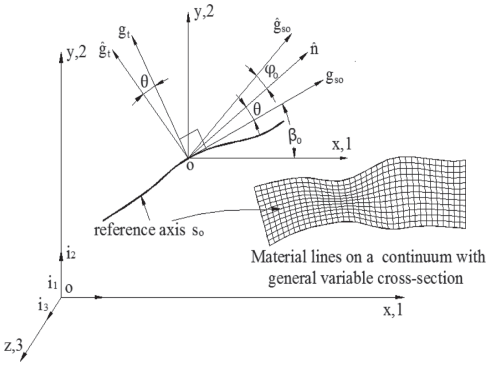

Figure 1. Tangent base vectors at reference axis.

x_o and y_o are the Cartesian coordinates of the reference axis s_o. The position vector **P** on a general material line can be expressed in terms of the curvilinear coordinate t such that:

$$\mathbf{P} = \left(x_o - t\sin\beta_o\right)\mathbf{i_1} + \left(y_o(x) + t\cos\beta_o\right)\mathbf{i_2} \tag{3}$$

Here β_o is the angle between the tangential line of the profile reference axis s_o at point $\mathbf{P_o}$ and the positive direction of the x-axis. The covariant tangent base vectors can be derived using Equation (3), hence:

$$\mathbf{g_s} = \frac{\partial \mathbf{P}}{\partial s} = \left(1 - t\frac{d\beta_o}{ds}\right)\left(\cos\beta_o\mathbf{i_1} + \sin\beta_o\mathbf{i_2}\right) + t_{,s}\left(-\sin\beta_o\mathbf{i_1} + \cos\beta_o\mathbf{i_2}\right) \tag{4}$$

$$\mathbf{g_t} = \frac{\partial \mathbf{P}}{\partial t} = -\sin\beta_o\mathbf{i_1} + \cos\beta_o\mathbf{i_2} \tag{5}$$

The covariant tangent base vector at the reference axis (t=0) is:

$$\mathbf{g_{so}} = \cos\beta_o\mathbf{i_1} + \sin\beta_o\mathbf{i_2} \tag{6}$$

Using Equations (6) and (5), the covariant tangent base vector in equation (4) can be rewritten with respect to the basis $\{\mathbf{g_{so}}, \mathbf{g_t}\}$ as:

$$\mathbf{g_s} = \left(1 - t\frac{d\beta_o}{ds}\right)\mathbf{g_{so}} + t_{,s}\mathbf{g_t} \tag{7}$$

The contravariant base vectors can be derived from equations (4) and (5) as:

$$\mathbf{g^s} = \frac{\mathbf{g_{so}}}{\left(1 - t\frac{d\beta_o}{ds}\right)} \quad \mathbf{g^t} = -\frac{t_{,s}}{\left(1 - t\frac{d\beta_o}{ds}\right)}\mathbf{g_{so}} + \mathbf{g_t} \tag{8}$$

The covariant tangent base vectors in the deformed state are:

$$\hat{\mathbf{g}}_\mathbf{i} = \left(\delta_i^j + u^j\Big|_i\right)\mathbf{g_j} \tag{9}$$

The indices i and j in equation (9) take on values of s or t. δ_i^j is the kronecker delta. $\mathbf{g_j}$ are the covariant tangent base vectors in the initial state and $u^j\Big|_i$ represent the covariant derivatives. The Einstein summation convention is adopted.

The displacement vector **u** is given by:

$$\mathbf{u} = \frac{u_o - t\sin\theta}{1 - t\frac{d\beta_o}{ds}}\mathbf{g}_s + \left(v - t\left(1 - \cos\theta\right) - \frac{t_{,s}\left(u_o - t\sin\theta\right)}{1 - t\frac{d\beta_o}{ds}}\right)\mathbf{g}_t \tag{10}$$

Where θ is the bending rotation taken as a function of the profile coordinate s only. u_o and v are the displacement components of the reference axis in the tangential direction and in the t direction respectively.

In the curvilinear coordinate system, the covariant derivatives of displacement vector are:

$$u^j\Big|_i = u^j{}_{,i} + u^k\Gamma^j_{ki} \tag{11}$$

The Christoffel symbols can be calculated from the base vectors in equations (4) and (5) and are given by:

$$\Gamma^t_{tt} = \Gamma^s_{tt} = 0 \tag{12}$$

$$\Gamma^s_{ss} = -\frac{2t_{,s}\frac{d\beta_o}{ds} + t\frac{d^2\beta_o}{ds^2}}{1 - t\frac{d\beta_o}{ds}} \tag{13}$$

$$\Gamma^s_{st} = \Gamma^s_{ts} = \frac{-\frac{d\beta_o}{ds}}{1 - t\frac{d\beta_o}{ds}} \qquad \Gamma^t_{ts} = \Gamma^t_{st} = \frac{t_{,s}\frac{d\beta_o}{ds}}{1 - t\frac{d\beta_o}{ds}} \tag{14}$$

$$\Gamma^t_{ss} = \frac{t_{,s}\left(2t_{,s}\frac{d\beta_o}{ds} + t\frac{d^2\beta_o}{ds^2}\right)}{1 - t\frac{d\beta_o}{ds}} + \frac{d\beta_o}{ds}\left(1 - t\frac{d\beta_o}{ds}\right) + t_{,ss} \tag{15}$$

Substituting Equations (12)-(15) and (10) into Equations (11), and then substitute Equations (11) into Equations (9), the covariant tangent base vectors in the deformed state can be derived, we have:

$$\hat{\mathbf{g}}_{\mathbf{s}} = \left(1+u^{s}\big|_{s}\right)\mathbf{g}_{s} + u^{t}\big|_{s}\,\mathbf{g}_{t}$$
$$= \left(1+\tilde{u}_{o,s} - t\cos\theta\frac{d}{ds}\left(\beta_{o}+\theta\right) - t_{,s}\sin\theta\right)\mathbf{g}_{\mathbf{so}} \qquad (16)$$
$$+\left(\tilde{v}_{,s} - t\sin\theta\frac{d}{ds}\left(\beta_{o}+\theta\right) + t_{,s}\cos\theta\right)\mathbf{g}_{t}$$

$$\hat{\mathbf{g}}_{t} = u^{s}\big|_{t}\,\mathbf{g}_{s} + \left(1+u^{t}\big|_{t}\right)\mathbf{g}_{t}$$
$$= \frac{-\sin\theta}{1-t\dfrac{d\beta_{0}}{ds}}\mathbf{g}_{s} + \left(\cos\theta + \frac{t_{,s}\sin\theta}{1-t\dfrac{d\beta_{0}}{ds}}\right)\mathbf{g}_{t} \qquad (17)$$

where

$$\tilde{u}_{o,s} = u_{o,s} - v\frac{d\beta_{o}}{ds} \qquad \tilde{v}_{,s} = v_{,s} + u_{o}\frac{d\beta_{o}}{ds} \qquad (18)$$

At the reference axis ($t=0$), we have:

$$\hat{\mathbf{g}}_{s}\cdot\mathbf{g}_{s} = \lambda_{so}\cos\left(\theta+\varphi_{o}\right) = \left(1+\tilde{u}_{o,s}\right) \qquad (19)$$

$$\hat{\mathbf{g}}_{s}\cdot\mathbf{g}_{s} = \lambda_{so}\cos\left(\theta+\varphi_{o}\right) = \left(1+\tilde{u}_{o,s}\right) \qquad (20)$$

where φ_{o} is the shear angle, λ_{so} is the stretch of the reference axis. Rearranging equation (19) gives:

$$\hat{\gamma}_{so} = \lambda_{so}\cos\varphi_{o} = \left(1+\tilde{u}_{o,s}\right)\cos\theta + \left(\tilde{v}_{,s}\right)\sin\theta \qquad (21)$$

$$\hat{\gamma}_{t} = \lambda_{so}\sin\varphi_{o} = -\left(1+\tilde{u}_{o,s}\right)\sin\theta + \left(\tilde{v}_{,s}\right)\cos\theta \qquad (22)$$

where $\hat{\gamma}_{so}$ and $\hat{\gamma}_{t}$ are the normal component and tangential shear component of the stretch of reference axis.

The deformation gradient tensor $\mathbf{F}$ is defined as:

$$\mathbf{F} = \hat{\mathbf{g}}_{\mathbf{i}}\otimes\mathbf{g}^{\mathbf{i}} \qquad (23)$$

The deformation gradient tensor $\mathbf{F}$ can be decomposed into two tensors, such that:

$$\mathbf{F} = \mathbf{R}\mathbf{F}^{*} \qquad (24)$$

where $\mathbf{R}$ is a rotation tensor and $\mathbf{F}^{*}$ is a rotated deformation tensor. Hence:

$$\mathbf{F} = \begin{bmatrix} \dfrac{1+\tilde{u}_{o,s} - t\cos\theta\dfrac{d}{ds}\left(\beta_{o}+\theta\right)}{1-t\dfrac{d\beta_{o}}{ds}} & -\sin\theta \\ \dfrac{\tilde{v}_{,s} - t\sin\theta\dfrac{d}{ds}\left(\beta_{o}+\theta\right)}{1-t\dfrac{d\beta_{o}}{ds}} & \cos\theta \end{bmatrix} \qquad (25)$$

$$\mathbf{R} = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} \qquad (26)$$

$$\mathbf{F}^{*} = \begin{bmatrix} \dfrac{1}{1-t\dfrac{d\beta_{o}}{ds}}\left(\hat{\gamma}_{so} - t\frac{d}{ds}\left(\beta_{o}+\theta\right)\right) & 0 \\ \dfrac{1}{1-t\dfrac{d\beta_{o}}{ds}}\hat{\gamma}_{t} & 1 \end{bmatrix} \qquad (27)$$

The Green deformation tensor $\mathbf{C}$ can now be expressed in terms of the rotated deformation tensor $\mathbf{F}^{*}$, such that:

$$\mathbf{C} = \mathbf{F}^{\mathbf{T}}\mathbf{F} = \mathbf{F}^{*\mathbf{T}}\mathbf{F}^{*} \qquad (28)$$

The Jacobian J obtained from equation (27) is:

$$J = \det\left(\mathbf{F}\right) = \det\left(\mathbf{F}^{*}\right)$$
$$= \frac{1}{1-t\dfrac{d\beta_{o}}{ds}}\left[\hat{\gamma}_{so} - t\frac{d}{ds}\left(\beta_{o}+\theta\right)\right] \qquad (29)$$

3 HYPERELASTIC CONSTITUTIVE RELATIONS

A physical Lagrangian stress tensor is defined and established by applying vector transformation to the second Piola Kirchhoff stress tensor Π components using equation (27), such that:

$$\mathbf{S} = \prod\mathbf{F}^{*\mathbf{T}} = \begin{bmatrix} S^{nn} & S^{nt} \\ S^{tn} & S^{tt} \end{bmatrix} \qquad (30)$$

where S^{nn} is the normal stress component while S^{nt} is the tangential shear stress component.

The strain energy density function U for a compressible isotropic neo-Hookean material (see Attard & Hunt (2004)) is given by:

$$U = \tfrac{1}{2}G\left(tr\left(\mathbf{C}-\mathbf{I}\right) - 2\ln J\right) + \tfrac{1}{2}\Lambda\left(\ln J\right)^{2} \qquad (31)$$

where tr signifies the trace of a tensor, G is the shear modulus, Λ is the Lamé constant, E is the elastic modulus and μ is the Poisson's ratio. A constitutive relationship for the second Piola Kirchhoff stress tensor $\prod$ and its conjugate Green's stain tensor $\mathbf{C}$ for a hyperelastic material is given by (see Attard & Hunt (2004)):

$$\prod = 2\frac{\partial U}{\partial\mathbf{C}} = G\,\mathbf{I} - p_{h}\mathbf{C}^{-1} \qquad p_{h} = G - \Lambda\ln J \qquad (32)$$

where p_{h} represents a hydrostatic stress. From equations (28) and (32) the constitutive relationship

for the physical Lagrangian stress **S** can be obtained as:

$$\mathbf{S} = \prod \mathbf{F}^{*\mathbf{T}} \cong G\left(\mathbf{F}^{*\mathbf{T}} - \mathbf{F}^{*\text{-}\mathbf{1}}\right) + \Lambda(J-1)\mathbf{F}^{*\text{-}\mathbf{1}} \tag{33}$$

The constitutive relations for the physical Lagrangian stress components in terms of the deformations are obtained as:

$$S^{nn} = \frac{E}{1 - t\dfrac{d\beta_o}{ds}}\left[\left(\hat{\gamma}_{so} - 1\right) - t\frac{d\theta}{ds}\right] \tag{34}$$

$$\mathbf{S}^{nt} = \frac{G}{1 - t\dfrac{d\beta_o}{ds}}\hat{\gamma}_t \tag{35}$$

The reference axis is such selected that the following geometric property is satisfied:

$$\int_A \frac{t}{1 - t\dfrac{d\beta_o}{ds}}\, dA = 0 \tag{36}$$

The cross-sectional area and the second moment of area are defined by:

$$\tilde{A}(s) = \int_A \frac{1}{1 - t\dfrac{d\beta_o}{ds}} dA \quad \tilde{I}(s) = \int_A \frac{t^2}{1 - t\dfrac{d\beta_o}{ds}} dA \tag{37}$$

Integrating the stresses over the cross-sectional area yields the internal actions:

$$N = \int_A S^{nn} dA = E\tilde{A}(s)\left(\hat{\gamma}_{so} - 1\right) \tag{38}$$

$$Q = \int_A S^{n2} dA = G\tilde{A}_s(s)\hat{\gamma}_t \tag{39}$$

$$M = \int_A -tS^{nn} dA = E\tilde{I}(s)\frac{d\theta}{ds} \tag{40}$$

4 VIRTUAL WORK

Writing the virtual work equation δW in terms of the physical Lagrangian stress tensor, we have:

$$\delta W = \int_V tr\left(\mathbf{S}\prod \mathbf{F}^{*}\right) dV + \delta W_E = 0 \tag{41}$$

With V being the volume in the undeformed state, the symbol δ denotes kinematically admissible variations, δW_E is the variation of the external virtual work and the integral represents the internal virtual work.

Incorporating the physical Lagrangian stress tensor and integrating over the cross-sectional area, the virtual work equation is reduced to:

$$\delta W = \int_0^L \left[N\delta\hat{\gamma}_{so} + Q\delta\hat{\gamma}_t + M\delta\kappa\right] ds_o + \delta W_E = 0 \tag{42}$$

where L is the length of the column along the longitudinal reference axis.

From equation (42), the following equilibrium equations can be obtained:

$$\frac{dN}{ds_o} - Q\kappa + p_n = 0 \tag{43}$$

$$\frac{dQ}{ds_o} + N\kappa + p_t = 0 \tag{44}$$

$$\frac{dM}{ds_o} + m_t = N\hat{\gamma}_t - Q\hat{\gamma}_{so} \tag{45}$$

Vectors **p** and **m** are the distributed force and moment load intensities:

$$\mathbf{p} = p_n\,\hat{\mathbf{n}} + p_t\,\hat{\mathbf{g}}_{\mathbf{t}} \qquad \mathbf{m} = m_n\,\hat{\mathbf{n}} + m_t\,\hat{\mathbf{g}}_{\mathbf{t}} \tag{46}$$

5 IN-PLANE BUCKLING OF TAPERED CANTILEVER COLUMNS

5.1 *Kinematics*

We consider a doubly symmetric cantilever column of variable cross sections with an axial concentrated force acted on the top end of the column ($x = L$). The x-axis coincides with the longitudinal reference axis with the origin at the fixed base end of the column ($x = 0$). The geometric characteristics are depicted in Figure 2. For the rectangular

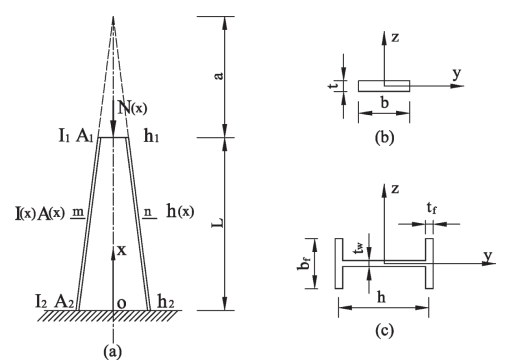

Figure 2. (a) Tapered cantilever column under compression (b) Width-tapered rectangular section (c) web-tapered I-section.

section case, the thickness t is constant while the width tapers from the base of the column to the top end. In the case of the I-section, the column is tapering in web while the other dimensions of the cross-section are uniform along the length of the column.

In the numerical analysis of tapered cantilever columns, the representative elastic-to-shear rigidity ratios $EA/GA_s = 3, 25$ and 100 are adopted. The taper ratio of the column is defined by I_1/I_2. I_1 is the second moment of area at the top free end, while I_2 is the second moment of area at the fixed base end.

The second moment of area of an arbitrary section mn of the tapered cantilever column can be expressed as:

$$I_x = I_2\left(1 + c\frac{x}{L}\right)^n \tag{47}$$

where c is a constant depending on the second moment of area I_1 at the top end of the tapered column. n takes on the value of 2.

The flexural rigidity of an arbitrary section of the tapered column can be written as a power function using the equation (47), such that:

$$EI_x = EI_2\left(1 + c\frac{x}{L}\right)^n \tag{48}$$

5.2 *Cross-section actions*

Consider a rotation angle ς about z-axis as shown in Figure 3. The rotation tensor denoted by the symbol $\mathbf{R}_\varsigma$ and its inverse $\mathbf{R}_\varsigma^{-1}$ are in the forms:

$$\mathbf{R}_\varsigma = \begin{pmatrix} \cos\varsigma & \sin\varsigma \\ -\sin\varsigma & \cos\varsigma \end{pmatrix} \quad \mathbf{R}_\varsigma^{-1} = \begin{pmatrix} \cos\varsigma & -\sin\varsigma \\ \sin\varsigma & \cos\varsigma \end{pmatrix} \tag{49}$$

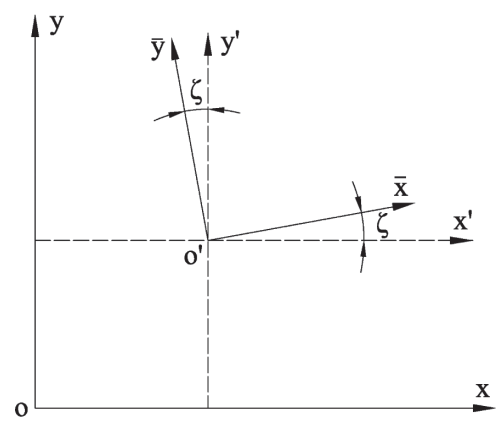

Figure 3. Rotated axes directions at a generic point.

Applying the rotation ς to the x and y axes gives:

$$\bar{\mathbf{y}} = \mathbf{R}_\varsigma \mathbf{y} = \cos\varsigma \mathbf{y} + \sin\varsigma \mathbf{z} \tag{50}$$

$$\bar{\mathbf{z}} = \mathbf{R}_\varsigma \mathbf{z} = -\sin\varsigma \mathbf{y} + \cos\varsigma \mathbf{z} \tag{51}$$

Now applying the bending rotation θ to the cross-section actions as depicted in Figure 4, it gives:

$$\begin{bmatrix} P_x \\ P_y \end{bmatrix} = \mathbf{R}_\theta^{-1} \begin{bmatrix} N \\ Q \end{bmatrix} = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} \begin{bmatrix} N \\ Q \end{bmatrix} \tag{52}$$

Equation (52) can be written as:

$$P_x = \cos\theta N - \sin\theta Q \quad P_y = \sin\theta N + \cos\theta Q \tag{53}$$

where P_x and P_y are the internal force resultants in the x-direction and the y-direction respectively.

5.3 *Buckling equations*

The variation principle is applied to formulate the elasticity problem of tapered cantilever columns under compressive load $N(x)$. Before the buckling takes place, the initial values are:

$$\begin{aligned} &P_x = N_o(x) \quad P_y = 0 \quad N = N_o(x) \\ &Q = 0 \quad M = 0 \quad m_t = 0 \quad \varphi_o = 0 \quad \theta = 0 \end{aligned} \tag{54}$$

where $(.)_o$ denotes the initial values.

The differential buckling equations of equilibrium are derived as:

$$\frac{d}{dx}\left[EI(x)\frac{d\delta\theta}{dx}\right] = -N_o(x)b_o(x)\delta\theta \tag{55}$$

$$\text{where } b_o(x) = \frac{N_o(x)}{GA(x)} - \left(\frac{N_o(x)}{EA(x)} + 1\right) \tag{56}$$

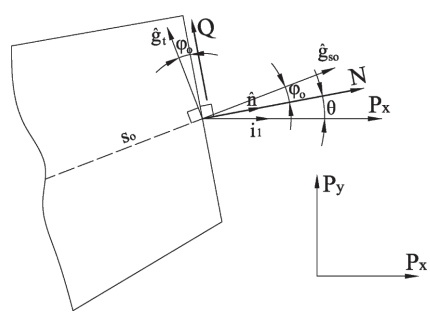

Figure 4. Two-dimensional column cross-section actions.

5.4 *Solution tactics*

The Galerkin method is suitable to solve the differential buckling equations. The assumed approximation deflection function satisfies the boundary conditions as depicted in Figure 5.

The approximation deflection function for the buckled configuration is assumed as:

$$\tilde{\theta} = a_i \sin\left(\frac{(2i-1)\pi x}{2L}\right) \qquad i = 1,2 \tag{57}$$

It can be verified that the assumed deflection function satisfies the required boundary conditions.

According to the Galerkin method, the integral expression should be satisfied, such that:

$$\int_0^L W_i R(x)\,dx = 0 \qquad \text{for } i = 1,2 \tag{58}$$

where $R(x)$ is a residual in domain $(0, L)$ resulting from substituting the approximate deflection function into the governing differential equation (55), that is:

$$R(x) = \frac{d}{dx}\left[EI(x)\frac{d\delta\theta}{dx}\right] + N_o(x)b_o(x)\delta\theta \tag{59}$$

where W_i is the weight function:

$$W_1 = \sin\left(\frac{\pi x}{2L}\right) \qquad W_2 = \sin\left(\frac{3\pi x}{2L}\right) \tag{60}$$

Substituting equations (59) and (60) into equation (58), we have:

$$\int_0^L \sin\left(\frac{(2i-1)\pi x}{2L}\right)\left(\begin{array}{l}\dfrac{d}{dx}\left[EI(x)\dfrac{d\delta\theta}{dx}\right] \\ +N_o(x)b_o(x)\delta\theta\end{array}\right)dx = 0 \tag{61}$$

$i = 1,2$

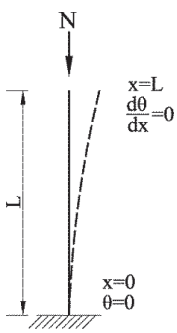

Figure 5. Boundary conditions.

Equations (61) represent the simultaneous algebraic equations that result in a generalized eigenproblem to be solved.

6 NUMERICAL EXAMPLE

Consider a tapered cantilever column of span L (L = *10,000* mm) subjected to a conservative concentrated axial load as illustrated in Figure 2a. Since no distributed loads are acted along the column, $p_n = p_t = m_t = 0$ in equations (43)-(45), the equilibrium equations are written in the forms:

$$\frac{dN}{dx} - Q\kappa = 0 \quad \frac{dQ}{dx} + N\kappa = 0 \quad \frac{dM}{dx} = N\hat{\gamma}_y - Q\hat{\gamma}_x \tag{62}$$

The initial values of loading, shear angle and bending angle:

$$\begin{array}{llll} P_x = N_o & P_y = 0 & N(x) = N_o & \\ Q = 0 & M = 0 & \varphi_o = 0 & \theta = 0 \end{array} \tag{63}$$

The governing differential buckling equations are therefore:

$$\frac{d}{dx}\left[EI(x)\frac{d\delta\theta}{dx}\right] = -N_o b_o(x)\delta\theta \tag{64}$$

The in-plane buckling loads obtained by the numerical results obtained from the differential

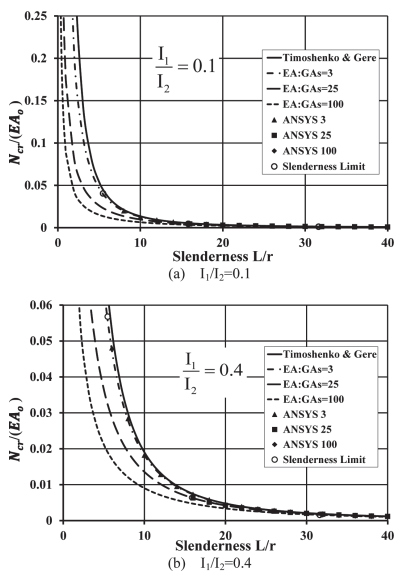

Figure 6. Normalized buckling loads versus slenderness.

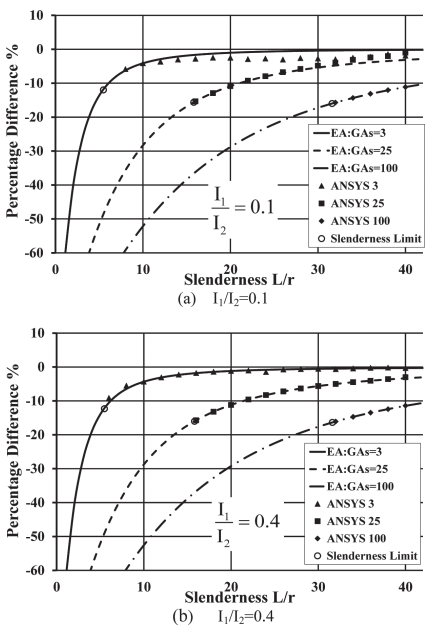
buckling equations (61) are also compared with finite element method using the ANSYS software. In the ANSYS simulation, the tapered beam is modelled using the 4-node plane elements (PLANE 182).



6.1 *Normalized buckling loads*

The governing differential Equation (64) is solved using the Galerkin numerical method for the buckling loads. Finite element method using ANSYS software are included in the curves of the normalized buckling loads versus column slenderness are plotted in Figure 6.

As shown in Figure 6a,b, the comparison of the obtained normalized buckling loads indicates that the behavior of the obtained buckling loads are in good agreement with those by (Timoshenko & Gere 1961).

6.2 *Percentage difference of buckling loads*

Figure 7a,b show the percentage difference between the obtained buckling loads including the effects of shear deformation and those from (Timoshenko & Gere 1961) where the shear deformations were not taken into account in the buckling analysis. Shear deformations are shown to reduce the buckling capacity and are significant for columns of smaller slenderness and columns with larger elastic-to-shear rigidity.

(a) I_1/I_2=0.1

(b) I_1/I_2=0.4

Figure 7. Percentage difference between buckling loads.

7 CONCLUSION

A finite strain elastic stability analysis is presented for the in-plane buckling problem of column with variable cross-section. A consistent hyperelastic constitutive model is adopted to define the constitutive relationship for stresses and finite strain. The shear effects are included in the formulation. The generalised equilibrium equations are derived for columns with variable cross-section using the virtual work principle. The variation method is applied to derive the differential buckling equations for tapered cantilever columns. Numerical solutions are obtained using the Galerkin method. Finite element method by means of ANSYS model is also carried out to investigate the stability of tapered columns under compressive loads. Distribution of the column flexural rigidity is expressed as a power function of the x-coordinate. The representative elastic-to-shear rigidity ratios equal 3, 25 and 100 respectively. Non-dimensional numerical parametric study is performed to exhibit the in-plane buckling behavior of tapered cantilever columns. The behaviors of normalized buckling loads versus slenderness agree well with the results of published classical literature ((Timoshenko & Gere 1961)). By comparison with those of the existing literature of (Timoshenko & Gere 1961), it's indicated that the factor of shear deformations is very significant for short columns and columns weak in shear rigidity.

ABSTRACT: A stability analysis is presented for Timoshenko-type beams with variable cross sections considering the shear effects under nonlinear theory. The constitutive laws for stresses and finite strains are defined adopting the consistent hyperelastic constitutive material modeling using tensor notation to simplify the complex geometric presentation. The second variation of the Total Potential is also derived which enables the application of the finite element modelling where an extra node is introduced in the middle of the element for shear rotation displacement. In presence of tapering, all section properties are not constant, with the aid of the efficient numerical approach and the software development, the locations of the centroidal and shear center axes are precisely determined on every cross section instead of using approximate method. The numerical example of web-tapered doubly symmetric and monosymmetric I- beams under moment gradient is investigated. The obtained flexural-torsion critical load predictions agree well with published solutions.

1 INTRODUCTION

Variable cross-sectional beams are found to be widely used in various kinds of structures in many forms and sizes and in many materials, buckling analyses of thin-walled variable cross-sectional structural members are the fundamental components of structural analysis and design. Shear deformations are important factors in buckling analysis, however, buckling analysis considering shear deformations remains a problem with several unresolved issues ((Ziegler 1982, Attard et al., 2008, Attard & Hunt 2008, Attard 2003, Bažant & Cedolin 1991), (Lee et al., 2009), (Machado 2008), (Reissner 1989)). The different assumptions of the shear force orientation defined in the constitutive laws have given rise to the discrepancy in the two controversial approaches of Engesser and Haringx for the inclusion of shear deformation in the column buckling modelling devisal. The adoption of the conventional constitutive relationship defined between the second Piola Kirchhoff stress tensor and its conjugate Green's strain tensor would lead to incorrect expression of strain energy density for a compressible isotropic neo-Hookean material. To address this, the constitutive relationship for stresses and finite strain is proposed in this paper using a consistent finite strain hyperelastic formulation. The tensor analysis method in the mechanics of continuum is adopted in the formulation to simplify the complex geometrical representation of finite strain analysis of the variable cross-sectional beams including shear deformations.

2 KINEMATICS

Consider a beam of variable cross sections. In the initial configuration the position vector $\mathbf{P}$ of an arbitrary point on a general material line with respect to a right-handed rectangular Cartesian coordinate system is given by:

$$\mathbf{P} = x\mathbf{i_1} + y\mathbf{i_2} + z\mathbf{i_2} \tag{1}$$

$\mathbf{i}_1$ and $\mathbf{i}_2$ signify the unit base vectors aligned with the x and y axes respectively. x, y and z are the coordinates of an arbitrary point on a general material line.

The covariant tangent base vectors on a general material line in the initial state can be obtained using Equation(1), we have:

$$\mathbf{g_1} = \frac{\partial \mathbf{P}}{\partial x} = \mathbf{i_1} + y,_x\mathbf{i_2} + z,_x\mathbf{i_2} \tag{2}$$

$$\mathbf{g_2} = \frac{\partial \mathbf{P}}{\partial y} = \mathbf{i_2} \qquad \mathbf{g_3} = \frac{\partial \mathbf{P}}{\partial z} = \mathbf{i_3} \tag{3}$$

$\mathbf{g}_{1s}$ is the tangent base vector defined at the shear center axis material line, hence:

$$\mathbf{g_{1s}} = \frac{\partial \mathbf{P}}{\partial x} = \mathbf{i_1} + y_{s,x}\mathbf{i_2} + z_{s,x}\mathbf{i_2} \tag{4}$$

In the above equation, y_s, z_s are the coordinates at the shear center axis.

The contravariant base vectors on a general material line are derived as:

$$\mathbf{g^1} = \mathbf{i_1} \qquad \mathbf{g^2} = -y_{,x}\mathbf{i_1} + \mathbf{i_2} \qquad \mathbf{g^3} = -z_{,x}\mathbf{i_1} + \mathbf{i_3} \tag{5}$$

The Euler angles and two shear angles are used to describe the cross-sectional displacement of the beam under twisting, bending and shear deformations. Apply tortuosity ψ, bending rotation θ, twisting rotation ϕ, shear rotations α_o and φ_o to the associated axes, we have:

$$\hat{\mathbf{b}} = -\sin\psi\ \mathbf{i}_2 + \cos\psi\ \mathbf{i}_3 \qquad \hat{\mathbf{h}} = \cos\psi\ \mathbf{i}_2 + \sin\psi\ \mathbf{i}_3 \tag{6}$$

$$\hat{\mathbf{n}} = \cos\theta\ \mathbf{i_1} + \sin\theta\ \hat{\mathbf{h}} \qquad \hat{\mathbf{t}} = -\sin\theta\ \mathbf{i_1} + \cos\theta\hat{\mathbf{h}} \tag{7}$$

$$\hat{\mathbf{g}}_2 = \sin\phi\hat{\mathbf{b}} + \cos\phi\ \hat{\mathbf{t}} \qquad \hat{\mathbf{g}}_3 = \cos\phi\hat{\mathbf{b}} - \sin\phi\ \hat{\mathbf{t}} \tag{8}$$

$$\hat{\mathbf{g}}_{\mathbf{1s}} = L_{sn}\hat{\mathbf{n}} + L_{s2}\hat{\mathbf{g}}_{\mathbf{2}} + L_{s3}\hat{\mathbf{g}}_{\mathbf{3}} \tag{9}$$

Where λ_{1s} is stretch of the shear center axis. $L_{sn,}$ L_{s2} and L_{s3} are the deformed shear center axis components aligned with the axes in the moving triad orthonormal vector system $\hat{\mathbf{n}}$, $\hat{\mathbf{g}}_{\mathbf{2}}$ & $\hat{\mathbf{g}}_{\mathbf{3}}$.

$$\begin{aligned} L_{sn} = {} & \lambda_{1s}\left(\cos\varphi_o - \tilde{y}_{s,x}\sin\varphi_o\right)\cos\alpha_o \\ & - \lambda_{1s}\tilde{z}_{s,x}\sin\alpha_o \end{aligned} \tag{10}$$

$$\begin{aligned} L_{s2} = {} & \lambda_{1s}\cos\phi\left(\sin\varphi_o + \tilde{y}_{s,x}\cos\varphi_o\right) \\ & + \lambda_{1s}\sin\alpha_o\left(\cos\varphi_o - \tilde{y}_{s,x}\sin\varphi_o\right)\sin\phi \\ & + \lambda_{1s}\tilde{z}_{s,x}\cos\alpha_o\sin\phi \end{aligned} \tag{11}$$

$$\begin{aligned} L_{s3} = {} & -\lambda_{1s}\sin\phi\left(\sin\varphi_o + \tilde{y}_{s,x}\cos\varphi_o\right) \\ & + \lambda_{1s}\sin\alpha_o\left(\cos\varphi_o - \tilde{y}_{s,x}\sin\varphi_o\right)\cos\phi \\ & + \lambda_{1s}\tilde{z}_{s,x}\cos\alpha_o\cos\phi \end{aligned} \tag{12}$$

The covariant tangent base vectors in the deformed state are defined by:

$$\hat{\mathbf{g}}_{\mathrm{i}} = \left(\delta_i^j + u^j\big|_i\right)\mathbf{g}_{\mathrm{j}} \tag{13}$$

The indices i and j in Equation (13) take on values of 1, 2 or 3 corresponding to the orthogonal coordinates x, y and z axes. δ_i^j is the kronecker delta. $u^j\big|_i$ is the covariant derivatives of displacement vector $\mathbf{u}$. The Einstein summation convention is adopted.

The covariant tangent base vector in the deformed state in Equation (13) is augmented to include the warping about the unit normal to the plane of the cross section, we have:

$$\begin{aligned} \hat{\mathbf{g}}_{1w} = {} & \left(L_n - (y - y_s)\kappa + (z - z_s)\kappa' - \omega\tau_{,x} - \tau\omega_{,x}\right)\hat{\mathbf{n}} \\ & + \left[L_2 - \tau\left(z - z_s + \omega\kappa\right)\right]\hat{\mathbf{g}}_{\mathbf{2}} \\ & + \left[L_3 + \tau\left(y - y_s + \omega\kappa'\right)\right]\hat{\mathbf{g}}_{\mathbf{3}} \end{aligned} \tag{14}$$

$$\hat{\mathbf{g}}_{\mathbf{2}\omega} = \hat{\mathbf{g}}_{\mathbf{2}} - \tau\,\omega_{,y}\hat{\mathbf{n}} \qquad \hat{\mathbf{g}}_{\mathbf{3}\omega} = \hat{\mathbf{g}}_{\mathbf{3}} - \tau\,\omega_{,z}\hat{\mathbf{n}} \tag{15}$$

In the above Equations (14) and (15), warping ω is a function of cross-sectional geometry. τ, κ, κ' are the deformation torsion, curvature about the y and z axes respectively.

$L_{n,}$ L_2 and L_3 are the components aligned with the axes in the moving triad orthonormal frame $\hat{\mathbf{n}}$, $\hat{\mathbf{g}}_{\mathbf{2}}$ & $\hat{\mathbf{g}}_{\mathbf{3}}$ on a general material line.

The deformation gradient tensor $\mathbf{F}$ is given by:

$$\mathbf{F} = \hat{\mathbf{g}}_{\mathrm{i}} \otimes \mathbf{g}^{\mathrm{i}} \tag{16}$$

The deformation gradient tensor $\mathbf{F}$ can be decomposed into two tensors, a rotation tensor $\mathbf{R}$ and a rotation deformation tensor $\mathbf{F}^*$ such that:

$$\mathbf{F} = \mathbf{R}\mathbf{F}^* \tag{17}$$

Rearranging Equations (16), (17), substituting the covariant tangent base vectors in the deformed state in Equations (14) (15) and the contravariant tangent base vectors in the initial configuration in Equations (5), the rotated deformation tensor $\mathbf{F}^*$ can be derived as:

$$\mathbf{F}^* = \begin{bmatrix} \lambda_n - (y - y_s)\kappa + (z - z_s)\kappa' - \omega\tau' - \tau\omega' & -\omega_{,y}\tau & -\omega_{,z}\tau \\ \left[\lambda_2 - y_{,x} - \tau\left(z - z_s + \omega\kappa\right)\right]\cos\phi - \left[\lambda_3 - z_{,x} + \tau\left(y - y_s + \omega\kappa'\right)\right]\sin\phi & \cos\phi & -\sin\phi \\ \left[\lambda_2 - y_{,x} - \tau\left(z - z_s + \omega\kappa\right)\right]\sin\phi + \left[\lambda_3 - z_{,x} + \tau\left(y - y_s + \omega\kappa'\right)\right]\cos\phi & \sin\phi & \cos\phi \end{bmatrix} \tag{18}$$

3 CONSTITUTIVE RELATIONS

A physical Lagrangian stress tensor is defined using the second Piola Kirchhoff stress tensor $\prod$ components and the rotated deformation tensor $\mathbf{F}^*$ in Equation(18), such that:

$$\mathbf{S} = \prod \mathbf{F}^{*\mathbf{T}} = \begin{bmatrix} S^{nn} & S^{n2} & S^{n3} \\ S^{2n} & S^{22} & S^{23} \\ S^{3n} & S^{32} & S^{33} \end{bmatrix} \tag{19}$$

The constitutive relationship for normal stress component S^{nn} and tangential shear stress components S^{n2}, S^{n3} in terms of the deformations are obtained:

$$S^{nn} = \mathrm{E}\left\{ \begin{pmatrix} (\lambda_n - \omega\tau' - 1) \\ +\frac{1}{2}\begin{pmatrix} \tau\left[\hat{\gamma}_3 (y - y_s) - \hat{\gamma}_2 (z - z_s)\right] \\ +R_o^2 \tau^2 \end{pmatrix} \end{pmatrix} \right\} \tag{20}$$

$$\mathrm{S}^{n2} = G\left(\hat{\gamma}_2 - \tau\left(z - z_s + \omega_{,y}\right)\right) \tag{21}$$

$$\mathrm{S}^{n3} = G\left(\hat{\gamma}_3 + \tau\left(y - y_s - \omega_{,z}\right)\right) \tag{22}$$

Where E is the elastic modulus, G is the shear modulus, $\hat{\gamma}_2$ and $\hat{\gamma}_3$ are the shear deformations.

4 EQUILIBRIUM EQAUTIONS

The virtual work equation is written in terms of the physical Lagrangian stress tensor and the rotated deformation tensor $\mathbf{F}^*$:

$$\delta W = \int_V tr\left(\mathbf{S}\boldsymbol{\delta}\mathbf{F}^*\right) dV + \delta W_E = 0 \tag{23}$$

Where *tr* denotes the trace of a tensor, V is the volume of the beam in the undeformed state, the symbol δ denotes kinematically admissible variations, δW_E is the variation of the external work and the integral signifies the internal work.

Integrating the virtual work over the cross-sectional area, the virtual work Equation (23) can be reduced to:

$$\delta W = \int_0^L \begin{bmatrix} N\delta\left(\hat{\gamma}_1 + y_s\kappa - z_s\kappa'\right) + Q_2\delta\hat{\gamma}_2 + Q_3\delta\hat{\gamma}_3 \\ +M_2\delta\kappa' + M_3\delta\kappa \\ +\left(M_t + M_{wagner}\right)\delta\tau + M_\omega\delta\tau_{,x} \end{bmatrix} dx + \delta W_E \tag{24}$$

The equilibrium equations are developed from the virtual work equation:

$$\frac{dN}{dx} - Q_t\tilde{\kappa} - Q_b\tilde{\kappa}' + p_n = 0 \tag{25}$$

$$\frac{dQ_t}{dx} + N\tilde{\kappa} - Q_b\left(\tau - \frac{d\phi}{dx}\right) + p_t = 0 \tag{26}$$

$$\frac{dQ_b}{dx} + N\tilde{\kappa}' + Q_t\left(\tau - \frac{d\phi}{dx}\right) + p_b = 0 \tag{27}$$

$$\frac{d\tilde{M}_1}{dx} - \tilde{M}_2\tilde{\kappa} - \tilde{M}_3\tilde{\kappa}' + m_n - Q_2 z_{,x} + Q_3 y_{,x} = 0 \tag{28}$$

$$\frac{d\tilde{M}_3}{dx} + \tilde{M}_1\tilde{\kappa}' + \tilde{M}_2\left(\tau - \frac{d\phi}{dx}\right) + m_b = N\lambda_t - Q_t\lambda_n \tag{29}$$

$$\frac{d\tilde{M}_2}{dx} + \tilde{M}_1\tilde{\kappa} - \tilde{M}_3\left(\tau - \frac{d\phi}{dx}\right) + m_t = -N\lambda_b + Q_b\lambda_n \tag{30}$$

Where p_n, p_t, p_b and m_n, m_t, m_b are the distributed forces and moments along the axes in the moving triad orthonormal frame $\hat{\mathbf{n}}, \hat{\mathbf{t}}$ & $\hat{\mathbf{b}}$ respectively.

5 TOTAL POTENTIAL

Take a variation of the equilibrium Equations (25)-(30) and then apply the virtual displacements principle using the Ritz variational technique, incorporating the constitutive relationships, using the section properties parameters, adopting a second order approximation for displacement components and internals actions, and evaluating the conservative surface tractions at the boundaries, for monosymmetric beams, consider the case of no initial force and ignoring the axial displacement terms, the second variation of Total Potential equation can be reduced to:

$$\delta^2 W = \frac{1}{2}\int_0^L \begin{bmatrix} GA\left(\delta\gamma_3\right)^2 + EI_{yy}\left(\delta\omega_{2,x}\right)^2 \\ +GJ_t\left(\delta\omega_{1,x}\right)^2 + EI_\omega\left(\delta\omega_{1,xx}\right)^2 \\ +2Q_2^o\left(\delta\gamma_3 - \delta\omega_2\right)\delta\omega_1 \\ -Q_2^o\dfrac{G^* I_{yy}}{A}\delta\omega_{2,x}\delta\omega_{1,x} \\ -M_3^o\beta_1^* E^*\left(\delta\omega_{1,x}\right)^2 \\ +M_3^o\left(2\delta\omega_{1,x}\delta\omega_2 - \delta\gamma_3\delta\omega_{1,x}\right) \\ +q_y^o e_y\delta\omega_1{}^2 \end{bmatrix} dx + \frac{1}{2}P_y^o a_y\delta\overline{\omega}_1^2 \tag{31}$$

The displacements components and internal actions in the above second variation of Total Potential Equation (31) are second order approximations obtained by truncated the expressions for displacements components and internal actions

in the virtual Equation (24). The solutions thus obtained are comparable to other lateral torsional buckling formulations which are based on second order approximations.

The truncated expressions for the displacements also enable the application of finite element modelling formulation to investigate the lateral buckling behavior of variable cross-sectional beams.

6 FINITE ELEMENT MODEL

In the proposed formulation where the shear deformations are taken into consideration, the displacement derivatives in y and z axes directions are not equal to the bending rotation about y and z axes due to the presence of shear angles. The shear angles are the difference between displacement derivatives and the bending angles about the y and z axes and are expressed as:

$$\gamma_2 = v_{s,x} - \omega_3 \quad \gamma_3 = w_{s,x} + \omega_2 \tag{32}$$

Along a beam element as shown in Figure, each node at the ends of the element consists of the usual six generalised displacement for spatial frame element and the displacement associated with warping. In addition to the aforementioned seven displacements, two rotations about y and z axes are included to account for the shear deformations. An extra node is also introduced in the middle of each element to achieve the compatibility between displacements associated with displacement derivatives and shear rotations.

For the generalized displacements for each element in the finite element model, nine generalised displacements are at each end of the element, while two displacements associated with y and z axes are at the middle note of each element. The generalized displacements are depicted in Figure 1.

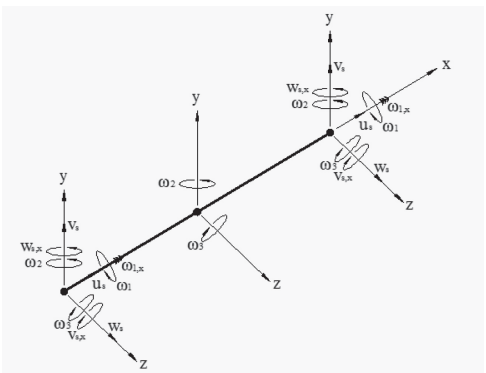

Figure 1. Generalised elemental displacements.

The stiffness and stability element matrices are constructed based on the presented generalized displacements in the finite element model. The stiffness and stability structure matrices are assembled depending on the node numbering at the ends of the element regardless of the node in the middle of the element. The critical buckling loads are then obtained by solving the eigenproblem resulted from the tangent stiffness for the whole structure.

The accuracy of the proposed finite element modeling method in dealing with stability problem of tapered beams is demonstrated by yielding solutions to the numerical examples. In all cases good agreement with published solutions is exhibited.

7 NUMERICAL EXAMPLES

7.1 *Lateral buckling of a simply supported singly symmetric prismatic I-beam under uniform bending*

The accuracy of the lateral buckling analysis formulation and the finite element modelling method is first assessed by considering a 6m simply supported I-beam with constant monosymmetric section under uniform bending moments about its major axis as illustrated in Figure 2.

The geometric dimensions of the monosymmetric cross section are shown in Figure 3. The material properties are elastic modulus E = 65120 MPa and shear modulus G = 25970 MPa. The geometric data of the beam section are computed from its dimensions and are given as:

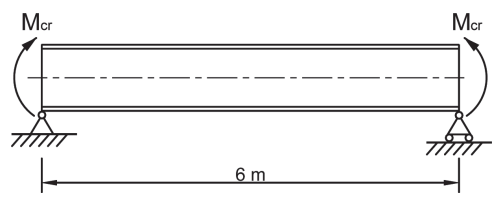

Figure 2. Simply supported prismatic I-beams under uniform bending.

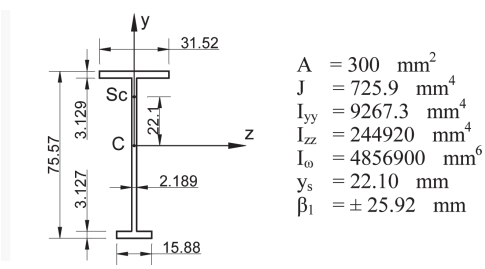

Figure 3. Monosymmetric constant section of simply supported I –beam.

The dimensionless analytical solution was provided by Goodier (1942) to the lateral buckling problem of simply supported singly symmetric I-beam under equal and opposite bending moments. Attard (1986) carried out the finite element method with a beam discretization of six elements based on the lateral buckling formulation developed by the author to investigate the same stability problem. A comparison of the critical bending moments is made and tabulated in Table 1 which shows good agreement.

7.2 *Lateral buckling of simply supported web-tapered I-beams with doubly symmetric and singly symmetric cross-sections under moment gradient*

The accuracy of the developed stability analysis approach and the finite element formulation is further tested by solving the lateral buckling problem of a simply supported web-tapered I-beam under moment gradient as illustrated in Figure 4. The beam tapers from the maximum height h_{max} at the left support to αh_{max} at the other support. The tapering constants are taken as 0.6, 0.8 and 1.0 for the beam lengths of 4m and 6m respectively. For each case, the moment gradient coefficient ψ varies from 0.25 to 1.0.

The lateral buckling behaviors of web-tapered I—beams with doubly symmetric and monosymmetric sections are both investigated. The Young's modulus is E = 210,000 MPa and the shear modulus is G = 80,000 MPa. The dimensions of doubly symmetric and monosymmetric sections for the simply supported web-tapered I-beam are depicted in Figure 5.

The critical buckling moments obtained from the solutions based on the developed formulation and the finite element model are shown in Table 1,2 for doubly symmetric section and in Table 3 for monosymmetric section. In these tables, a comparison is made with the solutions proposed by Zhang & Tong (2008) where the Rayleigh-Ritz method was used by the authors to solve this stability problem, as well as the critical loads results presented by Asgarian et al. (2013) in which the authors employed the finite element method by means of Ansys software and the numerical model by means of power series method.

It can be observed that the lateral buckling behaviors agree well with solutions in the existing literatures. It can therefore concluded that the stability problem formulation and finite element modelling method proposed in this paper are capable of making accurate predictions of the elastic flexural- torsional buckling loads of web-tapered doubly symmetric and monosymmetric I-beams incorporating the shear deformations.

8 CONCLUSION

An elastic stability analysis is presented in this paper for Timoshenko-type beams with variable cross sections taking into consideration the effects of shear deformations under the geometrically non-linear theory based on large displacements and rotations. The constitutive relationship for stresses and finite strains based on a consistent finite strain hyperelastic formulation is proposed. The generalized equilibrium equations for varying arbitrary cross-sectional beams are developed from the virtual work equation. The second variation of the Total Potential is also derived which enables the application of the finite element method which is capable of making accurate prediction of the elastic flexural-torsional critical buckling loads of tapered, doubly symmetric and singly symmetric I-section beams including the shear deformations. In the finite element formulation, the element displacement field is assumed using polynomial functions, in discretizing the beam, one extra node is introduced in the middle of the element. The usual generalized displacements are at the ends of each element while the additional displacement associated with shear rotations are both at the ends of each element and at the middle node of each element to achieve compatibility between displacements corresponding to rotations results from bending and shear deformations. In presence of tapering, all section properties are non-constant along the length of the beam, the shear center and centroidal axis representations were abandoned due to difficulties in specifying their positions caused by the cross-sectional tapering in previous studies. In this paper, with the aid of the efficient numerical approach and the software development, the locations of the centroidal and shear center axes on the cross sections are precisely determined

through accurate calculation instead of using approximate method. The accuracy and validation of the developed stability analysis formulation and finite element modelling are tested by solving the numerical examples to which the solutions are available in the published literature. The problems being considered is a 6m simply supported mono-symmetric I-beam under equal and opposite bending moments about its major axis. The accuracy of developed formulations are further investigated by looking at the flexural-torsional buckling problems of a simply supported web-tapered doubly symmetric and singly symmetric I-beams under moment gradient, the moment gradient coefficient varies from 0.25 to 1 for beam lengths of 4m and 6m with tapering constant equal to 0.6, 0.8 and 1.0 respectively. For all the numerical examples being investigated, the obtained lateral critical buckling moments predictions show a great agreement with published solutions.

Methodology for the quantitative risk assessment of road bridges exposed to accidental events

M. Sykora & M. Holicky
Klokner Institute, Czech Technical University in Prague, Prague, Czech Republic

P. Maňas
Faculty of Military Technology, University of Defence, Brno, Czech Republic

ABSTRACT: Road bridges in accidental situations represent the most vulnerable components of transportation networks. Accidental situations may be caused by natural or man-made hazards. Decisions concerning protective measures can be based on the probabilistic optimisation of expected costs. In general, total structural costs consist of initial, service costs and consequences of structural failure. The initial cost comprises of construction cost including cost of protective measures; service costs cover maintenance expenditures and safety guards expenses; the failure consequences account for direct costs related to structural failure and follow-up costs due to malfunction of transportation network. Proposed general procedure for the risk assessment is based on Bayesian (causal) networks. It appears that this technique provides valuable background information for the decisions concerning efficient protective measures for bridges endangered by various types of hazards.

1 INTRODUCTION

The European road network has a vital importance for the European economy. Even smaller disruptions due to traffic restrictions or failure of some elements of the network may result in high consequences, Imam & Chryssanthopoulos (2012). Due to the interdependence of the road transport network with rail, air and shipping traffic, a failure of important connections may yield a domino effect, Andersen et al. (2013).

In such a case the network and its major components are classified as a "critical infrastructure (object)" that is defined according to the European *COUNCIL DIRECTIVE 2008/114/EC* (identification and designation of European critical infrastructures and the assessment of the need to improve their protection) as:

an asset, system or part thereof which is essential for the maintenance of vital societal functions, health, safety, security, economic or social well-being of people, and the disruption or destruction of which would have a significant impact in a state as a result of the failure to maintain those functions.

The *Communication from the Commission on a European Programme for Critical Infrastructure Protection COM(2006) 786* further provides the criteria for designation of critical infrastructures. The unavailability of a particular critical infrastructure should be rated by the extent of affected geographic area, number of population, related economic loss, environmental, political or psychological effects. The protection of critical infrastructures is to be based on an all-hazards approach; recognising the threat from terrorism as a priority.

Bridges (together with tunnels) are perceived as the most vulnerable components of the road network, Bocchini & Frangopol (2011). Due to their bottleneck function terrorist attacks are one of the most dangerous threats for such structures, Andersen et al. (2013).

In this study assessments of individual road bridges exposed to accidental situations are discussed from a general point of view. Stewart (2010) recommended cost-benefit and other risk-based approaches particularly for low probability-high consequence events where public safety is a key criterion for decision making. That is why methodology of the risk optimisation based on Bayesian networks is developed here. It is noted that the terminology accepted in Eurocodes (*EN 1990:2002* for the basis of structural design and *EN 1991-1-7:2006* for accidental actions) and other European documents (*DIRECTIVE 2008/114/EC* and *Communication COM(2006) 786*) is adopted.

2 IDENTIFICATION OF POSSIBLE CRITICAL BRIDGES

According to SeRoN (2012) the following aspects should be taken into account when selecting critical bridges:

- Location in urban environment,
- Conventional construction type,
- Possible traffic bottleneck formation,
- Large bridge over the sea,
- Landmark bridge,
- Very well-known bridge,
- Hard to rebuild bridge,
- Small bridge but important due to traffic volume.

Detailed procedure for the identification of possible critical bridges is provided in SeRoN (2012). Failure consequences can be seen as a good indicator of the importance of a bridge as indicated by Imam & Chryssanthopoulos (2012).

3 PRINCIPLES OF RISK OPTIMISATION

In general, risk analysis aims at consideration of all possible events together with their unfavourable consequences. Such events are often caused by extreme hazards or human errors. Table 1 indicates frequent causes of in-service failures of bridges; overview of recent important failures of construction works was provided by Agarwal et al. (2012).

Table 1. Causes of in-service failures of bridges adapted from Scheer (2010) and Vrouwenvelder et al. (2012).

Cause	Examples
Overload	Impact (vehicle, ship) Flooding, ice floes, floating timber Fire Explosion Seismic activity Wind action
Material degradation	Corrosion fatigue
Problems with foundations	Settlements
Malevolent human actions	Terrorist attack Vandalism
Human error	Design errors including incorrect dimensioning, neglected dynamic effects, unrecognised stability problems Construction errors such as material flaws and incorrect assembly
Unknown (unforeseeable)	Unknown stability problems

Adequate hazard scenarios and relevant occurrence probabilities need to be estimated, often on the basis of expert assessments and judgements. When for mutually independent hazard situations H_i the failure F of the component given a particular situation H_i occurs with the conditional probability $P(F|H_i)$, then the total probability of failure P_f is given by the law of total probability as:

$$P_f = \sum_i P(F|H_i)\, P(H_i) \quad (1)$$

The conditional probabilities $P(F|H_i)$ are determined by analyses of situations H_i. Annual reference period is normally accepted.

The situations H_i may lead to several events E_{ij} (e.g., excessive cracking, failure of a structural member, collapse of the bridge) with adverse consequences C_{ij} that are commonly expressed in monetary units. The total annual risk R corresponding to the hazard situations H_i can be expressed as:

$$R = \sum_{ij} C_{ij}\, P(E_{ij}|H_i)\, P(H_i) \quad (2)$$

If an acceptable risk R_t is specified, the bridge or its structural members can be assessed on its basis, $R < R_t$. When the criterion of acceptable risks is not fulfilled, it is necessary to modify the system by appropriate interventions aiming at the reduction of probability of occurrence of adverse events or at the reduction of their consequences.

Further information on the probabilistic risk analysis can be obtained from *ISO 13824:2009* on the general principles on risk assessment of systems involving structures, the Joint Committee on Structural Safety document JCSS (2008) or the monograph by Stewart & Melchers (1997).

From an economic point of view the objective is to minimize the total working-life cost of the bridge. For simplification assessment of the cost efficiency of a single protective measure is considered hereafter (with straightforward extensions for the decisions concerning several protective measures).

The decision parameter(s) d to be optimised may represent resistance in the case of upgrading, stand-off distance, properties of energy absorbing shields etc. The parameter may be continuous, discrete or attain a single value. In general the costs of the measure consist of:

- Cost C_0 independent of the decision parameter (costs related to surveys, design, administration and management, economic losses due to traffic interruptions in the case of existing structures),
- Marginal cost C_m dependent on the decision parameter (costs of construction materials, safety equipment, monitoring).

The failure consequences C_f can be estimated on the basis of the total annual risk R. Since the main reason for the existence of civil infrastructures is

the public interest, failure consequences need to include all societal losses (see Section 5.2).

For consistency, all the costs need to be expressed on a common basis. Costs of the measure are normally specified in a present value. All the expected failure costs that may occur within a reference period should thus be likewise estimated in the present worth. Assuming almost independent failure events in subsequent years and small probabilities $P(H_i)$, the expected failure cost related to a reference period t_{ref} (in years) can be estimated (Holicky (2013)):

$$E[C_f(t_{ref},d)] \approx R(d)\,[1 - 1/(1+q)^{tref}]/[1 - 1/(1+q)] = R(d)\,Q(q, t_{ref}) \quad (3)$$

where q = annual discount rate; and Q = time factor. The discount rate is commonly around 0.03 (an approved draft of *ISO 2394* from 2014 suggests 0.01–0.03 for most Western economies and 0.05–0.08 for most Asian economies; *ISO 15686-5:2008* on life-cycle costing for buildings assumes typical discount rates 0–0.04).

The expected total costs C_{tot} can now be expressed (omitting the symbol of expectation for convenience of notation) as:

$$\text{Measure: } C_{tot}(t_{ref};d) \approx C_0 + C_m\, d + R(d)Q(q, t_{ref}) \quad (4a)$$

$$\text{No measure: } C_{tot}(t_{ref}) = R(\text{no measure})\, Q(q, t_{ref}) \quad (4b)$$

From Equation (4a) the optimum value of the decision parameter d_{opt} (optimum measure) can be assessed:

$$\text{minimum}_d\, C_{tot}(t_{ref};d) = C_{tot}(t_{ref};d_{opt}) \quad (5)$$

No measure is accepted when the total cost according to Equation (4b) is less than the total cost of the optimum upgrade.

Apparently a more complex cost model would consider costs of inspections, maintenance, upgrades and other life-cycle costs. However, in most cases such extensions hardly improve the optimum measures mitigating risks in accidental situations.

4 RISK OPTIMISATION USING BAYESIAN NETWORKS

4.1 *Advantages of Bayesian networks*

In accordance with Stewart & Melchers (1997) risk of various technical systems in hazard situations can be analysed using the standard techniques such as fault trees, event trees, cause-consequence method, Bayesian (causal) networks and Petri networks.

In case of dependent basic events, fault trees become non-intuitive and difficult to handle, Mahboob & Straub (2011). This may be a serious limitation for civil engineering applications. In principle event trees can deal with such dependencies; however this requires great care during an analysis as observed by Faber & Stewart (2003). Moreover both methods suffer from the difficulty in updating based on new information. Petri Nets provide a powerful platform, but the evaluation often takes basis in Monte Carlo simulations requiring considerable computational demands, Nishijima et al. (2009). These drawbacks can be overcome by the use of Bayesian probabilistic networks with discrete nodes supplemented by decision and utility nodes, Nielsen & Jensen (2007).

With regard to practical applications Bayesian networks facilitate (adopted from Holicky et al. (2013)):

- Breakdown of a complex task (system of structural elements) into smaller sub-tasks (foundations, piers, super-structure) that can be analysed separately by different experts,
- Transparent interpretation of knowledge concerning structural elements based on results of measurements and expert appraisals,
- Consideration of uncertainties in action effects, material and geometrical properties, and also in the applied theoretical models,
- Modelling of complicated dependencies amongst initiation events of actions, their effects, structural properties and effects of protective measures,
- Updating of results when new information is available (Bayesian networks are transparent and can be readily modified).

It is fair to note that Bayesian networks require additional expertise in comparison with tree-based analyses. In addition the logic relations between components of the system (e.g., AND, OR) cannot be directly observed from the graphical representation, Mahboob & Straub (2011).

The analysis of Bayesian network is based on the specification of conditional probabilities of nodes under assumption of information on other nodes (in the direction of casual links). The analysis is based on the concept of conditional probabilities and the theory of probability. Detail information is provided e.g., by Holicky (2009), Nielsen & Jensen (2007) and Stewart & Melchers (1997).

4.2 *Example of the network*

Figure 1 shows an example of the Bayesian network (influence diagram) that provides a general basis for a particular assessment. Note that the network is significantly simplified and has to be modified to reflect specific conditions of an analysed structure and considered accidental

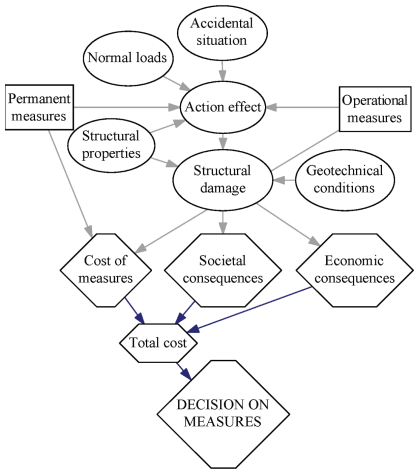

Figure 1. Example of the Bayesian network.

situations. In practical applications each random node may represent a sub-system and additional utility nodes may be needed. The following nodes are included in Figure 1:

- Chance nodes—Accidental situation, Action effect, Structural damage, Geotechnical conditions, and Structural properties,
- Decision nodes—Permanent and Operational measures,
- Utility nodes—Cost of measures, Societal and Economic consequences, and Total cost.

Directional arrows, interconnecting all the nodes, indicate the causal links between parent and children nodes.

Given an accidental situation the action effects, influenced by accepted protective measures, may lead to structural malfunction (covered in the network by the random node Structural damage) due to damage, local failures, partial or total collapse of the bridge. Probability of structural damage and its extent will likely depend on geotechnical conditions and structural properties.

Structural damage may result in societal and economic consequences. The utility node Societal consequences describes the expected number of fatalities and injuries given structural collapse and related compensation costs, which may be based on the so-called societal value of statistical life, Holicky (2009).

5 MODELLING OF SELECTED NODES

5.1 *Action effects*

In accordance with Vrouwenvelder et al. (2012) bridges may be exposed to the following actions (cf. Table 1):

- Normal—self weight, traffic, thermal, wind load,
- Accidental (natural)—earthquake, landslide, wind action, avalanche, rock fall, flood and tsunami,
- Accidental (man-made—malevolent or unconscious)—explosion, fire, impact of vehicle, ship or projectile, mining settlement,
- Human errors—design error, material flaw, construction error, misuse, lack of maintenance.

The model of an accidental action takes into account the annual probability of occurrence of the accidental situation and the conditional probability of the accidental action (e.g., success rate in the case of blast terrorist attack).

To provide more specific information, modelling of a terrorist attack is further discussed. The information needed for the analysis may be gained from experts, scenario analysis and analysis of available data, Stewart & Mueller (2012). Limited statistical information was provided by Stewart (2010). Based on a literature review, the annual probability of terrorist attack on US commercial buildings was estimated as $P(H) \approx 10^{-6}$–10^{-7} per building. Ellingwood (2006) suggested increasing the minimum attack probability $P(H)$ to ~10^{-4}/ building/ year for high density occupancies, key governmental and international institutions, monumental or iconic buildings or other critical facilities with a specific threat. As a first approximation key bridges may be associated with this value. It is interesting to observe that this value is comparable to the annual probability of a vehicular collision ($P(H) \approx 6 \times 10^{-4}$/ building/ year given by Ellingwood (2002)).

However, for terrorism the threat comes from an intelligent adversary who adapts to changing circumstances to maximise likelihood of success, Stewart (2010). Moreover, the probability $P(H)$ depends on a policy of the country (involvement in military operations abroad, approach to minorities). Although some statistical approaches exist for terrorist threat prediction, these rely heavily on judgments of security experts, game theory, etc. so the inherent uncertainties remain still high. For this reason, the report by the US Department of Homeland Security (2009) states that *the assessment of the probabilities that adversaries will choose courses of action should be the outputs of analysis, not required input parameters*. Hence, Stewart (2010) recommended using the cost-benefit analysis to specify the minimum (threshold) threat probability below which a specific protective measure becomes cost-ineffective.

Guidance for the development of probabilistic models of accidental action effects was provided by Vrouwenvelder (2000); for instance the model for blast loading was discussed by Netherton &

Stewart (2010), models for earthquake, impact load and fire by JCSS (2001).

Damage on the bridge exposed to normal and accidental loads is then estimated on the basis of system modelling considering the effects of applied protective measures.

5.2 *Failure consequences*

Overview of possible consequences of bridge failure is provided in SeRoN (2012):

- Direct consequences resulting directly from the structural damage, examples include:
  - Fatalities or injuries due to structural collapse, blast pressure or secondary projectiles (concrete, steel, glass),
  - Economic losses due to cost of rehabilitation or rebuilding, cost of damaged vehicles,
- Follow-up (indirect) consequences describing other impacts on the society, for instance:
  - Fatalities or injuries due to malfunction of the bridge (e.g., in an emergency situation),
  - Losses due to detours, losses of local businesses affected by malfunction of the bridge,
  - Environmental impacts (air pollution, energy use or fuel consumption),
  - Psychological consequences including loss of reputation or undue changes in professional practice,
  - Infrastructure interdependency costs etc.

Guidance for the quantification of these consequences is provided by Imam & Chryssanthopoulos (2012) and Thoft-Christensen (2009).

5.3 *Protective measures*

Permanent or operational protective measures may include (adapted from Berrick (2009)):

- Restriction of physical access (barriers, security officers to control access, eliminated parking near critical structures, landscaping to increase standoff distance),
- Surveillance and detection efforts (inspections, warning that the bridge is being monitored, enhanced lighting, motion sensors, removal of overgrown vegetation),
- Security planning and coordination (security plans to identify critical components and establish their protection, emergency telephones, means for rerouting traffic to enable access of emergency vehicles, restricted access after span failure),
- Structural modifications (protection of lower parts of cables on cable-stayed and suspension bridges, reinforce welds and bolted connections to ensure plastic capacity, use energy absorbing bolts to strengthen connections and reduce deformations, alternate load paths).

It is noted that efficiency has to be assessed for all considered measures. For instance investments into motion sensors may decrease needs for the restriction of physical access. The control of access by guards is often ineffective since they can be intentionally distracted by secondary attacks. For blast attacks the stand-off distance is a key parameter and can be hardly replaced by protective walls. However, quantification of the effects of protective measures may be difficult (e.g., estimating reduction of the probability of attack when safety guards patrol a bridge).

6 DISCUSSION

In accordance with Stewart & Mueller (2012) risk and cost-benefit considerations provide important insights into how security measures should perform, reduce risks and are cost-effective.

A risk-averse attitude in which severe consequences are more weighed is commonly accepted in decision-making, Cha & Ellingwood (2012). Despite this a risk-neutral attitude is suggested in this study to obtain the most efficient option in terms of the expected life cycle cost.

While quantitative decision support tools have many advantages for decision-making, they cannot capture the full and diverse range of societal considerations of risk acceptability, Stewart (2010). More specifically many societal, economic, cultural, environmental, political and other considerations are hardly quantifiable. That is why the probabilistic risk assessment should be viewed only as a tool supporting decision-makers.

Highway and road authorities and network managers may be more interested in the risks of a whole network rather than to the risks of an individual bridge. In this case the methodology proposed here should be extended similarly as proposed by Bocchini & Frangopol (2011).

7 CONCLUDING REMARKS

The present study leads to the following conclusions:

- Bridges and tunnels represent the most vulnerable components of road networks.
- Decisions concerning selection of protective measures can be based on the risk-based optimisation of expected costs; Bayesian networks provide an effective tool for risk estimation under uncertainties.

– Actions to be considered in the assessment may include normal and accidental (natural or man-made) loads and effects of human errors.
– Protective measures may include restriction of physical access, detection efforts, security planning and coordination, and construction modifications aiming to improve structural robustness.

Further research will be focused on illustrative applications on the developed methodology in the assessment of Czech highway bridges and tunnels.

ACKNOWLEDGEMENTS

The study is based on outcomes of the research project VG20122015089 supported by the Ministry of the Interior of the Czech Republic.

Point estimate of dynamic reliability considering parameter uncertainties

Y.G. Zhao
Department of Architecture, Kanagawa University, Yokohama, Japan

Z.H. Lu
School of Civil Engineering, Central South University, Changsha, China

1 INTRODUCTION

Assessment of dynamic structural reliability is a complex procedure, even with given system parameters. It has been realized that the effect of uncertainties in system parameters including structural properties such as stiffness, damping, and strength and excitation characteristics such as frequency content and duration may be equally important, even dominant, as far as the overall dynamic structural reliability is concerned. An important focus in recent research has been to incorporate parameter uncertainties into reliability analysis.

Approximate methods for evaluating dynamic structural reliability considering uncertainties described in terms of random variables have been developed by many researchers. For a linear oscillator, a first-order reliability method was proposed by Hohenbichler and Rackwitz (1981) in which the distribution of the maximum peak of the response is used, and the method has been used in case of non-stationary excitation by Quek et al. (1990) and Balendra et al. (1991). For the general problem, reliability estimation methods were proposed by Gueri and Rackwitz (1986) and Madsen (1987), in which auxiliary variables were introduced, and the first-order reliability method can be used. A practical treatment of reliability with response as a nonlinear combination of scalar Gaussian processes can be found in the study of Madsen and Moghtaderi-Zadeh (1987). A more general discussion of dynamic structural reliability analysis is provided by Wen and Chen (1987). By incorporating these methods, a nested first-order reliability method is proposed by Madsen and Tvedt (1990) on the basis of a discussion of the calculation of the failure probability with given parameters.

The purpose of this study is to review the recently developed available methods and propose an effective method for evaluating dynamic structural reliability. The general performance function is investigated, and equivalence of several first-order formulations is discussed. A point estimate method for dynamic reliability analysis considering parameter uncertainties is developed, and efficiency of the method is demonstrated using a simple example.

2 DEFINITION OF THE PROBLEM

For time-invariant structural reliability, the problem is generally described by a performance function $G(\mathbf{X})$, in which $\mathbf{X}$ is a vector of random variables of system parameters, and the probability of failure (limit state being reached) can be formulated by

$$P_F = \int_{G(\mathbf{X})\le 0} f_{\mathbf{X}}(\mathbf{x})dX \tag{1}$$

The powerful and efficient first-order method can be used to perform this integration, and the required information includes the explicit form of the performance function, G, and the joint probability density function (PDF) of variables, $\mathbf{X}$.

For dynamic structural reliability, the problem is generally described as a structural system with parameters $\mathbf{X}_1$ under the action of time-varying loadings $\mathbf{S}(t, \mathbf{X}_2)$, where $\mathbf{S}$ is a vector random process of time, and the process is specified by a set of parameters $\mathbf{X}_2$. Let $\mathbf{X}$ denote all parameters in the structure and loadings, where $\mathbf{X}$ is a vector of quantities that are uncertain but time invariant. The performance function must include a vector of random response variables, $\mathbf{R}$, because $\mathbf{R}$ is dependent not only on $\mathbf{X}$ but also on the random process, $\mathbf{S}$. The probability of failure can be similarly formulated by

$$P_F = \int_{G(\mathbf{X},\mathbf{R})\le 0} f_{\mathbf{X},\mathbf{R}}(\mathbf{x},\mathbf{r})d\mathbf{x}d\mathbf{r} \tag{2}$$

For the case of barrier crossing at a constant level, η, of a single-degree-of-freedom oscillator,

Hohenbichler and Rackwitz (1981) formulated the limit-state function as

$$G(\mathbf{X}, S) = h - S(t, \mathbf{X}) \tag{3}$$

where the failure domain is defined by the region $G(\mathbf{X}, S) < 0$. S is a random process of time, which is included as one of the basic variables, together with $\mathbf{X}$. For a stationary Gaussian base acceleration with Tajimi–Kanai frequency spectrum, probability distribution of S can be obtained. The problem can be reduced to a time-invariant one with $n + 1$ uncertain basic parameters, which can be solved by the first-order reliability method. Here n is the number of system parameters, $\mathbf{X}$. The method developed by Hohenbichler and Rackwitz (1981) has been used by Quek et al. (1990) and Balendra et al. (1991) to solve dynamic reliability of a linear oscillator, considering uncertainties of structural and input model parameters in case of non-stationary excitation.

For a general structural system and limit state, similar to the case of barrier crossing at a constant level of a single-degree-of-freedom oscillator, Gueri and Rackwitz (1986) included $\mathbf{R}$ as basic variables, together with $\mathbf{X}$, and reduced the dynamic problem to a time-invariant one with $n + m$ basic variables; therefore, the first-order reliability method can be used, where m is the number of response variables. The required information includes the explicit form of the performance function, G; the probability distributions not only of system parameters, $\mathbf{X}$, but also of response variables, $\mathbf{R}$; and even the joint PDF, $f\mathbf{X}, \mathbf{R}(\mathbf{x}, \mathbf{r})$. The method is very complicated because of the number of response variables and the difficulty of determining the distribution of response variables of interest. For some limit states, it may not be possible to identify $\mathbf{R}$ and determine the performance function in the explicit form.

To simplify the problem, it is assumed that the performance function of the structure can be described by a function $h[\mathbf{X}, \mathbf{R}(t)]$, in which $\mathbf{X}$ denotes system parameters, and $\mathbf{R}(t)$ denotes structural responses, a vector random process. Madsen (1986) formulated the reliability problem as the limit state being reached if the minimum value of $h[\mathbf{X}, \mathbf{R}(t)]$ in the time period under consideration is less than zero; the probability of failure including the uncertainty in $\mathbf{X}$ is

$$P_F = \int_{\mathbf{X}} P\left\{\min h[\mathbf{X}, \mathbf{R}(t)] \le 0\right\} f_{\mathbf{X}}(\mathbf{x}) d\mathbf{x} \tag{4}$$

Introducing an auxiliary variable

$$X_{n+1} = min\ h[\mathbf{X}, \mathbf{R}(t)] \tag{5}$$

and express the performance function

$$\mathrm{G}(\mathbf{X}, \mathrm{X}_{n+1}) = \mathrm{X}_{n+1} \tag{6}$$

where $G < 0$ corresponds to failure, note X_{n+1} depends on $\mathbf{X}$, G is a function of $\mathbf{X}$ implicitly.

To determine the design point on the limit state surface using the first order method, the gradients of the performance function with respect to $\mathbf{u}$ which are the standard normal variables transformed from $\mathbf{X}$ by Rosenblatt transformation are needed.

$$\nabla G_{\mathbf{U}}(\mathbf{u}) = \left[J^{-1}\right]^T \nabla G_{\mathrm{X}}(\mathbf{x}) \tag{7}$$

where $[J]$ is the Jacobian matrix for transformation of variables.

When searching for the design point along the limit state surface, the terms in the Jacobian matrix are needed only at $X_{n+1} = 0$. Thus dynamic reliability problem is much simplified because only one auxiliary variable is introduced. Note however, the determination of the conditional distribution of X_{n+1} with given $\mathbf{X}$ and their derivatives may also not be straightforward, and the function η may not be easy to find especially when damage and collapses of the structures are of concern. Therefore, dynamic reliability problem expressed by Eq. (2) is generally difficult.

On the other hand, if reliability of the structural system for given parameter values of $\mathbf{X} = \mathbf{x}$ can be evaluated from state-of-the-art techniques, e. g., those based on random process and vibration methods, then one can first solve the dynamic problem with given parameters and then integrate over system parameters to find overall reliability formulated by

$$P_F = \int_{\mathbf{X}} P_f(\mathbf{x}) f(\mathbf{x}) d\mathbf{x} \tag{8}$$

where $P_f(\mathbf{x})$ is the conditional probability of failure for given $\mathbf{X} = \mathbf{x}$, which is evaluated from state-of-the-art techniques, and $f(\mathbf{x})$ is the joint PDF of $\mathbf{X}$.

The computation of Eq. (8) is generally excessively difficult because repeated solutions of the structural response under stochastic loadings are required, in particular when a large number of system parameters are considered. Alternatively, one can use Monte Carlo simulations; again, when the safety level is high, a large number of simulation trials are required to obtain results with high confidence. Moreover, the process becomes very expensive for problems of practical interest. To reduce the computational cost, one can also use approximate methods such as the second moment method, in which the overall probability of failure is obtained from the following formulation

$$P_F = P_f(\mu_x) + \frac{1}{2}\sum_i \sum_j \frac{\partial^2 P_f(\mathbf{x})}{\partial_{xi}\partial_{xj}} \rho_{ij}\sigma_{xi}\sigma_{xj} \tag{9}$$

The accuracy depends on variabilities of a vector of random variables **X** and smoothness of the probability of failure, P_f, with respect to **X**. Therefore, approximate methods with good accuracy and numerical efficiency are required.

3 PREVIOUS METHODS FOR DYNAMIC RELIABILITY

3.1 *Performance function for dynamic structural reliability*

Since performance function for solving Eq. (8) is not explicitly konwn, FORM can not be directly used to solve Eq. (8). Wen and Chen (1987) created a performance function directly in the transformed standard normal space:

$$G_U(\mathbf{U}, U_{n+1}) = U_{n+1} - \Phi^{-1}\left\{P_f[T^{-1}(\mathbf{u})]\right\} \tag{10}$$

where U_{n+1} is an auxiliary standard normal variable independent of **U**, $T^{-1}(\mathbf{u})$ are inverse Rosenblatt transformation. Neither the auxiliary variable X_{n+1} nor the Rosenblatt transformation from X_{n+1} to U_{n+1} is needed in equation (10), so the difficulties described above can be avoided.

Introduce an auxiliary variable X_{n+1} which can be taken arbitrary probability distribution but satisfy with

$$F_{X_{n+1}}(0 \mid \mathbf{x}) = P_f(\mathbf{x}) \tag{11}$$

then one can easily obtain

$$\begin{aligned} P_F &= \int_{\mathbf{X}} P_f(\mathbf{x}) f(\mathbf{x}) d\mathbf{x} \\ &= \int_{\mathbf{X}} \left[\int_{X_{n+1} \le 0} f_{X_{n+1}}(x_{n+1} \mid \mathbf{x}) dx_{n+1} \right] f(\mathbf{x}) d\mathbf{x} \\ &= \int_{X_{n+1} \le 0} \left[\int_{\mathbf{X}} f_{X_{n+1}}(x_{n+1} \mid \mathbf{x}) f(\mathbf{x}) d\mathbf{x} \right] dx_{n+1} \end{aligned} \tag{12}$$

Comparing equation (12) with equation (1), one can obtain

$$\mathrm{G}(\mathbf{X}, \mathrm{X}_{n+1}) = \mathrm{X}_{n+1} \tag{13}$$

This is the general performance function, note that it is different from equation (6) because X_{n+1} in equation (6) is defined by equation (5) but here X_{n+1} is defined by equation (11).

In order to obtain the gradients of the new performance function *G*, the Jacobian matrix corresponding to equations (8) and (9) is expressed as:

$$[J_{n+1}] = \left[\frac{\partial \mathbf{u}}{\partial \mathbf{x}}\right] = \begin{bmatrix} J_n & \{0\}_n \\ \left\{\dfrac{\partial u_{n+1}}{\partial x_i}\right\}^T_{i \le n} & \dfrac{\partial u_{n+1}}{\partial x_{n+1}} \end{bmatrix} \tag{14}$$

where

$$\left\{\frac{\partial x_{n+1}}{\partial u_i}\right\}_{i \le n} = -\left[J_n^{-1}\right]^T \left\{\frac{\partial u_{n+1}}{\partial x_i}\right\}_{i \le n} \frac{\partial x_{n+1}}{\partial u_{n+1}} \tag{15}$$

From equation (15) and equation (11) one can finally obtain the gradient of *G* at point on the failure surface with the aid of Rosenblatt transformation,

$$\left\{\frac{\partial x_{n+1}}{\partial u_i}\right\}_{i \le n} = -\left[J_n^{-1}\right]^T \left\{\frac{\partial pf(\mathbf{x})}{\partial x_i}\right\}_{i \le n} \tag{16}$$

$$\frac{\partial x_{n+1}}{\partial u_{n+1}} = \phi(u_{n+1}) \tag{17}$$

where

$$u_{n+1} = \Phi^{-1}\left[p_f(\mathbf{x})\right] \tag{18}$$

where Φ is the normal distribution function, ϕ is the normal distribution density function and $P_f(\mathbf{x})$ the conditional probability of failure for given $\mathbf{X} = \mathbf{x}$.

Based on equations (18), (19) and (20) the integration in equation (10) becomes quite easy to use the first order reliability method. Note it does not include the probability distribution of X_{n+1} and the explicit form of performance function *G* in the equations, and so that X_{n+1} can be a random variable with arbitrary probability distribution as long as it satisfies with equation (13) and the difficulties in identifying **R** and determination of their distribution functions and finding an explicit performance function *G* or *h* can be avoided.

3.2 *Equivalence of the first order formulations and the graphical interpretation of the method*

Since equation (1) and equation (10) are different expressions for the same problem, we have

$$\begin{aligned} P_F &= \int_{G(\mathbf{X},\mathbf{R}) \le 0} f_{\mathbf{X},\mathbf{R}}(\mathbf{x},\mathbf{r}) d\mathbf{x} d\mathbf{r} \\ &= \int_{\mathbf{X}} P_f(\mathbf{x}) f(\mathbf{x}) d\mathbf{x} \end{aligned} \tag{19}$$

From the basic conception of probability theory, one can obtain

$$P_f(\mathbf{x}) = \int_{G(\mathbf{R}|\mathbf{X})\le 0} f_{\mathbf{R}|\mathbf{X}}(\mathbf{r} \mid \mathbf{x}) d\mathbf{r} \tag{20}$$

Let $z = G(\mathbf{r}|\mathbf{x})$, note z is an expression of the actual performance function and it is a function of $\mathbf{X}$, one can obtain

$$F_Z(z=0) = P_f(\mathbf{x}) \tag{21}$$

Note that it is unnecessary to determine the explicit form of performance function and determine the probability distribution of X_{n+1}.

3.3 *Response surface approach*

The performance function expressed by equation (11) or (14), enables an evaluation of the dynamic structural reliability that includes parameter uncertainties can be performed using FORM. Calculation of the gradients of the performance function is an important step of the FORM. However, it is not always easy to obtain these gradients, (especially for the case where non-linearity of the structural performance is considered). Yao and Wen (1996) have introduced response surface approach (RSA) to avoid the sensitivity analysis required in FORM, where the response surface function is expressed as a polynomial of basic random variables in original space. For simplification, the performance function shown in equation (11) is approximated by the following second-order polynomial of standard normal random variables, in which the mixed terms are neglected.

$$G(U) = a_0 + u_{n+1} + \sum_{j=1}^{n} \gamma_j u_j + \sum_{j=1}^{n} \lambda_j u_j^2 \tag{22}$$

where a_0, γ_j, and λ_j are 2_{n+1} regression coefficients with j ranging from 1 to n. If the practical performance function $G(\mathbf{U})$ in equation (11) is fitted by $G(\mathrm{U})$ of equation (22) at the fitting points in the vicinity of the design point, the regression coefficients a_0, γ_j, and λ_j can be determined from the linear equations of a_0, γ_j, and λ_j obtained at each fitting point. For the obtained design point in standard normal space, fitting points along the coordinate axes are selected.

Because the design point is not generally known beforehand, iterative RSA procedure in the point-fitting SORM to approach the performance function (Zhao & Ono 1999) are generally used in the course of obtaining the design point. In the present paper, methods of moments will be used to obtain the probability of failure.

3.4 *Approximate distribution of the performance function*

If the first three or four moments of $G(\mathbf{X})$ expressed by Eq. 11 are obtained, the reliability analysis becomes a problem of approximating the distribution of a specific random variable with its known first three or four moments.

Approximating the distribution of a random variable using its moments of finite order is a well known problem in statistics, and various approximations such as the Pearson, Johnson and Burr systems, the Edgeworth and Cornish-Fisher expansions were developed (Stuart and Ord 1987). Their applications in structural reliability have been examined by Winterstein (1988), Grigoriu (1983), Hong (1996). In the present study, the fourth moment standardization function will be used. For the standardized performance function,

$$Z_s = \frac{Z - \mu_G}{\sigma_G} \tag{23}$$

The fourth moment standardization function is expressed as (Zhao & Lu 2007)

$$Z_s = S(U, \mathbf{M}) = -l_1 + k_1 U + l_1 U^2 + k_2 U^3 \tag{24}$$

where

$$l_1 = \frac{\alpha_{3G}}{6(1+6l_2)} \tag{25}$$

$$l_2 = \frac{1}{36}\left(\sqrt{6\alpha_{4G} - 8\alpha_{3G}^2 - 14} - 2\right) \tag{26}$$

$$k_1 = \frac{1-3l_2}{(1+l_1^2-l_2^2)} \tag{27}$$

$$k_2 = \frac{l_2}{(1+l_1^2+12l_2^2)} \tag{28}$$

Since

$$F(Z_s) = \Phi(U) = \Phi[S^{-1}(Z_s, \mathbf{M})] \tag{29}$$

The reliability index is expressed as

$$\beta_{4M} = D_0 p - \frac{1}{D_0} + l \tag{30}$$

where

$$D_0 = \sqrt[3]{2}\left(\sqrt{q_0^2 + 4p^3} - q_0\right)^{-1/3} \tag{31}$$

$$q_0 = l\left(2l^2 - k_1/k_2 - 3\right) + \beta_{2M}/k_2 \tag{32}$$

$$p = k_1/k_2/3 - l^2; l = l_1/k_2/3 \tag{33}$$

4 POINT ESTIMATE FOR DYNAMIC RELIABILITY

Rewrite Eq. (10) in standard u-space, the probability of failure considering parameter uncertainties is espressed as

$$P_F = \int_{\mathbf{u}} P_f[T^{-1}(\mathbf{u})]\phi(\mathbf{u})d\mathbf{u} \tag{34}$$

where

$T^{-1}(\mathbf{u})$ denotes inverse Rosenblatt transformation.

$\phi(\mathbf{u})$ denotes the PDF of standard normal variables.

Practically, the integral in Eq. (34) cannot be evaluated analytically because of the high dimensionality and the complicated integration. In order to avoid this problem, in the present paper, the point estimate method (Zhao & Ono 2000) is used to determine the moments of the performance function such as Eq. 11 for a series system. For a function of only one random variable $y = y(x)$, the moments of y can be point-estimated as

$$\mu_y = \sum_{k=1}^{m} P_k y\left[T^{-1}(u_k)\right] \tag{35}$$

where μy, iσ the mean value of $y(x)$, T^{-1} is the inverse Rosenblatt transformation. $u_1, u_2, ..., u_m$ are the estimating points and $P_1, P_2, ..., P_m$ are the corresponding weights.

The estimating points *ui* and their corresponding weights P_i can be readily obtained as (Zhao & Ono 2000),

$$u_r = \sqrt{2}x_r, P_r = \frac{w_r}{\sqrt{\pi}} \tag{36}$$

where x_i and w_i are the abscissas and weights for Hermite integration with the weight function $\exp(-x^2)$ that can be found in Abramowitz and Stegum (1972).

Specially, for a five point estimate in standard normal space (Zhao and Ono 2000),

$$u_0 = 0 \; P_0 = 8/15 \tag{37a}$$

$$u_1 + = -u_1 - = 1.3556262 \; P_1 = 0.2220759 \tag{37b}$$

$$u_2 + = -u_2 - = 2.85697 \; P_2 = 1.1257 \times 10^{-2} \tag{37c}$$

whereas for a seven point estimate in standard normal space,

$$u_0 = 0 \; P_0 = 16/35 \tag{38a}$$

$$u_1 + = -u_1 - = 1.1544054 \; P_1 = 0.2401233 \tag{38b}$$

$$u_2 + = -u_2 - = 2.366759 \; P_2 = 3.0757 \times 10^{-2} \tag{38c}$$

$$u_3 + = -u_3 - = 3.75044 \; P_3 = 5.4827 \times 10^{-4} \tag{38d}$$

Since $P_f(\mathbf{x})$ is a function of many variables where $\mathbf{x} = x_1, x_2, ..., x_n$, the joint probability density is generally assumed to be concentrated at points in the m^n hyperquadrants of the space defined by the n random variables, in which m is the number of estimating points used in the point estimates for functions of the respective single random variables. Then the moments of $Z = G(\mathbf{X})$ can be point-estimated as,

$$P_F = \sum \prod_{i=1}^{n} P_{Ci} P_f(T^{-1}(u_{c1}, u_{c1}, ..., u_{cn}) \tag{39}$$

where c is a distinct combination of n terms from a group [1, 2, ..., m], ci is the ith term of c. u_{ci} is the cith estimating point and P_{ci} is the weight corresponding to u_{ci}. n is the number of random variables and m is the number of estimating points, T^{-1} is the inverse Rosenblatt transformation.

Since all the distinct combinations have to be considered, m^n times of function calls for computing $P_f(\mathbf{x})$ are required. The computations involved in Eq. 8, therefore, can be massive when n is large. In order to avoid this problem, using the first order expansion of the function $P_f(\mathbf{x})$, PF can be approximated estimated as

$$P_F = \sum_{i=1}^{n} \mu_{fi} - (n-1)P_f(\mu) \tag{40a}$$

where μ_{fi} is the mean value of

$$P_{fi} = P_f[T^{-1}(\mathbf{U}_i)] \tag{40b}$$

$\boldsymbol{\mu}$ represents the vector in which all the random variables take their mean values, and $\mathbf{U}_i = [u_{\mu 1}, u_{\mu 2}, ..., u_{\mu i-1}, u_i, u_{\mu i+1}, ..., u_{\mu n}]T$, where $u\mu k$, $k = 1, ..., n$ except i, is the kth value of u_μ, which is the vector in u-space corresponding to $\boldsymbol{\mu}$.

Since *Pfi* is a function of only one standard normal random variable *ui*, its mean value can be point-estimated from Eq. 35. For a problem with n variables, if the probability moments of μ_{fi} is estimated using m-point estimate, only mn function calls of $P_f(\mathbf{x})$ are required for estimating the general probability of failure.

Further more, since $P_f(\mathbf{x})$ has strong non-linearity, in this study the conditional reliability index $\beta_f(\mathbf{x})$ will be used instead of $P_f(\mathbf{x})$. The reliability index with consideration of parameter uncertainties is written as

$$\beta = \int_{\mathbf{u}} \beta_f[T^{-1}(\mathbf{u})]\phi(\mathbf{u})d\mathbf{u} \tag{41}$$

5 NUMERICAL EXAMPLES

Consider a example of a linear single degree of freedom system under dynamic excitation. the excitation is modeled as Gaussian white noise, the intensity S, the duration D of the excitation and the natural frequency f, damping ratio ζ are uncertain and modeled as random variables as shown in Table 1. For a simple limit state of a given threshold level of the displacement being exceeded, the failure probability with deterministic system parameters is

$$P_f = 1 - \exp\left\{-fD\exp\left[-\frac{1}{2}\left(\frac{d}{\sigma_r}\right)^2\right]\right\}$$

where

$$\sigma_r = \sqrt{\frac{\pi S}{4(2\pi f)^3\zeta}}$$

With consideration of parameter uncertainties, the problem is expressed as

$$P_F = \int_{s,D,f,\zeta} P_f(s,D,f,\zeta)f(s,D,f,\zeta)dsdDdfd\zeta$$

The problem is solved by Monte-Carlo method, method of moment, and the fast integration described above. For threshold $d = 0.35$, considering only the uncertainties contained in duration D and damping ratio ζ, using Eq. (41), the reliability index obtained as $\beta = 2.372$.

Table 1. Probabilistic properties of uncertain parameters.

Parameter	Distribution	Mean	Uncertainty
s	Type II extreme value	0.25	0.60
D	Lognamal	10 sec	0.3
f	Normal	2 Hz	0.1
ζ	Lognormal	0.02	0.4

Using the MCS with 5,000,000 samples, the probability of failure for this performance function is obtained as 0.00933 with corresponding reliability index of $\beta = 2.352$. One can see that the probability of failure obtained using the proposed method is close to the result of MCS, the reliability analysis can be easily conducted without shortcomings associated with the design points, and do not require iteration or computation of derivatives.

The results of different threshold level are shown in Fig. 2 in which, the results of Monte-Carlo method is obtained by 100,000 sampling and the results of second moment is obtained from Eq. (11).

From Figure 1, it can be seen that the curve obtained by the method of this paper is quite near to the curve obtained by the Monte-Carlo method while that of the moment method is much different, so the method in this paper has a good accuracy. It can be also seen that the degree of the slope of the curve obtained with consideration of parameter uncertainties is much smaller than that with given parameters, that is to say the limit state in the reliability analysis with consideration of parameter uncertainties is not so dominant as in that with given parameters.

From Fig. 1, it can be also seen that for this example when the reliability index is high the limit state probability results with consideration of parameter uncertainties is larger than that with given parameters, on the other hand, when the reliability index is negative (in the case of dangerous structures or structures subjected to large intensity but low occurrence rate load), the results with consideration of parameter uncertainties is smaller than that with given parameters. Therefore the negligence of the parameter uncertainties overestimated the structural reliability for high safety structures and underestimated the structural reliability for low safety structures.

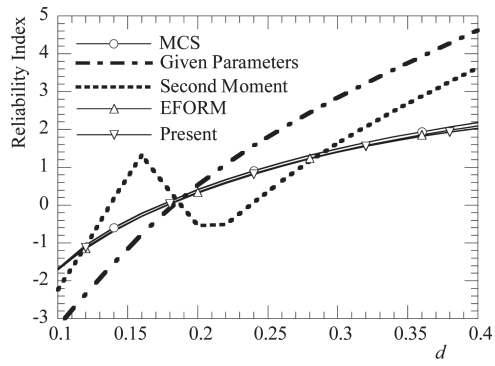

Figure 1. Reliability function.

6 CONCLUSIONS

1. A computationally effective method for dynamic structural reliability is proposed and examined. The method directly calculates the reliability indices (and associated failure probabilities) using point estimate. It does not need the iterative computation of derivatives, and does not require any design points. Thus, the proposed method should be more effective for the reliability evaluation of complex structures than currently available methods.
2. The accuracy of results, obtained with the proposed method has been examined by comparisons with large sample Monte Carlo simulations (MCS).
3. Neglecting effects of parameter uncertainties overestimates structural reliability of high-safety structures and underestimates that of low-safety structures.

The reliability analysis of welded tanks for oil storage

Z. Kala
Faculty of Civil Engineering, Brno University of Technology, Brno, Czech Republic

ABSTRACT: Large cylindrical steel storage tanks are very thin shell structures of shape and design layout, which ideally meet requirements. Standards EEMUA 159 and API 653 specify the minimum wall thickness of the sheet metal of cylindrical tanks. A storage tank is considered reliable if the wall thickness is higher than the minimum thickness listed in standards. This article aims to determine the failure probability of real crude oil tanks. The material and geometrical characteristics of the steel storage tank are considered as random quantities. The Latin hypercube sampling simulation method will be used for probability evaluation. Methods of standards EEMUA 159 and API 653 will be verified using probabilistic approaches.

1 INTRODUCTION

Oil reserves in the Czech Republic are considered for 90 days. The European Communities adopted legislation obliging member States to maintain oil reserves covering at least 90 days consumption after the oil crisis in the 1970s. The Czech Republic conformed to this law during negotiations on its entry into the European Union. Crude oil is brought into the Czech Republic via the Druzhba pipeline from Russia and the IKL pipeline form Bavarian Vohburg near Ingolstadt, where it is connected with the Transalpine pipeline from the region of the Caspian Sea, Middle East and North Africa.

Crude oil is stored in large cylindrical storage tanks, constructed not far from the village Nelahozeves. If the pipelines were to suddenly dry up, transportation in the Czech Republic could function without problem for another 90 days. Storage tanks are managed by the firm Mero, a.s., which took over management of the pipelines in 1994.

The largest tank has a height of 27 m and can hold 125 000 m^3 of crude oil, see Figure 1. The mentioned storage tank is the largest of its kind in the world. The tanks have floating roofs, which float directly over the crude oil surface to prevent evaporation. The floating roof is the size of a football field and covers crude oil worth 57 million Euros. The actual tank type in the central crude oil tank farm is a Czech invention and is considered the most advanced in the world. Safety is ensured by a double steel cover. A technical curiosity is the double bottom of the tank, where vacuum is created in the gap between the bottom 8 mm plate and top 6 mm riffled plate, which provides tightness of the bottom during operation. Inside the tank is a floating roof chamber, which moves together with the media level in the tank.

In case of damage to the inner shell oil is trapped by the outer shell. Thanks to the double casing tanks can be erected closer to each other leading to savings on space otherwise needed for containment dikes. The most likely place for fire to occur is between the roof and tank, which is fitted with a special rubber seal. Safety is ensured by a highly modern fire system. The tanks are located in a place where sand was once mined. The strategic location of the tanks near the Vltava River enables highly effective cooling of the tanks with water from the river in the event of fire.

Crude oil is a strategically important raw material and therefore it is necessary to pay increased attention to its transportation and storage. The dominant load case of cylindrical tanks is loading of the inner shell by hydrostatic pressure of the oil. The article is aimed at the analysis of failure probability of the inner shell with regard to random geometric and material imperfections. The article

Figure 1. Welded tank for oil storage.

builds on the probabilistic reliability studies, see e.g. (Kala 2007, Kala 2012, Gottvald et al. 2012).

2 REJECTION LIMITS FOR SHELL PLATES

The principal factor, which determines the thickness of the tank shell, is the internal loadings due to the liquid head. The minimum acceptable thickness for welded tank shells may be calculated from the following formula used in BS2654 and in EEMUA 159 for the basic design of tank shells:

$$t_{min} = \frac{D}{20 \cdot S \cdot E}\left(98 \cdot W \cdot \left(H - 0.3\right) + P\right) \tag{1}$$

where:
t_{min} is the minimum acceptable thickness in mm from the above formula (1), but should not be less that 2.5 mm or 50% of the original shell plate thickness, whichever is greater
D is the nominal diameter [m]
H height from the point under consideration to the maximum filling height [m], see Figure 2
W specific gravity of the content
P design vapour pressure in mbar
S maximum allowable stress in MPa
E original joint efficiency for the tank
$E = 0.85$ if original E is unknown
$E = 1.0$ when evaluating the retirement thickness in a corroded plate, when away from welds or joints by at least the greater of 25 mm or twice the plate thickness.

A similar formula is also listed in standard API 653.

It is apparent from Figure 2 that the pressure varies with the liquid head and thus the shell thickness varies from almost zero at the top, to the maximum at the bottom. It is impractical to have a shell with tapering thickness so it is constructed from a number of plate shell courses (the term "course" is used in the standards EEMUA and API) each of uniform thickness. However, each successive shell course is thinner than the one below. The top courses are governed by Codes, which list the minimum recommended thickness. The consequence of using courses with diminishing thickness is that, at the joint between two adjacent courses, the lower, thicker course provides some stiffening to the top, thinner course leading to an increase in stress in the upper part of the lower course and a reduction in stress in the lower part of the upper course. The codes empirically assume that reduction in stress in the upper course reaches a maximum value 0.3 m (one foot) above the joint. The effective acting head is measured at this point on each course. This calculation method is referred to as the "one foot" method (Long 2004).

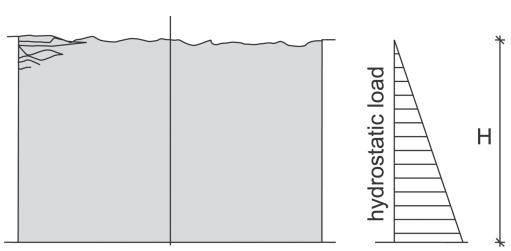

Figure 2. Hydrostatic loading of the tank shell.

3 RELIABILITY CONDITION

Formula (1) is based on the static analysis of the shell of a cylindrical tank with constant wall thickness. Let us consider a thin-walled circular cylindrical tank of height H, internal radius r (distance from the vertical axis of symmetry to the wall surface) and wall thickness t, see Figure 3.

Hydrostatic pressure p [Nm^{-2}] at height h is evaluated as:

$$p = \rho \cdot g \cdot h \tag{2}$$

where ρ is the oil density at temperature 20°, which at present is within the interval of approximately 790–880 kgm^{-3} (worldwide values are 730–1000 kgm^{-3}), g is gravitational acceleration, which is approximately $g = 9.81$ ms^{-2} for our latitude (49°). Perpendicular to the surface of the tank at depth h acts uniform load f:

$$f = \rho \cdot g \cdot h \cdot dh \tag{3}$$

where f has the unit Nm^{-1}. At depth h uniform load f induces normal stress σ perpendicular to the plane passing through axis x.

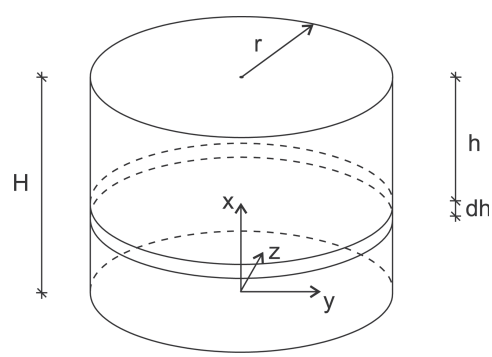

Figure 3. Scheme of circular cylindrical tank.

Normal stress on the surface $dh \cdot t$ is induced by force F, which can be calculated as the reaction of a planar semi-circular arc (half hoop), see Figure 4. The computational model of the planar arc in Figure 4 is based on the assumption that the loaded tank for $x > h$ and $x < h$ does not affect the loading of the tank for $x = h$.

Force dS, which can be decomposed into the horizontal dS_H and vertical dS_V components, acts on arc length $ds = r \cdot d\alpha$. With consideration to symmetry reaction F [N] can be evaluated as:

$$F = \int_0^{\frac{\pi}{2}} dS_V = \int_0^{\frac{\pi}{2}} dS \cdot \sin(a) = \int_0^{\frac{\pi}{2}} f \cdot r \cdot \sin(\alpha) d\alpha$$
$$= \rho \cdot g \cdot h \cdot dh \cdot r \int_0^{\frac{\pi}{2}} \sin(\alpha) d\alpha = \rho \cdot g \cdot h \cdot r \cdot dh \qquad (4)$$

The value of reaction H_y is zero. This can be evaluated, for e.g., using the finite element method. The arc shown in Figure 4 is not stressed by bending moment. Force F evokes normal stress in the direction of the tangent to the centre line of the shell plate of thickness t and height dh, where the centre line has the shape of a circle lying in the plane perpendicular to the axis x. For reliable operation force F must be less than or equal to the plate resistance R:

$$G = R - F \geq 0 \qquad (5)$$

Resistance R can be calculated as:

$$R = f_y \cdot t \cdot dh \qquad (6)$$

where f_y is the yield strength. The reliability condition (5) can be rewritten with consideration to (4) and (6) as:

$$G = f_y \cdot t - \rho \cdot g \cdot h \cdot r \geq 0 \qquad (7)$$

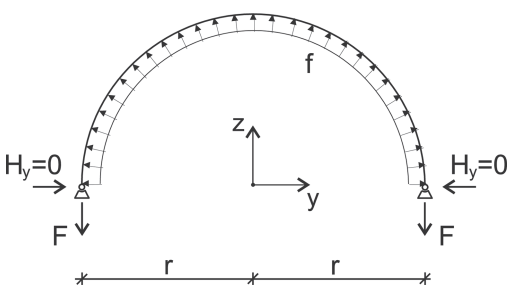

Figure 4. Loading of circular arc at depth h.

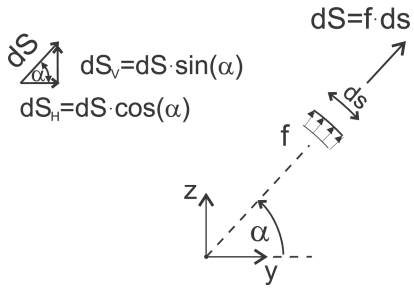

Figure 5. Force decomposition.

Inequality (7) is the basic equation for the assessment of design reliability or service reliability of circular cylindrical tanks of a series of standards, for e.g. EEMUA 159 or API 653, see, for e.g. the comparison of (7) and (1). Standardized approaches ensure reliability primarily by considering conservative (safely low) values of yield strength.

4 FAILURE PROBABILITY

The condition of reliability (7) must be fulfilled for reliable operation of the tank. A possible approach for the assessment of reliability of steel structures is using probabilistic methods based on Monte Carlo simulation methods, see, for e.g. (Kala 2007).

Variables in equation (7) are considered as random during probabilistic reliability assessment. Failure occurs if inequality (7) is not satisfied. Failure probability is evaluated as:

$$P_f = P(G < 0) \qquad (8)$$

Operation of the tank may be considered safe if the probability of failure P_f is sufficiently small.

Let us consider the tank depicted in Figure 1 with a capacity of 125,000 m^3 of crude oil. The tank has the following parameters:

- Tank radius is 42.235 m, fill height is 22.3 m, tank height is 24.0 m.
- Nominal height of shell courses from bottom to top: 2.2 m, 2.4 m, 2.4 m, 2.8 m, 2.8 m, 2.85 m, 2.85 m, 2.85 m, 2.85 m.
- Nominal thickness of shell courses from bottom to top: 39 mm, 35 mm, 30 mm, 26 mm, 22 mm, 17 mm, 12 mm, 11 mm, 10 mm.
- Steel of grade S355 is used apart for the last two top shell courses, which are from steel S235.

The reliability of all shell courses can be evaluated using the reliability index according to Cornell

(Cornell 1969), which is defined as the reciprocal of the variation coefficient of the reliability reserve and is determined under the assumption of normality of the distribution of quantity G according to the relation:

$$\beta = \frac{m_G}{S_G} \tag{9}$$

where m_G is the mean value and S_G is the standard deviation of random variable G. The reliability index according to Cornell is sometimes considered to be more illustrative than P_f, and is introduced due to uncomfortable handling of small values of failure probability.

The tank during operation is exposed to environmental effects, which cause weakening of the thickness of the tank plates. Plate thicknesses are continuously measured by the tank operators. The most common cause of reduction in the thickness of plates is corrosion. The basic criteria for the assessment of service reliability of tanks are provided by standards EEMUA 159 and API 653. The standards list the calculation of the minimum plate thickness, which has to be maintained for reliable operation.

An alternate approach to the assessment of reliability is the analysis of the failure probability. The effect of changes in the thickness of tank plates on the safety and reliability of the tank can be studied using the reliability index β (9).

Let us examine the effect of changes in nominal plate thickness t of the bottom shell course on β. Depth h = 22.3–0.3 = 22 m (depth 0.3 m from bottom) was considered in (7). The spacing 0.3 m is considered because the reliability condition (7) near the edge of the shell course (during change in plate thickness) is imprecise. The spacing value of 0.3 m is considered according to standard EEMUA 159 and API 653. Input random variables for the probabilistic analysis are clearly listed in Table 1.

All input random quantities in Table 1 have Gauss probability density functions. The mean value and standard deviation of yield strength were considered according to results of experimental research (Melcher et al. 2004, Strauss et al. 2006, Kala et al. 2009). It may be noted that experimental research provides important input data for a number of probabilistic reliability studies, see. e.g. (Frydrýšek et al. 2013, Kala 2008, 2010, 2013, Krejsa 2014).

Table 1. Input random quantities.

No.	Quantity	Symbol	Mean value	Std. deviation
1.	Oil density	ρ	880 kgm^{-3}	8.8 kgm^{-3}
2.	Yield strength	f_y	393.5 MPa	25.4 MPa
3.	Thickness	t	t	$0.04 \cdot t$

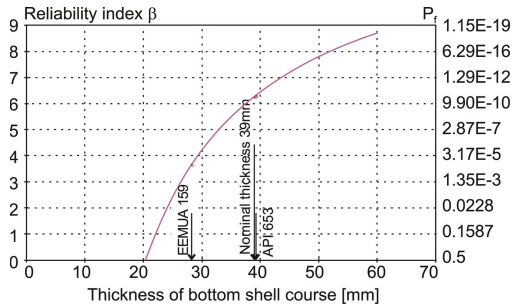

Figure 6. Reliability index β vs t.

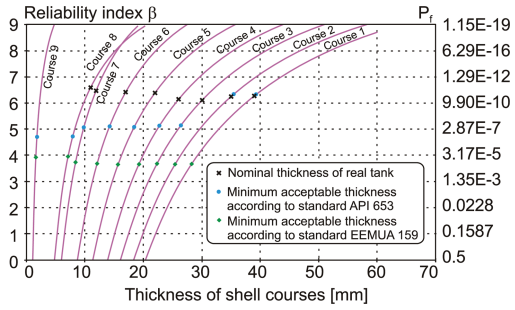

Figure 7. Reliability index β vs thickness t.

Coefficient β (9) was evaluated using the Latin Hypercube Sampling method (McKey et al. 1979) for 100 simulation runs. The dependence of β on t is shown in Figure 6. For clarity the Gauss probability density function and scale P_f, which is evaluated from β, is shown on the right side of the figure.

The procedure was similar for the reliability analysis of other shell courses, see Figure 7. A point 0.3 m from the bottom edge of the corresponding shell course was always considered for each evaluation. The reason for the spacing of 0.3 m is the same as for the calculation of β for the bottom of the shell course. Equation (7) cannot be reliably used to indicate failure in the vicinity of the step change of the plate thickness. Yield strength was considered according to Table 1 for all shell courses apart from the last two shell courses, which are of steel grade S235. Steel grade S235 has a mean value of 284.5 MPa and standard deviation 21.5 MPa.

5 CONCLUSION

It is apparent from Figure 7 that the dependence of β on the thickness of plate courses *t* is non-linear. Reliability index β for nominal thickness of the real tank (cross) is approximately constant with the exception of the top shell course 9, which has a very high reliability $\beta \approx 10.4$. The reliability indices β for the first two shell courses evaluated according to API 653 (blue dots) are $\beta \approx 6.3$, see Figure 7. The minimum acceptable thickness evaluated for the first two bottom shell courses according to standard API 653 (blue dots) is higher than the nominal value of plate thickness of the assessed tank. Strictly speaking, the tank does not comply with the requirements of standard API 653, however, the difference is so small that the tank can be practically considered reliable (blue dot practically overlaps the cross).

Reliability indices β evaluated for standard EEMUA 159 (green squares) are lower than the reliability indices evaluated for standard API 653 in all cases, see Figure 7. At the same time the minimum acceptable thickness evaluated for standard EEMUA 159 (green squares) are lower than the minimum acceptable thickness evaluated for standard API 653. This means that the rejection limits of standard API 653 are safer (more conservative) than the rejection limits of standard EEMUA 159.

Minimum acceptable thickness evaluated according to standard EEMUA 159 are approximately constant, on the contrary standard API 653 prescribes higher reliability for the first two shell courses. If we consider that the greater the depth the more oil could leak during accident, then it is appropriate to have higher reliability for greater depth, thus the approach of standard API 653 can be approved.

It is interesting that the curves of shell course 1 to 7 in Figure 7 are similar in shape (graphically). For example the curve of the second shell course is obtained graphically by shifting the curve of the first shell course to the left and also decreasing the scale of the horizontal size of the rectangular border of the curve. This graphical similarity suggests even more general mathematical dependence. Similarly, the curves of shell courses 8 and 9 from steel S235 are similar in shape.

It should be noted that reliability is affected by many other parameters including soil (Amšiejus et al. 2014, Kelevišius et al. 2014, Martinkus et al. 2014). Tanks are regularly checked and discovered defects are analysed so that obtained data serves as basis for the implementation of the methodology of Risk Based Inspection (Shuai et al. 2012). The results are then used to assess the state of the tank and plan inspections.

The article was elaborated within the framework of projects of GAČR14-17997S and TAČR TA01020307.

ABSTRACT: Life Cycle Cost Analysis (LCCA) was performed to determine the design load of a pile-guide system that was intended to maintain the position of large-scale floating installations. The positioning system consisted of guide piles supporting the floating installation, a subsea truss structure cross-linking the piles, and a seabed platform fixed to the seabed. For the LCCA, Capital Expenditure (CAPEX), Operating Expenditure (OPEX) and Risk Expenditure (RISKEX) were considered. Environmental loads such as wave, current, and wind loads applied to the positioning system were taken into account. Probability models were used to consider the frequency of external loads in the target area. As a result, the design load of the installation were determined to give the minimum Life Cycle Cost (LCC).

1 INTRODUCTION

This study was performed to determine the design load for offshore large-scale floating installations. To determine the design load of an offshore structure, LCCA and probability models were employed.

Many studies in extreme environmental conditions such as gust wind speed and significant wave height were carried out. Estimation of the extreme wind speeds, using a national wind map with Gumbel & Weibull distribution, for the structural stability of a wind power plant station hub was conducted by B.H. Lee et al. (2010). H.S. Jung (2012) performed stochastic estimation of wind speed when affected by a typhoon for three different sites (Ulsan, Yeonggwng, and Geoge) in which long span bridges were located. Studying the wave itself, S.H. Kwon et al. (1991) used a statistical estimation-methodology of an extreme sea level using Weibull distribution function (Type III). T.I. Lee et al. (1992) developed computational methods based on the Weibull distribution for estimation of extreme sea level. H.J. Ryu & D.Y. Kim (2004) studied the statistical properties of extreme waves in Hong-do, an island in Korea, during typhoons. A study on the projection of future wave climate changes was conducted by J.S. Park et al. (2013). Thus, the extreme environmental conditions that correspond to the return period could be estimated by extreme distribution functions such as Gumbel-distribution (Type I), Frechet-distribution (Type II), and Weibull-distribution (Type III). However, in these studies, a method for making practical use of the extreme environmental conditions estimated for a structure design was not considered.

For the design of an offshore structure, the codes and specifications have been used in prescriptive ways because alternative methods for a newly developed structure have not been considered thus far. The environmental load, occurring once in 100 years, has been generally used for structure design, based on rule-based design. According to International Organization for Standardization (ISO 19902) (2007) and the fixed offshore structure rules of the Korea Register (KR) (2012), a 100 year return period should be taken into account for an offshore structure design. The maximum wave height, wind speed, and current, corresponding to the return period, should be considered. Using a 100 year or more return period for a structure design was quite vague and the design load could be changed depending on the types of structures and installation locations. In other areas such as bridge designs on onshore, many studies on new design methodologies such as using LCCA have been carried out by Sang-Hyo Kim et al. (2013). However, these studies have not included offshore installations.

In this study, a methodology for determining design load was taken into consideration in terms

of an offshore structure newly developed. The Pile Guide System (PGS), an offshore mega-floater, was considered for the case study and Busan New Port in the Republic of Korea was selected as the target site. Gumbel distribution function was employed to estimate the extreme environmental conditions at the target site. ANSYS AWQA, a commercial code for offshore structures, was used to calculate extreme environmental loads, considering wave, wind, and current loads applied to the floater only. Nine return periods (30, 50, 100, 300, 500, 1 000, 3 000, 5 000 and 10 000 years) of extreme environmental loads were considered for the structure design. The PGS structures were designed to withstand each design load case. For the LCCA, CAPEX, which was the initial investment costs which include material cost, fabrication cost, and installation cost, was estimated based on the material costs of the structures. RISKEX, which included the costs of failed components, the rental fee of an offshore crane vessel, and production loss during repair-time, was also taken into account according to the safety philosophy of the PGS.

2 METHODOLOGY: DETERMINATION OF DESIGN LOAD

Unlike the design of a process system, so far rule-based design has been considered to make offshore structures. Most offshore structures have been designed with a load coming once every 100 years (ISO 19902. 2007). However, these offshore structures have occasionally failed due to strong environmental loads which were not taken into account at the early design stage. Sometimes, these accidents have led to considerable production loss. When the strength of the offshore structures was increased to prevent damage in accidents and production loss, CAPEX also increased. Thus, in this study, the most cost-effective design load was found using LCCA and compared with the load occurring once every 100 years. The design procedure for LCCA is shown in Figure 1.

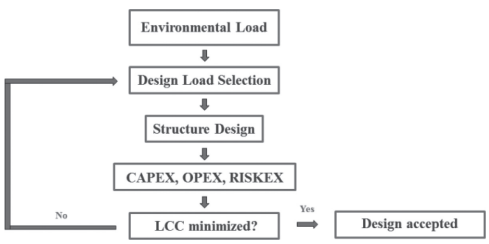

Figure 1. Design procedure for the LCCA.

Step 1: Estimation of external loads applied to mega-scale floaters

- Investigation of environmental conditions for the target site (Busan New Port)
- Estimation of environmental loads with the commercial codes (ANSYS-AQWA)

Step 2: Design Load Selection

- Considering extreme environmental conditions at the target site, using the Gumbel distribution (Type I), an extreme probabilistic model
- Nine return periods taken into consideration for the structure design: 30, 50, 100, 300, 500, 1 000, 3 000, 5 000 and 10 000 years
- Estimation of T-year return values for Significant Wave Height (SWH), wind, and current applied to the floater and selection of a design load for the structure design.

Step 3: Structure design

- Determination of initial dimension for the supporting structures including guide piles and truss structures
- Considering the weight optimization for reducing material costs of the PGS with two commercial codes (ABAQUS, PIANO).

Step 4: Estimation of LCC (including CAPEX and RISKEX)

- Calculation of CAPEX based on material costs of the PGS
- Estimation of RISKEX which included costs of failed components, rental fee of an offshore crane vessel, and production loss during repair-time was also taken into account for LCCA, using the safety philosophy of the PGS.

Step 5: Iteration for minimized LCC

- Repetition of this design procedure and LCC estimation to find minimized LCC and optimized design load.

3 CASE STUDY: PGS IN BUSAN NEW PORT

3.1 *Backgrounds of case study*

Because oceans have continued to provide sites for energy development and utilization, mega-scale floaters have been playing a critical role in energy sectors. Without doubt, their role will continue to increase in the future. Thus, many technologies have been developed to maintain the position of offshore installation. In this case study, PGS, a position keeping solution for mega-scale floaters, was taken into consideration.

3.1.1 *Pile Guide System*

The PGS, shown in Figure 2 is a type of supporting structure for offshore installations such as jacket structures and gravity based structures. Multiple piles are mounted and connected with a seabed base platform, which is fixed to the seabed rock layer with fixing piles. Connection parts between the floater and the guide pile are specially designed to allow the floating giant vessel to have vertical motions only in accordance with the water level. Seabed truss structures are able to prevent the guide piles moving horizontally due to environmental loads applied to the floater.

3.1.2 *Busan New Port (target port)*

Busan New Port in the Republic of Korea is selected as the target site for this case study. Busan Port Authority (BPA) has a plan to make Busan New Port an international logistics center port of Northeast Asia. In accordance with the technical report (J.W. Lee et al. 2009), many offshore installations will be taken into consideration for the shipping infrastructure near the Busan New Port.

3.2 *Step 1: Estimation of external loads applied to mega-scale floaters*

To estimate extreme weather conditions such as wind, Significant Wave Height (SWH) and current, as well as 3 extreme distribution functions (Type I Gumbel distribution function, Type II Frechet distribution function, and Type III Weibull distribution function) are generally employed. Of these extreme distribution functions, Gumbel distribution is used at this step because it can model maximum wind velocity and significant wave height and gives conservative values compared with other distribution functions.

3.2.1 *Maximum wind speed*

Eq. 1 is the cumulative Gumbel distribution function. Scale parameter, a, and location parameter, b, are characteristic values of Gumbel distribution function. They can be calculated by the mean value (23.0955 m/s) and standard deviation (3.3985 m/s) of the maximum instantaneous wind speed, extracted from the numerical weather data for 50 years at the target site. (Lee, B.H. et al. 2010)

$$F(V) = \exp[-\exp^{-Y}],\ Y = a(V-b)$$
$$a = \frac{1}{0.78\sigma}, \qquad b = \mu - 0.45\sigma \tag{1}$$

If it is assumed that the maximum instantaneous wind speed follows the Gumbel distribution, the relation between return period (T) and the cumulative distribution function can be expressed by Eq. 2. Using Eq. 1 and Eq. 2, Eq. 3 is induced to calculate extreme environmental conditions at the target site. (Lee, B.H. et al. 2010)

$$F(V) = 1 - \frac{1}{T} \tag{2}$$

$$V(T) = -\frac{1}{\alpha}\ln\left[\ln\left(\frac{T}{T-1}\right)\right] + b \tag{3}$$

3.2.2 *SWH (Significant Wave Height)*

In terms of the wave, accumulation data are insufficient because a buoy, which is able to measure wave height, has recently been installed near Busan New Port. Change in wind speed can affect the SWH because wind speed and SWH have a strong correlation. Thus, the interaction formula between fully developed SWH and wind speed is expressed as Eq. 4 (J.S. Park et al. 2013).

$$SWH = 0.0246 \times (wind\ velocity)^2 \tag{4}$$

3.2.3 *Current*

Current is divided into two types: wind current and tide current. In terms of current affected by wind, 1% of wind velocity was assumed (K.S. Choi 2013). Thus, the velocity of wind current is not significant at approximately 0.5 m/s. The wind current is at a maximum at sea level and decreases linearly to the seabed. On the target site, Busan New Port, the tide current is more considerable than the wind current. According to records at the buoy near the target site, the maximum velocity of the tide current is 1.869 m/s.

The extreme environmental conditions (wind, current, and SWH) at Busan New Port are shown in Table 1.

3.3 *Step 2: Design load selection*

Extreme environmental loads applied to the PGS are estimated using a commercial code, ANSYS AQWA. In this paper, the detail procedure of

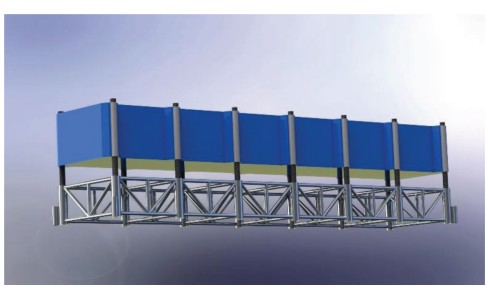

Figure 2. Three-dimensional drawing of pile guide system.

Table 1. Extreme environmental conditions at the target site.

Return period (years)	Wind (m/s)	Current (m/s)	SWH (m)
30	30.5	1.869	2.03
50	31.9	1.869	2.30
100	33.8	1.869	2.70
300	36.7	1.869	3.39
500	38.0	1.869	3.74
1 000	39.9	1.869	4.24
3 000	42.8	1.869	5.09
5 000	44.1	1.869	5.52
10 000	46.0	1.869	6.12

AQWA is ignored. The calculated external loads, occurring once in 30, 50, 100, 300, 500, 1 000, 3 000, 5 000 and 10 000 years, are shown in Table 2. This study are considered the environmental loads applied to the floater, not including seabed truss structures. As a future study, the current load applied to the seabed structures should be taken into account for the structure design.

3.4 *Step 3: Structure design*

At the structure design step, the dimensions of guide piles and seabed truss structures are determined to withstand the selected design load. Commercial codes, ABAQUS and PIANO, are used to conduct optimization, of which the objective function is to reduce the total weight of the PGS structures. Through sensitivity analysis, some design variables are selected. The ABAQUS model for the structure design is shown in Figure 3 and the dimensions of guide piles and truss structures against each design load are shown in Table 3.

3.5 *Step 4: Estimation of LCC (Life Cycle Cost including CAPEX & RISKEX)*

LCCA is performed to determine the design load of the PGS structure. CAPEX and RISKEX are taken into consideration for LCCA. OPEX can be negligible compared with CAPEX and RISKEX because it only included regular maintenance costs in terms of a structural design (D.J. Chang & G.P. Chang 2013). Some assumptions are needed to conduct the LCCA because it is difficult to exactly determine the extent of structure damage.

The CAPEX is the initial investment costs which include material cost, fabrication cost, and installation cost. ASTM A135 steel is employed for piles and truss structures. Price of ASTM A135 is approximately 780 $/ton. Using the dimensions of piles and truss structures, material costs could be calculated. To estimate the CAPEX of the whole structures, it was assumed that the material costs are 38.8% of the CAPEX.

This study assumed that the PGS structure can be used for a LNG bunkering terminal in the near future. The RISKEX consists of replacement costs of 4–6 guide piles, rental fee of offshore crane vessels, and suspension of LNG sales during the repairing time. LNG price is approximately 10 $/MMBTU which is corresponding to

Table 2. Extreme loads applied to the PGS.

Return period (years)	Force/moment				
	X (ton)	Y (ton)	RX (ton·m)	RY (ton·m)	RZ (ton·m)
30	1 590	7 494	163 041	785 613	330 477
50	1 711	7 906	184 578	909 588	375 409
100	2 058	9 135	209 314	1 098 637	434 992

1 000	3 206	15 162	346 916	1 725 239	685 517
3 000	3 955	18 925	426 936	1 974 549	835 338
5 000	4 291	20 864	466 981	2 139 240	905 159
10 000	4 768	23 688	524 545	2 492 259	1 005 146

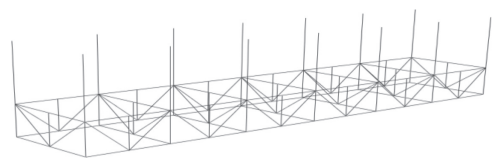

Figure 3. ABAQUS model for the truss structure design.

Table 3. Dimension of guide pile & truss against each design load.

Return period (years)	Diameter		
	Guide pile (m)	Truss X (m)	Truss Y (m)
30	2 535	1 444	1 698
50	2 599	1 480	1 741
100	2 805	1 597	1 879
300	3 132	1 784	2 098
500	3 324	1 893	2 227
1 000	3 598	2 049	2 411
3 000	4 065	2 315	2 724
5 000	4 295	2 446	2 878
10 000	4 626	2 635	3 099

234 $/$m^3$. The following assumptions are considered for the RISKEX:

- Intentionally failed components, guide piles, of which it is easy to conduct maintenance and replacement, are considered. 4–6 guide piles failed only when the loads exceeded the design load due to the yaw motions of the floater.
- Rental fee of an offshore crane vessel for replacement of the guide-piles failed: 100 000 $/day
- Lifespan of the PGS structure: 50 years
- Suspension of LNG sales (Production loss): 10% of the amount of LNG sold per day (LNG sales: 53 700 m^3/day) (S.T. Yun 2012)

3.6 *Step 5: Iteration for minimized LCC*

At the last step, iterations are performed to find the minimized LCC. Nine design loads, which are estimated at the step 2, are taken into consideration to conduct the structure design and to estimate the LCC of the PGS. Finally, the most cost-effective design load for the PGS is determined.

4 RESULTS AND DISCUSSION: DETERMINATION OF DESIGN LOAD

In this study, nine extreme environmental loads are taken into account for the design of the PGS structure and compared with the original design load occurring once in 100 years. The LCC for the nine design loads are shown on Figure 4 as a blue line. When the strength of the PGS structure is increased, the CAPEX also increases. The increasing trend of the CAPEX is very similar to that of extreme design loads. On the other hand, the RISKEX decreased when the design load for the PGS increased. RISKEX initially declined rapidly, but later decreased slowly. Nine return periods considered in this paper are enough to find minimized LCC because the tendency of CAPEX to increase is greater than that of the RISKEX to decrease with the design load occurring once in 300 years, and the difference between 300 years LCC and 500 years

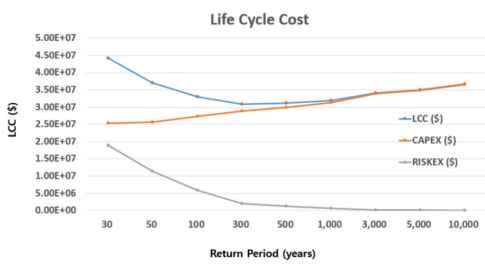

Figure 4. Life Cycle Cost for the nine design loads.

LCC are not significant. Thus, using a smaller interval of return periods might be unnecessary. As a result, preparation for the environmental loads, occurring once in 300 years, is the most economical for the structure design of the PGS at the target site, even though CAPEX of the structure increases.

LCCA for the design load selection of offshore structures has many uncertainty factors because it is conducted at the early design stage in which specific information of the structure is unavailable. Another uncertainty factor is that material cost, rental fee, and production loss during the repair time (which are taken into consideration to estimate the LCC), might be changed in real time. Subdivided levels of the consequence are also required for exactly estimating RISKEX. Some assumptions are needed to calculate structure availability and to estimate CAPEX and RISKEX. Thus, an uncertainty study and sensitivity analysis are required to verify the most sensitive variable in this design load selection procedure.

5 CONCLUSION

A methodology for the determination of design load was taken into account. The PGS was considered and Busan New Port was selected as a target site for the case study. Gumbel distribution was employed to estimate extreme environmental conditions and ANSYS AWQA was used to calculate extreme environmental loads. Nine return periods (30, 50, 100, 300, 500, 1 000, 3 000, 5 000 and 10 000 years) of extreme environmental loads were considered for the PGS structure design. For LCCA, CAPEX was estimated based on material costs and RISKEX, while the costs of failed components, the rental fee of an offshore crane vessel, and production loss were also taken into account.

This study was performed only for the case in which the PGS was installed near Busan New Port. The considerable design load could be changed depending on the types of structures, various types of target sites, and environmental conditions. However, the proposed procedure of design load selection would be meaningful and applicable to design of a newly developed offshore structure.

In this study, only environmental loads such as wave, wind, and current were taken into consideration for estimation of the external loads applied to the PGS. Considering other types of environmental loads and accidental loads such as mooring loads and ship collisions would be required.

Analysis of reliability and retaining levels of safety barriers

K. Jung & J. Marková
Klokner Institute, Czech Technical University in Prague, Czech Republic

ABSTRACT: Retention levels of road safety barriers are specified on the basis of risk assessment taking into account accidental data and further information available in the Czech Republic and also selected recommendations of Road Safety Association PIARC. The method of Bayesian networks is applied in the analysis and compared with event tree method. Newly proposed classes of retention for several categories of road surroundings considering the intensity of heavy traffic and two levels of hazard situation are incorporated to the revision of national prescriptive document that is expected to enhance the road safety.

1 INTRODUCTION

Thousands of human lives are annually lost on European roads. Therefore, the authorities in most countries are concerned about the numbers of people killed and injured, leading to enormous social and economic costs. In the Czech Republic, more than 85 people per one million inhabitants lose their life annually. It means that on the average 897 people was killed per year in the last ten years. It should be noted that the number of fatalities are below the mean in the last 5 years. Protective measures have significant influence on reduction of consequences of car accidents. Various national or European prescriptive documents give basic guidance for their application.

Road safety barriers provide protection of traffic on roads as well as their close surroundings. Various aspects have to be considered for selection of appropriate types of safety barrier including road categories, surface characteristics, road surroundings, allowable velocity of cars, types of danger places in road surroundings and traffic intensity including expected future trends. For selection of appropriate safety measures, the retention level for road barriers has to be determined considering danger sections of roads and protection of road surroundings.

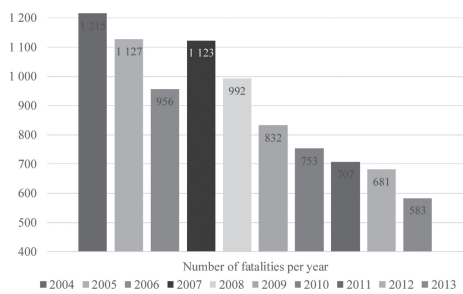

Figure 1. Number of fatalities per year in the Czech Republic.

Presented study is focused on optimization of retention level of safety barriers taking into account accident data recorded in the Czech Republic in the last few years. Results of analyses and further information are expected to be used as background materials for revision of the Czech technical conditions TP 114 (2010).

2 RISK ANALYSIS

The Bayesian network is applied for analysis of retention level of safety barriers facilitating to describe various accidental scenarios, and also for verification of event tree method used in previous studies (Markova & Jung, 2006). Individual risk R_i is given as

$$R_i = p_i \times C_i \tag{1}$$

where p_i is the probability of occurrence of accident i and C_i its expected consequence. The total risk R is specified as a sum of all considered risks given as

$$R = \sum_i p_i \times C_i \tag{2}$$

Five types of vehicles are considered in analyses:

– Heavy Goods Vehicles (HGV),
– Danger Goods Vehicles (DGV),
– buses,

– cars,
– motorcycles.

The traffic composition is based on traffic data provided by the Road and Motorway Directorate of the Czech Republic.

The number of accidents n_{veh} for considered type of vehicles per one year is expressed as

$$n_{veh} = N \times L \times p_{veh} \times p_a \tag{3}$$

where N is the intensity of all vehicles on the road, L is the length of considered road section, p_{veh} is the ratio between the number of relevant type of vehicles to total number of all vehicles in the road, p_a is the annual probability of accident occurrence for the type of vehicle.

For the analysis of retention level of safety barriers, the data of accidents are available, recorded in electronic version in the last few years. Different causes of car impacts are distinguished including impacts to bridge columns, safety barriers, walls, buildings, car collisions etc. Three types of roads are considered: motorways and 1st and 2nd class roads (country national and main roads). Figure 2 and Figure 3 indicate that the main risk with respect to the obstacles near roads is associated with impact to trees, bridge piers and walls.

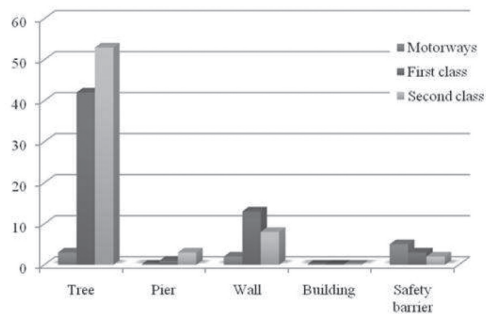

Figure 2. Number of fatalities for motorways and 1st and 2nd class roads in the Czech Republic (year 2007).

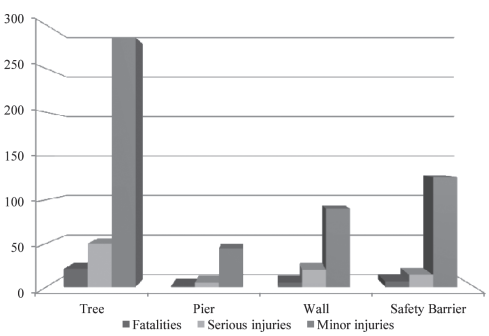

Figure 3. Number of fatalities and injuries for 1st class roads in the Czech Republic (year 2011).

3 CONSEQUENCES

Social, economic and ecological consequences should be considered in accidental situations due to car collisions. Social consequences are the most significant in this consideration as human lives are endangered during accidents.

Consequences of car accidents and probabilities of serious injuries or fatalities are based on comparison of the kinetic energy E_k of considered type of vehicle and the capacity of safety barriers. The kinetic energy of impacting vehicle is given as

$$E_k = \frac{1}{2} m \times (v \times \sin\alpha)^2 \tag{4}$$

where m is the vehicle mass, v its velocity and α a direction angel of impact. The maximum permitted velocities for vehicles in relevant types of roads are considered in the analyses.

It is assumed that the structure reacts rigid plastics, then the maximum displacement follows from

$$\frac{1}{2} m \times \varepsilon \times (v \times \sin\alpha)^2 = F_c \times u_d \tag{5}$$

where F_c is the static force and u_d deformation of the structure at fracture. Failure occurs if u_d exceeds the deformation capacity of the barrier which depends on materials properties. A perfectly elastic collision has a coefficient of restitution of $\varepsilon = 1$. Typical collision has coefficient of restitution ε between 0,55 and 0,8 (Coon & Reid, 2006). It is clear that barriers made of materials with higher deformation capacity could provide better protection and due to less force lower danger for passenger.

The capacities of safety barriers for several levels of retention N1 to H4b are given in Table 1 according to standard EN 1317-1 and national prescriptive document TP 114.

The total risk R may be determined from formula

$$R = 1000 \times C_s \times L + \sum p_{f,n} \times C_n + \sum p_{f,en} \times C_{en} \tag{6}$$

Table 1. Capacity of safety barriers E_k [kNm].

Type	N1	N2	H1	H2	H3	H4a	H4b
E_k	43,3	82,9	126,6	287,5	426,1	527	724,6

where C_s are the costs of getting the safety barriers, L is the length of road section, $p_{f,n}$ is the probability of human fatalities of injuries, C_n are relevant social costs, $p_{f,en}$ is the probability of accident occurrence for different types of vehicles, C_{en} are economical or ecological loses due to accident, expressed in monetary units.

The main risk is connected with lose of human lives. The costs of a human life or an injury applied in presented analysis are based on information of the Transport Research Center (www.cdv.cz). Economical lose for one fatality is considered here as 333 000 EUR, for serious injury as 112 000 EUR and minor injury as 12 500 EUR.

It should be noted that these values seem to be rather low. Each fatality prevented on British roads represents an approximate overall saving of £1,3 m and each serious injury prevented represents a saving of £150,000 (Farmer 2004). These analyses are based on economic as well as social and environmental factors including loss of earnings, costs of hospital treatment and other social costs. The value of preventing the road traffic accident may be estimated on the basis of cost-benefit analysis, see e.g. recently revised ISO/CD 2394 (2014).

Other possibility to describe loses due to accidents may be also described by ICAF (Implied Cost of Averting a Fatality) given as

$$\mathrm{ICAF} = g \times e \times (1\text{-}w) / (4 \times w) \tag{7}$$

where g is the gross domestic product per person per year [€/year], e is the life expectancy at birth [year] and w is the proportion of life spent in economic activity (Diamantidis 2002).

4 RISK ASSESSMENT

The presented study is focused on the determination of retention level of safety barriers taking into account accident data recorded in the Czech Republic in the last few years. The aim is to provide backgrounds for selection of safety barriers.

Accidents involving impact from vehicles can be caused by many factors and include many consequences.

Main parameters affecting accidents are

- Speed, mass and direction of impacting road vehicle
- Rigidity and construction of the structural elements of barriers
- Roads layout and geometry (curves, slope)
- Usage of roads surrounding at time of the incident.

Main parameters affecting accidents which are not covered in this analysis include

- Act of sabotage
- Human failure.

The study is based on minimization of risks. The retention level H1 corresponds to kinetic energy E_k = 126,6 kNm (see Table 1). Lower and higher retention level increases the risk. Selection of lower retention level increases risks as the protection could not be sufficient. Selection of higher retention level increases risks for passengers in cars, while the surrounding is more protected.

5 BAYESIAN NETWORK

A Bayesian network was developed for verification and comparison of achieved result by event tree method. The network was developed in program Genie and contains 5 random nodes, 5 utility nodes, and 2 decision nodes.

5.1 *Decision nodes*

There are two decision nodes in the presented study—the *Intensity of traffic* and the proposed type of the road *Safety barriers*. The decision node "*Intensity of traffic*" has three states.

- Small intensity
- Medium intensity
- High intensity.

The decision node "*Type of safety barriers*" has eight states, first state "No barriers" is unprotected surrounding. Other seven states cover classes of

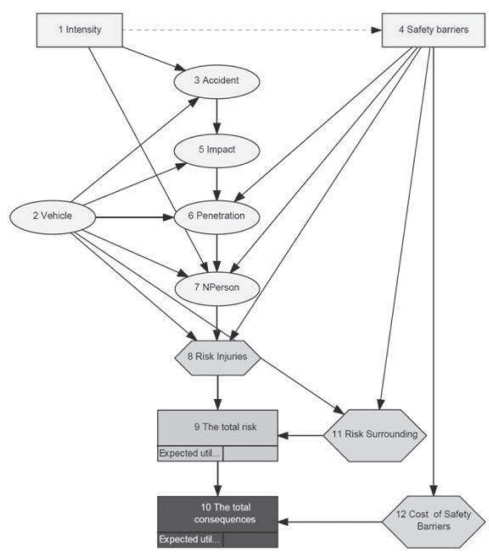

Figure 4. Bayesian Network used for analysis of safety barriers.

the retention capacity of safety barriers. The levels are given in Table 1 according to the standard EN 1317-1. The eighth state is for surrounding without need of protection. No barriers could be accepted only in places not covered by surrounding considered here and where are sufficient and safe leaving zones.

5.2 *Utility/Value node*

A utility node represents an additive contribution to the utility function in an influence diagram. Thus, the utility function is the sum of all utility nodes in the influence diagram. *Cost of Safety Barriers*—this node describes the cost of new safety barriers. The cost is based on the price per 1 kilometre. The utility nodes represent the economic factors and adverse consequences.

A more detailed description of the nodes is provided in the following list, which also indicates difficulties in input data specification.

The utility nodes describe risks due to economic and environmental lose on surroundings considered as:

- Cost of Safety Barriers,
- Risk Surrounding,
- Risk Injuries,
- The Total Risk,
- The Total Consequence.

The Total Risk is a sum of all risks for each type of safety barriers. The Total Consequence is a sum of all Risk, Consequences and Costs of Safety Barriers.

5.3 *Random nodes*

These nodes describe randomness in the proposed analysis. There are five random nodes

- Collisions
- Impact
- Penetration
- Vehicles
- NPersons.

5.3.1 *Node "Accident"*

Node "Accident" describes probability of a collision per one year and one kilometer of road. Following

Tables 2 to 4 show probabilities for three intensities.

5.3.2 *Node "Impact"*

Random node "*Impact*" describes the probability of vehicle collision with safety barriers. The records in the Czech Republic show that about 60% of all accidents on motorways results from impact into safety barriers".

Table 2. Probability of collision per 1 kilometer and 1 year—small intensity.

	HGV	DGV	Car	Bus	Motorbike
NoCollision	0,983	0,999	0,952	0,997	0,993
Collision	0,017	0,001	0,048	0,003	0,007

Table 3. Probability of collision per 1 kilometer and 1 year—medium intensity.

	HGV	DGV	Car	Bus	Motorbike
NoCollision	0,900	0,999	0,723	0,979	0,960
Collision	0,100	0,001	0,277	0,021	0,040

Table 4. Probability of collision per 1 kilometer and 1 year—high intensity.

	HGV	DGV	Car	Bus	Motorbike
NoCollision	0,730	0,998	0,255	0,946	0,891
Collision	0,270	0,002	0,745	0,055	0,110

5.3.3 *Node "Penetration"*

The impacting vehicle either crosses the barrier into opposite carriageway or surrounding, rebounds back into the original carriageway, or remains on, or close to the barrier. Random node "*Penetration*" describes the probability of penetration into surrounding. Williams (2007) shows that about 7% of all accidents involved in impacting a safety barrier crosses through into surrounding.

Further these probabilities are affected by containment level of safety barriers and the type of vehicle.

Probability that the safety barriers for each retention capacity and vehicle type might be overcome should be estimated. Number of endangered passengers is described by probability for each type of vehicle and each type of barriers.

5.3.4 *Node "NPersons"*

Node "*NPerson*" describes the number of endangered persons for each type of vehicle.

This node has six states (No Person, N1, N2, N5, N10 and N25).

5.3.5 *Probability of impact into barriers*

It is estimated for different speed categories and types of vehicles.

The main parameters describing the kinematics of vehicle are the velocity and angle. Data concerning velocity are not available. The direction angle α varies from 0 to 30° or 40°; Raleigh distribution could be used for with a mean equal to 10–15° for tg α.

Table 5. Definition of scenarios and extent for vehicles.

Scenarios	S_{z1}	S_{z2}	S_{z3}	S_{z4}	S_{z5}	S_{z6}
Impact	Yes	Yes	Yes	No	No	No
Penetration	Yes	Yes	No	No	–	–
Secondary condition	Yes	No	Yes	No	Yes	No

5.3.6 *Probability of barriers penetration*

These probabilities are estimated in accordance with the permitted speed and type of vehicle. In case of safety barriers it is supposed that the structure is elastic and the colliding object is rigid. In accordance with EN 1317 it is assumed that the structure is designed to absorb the impact energy by plastic deformations, it must be ensured that its ductility is sufficient to absorb the total kinetic energy of the colliding object. In the limit case of rigid-plastic response of the structure, the above requirement is satisfied where F is the plastic strength of the structure, i.e. the quasi-static limit value of the force F; y_o is the displacement of the point of impact that the structure can undergo.

5.3.7 *Probability of secondary collision*

These probabilities are affected by the intensity of traffic and maximal speed. When the barriers are overcome, the secondary collision means collisions with vehicle going in opposite direction. In case the barriers are not overcome, the secondary collision is rear or side collision with vehicle in some direction. It is supposed that the consequences of secondary condition are lower than the collision with vehicle going in opposite direction.

This is due to the lower number of rear impact leads to serious casualties than frontal casualties and due to less structural possibilities may influence the outcome of a rear impact.

6 RESULTS FOR SELECTED EXAMPLES

6.1 *Drinking water resources*

Total intensity is 33 305 vehicles per day based on statistics of the year 2010.

Maximal allowed speed is 130 km/h for cars and motorbikes, 80 km/h for HGV and DGV and 100 km/h for buses.

The graph in Figure 5 shows results of risk analysis for drinking water resources, when as optimal decision is selected Safety barriers with retention level H4b which corresponds to $E_k = 724{,}6$ kNm.

6.2 *Central barriers*

This example is focused on analysis of the Central barriers on the highways, where the maximal allowed speed is 130 km/h for cars and motorbikes, 80 km/h for HGV and DGV and 100 km/h for buses.

Total intensity is 73 397 vehicles per day based on statistics from the year 2010.

In this case the optimal protection represent barriers with retention level H3 corresponding to $E_k = 426{,}1$ kNm as it is shown in the following Figure 6.

Table 6. Proportion of vehicles.

Type of vehicles	Number	Ratio
HGV	8748	30,78%
DGV	67	0,20%
Buses	373	1,12%
Cars	24023	72,13%
Motorbike	94	0,28%

Table 7. Proportion of vehicles.

Type of vehicles	Number	Ratio
HGV	14410	19,63%
DGV	147	0,20%
Buses	451	0,85%
Cars	6220	79,05%
Motorcycles	45	0,27%

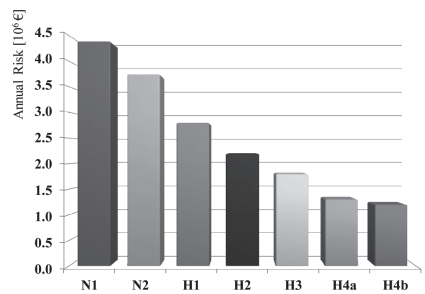

Figure 5. Results of the analysis based on Bayesian network.

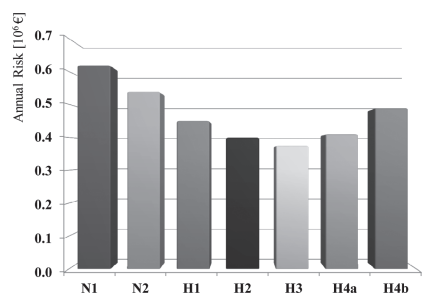

Figure 6. Results of the analysis based on Bayesian network.

7 RECOMMENDED RETENTION LEVEL OF SAFETY BARRIERS

Proposal for retention level of safety barriers was prepared in co-operation with Czech authorities taking into account results of risk assessment, see Tables 8 and 9. Several classes of dangerous surroundings, intensity of heavy vehicles and two hazard levels (common and higher level) are considered.

Proposal for retention levels of safety barriers on roads is shown in Table 8. In case the higher hazard level needs to be considered in specific accidental situation, the level of retention should be increased.

Table 8. Recommended retention levels of safety barriers on roads in common hazard rate.

	Mean value of heavy vehicles per 24 hours		
Class Surrounding	<1000	1000–5000	>5000
1. Drinking water resources	H2	H2	H3
2. Railways	H1	H2	H2
3. Place with high frequency of pedestrians	H1	H2	H2
4. Buildings	H1	H1	H2
5. Central barriers	H1	H1	H2
6. Parallel roads	H1	H1	H2
7. Roads in different level	H1	H1	H2
8. Rivers or water reservoirs	N2	H1	H2
9. Scarps, embankments	N2	H1	H1
10. Other danger places (trees, portals)	N2	H1	H1
11. Noise barriers	N2	N2	N2

Table 9. Recommended retention levels of safety barriers on bridges in common hazard level.

	Mean value of heavy vehicles per 24 hours		
Class Surrounding	<1000	1000–5000	>5000
1. Drinking water resources	H2	H2	H3
2. Railways	H2	H2	H2
3. Places with high frequency of pedestrians	H1	H2	H2
4. Buildings	H1	H2	H2
5. Rivers or water reservoirs	H1	H1	H2
6. Parallel or crossing roads	H1	H1	H2
7. Central barriers	H1	H1	H2
8. Other danger places, portals	H1	H1	H2

Similar Table 9 was proposed for retention levels of safety barriers on bridges taking into account eight classes of surroundings.

8 CONCLUSIONS

Risk assessment based on accidental data for motorways and main roads facilitates to propose new retention levels of safety barriers to the revision of national prescriptive document TP 114.

Several classes of road environment are updated or refined. For decision on the retention levels of safety barriers several significant basic variables are identified including the daily average intensity of heavy vehicles, maximal permitted car velocities and the level of potential risk.

The retention level is analysed by event Bayesian network taking into account the road category, heavy car intensity and various types of road or bridge surroundings. The higher intensity of heavy goods vehicles increases the probability of accident and usually increases the needs for higher retention level of safety barriers. Therefore, for the passenger cars or motorbikes, it leads to significant risk increase.

Analyses of data indicate in some cases discrepancies on reported accidents including location of accidents, impacted safety barriers (central or lateral barriers) and description of consequences.

Many questions and uncertainties remain still open also in the risk analysis of road safety barriers. The behaviour of the barriers made from different materials should be analysed in more detail. Wire-rope barriers represent a special problem. Are the wire-rope barriers dangerous for motorcyclist and could they endanger a convertible car? Is it acceptable to use on our roads the safety barriers which could protect one type of passengers however be danger for other passengers?

It should be noted here that implementation of safety measures is a complex process involving official authorities, designers, road maintenance service, producers of safety barriers, testing institutions etc. It is expected that newly proposed provisions for retention levels will facilitate the selection of appropriate types of safety barriers.

Safe reliability assessment through probabilistic constraint reasoning

Elsa Carvalho, Jorge Cruz & Pedro Barahona
Centro de Inteligência Artificial, Universidade Nova de Lisboa, Portugal

ABSTRACT: Reliability quantifies the ability of a system to perform its required function under variable conditions. The adequate functioning of a system is often represented by inequality constraints, and its reliability is the probability that such constraints are satisfied, given the uncertainty the variables are subject to. Since this computation is very hard, namely when the systems are modeled with nonlinear constraints, traditional methods adopt a number of approximations, thus computing a value that may be far from the exact one. Moreover, these methods do not provide any guarantees regarding the correctness of the computed results. In this paper, we use the probabilistic continuous constraints framework to efficiently compute safe bounds for the reliability of a system, and illustrate it on a number of representative examples.

1 INTRODUCTION

Reliability analysis studies the ability of a system to perform its required function under variable conditions. In this context, reliability assessment quantifies the chance of system failure at any stage of a system's life. This research area has a wide range of applications, including the aeronautical (Nikolaidis, Ghiocel, & Singhal 2007), chemical (Goel, Grievink, Herder, & Weijnen 2002) and building (Huang, Chan, & Lou 2012) industries.

Reliability is reported in terms of the probability of adequate functioning of a system and its exact quantification requires the calculation of a multi-dimensional integral with a nonlinear integration boundary. Because there is rarely a close-form solution, this calculation is one of the major concerns of classical approaches to solve reliability problems, which adopt approximation methods that rely on several simplifications of the original problem to compute a reliability estimate, often leading to inaccurate results, especially in highly nonlinear problems.

When choosing among several alternative configurations of a system it is important to obtain safe bounds for their reliability, since designs with a high reliability estimate but high uncertainty on such estimation are not credible options. Such safe bounds are not available with classical approaches, but they can be provided by the Probabilistic Continuous Constraint framework that we have been developing to integrate probabilities and constraint programming, and that has already been successfully applied to inverse problems (Carvalho, Cruz, & Barahona 2013).

The paper is organized as follows. Section 2 briefly introduces the concepts of reliability assessment and describes classical techniques, such as FORM (Hohenbichler & Rackwitz 1983), SORM (Fiessler, Neumann, & Rackwitz 1979), and Monte Carlo simulation (Halder & Mahadevan 1999), used to address such problem, discussing their limitations. In sections 3 and 4 we introduce our Probabilistic Continuous Constraint approach, discussing the features that are required toaddress reliability assessment. Section 5 illustrates our framework on a set of representative examples, comparing it with traditional methods, highlighting the importance of the safe bounds we efficiently obtain. The last sectionsummarizes the main conclusions and directions for future work.

2 RELIABILITY ASSESSMENT

A limit-state is a condition beyond which a system no longer fulfills the desired functionality. Reliability assessment calculates and predicts the probability of limit-state violations at any stage of a system's life.

The probability of occurrence of a limit-state violation in a system represents its probability of failure, P_f, whereas $P_s = 1 - P_f$ represents its reliability.

Failure events are represented as limit-state constraints g is a limit-state function and x is a realization of the random vector X (defined in Ω_X) that represents all the relevant uncertainties influencing the probability of failure and has joint Probability Density Function (PDF) f_X. Thus,

the failure event is $F = \{x \in \Omega_{\boldsymbol{X}} : g(x) < 0\}$ and the probability of failure is the probability of the failure event:

$$P_f = P(x \in F) = \int_{g(x)<0} f_{\boldsymbol{X}}(x)dx \tag{1}$$

More generally, we are interested in problems that can be defined by one or more limit-state functions. In series systems, global failure occurs when at least one limit-state functions is violated, whereas in parallel systems, it occurs when all limit-state functions are violated. So, the failure events for series and parallel systems with k limit-state functions, are, respectively:

$$F = \bigcup_{i=1}^{k} \{x \in \Omega_{\boldsymbol{X}} : g_i(x) < 0\} \qquad \text{and} \tag{2}$$

$$F = \bigcap_{i=1}^{k} \{x \in \Omega_{\boldsymbol{X}} : g_i(x) < 0\} \tag{3}$$

2.1 *Classical techniques*

Reliability assessment involves the calculation of a multi dimensional integral in a possibly highly nonlinear integration boundary (Equation (1)). Analytical computation of such integral is usually impossible, so various simulation-based and numerical methods have been proposed to deal with this problem.

In (Hasofer & Lind 1974), Hasofer and Lind introduced the reliability index technique for calculating approximations of the desired integral with reduced computation costs. The reliability index has been extensively used in the first and second order reliability methods (FORM (Hohenbichler & Rackwitz 1983) and SORM (Fiessler, Neumann, & Rackwitz 1979)).

The main idea is to move the reliability problem from the space of random vector $\boldsymbol{X}$ to the space of standard normal statistically independent random variables $\boldsymbol{U} = \langle U_1, \ldots, U_n \rangle$ using a suitable transformation $\boldsymbol{U} = T(X)$, such as Rosemblatt (Rosenblatt 1952) or Nataf (Nataf 1962) transformations (see (Hohenbichler & Rackwitz 1981, Melchers 1999) for an overview). In the $\boldsymbol{U}$ space, Equation (1) can be expressed as:

$$P_f = \int_{g(\boldsymbol{u})<0} f_{\boldsymbol{U}}(\boldsymbol{u})d\boldsymbol{u} = \prod_{i=1}^{n} \int_{g(u)<0} \phi_{U_i}(u_i)du_i$$

where ϕ_{U_i} is the standard normal PDF of U_i.

In FORM an approximation to the probability of failure is obtained by making the failure surface, $g(\boldsymbol{U}) = 0$, linear at the design point, $\boldsymbol{u}^*$, often called the Most Probable Point of failure (MPP). This is the point on the failure surface closest to the origin and with the highest probability (local maximum) in the failure domain of the standard normal space. The distance from the origin to the design point is the reliability index $\beta = \|\boldsymbol{u}^*\|$.

Since the standard normal space is rotational symmetric, probability of failure can be directly obtained using the reliability index, $P_f = \Phi(-\beta)$, where Φ is the standard normal cumulative probability function.

As the limit state function is in general nonlinear it is not possible to know the design point in advance and this has to be found iteratively. The design point is thus, the solution to the constrained optimization problem:

$$\beta = \min_{u \in \{g(u)=0\}} \|u\|$$

This problem, being the most expensive part of FORM algorithm, may be solved in a number of different ways (see (Eldred, Bichon, & Adams 2006) for an overview). An appropriate iteration scheme converges after some iterations, providing the design point $\boldsymbol{u}^*$ as well as the reliability index β, which may be related directly to the probability of failure. However, with non convex optimization problems, it is not guaranteed that the solution point will be the global minimum-distance point.

FORM usually works well when the failure surface has only one minimal distance point and the function is nearly linear in the MPP neighborhood. However, for increasingly nonlinear failure surface the probability of failure estimated by FORM becomes increasingly inaccurate (and possibly unreasonable) (Melchers 1999). To address such non linearity SORM incorporates some curvature in the limit state approximation through a parabolic approximation to the failure surface (Breitung 1984).

In both methods, it is assumed a single limit-state function with a single design point where only the region around such point contributes to the probability of failure. In limit-state functions with multiple design points (and in problems with multiple limit-state functions), application of FORM or SORM around a single design point results in erroneous estimates for the probability of failure. So, the problem of identifying the multiple design points was addressed by several authors (e.g. (Kiureghian & Dakessian 1998, Barranco-Cicilia, de Lima, & Sudati-Sagrilo 2009)).

In series systems, generally there exists one design point for each limit-state function (which contributes to the identification of the feasible region). In contrast, in parallel systems there usually exists one design point for each pairwise inter-

section of limit-state functions (again contributing to the identification of the unfeasible region).

Once all design points are identified, FORM or SORM approximations are constructed at these points and the failure probability is computed by series system reliability analysis (for multiple design points in a single limit-state function or series systems) or by parallel system reliability analysis (for parallel systems) (see (Sørensen 2004, Notes 6 and 7) for details).

Other techniques include sampling, based on Monte Carlo simulation (MCS) (Halder & Mahadevan 1999) and work well for small reliability requirements. Nevertheless, as the desired reliability increases, the number of samples must also increase to find at least one infeasible solution.

Since Monte Carlo method is basically a sampling process, the results are subjected to sampling error that decreases with the sample size. However, using procedures known as variance reduction techniques the error may be reduced without significantly increasing the sample size. One of such procedures with a high convergence rate is the Monte Carlo with Importance Sampling (MCIS) (Melchers 1999). In MCIS, the regions of interest for the simulation process are those around the points in the failure domain having the largest values, i.e., the design points.

Given the simplifications adopted and their approximate nature, none of the above methods provides guarantees on the reliability values computed, specially for nonlinear problems. In contrast, the Probabilistic Continuous Constraint framework does not suffer from this limitation, guaranteeing safe bounds for the probability of failure.

3 CONTINUOUS CONSTRAINT PROGRAMMING

Continuous constraint programming has been widely used to model safe reasoning in applications where uncertainty arises. A Continuous Constraint Satisfaction Problem (CCSP) (Lhomme 1993, Benhamou, McAllester, & van Hentenryck 1994, Sam-Haroud & Faltings 1996) is a triple $\langle X, D, C \rangle$ where X is a tuple of n real variables $\langle x_1, \ldots, x_n \rangle$, D is a Cartesian productof intervals $I_1 \times \ldots \times I_n$ (a box), where each I_i is the domain of variable x_i and C is a set of numerical constraints (equations or inequalities) on subsets of the variables in X. A solution of the CCSP is a value assignment toall variables satisfying all the constraints in C. The feasible space $\mathcal{F}$ is the set of all CCSP solutions within D.

Constraint reasoning relies on branch-and-prune algorithms to obtain sets of boxes that cover exact solutions for the constraints (the feasible space). These algorithms begin with an initial crude cover of the feasible space (the initial search space, D) which is recursively refined by interleaving pruning and branching steps until a stopping criterion is satisfied. The branching step splits a box from the covering into sub-boxes (usually two). The pruning step either eliminates a box from the covering or reduces it into a smaller (or equal) box maintaining all the exact solutions. Pruning is achieved through a constraint propagation algorithm ($\mathcal{CPA}$) which combines constraint propagation and consistency techniques (Benhamou, Goualard, Granvilliers, & Puget 1999) based on interval analysis methods (Moore 1966).

Interval analysis is an extension of real analysis that allows computations with intervals of reals instead of reals. Common operations and unary functions are extended for interval operands. For instance, [1,2] + [3,6] results in the interval [4,8], which encloses all the results from a point-wise evaluation of the real arithmetic operator on all the values of the operands. In practice these extensions simply consider the bounds of the operands to compute the bounds of the result, since the involved operations are monotonic.

Interval extensions [f], allow computing enclosures of the range of real functions f, over boxes. The natural interval extension of a function is obtained by evaluating its expression for interval arguments using interval arithmetic.

The branch-and-prune algorithm usually maintains two coverings of the feasible space $\mathcal{F}$ of a CCSP $\langle X, D, C \rangle$: one outer and one inner box cover, as follows.

Outer Box Cover A set of almost disjoint boxes[1] $\mathcal{F}_{\square} = \{B_1, \ldots, B_n\}$, where $\forall_{1 \le i \le n} (B_i \subseteq D \wedge vol(B_i) > 0)$, is an outer box cover of $\mathcal{F}$ iff $\mathcal{F} \subseteq \bigcup_{i=1}^{n} B_i$.

A complementary concept is that of inner box cover, where an inner box of a CCSP is a box totally contained in the feasible space.

Inner Box A box $B \subseteq D$ with $vol(B) > 0$ is an inner box of $\mathcal{F}$ iff $B \subseteq \mathcal{F}$.

Inner Box Cover A set of almost disjoint boxes $\mathcal{F}_{\blacksquare} = \{B_1, \ldots, B_n\}$ is an inner box cover of $\mathcal{F}$ iff $\bigcup_{i=1}^{n} B_i \subseteq \mathcal{F}$.

We are particularly interested in maintaining an inner box cover that is a subset of the outer box cover.

[1]Two boxes B_1 and B_2 are almost disjoint iff $vol(B_1 \cap B_2) = 0$. The volume of a box $B \subseteq \mathbb{R}^n$ is the product of the width of its intervals, i.e., $vol(B) = wid(I_1) \times \ldots \times wid(I_n)$.

Joint Box Cover A joint box cover $\mathcal{F}_{\boxplus}$ of $\mathcal{F}$ is a pair $\langle \mathcal{F}_{\square}, \mathcal{F}_{\blacksquare} \rangle$, with $\mathcal{F}_{\blacksquare} \subseteq \mathcal{F}_{\square}$.

Often it is important to know whether a joint box cover represents the feasible space more accurately than another. For this purpose we define a partial order ($\preceq$) as follows.

Tighter Joint Box Cover Given a CCSP $\langle X, D, C \rangle$ and two joint box covers of $\mathcal{F}$, $\mathcal{F}_{\boxplus 1} = \langle \mathcal{F}_{\square 1}, \mathcal{F}_{\blacksquare 1} \rangle$ and $\mathcal{F}_{\boxplus 2} = \langle \mathcal{F}_{\square 2}, \mathcal{F}_{\blacksquare 2} \rangle$, $\mathcal{F}_{\boxplus 2}$ is a tighter joint box cover of $\mathcal{F}$ than $\mathcal{F}_{\boxplus 1}$, (written $\mathcal{F}_{\boxplus 2} \preceq \mathcal{F}_{\boxplus 1}$) iff:

$$\bigcup \mathcal{F}_{\square 1} \supseteq \bigcup \mathcal{F}_{\square 2} \text{ and } \bigcup \mathcal{F}_{\blacksquare 1} \subseteq \bigcup \mathcal{F}_{\blacksquare 2}$$

The branch-and-prune algorithm *B & P* (Algorithm 1, similar to (Granvilliers & Benhamou 2006)) receives a joint box cover and computes a tighter one. For that purpose, and while the stoping criterion is not satified, the algorithm removes a box from the outer box cover that, simultaneously, verifies the *eligible* predicate and is selected by the *order* function (line 2), and splits it (line 3). Subsequently it modifies the inner and outer box covers of the joint cover. If the retrieved box is already in the inner box cover (line 4) then it is replaced by the boxes resulting from the *split*, which are also added to the outer box cover. Otherwise (line 5) the boxes resulting from the *split*, are pruned by the constraint propagation algorithm and added to the outer box cover (line 6). Those that are inner boxes are also added to the inner box cover (line 7).

Typically, in Algorithm 1, the *split* function splits the box by the midpoint of its largest interval; the *inner* predicate relies on natural interval extensions

Algorithm 1. *B & P* ($\langle \mathcal{F}_{\square}, \mathcal{F}_{\blacksquare} \rangle$, C, ε, *stop*, *order*).

induced by each constraint[2], replacing the variables by the intervals of the box, and checking whether all values in the resulting interval are solutions for that constraint; and the $eligible_{\varepsilon}$ predicate requires the width of the largest interval of the box to be larger than a given ε. The *stop* predicate imposes the stopping criterion and the *order* function specifies which box is selected for processing. Both *stop*, *order* and ε are parameterizable.

4 PROBABILISTIC CONSTRAINT PROGRAMMING

In classical CCSPs, uncertainty is modeled by intervals that represent the domains of the variables. Constraint reasoning reduces uncertainty providing a safe method for computing a set of boxes enclosing the feasible space. Nevertheless this paradigm cannot distinguish between different scenarios and all combination of values within such enclosure are considered equally plausible. In (Carvalho 2012) and (Carvalho, Cruz, & Barahona 2013) the authors proposed the Probabilistic Continuous Constraint paradigm (hereafter referred as PC), that extends the continuous constraint framework with probabilistic reasoning, allowing to further characterize uncertainty with probability distributions over the domains of the variables.

4.1 *Probabilistic continuous constraints*

Probability provides a classical model for dealing with uncertainty (Halpern 2003). The basic elements of probability theory are a) random variables and b) events, which are appropriate[3] subsets of the sample space Ω. A probabilistic model is an encoding of probabilistic information that allows the probability of events to be computed, according to the axioms of probability. In the continuous case, the usual method for specifying a probabilistic model assumes a full joint PDF over the considered random variables.

In order to complement the interval bounded representation of uncertainty with a probabilistic characterization of the values distributions, we define a probabilistic continuous constraint space. Firstly, a probability space is associated with a CCSP.

PC Probability Space Given a CCSP $\langle X, D, C \rangle$, the associated probability space is $\langle \Omega, \mathcal{B}^n, P \rangle$ where $\Omega \supseteq D$, $\mathcal{B}^n$ is the n-dimensional Borel σ-algebra on Ω and P is a probability measure.

Secondly, the variables of the CCSP are mapped onto random variables.

[2] In this paper we consider only inequality constraints.
[3] In the sense that it is possible to assign them a measure.

PC Random Vector Given a PC probability space on $\langle\langle x_1, \ldots, x_n\rangle, D, C\rangle$, an identity random vector $\mathbf{X} = \langle X_1, \ldots, X_n\rangle$ is considered, such that $X_i : \mathbb{R}^n \to \mathbb{R}$ is defined as $X_i(\Omega) = \Omega_i$.

Thirdly, the probability measure P is defined.

PC Probability Measure Given a PC probability space, PC random vector $\mathbf{X}$ with joint PDF $f(\cdot)$ and an event $\mathcal{H} \in \mathcal{B}^n$, the probability measure P is defined as:

$$P(\mathcal{H}) = \int \cdots \int_{\mathcal{H}} f(x_1, \ldots, x_n) dx_n \ldots dx_1$$

Finally, a probabilistic continuous constraint problem space may be defined.

PC Problem Space A PC problem space is a pair $\langle\langle X, D, C\rangle, f\rangle$ where $\langle X, D, C\rangle$ is a CCSP and f is the joint PDF of the PC random vector $\mathbf{X}$.

In this context, a PC event, hereafter referred as $\mathcal{H}$, is the feasible space of a CCSP $\langle X, D, C\rangle$.

4.2 *Multidimensional integration over a region*

In general the multidimensional integral to obtain the probability of a PC event cannot be easily computed, since it may have no closed-form solution or the event may establish a complex nonlinear integration boundary. The PC framework relies on continuous constraint programming to get a tight joint box cover $\langle \mathcal{H}_{\square}, \mathcal{H}_{\blacksquare} \rangle$ of the region of integration $\mathcal{H}$ and on Taylor models integration techniques to compute safe enclosures for the integrals over the obtained boxes.

Taylor Models A Taylor model of $g : \mathbb{R}^n \to \mathbb{R}$ inside an n-dimensional box B is a pair $\langle p, R\rangle$, where p is a polynomial and R is an interval satisfying, $\forall \boldsymbol{x} \in B$, $g(x) \in p(x) + R$. The order of the Taylor model is the degree of p.

A Taylor model of a function can be obtained from its multivariate Taylor expansion, using the interval evaluation of the highest order derivatives to compute rigorous bounds for the remainder.

Lemma 4.1 (From (Berz & Makino 1999)) *Given a Taylor model $\langle p, R\rangle$ of a function $g : \mathbb{R}^n \to \mathbb{R}$ inside an n-dimensional box B*:

$$[I]_{TM}(B, g) = \int_B p(x) dx + R\, vol(B) \ni \int_B g(x) dx$$

$[I]_{TM}$ can be used to obtain a sharp enclosure for the integral of a function over some region defined as a box (for more details about verified quadrature with Taylor models see (Goldsztejn, Cruz, & Carvalho 2014)).

Input: $\langle\langle X, D, C\rangle, f\rangle$: PC problem space; ε, δ: double
Output: I: interval;
1 $stop_\delta(\mathcal{H}_{\boxplus}) \equiv wid([P_{\mathcal{H}}](\mathcal{H}_{\boxplus}, f)) \leq \delta$;
2 $\mathcal{H}_{\boxplus} \leftarrow B\&P(\langle\{D\}, \varnothing\rangle, C, \varepsilon, stop_\delta, order_P)$;
3 **return** $[P_{\mathcal{H}}](\mathcal{H}_{\boxplus}, f)$;

Algorithm 2. *probEnclose*($\langle\langle X, D, C\rangle, f\rangle, \varepsilon, \delta$).

4.3 *Probability of a PC event*

The probability of a PC event can be enclosed by summing up the integral contributions of all the boxes from its joint cover, as follows.

Enclosure for the Probability of $\mathcal{H}$ Given a joint box cover $\mathcal{H}_{\boxplus} = \langle \mathcal{H}_{\square}, \mathcal{H}_{\blacksquare} \rangle$ of a PC event $\mathcal{H}$, an enclosure for the probability of $\mathcal{H}$ is given by[4]:

$$[P_{\mathcal{H}}](\mathcal{H}_{\boxplus}, f) = \sum_{B_i \in \mathcal{H}_{\blacksquare}} [I]_{TM}(B_i, f) + \sum_{B_i \in \mathcal{H}_{\square} \setminus \mathcal{H}_{\blacksquare}} [0] \uplus [I]_{TM}(B_i, f)$$

Notice that for non inner boxes, where the feasible region is some unknown subset of the box, the integral ranges from zero to the integral of the function over the box. In this case it is no longer worth computing a sharp (and more costly) enclosure and a lower order Taylor model can be used.

Since Taylor Models are used to compute safe enclosures for the integral over each box, the result is guaranteed to include the correct probability value.

Algorithm 2 computes bounds for the probability of a PC event. It uses the *B & P* algorithm where the $stop_\delta$ predicate imposes a specified accuracy δ for the probability enclosure computed over its joint box cover argument (line 1) and the $order_P$ function specifies that the box with highest uncertainty in its probability enclosure is chosen first.

For a PC problem space, with an associated PC event $\mathcal{H}$, *B & P* computes increasingly tighter covers of $\mathcal{H}$ until the intended accuracy δ for its probability is reached (line 2). The final joint box cover is used to compute an enclosure for the probability of $\mathcal{H}$[5] (line 3). The parametrization of *B & P* implies choosing boxes with higher uncertainty in their probability, in order to reduce such uncertainty. In practice, the accumulation of round-

[4]The union hull interval operator $\uplus$ returns the smallest interval containing both interval arguments.

[5]In fact, in the implementation of the algorithm, the probability enclosure is maintained and updated during the process, to check the stop criterion, and then returned in the end.

ing errors may prevent the algorithm to deliver the required accuracy. When this accuracy is too sharp, *B & P* may stop because there are no more eligible boxes (all the boxes are already small wrt ε) without achieving the required accuracy.

4.4 *Reliability assessment*

Reliability analysis can be used to analyze existing systems, thus being a significant support for those in charge of decision-making. In the following we describe how the PC framework can be used to obtain safe results on such problems.

For the formulation of a reliability assessment problem as a PC problem space, we distinguish between series and parallel systems.

Parallel and Series Systems as a PC problem space Consider a parallel system with an associated random vector $\boldsymbol{X} = \langle X_1, \ldots, X_n \rangle$ with joint PDF f_x defined in $\Omega_{\boldsymbol{X}} \subseteq \mathbb{R}^n$ and a set of k limit-state functions that define the failure event F as in (3). This system is modeled as a PC problem space, $\langle \langle X, D, C \rangle, f \rangle$, such that:

$$D \subseteq \Omega_{\boldsymbol{X}} \qquad X = \langle x_1, \ldots, x_n \rangle$$
$$C = \{g_i(x) \leq 0 : 1 \leq i \leq k\} \qquad f = f_{\boldsymbol{X}}(x)$$

Its probability of failure is $P_f = P(\mathcal{F}(\langle X, D, C \rangle))$ and its reliability is $P_s = 1 - P_f$.

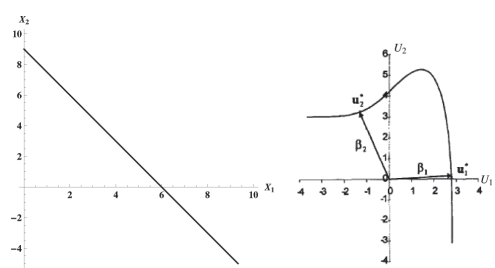
The formulation of a series system as a PC problem space is adapted from the previous, where $C = \{g_i(x) \geq 0 : 1 \leq i \leq k\}$ and $\mathcal{F}(\langle X, D, C \rangle)$ defines the success event. So the computed probability $P_s = P(\mathcal{F}(\langle X, D, C \rangle))$ is the reliability of the system.

From these formulations, Algorithm 2 can be used to compute the probability of event $\mathcal{H} = \mathcal{F}(\langle X, D, C \rangle)$ and obtain enclosures for the reliability (or probability of failure) of series or parallel systems.

Notice that reliability problems do not impose bounds on the random variables, which is not possible to model in the PC framework, where $D \subseteq \Omega_{\mathbf{X}}$ must be a bounded box. Thus, to guarantee the safety of the computed probability enclosures when $D \subset \Omega_{\mathbf{X}}$, a small correction term must be added to such enclosure. This is done by computing $[P](\mathcal{D})$, an enclosure for the probability of event $\mathcal{D} = \mathcal{F}(\langle X, D, \{\} \rangle)$ and $[P](\boldsymbol{\Omega}_{\mathbf{X}} \backslash \mathcal{D}) = 1 - [P](\mathcal{D})$, an enclosure for the neglected probability. Then the term $[0] \uplus [P](\Omega_{\mathbf{X}} \backslash \mathcal{D})$ is added to the enclosure computed by Algorithm 2.

5 EXPERIMENTAL RESULTS

To illustrate the limitations of the classical techniques (FORM, SORM and Monte Carlo) described in Section 2.1, several examples of reliability assessment problems found in the literature are modeled as PC problem spaces. The algorithms were implemented over RealPaver 1.0 (Granvilliers & Benhamou 2006), and the experiments were carried out on an Intel Core i7 CPU at 2.4 GHz.



The results obtained with the classical approaches are compared with those computed with algorithm 2 with $\delta = 10^{-6}$, $\varepsilon = 10^{-15}$ and a Taylor order of 6 for inner boxes (and 1 otherwise), hereafter referred as PCTM. All the results obtained with the PCTM algorithm are presented after adding the correction term.

In the experiments, function *NProbability* (from *Mathematica* v9.0.0.0 Wolfram Research 2012)) with the default parametrization, is also used to compute the required probabilities as a complementary source of comparison. Although, in the proposed examples, all *Mathematica* estimates are within the enclosure computed by the PCTM algorithm, this is not the case in general (see (Carvalho, Cruz, & Barahona 2013) for some examples). Moreover different parameterizations provide different values. Although the differences might be small, *Mathematica* does not provide bounds for the errors.

The first example illustrates the non linearity induced in the limit-state function resulting from the transformation of a non Gaussian distribution into a standard normal distribution.

Example 5.1. Consider the reliability problem, originally introduced in Hohenbichler & Rackwitz 1981, with $\boldsymbol{X} = \langle X_1, X_2 \rangle$, joint PDF $f_{\mathbf{X}}(x_1, x_2) = (x_1 + x_2 + x_1 x_2) e^{-(x_1 + x_2 + x_1 x_2)}$ defined in $\Omega = [0, \infty] \times [0, \infty]$ and limit-state function $g(x_1, x_2) = 18 - 3x_1 - 2x_2$.

Although the limit-state function is linear in the original space, it becomes highly nonlinear and has two design points in the standard normal space, due to the strong non normality of the random variables. Figure 1 shows the limit-state function

(a) Linear limit-state. (b) $\boldsymbol{U} = T_1(\boldsymbol{X})$.

Figure 1. Linear limit-state in the original space and nonlinear in the standard normal space.

(a) in the original space and (b) in the standard normal space.

The problem is formulated as a PC problem space:

$$X = \langle x_1, x_2 \rangle \qquad D = [0,30] \times [0,30]$$
$$C = \{g(x_1, x_2) \le 0\} \qquad f = f_{\boldsymbol{X}}(x_1, x_2)$$

The bounds for D guarantee a negligible probability for the neglected Ω region, $[P](\Omega \backslash \mathcal{D}) \le 4.5 \times 10^{-11}$.

The results obtained with the classical approaches (from) and with the PCTM algorithm are shown in Table 1. It presents the approximations obtained by FORM and SORM methods when only one of the design points is considered and when both are considered for both transformations $T_1(\mathbf{X})$ and $T_2(\mathbf{X})$, described in (Hohenbichler & Rackwitz 1981). For Monte Carlo (MC) and PCTM algorithms this does not apply.

It is clear from Table 1 that the results obtained with FORM and SORM have a great variability, depending on the chosen configuration, and, except for one, are outside the safe enclosure computed by PCTM algorithm (in 0.12 seconds CPU time). Using *Mathematica* the obtained result (in 0.12 seconds CPU time) was 0.294486×10^{-2}.

The next example illustrates a nonlinear limit-state function where the original space is normal (although not standard normal).

Example 5.2. Consider the reliability problem from (Choi, Grandhi, & Canfield 2010), with $\boldsymbol{X} = \langle X_1, X_2 \rangle$, where $X_1 \sim \mathcal{N}(10,5)$ and $X_2 \sim \mathcal{N}(10,5)$ are independent random variables defined in $\Omega = \mathbb{R}^2$, and limit-state function $g(x_1, x_2) = x_1^4 + 2x_2^4 - 20$. The problem is formulated as a PC problem space:

$$X = \langle x_1, x_2 \rangle \qquad D = [-40,60] \times [-40,60]$$
$$C = \{g(x_1, x_2) \le 0\}$$
$$f = \frac{1}{50\pi} e^{-\frac{1}{2}\left[\left(\frac{x_1-10}{5}\right)^2 + \left(\frac{x_2-10}{5}\right)^2\right]}$$

The bounds for D guarantee a negligible probability for the neglected Ω region, $[P](\Omega \backslash \mathcal{D}) \le 2.8 \times 10^{-13}$.

The results obtained with the classical approaches (from (Choi, Grandhi, & Canfield 2010, pag. 132–136)) where two SORM versions are considered (see (Choi, Grandhi, & Canfield 2010, Chapter 4) for details) and with the PCTM algorithm are shown in Table 2.

The result obtained with FORM grossly overestimates the probability of failure. Those obtained with both versions of SORM are closer to the correct value, however are still far from the exact value. Simulation with Monte Carlo produces the result closer to the correct value with an 5.23% error. Using *Mathematica* the obtained result (in 1.17 seconds CPU time) was 0.185252×10^{-2}, which is within the enclosure computed by the PCTM algorithm (in 0.84 seconds CPU time).

The problems in the following example are found in (Sørensen 2004) to illustrate series and parallel systems.

Example 5.3. Consider the reliability assessment problems from (Sørensen 2004, Note 6) (series system) and (Sørensen 2004, Note 7) (parallel system), with $\boldsymbol{X} = \langle X_1, X_2 \rangle$, where X_1 and X_2 are independent standard normal random variables defined in $\Omega = \mathbb{R}^2$, and the limit state functions of Table 3.

Table 1. Probability of failure $\times 10^2$.

	u_1^* alone		u_2^* alone		u_1^* and u_2^*			
	FORM	SORM	FORM	SORM	FORM	SORM	MC	PCTM

SORM Tvedt	0.2087
MC	0.1950
PCTM	[0.185162, 0.185263]

Table 3. Limit state functions.

	Series system	Parallel system
$g_1(x_1, x_2)$	$e^{x1} - x_2 + 3$	$e^{x1} - x_2 + 1$
$g_2(x_1, x_2)$	$x_1 - x_2 + 5$	$x_1 - x_2 + 1$
$g_3(x_1, x_2)$	$e^{x1+4} - x_2$	$e^{x1+2} - x_2$
$g_4(x_1, x_2)$	$0.1x_1^2 - x_2 + 4$	$0.1x_1^2 - x_2 + 2$

(a) Series system. (b) Parallel system.

Figure 2. Series and parallel systems.

Table 4. Probability of failure $\times 10^2$.

	Series system	Parallel system
SB	[0.02241, 0.05190]	[0.0762, 2.1692]
DB	[0.03516, 0.04091]	[0.1264, 0.2256]
PCTM	[0.031265, 0.031366]	[0.170314, 0.170415]

Figure 2 shows the limit-state functions and the safe/failure regions of these problems. The problems are formulated as PC problem spaces:

$$D = [-10,10] \times [-10,10] \qquad X = \langle x_1, x_2 \rangle$$

$$f = \frac{1}{2\pi} e^{-\frac{1}{2}(x_1^2 + x_2^2)}$$

$$C = \{g_i(x,y) \geq 0 : 1 \leq i \leq 4\} \quad \text{series system}$$

$$C = \{g_i(x,y) \leq 0 : 1 \leq i \leq 4\} \quad \text{parallel system}$$

In both problems 10 standard deviations around the mean value are assumed for the bounds of D, with $[P](\Omega \backslash \mathcal{D}) \leq 2.8 \times 10^{-13}$.

The results obtained with the classical approach for series and parallel systems analysis, where simple (SB) and Ditlevsen (DB) bounds are considered (see (Sørensen 2004, Notes 6 and 7) for details) and with the PCTM algorithm[6] are shown in Table 4.

We conclude that the simple bounds are too wide to be informative. The more accurate Ditlevsen bounds, for the series system, do not include the exact value in the safe enclosure computed by the PCTM algorithm (in 0.38 seconds CPU time). For the parallel system, they do include the safe enclosure computed by the PCTM algorithm (in 0.73 seconds CPU time) but are much wider. The results obtained with *Mathematica* were, for the series system, 0.0312962×10^{-2} (in 0.92 seconds CPU time) and, for the parallel system, 0.170394×10^{-2} (in 0.47 seconds CPU time).

[6]For the series system, the probability of failure was obtained from the reliability computed by the PCTM algorithm.

6 CONCLUSIONS AND FUTURE WORK

In this paper we propose to use the Probabilistic Continuous Constraints framework to deal with reliability assessment problems. Given its grounding on continuous constraint solving, this framework computes safe bounds for the reliability of series and parallel systems, contrary to classical approaches. The various kinds of approximations used by these approaches may turn the computed reliability value of little practical use, since they do not provide any bounds to the errors incurred. This is particularly significant in systems modeled by means of nonlinear constraints.

Moreover, the proposed framework, while guaranteeing the robustness of the computed values, does it very efficiently, being highly competitive when compared with *Mathematica*, that computes non-guaranteed results.

In the future the authors aim to extend the framework to address systems that are formulated as a combination of series and parallel components. Another interesting add-on would be the ability to model problems with a mixture of integer and continuous random variables, since these are an important class of problems appearing in science and engineering.

ABSTRACT: The paper presents an application of the probabilistic analysis of structural resistance of the containment of a VVER 440/213. The evaluation is based on an extension of the smeared crack model developed on the basis of Kupfer's bidimensional failure criterion and implemented into ANSYS. The non-linear analysis is considered for the median values of the input data and the probabilistic analysis models the uncertainties of loads, material resistance and other modeling issues. Results show that the effects of thermal load are relevant mainly for the bubble condenser and at the interface between the floor of hermetic zone and the rooms beneath. A comparison of the performance of linear and non-linear analyses is also reported.

1 INTRODUCTION

The definition of the fragility curve for containment of a Nuclear Power Plant (NPP) generally represents a crucial step for the level 2 probabilistic safety assessment (PSA L2), where the probability of containment failure can be evaluated as the convolution of the fragility curve with the load curve (SSG-4). The assessment of the structural strength of the containment of a nuclear power plant has acquired even a greater importance in the framework of post-Fukushima stress tests where the assessment of the safety margin and off-design conditions.

The overpressure in the containment can arise after a loss-of-coolant accident initiating event or a progression of an accident to severe accident conditions (after primary depressurization). In such cases, the primary steam is released in the hermetic zone and expands from the reactor hall to the bubble condenser.

In the past, the calculation of the structural reliability for containment of the type of VVER 440/213 was carried out determining the probability density function for the ultimate pressure before leakage and rupture. These calculations were based both on linear and non-linear analysis, depending whether the update of the properties were considered in the modeling.

The present work analyses the impact of combination of pressure load with thermal load that can arise in extreme situations related to severe accident progression. For the purpose, a detailed finite-element analysis of the concrete structure is carried out with ANSYS software combined with the program CRACK (Králik 2009, 2013). In the following, the basis for the probabilistic evaluation of structural reliability are reviewed, considering the uncertainties connected with loads and material properties. In the result section, a comparison with linear evaluation is also reported.

2 STRUCTURAL MODEL OF THE CONTAINMENT

The NPP buildings with the reactor VVER 440/213 consists the turbine hall, middle building, reactor building and bubble condenser (Fig. 1).

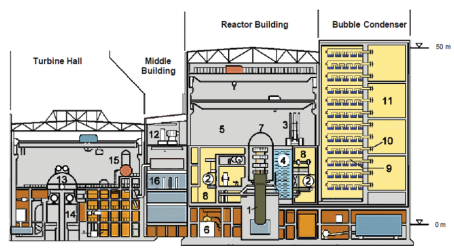

Figure 1. Section plane of the condenser containment.

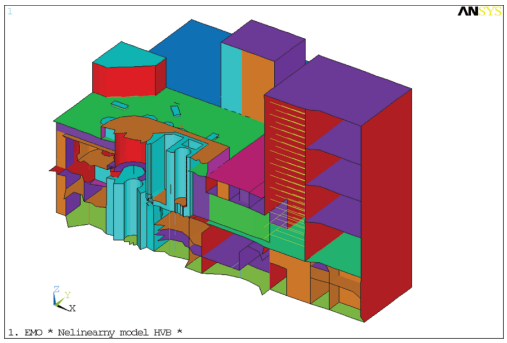

Figure 2. Calculation model of NPP VVER 440/213.

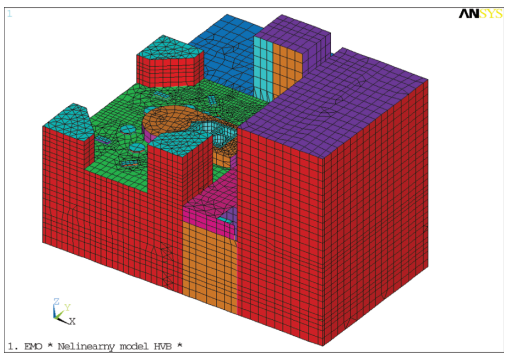

Figure 3. FEM model of NPP with reactor VVER440/213.

The building of the power block was idealized with a FEM model consisting of 28.068 elements with 104.287 DOF (Figs. 2 and 3).

3 DEFINITION OF LOADS AND BOUNDARY CONDITIONS

The definition of loads connected with the accident evolution is derived from an extreme scenario with a loss of primary coolant combined with the total loss of containment cooling (all means for hermetic zone heat removal are considered as not available, including external spraying of borated water). In such scenario, the environmental condition evolution in the long term is characterized by a combined pressurization and heating of the containment. An example of pressure evolution is reported in Figure 4; as for the temperature, while in a first approximation it can be considered as saturated in equilibrium with the temperature, in severe accident conditions the energetic contribution to heating from hydrogen recombination and explosion shall also be accounted.

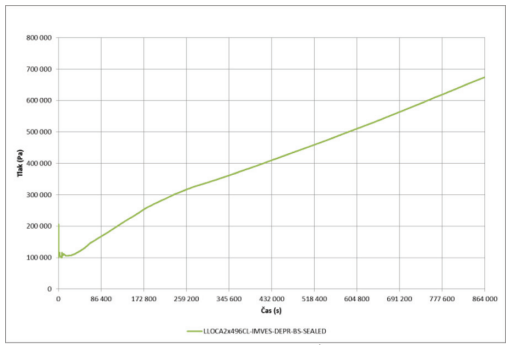

Figure 4. Pressure evolution (in kPa^{abs}) in the hermetic zone of a VVER 440/213 in an extreme scenario of total loss of containment heat removal.

The temperature boundary conditions are defined in accordance with the updated revision of reference temperature from the Slovak hydrometeorological institute (SHMU) and relevant standard STN EN 1991-1-5 NA. A return period of 10000 year is a reasonable choice for this type of evaluation. The lowest annual temperature where chosen as they correspond to the case where the thermal stress is maximized (i.e., largest heat flux at the external walls). An estimation for the ground temperature is consider in accordance with STN EN 1991-1-5 NA for defining the boundary conditions at the bottom of the hermetic zone, considering a simplified but conservative modeling for the rooms underneath.

A standard thermal model with convection and conduction is consider in ANSYS to model the temperature propagation in the containment structure due to internal and external thermal boundary conditions.

4 NON-LINEAR MODEL OF REINFORCED CONCRETE STRUCTURE

The theory of large strain and rate-independent plasticity is modeled using layered shell element SHELL181 from ANSYS library (Kohnke, 2008).

The vector of the displacement of the *l*th shell layer $\{u^l\} = \{u_x^l, u_y^l, u_z^l\}^T$ is approximated by the quadratic polynomial (Králik, 2009) in the form

$$\left\{u^l\right\} = \begin{Bmatrix} u_x^l \\ u_y^l \\ u_z^l \end{Bmatrix} = \sum_{i=1}^{4} N_i \cdot \begin{Bmatrix} u_{xi} \\ u_{yi} \\ u_{zi} \end{Bmatrix} + \sum_{i=1}^{4} N_i \cdot \frac{\zeta \cdot t_i}{2} \cdot \begin{bmatrix} a_{1,i} & b_{1,i} \\ a_{2,i} & b_{2,i} \\ a_{3,i} & b_{3,i} \end{bmatrix} \cdot \begin{Bmatrix} \theta_{xi} \\ \theta_{yi} \end{Bmatrix} \quad (1)$$

where N_i is the shape function for i-node of the 4-node shell element, u_{xi}, u_{yi}, u_{zi} are the motion of i-node, ζ is the thickness coordinate, t_i is the thickness at i-node, $\{a\}$ is the unit vector in x direction, $\{b\}$ is the unit vector in plane of element and normal to $\{a\}$, θ_{xi} or θ_{yi} are the rotations of i-node about vector $\{a\}$ or $\{b\}$.

In the elastic case, the stress-strain relations for the lth-layer are defined in the form

$$\{\sigma^l\} = [D_e^l]\{\varepsilon^l\} \tag{2}$$

where strain and stress vectors are as follows

$$\{\varepsilon^l\}^T = \{\varepsilon_x, \varepsilon_y, \gamma_{xy}, \gamma_{yz}, \gamma_{zx}\}, \{\sigma^l\}^T = \{\sigma_x, \sigma_y, \tau_{xy}, \tau_{yz}, \tau_{zx}\}$$

and the matrix of the material stiffness

$$[D_e^l] = \begin{bmatrix} B^l E_x^l & B^l \mu_{xy}^l E_x^l & 0 & 0 & 0 \\ B^l \mu_{xy}^l E_x^l & B^l E_y^l & 0 & 0 & 0 \\ 0 & 0 & G_{xy}^l & 0 & 0 \\ 0 & 0 & 0 & \dfrac{G_{yz}^l}{k_s} & 0 \\ 0 & 0 & 0 & 0 & \dfrac{G_{zx}^l}{k_s} \end{bmatrix} \tag{3}$$

where $B^l = (E_y^l)/(E_y^l - (\mu_{xy}^l)^2 E_x^l)$, E_x^l (versus E_y^l) is Young modulus of the lth-layer in the direction x (versus y), $G_{xy}^l, G_{yz}^l, G_{zx}^l$ are shear moduli of the lth-layer in planes XY, YZ and ZX; k_s is the coefficient of the effective shear area ($k_s = 1 + 0.2\,A/25t^2 \geq 1.2$), A is the element area, t is the element thickness. In the following sub-sections, various sources of non-linearity considered in the modeling of containment capacity are briefly reviewed.

4.1 *Geometric non-linearity*

If the rotations are large but the mechanical strains are small, then a large rotation approximation can be used in ANSYS (Kohnke, 2008).

The strain in the n-step of the solution can be computed from the relations

$$\{\varepsilon_n\} = [B_o][T_n]\{u_n\} \tag{4}$$

where $\{u_n\}$ is the deformation displacement, $[B_0]$ is the original strain-displacement relationship, $[T_n]$ is the orthogonal transformation relating the original element coordinates to the convected (or rotated) element coordinates. The convected element coordinate frame differs from the original element coordinate frame by the amount of rigid body rotation. Hence $[T_n]$ is computed by separating the rigid body rotation from the total deformation $\{u_n\}$ using the polar decomposition theorem.

4.2 *Material non-linearity*

The presented constitutive model is a further extension of the smeared crack model (Bažant et al., 2007; Červenka, 1985; Hinton and Owen, 1984; Hughes, 1984), as developed in (Králik, 2009). Following the experimental results (Červenka, 1985; Jerga and Križma, 2006) a new concrete cracking layered finite shell element was developed and incorporated into ANSYS (Králik, 2009). The processes of the concrete cracking and crushing are developed during the increasing of the load, whereas the concrete compressive stress f_c, the concrete tensile stress f_t and the shear modulus G are reduced after the crushing or cracking of the concrete (Kolmar, 1986).

The stress-strain relation, plotted in Figure 5, is defined following STN EN 1992-1-1 as

➲ Loading—compression region $\varepsilon_{cu} < \varepsilon^{eq} < 0$

$$\sigma_c^{ef} = f_c^{ef} \cdot \frac{k \cdot \eta - \eta^2}{1. + (k-2) \cdot \eta}, \quad \eta = \frac{\varepsilon^{eq}}{\varepsilon_c} \tag{5}$$

($\varepsilon_c \doteq -0.0022$, $\varepsilon_{cu} \doteq -0.0035$)

➲ Softening—compression region $\varepsilon_{cm} < \varepsilon^{eq} < \varepsilon_{cu}$

$$\sigma_c^{ef} = f_c^{ef} \cdot \left(1 - \frac{\varepsilon^{eq} - \varepsilon_c}{\varepsilon_{cm} - \varepsilon_{cu}} \right) \tag{6}$$

➲ The tension region $\varepsilon_t < \varepsilon^{eq} < \varepsilon_m$

$$\sigma_c^{ef} = f_t \cdot \exp(-2 \cdot (\varepsilon^{eq} - \varepsilon_t)/\varepsilon_{tm}) \tag{7}$$

($\varepsilon_t \doteq 0.0001$, $\varepsilon_{tm} \doteq 0.002$)

In the plane of principal stresses (σ_{c1}, σ_{c2}), the relation between the one-and bi-dimensional stresses state due to the plasticity function by Kupfer can be defined as follows (see also Fig. 6):

➲ Compression-compression

$$f_c^{ef} = \frac{1 + 3.65.a}{(1+a)^2} \cdot f_c, \quad a = \frac{\sigma_{c1}}{\sigma_{c2}} \tag{8}$$

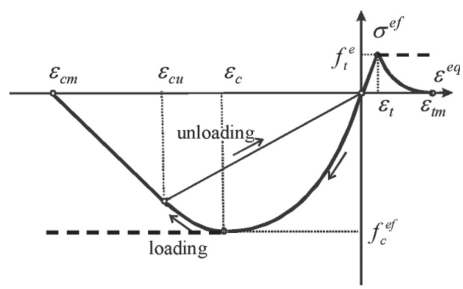

Figure 5. The concrete stress-strain diagram.

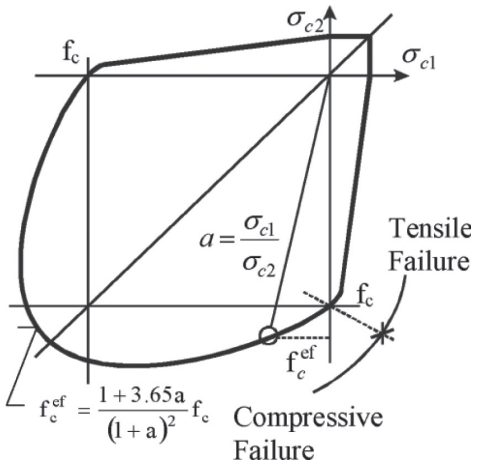

Figure 6. Kupfer's plasticity function.

➲ Tension-compression

$$f_c^{ef} = f_c \cdot r_{ec}, \quad r_{ec} = \left(1 + 5.3278\frac{\sigma_{c1}}{f_c}\right), \quad r_{ec} \geq 0.9 \quad (9)$$

➲ Tension-tension

$$f_t^{ef} = f_t \cdot r_{et}, \quad r_{et} = \frac{A + (A-1)\cdot B}{A \cdot B}, \quad B = K \cdot x + A,$$
$$x = \sigma_{c2}/f_c, \quad r_{et} = 1. \Leftrightarrow x = 0, \quad r_{et} = 0.2 \Leftrightarrow x = 1 \quad (10)$$

The shear concrete modulus G is defined for cracking concrete as in (Kolmar, 1986) in the form:

$$G = r_g \cdot G_o, \; r_g = \frac{1}{c_2}\ln\left(\frac{\varepsilon_u}{c_1}\right), \; c_1 = 7 + 333(p - 0.005),$$
$$c_2 = 10 - 167(p - 0.005) \quad (11)$$

where G_o is the initial shear modulus of concrete, ε_u is the strain in the normal direction to crack, c_1 and c_2 are the constants dependent on the ratio of reinforcing, p is the ratio of reinforcing transformed to the plane of the crack ($0 < p < 0.02$).

The crack in each layer of shell element is oriented perpendicular to the orientation of principal stresses. The membrane stress and strain vector depends on the direction of the principal stress and strain in each layer

$$\{\varepsilon_{cr}\} = [T_\varepsilon]\{\varepsilon\}, \quad \{\sigma_{cr}\} = [T_\sigma]\{\sigma\} \quad (12)$$

where $[T_\varepsilon]$, $[T_\sigma]$ are transformation matrices for the principal strain and stress in the direction θ in the layer.

The strain-stress relationship in the Cartesian coordinates can be defined as a function of the direction of the crack as:

$$[\sigma_{cr}] = [D_{cr}]\{\varepsilon_{cr}\} \text{ and } [\sigma] = [T_\sigma]^{\mathrm{T}}[D_{cr}][T_\varepsilon]\{\varepsilon\} \quad (13)$$

The stiffness matrix of the reinforced concrete for the lth-layer can be written in the following form

$$[D_{cr}^l] = [T_{c.\sigma}^l]^{\mathrm{T}}\left[D_{cr}^l\right]\left[T_{c.\varepsilon}^l\right] + \sum_{s=1}^{N_{rein}}\left[T_s^l\right]^{\mathrm{T}}\left[D_s^l\right]\left[T_s^l\right] \quad (14)$$

where $[T_{c.\sigma}]$, $[T_{c.\varepsilon}]$, $[T_s]$ are the transformation matrices for the concrete and the reinforcement separately, N_{rein} is the number of the reinforcements in the lth-layer.

After cracking the elasticity modulus and Poisson's ratio are reduced to zero in the direction perpendicular to the cracked plane, and a reduced shear modulus is employed. Considering the principal directions in the plane of the structure, the stress-strain relationship for the concrete lth-layer cracked is

$$\begin{Bmatrix}\sigma_1\\ \sigma_2\\ \tau_{12}\\ \tau_{13}\\ \tau_{23}\end{Bmatrix}_l = \begin{bmatrix}0&0&0&0&0\\ 0&E&0&0&0\\ 0&0&G_{12}^{cr}&0&0\\ 0&0&0&G_{13}^{cr}&0\\ 0&0&0&0&G_{23}^{cr}\end{bmatrix}_l \begin{Bmatrix}\varepsilon_1\\ \varepsilon_2\\ \gamma_{12}\\ \gamma_{13}\\ \gamma_{23}\end{Bmatrix}_l \quad (15)$$

where the shear modulus are reduced by the coefficient of the effective shear area k_s and parameter r_{g1} by Kolmar (11) as follows:

$$G_{12}^{cr} = G_o \cdot r_{g1}, \quad G_{13}^{cr} = G_o \cdot r_{g1}, \quad G_{23}^{cr} = G_o / k_s$$

When the tensile stress in the 2nd direction reaches the value f_t', the latter cracked plane perpendicular to the first one is assumed to occur and the stress-strain relationship becomes:

$$\begin{Bmatrix}\sigma_1\\ \sigma_2\\ \tau_{12}\\ \tau_{13}\\ \tau_{23}\end{Bmatrix}_l = \begin{bmatrix}0&0&0&0&0\\ 0&0&0&0&0\\ 0&0&G_{12}^{cr}/2&0&0\\ 0&0&0&G_{13}^{cr}&0\\ 0&0&0&0&G_{23}^{cr}\end{bmatrix}_l \begin{Bmatrix}\varepsilon_1\\ \varepsilon_2\\ \gamma_{12}\\ \gamma_{13}\\ \gamma_{23}\end{Bmatrix}_l \quad (16)$$

where the shear moduli are reduced by the parameter r_{g1} and r_{g2} by Kolmar in Eq. (11) as follows:

$$G_{12}^{cr} = G_o \cdot r_{g1}, \quad G_{13}^{cr} = G_o \cdot r_{g1}, \quad G_{23}^{cr} = G_o r_{g2}.$$

The cracked concrete is anisotropic and these relations must be transformed to the reference axes *XY*. The simplified averaging process is more convenient for finite element formulation than the singular discrete model. A smeared representation for the cracked concrete implies that cracks are not discrete but distributed across the region of the finite element. The smeared crack model used in this work is based on the assumption that the field of multiple micro-cracks is created (Červenka, 1985). The validity of this assumption is determined by the size of the finite element, hence its characteristic dimension $L_c = \sqrt{A}$, where A is the element area (versus integrated point area of the element).

5 NON-LINEAR DETERMINISTIC ANALYSIS

The critical sections of the structure are determined on the basis of the deterministic non-linear analysis. The resistance of these critical sections is considered taking into account the design values of material characteristics and loads. The combination load and design criteria is considered for the Beyond Design Basic Accident (BDBA) state in accordance with the international standard (IAEA, 2010).

The leakage condition is connected to the expansion of cracking, which is here linked to the assumption of constant failure energies G_f =*const* in the form

$$G_f = \int_0^{\infty} \sigma_n(w)\, dw = A_G \cdot L_c, \quad w_c = \varepsilon_w .\, L_c \tag{17}$$

where w_c is the width of the failure, σ_n is the stress in the concrete in the normal direction, A_G is the area under the stress-strain diagram of concrete in tension. Concrete modulus for descend line of stress strain diagram in tension (crushing) can be described according to (Červenka, 1985) as a function of the failure energies in the form

$$E_{c,s} = \frac{E_c}{1-\lambda_c}, \quad \lambda_c = \frac{2G_f E_c}{L_c \cdot \sigma_{\max}^2} \tag{18}$$

where E_c is the initial concrete modulus elasticity, σ_{max} is the maximal stress in the concrete tension. From relation in (18), it can be proven that the characteristic dimension of element must satisfy the following condition:

$$L_c \le \frac{2G_f E_c}{\sigma_{\max}^2} \tag{19}$$

The characteristic dimension of the element is determined by the size of the failure energy of the element. The CEB-FIP Model Code (1991) define the failure energies G_f [N/mm] depending on the concrete grades and the aggregate size d_a as follows

$$G_f = \left(0.0469 d_a^2 - 0.5 d_a + 26\right)\left(f_c\,/10\right)^{0,7} \tag{20}$$

The limit of damage at a point is controlled by the values of the so-called crushing or total failure function F_u. The modified Kupfer's condition for the *l*th-layer of section is following

$$F_u^l = \sqrt{\beta(3J_{\varepsilon 2}) + \alpha I_{\varepsilon 1}} - \varepsilon_u = 0, \tag{21}$$

where $I_{\varepsilon 1}$, $J_{\varepsilon 2}$ are the strain invariants, and ε_u is the ultimate total strain extrapolated from uniaxial test results ($\varepsilon_u = 0.002$ in the tension domain, or $\varepsilon_u = 0.0035$ in the compression domain), α, β are the material parameters determined from the Kupfer's experiment results (i.e., $\beta = 1.355$, $\alpha = 0.355\varepsilon_u$).

The failure function of the whole section will be obtained by the integration of the failure function through to the whole section in the form

$$F_u = \frac{1}{t} \cdot \int_0^t F_u^l\left(I_{\varepsilon 1}; I_{\varepsilon 2}; \varepsilon_u\right) dz = \frac{1}{t} \sum_{l=1}^{N_{lay}} F_u^l\left(I_{\varepsilon 1}; I_{\varepsilon 2}; \varepsilon_u\right) t_l \tag{22}$$

where t_l is the thickness of the *l*th-shell layer, t is the total shell thickness and N_{lay} is the number of layers. The failure state of the reinforced concrete structure is determined by the maximum strain ε_s of the reinforcement steel in the tension area ($\max(\varepsilon_s) \le \varepsilon_{sm} = 0.01$) and by the maximum concrete crack width w_c ($\max(w_c) \le w_{cm} = 0.3\,\text{mm}$).

In the present analysis, two critical areas are identified, namely the walls and the top plate of the bubbler tower building. The tension forces and the bending moments are concentrated along of the middle section of the wall. The difference between the interior end the exterior temperature has the significant influences to the peak strain in the structures. Based on the non-linear analysis of the containment resistance for median values of the material properties and failure function in Eq. (22) the mean value of the critical overpressure is above 350 kPa^g and the maximal strain

is lower than 0.002 in the middle plane of the reinforced concrete panel. The cracking process ($\varepsilon_1 \geq \varepsilon_t \doteq 0.0001$) at any layers of the section of the reinforced concrete is not experienced for overpressure below 250 kPa^g, hence as described in next section the only failure mode of interest in the load range under analysis is the leakage (catastrophic rupture is excluded).

6 PROBABILISTIC ASSESSMENT

After the identification of the critical sections using deterministic FEM calculation, the probability of the containment failure for the critical structure areas are considered for the various level of the overpressure. Most problems concerning the reliability of building structures are defined today as a comparison of two stochastic values, loading effects E and the resistance R, depending on the variable material and geometric characteristics of the structural element (Haldar and Mahadevan, 2000; Králik, 2009, 2013; Bažant et al., 2007; Kala, 2011; Novák et al., 2003). The variability of those parameters is characterized by the corresponding functions of the probability density $f_R(r)$ and $f_E(e)$.

The probabilistic definition of the reliability condition is of the form:

$$RF = g(R,E) = R - E \geq 0 \tag{23}$$

where $g(R,E)$ is the reliability function.

The probability of failure can be defined by the simple expression

$$P_f = P\left[R < E\right] = P\left[(R-E) < 0\right] \tag{24}$$

The reliability function RF can be expressed generally as a function of the stochastic parameters X_1, X_2 to X_n, used in the calculation of R and E.

$$RF = g(X_1, X_2, ..., X_n) \tag{25}$$

The failure function $g(\{X\})$ represents the condition of the reliability, which can be either an explicit or implicit function of the stochastic parameters. $g(\{X\})$ can be single (defined on one cross-section) or complex (defined on several cross-sections, e.g., on a complex finite element model).

In the case of simulation methods the failure probability is calculated from the evaluation of the statistical parameters and theoretical model of the probability distribution of the reliability function $Z = g(X)$. The failure probability is defined as the best estimate on the basis of numerical simulations in the form

$$p_f = \frac{1}{N}\sum_{i=1}^{N} I\left[g(X_i) \leq 0\right] \tag{26}$$

where N in the number of simulations, $g(\cdot)$ is the failure function, $I[\cdot]$ is the characteristic function with value 1, if the condition in the square bracket is fulfilled, and 0 otherwise.

The semi-probabilistic method is applied for the evaluation of the containment fragility and the propagation of uncertainty is carried out as detailed in next section.

7 UNCERTAINITIES OF THE INPUT DATA

Among the various simulation methods for uncertainty propagation, the RSM (Response Surface Method) approximation is considered in this paper. The RSM method generates the explicit performance function for the implicit or complicated limit state function. The RSM method is based on the assumption that it is possible to define the dependency between the variable input and the output data through the approximation functions in the following form:

$$Y = c_o + \sum_{i=1}^{N} c_i X_i + \sum_{i=1}^{N} c_{ii} X_i^2 + \sum_{i=1}^{N-1}\sum_{j>i}^{N} c_{ij} X_i X_j \tag{27}$$

where c_o is the index of the constant member; c_i are the indices of the linear member and c_{ij} the indices of the quadratic member determined using the regression analysis after calculating the response (here based on 5 structural analysis corresponding to different pressure loads). Approximate polynomial coefficients are given from the condition of the error minimum, usually by the "Central Composite Design Sampling" (CCD) method or the "Box-Behnken Matrix Sampling" (BBM) method (Kohnke, 2008).

The uncertainties on the input data are set in accordance with the standard requirements (see Table 1).

Table 1. Probabilistic model of the input data.

	Quantities		Histograms		
Input data	Charact. value	Variable value	Type	Mean (μ)	Deviation σ [%]
Dead load	G_k	g_{var}	*N*	1	10
Live load	Q_k	q_{var}	*Beta*	0.643	22.6
Pressure	P_k	p_{var}	*N*	1	8
Temper.	T_k	t_{var}	*Beta*	0.933	14.1
Model	E_k	e_{var}	*N*	1	5
Resist.	R_k	r_{var}	*N*	1	5

The action effect E are calculated considering the uncertainties of the input data:

$$E = G_k g_{\text{var}} + Q_k q_{\text{var}} + P_k p_{\text{var}} + T_k t_{\text{var}} \tag{28}$$

where the resistance R can be written as follows:

$$R = R_k r_{\text{var}} \tag{29}$$

8 EVALUATION OF THE FRAGILITY CURVE

The PSA approach to the evaluation of probabilistic pressure capacity involves limit state analyses. The limit states represent the ensemble of possible failure modes of the confinement functions. In principle, containment failure may be interpreted as incipient leakage (which may be a small controlled leak) or a large catastrophic break. The median capacity of a given failure mode is typically dependent on several factors, including material properties, modelling assumption and failure criteria. Considerable uncertainty and variability may be introduced in these factors and should be properly accounted for in the probabilistic overpressure fragility evaluation. To incorporate the uncertainty and variability in the formulation, the pressure capacity for each failure mode is represented as a random variable with a lognormal distribution.

The first step of a probabilistic evaluation is the identification of potential failure modes. Once the potential failure modes are identified, failure criteria are estimated from the median capacities. For each failure mode, the median capacities are to be evaluated by conducting independent limit state analyses using the specific failure criteria with the application of temperature, pressure and dead load.

In the present work, the probability of the containment failure is determined for the critical sections on the basis of the non-linear deterministic analysis of the containment for the various level of the overpressure Δp = 250, 300, 350, 400, 450 kPa^g. No catastrophic containment rupture at this pressure are evidenced, hence only potential failure mode considered here is the leakage. The function of the failure was considered as in Eqs. (21) and (22) and 10^6 Monte Carlo simulations are carried out in program FReET (Novák et al., 2003). The probability of containment failure is calculated from the probability of the reliability function RF in the form:

$$P_f = P(RF < 0) \tag{30}$$

where the reliability condition RF is defined depending on a concrete failure condition in Eq. (26)

$$RF = 1 - F_u\,(\mathrm{I}_{\varepsilon 1};\, J_{\varepsilon 2};\, \varepsilon_u)/\varepsilon_u, \tag{31}$$

where the failure function $F_u(.)$ was considered in the form of Eq. (23). As an example, Figure 7 shows the probability density function for a section at the bottom level of the bubble condenser with overpressure corresponding to 5% probability of failure.

A comparison of the linear and non-linear results is provided in Table 2, where the increase in the resistance connected with non-linear evaluation for different quantile is shown. The advantage of non-linear methodology is particularly evident at low probability, with resistance increase above 25% (i.e., non-linear estimation of containment capacity for the given quantile is more than ¼ higher than the linear estimation).

A comparison of strains from the linear and non-linear solution is reported in Figures 8 and 9. As expected, in comparison with the linear model, strains increase in the non-linear solution, whereas it can be shown that corresponding non-linear stresses decrease.

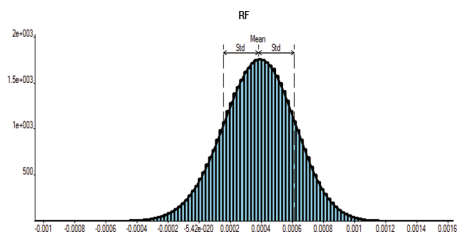

Figure 7. Density of the failure function RF at bottom level of the bubbler tower plate with overpressure corresponding to 5% probability of failure.

Table 2. Comparison of non-linear versus linear results (% increase in resistance).

Quantiles	Variation non-linear vs linear
5th	+25%
10th	+38%
20th	+12%
50th	+6%

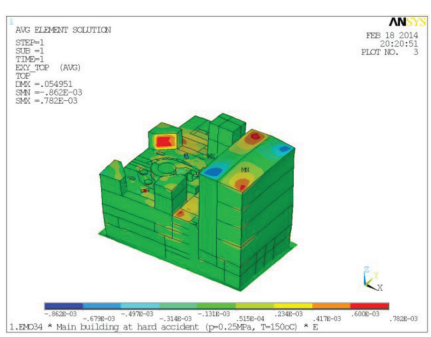

Figure 8. Strain deformation from the linear analysis.

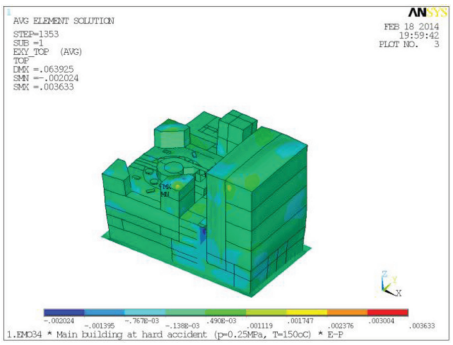

Figure 9. Strain deformation from the non-linear analysis.

9 CONCLUSIONS

The probability analysis of the loss of the concrete containment integrity is evaluated in a range of overpressure from 250 kPa^{g} to 500 kPa^{g} using the non-linear solution of the static equilibrium problem, considering both geometric and material non-linearity of the reinforced concrete. The non-linear analyses are performed in the CRACK program, which was developed by one of the Authors and implemented into the ANSYS system (Králik, 2009, 2013). The uncertainties of the loads level (temperature, dead and live loads), the material model of the composite structure (concrete cracking and crushing, reinforcement) and other influences following from the inaccuracy of the calculated model and the numerical methods are taken into account in the Monte Carlo simulations (Králik, 2009). The reliability function RF is defined in dependency on the failure function F_u ($I_{\varepsilon 1}$; $J_{\varepsilon 2}$; ε_u) for requirements of the PSA analysis in the form of Eq. (23). The analysis confirms that even for the combined case of temperaturee and pressure loads the probability of the loss of the concrete containment integrity is significantly below 1% for a load of 250 kPa^{g} (350 kPa^{abs}).

ACKNOWLEDGEMENT

The project was performed in the framework of the contract no. 4600009153 with Slovenské elektrárne a.s. The theory of the non-linear probabilistic analysis was developed in the framework of the VEGA grant project (VEGA 1/1039/12).

Reliability updating based on monitoring of structural response parameters

B.J. Leira
Department of Marine Technology, Trondheim, Norway

ABSTRACT: Short- and long-term aspects related to measurement of structural response parameters are addressed. Two specific examples of such measurements are considered for the purpose of illustration as well as to focus the discussion. These examples are taken from the petroleum industry (monitoring of riser response) and from the shipping industry (monitoring of ice-induced strains in a ship hull). Similarities and differences between the two cases are elaborated with respect to which are the most relevant mechanical limit states. Furthermore, main concerns related to the inherent reliability levels both with respect to extreme response and accumulated damage are highlighted.

1 INTRODUCTION

What is the benefit of monitoring structural response parameters? This question is generally addressed within the framework of so-called structural health monitoring which has received increasing attention and accordingly also attracted significant research efforts during the last decades.

The main objective of the present paper is to address the short- and long-term benefits of measurements/monitoring of structural response. Two specific examples are considered in order to focus the discussion: The first example deals with monitoring of the angular components at the lower flex joint of a marine drilling riser, while the second example is concerned with measurement of strains that are induced by ice loading on a ship hull.

There are usually multiple objectives associated with measurement of structural response processes and parameters. One such objective is frequently to monitor "the conditions" (or performance indicators) on-line such that counteractive measures can be activated when a critical threshold is reached. A second objective can be to perform extrapolation of key parameter values into the future in order to estimate when a critical condition will be reached. A third objective is related to the long-term learning process, i.e. to gain improved understanding of structural behavior as well as updating of the calculation models that are applied. Hence, an overarching objective is to provide a tool that may serve to supply basic information for the purpose of decision support in a wide sense. This applies both to the short-term and long-term time horizons.

In relation to updating of the applied calculation models, possible observed deviations between the measured and computed response implies that the calculation model needs to be revised. Such a revision can in some cases consist of more than a pure updating of particular parameters in the sense that the whole analysis framework needs to be upgraded.

An important issue in relation to how the measurements are processed is also which type of limit state that is critical. For the case that the fatigue limit state is anticipated to be the dominant one, the accumulated effects caused by a sequence of short-term stationary conditions is estimated. Prediction of the time until the critical threshold is reached will be the "performance measure". On the other hand, if the extreme response within a short-term condition (with a duration of a few hours) could possibly exceed the critical level, response prediction within a much shorter time horizon will be required.

These issues are highlighted in the following. The presented results which are obtained from measurements and calculated response are mainly based on the following sources: Stange (2013), Stange and Leira (2013), Suyuthi (2013) and Suyuthi et. al. (2012a, 2012b, 2013).

2 MONITORING OF RISER ANGLES FOR ASSESESSMENT OF WELLHEAD FATIGUE

2.1 *General*

The first example is related to the issue of wellhead fatigue during offshore drilling. This potential

failure mode has been increasingly focused upon during the last decade. There are multiple reasons for this increasing concern, such as: (i) The specific values which were assumed for the design parameters during initial design may no longer apply. (ii) The size and weight of the Blow-Out Preventers (BOPs) that are being applied have steadily been increasing. (iii) Larger surface vessels which operate in more and more hash weather are put into operations. (iv) For each well, there are more BOP days than assumed during initial design. Accordingly, it does not come as a surprise that well-head fatigue and the associated potential failure modes are coming strongly into focus.

Extreme response on the other hand is (at least in principle) taken care of: For angles exceeding a certain level, automatic emergency disconnect of the riser from the BOP is assumed to occur. Such a disconnect can be initiated e.g. by a drift-off or a drive-off of the surface vessel which frequently is associated with failure of the positioning system (e.g., errors related to the GPS-measurements). This implies that extreme loading which will endanger the integrity of the well-head can be disregarded (if the automatic disconnect system is activated).

Monitoring of the riser angles will also provide guidance in relation to when a manual disconnect action will need to be initiated in the case that the automatic emergency disconnect should fail. The time scale associated with such an operation is quite short, i.e. of the order of minutes.

Assuming that extreme loading is properly taken care of, the fatigue limit state comes into focus for all the mechanical components of the system. The riser itself can be inspected at regular intervals after retrieval when the drilling operation is completed. This implies that the condition of the permanently installed seabed components are of most concern as these cannot easily be inspected. In particular, estimation of the accumulated fatigue damage at the well-head is of key importance.

2.2 *The measurement system*

A schematic layout of the marine drilling riser is shown in Figure 1. The riser is attached to an Aker H-3 rig at a water depth of 325 m in the North Sea. The interface between the local and global analysis models are at the transition between the top of the wellhead and the lower face of the BOP.

The components of the instrumentation system are shown in Figure 2. The two orthogonal components of the riser angles at the Lower Flex Joint (LFJ) are measured by means of Inertial Measurement Units (IMU). Based on the measured angles, the loads which are acting on the wellhead can be estimated by introducing a local stress analysis model (i.e., by application of a Finite Element representation).

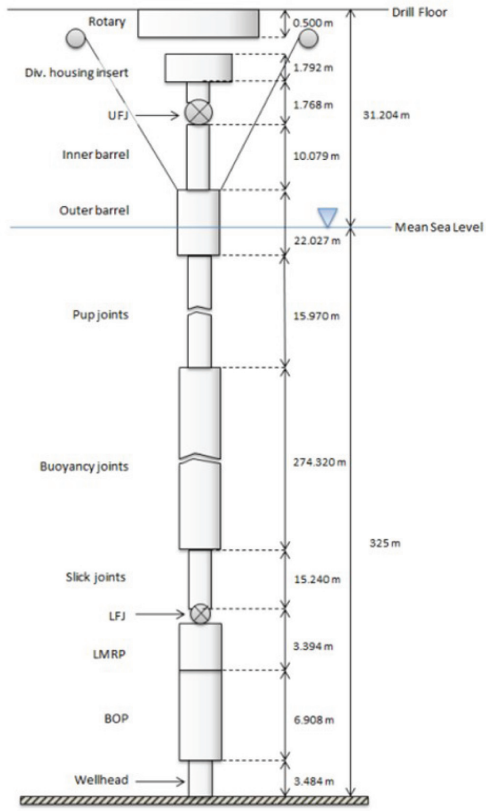

Figure 1. Basis for numerical riser model, Stange (2012).

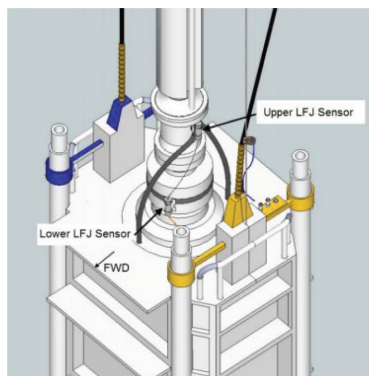

Figure 2. Overview over IMU location at the Lower Marine Riser Package (LMRP), from Stange (2012).

This is shown schematically in Figure 3 where the tension, bending moment and shear force are indicated (for the case of a 2D load-effect representation). These force components are

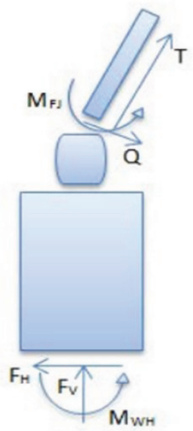

Figure 3. Simplified model of forces which are acting at the wellhead datum.

first transformed to force and bending moment components at the interface between the BOP and the wellhead. A local model of the well-head can subsequently be applied. Clearly, a more comprehensive model which comprises both the wellhead and the BOP can also be applied if this is required e.g. based on relative flexibility concerns.

An example of a measurement sequence for the two riser angle components is shown in Figure 4(a). A level plot of the histogram which represents the relative time the angular process spends in each square block is shown in Figure 4(b). It is found that a bivariate Gaussian model provides an adequate analytical model for the histogram.

In Figure 5, a number of projection planes for the angular process are indicated by straight lines. This will serve for the purpose of estimating the fatigue damage contributions from different directions. The cycle histogram can be established for each of these directions and subsequently the corresponding contribution to the well-head fatigue damage can be established.

2.3 *Comparison between full-scale measurements and numerical simulations*

By computing the resulting total angle for each of the blocks in Figure 4(b), a "one-dimensional" cycle distribution can be established for the angle range. The result is shown in Figure 6.

The frequency distribution of the response process components is also of significant interest. The response spectral densities for the total angle are shown in Figure 7 (a), (b) and (c) for three consecutive hours. It is seen that for the first two hours the frequency distribution is quite similar with two main peaks within two distinctive frequency

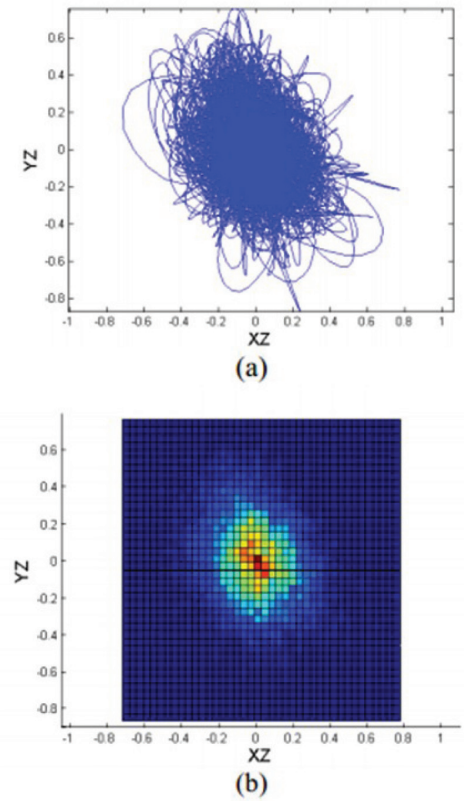

Figure 4. Angular response distribution.

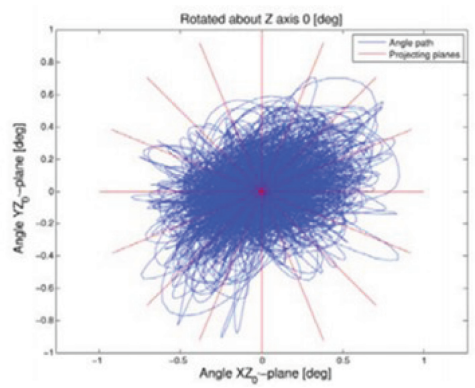

Figure 5. Projection planes for registration of angular response.

intervals. However, for the third hour there is a pronounced shift with the main peak being located at very low frequencies while the secondary small peak is located within the same frequency band as the main peak of the first two hours.

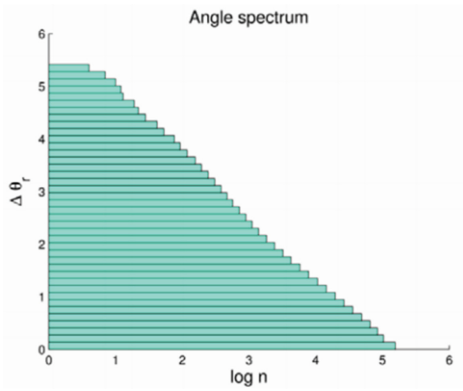

Figure 6. Histogram of angular cycles based on full-scale measurements.

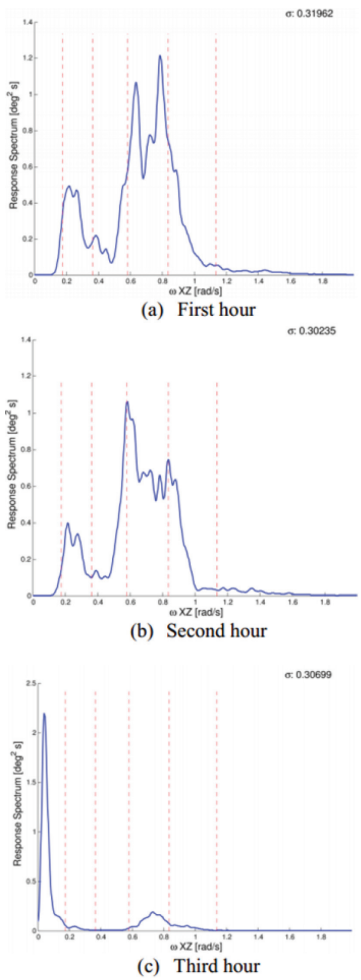

Figure 7. Spectral densities based on three consecutive one-hour periods of full-scale measurements.

The long-term distribution of angular cycles which is based on numerical simulations by application of the computer program Riflex, Marintek (1995) is shown in Figure 8. A fitted Weibull distribution is also shown. It is seen that there is a cut-off at a certain angle range (i.e. the very high amplitudes with a low number of cycles are missing as compared to the results in Figure 6).

This is more clearly seen by comparing the cycle distributions corresponding to Figure 6 and Figure 8 in the same graph, see Figure 9. The deviation for the highest cycle ranges are clearly observed. As the number of cycles within this range is very low, this is an indication that low-frequency response energy (e.g. due to slow-drift motion) is missing in the simulations.

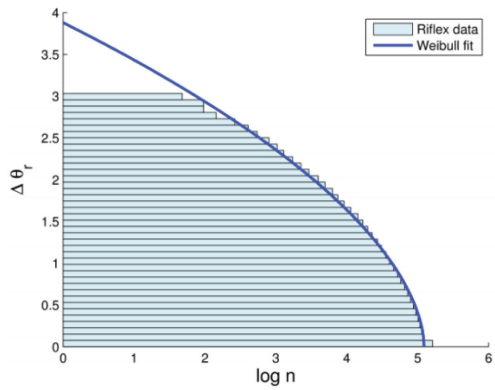

Figure 8. Histogram of angular cycles based on numerical simulations. Fitted Weibull distribution shown as blue line.

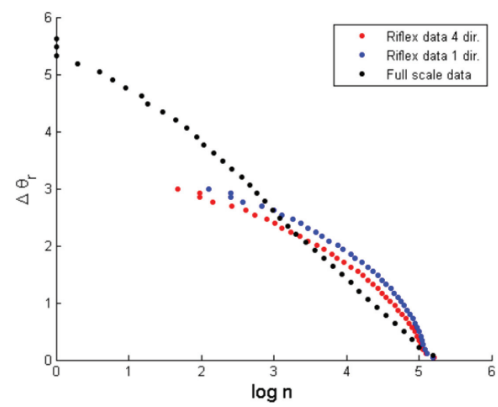

Figure 9. Comparison between long-term cycle distributions of riser angle which are estimated from measurements (black dots) versus numerical calculations (blue and red dots).

In order to investigate this in more detail, the computed response spectral densities are shown in Figure 10 for the two respective angular components. There are two-peaks in the spectral density also for this case for the case that the so-called Torsethaugen spectral model is applied. As observed, there is no response at very low-frequencies, which is due to slow-drift motion not being included in the analyses.

A more compact comparison between measured and calculated response is achieved by comparing the standard deviation of the angular response. The results in Figure 11 provide as comparison as a function of the mean heading direction. The straight horizontal lines correspond to the measured response with the middle line corresponding to the mean value and the upper and lower lines represent the 95 percent confidence interval.

For the computed response, a number of different cases are considered. These differ with respect to the type of wave spectral density that is applied

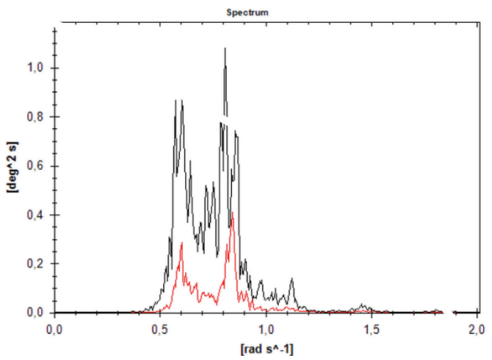

Figure 10. Computed response spectral densities based on numerical riser model.

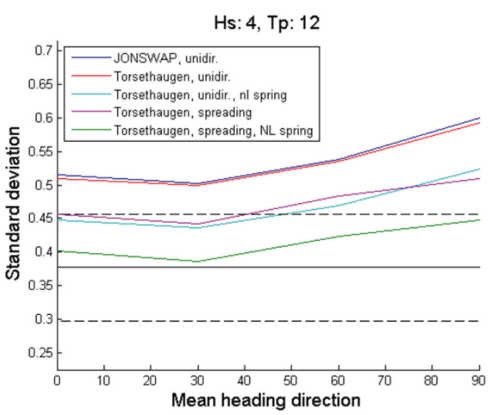

Figure 11. Comparison between angular standard deviations estimated from measurements versus numerical calculation model.

(i.e. Jonswap and Torsethaugen models), the wave spreading and the characteristic of the spring which represents the flex joint (i.e. a linear versus a nonlinear model is applied). It is found that the Torsethaugen model combined with unidirectional waves and a non-linear spring models gives good agreement. The same applies to the Torsethaugen model combined with wave spreading and a linear spring model.

2.4 *Comparison of measured and computed response for the case without low-frequency contribution*

A comparison between the cycle distributions for a measurement sequence without the low-frequency response component being present in the measurements is shown in Figure 12. A much better agreement is observed than for the results in Figure 9. The discrepancy in the high-amplitude range is now much less, and for the most relevant cycle amplitude range with respect to accumulation of fatigue damage the agreement is now extremely good.

Summarizing the findings from the comparison between full-scale measurements and the numerical simulations, the main observation is accordingly that the agreement is good provided proper models of the wave environment and the nonlinear structural behavior are applied.

However, the low-frequency response energy needs to be considered in more detail. The first step of such a study will be to include the slow-drift excitation in the numerical response analysis. In addition, the effect of low-frequency load energy caused by possible vessel motion induced by wind excitation should also be looked into.

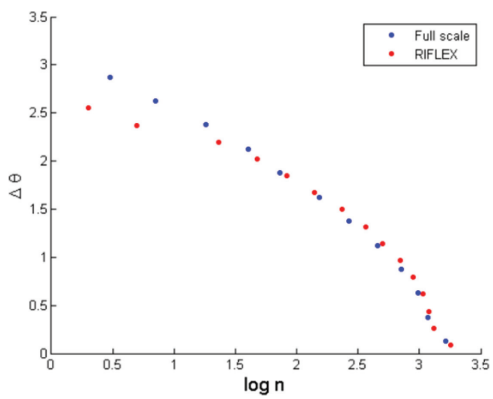

Figure 12. Comparison between short-term cycle distributions of riser angle which are estimated from measurements (blue dots) versus numerical calculations (red dots).

In addition, the reason that the measured low-frequency component is present only part of the time should be investigated in more detail by also looking at measurements of surface vessel motions. This will allow to decide whether this response component is due to top end motions or direct hydrodynamic loading on the riser itself.

3 MONITORING OF ICE-INDUCED STRAINS IN A SHIP HULL DUE TO ICE LOADING

The layout of the vessel KV Svalbard is shown in the uppermost part of Figure 13. The location of the strain sensors in the form of fiberoptic cables in the bow region are also shown in the same horizontal projection. The location of one of the fiberoptic cables on a vertical hull stiffener is also shown in the left middle photo, while the vessel itself is shown in the right middle photo. The route of the vessel through the waters around the Svalbard islands is shown on the map in the lowermost part of the figure.

An example of a time series showing the sequence of estimated ice load peaks (in kN/m) is given in Figure 14. The vertical arrows indicate the magnitude of each of the peaks.

Empirical short term cumulative distributions are shown in Figure 15 corresponding to four different measurement periods. It is observed that a bi-linear shape generally occurs for all the four periods. This implies that the standard types of analytical models will struggle to fit the data points adequately.

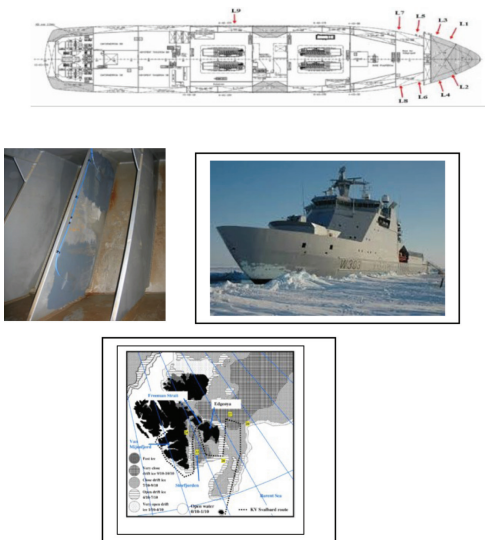

Figure 13. Fiberoptic cable instrumentation system for coast guard vessel KV Svalbard and expedition route.

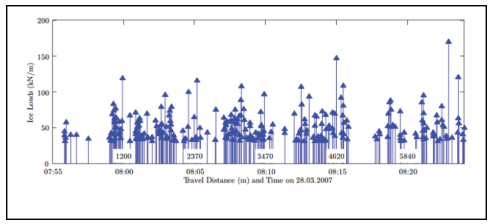

Figure 14. Example of estimated ice load peak sequence (magnitude in kN/m along vertical axis versus time along horizontal axis), Suyuthi (2013).

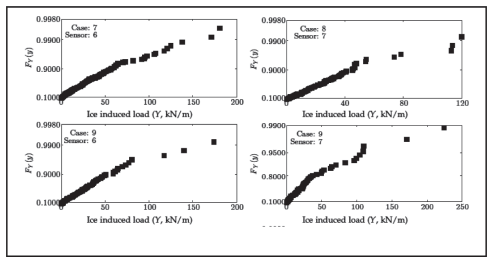

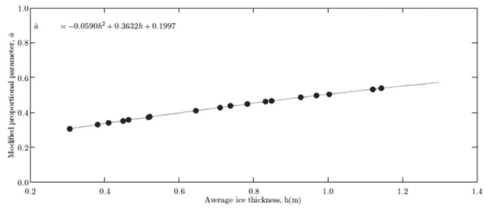

Figure 15. Empirical short-term cumulative distributions of load peak magnitudes (vertical axis) corresponding to four different measurement periods. Load level in kN/m along horizontal axis, Suyuthi (2013).

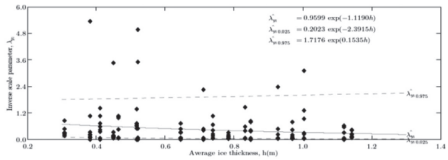
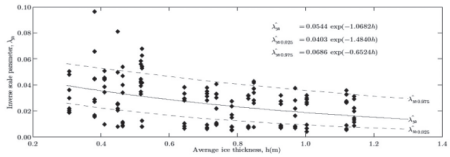
Still, the short-term distribution of the peaks is found to be well described by a three-parameter exponential distribution. This distribution was found to provide the best fit as compared to the Weibull and the Lognormal models. These latter distributions are frequently being applied in order to represent ice loading magnitudes. The conditional three-parameter model with the ice thickness (i.e. the "constant" h) as an indexing parameter is expressed as follows:



$$F_{Y|H}(y\,|\,h) = a(h)\left\{1-\exp\left(-\lambda_{y1}(h)y\right)\right\} + \left(1-a(h)\right)\left\{1-\exp\left(-\lambda_{y2}(h)y\right)\right\} \quad (1)$$

where $a(h)$ is a proportionality constant (i.e., "mixing parameter" for the two individual exponential distributions with inverse intensity parameters that are equal to $\lambda_{y1}(h)$ and $\lambda_{y2}(h)$, respectively.



The variation of these three parameters as functions of the ice-thickness are shown in Figure 16. Both the mean curve and the upper and lower bounds which represent the respective 95% confidence intervals are shown. A significant scatter of

(a) Proportionality factor

(b) Inverse intensity parameter of first exponential model

(c) Inverse intensity parameter of second exponential model

Figure 16. Variation of the three parameters of the combined exponential models as functions of ice thickness (horizontal axis). (a) Proportionality factor (b) Inverse intensity parameter of first exponential model (c) Inverse intensity parameter of second exponential model.

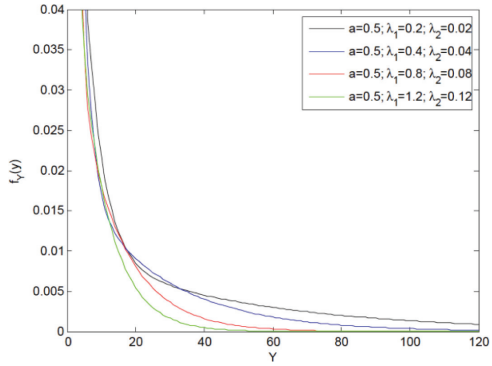
the data points implies that the confidence intervals are rather wide.

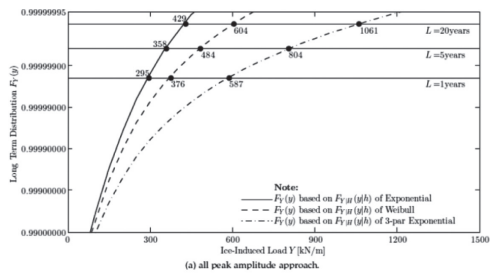
The variation of the shape of the three-parameter distribution for a proportionality factor $a(h) = 0.5$ is illustrated by Figure 17. The first inverse intensity parameter varies between 0.2 and 1.2 whereas the second inverse intensity parameter varies between 0.02 and 0.12.

The procedure for prediction of the short-term extreme values for a given distribution of the load peaks can be summarized as follows: (i)The time history is divided into one minute intervals (ii)The maxima in each interval are identified (iii) These maxima form the basis for fitting an extreme value distribution of the Gumbel type.

For prediction of long-term extremes two different approaches are applied. These are referred to as the all peak amplitude approach and the m-nautical mile approach. For each of these two approaches three different analytical models are applied in order to study the sensitivity to these models.

The resulting cumulative distribution functions for the long-term extreme values are shown in Figure 18(a) for the "all peak amplitude approach" and in Figure 18(b) for the m-nautical





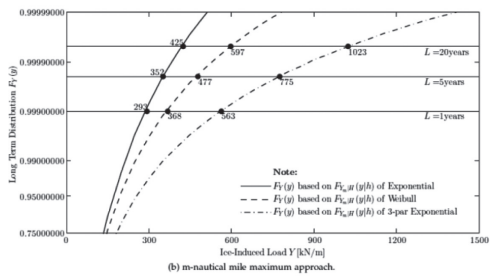


Figure 17. Variation in shape of three-parameter Weibull distribution for a proportionality factor of 0.5 Inverse intensity parameter of first exponential distribution varies between 0.2 and 1.2. Inverse intensity parameter of second exponential distribution varies between 0.02 and 0.12.

(a)All peak amplitudes are included

(b)Largest peaks during m nautical miles are included

Figure 18. Long-term extreme value distributions obtained by two different approaches: (a) All load peaks (b) Only the extreme peaks observed during a voyage of m nautical miles. Three different initial distributions are considered in each case: A. 1-parameter exponential (leftmost curves) B. Weibull distribution (middle curve) C. 3-parameter exponential distribution (rightmost curve).

mile approach. For both cases the rightmost curve corresponds to the three-parameter exponential distribution. The intersection between the distribution functions and the three different horizontal lines provide the values of the peak amplitudes

that correspond to return periods of 100 years (uppermost horizontal line), 10 years (middle horizontal line) and 1year (lowermost horizontal line).

It is clearly observed that for both cases the three-parameter exponential distribution gives the highest values. Furthermore, the percentwise difference between the predictions obtained by application of the two different approaches is quite modest.

Fatigue damage can also be estimated e.g. as being conditional on a specific (stationary) ice thickness, h. The unconditional damage is subsequently found by integration with respect to the ice thickness density.

The probabilistic model for the peak amplitudes will form the basis for calculation of the fatigue damage. Accordingly, the three-parameter exponential model will be highly relevant also for this case since the probabilities associated with the whole range of different peak levels are represented in an adequate way.

Additional parameters such as the vessel speed, v, can also be taken into account which results in a two-dimensional integration. Other types of effects, such as operational limits with respect to ice thickness or vessel speed can also be accommodated by introducing proper integration limits for these expressions.

The procedure for estimation of total fatigue damage (during a specified time interval length.) is illustrated in Figure 19.

An example of results for the computed fatigue damage is shown in Figure 20. The two parameters along the horizontal and vertical axis correspond the those for the long-term ice thickness distribution which is of the Gamma type. The figure shows the iso-contour lines for the fatigue damage levels. The level curves corresponding to increasing ice thickness are also shown. The reason that there is a peak for the fatigue damage values (and not a monotonous increase is that there is a vessel operation limit which here is assumed to be an ice thickness of 1 m.

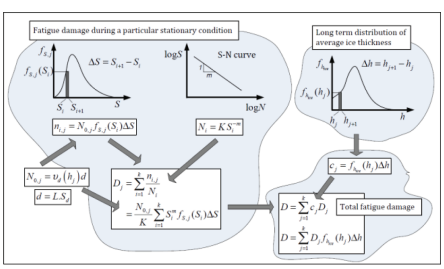

Figure 19. Illustration of steps which are associated with estimation of fatigue damage accumulation, Suyuthi (2013).

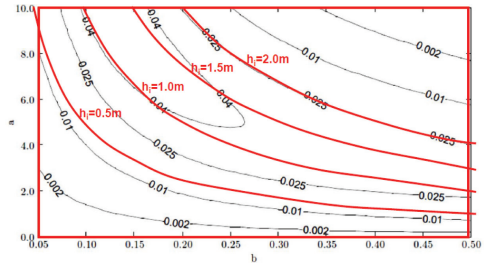

Figure 20. Iso-fatigue-damage contours and ice-thickness contours as functions of the two Gamma parameters (a and b) which define the ice-thickness distribution. Ice thickness operation limit is 1 m.

The fatigue limit state is controllable in the sense that regular inspection of the ship hull can be performed. Accordingly, estimation of the extreme value of the ice loading both within a short-term and long-term time horizon comes into focus in relation to the objective of the measurements. However, in relation to the implied learning process, improvement of fatigue design procedures is at least of equal importance.

4 CONCLUDING REMARKS

The role of structural response monitoring in relation to accumulation of more precise information for improvement of design has been a key topic in the present paper. Clearly, such response monitoring will also give information about the present condition of the structure once the measurements are combined with mechanical/numerical models in the light of acceptable threshold limits.

In general, measurements imply that more precise information becomes available which tends to reduce the level of uncertainty. In some cases, it is found that the numerical models which are applied for design purposes need to be updated. This leads to a reduction of the uncertainties related to the mechanical calculation models themselves.

In both cases, the measurements tend to improve the reliability level. In the latter case, the nominal value of the reliability level is improved by a reduction of the inherent model uncertainties (provided that they are included in the probabilistic representation).

For both examples of application, response monitoring may further serve as a decision support tool. Such decisions are related to specification of operation parameters as well as decommissioning of the structure or parts of the structure.

Regarding the mechanical limit states which are involved, the first case is mainly concerned with

the fatigue damage accumulation (also keeping in mind that direct information about presence of possible cracks is generally not available). The second case is more focused on the short- and long-term extreme values (still, the fatigue strength also needs to be verified, but inspection can be performed at regular intervals).

As a general observation it is found that instrumentation technology becomes increasingly advanced with time. The costs associated with instrumentation and monitoring systems also tend to be reduced. Monitoring and data acquisition are accordingly greatly facilitated and can be performed both on-line and off-line. Hence, the scope of application of such systems is expected to expand in the future. Application to vastly different types of structures is anticipate, which hopefully is also illustrated by the present paper.

However, a note of warning should clearly also be given: A number of potential failure modes (both of the mechanical type and other categories) are not covered by a particular instrumentation system, i.e. in the sense that no information about the parameters which are relevant are provided by the system. Hence, it should be ascertained that data which are relevant for the most important failure modes are provided by the measurements.

Altogether, the present paper has hopefully served to illustrate the benefit of response monitoring (i.e. structural health assessment) as a versatile tool within different areas of application.

ACKNOWLEDGEMENTS

The author is grateful to 4Subsea for access to the riser measurements and to DNV for access to the ship hull measurements. The contributions of the co-authors of the respective papers are also greatly acknowledged.

Comparative analysis of rapid calculation methods for physical explosions of pressure vessels

R. Bubbico & B. Mazzarotta
Dipartimento Ingegneria Chimica Materiali Ambiente, Università di Roma "La Sapienza", Rome, Italy

ABSTRACT: A large number of correlations are available in the literature to estimate the overpressure profiles deriving from the physical explosion of vessels containing compressed gases. However, none of them is widely recognized as the most general and reliable, and in many cases the respective range of applicability is not always very clear. The paper presents a comparative analysis applying two of the most commonly used calculation procedures to a great number of study cases, in order to highlight the dependence of the results on the main input parameters: substance, size of the vessel and the operating conditions (P, T). The results were related to the operating variables and to the physical properties of the substances, in order to obtain guidelines about the use and the reliability of the rapid methods.

1 INTRODUCTION

A large number of correlations and calculation methods are available in the literature to estimate the overpressure profiles deriving from the physical explosion of vessels containing compressed gases. As a matter of fact the physical phenomenon, consisting in the sudden expansion of the gas, released in ambient air, is rather complex, and involves many variables dependent on the physical properties of the gas, the characteristics of the vessel, the operating conditions before the explosion occurs, and the modality of the explosion. An accurate estimate of the main parameters of interest (such as peak overpressure and impulse) would require an equally accurate modeling of the explosion, which may be difficult to be obtained even using Computational Fluid Dynamics (CFD) which is a rather demanding technique, in terms of expertise of the analyst and computational complexity. Accordingly, in several process and safety engineering applications a detailed approach (e.g CFD) may be unsuitable, especially in preliminary risk analyses, where the assessment of the effect zones for a great number of potential hazard sources is required. In such cases the estimates of the explosion parameters are carried out using simplified models, which are based on hypotheses that, on one hand, make calculations easier and faster but, on the other hand, make the results more uncertain. In fact, a number of simplified models are available, but none of them is widely recognized as general and reliable, and in many cases the respective range of applicability is not always very clear.

The aim of the present paper is to compare the pressure profiles generated by a gas explosion, calculated according to the two most widely used rapid methods for different substances, volumes and operating conditions. The attention will be focused on the predictions of peak overpressure in the middle-far range, taking into account that, in the short range, its values generally largely exceeds the thresholds of human lethality and of vessel collapse, which can be estimated around 0.3 bars.

2 SIMPLIFIED GAS EXPLOSION MODELS

In this paragraph the main features of Baker's (Baker et al., 1983) and Prugh's (Prugh, 1988) models are briefly recalled: they are the two probably most common models used in risk analysis to predict the pressure profiles generated by a gas explosion.

2.1 *Baker's model*

Baker derived the model for pressure vessel bursts based on small scale experiments (Baker et al., 1983); in the present work reference will be made to the "basic" version (AIChE/CCPS, 1994).

The energy of explosion is calculated by means of the Brode equation (Brode, 1959): this expression determines the energy required to raise the pressure of the gas at constant volume from atmospheric pressure, P_0, to the initial, or burst, pressure, P_1:

$$E = \frac{\left(P_1 - P_0\right) \cdot V}{\gamma - 1} \tag{1}$$

where: E = energy (J); P_1 = initial pressure of the expanding gas (Pa); P_0 = final (ambient) pressure

of the expanding gas (Pa); V = gas initial total volume (m^3); γ= gas heat capacity ratio, C_p/C_v (–).

However, in a real explosion, the gas behaves differently from Brode's assumption, finally reaching an equilibrium condition after an irreversible expansion from an initial volume at the burst pressure P_1 to a final (different) volume at ambient pressure P_0. Moreover, the expansion energy of the gas is partly dissipated in other phenomena accompanying the explosion, such as in vessel deformation and rupture, in vessel fragments projection, in heat dispersion, etc., which may account up to 50% of the total internal energy of the system. Despite these considerations, the energy released during a gas explosion is often calculated based on the Brode equation (AIChE/CCPS, 2000), possibly introducing some correction coefficients (Crowl and Louvar, 2002).

Most pressure gas vessel explosions happen close to the ground, where shock wave reflection occurs, increasing the intensity of the shock wave: in order to account for this phenomenon, the calculated explosion energy has to be doubled.

Once estimated the explosion energy, the peak overpressure at a given distance can be derived from generalized graphs, where the normalized overpressure as a function of the non-dimensional distance is reported. The non dimensional distance is calculated using the Sachs scaling law (AIChE/CCPS, 1999):

$$\bar{R} = r \cdot \left(\frac{P_0}{E} \right)^{\left(\frac{1}{3}\right)} \tag{2}$$

where: r = absolute distance (m); $\bar{R}$ = scaled distance (–).

Applying this method in the near field, i.e. close to the vessel surface, the calculated overpressures may results higher than the burst pressure, which is physically impossible. This inconvenience can be solved using a modified procedure for $\bar{R} < 2$ (Baker et al., 1983): this will introduce a discontinuity in the overpressure values calculated at $\bar{R} = 2$.

2.2 *Prugh's model*

Prugh's method (Prugh, 1988) estimates the explosion energy assuming an isothermal expansion of an ideal gas (Brown, 1985):

$$E = \frac{V}{V_R} \cdot \frac{P_1}{P_R} \cdot R \cdot T_1 \cdot \ln\left(\frac{P_1}{P_0} \right) \tag{3}$$

where: R = ideal gas constant (8314 J/kmol K); V = initial volume of the compressed gas (m^3); P_R = pressure at standard conditions (101300 Pa); V_R = volume of 1 kmol of gas at standard conditions (0.022414 m^3).

Then, the calculated energy is converted in an equivalent amount of TNT, which is used to estimate shock wave effects, using the TNT equivalency method. This is based on the Hopkinson's law as scaling method to evaluate the blast pressure profile as a function of the normalized distance (AIChE/CCPS, 1994).

The estimate of the explosion energy suffers from the same type of inconvenience of Brode's equation, and the analogy of the explosion of a pressurized gas vessel to a TNT one appears improper in the near field, since the vessel cannot be regarded as a point source. In this case, the correction method uses a virtual distance from the explosion center (Petes, 1971), to fictitiously move the explosion centre with respect to the surface of the expanding gas. The maximum overpressure of the shock wave, i.e. that at the contact surface between the initial expanding gas sphere and the air, is evaluated as (Baker et al., 1983; Prugh, 1988):

$$P_b = P_s \left[1 - \frac{3.5(\gamma - 1)(P_s - 1)}{\sqrt{\left(\frac{\gamma T_1}{M} \right)(1 + 5.9 P_s)}} \right]^{-2\frac{\gamma}{\gamma - 1}} \tag{4}$$

where: M = molecular weight (kg/kmol); T = absolute temperature of the expanding gas (K); P_b = blast pressure (Pa); P_s = pressure at vessel surface (Pa).

The virtual distance is then obtained by subtracting the geometrical distance between the centre and the external surface of the vessel (expanding gas initial surface), from the distance calculated by the TNT model to get the P_s overpressure. The proper distance to be used in the TNT equivalency method (AIChE/CCPS, 2000), is obtained adding the actual geometrical distance to the virtual distance.

$$Z = \frac{r}{W^{\left(\frac{1}{3}\right)}} \tag{5}$$

where: Z = scaled distance (m/kg$_{TNT}^{1/3}$); r = absolute distance (m); W = TNT equivalent mass (kg).

3 MODEL'S ANALYSIS

The focus of the present work is on the peak overpressure profile generated by the explosion of a vessel containing a pressurized gas. To this end, the previous models are applied to a number of study cases, changing the values of the parameters appearing in the model equations and comparing the calculated peak overpressure profiles.

Most attention will be devoted to the behavior of the models in the far range: in fact, in the near range, peak overpressure values generally greatly exceed the threshold values for damages to humans and structures (30 kPa).

3.1 *Parameters of interest*

The models summarized in the previous paragraph, contains different variables, related to the physical properties of the gases, the operating and ambient conditions, and the volume of the vessel.

The physical properties of the gas used in the calculations are the gas heat capacity ratio and the molecular weight: the substances listed in Table 1 were selected to cover a wide range of both variables.

Heat capacity ratio slightly depends on both pressure and temperature: data available for air (Cramer, 1993) show that γ variations are negligible in the temperature range –20/+50°C, while the influence of the pressure is more important. In fact, γ value increases from 1.402 to 1.57 increasing the pressure from 1 to 100 bars, at ambient temperature.

The operating conditions of a pressure vessel may vary considerably depending on its service. Storage vessels operate at ambient temperature, and at different pressure, based on the destination of the gas and the size of the vessels: the highest pressures are adopted for the smallest containers (e.g. gas cylinders). In the present work, the vessel size will vary from 0.5 to 200 m^3, the operating pressure from 2 to 200 bar, and the temperature from –10 to +40°C: as "reference" case as a 10 m^3 cylindrical vessel at 20°C is assumed.

3.2 *Influence of the physical properties of the gas*

In Baker's model the explosion energy is a function of the heat capacity ratio according to Brode equation (1) while, in Prugh's one, it does not depend on the physical properties of the stored gas, according to Brown equation (3). Figure 1 compares the results obtained applying the two equations to the reference case, assuming different gases. For low values of the blast pressure (up to around 20 bar) Brown's estimates of the explosion energy are lower than Brode's one, but the opposite occurs at higher pressures (20–50 bar, depending on the gas).

Table 1. Physical properties of the selected gases.

Substance	Heat capacity ratio at ambient conditions	Molecular weight (kg/kmol)
Air	1.402	29
Ethylene	1.22	28
Hydrogen	1.41	2
Hydrogen chloride	1.41	36.5
Nitrogen	1.41	28

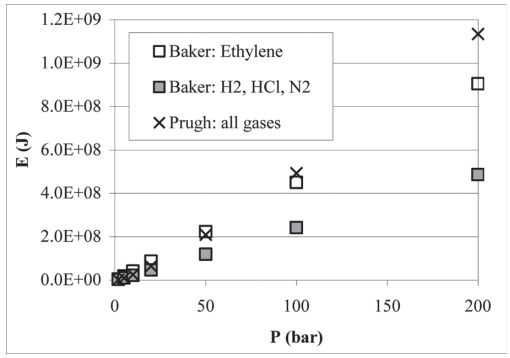

Figure 1. Explosion energy for a 10 m^3 vessel at 20°C, according to Brode's and Brown's equations.

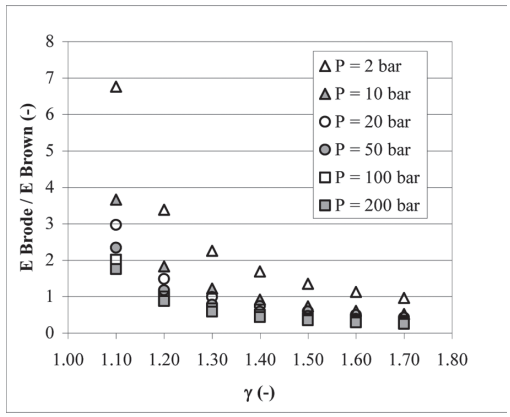

Figure 2. Ratio of the explosion energies for a 10 m^3 vessel at 20°C, according to Brode's and Brown's equations, vs. the gas heat capacity ratio.

In Brode's equation, which is used in Baker's model, larger values of the heat capacity ratio result in lower explosion energies. As highlighted before, since larger values of the heat capacity ratio correspond to increasing pressures, from this point of view, the direct influence of the burst pressure on the explosion energy in the Baker's model is somehow counterbalanced by the variability of γ, and this explains the slower increase of the explosion energy with respect to that calculated with the Brown equation.

Figure 2 shows the trend of the ratios between the energy of explosions calculated with the Brode and with the Brown equations (1) and (3) as a

function of the heat capacity ratio, in the range 1.1–1.7.

It can be noticed that for low values of γ, the Brode equation calculates higher explosion energies with respect to the Brown equation, while the opposite is true at high γ values. The ratio of the explosion energies, as defined above, increases noticeably by decreasing the blast pressure.

Figure 3 compares the explosion energy calculated with Brode equation (1), for air, either assuming a constant heat capacity ratio at the value corresponding to 1 bar (γ= 1.402), and then taking into account its dependency on the pressure (Cramer, 1993): the values at the burst pressures have been used in the calculations. It can be noticed that assuming the constant, ambient-pressure (low) value of the heat capacity ratio, may result in a overestimation of the explosion energy. However, Figure 3 emphasizes the influence of this parameter, since calculations should be more properly carried out with a suitable pressure averaged γ value, and not just based on its initial (high) value. Furthermore, taking into account that, according to the procedure of Baker, in case of explosion occurring close to the ground, the explosion energy calculated with the Brode's equation should be almost doubled to account for shock wave reflection, before being inserted in Baker's model, it is apparent that the heat capacity ratio deserves great attention and the use of a correct estimate of its value is highly recommended, especially at high burst pressures. However, peak overpressure profiles depend not only on the explosion energy, but also on the relationship between this energy, the generated overpressure and the scaled and actual distances. From this point of view, the estimates based on Baker's model (multiplying the explosion energy calculated with Brode equation by 2, to account for ground effects) appear to be only slightly sensible to the change of γ with the pressure, up to P values around 50 bar.

Figure 4 shows the peak overpressure profiles calculated at P = 200 bar: at this higher burst pressure, assuming the constant ambient pressure γ value (1.402) will give rise to higher peak overpressures than using the γ value at 200 bar (estimated as 1.719, according to Cramer, 1993). Figure 4 also shows the peak overpressure profiles calculated according to Prugh's model.

In agreement with the definition of the explosion energy, in this case no difference is observed between the curves calculated with the heat capacity ratios relevant to atmospheric or high pressure. From Figure 4 it can be also noticed that, despite the higher values of the explosion energy calculated by Brown's equation with respect to Brode's one (see Fig. 1), at high pressure, the peak overpressure profiles obtained according to Prugh's model fall below those of Baker's model, even if the differences decrease with increasing the actual distance r from the vessel. However, from this point of view, it should be remarked that, in the common practice, when applying Prugh's model, the energy values calculated with Brown equation (3) are not corrected to account for ground effects, even when the explosion source is located close to the ground, as for storage vessels (e.g. see the worked example of Prugh's model application in AIChE/CCPS, 2000). However, this procedure appears questionable, since shock wave reflection should be taken into consideration even in this case. The calculations according to Prugh's model were then repeated, multiplying by 2 the explosion energy calculated with Brown equation: Figure 5 compares the obtained results with the previous ones, assuming the heat capacity ratio at ambient pressure. It can be noticed that multiplying by 2 the explosion

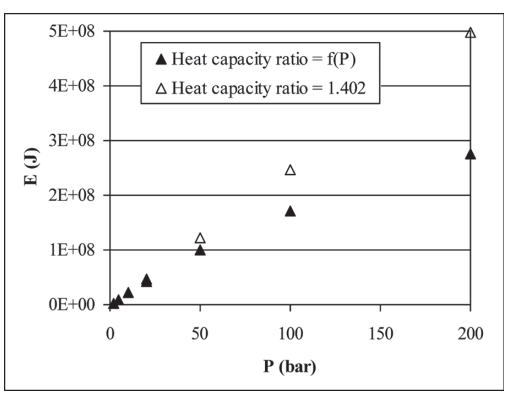

Figure 3. Explosion energy for a 10 m^3 vessel at 20°C, containing air according to Brode equation model.

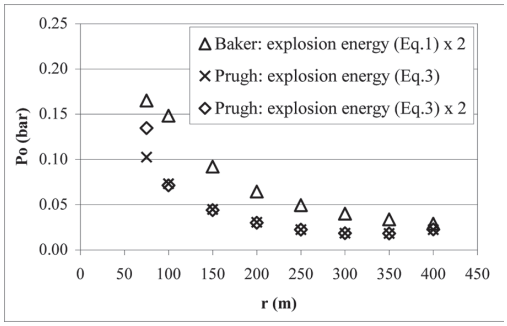

Figure 5. Overpressure profiles at 200 bar and 20°C for a 10 m^3 vessel containing air, according to Baker's and Prugh's models.; the heat capacity ratio was assumed $\gamma = 1.402$.

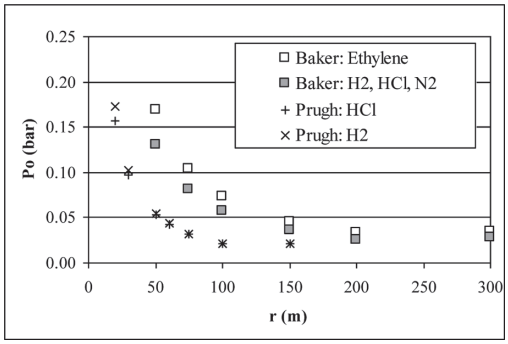

Figure 6. Overpressure profiles for a 10 m^3 vessel at 20°C and 20 bar, according to Baker's and Prugh's models.

energy value in the Prugh's model produced effects only in the near field, while the peak overpressure profiles does not change for $r > 100$ m. In any case, the overpressure values predicted according to Prugh's model still fall below those obtained using Baker's model, which appears to generally give more conservative results.

The influence of the physical properties of the substances can be better investigated by comparing the results obtained with different substances. Figures 6 and 7 compare the overpressure profiles obtained with Baker's and Prugh's models for the examined gases at pressure of 20 and 200 bar.

These substances have been adopted to cover a wide range of variability of both the heat capacity ratio and the molecular weight (see Table 1). In all cases the calculations were carried out based on the heat capacity ratio at ambient conditions; for Prugh's model the value deriving from Brown's equation (3) was used. Over all the investigated blast pressure ranges, the overpressure profiles calculated according to Baker's model remain

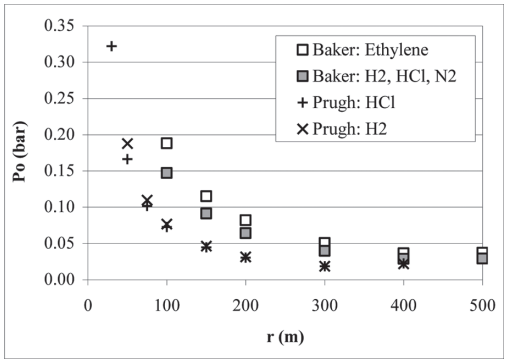

Figure 7. Overpressure profiles for a 10 m^3 vessel at 20°C and 200 bar, according to Baker's and Prugh's models.

always above those calculated according to Prugh's model, and the curves become closer as distance increases, and peak overpressure decreases. In other terms, at larger distances from the explosion source the choice of the model does not matter so much. Furthermore, the absolute distance between the peak overpressure curves increases with increasing the burst pressure value.

The differences observed among the results obtained from Baker's model for the different gases depend on the heat capacity ratio of the substance involved in the explosion, and the influence of this parameter appears noticeable, regardless of the narrow range of variation examined (1.22–1.41): γ values closer to the unity give rise to much higher values of the explosion energy, based on Brode's eq. (1) and, hence, to higher peak overpressure values, at fixed distance. Conversely, the influence of the physical properties of the substance appears much less remarkable for Prugh's model, where, together with the heat capacity ratio, also the molecular weight appears in the calculation of the pressure at the vessel surface, P_s, according to equation (4).

Figures 8 and 9 show the trend of P_s as a function of the heat capacity ratio and of the molecular weight of the gas, respectively.

It can be noticed that the influence of the heat capacity ratio on the pressure at the vessel surface is remarkable, especially at low γvalues and at high pressure: the value of P_s increases as the heat capacity ratio gets closer to the unity. The influence of the molecular weight of the gas on the pressure at the vessel surface appears even more remarkable, over the range of M values (2–58 kg/kmol) reported in Figure 9. By decreasing the molecular weight of the gas involved in the explosion, the value of P_s greatly increases, and, as already observed for the influence of the heat capacity ratio, the effect increases as the blast pressure increases.

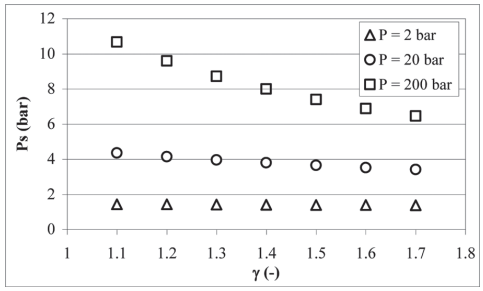

Figure 8. Trend of the pressure at the vessel surface vs. the heat capacity ratio for a 10 m^3 vessel at 20°C, containing a gas with molecular weight 28 kg/kmol.

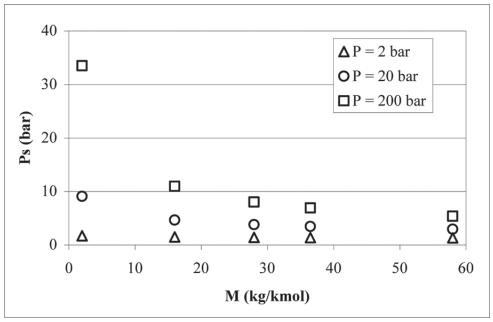

Figure 9. Trend of the pressure at the vessel surface vs. the molecular weight for a 10 m^3 vessel at 20°C, containing a gas with heat capacity ratio 1.4.

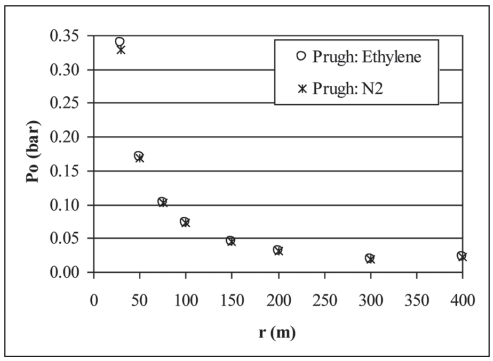

Figure 10. Overpressure profiles for a 10 m^3 vessel at 20°C according to Prugh's model: burst pressure 200 bar.

The actual influence of the heat capacity ratio and of the molecular weight of the gas on the overpressure profiles calculated with Prugh's model is shown in Figures 10 and 11: Figure 10 compares the results obtained for substance with the same molecular weight, but different heat capacity ratios,

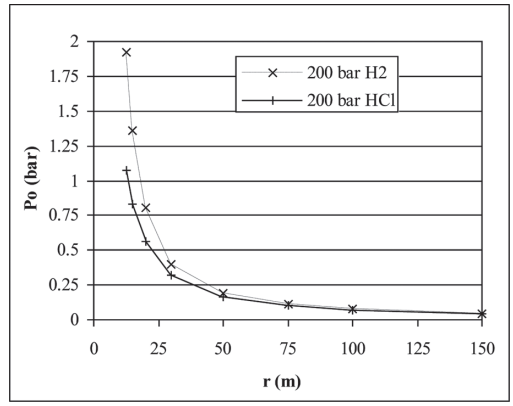

Figure 11. Overpressure profiles for a 10 m^3 vessel at 20°C according to Prugh's model: burst pressure 200 bar.

while Figure 11 compares those for substances with the same heat capacity ratio, but different molecular weight.

According to Prugh's model the influence of the heat capacity ratio seems negligible, even if, moving closer to the explosion centre, peak overpressure values are slightly higher for the substance with γ value closer to the unity. When reference is made to substances with different molecular weight, in the examined range 2–36.5 kg/kmol, (where the former refers to hydrogen and the latter to hydrogen chloride) the peak overpressure profile does not change appreciably. However, as the distance from the explosion decreases, higher peak overpressure values are observed for the substance with smaller molecular weight; this effect is more visible at high blast pressures. The influence of the molecular weight of the substance is more evident when applying Prugh's model in the near field, as shown in Figure 11.

3.3 *Influence of the vessel size*

The calculations of the overpressure profiles according to Baker's and Prugh's were repeated for differently sized vessels, namely 0.5 and 200 m^3. Increasing the vessel volume correspondingly increase the explosion energy for both models (eqs. 1 and 3), which linearly depends on this variable; an increase in peak overpressure also occurs, but for this parameter, the trend is less immediate than for explosion energy.

Figure 12 shows the results according to Baker's model, for vessels containing ethylene. A discontinuity can be observed in the curves, at low distance from the explosion, which is due to the varying adjustment factor for the overpressure for cylindrical vessels (Baker et al., 1975), which is a function

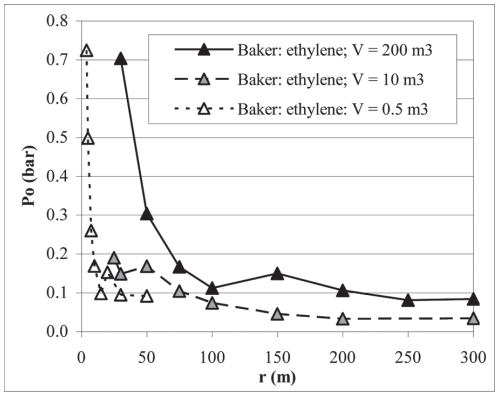

Figure 12. Overpressure profiles at 20°C according to Baker's model: burst pressure 20 bar.

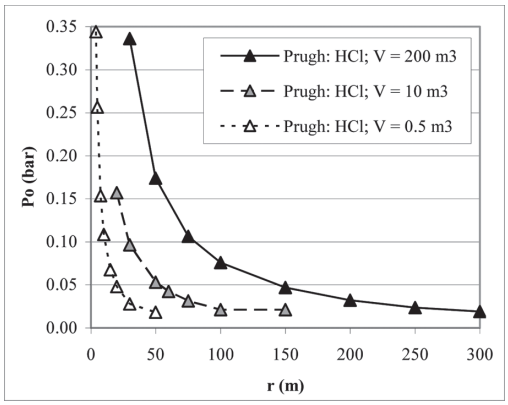

Figure 13. Overpressure profiles at 20°C according to Prugh's model: burst pressure 20 bar.

of $\overline{R}$. All the presented calculations were carried out for $\overline{R} > 2$; nevertheless, at $\overline{R} < 3.5$ the multiplier changes from 1.6, to 1.4 (in all previous graphs the reported values refer to $\overline{R} > 3.5$ and, therefore, no discontinuity is shown).

At 50 m from the explosion, where the same, lower, multiplier value holds for all vessels, the peak overpressures increase by a factor around 1.8 for each 20 time increase of the volume (from 0.5 to 10, and from 10 to 200 m^3).

Figure 13 shows the peak overpressure profiles calculated under the same operating conditions according to Prugh's model. At 50 m from the explosion the peak overpressures increase by a factor around 3 for each 20 time increase of the volume (from 0.5 to 10, and from 10 to 200 m^3), exhibiting a much greater dependence of the peak overpressure on the vessel volume, with respect to Baker's model.

3.4 *Influence of the temperature*

The results from Baker's model are not influenced by the temperature, since this variable does not appear in the calculations of the explosion energy, nor in those of peak pressure profiles. On the contrary, Prugh's model estimates are dependent on the temperature, which appears both in the estimate of the explosion energy and in the calculations of the maximum overpressure of the shock wave, according to equations (3) and (4).

Figure 14 compares the values of the explosion energy, calculated with Brown's equation, for the 10 m^3 vessel at different temperatures; the examined range includes usual ambient temperatures (–10/+40°C) and some higher values which may occur in process vessels. It can be noticed that the explosion energy calculated according to the Brown equation (3) appears remarkably influenced by this variable: by increasing the ambient temperature from –10°C to +40°C, the explosion energy increases, by a factor equal to 1.19; by further increasing the temperature, at 300°C, the explosion energy is almost double than at ambient temperature. As already shown in Figure 1, the explosion energy values calculated by the Brown equation do not depend on the selected gas.

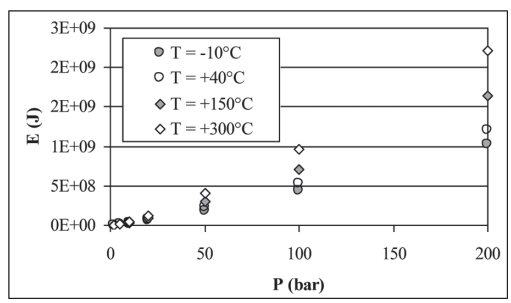

Figure 14. Explosion energy for a 10 m^3 vessel, according to Brown equation.

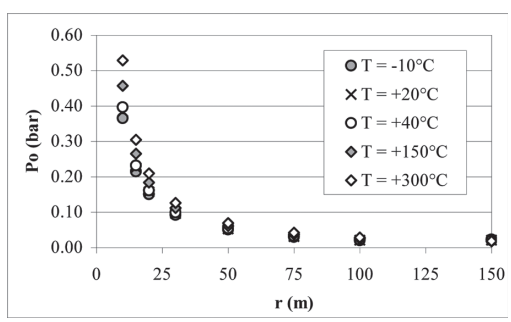

Figure 15. Overpressure profiles according to Prugh's model for a 10 m^3 vessel containing HCl: burst pressure 20 bar.

The overpressure profiles calculated for the explosion of a 10 m^3 vessel containing HCl at 20 bar and at different temperatures, according to Prugh's model are compared in Figure 15. The curves relevant to higher temperatures give rise to higher values of the peak overpressure: the influence appears remarkable in the near field, while at large distances (above 100 m, with reference to the examined study case) all the overpressure profiles almost collapse on the same curve, independently of the temperature.

4 DISCUSSION

Both the models analyzed are based on simplifying hypotheses concerning the estimation of the explosion energy, which, on one side, speed up calculations, but, on the other side, do not allow to properly simulate the involved phenomena. As a matter of fact, the explosion energy values estimated according to Brode's and Brown's equations may be remarkably different: the gas heat capacity ratio greatly affects the explosion energy calculated by the Brode equation, while, according to the Brown equation, no physical property of the gas enters in the explosion energy calculation. Therefore, greater uncertainty exists in the estimates based on Brode equation, taking into account that the difference $(\gamma - 1)$ at the denominator of eq.(1) is very small. Moreover, most of the available values of the heat capacity ratio are given at ambient temperature and atmospheric pressure: the influence of the pressure is not negligible, and may decrease the estimated explosion energy, especially at high burst pressure. Further uncertainty affects also the value of the explosion energy to be inserted in the expressions for estimating the peak overpressure profiles: following Baker's method, the value calculated from Brode equation should be doubled to account for ground effects, while this correction is not reported for Prugh's method.

Both methods cannot be safely extrapolated in the near field, and both require some "adjustment" procedure: using Baker's method, a discontinuity will occur, not only at the scaled distance $\overline{R} = 2$, limit for the near field zone, but also at $\overline{R} = 3.5$, due to a multiplier factor to be used for cylindrical vessels, which change its value from 1.6 to 1.4 at $\overline{R} = 3.5$ (AIChE/CCPS, 2000). On the contrary, Prugh's method makes use of a virtual distance, to properly adjust the distance from the explosion centre, and no discontinuity is observed in the peak overpressure profiles. Nevertheless, in the near field, the estimates obtained applying both methods likely suffer from greater uncertainty; on the other hand, it should be honestly admitted that, in the near field, peak overpressure values often largely exceed the damage thresholds of interest, and, therefore, most interest is devoted to the estimates in the far field. Different overpressure profiles have been obtained by simulating the same study cases with Baker's and Prugh models, even at distances exceeding the "near field" as defined above. In all cases, the estimates according to Baker's model give rise to higher values of the peak overpressure, at any given distance, with respect to Prugh's one. This difference does not derive from the multiplying factor of 2 used for the explosion energy in Baker's model, since, applying the same correction in Prugh's model, peak overpressure values slightly increase only in the near field.

Taking into account that the peak overpressure profiles are generally used to estimate damage distances when carrying out consequence analysis, using Baker's model will give conservative results.

The physical properties of the involved gases affect the overpressure profiles: higher heat capacity ratio results in lower peak overpressure values, in agreement with the influence of this parameter on the explosion energy. In Prugh's model, the involved physical properties (heat capacity ratio and molecular weight of the gas) exhibit a limited influence on the results, with respect to Baker's model. However, a decrease of the heat capacity ratio and of the molecular weight results in higher peak overpressures, especially in the near field and at high burst pressure.

For both models, increasing the vessel volume will linearly increase the explosion energy, but the effects on the peak overpressure profiles are something different, especially at moderate distance from the explosion, since, as usual, in the very far field all the peak overpressure profiles converge to almost a single curve. Close to the vessel (but not properly in the "near" field), Prugh's model appears much more sensitive to the vessel size than Baker's one. As a rough "rule of thumb" increasing 20 times the volume of the vessel will double the peak overpressure values according to Baker's model and will triplicate those estimated with Prugh's model.

The operating temperature does not affect the results of Baker's model, while the values calculated with Prugh's model increase with increasing the temperature. Accordingly, when the temperature is well above ambient values, the use of Prugh model may be preferred, to obtain conservative estimates.

5 CONCLUSIONS

The obtained results allowed to draw some considerations concerning the most commonly used models for estimating the overpressure profiles originated by the physical explosion of vessels containing compressed gases and their dependency on the

physical properties of the gas and some operating parameters. Their estimates suffer from some uncertainties, implicit in the models, concerning the way the explosion energy is calculated, and the near field is modeled. Baker's model appears to give conservative estimates, and may be preferred in most cases, but requires particular attention in the selection of the proper heat capacity ratio; Prugh's model is less influenced by the physical properties of the gas, but more sensitive to the temperature, and may be preferred for high temperature vessels. In the far range all the estimated peak overpressure profiles converge, and the differences become negligible.

A study of determination of the design accidental fire load based on the quantitative Fire Risk Assessment with the treatment of uncertainty

B. Chu & D. Chang
Korea Advanced Institute of Science and Technology, Daejoen, Korea

ABSTRACT: This study proposed the new methodology for determining the Design Accidental Load (DAL) fire for further structural response analysis based on the probabilistic risk assessment with treatment of uncertainty. Although the probabilistic risk assessment procedure is regarded as the most rational and sophisticated method for determination of DAL fire, it is always subject to various uncertainty. There are three main sources of uncertainty: assumptions and simplifications, selection of representative scenarios, and probabilistic and statistical approaches. To increase the confidence of results and reduce the risk of making wrong decision, inherent uncertainty should be suitably treated and gives additional information about uncertainty. Latin Hypercube Sampling (LHS) technique is used throughout the procedure to select representative scenarios and cover the full extent of the parameter for treating uncertainty. The confidence interval and error factor are introduced to define probability distributions of parameters. With the proposed methodology, distribution of fire exceedance plots was obtained and instructed average and variance of DAL. With these additional information, the confidence in the results increased and the risk of making wrong decision was reduced.

1 INTRODUCTION

Offshore installations, which are operated in extreme marine environment, are essentially threatened by the various hazards to cause harms: injury or death of humans, damage to asset, degradation of the physical and biological environment, and interruption of oil and gas production and disruption of business (Spouge 1999).

There are four main hazards: ship collision, dropped objects, fire, and explosion. Specially, the topsides of the offshore platform, which treats combustible oil and gas, are always exposed hydrocarbon fire hazards bring out a high consequence disaster. Moreover, damages from fire accidents have increasingly been astronomical in accordance with the growing scale and complexity of the recent plants, as seen in the Deepwater Horizon incident.

In this situation, a concept of "Design Accidental Loads (DAL)" is introduced to ensure safety of offshore installations. The purpose of identifying and assessing accidental loads is to verify that accidents do not cause risks exceeding defined criteria for design of structures (ABS 2013, DNV 2010).

DAL is determined by Quantitative Fire Risk Assessment (FRA) as a rational and rigorous method for the risk estimation. The FRA uses a systematic analysis to quantify risks, which are expressed as a combination of frequency and consequences, and to provide input to a decision-making process. Consequently, it has made great advances in recent decades thanks to plentiful theoretical investigations and experiments.

FABIG (2010) proposes the approach for determining the DAL fire based on FRA with Computational Fluid Dynamics (CFD) and calculating temperature and strain in structure. This procedure is divided into two sections as shown in Figure 1. The main output from section 1 is the exceedance

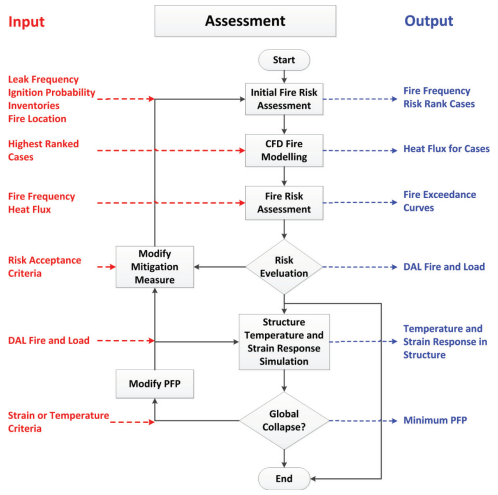

Figure 1. Schematic flow diagram of probabilistic fire load procedure.

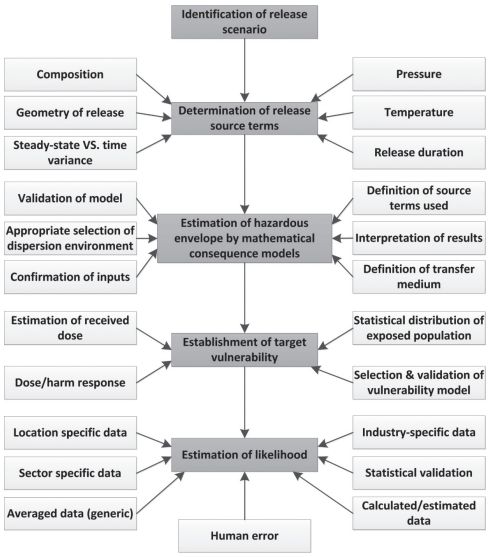

Figure 2. Sources of uncertainty in risk assessment.

curve and the DAL fire which is used as input in the structural response calculations.

Even though the FRA has made much advance in recent decades, most types of them have overlooked inherent uncertainty. HSE (2006) defines several sources of uncertainty in the FRA for hydrocarbon fire hazards as shown in Figure 2. They proposed inaccuracy and incompleteness from selecting representative scenarios and considered conservative assumptions to deal with uncertainty in the consequence and frequency estimation.

This study presents the uncertainty of the probabilistic fire load procedure of FABIG Technical Note 11. The main limitations of the procedure are described as sources of the uncertainty. A case study is also performed to involve uncertainty of the procedure. This study only covers section 1 of the procedure.

2 MAIN SOURCES OF UNCERTAINTY IN THE PROBABILISTIC FIRE LOAD PROCEDURE

As the first step of determining fire load, the initial fire risk assessment is performed to assign risk ranking to potential cases by combining leak frequency, ignition probability, segment inventories and fire types. Representative cases with the highest potential risk are selected for further detailed consequence analysis.

Within representative leak cases, fire scenarios to be modelled are selected. For the further consequence estimation with CFD, the detailed numerical data (e.g., hole size, wind direction, wind speed etc.) is needed as input and assumptions in the analysis. It is obvious that considering more scenarios will make the measured risks more accurate. However, since the scenario is the sequential combination of numerous parameters, it is absolutely impossible to model the total number of cases and possibilities due to time constraints. Accordingly, analysts have a challenge to select the limited number of parameters, which have a vital influences on the risks, and scenarios, which represent possible events. This work, despite of its significance to the risk assessment, offers serious causes of uncertainty due to incompleteness of selecting major parameters and credible scenarios.

Especially, selecting representative values of leak size is the most crucial part in the selection of scenario selection. Hydrocarbon fire scenarios begin with a leak and estimated risks are effected most by selecting initial leak sizes. Although the selection of leak sizes is one of the biggest uncertain part causing inaccuracy in the FRA, there is no definite basis and criterion for choosing representative values. Typically, median values within the range of leak size which is qualitatively categorized are selected as input parameters for the further analysis.

In the FRA, consequence of the credible scenarios is modeled by CFD simulations to predict fire profiles and damages. Although precision of CFD simulations largely depends on the ability of simulators, the numerical algorithm of CFD methods for the offshore fire consequences has been advanced enough to show accurate solutions comparing the experimental data (Paik et al., 2010). Thus, this type of uncertainty is so small and can be ignored in the QRA for hydrocarbon fire risks. However, one thing that is certain is that CFD results should be valid when the each of the credible scenarios is well defined.

Fire frequency in the FRA is expressed by a combination of leak frequency and ignition probability. Quantification of frequency is fundamentally based on probabilistic and statistical approach using historical records and statistical data for calculating fire frequency. The main benefits of this approach are making the analysis relatively simple and providing objective criteria from previous experiences for solving problems.

Use of statistical value means selecting an average value as an input variable and ignoring the details in each case. For instance, leak frequency of the target segment may differ from the statistical average value, but it is difficult to consider a specific factor about the detailed difference between them.

The obvious problem of probabilistic and statistical approach is that the approach comprehensively overlooks inaccuracy and unsuitability included in most of statistical data. This type of uncertainty would propagate throughout the analysis and be a main source which makes the measured risk insecure and unconfident.

Especially, offshore hydrocarbon fire accidents are typically high consequence and low frequency disasters. Zio and Aven (2013) emphasized that this type of accidents was typically accompanied by uncertainty from a scarcity of empirical and statistical information data compared with its occurrence.

This uncertainty can arise from following sources (Spouge 1999): *small number of events* which may contribute to the incredibility of the derived frequency from distorted statistics; *incomplete recording of events* due to omission and loss of event data; *inadequate screening of events* due to wrongly eliminating or leaving events; *inaccurate measures of exposure* arising from screening and underreporting of data on accident events; *frequency trends* in accordance with safety improvements and changing related standards; and *inapplicability of frequency data* due to overlooking difference of the collected age and installations. In the case of the FRA with respect to new systems or/and historically rare events, this uncertainty is much larger due to highly limited information and should be treated in suitable ways.

Fire exceedance plot as main output of the FRA is established by combining consequence and frequency analysis results as shown in Figure 3. The DAL fire of the target system is obtained on the x-axis for a given acceptance criteria. The criteria used for selecting the DAL fire are largely dependent on the social, economical and cultural factors (Zio and Aven 2013). Therefore, the DAL fire varies according to criteria analyst chooses.

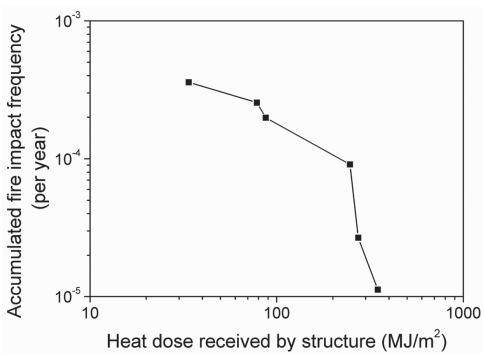

Figure 3. Fire exceedance plot.

3 TREATMENT OF UNCERTAINTYY

In the previous section, we investigated main sources of uncertainty in the probabilistic fire load procedure. There are many parameters to be used for the risk assessment. Each parameter is uncertain and can be expressed by probability distributions. For instance, when leak size distributions are represented by uniform distribution with specific ranges. Representative values are randomly selected in accordance with their distributions. These sets of values compose the sets of representative scenarios and are also used as input for simulating time-dependent leak rate profile and radiation intensity of fire.

Another concern is inherent uncertainty in the statistical data used in frequency analysis. They should be expressed by intervals, not one value, which involve information about uncertainty. This interval, which is called a confidence range, has the maximum and minimum value with statistical average value. The both sides of end points are determined by error factors of average value. For example, in the lognormal distribution, if the target segment has 4.691×10^{-2} of a median value and 10 of an error factor for 1 kg/s of leak rate, confidence range is from 4.691×10^{-3} to 4.691×10^{-1}. Other frequencies and probabilities can be also presented as confidence ranges. And events likelihood can be analytically calculated by statistical theory depending on their dependency such as leak frequency, ignition probability, and conditional probability of failure cases. Estimated confidence range of events likelihood can be used interval form between the minimum and maximum value, or randomly sampled from lognormal distribution function.

4 CASE STUDY

4.1 *Case definition*

The target system is divided into two isolatable segments by ESD valves. Inventory conditions within an isolatable section are identical. In the event of a leak, only the inventory in an isolatable section is assumed to be available if the ESD valves close as intended. The isolatable segments and major gas inventories are listed in Table 1.

4.2 *Selection of leak size*

Leak size is categorized into three different ranges which are small, medium, and large. The defined ranges vary with characteristics of the segment including inventory conditions and facility characteristics.

Table 1. Isolatable segments.

Item	Case 1	Case 2
Case name	LP	HP
Leak medium	Gas	Gas
Pressure, bar	10	50
Temperature, K	300	300
Molecular weight, kg/kmole	16.04	16.04
Ratio of specific gas	1.328	1.463
Inventory of gas in segment, kg	558	1342

Table 2. Initial leak rate.

Leak category	Small	Medium	Large
Leak rate range, kg/s	0.1~2	2~15	> 15
Representative initial rates, kg/s	0.5	5	20

The Latin Hypercube Sampling (LHS) technique is employed to extract random values from each uniform distribution of leak rate range, and each sampling iteration forms a set of representative scenarios. For the target system, this iteration is repeated 100 times, and 100 sets of representative scenarios are randomly produced for estimating 100 different exceedance plots.

4.3 *Fire load modelling*

Fire load is estimated by following values listed in Table 3 (Scandpower 2004).

With above values, heat dose is governed by the leak rate variation. It is assumed that ESD and blowdown work normally for all leak cases.

4.4 *Frequency analysis*

Estimating fire frequency should include information of uncertainty. A lognormal distribution is allocated for describing uncertainty of fire frequency. Table 4 shows detailed information about fire frequency for Case 2. From these distributions, 100 values of fire frequency are obtained using the LHS technique and assigned to 100 set of representative scenarios.

It is assumed that impact probabilities such as fire duration, leak direction, and fire size are 1 for all leak cases.

4.5 *Risk assessment: fire exceedance plot*

The fire exceedance plots are established by combining heat dose and end event frequency. Each set of representative scenarios from the LHS technique makes different fire exceedance plots as shown in Figure 4.

Table 3. Incident heat fluxes for jet fire.

	For leak rates m > 2kg/s	For leak rates m > 0.1kg/s
Local peak heat load, kW/m2	350	250
Global average heat load, kW/m2	0	100

Table 4. Incident heat fluxes for jet fire.

Leak size category	Small	Medium	Large
Best-estimate value, per year	1.12E-5	6..44E-5	1.07E-4
Medium value, per year	3.59E-6	2.06E-5	3.43E-5
Lower confidence limit, per year	2.99E-7	1.71E-6	2.86E-6
Upper confidence limit, per year	4.31E-5	2.47E-4	4.11E-4
Error factor	12	12	12

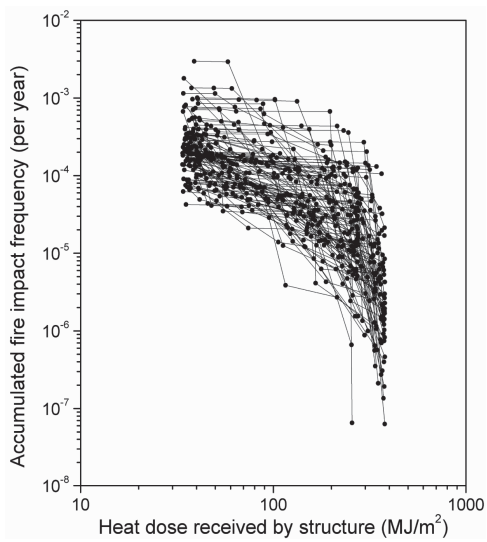

Figure 4. Fire exceedance plots with treatment of uncertainty.

5 CONCLUSION

The main sources of uncertainty in the probabilistic fire load procedure were discussed in this study. Parameter uncertainty can be expressed by probability distributions and treated by LHS sampling technique. 100 different exceedance plots were obtained over the sets of representative scenarios. Theses plots indicated the inaccuracy and discredit of previous DAL procedure, which had used only one fire exceedance plot.

Distribution of fire exceedance plots on the x-axis came from selection of different leak sizes in each set of representative scenarios. On the other hand, distribution of fire exceedance plots on the y-axis included information of uncertainty in fire frequency analysis. As a result, different fire exceedance plots involved information about uncertainty of the probabilistic fire load procedure. However, to cover the full extent of parameters, much more scenarios should be generated and simulated. In this situation, the non-CFD model was only qualified for the consequence analysis due to simple input and output.

Sobol's sensitivity analysis of stability problems of steel beams

Z. Kala & J. Kala
Faculty of Civil Engineering, Brno University of Technology, Brno, Czech Republic

ABSTRACT: The presented article reviews Sobol's sensitivity analysis of the effects of initial imperfections on the load carrying capacity of pin-ended steel I-beams subjected to bending. Failure due to lateral-torsional buckling occurs prior to the attainment of the full in-plane carrying capacity if these elements are not properly braced against lateral deflection and twisting. The load carrying capacity was evaluated using SHELL finite elements and non-linear computational methods of the ANSYS programme. The load carrying capacity is an output random quantity dependent on input random imperfections. The effect of residual stress was also taken into consideration. Latin Hypercube Sampling Method was used for sampling simulations.

1 INTRODUCTION

Majority of thin-walled beams are slender and have open section shapes. I-beams loaded in flexure have much higher strength and stiffness in the plane of the major axis, i.e., plane in which the loads are applied, than in the plane of the minor axis. Failure of the beam, due to lateral buckling of the compression flange, occurs if the I-beam is not supported in the lateral direction, i.e. perpendicular to the plane of bending, and the flexural load reaches its critical limit. The top of the I-beam is in compression, and the bottom is in tension. The cross section twists in torsion during lateral buckling of the compression flange. Failure then occurs due to bending or torsion rather than direct compression of the beam.

Generally, beams have many imperfections (geometrical and material), which can decrease its load carrying capacity. The article studies the influence of initial geometrical and material imperfections on the static load carrying capacity. Imperfections are generally random, quantifiable in a statistical sense with certain probability distributions. Non-linear analyses were performed using the finite element method of the ANSYS programme. Most of the input imperfections were measured. The Latin Hypercube Sampling method (McKey et al. 1979, Iman et al. 1980) was then employed for the computation of their random realizations using their histograms (Kala et al. 2009). Residual stresses, which influence the variability of the load carrying capacity with its random variability, were taken into consideration in the computational model. Sobol's sensitivity analysis (Sobol 1993, Saltelli et al. 2004) was employed in the study.

2 COMPUTATIONAL MODEL

2.1 *Shell finite elements and meshing*

The web and flanges of the beam were meshed in the programme ANSYS using shell elements SHELL 181, see Figure 1. Shell elements can typically be used for slender beams with negligible thickness compared to its length and width. Deflections of the nodes in the web of profile IPE 20 in the direction perpendicular to web were fixed at the edge of the loaded beam. On the lower flange of this edge, deflections in the direction perpendicular to the flange were also fixed. The upper flange was left free.

2.2 *Non-linear computational methods*

The Euler method based on proportional loading was applied in combination with the Newton-

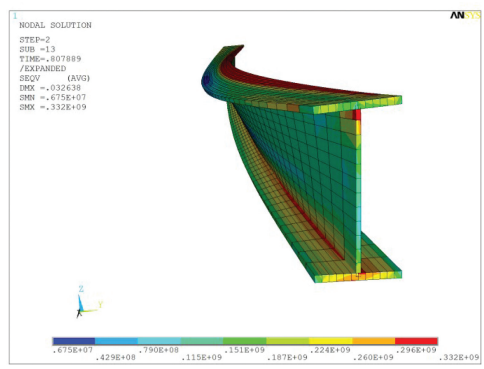

Figure 1. Lateral beam buckling of the shell model.

Raphson method for the geometrical and material non-linear FEM analysis (Kala & Kala 2010). The load carrying capacity was determined as the loading constant at which the determinant of incremental stiffness matrix K_t of the structure approaches zero with certain accuracy. Automatic control of the loading step was used with the Euler method as an accuracy of 0.1% was required for the determination of the load carrying capacity. Bilinear kinematic material strengthening was assumed. Furthermore, it was assumed that initial plastification of the steel occurs when Mises stress exceeds the yield strength.

3 INITIAL IMPERFECTIONS

3.1 *Geometric imperfections*

The statistical characteristics of the sectional height h, sectional width b, web thickness t_1, and flange thickness t_2 of profile IPE 220 were considered according to (Kala et al. 2009). The upper and the lower flange thicknesses were considered as one random quantity t_2. The upper and lower flange heights were also considered as one random quantity b. These suppositions are correct, due to the strong correlation between the geometrical characteristics of the upper and lower flanges (Kala et al. 2009). A more exact model would require that the geometrical characteristics of the upper and lower flange are considered with correlation according to (Kala et al. 2009).

Initial lateral deflection and twisting of the element axis was modelled in the form of a half sine curve, see Figure 1. Amplitudes of initial lateral deflection e_0 and initial twisting φ_0 were considered as two statistically independent quantities. It is different from the approach in which the initial geometrical imperfections are assumed to follow the shape of the first eigenmode pertaining to lateral-torsional buckling, which is conservative but do not necessarily correspond with real imperfections that would be observed during experimental research. The amplitude e_0 of initial axial deflection was introduced as a random quantity with a Gauss density function. It was assumed that 95% of the realizations of random imperfection e_0 of the beam of profile IPE 220 lay within the tolerance limit 0.15% of the beam length L acc. to the European standard EN 10034.

3.2 *Material characteristics*

The presented study utilizes experimentally obtained results of material and geometrical characteristics of steel products produced by a dominant Czech producer. The analysis of the strength characteristics of plates were published, for e.g., in (Strauss et al. 2006, Kala et al. 2009). The statistical characteristics of yield strength of hot-rolled IPE members were considered acc. to results published in (Melcher et al. 2004). The yield strength is a basic strength characteristic, which is fundamentally limited by the ultimate limit state in the case of short or lateral braced beams.

Histograms of yield strength values obtained from experimental research are the basic source of input data of a series of reliability analysis; see for e.g., (Kala 2010, Kala 2012, Kala & Kala 2012, Kala & Kala 2013, Kala 2013). Young's modulus E was considered acc. to results of experimental research to have a Gaussian distribution with mean value 210 GPa and standard deviation 12.6 GPa (Soares 1988).

3.3 *Residual stress*

In hot-rolled steel members unsteady cross-sectional cooling down occurs after hot rolling. Cooling down occurs more rapidly at the flange edge and at the middle of the web. The primary tendency is the stabilization of volume changes during shrinkage.

The subsequent slower cooling down and shrinkage of thermally more exposed internal cross-sectional parts in the contact regions of the flanges and web results in compressive stress in the previously cooled down and volume stabilized regions. Shrinkage stress arises at the flange edge and in the web middle. Redistribution of these primary technology states of stress components can continue due to loading and unloading of the beam.

Residual stress was considered with mean value 70 MPa, standard deviation 20 MPa and triangular distribution on the flanges and web acc. to (Kala and Kala 2010), see Figure 2.

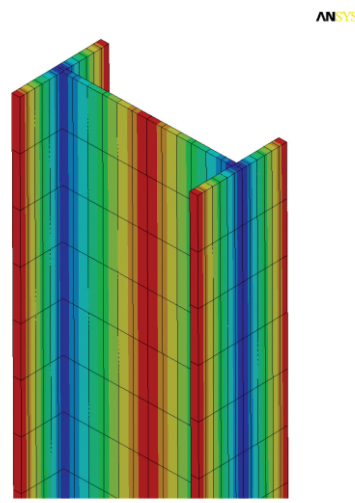

Figure 2. Model of residual stress.

Table 1. Input random quantities.

No.	Name	Symbol	Mean value	Std. deviation
1.	Sectional height	h^*	220.2 mm	0.975 mm
2.	Sectional width	b^*	110.5 mm	1.093 mm
3.	Web thickness	t_1	5.9 mm	0.247 mm
4.	Flange thickness	t_2	9.2 mm	0.421 mm
5.	Initial deflection	e_0	0	2.265 mm
6.	Initial twist	φ_0	0	0.51°
7.	Yield strength	f_y	297.3 MPa	16.8 MPa
8.	Young's modulus	E	210 GPa	12.6 MPa
9.	Residual stress	rs	70 MPa	20 MPa

*Histogram; **Gauss probability density function.

3.4 *Input random quantities*

Input random quantities were considered with histograms or Gauss density functions. All the input characteristics, which are clearly listed in Table 1, are statistically independent.

4 SENSITIVITY ANALYSIS

4.1 *What is sensitivity analysis*

Within the scope of modelling, sensitivity analysis means different things to different people, see for e.g. (Arwade et al. 2010, Mang et al. 2009, Kala 2011, Gottvald & Kala 2012). With the development of new concepts of reliability analysis, these procedures can contribute to a qualitative improvement of structural reliability analysis. Reliability of steel structures is dependent on the variance of input imperfections. In structural engineering, results of sensitivity analysis can be used for the optimization of control activities during production, which are aimed at lowering the variance of studied quantities.

4.2 *Sampling based methods*

Sampling based methods for sensitivity analysis are used to generate and explore mappings from uncertain analysis inputs to analysis results (Saltelli et al. 2004). If inputs values X_i are known unambiguously, then Y can be determined and presented as the unique outcome of the analysis. However, in majority of cases there is uncertainty with respect to the choice of appropriate values of inputs X_i, resulting in uncertainty in the value of Y (Saltelli et al. 2004). Uncertainty in inputs X_i and its associated effect on Y presents two closely related questions, i.e.: What is the uncertainty in Y, given the uncertainty in X_i? How important are the individual elements of X_i with respect to the uncertainty in Y? Attempts to answer these two questions are typically referred to as uncertainty analysis and sensitivity analysis, respectively.

4.3 *Sobol's sensitivity analysis*

Ilja M. Sobol, a mathematician, worked out the coherent concept of sensitivity analysis, which enables the analysis of the influence of arbitrary subgroups of input factors (doubles, triples, etc.) on a monitored output (Sobol 1993). Sobol's first order sensitivity index may be written as:

$$S_i = \frac{V\left(E\left(Y|X_i\right)\right)}{V\left(Y\right)} \tag{1}$$

S_i is a measure of the first order (for e.g. additive) effect (the so-called main effect) of X_i on the model output Y. The second order sensitivity index S_{ij} is the interaction term (2) between factors X_i, X_j, which captures that part of the response of Y to X_i, X_j that cannot be written as a superposition of the separate effects due to X_j and X_j:

$$S_{ij} = \frac{V\left(E\left(Y|X_i, X_j\right)\right)}{V\left(Y\right)} - S_i - S_j \tag{2}$$

Other Sobol's sensitivity indices enabling the quantification of higher order interactions may be expressed similarly. The sum of all sensitivity indices must be equal to 1:

$$\sum_i S_i + \sum_i \sum_{j>i} S_{ij} + \sum_i \sum_{j>i} \sum_{k>j} S_{ijk} + \cdots + S_{123\ldots M} = 1 \tag{3}$$

Sobol's sensitivity analysis of the influence of input imperfections (random inputs X_i from Table 1) on the load carrying capacity (random output Y) was performed in the presented study.

5 SENSITIVITY ANALYSIS RESULTS

The Latin Hypercube Sampling (LHS) method was used for the evaluation of sensitivity indices (McKey et al. 1979, Iman et al. 1980). The model output Y is the load carrying capacity evaluated in each simulation run of the LHS method. The conditional random arithmetical mean was evaluated for 330 simulation runs. The variance was also calculated for 330 simulation runs. All input random imperfections were considered as random quantities for the evaluation of the variance V(Y) of the load carrying capacity. 9000 simulation runs were applied. The second-order sensitivity indices S_{ij} were calculated analogously. The influence of imperfections on the load carrying capacity changes with increasing slenderness of the beam. Non-dimensional slenderness can be calculated acc. to EUROCODE 3 as:

$$\overline{\lambda}_{LT} = \sqrt{\frac{W_{pl,y} f_{y,n}}{M_{cr,n}}} \tag{4}$$

where $W_{pl,y}$ = 285.4 mm^3 is the nominal plastic sectional modulus of the cross section of profile IPE220, $f_{y,n}$ = 235 MPa is the nominal value of yield strength, and $M_{cr,n}$ is the elastic critical moment of a bilaterally hinged beam. A beam of length L = 2.96 m was considered. The non-dimensional slenderness calculated acc. to (4) is 0.8. Results of Sobol's sensitivity analysis are presented in Figure 3. It is possible to determine initial imperfections that can be fixed or simplified.

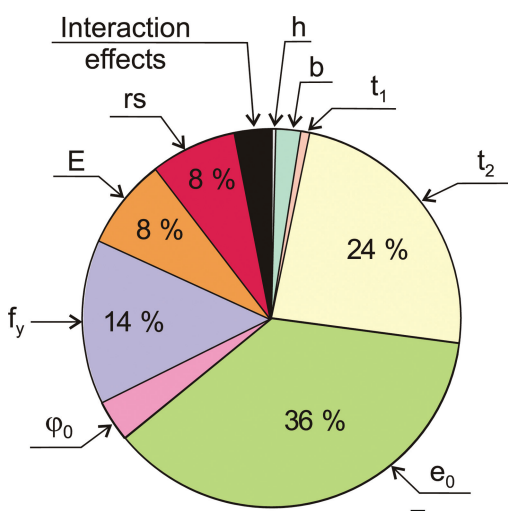

Figure 3. Sensitivity analysis results for $\overline{\lambda}_{LT}$ = 0.8.

6 CONCLUSION

The presented paper reviews bending stability problems of a simply supported hot-rolled I-beam with equal end moments. Obtained results of sensitivity analysis show that the load carrying capacity is most sensitive to the variability of the amplitude of initial deflection e_0. The variance of the load carrying capacity is minimal when e_0 is fixed (frozen), i.e. considered a constant quantity. Other crucial quantities include the flange thickness t_2, yield strength f_y, and residual stress rs. The variability of these imperfections can be influenced positively by manufacturing technologies. The variability of the amplitude of initial twist φ_0 has relatively little influence on the load carrying capacity. Therefore change in its variance does not affect the variance of the load carrying capacity significantly. The variance of this quantity need not be monitored so closely during manufacturing of hot-rolled steel beams. Furthermore, the tolerance standards do not state too strict rules for the adherence of its limits. Young's modulus is an example of an imperfection whose variability is insensitive to changes in technology.

The article was elaborated within the framework of projects of GAČR 14-17997S and VG20132015109.

Quantitative vs. qualitative treatment of uncertain assumptions in risk assessment

C. Berner & R. Flage
University of Stavanger, Stavanger, Norway

ABSTRACT: The results of quantitative risk assessments are conditional on the background knowledge that the assessments are based on, including phenomenological understanding, models, data and expert statements used, as well as assumptions made. Risk indices established in the risk assessment may have a more or less solid foundation, depending for example on the validity of assumptions made. Poor models, lack of data or simplistic assumptions are potential sources of uncertainty in a risk assessment. In the present paper, we review both quantitative and semi-quantitative methods to treat such uncertainties. We then analyse different situations faced when performing a risk assessment, considering beliefs about assumption deviation, sensitivity of the risk index, and the overall strength of knowledge involved. We conclude that there is a need to balance the use of the different approaches, and to this end we present some recommendations and guidance on how perform this balancing.

1 INTRODUCTION

When performing a risk assessment a number of assumptions are typically made. In a risk assessment of an offshore oil and gas producing platform, assumptions may for example relate to:

- the number of personnel on board the platform and the distribution of these between different parts of the platform;
- the impact energy that the platform will be able to withstand in the event of a ship collision; or
- the blowout rate in case of an uncontrolled blowout.

See Vinnem (2007) for details regarding risk assessment of offshore risk assessments. The results of the risk assessment are then conditional on these assumptions holding true, and do not reflect the possibility that, in reality, the conditions may deviate from what has been assumed.

The combined set of assumptions underlying a quantitative risk assessment may be summarized in an appendix to the risk assessment report, perhaps with a comment that it is important to be aware that the results and conclusions are only valid so long as the assumptions are valid. Other times assumptions are further highlighted by including a sensitivity analysis, giving an understanding and possibly a ranking of which assumptions are most important. Assumptions might hide uncertainties Aven (2010), and it is therefore important that they are treated and communicated in a suitable manner.

A risk assessment less reliant on assumptions is always preferable. Relying too heavily on assumptions could in some cases place undesirable restrictions on carrying out a specific activity, creating situations where a strong focus on fulfilment of the assumptions is required to secure the validity of the risk analysis. Ideally, any uncertain condition should be accounted for using some representation of uncertainty; however, the solution is often rather to make conservative assumptions, making the results more robust but at the same time not properly reflecting uncertainties.

Still, some assumptions are always required to establish the basis of either quantitative or qualitative risk assessments. In the present paper we consider the following setting: An unknown quantity Y is defined denoting some aspect of loss, for example the number of fatalities. A probabilistic risk index R in the form of the (possibly normalised) expected value of Y is defined, linking the expected value of Y with some other unknown quantity X. That is, conditional on X we have:

$$R(X) = cE[Y|X,K].$$

and conditional on $X = x_0$ we have

$$R(x_0) = cE[Y|X = x_0,K].$$

where c is a normalising constant and K is the background knowledge that the risk index is based on, including phenomenological knowledge, models, data, expert statements and assumptions. The

class of risk indices included in the above definition includes probabilities of specific events (e.g. individual risk, IR, defined as the probability of death for a randomly selected person in a population), frequencies (e.g. fatal accident rate, FAR, defined as the expected number of fatalities per 10^8 exposed hours) and the probability/frequency distribution of Y (e.g. f-N curve, defined as the frequency of events with N or more fatalities, here taking $N = Y =$ number of fatalities). For a comprehensive overview of risk measures/indices for loss of life and economic damage, including those mentioned above, see Jonkman et al. (2003); see also Vinnem (2007) for such indices in the context of offshore risk assessment in particular.

In any given risk assessment there will be a number of assumptions; more or less explicitly stated. In this paper we first simplify and focus on a single assumption that may be formulated as $X = x_0$ for some fixed value x_0. Later we will discuss the effect of several assumptions. Examples of assumptions made in offshore risk assessments are:

- "The blowout potential is 80 kg/s" (i.e. $X = x_0 = 80$, where X is the blowout rate).
- "The number of immediate fatalities for a blowout given immediate ignition is 1" (i.e. $X = x_0 = 1$, where X is the number of immediate fatalities following a blowout when an immediate ignition occurs).
- "The jacket structure will withstand a ship energy of 9 MJ" (i.e. $X = x_0 = 9$, where X is the resistance of the structure).
- "A gas leakage will be detected within 30 seconds" (i.e. $X = x_0 = 30$, where X is the detection time a leakage).
- "The gas concentration is assumed to be reduced by 50% each 8 meters away from the leakage point" (i.e. $X = x_0 = G(u,v) = u(1/2)^{v/8}$, where X is the gas concentration at a point v meters from a leakage source and u the gas concentration at the leakage point).

The last assumption in the list above involves a model G of gas dispersion, and in effect states that the model error $\Delta G(u,v) = G(u,v) - X$ is 0. The implication is that there is no need to consider model output uncertainty, i.e. uncertainty on the value of the model error. The terms model error and model output uncertainty is here used as defined by Aven & Zio (2013).

The assumptions made may be more or less reasonable, i.e. there may be more or less uncertainty about whether the condition (assumption) $X = x_0$ holds true. This uncertainty can in principle be handled quantitatively, perhaps most obviously using the law of total expectation but also using various non-probabilistic representations of uncertainty, such as interval or imprecise probability, possibility theory and evidence theory; see e.g. Aven et al. (2014). In practice both these approaches may be prohibitively difficult to carry out, due to a large number of assumptions leading to high dimensionality of X and hence a high workload involved in establishing its joint distribution, and/or because the background knowledge K on which to base the quantification of uncertainty about X is poor.

An alternative approach is to report the risk index without any quantitative integration of uncertainty related to potential deviation from $X = x_0$, and then perform a qualitative assessment of the strength of knowledge that the resulting risk index is based on. An example is the qualitative classification scheme suggested by Flage & Aven (2009) where a crude categorisation of strength of knowledge and risk index sensitivity is performed with respect to so-called 'uncertainty factors', including assumptions, models and data. Looking at these two aspects combined gives an impression of how important (critical) the factor is. This information can be used either to direct further analysis efforts, or it may be communicated to the decision-maker together with the results of the quantitative risk assessment, in particular the values of the relevant risk indices, so that the decision-maker is informed about the basis of the assessment. The result is a semi-quantitative approach to risk assessment, entailing a quantitative representation of uncertainty, typically probability, supplemented by a qualitative characterization of the background knowledge K. The purpose of the qualitative characterization is to capture aspects beyond what can be transformed into and expressed in quantitative form. A more formalised semi-quantitative approach is based on the concept of 'assumption deviation risk' (Aven, 2013b), where the risk related to deviations from the assumptions made is assessed quantitatively, along with a qualitative assessment of the background knowledge.

In the present paper we review of the following methods to treat uncertainty related to the condition (assumption) $X = x_0$:

1. Quantitative treatment of uncertainty
   a. Law of total expectation
   b. Interval probability
2. Semi-quantitative treatment of uncertainty
   a. Crude strength-of-knowledge and sensitivity categorisation
   b. Assumption deviation risk

The gas leakage assumption listed above is used as an example throughout the review, to highlight ideas. We then perform an analysis of different situations faced when performing a risk assessment, considering beliefs about deviation from x_0, the sensitivity of $R(x_0)$ with respect to x_0, and the

overall strength of knowledge on which to base an uncertainty quantification of X. The result is some recommendations and guidance on how to balance the use of the approaches mentioned above.

The approach to risk analysis considered in the present paper may be referred to as predictive Bayesian, which is based on the following principles (Aven, 2012 p. 49–50):

- 'Focus is placed on quantities Y expressing states of the "world", i.e. quantities of the physical reality or the nature, that are unknown at the time of the analysis but will, if the system being analysed is actually implemented, take some value in the future, and possibly become known. We refer to these quantities as *observable* quantities. […]
- The observable quantities are predicted.
- Uncertainties related to what values the observable quantities will take is expressed by means of knowledge-based probabilities $P(\cdot|K)$. This uncertainty is *epistemic*, i.e. the result of lack of knowledge.
- Models in a risk analysis context are deterministic functions linking (observable) quantities on different levels of detail. The models are simplified representations of the world.'

This type of analysis constitutes a form of level 1 purely epistemic uncertainty propagation approach. Hence we do not consider a level 2 aleatory/epistemic uncertainty propagation approach (e.g. the probability of frequency approach); see Aven et al. (2014, p. 59–78) for a detailed description of the meaning of a level 1 or level 2 uncertainty propagation approach. Furthermore, we leave out of the consideration the goodness of the risk index $R(X)$, i.e. to what extent the index appropriately characterises risk. Of course, having a well-founded uncertainty characterisation of X may be less important if $R(X)$ represents a poor characterisation of risk.

The issue of uncertainties related to the background knowledge of probabilities is addressed also by Mosleh & Bier (1996). They refer to a subjective probability $P(A|X)$ expressing the probability of the event A given a set of conditions X, and argue that for such a setting the concept of 'uncertainty about probabilities' is meaningful in the sense that $P(A|X)$, being a function of X, is uncertain (since X is uncertain, $P(A|X)$ is a random variable). Accordingly there is uncertainty about the random probability $P(A|X)$. They also describe taking the expectation of $P(A|X)$ to obtain the unconditional probability $P(A)$ which, as they describe, according to a subjective probability interpretation is not uncertain. In the present paper we start from an initial conditional probability assignment $P(A|X = x_0)$ and, looking at different analysis situations, discuss how to handle the potential for having deviations from the condition (assumption) $X = x_0$.

The remainder of the paper is organised as follows: In Section 2 and 3 we present quantitative and semi-quantitative treatment of uncertainty, respectively. In Section 4 we analyse and discuss these in light of different analysis situations, as described above. Section 5 concludes.

2 QUANTITATIVE TREATMENT

2.1 *Law of total expectation*

The risk index unconditional on X (but still conditional on K) can in principle be obtained using the law of total expectation as follows:

$$R = E\left[R(X) \mid K\right] = \int R(x)\,dF(x \mid K). \quad (1)$$

where $F(x|K) = P(X \leq x|K)$. Ideally, all uncertain quantities involved in the risk analysis should be handled this way, as it constitutes a coherent integration of the uncertainty description of X into the risk index, which then incorporates and reflects uncertainty about X.

However, introducing a new probability (distribution) typically introduces new assumptions and, more generally, a more or less strong background knowledge on which the new probability is based. Again focusing on the situation where such an assumption can be formulated as $Z = z_0$ for some unknown quantity Z, and the distribution above instead becomes $F(x|z_0, \mathrm{K}) = P(X \leq x|Z = z_0, \mathrm{K})$. If the background knowledge of the distribution is poor and the distribution is sensitive to changes in z_0, then much may not be gained by the type of integration described above, as the sensitivity with respect to z_0 to greater or lesser extent carries over to the resulting risk index $E[R(X)|z_0, K]$.

Consider the example of the gas detection time and suppose that the analysts establish a discretised probability distribution on the following possible values of X: 5, 15, 30, 60, 90; with associated probabilities 0.05, 0.35, 0.40, 0.04, 0.01. Then the integration with $R(X)$ is straightforward; however, the basis for this distribution could be more or less arbitrary. It could for example be based on an assumption saying that all gas detectors function perfectly, i.e. $Z = z_0 = 1$, where Z is the availability of the gas detectors. The probability distribution then does not reflect the possibility that the gas detectors in the area of the leakage do not function at the time of the leakage.

2.2 *Interval or imprecise probability*

Alternative approaches for representing uncertainty have been proposed, including those based on interval or imprecise probability, possibility

theory and evidence theory (e.g. Aven et al., 2014). It is argued that these approaches provide a more adequate treatment of uncertainty in situations of poor knowledge on the phenomena and scenarios studied in the risk assessment.

Here we focus on interval or imprecise probability. The term imprecise probability brings together a variety of different theories (Coolen et al., 2010). It refers to a generalization of probability theory where the uncertainty related to an event A is represented using a lower probability $\underline{P}(A)$ and an upper probability $\overline{P}(A)$, $0 \leq P(A) \leq \overline{P}(A) \leq 1$, rather than a single-valued probability $P(A)$. Subjective probabilities are expressions of degrees of belief, and so this does not mean that the true value of the probability is in the interval $[\underline{P}(A), \overline{P}(A)]$, as no such true value exists. It rather means that the person asked to assign the probability is not able or willing to precisely assign a single-valued probability $P(A)$.

Arguably it may be no easier to assign a well-founded probability interval than an exact probability. Suppose for example that we have assigned a well-founded unconditional probability distribution $F(x|Z, K)$, but have problems assigning a probability distribution of Z (to integrate with F using the law of total probability), where Z is known to take a value in the interval $[z_{min}, z_{max}]$. Then we may at least obtain a set of distributions $F(x|z, K)$ generated by z ranging in the interval $[z_{min}, z_{max}]$; or, equivalently, probability intervals $[P(A|z_{min}), P(A|z_{max})]$ (assuming that $P(A|z)$ is increasing in z) for events A determined by the outcome of Z. Such an approach could, of course, lead to rather wide intervals.

In the gas detection time example, suppose that the analysis group makes the judgement that a detection time longer than 120 seconds is so unlikely that this eventuality can be ignored. They are not willing, however, to make any further judgements about the time to detection. In an interval or imprecise probability setting this leads to a p-box for $F(x|z_0, K)$ bounded above by the distribution $\overline{F}(x \mid z_0, K) = 1$ and below by $\underline{F}(x \mid z_0, K) = 0$ for all x in the interval [0, 120]. This corresponds to ultimately assigning $[R(0), R(120)]$ as an interval for the risk index. An important underlying assumption that is introduced by this distribution is that the detection time will not exceed 120 seconds, i.e. $Z = X_{max} = z_0 = 120$.

3 SEMI-QUANTITATIVE TREATMENT

3.1 *Crude strength-of-knowledge and sensitivity categorisations*

A semi-quantitative approach entails a belief that the full scope of uncertainty and risk is not transformable into a quantitative format, using probability or another measure of uncertainty. On this basis, 'uncertainty factors' that are 'hidden' in the background knowledge K of the subjective probabilities are identified and assessed in a qualitative way. The identification and assessment is made using simple criteria to categorize the strength of the knowledge that supports the probabilistic analysis, as well as the sensitivity of the resulting risk indices. For example, the background knowledge is classified as weak if one or more of these conditions are true (Flage & Aven, 2009):

- The assumptions made represent strong simplifications
- Data are not available, or are unreliable
  There is lack of agreement/consensus among experts
- The phenomena involved are not well understood; models are non-existent or known/believed to give poor predictions.

On the other hand, if all of the following conditions are met, the knowledge is classified as strong (Flage & Aven, 2009):

- The assumptions made are seen as very reasonable
- Much reliable data are available
- There is broad agreement/consensus among experts
- The phenomena involved are well understood; the models used are known to give predictions with the required accuracy.

Cases in-between are classified as corresponding to moderate strength of knowledge. In addition a crude classification is made of the sensitivity of the risk index with respect to the uncertainty factors. For example, the sensitivity may be classified as follows (Flage & Aven, 2009):

- High: Relatively small changes in base case values needed to bring about altered conclusions (e.g. exceedance of risk acceptance criterion)
- Moderate: Relatively large changes in base case values needed to bring about altered conclusions
- Low: Unrealistically large changes in base case values needed to bring about altered conclusions

Returning to the example of the gas detection time assumption, suppose that the following assessments are made for the criteria described above:

There is manufacturer test data available on the availability of the gas detectors; however, there is no field data on neither automatic nor manual detection from the platform in question. There is broad agreement among the analysts performing the risk assessment that 30 seconds is a 'representative' detection time, but it is also acknowledged

that the detection time could easily exceed this number, at least to some extent. The phenomenon gas dispersion is well understood and Computational Fluid Dynamics (CFD) modelling is used in the risk analysis; however, the modelling is based on a 'representative' gas leakage scenario, chosen from a range of possible scenarios.

Detection is a barrier function that enters early in the event sequence of a process accident scenario; it will hence be among the first branching events of a corresponding event tree and so its performance will significantly influence the process accident risk model. Moreover, process accidents are characteristically found to be the dominating risk contributor in Quantitative Risk Assessments (QRAs) of offshore oil and gas producing platforms.

Based on the above, both the strength of knowledge and sensitivity of the detection time assumption are classified as moderate, leading to an overall moderate importance (criticality) of this assumption.

3.2 *Assumption deviation risk*

The concept of assumption deviation risk was coined by Aven (2013b) and refers to the risk related to the (assumption) deviation $X - x_0$. To assess this risk, Aven (2013b) recommends highlighting:

- The magnitude of the deviation
- The (subjective) probability of the magnitude to occur
- The effect of the change on the consequences C addressed in the risk assessment
- An overall judgment of the strength of the background knowledge of this triplet risk assessment is to be conducted

Different magnitudes of deviation may be considered, and the probability of these to occur could for example be assessed in terms of

$$p(d|z_0, K) = P(|X - x_0| > d| z_0, K),$$

for different values of d. Furthermore, the effect of such deviations could be studied in a sensitivity analysis of $R(x_0)$ with respect to x_0 over the range $[x_0 - d, x_0 + d]$. Finally, the strength of the background knowledge could be assessed with reference to the criteria in Section 3.1. The last point is important, as there are two cases where a deviation between X and x_0 would not be surprising, namely if:

- $p(d|y_0, K)$ is moderate or high, which would be the case if the spread of F is moderate or high; or
- $p(d|y_0, K)$ is low, but the strength of knowledge is considered moderate or low.

Table 1. Assumption deviation risk assessment of gas detection time.

Magnitude of deviation d	0 sec	30 sec	90 sec
Probability of deviation $\tilde{p}(d \mid z_0, K)$	0.2	0.05	Negl.
Effect on consequences $[R(x_0 + d) - R(x_0)]/R(x_0)$	–	+ 2%	+ 5%

In the gas detection time assumption example main concern is with deviations of the detection time upwards of $x_0 = 30$, and hence focus may be placed on

$$\tilde{p}(d \mid z_0, K) = P(X - x_0 > d \mid z_0, K).$$

In accordance with the recommendations above, an assumption deviation risk assessment may take the form as illustrated in Table 1. According to this table the analysts assign a probability 0.2 of having a detection time in excess of 30 seconds and a probability 0.05 of having a detection time in excess of 60 seconds. They also judge that the probability of having a detection time in excess of 90 seconds is negligible, i.e. that such an event is so unlikely that it can be ignored. Just as for the interval/imprecise probability distribution in Section 2.2, the probability distribution in Table 1 introduces an assumption that the detection time will not exceed 120 seconds, i.e. that $Z = X_{max} = z_0 = 120$. In addition to the elements of the assumption deviation risk assessments reflected in Table 1, the recommendations above prescribe an overall judgment of the strength of the background knowledge of the assumption deviation risk assessment. Such an assessment could be performed according to the strength-of-knowledge criteria presented in Section 3.1, and should address inter alia the basis for the judgement of a negligible probability of having a gas detection time in excess of 120 seconds (i.e. a deviation of 90 seconds).

4 DISCUSSION

The methods described in Section 2 and 3 can be used to treat uncertainties and reflect strength of knowledge in a quantitative risk assessment setting. Considering, as described in Section 1, the necessity to balance the desire for coherent quantitative uncertainty characterisation with practical limitations, there is a need for some guidance on when the different methods may be appropriate. In this section we perform an analysis of different settings faced when making assumptions in a risk assessment, and provide some guidance on how to

balance the use of the different methods reviewed in the previous sections. The characteristics of the different settings are summarised in Table 2.

Settings I and II are both characterised by a low degree of belief in deviation from x_0 and a risk index that is not sensitive with respect to x_0. In setting I, as the background knowledge is strong it would be possible to establish a well-founded probability distribution for X; however, since the analyst is confident in the deviation/sensitivity assessment due to the strong background knowledge, he/she could as a simplification resort to simply report $R(x_0)$ to characterise the risk level. The assumption $X = x_0$ of course still needs to be documented in the risk assessment, but it is not highlighted as critical when presenting the results to the decision-maker. If the assumption nonetheless turns out not to hold true, and this contributes to an accident, we experience a surprising extreme event relative to present knowledge/beliefs. This is one way to define black swan type of events (Aven, 2013a); such events require other risk assessment methods than those reviewed here, and are hence out of scope of the present paper.

In setting II the deviation/sensitivity classification remains low/low; however, this judgement is based on a moderate or weak background knowledge. The analyst acknowledges that deviations from x_0 could still occur due to circumstances not considered by the analyst. This is important to be aware of in the subsequent risk evaluation; however, since the basis for a quantification of this uncertainty would not be strong, the analyst could chose instead to highlight a qualitative strength-of-knowledge assessment as described in Section 3.1 when presenting the results to the decision-maker. The guidelines just described related to settings I and II are summarised in Table 3.

Table 2. Settings faced when making assumptions in a risk assessment.

Belief in deviation from assumption	Sensitivity of risk index wrt x_0	Strength of knowledge	
		Strong	Moderate/ weak
Low	Low	Setting I	Setting II
	Moderate/ high	Setting III	Setting IV
Moderate/ high	Low	Setting III	Setting IV
	Moderate/ high	Setting V	Setting VI

Settings V and VI are characterised by a moderate or high degree of belief in deviation from x_0, as well as moderate or high sensitivity of $R(x_0)$ with respect to x_0. Then there is a need to both characterise uncertainty related to X in a more comprehensive manner, as well as to integrate this uncertainty characterisation with the risk index $R(X)$ in a coherent manner. This necessitates a quantitative approach to uncertainty representation.

In setting V the background knowledge on which to base a quantitative uncertainty representation of X is strong; hence a well-founded probability distribution $F(x|z_0, K)$ may be established, which can be integrated with $R(X)$ according to Equation (1). Since the background knowledge is strong, the assumption $Z = z_0$ (Section 2.1) on which F is conditional is non-critical and does not need to be highlighted.

In setting VI the background knowledge on which to base a quantitative uncertainty representation of X is moderate or weak. It may still be possible to establish a probability distribution $F(x|z_0, K)$; however, such a distribution will be based on more or less reasonable assumptions, and so the risk index $E[R(X)|z_0, K]$ resulting from an integration according to Equation (1) needs to be supplemented by an assumption deviation risk assessment of the assumption $Z = z_0$. This could be achieved by reporting of (interval) probabilities

$$q(d|w_0, K) = P(|Z - z_0| > d|W = w_0, K)$$

for different values of d corresponding to different magnitudes of deviation; combined with highlighting of a qualitative strength of knowledge assessment of the background knowledge of the probability $q(d|w_0, K)$, including any new

Table 3. Guidance on treatment of uncertainty related to deviation from assumptions in settings I and II.

Belief in deviation from x_0	Sensitivity of $R(x_0)$ wrt x_0	Strength of knowledge	
		Strong	Moderate/weak

		Strong	Moderate/weak
Low	Moderate/ high	Report $R(x_0)$ Highlight assumption deviation risk assessment for assumption $X = x_0$, based on probability OR See Table 4	Report $R(x_0)$ Highlight assumption deviation risk assessment for assumption $X = x_0$, based on probability or interval/ imprecise probability OR See Table 4
Moderate/ high	Low		

assumption $W = w_0$ introduced for some unknown quantity W that q depends on.

Alternatively, the lack of knowledge could be reflected quantitatively by assigning an interval/ imprecise probability distribution on X, leading to an interval for the resulting risk index. The guidelines just described related to settings V and VI are summarised in Table 4.

Settings III and IV are characterised by conditions between settings I/II and settings V/VI; i.e. either by a low degree of belief in deviation from x_0 combined with a moderate or high sensitivity of $R(x_0)$ with respect to x_0, or vice versa.

If the frame conditions of the risk assessment are such that there is an expectation for or are resources available to perform a more detailed assessment, then the guidelines given for settings V and VI apply to settings III and IV, respectively. Otherwise an assumption deviation risk assessment should be performed; in setting III based on probability as the background knowledge is strong; in setting IV possibly based on interval/imprecise probability to reflect that the background knowledge is only moderate or weak. These guidelines for settings III and IV are summarised in Table 5.

The guidelines presented in Table 5 rely on two central premises. Firstly, the more important an assumption is, the more effort should be expended on characterising uncertainty and effect related to potential deviation. Six levels of importance are distinguished, corresponding to the settings I-VI. Secondly, the methods reviewed are associated with an increasing level of effort, ranging from low for the qualitative assessment as described in Section 3.1, through moderate for assumption deviation risk assessment as described in Section 3.2, to high for the establishment of a full (interval/imprecise) probability distribution on X as described in Section 2. The presented guidelines couple the different settings with different (combinations of) methods, in an attempt to balance the desire for coherent quantitative uncertainty characterisation with practical limitations.

5 CONCLUSION

Making assumptions are an inevitable aspect of performing risk assessments. The assumptions may be more or less reasonable, i.e. there may be more or less uncertainty about whether the conditions these specify hold true. In principle, this uncertainty can be handled quantitatively, but in practice, this may be prohibitively difficult due to a large number of assumptions and hence a high workload associated with establishing the required

probability distributions; and/or the background knowledge on which to base the quantification may be poor. Alternatively, a semi-quantitative approach can be taken, based on a combination of quantitative descriptions and qualitative methods.

In the present paper we review various quantitative and semi-quantitative methods. These are associated with different levels of effort and, based on the premise that the more important an assumption is the more effort should be expended on characterising uncertainty and effect related to potential deviation, we conclude that there is a need to balance the use of the different methods. We distinguish six different settings arising from different levels of beliefs about deviation from an assumption, sensitivity of the relevant risk index with respect to changes in the assumption, and overall strength of knowledge on which to base uncertainty quantification. These different settings are then coupled with different (combinations of) methods, in an attempt to balance the desire for coherent quantitative uncertainty characterisation with practical limitations. The resulting recommendations are summarised in Table 3, Table 4 and Table 5 in Section 4.

Comparison of uncertainty models of impact of teleinformation devices reliability on information quality

M. Stawowy
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: This research is a continuation of previous work related to the determination of Information Quality (IQ) for different systems. IQ is it a top level of evaluation of this information. IQ is depends on: accessibility, actual value, completeness, credibility, flexibility, form, meaning over time, relevance, reliability, selectivity, validity. But many researchers believed reliability of the teleinformation devices (the IT devices) is one of the main components of IQ. I would like to present a new approach for estimating the IQ with specific regard on reliability of the IT devices. This approach is based on modelling uncertainties. For this purpose, I used two known methods and compare it. Estimate IQ using the method Certainty Factor (CF) and Dempster-Shafer (DS) method.

1 INTRODUCTION

The reliability of data communication elements is an important constituent part on the quality of transferred information (IQ). It may be stated that IQ consists of: accessibility, actual value, completeness, credibility, flexibility, form, meaning over time, relevance, reliability, selectivity, validity (Olaisen 1990, MITIQ). All the above components of IQ tend to be encumbered by some uncertainty. Whether associated with measurement or caused by the unreliability of equipment or software. Hence, the proposal to determine IQ using uncertainty modelling. There are several major methods of uncertainty modelling. The best known are Bayes networks based on conditional probability, the theory mathematical evidence based on the Dempster-Shafer theory, the method making use of the Certainty Factor (CF) created by Buchanan, Shortliffe for the MYCIN expert system, the theory of fuzzy sets or the theory of rough sets.

This paper presents and compares methods: basing on the theory of mathematical evidence (Dempster 1967, Shafer 1976) (DS) and using the certainty factor of a hypothesis (Shortliffe & Buchanan 1984, Heckerman 1992, Stawowy 2013) (CF) to evaluate the information quality. Uncertainty models of impact of teleinformation devices reliability on information quality. These methods was chosen because make possible modelling uncertainty on the basis of values from various sources. Usually, known publications talking about statistical models like Vinay & Khelil & Suri 2010 or Weng & Vespa 2011. Presented work by Raghunathan 1999 was similar but not used presented in this article method and not compared it.

2 MODELLING UNCERTAINTY

The first part of this chapter specifies the dependencies used to calculate the values of the CF. It results from the variable directions of development of this method.

2.1 *Modelling the certainty factor of a hypothesis*

The formal simplified description of the certainty factor is as follows:

$$CF_{(s)} = MB_{(s)} - MD_{(s)} \tag{1}$$

where *CF*—certainty factor; *MB*—reflection of knowledge, that is measure of belief; *MD*—reflection of ignorance, that is measure of disbelief; *s*—hypothesis based on some information.

It is important to remember that:

$$MB \to [0,1]; MD \to [0,1] \; then \; CF \in [-1,1] \tag{2}$$

So, as it results from formula 2 the result of the calculations should fit within the range from –1 to 1. The value of 1 will indicate the highest IQ.

A model using the CF can be presented in the form of a graph where the nodes are the hypotheses and the branches are the certainty factors of the hypotheses. A sample model has been presented in Figure 1.

The whole begins from observation nodes (e1, e2), the node of hypothesis h1, which in fact becomes an observation in the further step of calculations, appears subsequently. The following

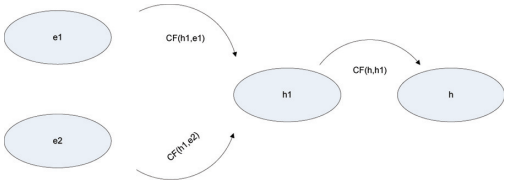

Figure 1. Sample CF model. Prepared by the author.

dependence has been used for calculation of parallel CFs (Heckerman 1992):

$$CF_{(h1,e1,e2)} = \begin{cases} CF_{(h1,e1)} + CF_{(h1,e2)} - CF_{(h1,e1)} \cdot CF_{(h1,e2)}, CF_{(h1,e1)}\ and\ CF_{(h1,e2)} \geq 0 \\ \dfrac{CF_{(h1,e1)} + CF_{(h1,e2)}}{1 - \min(\left|CF_{(h1,e1)}\right|;\left|CF_{(h1,e2)}\right|)}, \qquad CF_{(h1,e1)} \cdot CF_{(h1,e2)} < 0 \\ CF_{(h1,e1)} + CF_{(h1,e2)} + CF_{(h1,e1)} \cdot CF_{(h1,e2)}, CF_{(h1,e1)}\ and\ CF_{(h1,e2)} < 0 \end{cases} \tag{3}$$

The following dependence has been used for calculation of serial CFs (Heckerman 1992):

$$CF_{(h,h1,e1,e2)} = CF_{(h1,e2,e1)} \cdot CF_{(h,h1)} \tag{4}$$

Using formulas 3 and 4 the graph can folded down to a single branch with two nodes and the CF of this branch will be the sought value of the certainty factor of a hypothesis. We assume that such CF coefficient is the measure of information quality IQ. In this work only formula 3 was used because model was only parallel (Shortliffe & Buchanan 1984, Heckerman 1992, Stawowy 2013).

2.2 *Modelling uncertainty using the theory of mathematical evidence*

The theory of evidence assumes that it is possible to conduct a synthesis of information for particular elementary measures of probability. Information can be synthesised even if it is contradictory or comes from various sources (Dempster 1967, Shafer 1976). Such synthesis can be described by the following formula:

$$m_3(C) = \frac{\sum_{A_i \cap B_j = C} m_1(A_i) m_2(B_j)}{1 - \sum_{A_i \cap B_j = O} m_1(A_i) m_2(B_j)} \tag{5}$$

where *A, B and C*—sources of observations represent subsets of set Θ; m_1 *and* m_2—sets of masses; m_3—new set of mass.

This synthesis is called the Dempster combination rule (Dempster 1967).

The belief mass (called as *basic belief assignment* BBA) is defined as follows:

$$\begin{aligned} &m: 2^{\Theta} \rightarrow [0,1] \\ &m[\varnothing] = 0 \\ &\sum_{A \subseteq \Theta} m(A) = 1 \end{aligned} \tag{6}$$

Belief marked in brief Bel ∈ [0,1] measures the strength of acquired observations supporting the belief on the authenticity of the examined set of hypotheses.

$$Bel(A) = \sum_{B \subseteq A} m(B) \tag{7}$$

Plausibility designated in brief as Pl ∈ [0,1] determines how much the belief on authenticity A is limited by supporting evidence ¬A.

$$\begin{aligned} &Pl(A) = \sum_{B \cap A \neq 0} m(B) \\ &Pl(A) = 1 - Bel(\neg A) \end{aligned} \tag{8}$$

The combination rule affects the belief function and it can presented in such a way:

$$Bel1 \oplus Bel2(A) = \sum_{B \subseteq A} m_1 \oplus m_2(A) \tag{9}$$

Assume was that Bel is the measure of information quality IQ.

3 MODEL OF INFORMATION QUALITY OF A SELECTED DATA COMMUNICATION SYSTEM

Most often found is the data communication system based on TCP/IP (Transmission Control Protocol/ Internet Protocol) as well as IEEE 802 (Institute of Electrical and Electronics Engineers) protocols. By relying on the model of ISO OSI (International Organization for Standardization Open Systems Interconnection) the model of such a system can be presented in a manner shown in Figure 2.

Apart from normal damage of constituent elements of such a data communication system, data can also be damaged in spite of the fact that the recipient of this fails to notice. The possible causes are: imperfection of protection with CRC code (Cyclic Redundancy Check) in the layer of data links, incorrect configuration of transmission in the network layer e.g.: improperly set TTL (Time To Live) field in the IP protocol or unauthorised change of data.

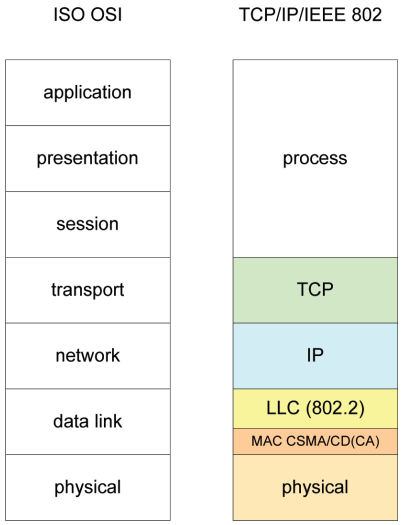

Figure 2. Model of a data communication system of TCP/IP as well as IEEE 802 protocols as compared to the model of ISO OSI. Prepared by the author based on International standards.

Values of all IQ components tend to be encumbered by some uncertainty. Whether associated with measurement or caused by the unreliability of equipment or software. Hence, the proposal to determine IQ using uncertainty modelling. The theory of mathematical evidence based on the Dempster-Shafer theory (DS) as well as the method of making use of the Certainty Factor (CF) created by Buchanan, Shortliffe for the MYCIN expert system have been applied here. These methods make it possible to model uncertainty on the basis of premises from various sources.

A model of information quality based on the CF or DS model may consist of one final hypothesis:

h—correctly provided data.

Observations can be as follows:

e1—correct transmission,
e2—data link layer errors (e.g.: imperfection of CRC,
e3—damage of transmission connection,
e4—damage of network control devices,
e5—damage or defective software,
e6—network layer errors (IP protocol),
e7—transport layer errors (TCP protocol).

3.1 *Modelling information quality of a selected data communication system by means of the certainty factor of a hypothesis*

The previous chapter describes two methods of uncertainty modelling. In the example concerned both can be used to evaluate the information quality (IQ). Using CF-based uncertainty modelling the graph may be presented as in Figure 3 and the value of particular CF presented as in Table 1. Values is not real but near real. Used for method demonstration only.

Calculated IQ using CF-based uncertainty modelling IQ(CF) was about 0,984.

Another step was the simulation. A special program has been written in order to conduct the simulation. This program uses standard normal distributions. The distributions have been used as multiply for all input values and limited with a range of values that may be accepted by the CF according to formula 2. The number of repetitions of the simulation amounted to 10000. The result of the simulation is presented in Figure 4. There is a density function of CF values after simulation.

3.2 *Modelling information quality of a selected data communication system using mathematical evidence*

Information from various sources can be synthesised using the theory of mathematical evidence. It has been described with formula 5.

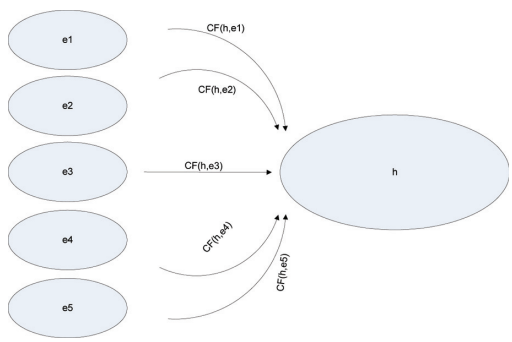

Figure 3. CF model graph. Prepared by the author.

Table 1. Assignment of particular CF values. Prepared by the author.

h
CF(h,e1) = 0.998
CF(h,e2) = $-0.2 * 10^{-2}$
CF(h,e3) = $-0.1 * 10^{-2}$
CF(h,e4) = $-0.1 * 10^{-2}$
CF(h,e5) = $-0.1 * 10^{-2}$
CF(h,e6) = $-0.1 * 10^{-2}$
CF(h,e7) = $-0.1 * 10^{-2}$

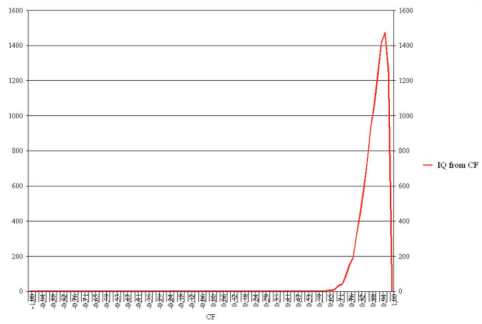

Figure 4. Result of CF model simulation. Result of operation of a program written by the author of the article.

Table 2. Observation Ze1. Prepared by the author.

	m_2 ({e1})	m_2 (Θ)
m_1 (Θ)	m_3 ({e1})	m_3 (Θ)

Table 3. Observation Ze2. Prepared by the author.

	m_4 ({e3, e4, e5})	m_4 (Θ)
m_3 ({e1})	m_5 ({Ø})	m_5 ({e1})
m_3 (Θ)	m_5 ({e3, e4, e5})	m_5 (Θ)

Table 4. Observation Ze3. Prepared by the author.

	m_6({e2, e3, e4, e5, e6, e7})	m_6 (Θ)
m_5 ({Ø})	m_7 ({Ø})	m_7 ({Ø})
m_5 ({e3, e4, e5})	m_7 ({e3, e4, e5})	m_7 ({e3, e4, e5})
m_5 ({e1})	m_7 ({Ø})	m_7 ({e1})
m_5 (Θ)	m_7 ({e2, e3, e4, e5, e6, e7})	m_7 (Θ)

Let's define the three observations of effects on the basis of observation of causes.

Ze1—correct transmission, (e1),
Ze2—data failed to reach destination (e3, e4, e5),
Ze3—data reached destination, but are incorrect (e2, e3, e4, e5, e6, e7).

Tables 2–4 present the subsequent stages of the analysis of observation of effects.

Θ = {e1, e2, e3, e4, e5, e6, e7}

m_1 (Θ) = 1
m_2 ({e1}) = 0.998 (10)
m_2 (Θ) = 0.002

m_4 ({e3, e4, e5}) = 0.003 (11)
m_4 (Θ) = 0.997

m_6 ({e2, e3, e4, e5, e6, e7}) = 0.007 (12)
m_6 (Θ) = 0.993

Bel (e1) = m7 (e1) (13)

If we assume that Bel (e1) = IQ is a result of calculations using the theory of mathematical evidence modelling, it is only slightly different from the result of modelling of the certainty factor of a hypothesis. However, the simulation may show that they differ only by the coefficient. Calculated IQ(DS) was about 0,998.

3.3 *Comparison of results of simulation of both methods*

Simulations was prepared like simulations CF in 3.1 chapter but for both models. During the simulations the values from both methods seem to be similar. After the completion of the simulation for different values of observations one can recognise that both

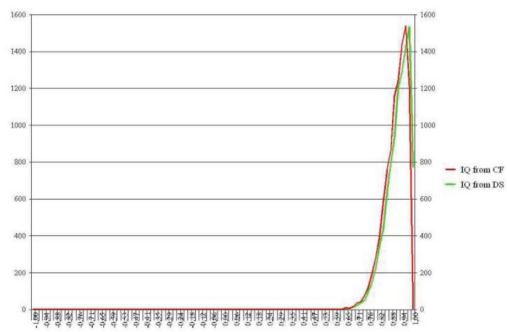

Figure 5. Result of simulation of DS and CF model. Result of operation of a program written by the author of the article.

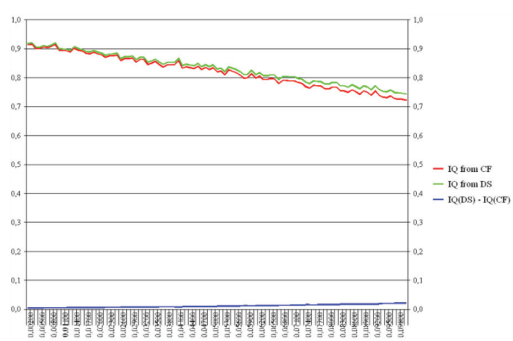

Figure 6. Result of simulation of DS and CF model e3 from 0,001 to 0,1 for DS and minus values for CF. Result of operation of a program written by the author of the article.

results are very similar (Fig. 5). The conclusion is that both methods are suitable for determination of information quality to an equal extent.

The next step was comparison of the simulations of IQ(CF) and IQ(DS) for the parameters of reliability of the elements of the sample system. Those elements were observations: e3, e4 and e5.

A simulation was carried out for e3, e4 and e5 variables in the range from 0.001 up to 0.1. The result has been presented in Figures 6, 7 and 8. There is values of IQ(CF), IQ(DS) and difference from it for different values of three observations: e3, e4 and e5. These observations are defined on the begin of this chapter and are related to reliability (Meeker, Stawowy 2010).

The CF method has greater dynamics, since the result may vary from –1 to 1, also on the simulation graph IQ (CF) changes faster than IQ (DS). Differences IQ (DS) – IQ (CF) take the form of a straight line. This means that the values IQ (DS) and IQ (CF) differ only by a constant factor.

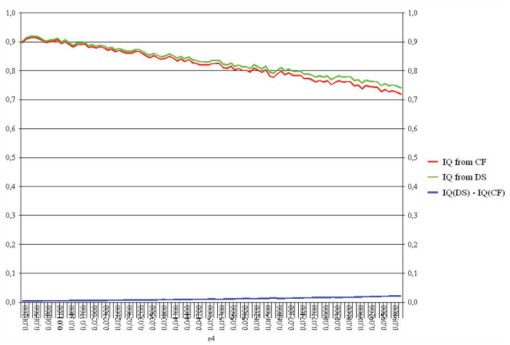

Figure 7. Result of simulation of DS and CF model e4 from 0,001 to 0,1 for DS and minus values for CF. Result of operation of a program written by the author of the article.

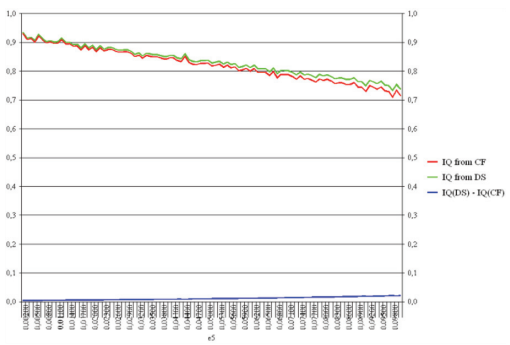

Figure 8. Result of simulation of DS and CF model e5 from 0,001 to 0,1 for DS and minus values for CF. Result of operation of a program written by the author of the article.

4 SUMMARY

This paper presents the method of determination of information quality (IQ) on the basis of reliability of the components of a data communication system using two different methods. The first was based on uncertainty modelling with the use of the certainty factor of a hypothesis, the other using the theory of mathematical evidence. Both methods have given a similar result. Difference is very small and it is result of different range of final values. Range of final value of IQ(DS) is [0,1] and IQ(DS) is [–1,1]. On the basis of the results, it can be concluded that the two methods give similar results and can be used to modelling the IQ.

Also a simulation of the example has been made using normal distributions along with a simulation comparing both methods.

Sensitivity analysis of geological parameters having impact on nuclear waste deep geological repository safety

J. Chudoba
Technical University of Liberec, Liberec, Czech Republic

ABSTRACT: When evaluating nuclear waste DGR safety it is necessary to confirm its safety in a long run and above all its safety towards the biosphere. With the aid of geologists a model of the Melechov Massif was elaborated and described with the use of geological and hydrogeological parameters. The paper results showed that ground water flow and transport of substances within the area (3D geometry) were the first ones to be determined. The Flow123D SW (Brezina 2012) was used for the determination. The resulting outcome represents a determination of transported substances concentration depending on time and its "function" is shown graphically or in the map form. The disadvantage of the model is the fact that all the input parameters were set deterministically. The problem is being solved using the sensitivity analysis.

1 INTRODUCTION

In the Czech Republic, there are two nuclear power plants: Dukovany and Temelin (with 6 blocks) producing highly-active nuclear waste. The waste has to be handled in a long run well to guarantee it will not be misused anytime anyway and—in the same time—to minimize risks for biotopes. Preparation-work and the future realization of such a Safe Nuclear Waste DGR has been carried by the Deep Geological Repository Authority of the Czech Republic (SURAO)—www.surao.cz.

The basic concept of the nuclear waste depository is described in the report: "The Reference Project of a Nuclear Waste DGR in a hypothetical locality and its Actualization" (Vokal 2011, Mandik 1999). The idea is that nuclear waste will be deposited in granite massive underground in the depth of about 500 m (in the Czech Republic). Now, suitable localities (that have been selected) are being checked and pass through for a detailed geological and hydrogeological research. The own building of such a DGR (Deep Geological Repository) is forecasted for the year 2040. The hot issue of nuclear waste DGR represents of course a complex problem—combined with THMC processes (thermo-hydro-mechanical and chemical processes).

Calculations on ground water flow and on dissolved substances transport are based on a hypothetical locality in the Melechov Massive. The locality is not determined for the a.m. DGR but a detailed geological and hydrological research had been carried there in the past. To calculate ground water flow and substances transport we used the SW Flow123D—https://dev.nti.tul.cz/trac/flow123d (Brezina 2012) The main advantage of the SW is that it processes data on flow and transport parameters on the 3D area, which is divided into 2D and 3D elements. The resulting output of a task on the flow is the determination of velocity and a direction of the flow and the determination of volume of a substance coming over the walls of the elements. Analogously, the resulting output of a task on the substance transport is the determination of a dissolved substance concentration (volume activity) depending on time in individual elements.

The paper deals with an analysis of critical radioactive substances transport out of a nuclear waste DGR. A 3D model of the area was designed and it is described with 37 000 elements (where the 2D elements represent fissure and the 3D elements represent the massive). The task on flow and substances transport was calculated with the SW Flow123D (Brezina 2012). The geological and hydrogeological parameters at the input corresponded with the geological and hydrogeological research, which had been carried out there in the Melechov massive in the past (Rukavickova 2008, Maryska 2010). The Melechov Model contains the following parameters:

- Hydraulic conductivity of rocks and fissures.
- Porosity of rocks and fissures zones.
- Fissures opening.

The substances transport is described with a real model containing the following:

- Time-variable radioactive substances release out of the near/far field border. Results on quantity of the released radioactive substances were

detected using the SW GoldSim—www.goldsim.com (GoldSim). All of the critical isotopes according to were covered.
– Radioactive Degradation of Substances
– Sorption Parameters K_d and Diffusion Coefficients D_e of transported radionuclides

The model did not consider the maximal dissolution of a substance in the water as the quantity of released radioactive substances is about 2 g/yr maximally. The output of the task is the determination of the substance concentration [ng/m^3] recalculated in volume activity [Bq/m^3] in individual elements—based on time. A special stress is put on the ground elements where radioactive substances penetrate into biotopes. To calculate the "received" dose [μSv] we chose a scenario based on a presumption that a human was drinking water from the ground (of the area) in the quantity of 0.002 [m^3/day].

A sensitivity analysis of the model was designed with a parameter change. The analysis is for finding parameters that have the most impact on the concentration change of the selected elements—mainly the ground ones. The following parameters were changed: hydraulic connectivity of rocks and fissures, rocks porosity, opening of fissures and—for each of the transported substances its sorption K_d. The changes describe changed hydrogeological conditions of the researched area in a long run. The output of the sensitivity analysis is a table where all of the stated parameters are shown, those which have the most impact on the increased concentration of substances on the ground elements.

The paper extends case studies issued before with the following:

– Time-variable feature of released isotopes.
– Radioactive degradation of substances.
– Implementation of sorption and diffusion coefficients.
– Calculation for more substances.
– Results re-calculation of received dose [μSv] for the selected scenario.

2 DESCRIPTION OF THE LOCALITY AND INPUT DATA OF THE MODEL

The designed model of the DGR is situated in the locality of the Melechov Massive located about 150 km to the Southeast from Prague.

In order to perform the desired analysis, a mathematical mesh was formed describing the massif of Melechov. The mesh covers the area of about 10 000 × 10 000 × 1300 m. The model mesh was created basing on geologic data, listed in (Rukavickova 2008, Maryska 2010). The suggested model contains a few vertical and horizontal rift fissures and 40 types of materials displaying different physical characteristics, such as hydraulic conductivity for example.

For the Melechov Massive—the geometry was prepared first. Then we generated a calculation mesh of the system. We used software Flow123D For the calculation of simulating task. The mesh contains in total 7174 nodes and 37 069 elements. There are 2140 ground elements, where a transport of radiation into the biosphere can happen. The challenge was to specify (make more accurate) the distribution function of concentrations in the elements of the area. (Chudoba 2012).

A geological research had been carried in the area in the past. The results of the research helped to set types of rocks, the location of fissures and to determine their hydraulic conductivity. Later, the following was discovered:

– Its geological structure—porous massif or fractural zones of the rock.
– Types of rocks there—granit of *melechov* type, granit of *kout* type, granit of *Lipnice* type, gneiss.

Then we considered different physical features of the environment according to the depth analysis of the area for the depths of 75, 150, 400, 600, 800, and more than 800 m. Input details of hydraulic conductivity for a particular type of a rock and fissures are stated in Table 1. To set the boundary condition, three basic parts of boundaries were stated within the simulated area. The Boundary condition and hydraulic conductivity in the

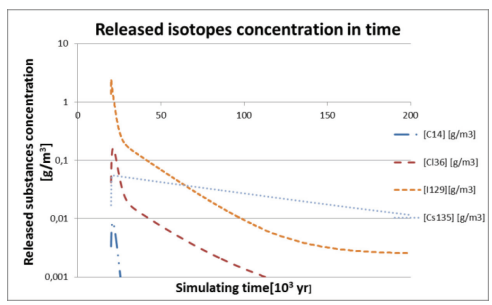

Figure 2. Quantity of released isotopes in time.

individual parts within the simulated massif were calibrated to:

– The piezometric height in the upper layer of the model area at the level of underground water.
– 1% of rain level deeper than 800 m under the ground.

Sorption Parameters K_d and Diffusion Coefficients D_e of substances were taken from a reference project (Vokal 2011). The values of those parameters are stated in the Table 2.

Another input into the model was substance quantity released from the near to the far field in time. A conservative case was considered—that was the container damage in the time of 20 000 years. A concrete plug is considered to be around the container with a bentonite package preventing immediate contamination of ground water. The calculation of the quantity of released substances was done through the simulation SW GoldSim. Figure 2 shows a graph describing critical isotopes release in time. Calculations of different variants of container damage were done in the analysis. Those scenarios were less conservative and that is why they are not mentioned here.

3 BASIC MODEL RESULTS

A model analysis, which was performed using the SW Flow123D (Brezina 2012), helped to determine the state of concentration (a volume activity) in time for all the elements used in the calculated mesh. We supposed the zero concentration of isotopes within the area at the beginning of the simulation. The DGR (Surao) in the calculated

mesh was modeled in the way that an element was withdrawn and a non-zero concentration on the walls of the withdrawn element was entered. Thanks to the element withdrawal it is possible to model variable-in-time quantity of released radioactive substances.

For modelling purposes the simulated time was 200 000 years with a damage of all the containers containing spent nuclear fuel set on 20 000 years. The time (20 000 years) represented quite a pessimistic forecast, more optimistic forecasts were also modeled (those ones also considered quite a different character of containers damage—e.g. the Weibull Distribution).

The input parameters of the model are stated in the Chapter 2 (the definition of the area geometry, hydraulic conductivity and porosity of rocks and fissures zones, fissures openings, substances sorption parameters, diffusion coefficient, released volumes of substances in time). These parameters are analyzed (in the view of the model sensitivity and supposing the same calculated mesh but different input parameters—e.g. those of hydraulic conductivity or porosity) in the Chapter 4.

Progress (state) of volume activities of ground water (Bq/m^3) in time was found for all the elements in the calculated mesh within the task. In total 2000 elements with non-zero concentration were recorded (from the total amount of 37 000) and from those elements the following ones were analyzed in a more detailed way:

– Elements that were found on the surface of the area where isotopes penetrated biotopes (out of the geosphere). There were 2140 surface elements within the area. In the paper, results for 1 element are presented. The element with the most volume activity of isotopes. Results of other elements are stated v (Chudoba 2014).

  Elements that formed the main transport line out of the DGR onto the surface of the area of the maximal recorded volume activity. The main transport line is formed with 10 elements.
– Elements that were found near the surface of the area (forming a layer at more than 400 m above the sea level), that could turn into surface elements (due to denudation) in future.

Within the task volume activity graphs were designed for each of the elements (in time). Another outputs of the task were maps showing substances concentration at the given sea level. Results obtained (for all the isotopes) were used in radioactive dose calculations. To determine the dose, the scenario of 1 m^3 ground water drunk by a human being a year had been chosen. Based on that scenario ingestion factors were found (SKB 2002) and were stated for all the critical radionuclides shown in Table 3.

Table 3. The ingestion factor for the critical isotopes, the maximal recorded volume activity on the surface element and the dose calculated basing on the given scenario.

Isotope	Ingestion factor [Sv/Bq]	Max. volume activity [Bq/m^3]	Dose [μSv/m^3]
C14	5,80E-10	30000	17,4
Cl36	9,30E-10	9500	8,8
I129	1,10E-07	540	59,4
Cs135	2,00E-09	700	1,4
Ra226	2,80E-07	85	23,8
		Sum	110,8

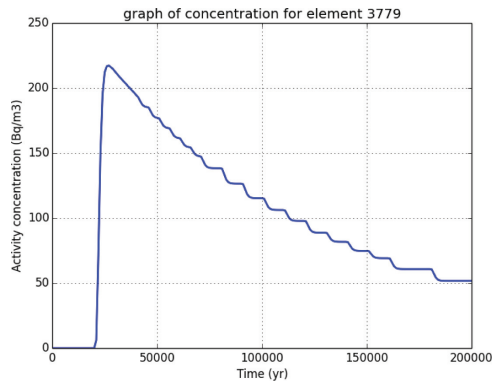

Figure 3. Volume activities of I129 on the surface element in time.

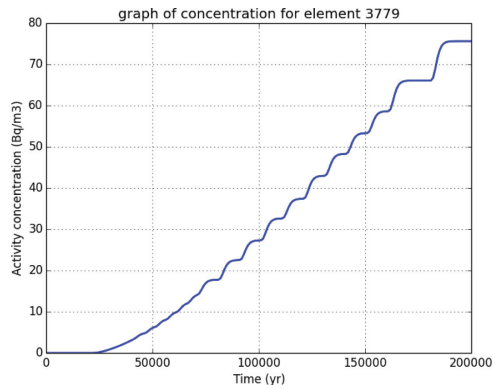

Figure 4. Volume activities of and Ra226 on the surface element in time.

In Figures 3 and 4 there are volume activity graphs for the critical isotopes for one surface element (the one of the maximal activity) in time. It is quite clear, that the released quantity of isotopes and the activity of elements on the surface are strongly dependent on

the simulated time, the half-life and the course of its release out of the near/far field borders.

The crucial impact on the total radioactive dose (after the containers damage) had the I129, which did not absorb, with unlimited dissolution and with a too long half-life (15.7 Myr). Another disadvantage is its immediate release out of the damaged container—resulting in the worst possible situation where all the containers are damaged at once in the given simulated time. The total dose therefore is not dependent on the time of the damage of all the containers—only a shift of the maximal activity towards the maximum is shown in the graph. Using the Weibull Distribution to describe the containers life-time it is necessary to consider the value of β.parameter. The similar problems are with I C14 with shorter half-life time and that absorbs very little. The both isotopes penetrate into biotopes and into food-chain too easily—increasing that way their potential perilousness.

Another of the elements that has a crucial impact on the total dose is the Ra226, arisen with radioactive degradation of uranium matrix—with a short half-life (1600 years) the released quantity is increasing with natural degradation of safety barriers and a large mass of U238 concentrated in a small volume of the DGR.

In Table 3 there are shown the maximal volume activities of isotopes on the surface element of the maximal volume activity in the given simulated time. The total dose received by a human with the given scenario (1 m^3 of ground water drunk a year) is calculated out of the volume activities. The other isotopes (not mentioned in Table 3) have lower impact on the given scenario—less 1 μSv. The total dose on other elements is lower (as it is shown in Fig. 4).

The map of volume activity was designed (pls. see Fig. 5) in a similar way. The map shows the surface area with volume activity of isotopes. It is clear that a substance reaches only a small part of the modeled area and that is why it is not necessary to extend the modelled area. Similar maps were designed for cuts of a given sea-levels. The cuts can be used to model denudation of the area in future.

The SW GoldSim (GoldSim) does not provide calculations of ground water flow. Knowing the preference line—1D geometry or cut geometry—2D area could be connected using components of physical relations and the resulting concentration of a substance (in the area) could be calculated. "Cell Pathway"—representing a mix chemical reactor and "Pipe Pathway"—representing chemical colony—belong among those basic components.

The transport module (knowing flow among components) is for the transport of more substances calculating: variable-in-time quantity released on the near/far filed border, sorption

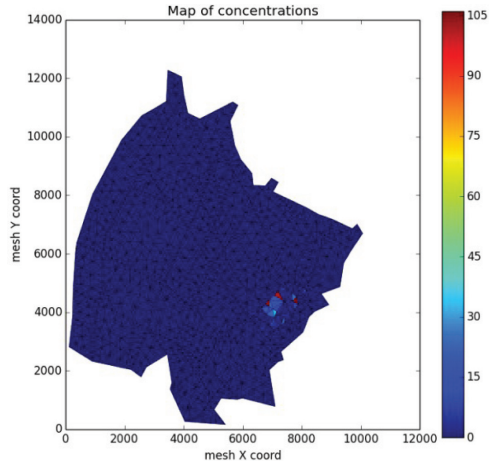

Figure 5. Map of volume activity (Bq/m^3) I 129 on surface elements in the simulated time of 50 000 years.

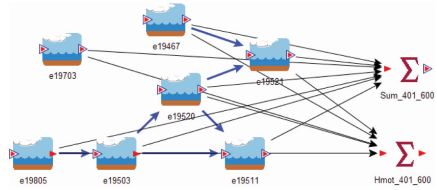

Figure 6. A sample of a modeled part designed using the SW GoldSim.

parameters, radioactive degradation, diffusion coefficient and the maximal dissolution of a substance in ground water.

The task model of flow and transport described at the beginning of the Chapter 2 (using the SW Flow123D) was also analyzed using the SW GoldSim. Geometry of the area was chosen basing on elements with non-zero concentration of a substance—they represented the input data for the model using the SW GoldSim. The Complexity of the Conversion was due to the fact that the elements entered using the SW Flow123D were of the tetrahedron shape and that is why the conversion of overflows between walls in the flow task was so complex. A sample of a part of the model for a few elements near the DGR is shown in the Figure 6. Both tasks reached quality—correspondence in model results.

4 SENSITIVITY ANALYSIS THROUGH PARAMETER CHANGE

Sensitivity Analysis through Parameter Change is based on a comparison of substance concentration

between the Reference Task and the Task with Changed Input Parameters (Chudoba 2010, Chudoba 2014). The basic parameters that are changed are the following:

- Hydraulic conductivity of fissures and rocks that was changed as follows: 0,1; 0,2; 0,5; 2; 5 and 10 multiple of the former value calculated for every type of rock or fissure. There are 38 types of rocks within the area, which represented 228 tasks in total.
- Fissures openings (14 types of openings in total) that were changed in 0,5 and 2 multiple of the former value, which represented 28 tasks in total.
- Porosity that was changed from the former value of 0,5 for 0,25 and 0,75 (mainly fissure zones and the surface area); the former value of 0,05 was changed for 0,02 and 0,10; the former value of 0,01 was changed for 0,005 and 0,02, which represented 76 tasks (38 × 2) in total.
- Sorption parameters of substances were changed as follows: 0,1; 0,5; 2 and 10 multiple of the former value (only for absorbing substances), which represented 4 tasks in total.

Those changes were made for all the isotopes of a higher radioactive dose (more than 1 μSv) in the basic model, which were: C14, Cl36, I129, Cs135 and Ra226. Each of them had to be evaluated individually due to their different half-life, different character of their release out of the near/far field and different absorption properties.

The designed tasks of transport with changed parameters were calculated using the SW Flow123D (Brezina 2012). The resulting concentrations (volume activities Bq/m^3) were analysed and tasks where the change of an input parameter caused the strongest response, i.e. an increase of substance concentration (volume activity) on selected elements were found, afterwards. Similar elements to those of the basic task could be included:

- Elements on the surface of the area, where a substance penetrates out of the geosphere into biotopes. Results for one element (the one of the biggest volume activity of isotopes) are stated in the paper. Results for the other elements are stated in (Chudoba 2014).
- Elements forming the main transport line out of the DGR up to the surface of the area with the maximal volume activity. The main transport line is composed of 10 elements.
- Elements at the selected (or higher) sea level. Those elements could describe penetration of a substance out of the geosphere into the biosphere taking into account the rock denudation.
- Elements that are found in a particular part of the modelled area with (supposing) a higher concentration of people.
- One crucial element could be analysed (e.g. a surface element of the maximal detected concentration or an element supposed in the area of a higher concentration of people).

The SW Flow 123D compares the substance concentration (activity) between the Reference Task and the Task with changed input parameters. A list of tasks of the strongest impact on the substance concentration change in the selected area is in fact the result of the SW analysis. The supposed "RATE" of the evaluation of particular tasks differences is the sum of the concentrations found on surface elements in the simulated time (all of the simulated time/s/). The surface elements were selected because of radioactive substances penetration out of the geosphere into biotopes.

The rate was "fixed" as we supposed that: (1) all the simulated time/s/ were of the same "weight"—the simulated time entry was done in an equidistant way, (2) elements were of the similar volume. That presumption was met, there was no "over-density" of any part of the area reflected on the calculated net. The total simulated time was 200 000 years and the results were recorded into the input files every 1000 years.

The resulting volume activities on selected elements were compared with the Reference Task and are stated in Table 4.

Table 4. Sensitivity analysis results.

	C14	Cl36	I129	Cs135	Ra226
The reference task, sum of activities [kBq/m^3]	16 950	3 400	148	1 850	1 450
Change parameters					
Rock near the DGR, hydraulic conductivity 0,1x	3.49x	3.46x	3.49x	3.42x	3.13x
Hornina blízko úložiště, vodivost 0,2x	2.25x	2.24x	2.26x	2.23x	2.10x
Rock near the surface, hydraulic conductivity 2x	2.07x	2.08x	2.08x	2.08x	2.08x
Hornina u povrchu, vodivost 5x	3.90x	3.91x	3.91x	3.92x	3.93x
Hornina u povrchu, vodivost 10x	4.86x	4.86x	4.86x	4.87x	4.88x

It is clear (from the results stated in the Table 4) that the strongest impact on the substance concentration increase in the surface area was caused by:

– Decrease of hydraulic conductivity in the surroundings of the DGR (with the types of rocks 9517, 9617), where the preference like is represented by a fissure system and where contamination is not diluted anyway. That is why concentration near the surface is increased (as dilution of concentration happens on the surface).
– Increase of hydraulic conductivity near the surface of the area (with the types of rocks 9112, 9212 and 9317), where transported substances are spread into greater "near the surface" area, due to higher hydraulic conductivity.
– Decrease of sorption coefficient K_d with substances of a higher sorption parameter. According the results, the sorption parameter has a strong impact on the substances transport in the surroundings of the DGR—having also an impact on the total weight (mass) of substances released out of the near/far field. The weight (mass) of the released substances could have an crucial impact on concentration (volume activity) on surface elements.

5 CONCLUSION

A complex task describing a substances-transport out of the DGR onto the surface of/within the area was presented in the paper. Our model covered a real area that had passed through a geological and hydrological research in the precedent years. The area was described by a geometry that included the basic geological types of rocks and the location of a fissures-net. The geological "situation" is described with: (1) hydraulic conductivity, (2) rock(s) porosity and (3) openings of fissures. The other input parameters were: (1) substance quantity released out of the near/far field border in the surroundings of the DGR, (2) sorption and diffusion coefficients of particular isotopes released out of the near/far field of the DGR.

A calculation net was designed for the area. Substance Flow and Substance Transport was calculated with the use of the SW Flow123D. The results of the transport task were verified with the use of the SW GoldSim afterwards.

The radioactive dose was calculated from the obtained substances concentrations (volume activities) of isotopes (in every element of the calculated net). The selected scenario supposed a human being who drinks 1 m^3 of ground water a year. The maximal dose on some surface elements was 110 μSv/year. That did not reach the limit of 3 mSv/year.

A sensitivity analysis was done through a parameter change in the model. Parameters of hydraulic conductivity, porosity, opening of fissures and sorption parameters were changed for every critical isotope and the impact of such a change on resulting concentration (volume activity) on surface elements was observed.

An impact of the operators and passengers behavior on the airport's security screening reliability

A. Kierzkowski & T. Kisiel
Wrocław University of Technology, Wrocław, Poland

ABSTRACT: The authors have developed a simulation model of the airport's security screening counters in terms of the impact of the behavioral characteristics of the operators and passengers on the reliability of the system. Intentionally been omitted reliability of technical objects, due to the fact, that the authors attempt to determine, where the failures occur during daily (reliable) functioning of the security screening system. The simulation model was developed to estimate the above-mentioned aspects for any configuration of counters with a wide ability to editing a method of conducting screening for given assumptions.

The developed model enabled the execution of simulation experiments for the counters with different capacities of contained areas in single security screening lane. In the next step was possible to determine the probability density function for the effectiveness of the process in the hourly period of time.

1 INTRODUCTION

1.1 *Legal requirements*

Bearing in mind the necessity to ensure a high level of security for air transport system, international law regulates, inter alia, the procedures relating to the control of the flow of passengers and luggage at the airport. The main law responsible for maintaining the level of security of air transport in Poland is the Regulation of the Minister of Transport, Construction and Maritime Economy of 31 July 2012 on the National Civil Aviation Security Program (Dz. U., 2012), referring to regulations (EU, 2010; EC, 2008; EC, 2009), setting out detailed procedures, the enforcement of which is the duty of the manager of the airport. Airports designate appropriate zones designed for the movements of passengers, baggage and the performance of the necessary ground handling processes:

- airside, with limited access,
- security restricted area, which is a part of the airside area and in which are also used other aviation security standards (for example, part of the airport designated for the movement of passenger flows after security control, part of an airport appointed for the movement of baggage flows subjected to security control, aprons while passengers boarding or luggage servicing),
- critical part of the restricted area, defined for airports, which employ at least 40 people with access cards to the restricted area. For critical part of the restricted area is included:
  - part of the airport where occur a passengers and luggage flow after the security control,
- separated area, which is a part of restricted area and designate an area separated from another area. This area has its application even to the departure hall, in order to separate the flows of passengers from Schengen and Non-Schengen zone.
- landside, which means that part of the airport, which does not belong to airside.

1.2 *Security screening*

Airport managing body shall designate boundaries between each zones clearly to differentiate by physical barriers that prevent access by unauthorized persons. Access to the restricted area is performed by security control system via counters with special devices able to detect potentially dangerous items. Before screening, passengers are required to prepare the cabin baggage to control and put outer garment to suitably cuvette in the area reserved for this purpose. Operator can also ask the passenger to insert additional garment into cuvettes, depending on the probability of occurrence of potential causes to occur the error to pass through the detectors

It is important that from cabin baggage is the need to remove large electronic devices, whose density can significantly affect the results obtained from the x-ray. These devices are subject to a separate inspection. Separate screening are also subject to fluids, which possibilities of transportation are regulated by the European Commission Regulation No 246/2013 (EU, 2013).

The next steps in the process are parallel baggage and passenger control. Screening of passengers can be carried out using:

– metal detectors,
– manual control,
– security scanners,
– devices for detection trace amounts of explosives combined with manual metal detectors,
– dogs to detect explosives in combined with manual control.

Screening of passengers can be carried out using:

– x-ray,
– manual control,
– explosives detection systems,
– dogs to detect explosives in combined with manual control.

Sniffer dogs and equipment for the detection of trace amounts of explosives may be used only as a supplementary means of screening during periods of increased risk. Control of passenger and baggage ends with a positive result only in case when the operator of the process is able to recognize clearly that the requirements of the screening process were provided. Any incorrect indication of control equipment must be diagnosed and eliminated. Otherwise, the passenger or luggage is subjected to re-inspection or decision is taken to refuse passenger from boarding the aircraft.

After completion of the screening process, passengers and their cabin baggage are protected from baseless intervention until departure of the aircraft, unless it would be "contamination" the passenger or luggage (contact with the passenger, luggage, which was not subjected to security checks). The algorithm of daily conducting security screening at the Wrocław Airport presents Figure 1.

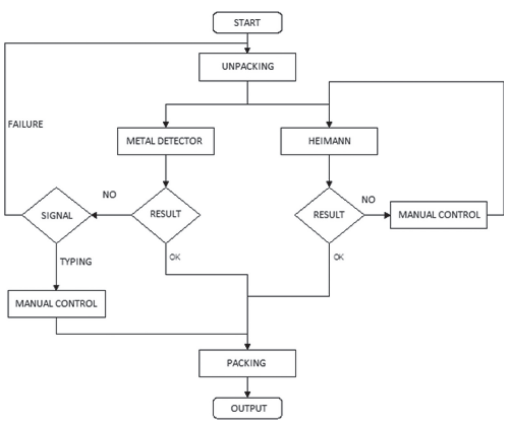

Figure 1. Scheme of security screening process.

1.3 *Modeling of security screening—literature review*

Modeling of ground handling services at airports is of interest to a wide group of scientists. In the literature can be found completely different approach. This is connected with numbers of different input variables and the diversity of the objectives to be attained.

There are several main directions of research. Very highly developed is the field of safety. Models in this area may even support in the development of technologies and procedures by assessing the impact of the implemented security technology (Akgun et al., 2010; Babu, et al., 2006; Chawdhry, 2009). Noteworthy are the models that in addition to the need to ensure the safety, indicate the need to minimize the inconvenience for the passenger (Gkritza et al., 2006).

Very well developed is also area of operational planning and design. Although for queuing systems are a variety of models for determining basic indicators—described in the literature as the queuing theory (Cooper, 1981). However, for complex processes, such as those at the airport are developed various models for engaging the wider analysis. From the old times, the models relate to the multicriterion analysis of passenger flows (Eilon et al., 1973). The issue of shortening the waiting time in queues with minimal use of resources was also discussed a long time ago and repeatedly (Baron et al., 1974; Manataki and Zagfros, 2010; Bevilacqua and Ciarapica, 2010). There are also a lot of models for allocating the appropriate number of resources (Roanes-Lozano et al., 2004; Solak et al., 2009).

The authors of this paper indicate how random is the flow of passengers through the security screening and show it in terms of reliability, to draw attention to the need for a wider analysis, particularly in regional airports, which due to low passenger traffic, often based on the basic characteristics. For the development of the simulation model the functioning of security checkpoints were used (Werbinska-Wojciechowska et al., 2013; Magott et al., 2009). The authors want to implement a Petri nets in further work (Kowalski, 2011). Today, many articles discuss the application of fuzzy logic for modeling complex systems (Vališ, 2014). In this work will also be taken into account reliability of the technical system (Magott et al., 2009; Plewa, 2009) and aspects of vulnerability (Vališ, 2012). Will be developed dependence functioning of the systems, as in (Vališ, 2012).

2 PROBLEM BACKGROUND

Knowledge of the procedures allows to forecast the basic efficiency characteristics of the carried

process. Theoretical estimates, which may take into account even the reliability of technical system, are purely illustrative. Security screening system is a system with relation machine-operator-environment in which, besides the basic characteristics of the reliability of technical system—causing the failures, are also failures, generated by the operators and the environment. Assuming the environment as a passengers of air transport system, can be seen a close relationship to the functioning of the line operator-environment-efficiency.

Airports, in the process of planning the necessary number of lanes to perform the assigned tasks, are often based on the primary statistical indicator—the arithmetic mean. However, in the case of non-uniform intensity of passengers notifications at a time, is really important a temporary efficiency of the process, which should ensure certain assumptions especially at the time of the increased flow of passengers (peak hours).

Passengers differ from each other in many categories. One of the important factors for the length of the performance of specific tasks in the next stages of the process, is the experience of traveling by air transport. Lack of knowledge of procedures significantly increases the time of service. The length of service time affects even the flight target. Another length of service is characterized by passengers of business flights (usually a low number of subjects to screening) and the other, for passengers of charter flights or low-cost (a large number of items subject to screening). This implies, that the process is stochastic. Time characteristics are presented later in this article.

3 DEVELOPED SIMULATION MODEL

3.1 *Assumptions*

The simulation model was developed by mapping procedure applicable in Wroclaw Airport. In the model, it has been assumed names of areas, in which take place specific tasks, as in Figure 2.

The passenger shall be notified to a queue common to all air operations. In the next step, depending on the availability of capacity of the unloading areas may move to an entry area. Because the simulation model applies to the double security screening counter (common metal detector for two lanes), entry area divides the input stream into two independent streams (*ELS*—entry left stream, *ERS*—entry right stream) and allocating passengers in one of them. The capacity for *ELS* stream is equal to:

$$C_{ELS} = C_{UA1} + C_{FU1} + C_{BAA1} \tag{1}$$

where C_{UA1} = capacity of UNLOADING AREA A1, C_{FU1} = capacity of FINAL UNLOADING 1 and C_{BAA1} = capacity of BUFFER AREA A1. Capacity for C_{ERS} is similar to C_{ELS}, but uses areas intended for the right stream. For both streams, capacity of some areas are deterministic and are equal:

$$C_{FU1} = C_{FU2} = 1 \tag{2}$$

$$C_{BAA1} = C_{BAA2} = 2 \tag{3}$$

The user put to the system the capacity of the entry area (C_{ELS}, C_{ERS}). Thus, indirectly determines the capacity of C_{UA1} and C_{UA2}, which can be determined after the transformation for example equation (1) for the left stream.

Passenger allocation to the appropriate entry stream is done on the basis of the shortest queue. In the case of absence of available place in both unloading areas, passenger is waiting for the available space to proceed to the unloading area. After passenger proceed to one of the streams of entry area, is respectively identified as a passenger of the left or right stream ($P_{LS_{(i)}}$—passenger of left stream, $P_{RS_{(i)}}$—passenger of right stream). Time

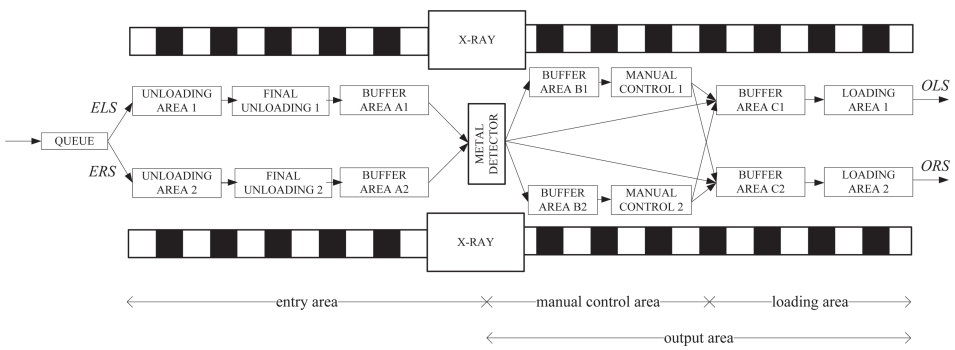

Figure 2. Structure of security screening counter.

of entry to unloading area ($t_{UAent_{(i)}} = t_{current}$) is recorded as a local label for each passenger, where $t_{current}$ = actual time of simulation. A passenger in this area received an information about the procedure and began to unload items on the conveyor, moving toward the final unloading area. Unloading time ($t_{1stunl_{(i)}}$) is a random variable of function $f_{(t_{1stunl})}$ (see Table 1). Flow of the *ELS* and *ERS* is based on the FIFO strategy.

A duration of the process ($t_{finunl_{(i)}}$) is determined by a random variable of function $f_{(t_{finunl})}$ (see Table 1). When the unloading process is completed, the passenger enters the buffer area (A1 or A2, depending on the side of the stream). Opportunity to enter the buffer area is therefore dependent on the availability of the capacity in the buffer area and when the equation (4) is true.

$$t_{current} - (t_{UAent(i)} + t_{UAwait(i)}) \geq t_{1stunl_{(i)}} + t_{finunl_{(i)}} \quad (4)$$

where: $t_{current}$ = current time of simulation, $t_{UAwait_{(i)}}$ = time when a passenger completed the process started in unloading area and had to wait for the input to the buffer area, due to the limited capacity. The algorithm for the entry area is shown in Figure 3.

Pass through a metal detector depends on the way from the three conditions. The first one concerns the separation between subsequent entrances. It is related to the functioning of a technical object, which indicates the possibility of entering the next passenger. Separation time is assumed as $t_{sep} = 2s$ (1st condition). Further conditions relate to the capacity of control area and receiving items area.

Passengers entering the metal detector from *ELS*, belong to the *OLS* (output left stream). Similarly, *ERS* passengers, upon entering the metal detector belong to the *ORS* (output right stream). Considering the *ELS*, the passenger of this stream can proceed to the metal detector, if the number of $P_{LS_{(i)}}$ in *OLS* is less than the capacity of the *OLS* (2nd condition):

$$\sum P_{OLS_{(i)}} < C_{OLS} \quad (5)$$

where, as passenger $P_{OLS_{(i)}}$ assumes the passenger $P_{LS_{(i)}}$ who has entered to the metal detector and are still in the system,

$$C_{OLS} = C_{BAC1} + C_{LA1} \quad (6)$$

where C_{BAC1}=capacity of buffer area 1, C_{LA1}=capacity of loading area 1. Capacity for C_{ORS} is similar to C_{OLS}, but uses areas intended for the right stream. For both streams, capacity of buffer area is deterministic and is equal:

$$C_{BAC1} = C_{BAC2} = 2 \quad (7)$$

This is related to the construction of the actual position of the test in Wroclaw Airport, where the loading area precedes the area separated from the

Table 1. Probability density function for specific tasks.

Task	Sign	Probability density function	Statistic test
First unloading	t_{1stunl}	$f(t_{1stunl}) = \frac{t_{1stunl}^{3,42}}{13,74^{4,42} \cdot \Gamma(4.42)} e^{-\frac{t_{1stunl}}{13,74}}$	0,4711
Final unloading	t_{finunl}	$f(t_{finunl}) = \frac{e^{-\frac{23,62}{t_{finunl}-0,94}}}{23,62 \cdot \Gamma(2,02) \cdot \left(\frac{t_{finunl}-0,94}{23,62}\right)^{3,02}}$	0,5786
Manual control	t_{mcont}	$f(t_{mcont}) = \frac{(t_{mcont}-16,95)^6}{2,13^7 \cdot \Gamma(7)} \cdot e^{-\frac{t_{mcont}-16,95}{2,13}}$	0,4041
Waiting for items	t_{wfi}	$f(t_{wfi}) = \frac{1}{B(0,67;2,56)} \cdot \frac{(t_{wfi}-2,93)^{-0,33} \cdot (139,10-t_{wfi})^{1,56}}{136,17^{2,23}}$	0,6551
Loading time	t_{load}	$f(t_{load}) = \frac{2,01}{23,62} \cdot \left(\frac{t_{load}-0,94}{23,62}\right)^{1,01} e^{-\left(\frac{t_{load}-0,94}{23,62}\right)^{2,01}}$	0,5768

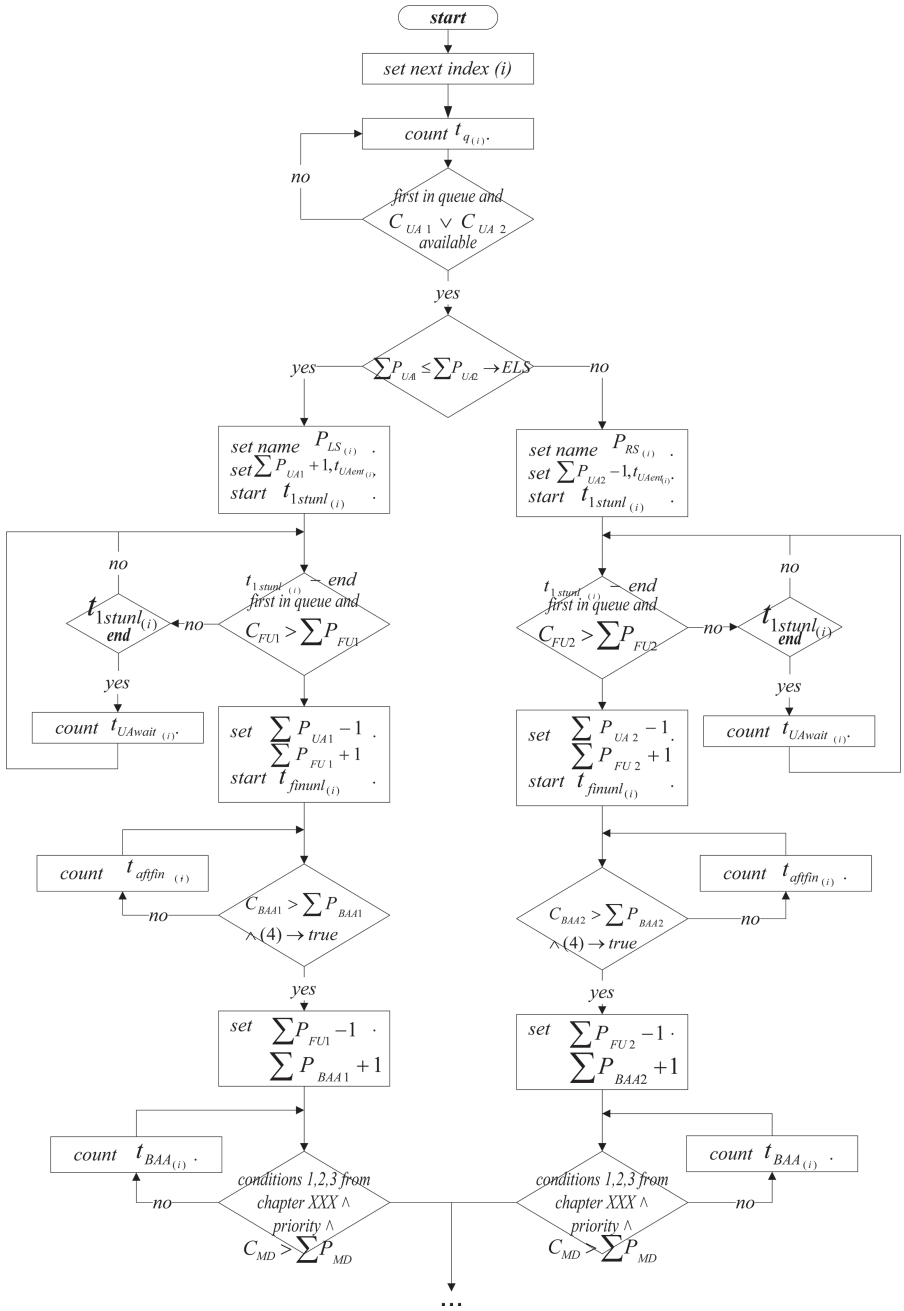

Figure 3. The algorithm for the entry area.

conveyor, used as a buffer area to increase the efficiency of the process.

Passenger flow strategy assumes assignment of two operators (both genders) for manual control of passengers. Passengers passing through the metal detector can be selected for manual control randomly or if has prohibited items. The intensity of the designation to the control is λ_c = 0,24 and was determined experimentally at the airport. The intensity of the direct flow

into the buffer area C is therefore is λ_{nc} = 0,76. Advantage of the double lanes counters in relation to the one lane counters is the fact that in the case of picking a passenger to manual control, the passenger flow is not suspended, because of the availability of the second operator conducting the process.

It is also possible to allocate buffer areas when the next passenger was directed to the same operator at the same time. Therefore, the third

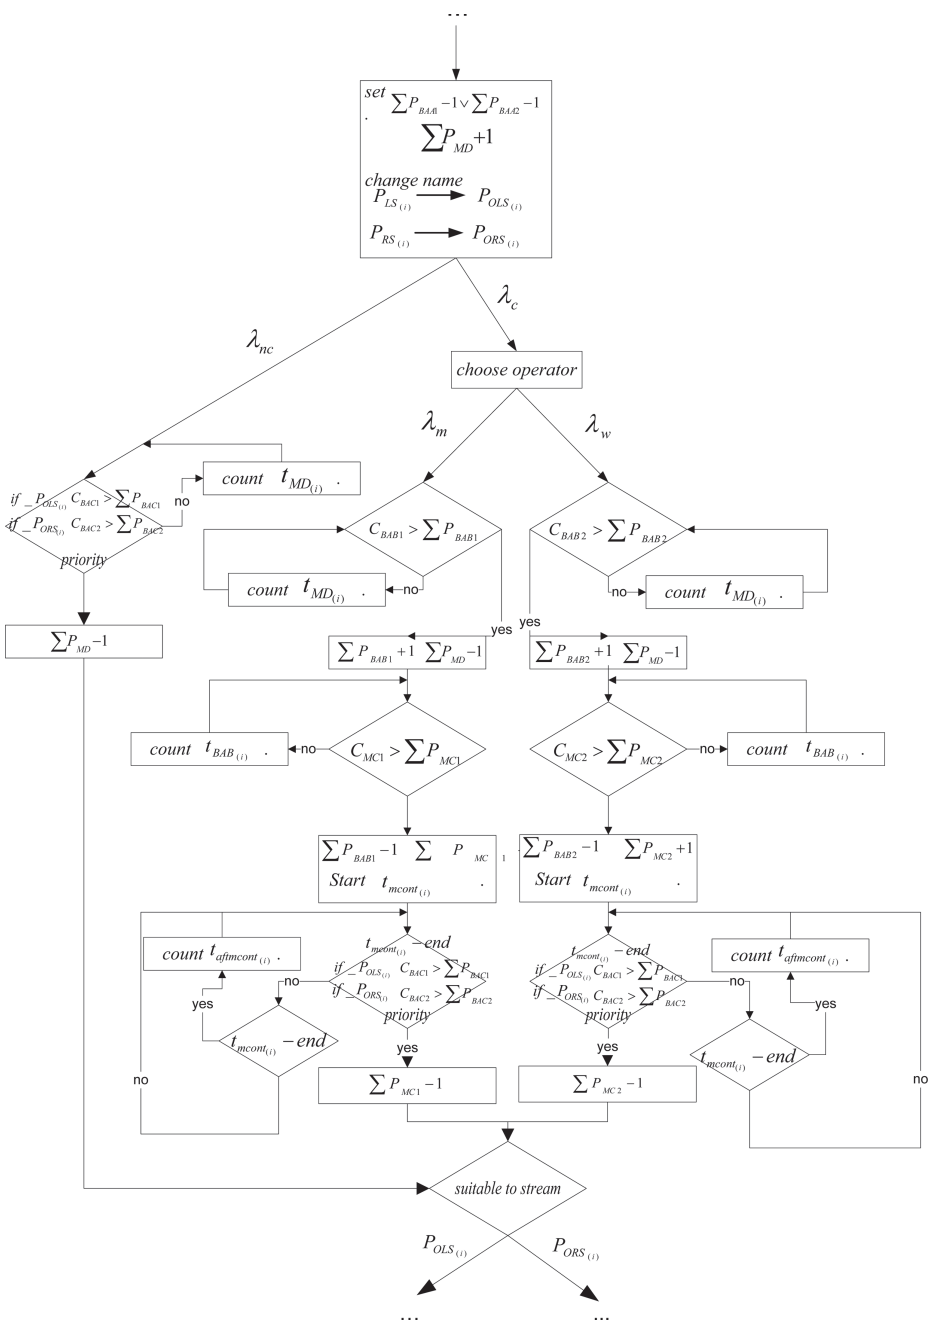

Figure 4. The algorithm for the manual control area.

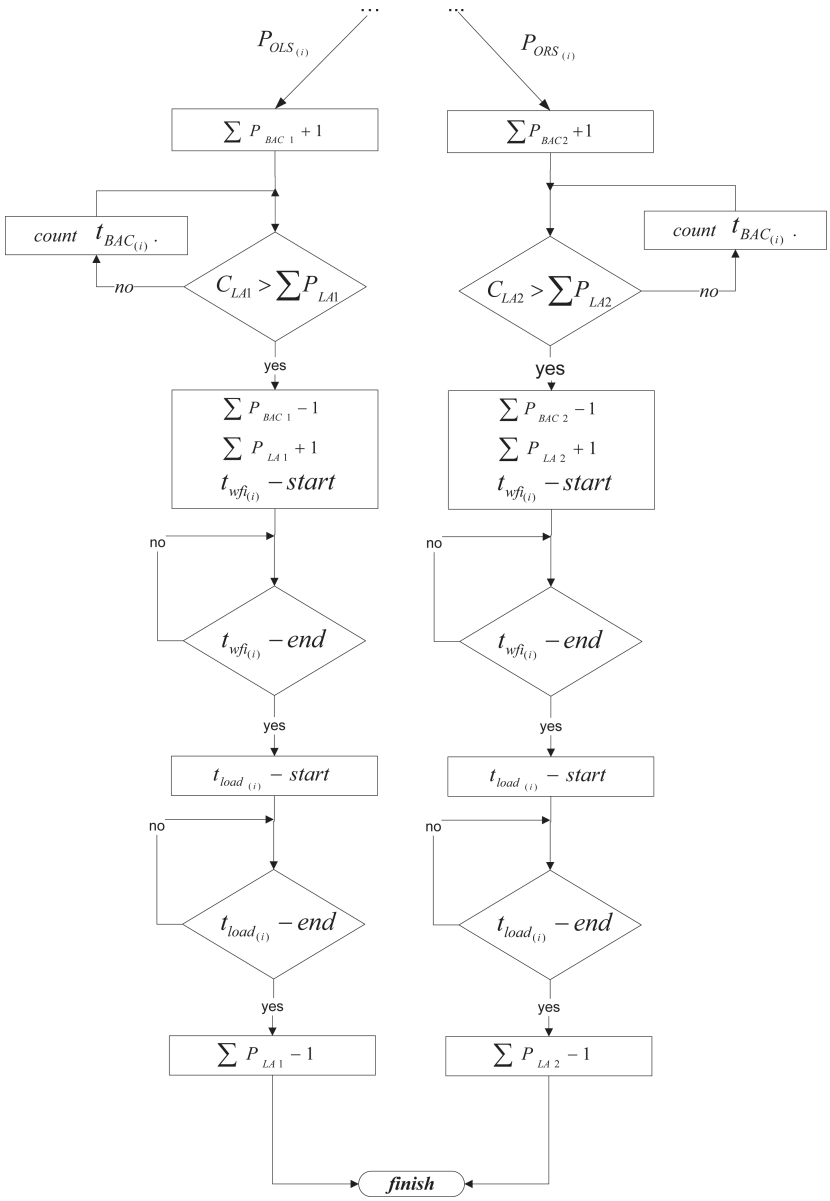

Figure 5. The algorithm for the loading area.

condition (3rd condition) for the possibility of entering the metal detector is to meet the equation (8), which says that at least, one operator must be available (9) and neither of the buffer areas can't be overloaded (10). Overloading too many passengers in the control area may adversely affect the proper conduct of control in terms of safety.

$$MD_{entconIII} = OP_{av} \wedge BA_{nov} \tag{8}$$

and:

$$OP_{av} = \left(\sum P_{MC1} = 0\right) \vee \left(\sum P_{MC2} = 0\right) \tag{9}$$

$$BA_{nov} = \sum P_{BAB1} < C_{BAB1} \vee \sum P_{BAB2} < C_{BAB2} \tag{10}$$

where: $\sum P_{MC1}$ = sum of total passengers inside manual control 1, $\sum P_{MC2}$ = sum of total passengers inside manual control 2, $\sum P_{BAB1}$ = sum of total pas-

sengers inside buffer area B1, $\sum P_{BAB2}$ = sum of total passengers inside buffer area B2, C_{BAB1} = capacity of buffer area B1, C_{BAB2} = capacity of buffer area B2. In described model the capacity are equal to:, $C_{BAB1} = C_{BAB2} = 1$.

Selected for manual control passenger is directed to an buffer area B for the same type process operator. Operator selection intensity was assumed as $\lambda_m = \lambda_w = 0{,}5$, where λ_m is a man and λ_w is a women. Entrance to the manual control 1 or 2 is possible if the area is available. Since the operator can control only one person at a time, capacity was taken as $C_{MC1} = C_{MC2} = 1$. Manual control time ($t_{mcont_{(i)}}$) is a random variable of function $f_{(t_{mcont_i})}$ (see Table 1). The algorithm for the control area is shown in Figure 4.

The next step is to proceed to the output area. Passengers after manual inspection or passing directly from the metal detector, enter the buffer area C1 or C2 (depending on flow stream) if there is a free capacity. Priority gets the passenger who came earlier to the output area. Buffer areas C are designed for waiting for the free capacity in the loading area 1 or 2. Capacity of buffer areas C have been assumed according to the actual system $C_{BAC1} = C_{BAC2} = 2$. Capacity of loading area 1 and 2 can be changed depending on a simulation scenario.

In the loading area there are two different variables assigned to the passenger. The first of these ($t_{wfi_{(i)}}$), determines how long passenger have to wait for items and is a random variable of function $f_{(t_{wfi})}$ (see Table 1). The second ($t_{load_{(i)}}$) is a random variable of function $f_{(t_{load})}$ (see Table 1). and determines the time of items loading. The sum of these two variables allows to leave the system by the passenger. The algorithm for the loading area is shown in Figure 5.

In summary, the total time a passenger in the system is equal:

$$\begin{aligned} t_{paxinsys_{(i)}} &= t_{q(i)} + t_{q\backslash stunl_{(i)}} + t_{UAwait_{(i)}} \\ &+ t_{finunl_{(i)}} + t_{aftfin_{(i)}} + t_{BAA_{(i)}} \\ &+ t_{MD_{(i)}} + t_{BAB_{(i)}} + t_{mcont_{(i)}} + t_{aftmcont_{(i)}} \\ &+ t_{BAC_{(i)}} + t_{wfi_{(i)}} + t_{load_{(i)}} \end{aligned} \tag{11}$$

where: $t_{q_{(i)}}$, $t_{UAwait_{(i)}}$, $t_{aftfin_{(i)}}$, $t_{BAA_{(i)}}$, $t_{MD_{(i)}}$, $t_{BAB_{(i)}}$, $t_{aftmcont_{(i)}}$, $t_{BAC_{(i)}}$ depend on the time of service and intensity of notification previous passengers and shall be designated during the simulation.

These values represent in the order as above: time in the queue to the system, the waiting time between the end of the initial unloading and the start of the final, waiting to enter the buffer area A after completion of final unloading, time in buffer area A, the waiting time at the output of the metal detector, the time in the buffer area B, the time in the buffer area C.

As input has been appointed times in subsequent steps in the process for $\alpha = 0{,}05$ (Table 1). For all the random variables are no grounds for rejecting the hypothesis of compliant empirical distributions with given theoretical (test statistics below 1.36).

3.1.1 *Results*

The model allows to determine the capacity in accordance with the specified input parameters. Capacity of entry area has been established as follows: $C_{ELS} = C_{ERS} \in \{3,4,5,6,7\}$. As input variables has also been established capacity of the loading area $C_{OLS} = C_{ORS} \in \{3,4,5,6,7\}$. Table 2 presents obtained mean capacity values for the screening process.

It should be noted that the currently functioning system of security screening in configuration 4×4 at Wrocław Airport obtain capacity of passenger flows through the metal detector at the level of 230-240PAX per hour. The developed simulation model reported a value of passenger stream flow at the level of 237PAX per hour. In order to achieve higher capacity, it is necessary to expand the entry area and/or expand the loading area after screening. From the obtained results, is clearly seen that expansion only of volume of the area to prepare for security checks will not increase the intensity of passenger flows. The key for Wroclaw Airport was to obtain capacity at the level of 300PAX/h This value may be achieved for $C_{ELS} = C_{ERS} = 6$ and $C_{OLS} = C_{ORS} = 5$.

However, while planning the allocation of resources to sustain the process, it should be brought into account some risk that the intended capacity will not be reached. If there will not be selected adequate spare of capacity, especially during the peak hours, the system can generate failures and be unreliable. The simulation model allows forecasting of counters capacity for selected intervals and counter's configuration (Fig. 6), which

Table 2. The average capacity depending on the size of the areas.

Loading area capacity	3	NO	216	NO	NO
	4	273	254	235	NO
	5	307	286	239	NO
	6	316	287	242	NO
		6	5	4	3
			Entry area capacity		

gives a greater understanding of the functioning of the process. There are also many other factors that could affect the reliability of the system in key moments of increased level of intensity of passenger flows (e.g. triggering radioactivity signal), which will be taken into account during further development.

3.2 *Model verification*

Model verification was carried out at Wroclaw Airport (PLW) on a sample of about 1000 PAX for each of the tested configuration. Due to the need to maintain high efficiency of the screening process in PLW, were verified only certain configurations, which are presented in Table 3. In the table as the value of NO was determined configurations that have not been verified.

Chi-square test at a significance level $\alpha = 0{,}05$ was verified hypotheses about the consistency of data obtained in the simulation model and observed in the PLW. The value of statistics $\chi^2_{0,05} = 16{,}919$, which proves the consistency of data in the simulation model with empirical data.

Verified were also times between subsequent notifications of passengers to the metal detector of security screening received in the simulation model and those observed in a functioning system. Results (after the split into time intervals) are presented in Figure 7. On significance level $\alpha = 0.05$ was verified compliance of distribution.

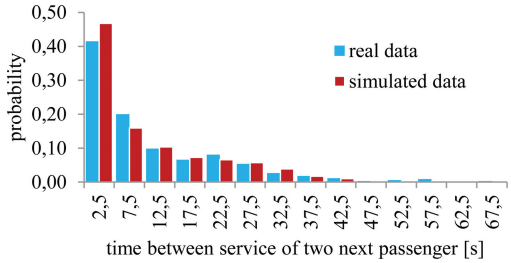

Figure 7. Verification of times between service of two next passenger.

Kolmogorov Smirnov statistic is equal $\lambda_k = 1{,}18$, whereas the limit value, obtained from the tables is equal $\lambda_{0,05} = 1{,}36$. This proves the compatibility of empirical data with simulation.

4 CONCLUSION

The paper presents a model of security screening, which allows the determination of the intensity of passenger flows at the selected input parameters. The advantage is versatility, which allows you to use it at any airport. However, it is necessary to insert the input data.

Further works are directed to the dependence of the system on subsequent factors affecting the reliability and an indication of the proper configuration of security checkpoints at a certain limited area available at Wroclaw Airport. Developed will also be an algorithm that will create a schedule for the operation of security checkpoints for a given timetable.

Risk analysis of the point on aging aircraft structure

M. Woch
Airworthiness Division, Air Force Institute of Technology, Warsaw, Poland

ABSTRACT: For complex systems, such as aircraft, the implementation of prognostic and health management techniques can effectively improve system performance. This paper presents some recent results of research on risk assessment for aircraft structures and intendeds to show the procedures of reliability calculations of the point of aircraft PZL-130 ORLIK TC II structure as an object under investigation. In this paper, the ways to determine failure rate and failure probability at the location on interest, which may be influenced by a different type of mission profile, have been presented. The goal of this paper was to answer the question of when inspections should be carried out depending on different types of missions. A technical risk management approach was applied to relieve the inventory problem to the highest degree possible, while ensuring safety.

1 INTRODUCTION

Typically, when one thinks of aging aircraft, safety is what comes to mind. However, another important aspect is readiness—that is the aircraft has to be available and reliable when needed. PZL-130 ORLIK TC II is a Polish two seat training aircraft designed by PZL Warszawa-Okecie. This aircraft was designed for basic and advanced training primarily for military pilot candidates. Constructed mostly of the 2024-T4 aluminium alloy, Orlik was design according to safe-life design procedures. Today Orlik is being called upon to last longer under more severe conditions. Consequently, the current tools of structural analysis must go beyond the specifics of strength, durability, fracture mechanics and into the realm of probabilities. The question became how to realize a huge cost-avoidance (acquiring Orlik TC-II aircraft earlier and more rapidly than planned) while ensuring safety and maintaining readiness (Koucky & Valis 2007). To address this dilemma a technical risk management approach was devised to relieve the inventory problem to the highest degree possible, while ensuring safety (Valis et al. 2012, Valis and Vintr 2007b). Risk-based approaches and tools have been widely adopted by the aircraft communities, especially by the military, to ensure aircraft availability and to reduce cost while maintaining structural safety.

Some work on reliability analysis has been already completed e.g. (Woch 2013) however there is lack of complete risk analysis for the aircraft Orlik.

The paper has been intended to present the procedures of reliability calculations of the point of aircraft structure as an object under investigation (Valis et al. 2012). In this paper the ways how to determine failure rate and failure probability of all points, which may be influenced by a mission profile, have been presented. The goal of this paper is also to answer to the question of when inspections should be carried out on demand types of missions.

Presented mathematical model is implemented in the computer program PRobability Of Fracture (PROF) and widely used at United State Air Force (Babish 2010, Iyyer and Kittur 2002, Gallagher et al. 2005, Berens et al. 1998, among others). National Research Council Canada (Liao et al. 2003, Liao et al. 2011) are using a similar mathematical approach, which is implemented at ProDTA (PRObabilistic Damage Tolerance Analysis) software. However, ProDTA uses different numerical integration subroutines, and is enhanced with Monte Carlo simulation on crack growth modelling.

2 METHODOLOGY

For every critical location in the aircraft structure failure is defined either as having a crack larger than a pre-defined size or encountering a stress cycle at a crack with smaller size that produces a stress intensity factor that exceeds the fracture toughness (Miedlar et al. 2005, Valis and Vintr 2006a, Valis and Vintr 2006b).

Pre-defined size a_{cr} is defined as the size that corresponds to the mean fracture toughness $\overline{K_{IC}}$ and the average stress (63% percentile) per flight $\overline{\sigma}$:

$$a_{cr} = g^{-1}\left(\frac{\overline{K_{IC}}}{\overline{\sigma}}\right) \tag{1}$$

where g^{-1} is the inverse of the function (2).

The defining relation between stress intensity factor K, stress σ, and crack size a is expressed as

$$K/\sigma = \sqrt{\pi a}\beta(a) = g(a) \tag{2}$$

2.1 *Failure rates and failure probabilities*

Failure rate function $\lambda(t)$ (Bedford and Cooke 2001, Koucky et al. 2009, Valis and Vintr 2007a) is defined as the limit, if it exists, of the ratio of the conditional probability that the instant of time, T, of a failure of an item falls within a given time interval $(t, t+\Delta)$ and the length of this interval, Δt, when Δt leads to zero, given that the item is in an up state at the beginning of the time interval, which can be described as (3).

$$\lambda(t) = \lim_{\Delta \to 0} \frac{P\{T \le t + \Delta \mid T > t\}}{\Delta} \tag{3}$$

If T has a density $f(t)$ and the distribution $F(t)$, it can be writen:

$$\lambda(t) = \frac{f(t)}{1 - F(t)} \tag{4}$$

Given the failure rate, the life distribution can be calculated by the equation:

$$F(t) = 1 - e^{-\int_0^t \lambda(x)dx} \tag{5}$$

This analysis assumes there are two primary failure rates for fracture at the location ($\lambda(t) = \lambda_1(t) + \lambda_2(t)$) Damage tolerance is lost and the aircraft is unsafe when a crack reaches the predefined size ($\lambda_1(t)$) or cracks smaller than a_{cr} encounter an exceptionally large stress and the materialâĂŹs fracture toughness is exceeded ($\lambda_2(t)$).

2.1.1 *Slow crack growth*

Probability that crack size can exceed the predefined size a_{cr} can be described by (Miedlar, Berens, Hovey, Boehnlein, & Loomis 2005):

$$F_{\mathrm{Lcr}}(t) = 1 - F_A(a^*(t_{cr} - t)) \tag{6}$$

where $F_A(a)$ is the distribution function of crack length at the start of the interval; $a^*(t)$ is the crack size, which correspond to the time to failure; t_{cr} is the time, when crack size will reach the predefining size a_{cr}.

The first failure rate, associated with cracks growing to a_{cr} is then given by:

$$\lambda_1(t) = \frac{f_{\mathrm{Lcr}}(t)}{1 - F_{\mathrm{Lcr}}(t)} \tag{7}$$

2.1.2 *Sudden fracture due to an unusually large load during a flight*

Fracture occurs when an applied stress procedures a stress intensity factor which exceeds the fracture toughness for the crack. Probability Of Fracture (POF) can be calculated as: $POF = P\{\sigma \ge \sigma_{cr}\}$. Critical value of stress can be calculated form (2) as $\sigma_{cr} = K_{Ic}/\beta(a)\sqrt{\pi a}$. Distribution of maximum stress peak in a flight can be model by Gumbel distribution function $H(\sigma)$.

From the distributions of three random variables, the probability that a peak load will cause a failure during a flight at time t for cracks that are less than a_{cr} is a double integral over crack size and fracture toughness, and can be described by:

$$POF(t) = \int_0^{\infty}\int_0^{a_{cr}} \widehat{H}(\sigma_{cr}(a,k_c)) f_A(a;t)da \cdot f_{K_{Ic}}(k_c)dk_c \tag{8}$$

where $\widehat{H}(\sigma) = 1 - H(\sigma)$ is the exceedance probability for the peak load per flight; $f_A(a;t)$ is the density of the flaw size distribution at time interval t; $f_{K_{Ic}}(k_c)$ is the density for fracture toughness.

The failure rate due to a large stress can then be approximated by (Vintr et al. 2012, Vintr and Valis 2012):

$$\lambda_2(t) = \frac{POF(t)}{t_f} \tag{9}$$

where t_f is the length of a flight.

The overall failure probability for one point on the structure can be calculated from equation (5).

2.2 *Crack size distributions*

The initiating crack size distribution either comes from an equivalent initial flaw size characterization or is inferred from the sizes of cracks that are detected during inspections of the location. This analysis assumes that detected cracks will be repaired. The proportion of cracks that is detected and repaired depends on the $POD(a)$ function of the NonDestructive Inspection (NDI) system.

$$POD(a) = POI \cdot \int_0^a \frac{1}{x\sigma\sqrt{2\pi}} \cdot \exp\left[-\frac{(\ln(x) - \mu)^2}{2\sigma^2}\right] dx \forall a > a_{\min} \tag{10}$$

where POI—probability of the inspection or nondestructive testing performed conformity with the approved documentation; $a_{\min}$ = the minimum detectable crack size; $e^{\mu} = a_{50}$ = the median detectable crack size; σ = scale parameter.

The cumulative crack size distribution after all inspections F_{af} can be calulated by:

$$F_{af}(a) = P \cdot F_r(a) + \int_0^a (1 - POD(x)) f_{bf}(x) dx \qquad (11)$$

where $P = \int_0^\infty POD(a) f_{bf}(a) da$ is the percentage of details that will be repaired after cracks are detected; $F_r(a)$ = equivalent repair crack size distribution; f_{bf} = probability density of the crack size distribution at a location immediately before an inspection.

3 NUMERICAL CALCULATION

In this section we will briefly show the required input parameters in order to perform risk analysis calculation. Preliminary analysis conducted with the use of finite element methods (Leski et al. 2008) in order to obtain the region of the points placement were performed. To perform further calculations the crack of main spar web in bottom part, right wing between ribs No. 5 and 6, below the hole for cables have been chosen.

3.1 *Distribution of plane-strain fracture toughness*

The parameter K_{IC} characterizes the resistance of a material to fracture in the presence of a sharp crack under severe tensile constraints. To determine the mean and standard deviation of K_{IC} 11 RTC samples, made of aluminium alloy 2024-T4 in the L-T reference directions were tested (Lisiecki & Bochenek 2013).

Results are presented in Table 1 where K_Q is the provisional value of K_{IC}.

The obtained mean value of plane-strain fracture toughness was $\mu(K_{IC}) = 36.75$ MPa$\sqrt{\text{m}}$ and standard deviation was $\sigma(K_{IC}) = 0.25$ MPa$\sqrt{\text{m}}$, in accordance with the standard (ISO-12737 2010).

Table 1. RTC samples (Lisiecki et al. 2013).

Samples	$K_Q(MPa\sqrt{m})$
1	37.4558
2	37.2230
3	36.8735
4	37.9447
5	36.5824
6	36.2398
7	36.3771
8	38.0453
9	37.1710
10	36.8731
11	36.8671

3.2 *Relation between stress intensity factor, stress, and crack size*

Relation between stress intensity factor, stress, and crack size, which is described as (2) was obtained from the damage tolerance analysis. Calculations were performed with the use of finite element methods; Patran and Nastran software, which are the world's most widely used pre/post-processing software. The results of calculations are listed in Table 2.

3.3 *Maximum stress distribution*

The distribution of maximum stress peak in a flight is modeled in terms of a Gumbel distribution of extreme values.

Based on 19 different types of missions, which were performed in order to obtain the average profile of 200 simulated flight hours (Leski & Dragan 2010), we obtained the following distribution, mathematically represented as:

$$H(\sigma) = e^{-\exp\frac{-(\sigma-84.8)}{10.43}} \qquad (12)$$

Another simulation was performed in order to obtain the distribution for which the construction suffers high stress cycles. The following distribution was obtained:

$$H(\sigma) = e^{-\exp\frac{-(\sigma-118.5)}{21.2}} \qquad (13)$$

The results of calculations of both simulations are showed on the Figure 1. The length of a average flight was designated as $t_f = 42$ min.

3.4 *Inspection capability*

Inspections are performed using the eddy-current testing, which was based on the electromagnetic

induction to detect flaws in conductive materials. In order to obtain the proper fitting (Fig. 2) to the cumulative lognormal equation (10) nonlinear fitting procedure based on Levenberg-Marquardt algorithm has been used. Parameters used for further calculations are as follows: POI = 1; $a_{min} = 0$; $a_{50} = 3.03$ mm $\sigma = 0.35$.

The lacking input data for the calculations were mainly adopted from literature (Miedlar et al. 2005, Valis and Pokora 2014).

3.5 *Failure rates and failure probabilities*

The numerical calculation of failure rates and failure probabilities were calculated using the computer program PRobability Of Fracture (PROF) which is based on a deterministic damage tolerance approach and uses the methodology described above.

Because of different types of missions, two separate analyses had to be performed. After calculations we obtained the following results of failure rate and failure probability, presented in Figures 3 and 4.

The challenge for this contribution was how long to leave this aircraft in service without inspections. In order to calculate intervals between inspections several analyses were performed. Finally, we obtained the results of calculations shown in the

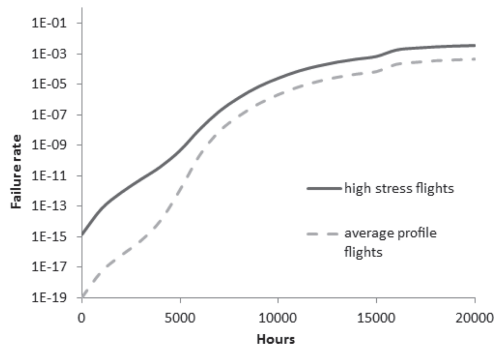

Figure 3. Failure rate.

3.6 *Conclusion*

A brief review of the Record of Airworthiness Risk Management (Liao M. & G. 2012) process shows that risk assessment is becoming a very important tool for managing aircraft airworthiness. For complex structural systems, both qualitative and quantitative risk assessments are needed to support decision-making.

In accordance with (MIL-STD-882E 2012, MILSTD-1530C 2005) a probability of catastrophic failure at or below 10^{-7} per flight $\lambda(t)$ for the aircraft structure is considered adequate to ensure safety for long-term military operations. Probabilities of catastrophic failure exceeding 10^{-5} per flight for the aircraft structure should be considered unacceptable. When the probability of failure is between these two limits, consideration should be given to mitigation of risk through inspection, repair, operational restrictions, modification, or replacement (Koucky et al. 2009, Valis and Vintr 2007a).

The challenge set for this contribution was how long to leave this aircraft in service without inspections. In order to guarantee safety and maintain readiness, the following times to perform the inspections, as is shown on the Figure 5 and presented in Tables 3 and 4, were suggested.

This example demonstrate how risk analyses might be used as one more source of information in evaluating inspection intervals. Although not shown in this paper, a similar analysis has been performed for different points and for multiple points. In that case, however, different types of input parameters have been chosen (Valis and Zak 2014, Valis and Krzak 2014).

ABSTRACT: The increase in the size and production capacity of air separation plants has boosted the need of developing methodologies to properly assess the risk related to major releases of liquefied gas. In this respect, the Leak-Before-Break (LBB) assessment is currently adopted to demonstrate the safety of the structures containing liquefied gas, under the assumption that the tank is always operated in nominal conditions. This assumption is questioned in this paper, which proposes a new methodology for the assessment of the risks related to cryogenic tank catastrophic rupture. The methodology provides a comprehensive understanding of the issues associated to the worst case rupture scenario: from the investigation of the causes of the undesirable operating conditions up to the analysis of the associated structural consequences, within a probabilistic framework.

1 INTRODUCTION

The increase in the size and production capacity of air separation plants, has led to a growing capacity of cryogenic liquid storage installations at production sites. Therefore, considering the potential hazards associated with liquid products has become a fundamental issue to address, together with the estimation of the effects of a major release of liquid on the local environment, and the development of preventive measures.

Nowadays, evaluating the structural safety of the cryogenic tanks by critically examining the integrity of new or existing constructions is a common practice. To do this, non-destructive testing methods for flaws detection are usually performed, whereas acceptability criteria for the revealed flaws have been defined in standards of the sector. In this respect, a typical approach to demonstrate the safety of a structure containing defects is to design it under the Leak-Before-Break (LBB) criterion; the scope is to guarantee that in nominal operating conditions the stress conditions inside the structure are such that the growth of flaws leaves time for a stable leak of the liquefied gas preceding the occurrence of a sudden disruptive break of the structure. Thus, a leakage of fluid through a crack can be detected before it reaches a critical dimension; this allows preventing catastrophic liquefied gas releases.

In practice, the LBB design criterion is based on setting two critical values for the crack length: l_C and l_L. The former represents the maximum length that prevents the tank from experiencing a catastrophic rupture; the latter represents the minimum length to have a fluid leakage. To meet the LBB criterion, the designers have to prove that $l_L < l_C$ with a suitable margin: in this case, a fluid leakage is detected before the catastrophic failure. In particular, the analysis is conducted at the most risky vessel sections, i.e, the sections with extreme loading conditions and poorest material properties.

However, the traditional LBB approach suffers from the limitation of considering the tank

behavior in nominal operating conditions, only. Indeed, it is also interesting to analyze the worst case rupture scenario, which, for the structure under study, coincides with the tank catastrophic rupture, caused by potential malfunctions of the control system or the safety devices.

In this context, the paper proposes a new approach to the assessment of the risks related to the catastrophic rupture of a flat bottom cryogenic tank containing Liquefied Oxygen (LOX). The rupture is considered catastrophic if it leads to an uncontrollable nearly-instantaneous release of the entire liquefied gas content. The assessment aims at reaching a comprehensive understanding of the problems related to the tank rupture, from the investigation of the causes of abnormal operating conditions up to the analysis of the associated structural consequences, within a probabilistic framework.

The proposed procedure consists of two parts. In the first part, Failure Mode and Effect Analysis (FMEA) and Fault Tree Analysis (FTA) guide the investigation of the storage system in order to identify the critical events that may evolve in dangerous scenarios affecting the structural safety of the tank, together with the associated occurrence frequencies. This part of the study also includes sensitivity and uncertainty analysis, which allow improving the robustness of the results. In the second part, structural analyses based on Finite Element Methods (FEM) are performed to investigate the behavior of the tank in both ordinary and abnormal operating conditions. In particular, the abnormal conditions are those in which the vessel is under exceptional stresses, due to the critical scenarios identified by FMEA and FTA. The combination of FMEA, FTA and FEM structural analyses allows identifying and assessing the stress conditions which may lead to a catastrophic rupture of the tank. The main outcome of such an analysis is a list of recommendations such as the installation of protective equipment and instrumentation, definition of a strategy for equipment inspection and testing, identification of the components for which a re-design may be convenient, etc. This allows reducing the occurrence of large releases of cryogenic fluids, by providing useful guidelines to the engineers directly involved in the design, installation, operation and maintenance of bulk cryogenic liquid storage systems.

2 CASE STUDY

The methodology is illustrated by way of a real case study concerning a LOX flat bottom cryogenic tank, owned by SOL Group and sited in Frankfurt. The analysis focuses on the cryogenic tank and all the pieces of equipment connected to it. This is compliant to the definition of tank given by EIGA IGC Doc. 127/13/E(EIGA 2013):

"the total fixed assembly of liquid storage tank(s) integrated with other equipment, such as pumps, filling equipment, pressure build-up vaporizers, controls and other related ancillary equipment that are connected to it."

The cryogenic tank is made up of two different structures: the internal vessel, which is designed to contain the cryogenic liquid, and the outer casing, which contains the insulating material that ensures a correct storage of the liquefied gas. The inner tank, with capacity of 2000 m^3, is made of stainless steel A240-304; this material is capable of withstanding cryogenic temperatures of the liquefied oxygen, which is stored at −183 °C, at nearly atmospheric pressure (−0.0022 bar < P < 0.095 bar). The outer casing, made of A283 grC, is not designed to withstand low temperatures, as it is not wetted by liquefied oxygen in normal operations.

Both vessels are connected to a number of components which allow performing the liquefied oxygen load and unload operations, and guarantee that the operating pressure, temperature and level conditions are close to the corresponding design values.

The tank is usually filled with the liquefied oxygen from the liquefaction unit, although sometimes it can be stocked up with liquid from tanker track. The unloading operation is performed by means of cryogenic pumps, which fill the tanker tracks for final distribution. A drain system is also installed on the inner vessel to allow the complete removal of the stored liquid in emergency conditions.

The annular space delimited between the inner and outer vessels is intended to ensure a thermal insulation. To this aim, it is filled up with perlite, an amorphous volcanic glass with high insulating characteristics and light weight. Moreover, to guarantee a better insulation quality, the annular space is also continuously flushed with nitrogen, which allows keeping the insulation in a dry state. The nitrogen flow is provided by nozzles located at the inner vessel bottom, and is released in proximity of the top of the tank.

Table 1 and Table 2 summarize the material properties and the operating conditions of the inner vessel and the annular space, respectively.

The operating conditions are controlled by two redundant systems: an equipment installed to regulate the value of the parameters during normal operations, and a set of safety devices to prevent the occurrence of dangerous conditions in the tanks, when regulating system fails. In addition, the vessels are provided with detectors and alarms, which go off when measured parameters assume unexpected values.

Table 1. Material properties.

	Oxygen	Nitrogen
Content in air	21 Vol%	78.1 Vol%
Gas density (1.013 bar, 15°C)	1.36 kg/m^3	1.19 kg/m^3
Boiling temperature (1.013 bar)	–183°C	–196°C
Liquid density (1.013 bar, boil T)	1.14 kg/l	0.8 kg/l

Table 2. Operating conditions for the LOX storage system.

	Inner tank	Annular space
	Oxygen	Nitrogen
Temperature	–183°C	+20°C
Vapor space press max	+0.095 bar	+0.01 bar
Max negative pressure	–0.0022 bar	–0.0022 bar
Max level	14.32 m	

3 A NOVEL APPROACH TO RISK ASSESSMENT OF A CRYOGENIC TANK

The risk associated to the catastrophic rupture of the cryogenic storage system described above has been studied by applying a novel and comprehensive approach, which can be summarized in the following three steps:

1. FMEA and FTA. These traditional techniques of risk analysis allow identifying the critical events that may lead to dangerous scenarios affecting the structural safety of the tank, and estimating the associated occurrence frequencies.
2. Uncertainty and sensitivity analyses, which are performed to assess the robustness of the results obtained from the previous step.
3. Structural analyses, performed to evaluate the severity of the consequences of the tank rupture both in ordinary operating conditions and in the critical scenarios identified by FMEA and FTA.

In the following Sections, the different steps are detailed, and the corresponding results commented.

3.1 *Identification of critical events dangerous for the structural safety of the cryogenic tank*

3.1.1 *Procedure*

In the first step of the procedure, a FMEA study is performed, whose core is to go over all the potential component failure modes, identify the consequent losses of system functionalities and configure the resulting outcomes from the accidental scenarios; a qualitative evaluation of the criticality of the failure modes is also given by the analysts in terms of severity of consequences and likelihood of occurrence. These two latter attributes, severity and likelihood, are the entries of a criticality matrix, which allows assessing whether the failure modes are critical and violate the safety requirements.

This analysis has supported a full understanding of the system at hand, and its main outcomes have been:

- The functions implemented by the system;
- The items involved in performing these functions;
- The consequence of each loss of function. This information is used for the identification of the most severe events in relation to the tank integrity, to be further investigated;
- The identification of the most critical elements of the system, whose malfunctions can affect the integrity of the tank or the success of functions that concur in assuring the structural integrity;
- The identification of the failure modes and failure rates associated to the critical items;
- The detection means of the different failure modes;
- The redundancies of the system, listed in the fields "compensatory measures" and "remarks".

Once the critical events have been identified, a quantitative FTA has been carried out to estimate the occurrence frequencies of the undesired events.

3.1.2 *Results*

The functioning of the storage system has been analyzed with respect to eight main functions:

1. Inner tank pressure regulation;
2. Inner tank pressure safety control;
3. Inner tank level safety control;
4. Liquid extraction;
5. Liquid introduction;
6. Insulation;
7. Annular space pressure safety control;
8. Oxygen containment.

The FMEA has shown that the safety related functions are the most critical among the eight above. This is an expected result, as safety related functions are involved in mitigating or compensating conditions potentially dangerous for the tank integrity. In this respect, Table 3 shows the critical functions and the subsystems involved in their implementations.

Table 3. Critical functions and related subsystems.

Functions	Associated subsystems
Inner tank pressure Safety control	Pressure safety valve PSV4001 Pressure safety valve PSV4002
Inner tank level Safety control	Differential pressure level meter LT/LI4002 Differential pressure level meter LT/LI4003 Level switch LSHH/LSH4004
Annular space pressure Safety control	Pressure safety valve PSV4003 Pressure safety vent PSE4001

Finally, the procedure has allowed to identify four critical events and their occurrence frequencies:

- TOP event 1: overpressure in the inner tank (pressure > 95 mbar), as consequence of the malfunction of the pressure safety subsystems;
- TOP event 2: under pressure (i.e., vacuum) in the inner tank (pressure < –2.2 mbar), as consequence of the malfunction of the pressure safety subsystems;
- TOP event 3: extreme liquid level in the inner tank (level > 14.32 m), as consequence of the malfunction of the level safety subsystems;
- TOP event 4: overpressure in the annular space (pressure > 10 mbar), as consequence of the malfunction of the pressure safety subsystems.

The failure frequencies of the four critical events, at time $t = 20$ years are listed in Table 4. In particular, these values refer to two different settings:

1. The Pressure Safety Valves (PSV) installed on the tank to protect the structure against overpressures are periodically inspected, with a period of 4 years;
2. PSV are not inspected.

In this respect, notice that the regular inspection and maintenance of the pressure safety devices is not mandatory for the typology of tank under analysis, since the particular vessel is not required to comply with the Pressure Equipment Directive (97/23/EC).

The two different work hypotheses yield two values of occurrence frequencies. In fact, the inspection interval enters the quantification of the availability of dormant devices such as the safety valves degradation (Zio 2007). In particular, from Table 3 it emerges that even when the PSV are not periodically inspected, the frequencies of the four top events have very small values (smaller than 10^{-7} y^{-1}). The small values of these frequencies are due to the fact that long sequences of failure events have to occur to get the top event; in addition, as illustrated in Table 3, there is redundancy of safety control devices.

Table 4. Occurrence frequencies of critical events.

	Failure frequency events/year	
	PSV inspected	PSV not inspected
TOP event 1	8.76 e-12	7.86 e-10
TOP event 2	3.64 e-10	3.27 e-8
TOP event 3	8.30 e-9	7.93 e-8
TOP event 4	1.85 e-10	1.68 e-8

On the other side, from Table 4 it also emerges that when the PSV are regularly maintained, then the occurrence frequencies of the top events decrease significantly. Therefore, a periodic inspection of the PSVs is highly recommended for any generic flat bottom cryogenic tank, even if not mandatory.

3.2 *Robustness of the results*

Importance, uncertainty and sensitivity analyses have been performed in order to investigate the robustness of the results. In particular, these additional analyses have been carried out for every critical event, with a twofold scope:

1. Identifying the component failures or basic events which most influence the event occurrence frequency. This allows to identify the system weaknesses, and provides guidelines for effective actions for system improvements;
2. Estimating the uncertainty on the critical event occurrence frequencies, which comes from the lack of precise knowledge about the failure model parameters.

3.2.1 *Importance analysis*

Generally speaking, Importance Measures (IMs) aim at quantifying the contribution of components or basic events to the considered measure of system performance, which can be the system reliability, unreliability, unavailability or risk, depending on the application (Zio 2007; Baraldi et al. 2009). Information about the importance of the components constituting a system with respect to its safety and availability is of great practical aid: the identification of the components which mostly determine the overall system behaviour allows identifying system vulnerabilities and the most effective actions for the system improvement.

Different IMs have been proposed in literature, which allow investigating different system features. In particular, the Birnbaum IM expresses the contribution to system reliability of the reliability of the various system components (Baraldi et al.

2013). In details, components for which a variation in the reliability results in the largest variation of the system reliability have the highest importance. Thus, a reduction in the occurrence probability of the most important events is expected to result in a reduction of the occurrence probability of the TOP event.

With reference to the analysed case study, the Birnbaum IM have been computed for each basic event constituting the Fault Trees of the four investigated critical events. This has allowed to identify the most important basic events, and thus the improvement actions with the highest priority.

The results of the analysis can be summarized as follows:

- The failure of the inner tank pressure Safety Valves greatly influences two out of four critical events (TOP event 1 and TOP event 2). Then, improving the reliability of these items is expected to lead to a great improvement in system reliability;
- Redundancy in the monitoring system of the control valves in the inner tank pressure would significantly reduce the occurrence probability of the critical TOP event 1;
- A good control during the operation of tank filling and emptying is recommended in order to reduce the probability of occurrence of the critical TOP events 2 and 3;
- The failure of the Pressure Control Valves PCV9039 (i.e., the valves regulating the nitrogen purging into the annular space between the inner and outer vessels) greatly influences the occurrence of the critical TOP event 4.

An uncertainty analysis has been performed in order to assess the robustness of the results of the importance analyses. In fact, the importance measures depend on the values of the failure probabilities of the components of the storage system, which are uncertain. Thus, the results of the importance analysis need to be checked against the variability due to the uncertainty in the model input parameters. To do this, uncertainty in the occurrence probabilities of the most important basic events has been considered by uniform distributions with lower and upper bounds provided by SOL experts. The analysis has highlighted that the uncertainties in the occurrence probabilities of the basic events do not impact on the ranking of the most important causes identified for each TOP event: thus, the results discussed above can be considered robust.

3.2.2 *Uncertainty and sensitivity analysis*

As mentioned in Section 3.1.1, FTA has been performed to calculate the occurrence probabilities of the four critical events identified by the FMEA study.

In general, FTA allows resolving a TOP event into the combination of single primary events, which contribute to its realization. Then, the probability of the TOP event is computed as function of the probabilities of the basic events. However, in practice it is often difficult to evaluate the exact probability values of the primary events, which are affected by uncertainties. These latter need to be propagated through the Fault Tree model to assess the variability in the Top event failure probability due to the variability in the probability values of the basic events.

Two different analysis have been carried out, both based on Monte Carlo (MC) method:

- Sensitivity analysis to identifying the contribution of the various basic events to the uncertainty in the TOP event.
- Uncertainty analysis to propagate the uncertainties from the basic events up to the TOP events.

The results of the sensitivity analysis have shown that the estimations of the probabilities of the critical events are significantly influenced by the uncertainties in the failure probability values of the PSVs, human errors and uncontrolled filling and emptying operations. Then, improving the knowledge about the occurrence probability values of the identified events would reduce the uncertainty in the overall system reliability.

Once the most influent basic events have been identified, MC sampling technique has allowed to estimate the probability distribution expressing the variability in the probability of occurrence of every TOP event considered. Such distributions have shown that the values of the occurrence probability calculated without uncertainty, are always near to the values of the distributions associated to highest probability (distributions modes). However, the occurrence probability reference values are located toward the low values of the probability distributions. This finding entails that disregarding the uncertainty in the top event probability values does not lead to conservative results, and thus highlights the importance of giving due account to the uncertainty in reliability assessments.

3.3 *Structural analysis*

The Finite Element Method (FEM) has been used to perform the structural analysis to demonstrate the LBB criterion in both nominal and deviated conditions. FEM is a numerical technique for resolving complex problems, widely used in structural mechanics. The structural system to be studied is modeled by a set of finite elements interconnected at points, called nodes, that are organized in a mesh. The analysis provides the stresses and displacements, in each single element of the

mesh. Therefore, the FEM methodology allows to identify the most stressed portions of the analyzed object.

For the case under study, the flat bottom tank has been modeled with a mesh of 262919 elements and 264267 nodes. The FEM analyses have been performed considering the tank behavior both in nominal operating conditions and in conditions of extreme loads, caused by the occurrence of the critical events identified by the previous failure analyses. The loads in ordinary conditions and the material strength have been set according to SOL internal documents.

As expected, the analysis performed in ordinary conditions has shown that the tank is not subjected to excessive stresses and strains when everything operates normally: both Von Mises stresses and displacements are smaller than the maximum allowable limit set by the designers. Moreover, the analysis has highlighted the weakness of the structure in correspondence of the conjunction between the wall and the dome of the inner vessel. This is due to the fact that the stresses concentrated in this portion of the structure are very high, as exemplified in Figure 1 which shows the stress level in the inner tank under external pressure, in nominal conditions.

Analyses relevant to the critical scenarios have been carried out with the purpose of identifying the extreme values of pressure (TOP event 1, 2 and 4) and liquid level (TOP event 3) that leads to the rupture of the tank structure. The resulting values are summarized in Table 5.

In particular, no value is reported for TOP event 3, corresponding to the scenario of tank overfilling. Indeed, the analysis has shown that the criticality of such scenario is not due to the hydrostatic pressure of the liquid, but to the overpressure generated by the pumps that introduce the LOX in the vessel. Therefore, the TOP events 3 is analyzed similarly to TOP event 1 (i.e., overpressure in the inner tank).

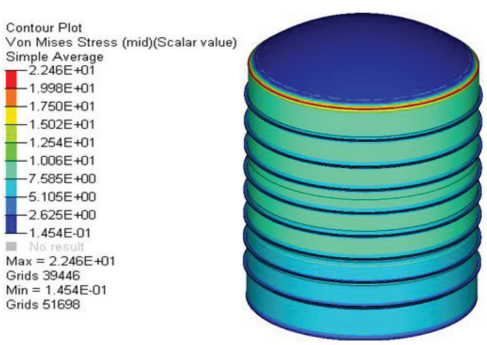

Figure 1. Von Mises stresses in the internal vessel under external ordinary pressure.

Table 5. Extreme loads that lead to tank rupture.

	Parameter	Max value
TOP event 1	Pressure inner tank	187.5 mbar
TOP event 2	Pressure inner tank	–175 mbar
TOP event 3	Level in inner tank	_
TOP event 4	Pressure annular space	1610 mbar

The values listed in Table 5 are expected to be reached gradually, with a slow variation in the level and pressure values. This operating condition makes reasonable to assume that if cracks appear on the metal surfaces, then they slowly propagate. In these conditions, the detection of the leak is possible before the sudden rupture of the tank. In details, the analyses have highlighted that TOP events 1, 2 and 3 lead to the rupture of the inner tank, whereas TOP event 4 generates failure on the outer casing. In the first case, the LOX penetrates into the annular space and ice forms on the outer casing; this can be visually detected. In the latter case, when the external vessel breaks, there is a release of perlite in the air, which, again, is easily detectable.

As in ordinary conditions, the loads corresponding to TOP events 1, 2 and 3 show that the weak section of the storage system lies in correspondence of the conjunction between the wall and the dome of the inner vessel. TOP event 4, instead, particularly stresses the surface of the vertical wall.

The results are compliant with the adopted manufacturing standards; in fact, quoting EIGA IGC Doc 127/13:

"The need to prevent a rupture by overpressure at the bottom of the inner tank is identified in the various available codes. API 650 talks of a frangible joint between the roof and the shell and gives it as a possible purchaser requirement. API 620, instead, establishes a link between the sizing of the anchorage straps and the design of the roof to shell junction. Finally, BS 7777 explicitly states that the weakest point of the structure shall not be at the bottom and present it as a further increase in safety".

3.4 *Conclusions*

The present study has been performed with the aim of evaluating the risks related to the catastrophic rupture of a flat bottom cryogenic tank containing liquefied gas. To do this, the cryogenic storage system has been deeply investigated in order to identify all the critical events that may evolve in dangerous scenarios affecting the structural safety of the cryogenic tank, together with their associated occurrence probabilities.

Four critical events have been identified, whose occurrence frequencies are very low. It has also emerged that regular inspections of PSVs yield a significant reduction in the occurrence frequencies of the top events.

The robustness of the risk analysis results has been checked by means of sensitivity and uncertainty analysis.

The structural behavior of the flat bottom tank has been analyzed both in ordinary operating conditions and in case of exceptional loads, due to the occurrence of the individuated TOP events, with the aim of assessing whether the identified scenarios produce loads that may lead to the rupture of the analyzed vessel.

As expected, the analysis performed in ordinary conditions has shown that the tank is not subjected to excessive stresses and strains. The analyses under the conditions brought by the critical events have allowed:

- Estimating the load conditions that lead to the rupture of the tank structure.
- Checking that there is a release of LOX or perlite when such load values are reached. This entails that both the failures of the inner and outer vessels can be detected.
- Verifying that an explosion of the tank can be regarded as improbable, due to the slow variation in level and pressure.

Finally, the structural analysis has also highlighted, in both ordinary and extreme conditions, the structure weakness in correspondence of the conjunction between the wall and the dome of the inner vessel, except for TOP event 4. This is compliant with the recommendations of the design codes API 620, API 650 and BS 7777, which require to design the vessels in such a way to ensure that the weakest point of the inner tank is not at the bottom cylindrical seam, but at the top of the vessel (EIGA 2013).

Modeling of a degradation path set with a Gamma process mixture—application to a maintenance decision rule

Edith Grall-Maës, Antoine Grall & Pierre Beauseroy
ICD-LM2S, Université de Technologie de Troyes, UMR 6281 CNRS, Troyes, France

ABSTRACT: A maintenance decision rule is considered for deteriorating systems executing successive working cycles and which can be inspected from time to time. A novel method is proposed to exploit jointly degradation measurements originating from a set of identical spare parts and maintenance practices for making a degradation prognosis. The systems experience different degradation processes depending on operational conditions, and assumed to be Gamma processes. The aim is to cluster the degradation paths in classes corresponding to the different operational conditions in order to group properly the data for the estimation of degradation process parameters. A model of Gamma process mixture is considered and an expectation-minimization approach is proposed to estimate the unknown parameters. The feasibility of the method is shown on simulated cases. Prognosis results obtained with the proposed method are compared with results obtained with basic strategies (considering each system alone or all systems together).

1 INTRODUCTION

In practice, most of the manufacturing systems have to execute successive jobs or working cycles. Some units or devices in the systems are deteriorating with usage. Wear or cumulative degradation can lead to failure with production downtimes or loss of quality of the end product. A relevant maintenance decision making ails to ensure balance between preventive planned maintenance and corrective one. In various situations different maintenance practices and different sets of spare parts procured from several suppliers have an impact on the degradation process.

This paper considers the case of a dynamic maintenance decision rule based on the remaining useful lifetime of the considered device or item. To estimate the Remaining Useful Lifetime (RUL) of a deteriorating system it is necessary to be able to model its deterioration in order to predict when the deterioration leads to a failure i.e. when it reaches a given threshold. To perform this RUL prognosis one generally relies on measurements of the degradation level and on a degradation model which is assumed to describe the degradation evolution in time (Si, Wang, Hu, & Zhou 2011, Nystad, Gola, & Hulsund 2012). For example, in the case of a metal pipe corrosion, the thickness provides a deterioration measure.

The Gamma process is widely used for degradation models when deterioration is non decreasing and gradual (Van Noortwijk 2009). This process is defined by a set of parameters, in particular the shape and scale parameters in the case of an homogeneous process. These parameters are usually unknown and must be estimated in order to perform prognosis. Obviously the reliability of prediction is directly related to the estimation precision. Most of the time, in operational conditions the amount of measurement is very limited. So when a set of similar systems is available, one can use the data coming from all the systems in the set to estimate the model parameters. The expected gain of using all measurements together is to improve the estimator precision (reduction of its variance for example).

By considering all systems as a single one while estimating the model parameters it is assumed that the degradation process model is the same for all systems. In most cases, the degradation process depends also on operating conditions that may be partially unknown. In the pipe corrosion example, the evolution of the pipe thickness depends on the used metal but it also depends on the characteristics of the fluid carried by the pipe (liquid/gaz, temperature, pressure …) and on the location (air/ground/underwater …) and on the environmental conditions of the pipe (temperature, humidity …).

In this paper, we consider that we have a limited amount of data from different systems. Each system has one operating condition among an unknown finite number. For each operating condition the degradation process is assumed to be ruled

by a Gamma process model. The aim is to estimate the parameters of these Gamma processes in order to predict their RUL for maintenance decision making purpose.

We propose a method to cluster the observed systems in classes, in order to estimate properly the Gamma process parameters. In order to tackle the hypothesis of a number of operating conditions, a model of Gamma process mixture is introduced. An expectation-minimization algorithm is considered to estimate the parameters of each process in the mixture model.

The problem is formalized in section 2. Then in section 3, the mixture model and the expectation-minimization algorithm (Ambroise & Govaert 1998) (Hu & Sung 2006) are presented to determine the clusters. In section 4, the considered prognosis is described and a maintenance decision rule is proposed. The maintenance policy assessment is used for comparing the prognosis values obtained according to different strategies of the Gamma process parameter estimation. In section 5, results on simulated data are presented and analyzed.

2 PROBLEM FORMULATION

This section first gives a description of the problem and notations and ends with a brief recall about the Gamma process.

2.1 *General aim*

The data we consider originates from N components which are inspected randomly. More precisely each component is inspected opportunistically e.g. when the system is stopped or between two production batches. It is assumed the time interval between two successive inspections is random and uniformly distributed between two bounds a and b. Each component is associated to a path describing its degradation process realizations. At a given time, each path $p_n, (n = 1, \ldots, N)$ is composed of $|p_n|$ observations $l_{n,i}$ with $i = 1..|p_n|$. The observation $l_{n,i}$ is characterized by the inspection time $t_{n,i}$, and the observed deterioration level $x_{n,i} = x(t_{n,i}) \in \Omega_x \subset \mathcal{R}$. Then $p_n = \{l_{n,i} = (t_{n,i}, x_{n,i})\}_{i=1..|p_n|}$.

We suppose that the observation set can be divided into K unknown clusters $C_k, (k = 1, \ldots, K)$. In practice, each cluster would correspond to an operating condition. Each cluster represents a deterioration process characterized by some unknown parameter vector belonging to the parameter set $\Theta = \{\theta_k\}_{k=1}^{K}$. Besides, the latent membership, or cluster labels of paths are denoted by $\mathbf{z} = \{z_n\}_{n=1}^{N}$ where $z_n = k$ means that the path p_n belongs to the cluster k. A set of cluster labels defines a partition of all paths. Obviously, for a given path n, all observations $l_{n,i}, (i = 1, \ldots, |p_n|)$ belong to the same cluster.

The aim is to determine the latent cluster label for each observation and jointly the parameter vector of each process. Afterwards this parameter vector can be used for remaining lifetime prognosis and maintenance decision-making. Each component is supposed "failed" as soon as its deterioration level crosses a threshold S hereafter referred as "failure limit".

In this paper the chosen model for the deterioration processes is the Gamma process, parameterized by 3 parameters, a, b and u described in section 2.2. The increments, given by $x(t_{n,i}) - x(t_{n,i-1})$ with $t_{n,0} = 0$ and $x(0) = 0$, are independent. Their density distribution in the cluster k depends on the time and on the parameter θ_k, and can be written as

$$f_k\left(x(t_{n,i}) - x(t_{n,i-1}) \mid t_{n,i}, t_{n,i-1}, \theta_k\right).$$

In the following, for simplicity we will use the notation $f_k(\Delta x_{n,i} \mid \theta_k)$. It has to be noticed that the density distributions of all the degradation increments are not the same because the increments are usually all different and/or the process may be not stationary.

The objective is to find out the unknown cluster labels $\{z_n\}_{n=1}^{N}$ and consequently the distribution parameter set $\theta = \{\theta_k\}_{k=1}^{K}$, such that paths in the same cluster originate from a process model with the same parameters.

The relevance of a partition described by $\mathbf{z}$ and a parameter set θ can be measured using the log-likelihood given by

$$l(\mathbf{z}, \theta) = \sum_{n=1}^{N} \sum_{i=1}^{|p_n|} logf_{z_n}(\Delta x_{n,i} \mid \theta_{z_n}) \quad (1)$$

2.2 *Gamma process*

2.2.1 *Definition*

Mathematically, the Gamma process is defined as follows: let $A(t)$ be a non-decreasing, right-continuous, real-valued function for $t \geq 0$, with $A(0) = 0$. The Gamma process with shape function $A(t)$ and scale parameter $b > 0$ is a continuous-time stochastic process $\{X(t), t \geq 0\}$ such that:

- $X(0) = 0$ with probability one;
- $\{X(t), t \geq 0\}$ is a stochastic process with independent increments;
- $\Delta_{s,t}X = X(t) - X(s)$ follows the Gamma distribution $\Gamma(A(t) - A(s), b)$ for $0 \leq s < t$

where the Gamma distribution is characterized by the p.d.f written as:

$$f_{u,v}(x) = \frac{v^u}{\Gamma(u)} x^{u-1} e^{-vx} \mathbb{I}_{(0,\infty)}(x) \quad (2)$$

with $u > 0$ the shape parameter, $v > 0$ the scale parameter, $\mathbb{I}_{(0,\infty)}(x)$ the indicator function and $\Gamma(x)$ the Gamma function.

The definition of the Gamma process leads to two straightforward properties:

- $\{X(t), t \geq 0\}$ is a non-decreasing process.
- For all $t \geq 0$, the expectation value and the variance of $X(t)$ could be written as:

$$\mathrm{E}(X(t)) = \frac{A(t)}{b} \quad \mathrm{Var}(X(t)) = \frac{A(t)}{b^2} \quad (3)$$

An homogeneous Gamma process corresponds to a particular case with $A(t) = at, (a > 0)$. In this case, $X(t) - X(s)$ follows the Gamma distribution $\Gamma(a(t-s), b)$, which means that the increments of the process depend only on the time increments $t - s$.

In the degradation modeling framework, a non-homogeneous Gamma process defined by $A(t) = at^u$, $(a > 0, u > 0)$ is often considered. Thus the process is described by three parameters: a, b, and u. In this case, $X(t) - X(s)$ follows the Gamma distribution $\Gamma(a(t^u - s^u), b)$.

2.2.2 *Parameter estimation*

Two methods are often mentioned for the parameter estimation of the Gamma process: the moments estimation and the maximum likelihood estimation (Cinlar, Osman, & Bazant 1977). The maximum likelihood estimator is asymptotically unbiased, which means the estimates converge to the true values as the number of observations increases as: $N \to \infty$. On the other hand, the moments approach leads to simpler formulae of the estimator. It is more straightforward to implement and the computation time is much reduced compared with the maximum likelihood method.

3 PROCESS CLUSTERING

The proposed approach is based on the computation of mixture models using the Expectation-Maximization (EM) algorithm (Dempster, Laird, & Rubin 1977). Beside, side information is considered according to (Shental, Bar-Hillel, Hertz, & Weinshall 2003).

3.1 *Related work*

The EM algorithm is an iterative method that produces a set of parameters that locally maximizes the log-likelihood of a given sample, starting from an arbitrary set of parameters. It is often used to estimate the unknown parameters of a mixture model of K p.d.f. f_k given by:

$$f(x \mid \theta) = \sum_{k=1}^{K} \alpha_k f_k(x \mid \theta_k)$$

where α_k is the probability of class k and $f_k(x \mid \theta_k)$ the a posteriori probability of class k.

Furthermore the procedure we use is based on the work of Shental et al. (Shental, Bar-Hillel, Hertz, & Weinshall 2003) which describes an EM procedure for a Gaussian mixture model and for handling positive constraints, indicating that some observations arise from the same source. The data set is assumed to be a set of chunklets, and each chunklet is a set of points that originate from the same source. Alternating E steps and M steps leads to the estimation of the probability of each class, and the parameters (mean and variance) of each Gaussian class. The solution can be considered as a soft partition.

3.2 *Proposed method*

The problem we deal with, in comparison with the problem considered in (Shental, Bar-Hillel, Hertz, & Weinshall 2003), has to lead to a hard partition. Then we add an intermediate classification step between the E and M steps. This has been suggested in (Celeux & Govaert 1992, Celeux & Govaert 1995) in a hard classification problem using mixture models without constraints.

In comparison with the problem considered in (Shental, Bar-Hillel, Hertz, & Weinshall 2003), there is another main difference. The model is not a Gaussian mixture model and especially the degradation increments have different density distributions. The density distributions of all the degradation increments would be the same only in the case of homogeneous Gamma process, and of regularly sampled paths.

Thus, we have proposed an algorithm based on the mixture models for the problem of statistical process clustering with the two following properties. On the one hand, it takes into account that observations in a same path belong to a same class, and on the other hand it takes into account that a hard classification is searched.

The E step at iteration m consists in calculating an estimation of the *a posteriori* probability for each observation using the parameters $\theta^{(m-1)} = (a^{(m-1)}, b^{(m-1)}, u^{(m-1)})$. The posterior probability $c_{nk}^{(m)}$ at iteration m that the path n belongs to class k, given p_n and the parameter $\theta^{(m-1)}$ writes according to

$$c_{nk}^{(m)} = p(z_n = k \mid p_n, \theta^{(m-1)}) = \frac{\alpha_k^{(m-1)} \prod_{i=1}^{|p_n|} f_k(\Delta x_{n,i} \mid \theta_k^{(m-1)})}{\sum_{r=1}^{K} \alpha_r^{(m-1)} \prod_{i=1}^{|p_n|} f_r(\Delta x_{n,i} \mid \theta_k^{(m-1)})} \quad (4)$$

with

$$f_k(\Delta x_{n,i} \mid (a_k, b_k, u_k)) \sim \Gamma(a_k (t_{n,i}^{u_k} - t_{n,i-1}^{u_k}), b_k)$$

The expectation of the log-likelihood over all possible assignments which comply the given constraints is given by:

$$E(l(\mathbf{z}, \theta)) = \sum_{k=1}^{K} \sum_{n=1}^{N} log \alpha_k p(z_n = k \mid p_n, \theta_k^{(m-1)}) + \sum_{k=1}^{K} \sum_{n=1}^{N} \sum_{i=1}^{|p_n|} log f(\Delta x_{n,i} \mid k, \theta_k) p \times (z_n = k \mid p_n, \theta_k^{(m-1)})$$

The M step at iteration m consists in computing the parameters $\alpha_k^{(m)}$, and $\theta^{(m)}$ that maximize the expected log-likelihood found on the E step. The parameter $\alpha_k^{(m)}$ is given by

$$\alpha_k^{(m)} = \frac{1}{N} \sum_{n=1}^{N} (z_n^{(m)} = k) \quad (5)$$

and the parameters $(a^{(m)}, b^{(m)}, u^{(m)})$ are determined by maximization of the log-likelihood.

Then the algorithm is the following one.

- Initialize the parameter set $\theta^{(0)}$
- Repeat until $l(\mathbf{z}^{(m)}, \theta^{(m)}) - l(\mathbf{z}^{(m-1)}, \theta^{(m-1)}) < \in$
  - compute $c_{nk}^{(m)}$ for each path n and each class k using relation (4)
  - determine the partition $\mathbf{z}^{(m)}$: choose $z_n^{(m)} = k$ corresponding to the largest value $c_{nk}^{(m)}$
  - determine the parameter vector $\theta^{(m)}$ that maximizes $l(\mathbf{z}^{(m)}, \theta^{(m)})$
  - compute the new value of the probability $\alpha_k^{(m)}$ for each class k using relation (5).

4 MAINTENANCE DECISION RULE

The proposed maintenance decision rule aims at controlling the risk of failure while having the longest life cycle as possible. It is based on the remaining useful lifetime of the considered item or system. When a maintenance action is planned, the actual operation occurs after a minimum delay time τ which corresponds to a maintenance setup time. During the delay time, the system still operates and deteriorates. Hence a failure can occur between the decision time and the onset of the maintenance action. After maintenance operation, the component is replaced and the system is supposed to be as good as new.

Let S be the failure or tolerance threshold and let p_n be the path for the n-th monitored device. The last observed degradation level is $x_{n,|p_n|}$ at time $t_{n,|p_n|}$. The class label for the path is z_n and is associated to a set of Gamma process parameters $\theta_{z_n} = (a_{z_n}, b_{z_n}, u_{z_n})$. Assuming the last degradation level is smaller than the failure threshold, i.e. $x_{n,|p_n|} < S$, then the remaining useful lifetime from time $t_{n,|p_n|}$ is a random variable $RUL_{\theta_{z_n}}(S, t_{n,|p_n|}) = \inf\{t > t_{n,|p_n|} \text{ s.t. } X_t \geq S\}$ and $\sigma_{n,\theta_{z_n}}(S) = t_{n,|p_n|} + \mathrm{RUL}_{\theta_{z_n}}(S, t_{n,|p_n|})$ is the first passage time of the failure level S.

The survival function of the first passage time $\sigma_{n,\theta_{z_n}}(S)$ given the last observed degradation level can be obtained from the Gamma process with parameters θ_{z_n} by:

$$\begin{aligned} &\mathbb{P}(\sigma_{n,\theta_{z_n}}(S) > t \mid t_{n,|p_n|}, x_{n,|p_n|}) \\ &= \mathbb{P}(X(t) \leq S \mid t_{n,|p_n|}, x_{n,|p_n|}) \\ &= \mathbb{P}(\Delta X_{t_{n,|p_n|},t}) \leq S - x_{n,|p_n|} \mid X(t_{n,|p_n|}) = x_{n,|p_n|}) \\ &= \overline{F}_{a_{z_n}(t^{u_{z_n}} - (t_{n,|p_n|})^{u_{z_n}}), b_{z_n}}(S - x_{n,|p_n|}) \end{aligned} \quad (6)$$

It is assumed that the system can be inspected every ΔT unit of time, where ΔT is a uniformly distributed random variable such that $a \leq \Delta T \leq b$.

For a given accepted upper limit $\in$ of the probability of failure, the following three-steps decision rule is considered:

Step1: Data acquisition and classification—no decision about maintenance can be taken until a first classification is available;

Step 2: The results of classification are considered for maintenance decision making. At inspection time t and considering the delay time τ
- if $\mathbb{P}(\Delta X_{t,t+\tau+b}) \geq S - x \mid X(t) = x) \geq \in$ with the estimated parameters θ_{z_n} of the Gamma process then plan to replace the component by a new one at the inspection time between $t + \tau$ and $t + \tau + b$.
- else wait for the next inspection.

Step 3: If the system is failed, replace it correctively by a new one.

For each path n, two quantities are considered for the policy assessment: the life cycle duration (time until preventive replacement or failure) and the type of replacement (preventive or corrective). In the case of simulated data, it is possible to derive the empirical the mean life cycle duration by class $\hat{T}$ and the empirical probability of failure $\hat{P}_f$.

5 RESULTS

Simulations have been done considering two situations. For both of them, there are 3 classes, each class with 12 paths. The time increments are within an uniform distribution between 4.75 and 5.25. Parameters for both situations are given in Table 1. The failure threshold s has been chosen equal to 500. The value ϵ to threshold the predicted probability has been chosen equal to 0.5.

The mean theoretical evolution respectively for situation 1 and situation 2 is described in Figure 1a and Figure 2a. In situation 2, the classes are more similar than in situation 1: at each instant the mean values for 2 different classes are closer than in situation 1. However the standard deviations are the same for both situations.

Table 1. Parameters—situations 1 and 2.

	Class 1	Class 2	Class 3
Situation 1			
a	28.41	20.00	16.0
b	1.14	1.00	0.94
u	0.8	0.8	0.8
Situation 2			
a	28.41	25.31	22.22
b	1.14	1.12	1.11
u	0.8	0.8	0.8

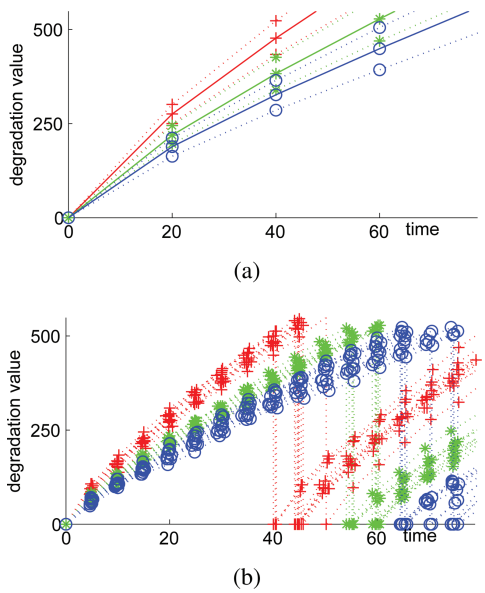

Figure 1. Evolution of degradation value in situation 1 (a) mean evolution using the theoretical parameters (b) example of simulated data.

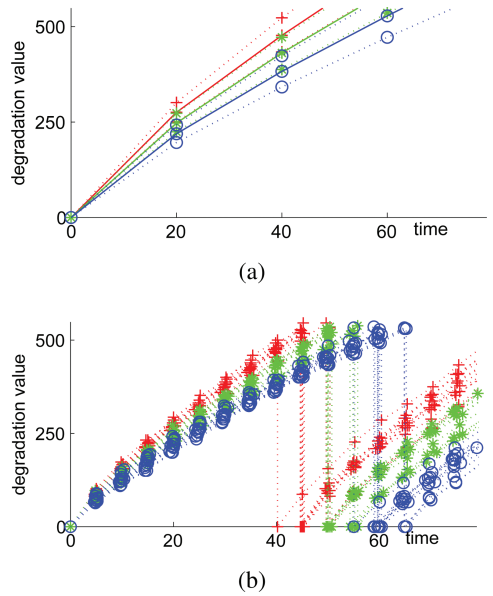

Figure 2. Evolution of degradation value in situation 2 (a) mean evolution using the theoretical parameters (b) example of simulated data.

Example of simulated data respectively corresponding to situation 1 and situation 2 are given in Figure 1b and Figure 2b.

Since we are in a case of simulated data, it is possible to compare the results obtained from the residual lifetime prognosis using the proposed approach with other classical approaches. The considered approaches are the following:

- theoretical clustering process: the real set of parameters Θ and the real class labels $\mathbf{z}$ are used;
- without clustering process (or 1-class): the estimated parameters using all the data are used;
- path case: a parameter set is estimated for each path using the available observations at the inspection time of the considered path;
- estimated 3-class clustering process: the available observations at the inspection time are used to determine jointly the class of each path ($\tilde{\mathbf{z}}$) and the parameter set of each class ($\tilde{\Theta}$).

The mean evolution of the Gamma process obtained with the estimated parameters in the three later cases is given is Figure 3, for situation 1, and an estimation done at time $t = 20$, meaning that approximatively 4 observations are available for each path. Similar illustrations are given on Figure 4, for situation 1, and an estimation done at time $t = 60$, and on Figures 5 and 6, for situation 2, and an estimation done at time $t = 20$ and $t = 60$ respectively.

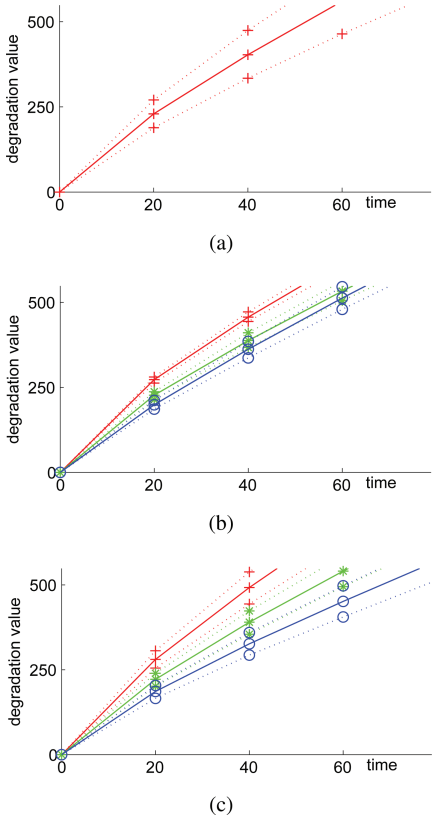

Figure 3. Evolution of the mean degradation value in situation 1 for (a) the estimated parameters with 1 class (b) the estimated parameters for each system (c) the estimated parameters with 3 classes. Each color corresponds to an estimated class. Estimation is done at $t = 20$.

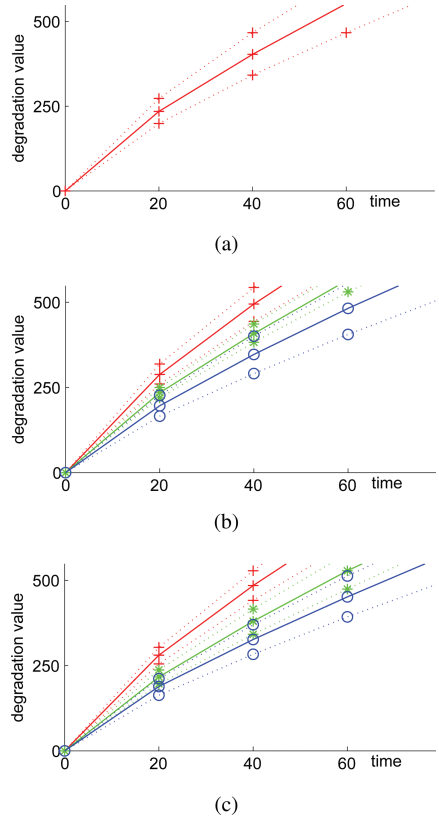

Figure 4. Evolution of the mean degradation value in situation 1 for (a) the estimated parameters with 1 class (b) the estimated parameters for each system (c) the estimated parameters with 3 classes. Each color corresponds to an estimated class. Estimation is done at $t = 60$.

As expected, the estimation is better when more observations are available. This is mainly the case when the estimation is done using only the observations of the considered path (path case). In the case of a clustering process, the estimation is better when more observations are available. This is particularly the case when the classes are more similar (situation 2 versus situation 1).

The estimated parameters have been used for the maintenance decision rule described in section 4. The delay time τ has been considered equal to 19 (approximatively equal to $4 * \Delta t$).

The simulation has been repeated for 500 path sets. The empirical probability of failure $\hat{P}_f$ and the empirical mean life cycle duration by class $\hat{T}$ are given in Table 2(a) and (b) for situation 1, with simulations done between $t = 0$ and $t = 100$. Similar results are given in Table 3 for situation 2 with simulations done between $t = 0$ and $t = 100$, and in Table 4 for situation 2 with simulations done between $t = 0$ and $t = 60$.

These tables show that grouping all the observations in a single set (1 class case) leads to very poor results. In both situations (1 and 2) one can observe that the ageing law estimated parameters correspond to an average behavior of all systems with a larger variance to fit the scatter of the different measurements. This leads to underestimate the degradation level when the degradation is rapid (class 1). As a consequence, less preventive maintenance operations are scheduled and more failures occur. On the contrary, the systems that experience slower ageing (class 3) gives low degradation measurements that lead to overestimate their residual life time, leading to more predictive maintenance and reducing the lifetime of the systems. For class 2, the model is more accurate and the results are acceptable.

Compared to the theoretical case, the strategy that consists to estimate the parameter for each path gives results that show an increase of corrective maintenance frequency (Tables 2a, 3a and 4a).

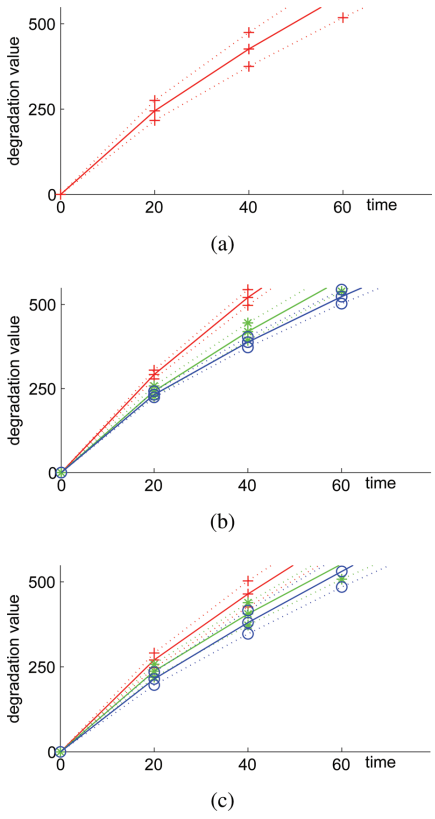

Figure 5. Evolution of the mean degradation value in situation 2 for (a) the estimated parameters with 1 class (b) the estimated parameters for each system (c) the estimated parameters with 3 classes. Each color corresponds to an estimated class. Estimation is done at $t = 20$.

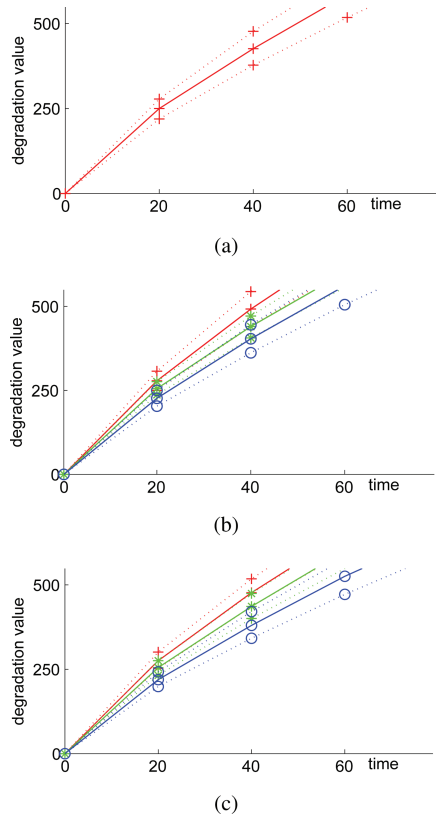

Figure 6. Evolution of the mean degradation value in situation 2 for (a) the estimated parameters with 1 class (b) the estimated parameters for each system (c) the estimated parameters with 3 classes. Each color corresponds to an estimated class. Estimation is done at $t = 60$.

This is due to the estimation which can not be good when the number of samples is too small. Thus, the estimated remaining useful life has a large variance. Consequently early conditional repairs occurs quite often and the mean lifetime is reduced (Tables 2b, 3b and 4b). Comparing results of Table 3a with Table 4a, it can be seen that the probability of corrective maintenance decreases when the study interval increases.

Considering the proposed approach, the results are much closer from the theoretical ones. The frequency of corrective maintenance is significantly reduced while maintaining a long mean life cycle duration.

In situation 2 these observations are a little less obvious which is normal because the deterioration processes of all systems are much similar, thus the one class strategy is not so bad even if it is by far not as pertinent as the proposed approach.

As expected, results obtained with the "estimated 3-class clustering process case" and the "path case" get closer to the theoretical results when the study interval increases. For the "estimated 3-class clustering process case" the results also improve when the classes are more different, since it is easier to class the process and then the parameters are

Table 2. (a) percentage of corrective maintenance actions and (b) mean life cycle duration, for situation 1 estimated on $t = [0,100]$.

better estimated if the path are correctly clustered. Then the clustering is a crucial step for estimating the Gamma process parameters that are used in any maintenance decision rule.

6 CONCLUSION

In this paper, a method is proposed for jointly clustering Gamma processes and estimating the Gamma process parameters, using degradation measurements on different systems. It is assumed that there are a number of operational conditions leading to different degradation processes. The aim is then to use the estimated parameters in a maintenance decision rule.

The proposed method consists in considering a mixture of Gamma process models. It allows to cluster the degradation paths in classes corresponding to the different degradation trends and to estimate the Gamma process parameters. It uses an expectation-minimization approach that takes into consideration that all measurements in a same path belong to the same class.

Estimating the Gamma process model parameters using only one system leads to poor results due to the limited number of samples. On the contrary, estimating the Gamma process model parameters considering only one Gamma process leads to poor results due tothe mixture of systems with different degradation trends.

Simulations have been done and demonstrate the feasibility of the method. They have shown that grouping paths originating from the same process allows to decrease the probability of failure while keeping a good mean life cycle duration in comparison with the two basic strategies (all paths in one class, one class per path).

The simulations have been done considering that the number of classes is known. A method for choosing the number of classes is currently being studied.

In a real case where the observations do not fit perfectly to Gamma process, a strategy consisting of increasing the number of classes with the number of observations could be considered. At the beginning it is not possible to distinguish different process so all the observations can be merged. On the contrary, when the time tends to infinity, it is feasible to consider one process per system.

Reliability of the delivery in the last 100 meters

K. Lewandowski
Wrocław Univeristy of Technology, Wrocław, Poland

ABSTRACT: The article presents the dependence of reliability of delivery in the last 100 meters, dependent on technical and organizational conditions when the car is stopped. The paper presents boundary conditions for the modeling deliveries in city logistics based on a study of real 900 sales points. This paper describes five specific cases deliveries in the last 100 meters, when the car is stopped.

1 INTRODUCTION

In common understanding the supply issues are analyzed primarily typical topics:

– arrangement of warehouses,
– routing directions for vehicles using various methods such as the task of a Salesman, ants algorithm, the method of the shortest paths in the network, the minimum spanning tree, zoning and other service areas.
– choice sequence transport to customers, using for example rule CRM, customer ratings, etc.

The presentation of the above issues concern the transport to the client, but rather in its close to.

The last phase of delivery-goods movement is recognized as a delivery time—Td.

From field research most of responders said that the maximal total time one operation of unloading and carrying gods to recipients is about 15 minutes (Lewandowski, K. et al, 2005) 56% less than 15 min. also in (Debauche W., 2007) 56% less than 15 min.

When we want to use this time to modeling of delivery process, we should check this from the point of view a efficiency a technical and organizational conditions of carrier equipment.

Meanwhile, the study made real conditions of delivery to the customer at the center of the city on the basis of 900 sales points indicates that it is wrong.

These studies reveal very different values to delivery time depending on several conditions governing. The article presents an analysis of five real cases to define the time of delivery tdo in modeling supply in city logistics.

2 PAPER REVIEW

In area of city logistics is very often use term delivery. The delivery process is a part of supply chain at the last link, from last warehouse to recipient. Here due to hard conditions for delivery vehicle, problems with stopping and obstacles with accessing time to city center, without possibility to stopping delivery vehicle in safety place for carrier and for other users of road traffic we can use term urban goods movement UGM (Debauche W. 2007), (Shimizu M. 2007) (Woudsma C. 2001). Urban goods movement UGM that is integrated modelling effort needed to address issues associated with congestion and air quality with respect to urban structure through land use transport interaction (Woudsma C. 2001).

Goods movement is the last phase of delivery process (Fig. 1).

The reliability of supply process mainly encompasses (Nowakowski, Werbińska 2007):

– delivery reliability—defined as the probability of in-full delivery being performed *without any delay with respect to the customer's specified time;*
– transport reliability—the probability of fault-free delivery being performed on time;

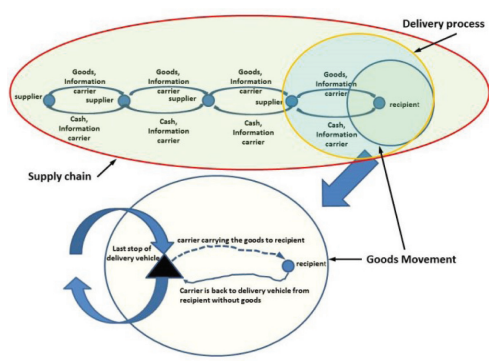

Figure 1. Place of goods movement in supply chain and delivery process (own work).

– reliability of logistic support infrastructure—which includes performance parameters of support personnel and support facilities (support and test equipment and support tools).

Reliability of the delivery process is regarded as the most important of the logistics processes with respect to potential losses (Nowakowski T. 2008).

There the service reliability for logistics networks is defined as (Nowakowski T. 2008):

$$Rd = P\,(Td < t0) \tag{1}$$

where:
Td—time of delivery,
*t*0—pre-specified time limit.

3 DEFINITION A PROBLEM

In this article is shown that delivery time Td is linked with technical and organizational conditions under unloading process and goods movement when the car is stopped. In this subject we analyze only influence of technical equipment of carrier to the pre-specified time limit *t*0. Is here proposition to calculation *t*0 where we don't add any influence of outside sources: road traffic, robbery, damage of cargo under unloading process and others.

4 BASE FOR RESULTS

Indicate the basis for determining the value of the delivery time tdo are the results of the supplies launched under the program DORED in the years 2004–2012 (Aniołowska A. et al, 2009), (Blaszyński M., 2011), (Gluz M., 2007), (Hałub A. et al., 2005), (Januszkiewicz R., 2007), (Jędra E., et al, 2007), (Kordas Ł., 2008), (Lewandowski, K. et al, 2005), (Lewandowski K., 2006), (Skoczylas I., 2007), (Stein S., 2011), (Wawrzyniak M., 2010), (Wędrak E., 2011), (Zachara R., 2006). During its course examined pond 900 sales points. The implementation of field studies conducted students of the Faculty of Mechanical Engineering Wrocław University of Technology in the framework of the thesis.

The results were based on studies in six cities: Wroclaw, Gdansk, Kępno, Opole and Jelenia Gora and Tourquay (UK) more than 900 points. The amounts of polls over time:

Gdańsk 2006-64,
Jelenia Gora, 2011-54,
Kępno 2010-50,
Opole 2006/2007-54,
Torquay (UK) 2007-70,
Wroclaw: 2004-135, 2004/2005-127, 2006/2007-229, 2008-16, 2008/2009-72, 2010-34

In addition, dozens of points has been studied based on the model developed by the author of the survey in Krakow. The results were publicly presented III Mobility Forum organized within the project Caravel/Civitas II. It was held in the Hall of the Portrait of the City of Kraków on 17 September 2007.

5 THE CONDITIONS THAT DETERMINE THE DELIVERY TIME TD

The main elements that determine the actual time of delivery is:

a. car type Rs:
   – Maximum payload/tare weight limit,
   – Whether it has a floor equal to over the entire width and length, this affects the whether it can use EUR pallet without demoulding, if you need the goods spread out on the vehicle,
b car equipment Ws
   – Is equipped with buildings inside the cargo space, if the shelf goods before delivery must be spread, if not, the goods can be loaded directly onto pallets as long as the floor is equal to over the entire width and length,
   – Is equipped with a self-unloading device, tail-lift or crane HDS,
c. the equipment driver unloading Wkpsr auxiliary equipment, platform trucks two or four wheels, etc.
d. the actual conditions of traveling to collect goods Fwrd:
   – Whether a dealer has its own place for the supply of goods,
   – If access to the site for delivery of goods is always ensured,
   – Whether the place of delivery for goods is not occupied by other vehicles,
   – Is a trading allows the use of pallets, ie whether its door openings are not too narrow for passing pallets 800 mm wide.
e. Equipment of recipient with the auxiliary unloading equipment, platform trucks two or four, etc. Wopsr
f. the size of the portion of delivery Wd.

Therefore can be saved the delivery time tdo depends on the aforementioned variables:

$$Td\{Rs, Ws, Wkpsr, Fwrd, Wopsr, Wd\} \tag{2}$$

Consider a hypothetical delivery of goods with a total mass of 250 kg.

6 CASES OF DELIVERY

6.1 *The primary method of delivery of the goods by the carrier when the vehicle is stopped is a hand delivery*

Ordered the load is usually in bulk packaging. Widely used in trade packs, boxes and bags for homogeneous goods in packages of individual (Fig. 2.):

- Sugar, flour and salt in a pack 1 kg, in packs of 10 kg;
- Drinks in baskets after 9.12 or 16 pieces, but with a mass of up to about 10–12 kg;
- Vegetables in bags and boxes weighing up to 10–15 kg, rarely are weight 25 kg, eg potatoes.

We assume that delivery truck gets a load in the form of packaging arranged in packets orders for each recipient. When the driveway to the next point need to add a delivery time of about 10 minutes to translate the load in the vehicle. This time can be added in the analysis of delivery to the next step. This situation occurs when to delivery is used cars that do not have a smooth floor of the load box over the entire width and length. The study 900 points were identified that 80% of deliveries were used cars without any self-unloading device. This way the load on the car without any hardware to self-unloading was observed in 55% of the surveyed points.

Figure 2. Delivery truck equipment with taillift with packages of cargo on pallets for each recipient. Own work.

In continuous operation which is cyclical and heavy reliance receiving cargo from a delivery truck to the store are applicable health and safety regulations 31. Rules of safety are given (Regulation 2000) (Act of Regulation 1997) on the general safety and health say:

a. for men:
   - 30 kg at continuous operation,
   - 50 kg casual work,
   - 30 kg to a height > 4 m,
   - 30 kg at a distance > 25 m.
b. for women:
   - 12 kg at continuous operation, 3 kg for pregnant women and breast-feeding,
   - 20 kg at a casual work (up to 4 times per hour during the work shift), 5 kg for pregnant women and breast-feeding.
c. In addition, it is unacceptable team moving objects at a distance greater than 25 m and a weight more than 500 kg and keep in mind that lifting and moving by one employee objects with a weight more than 50 kg is prohibited. (Regulation 2000) (Act of Regulation 1997).

As a result of more than 900 actual sales points established, in 49% of them delivery truck is staying up to 5 m. And 32% at a distance of 5 to 20 m, 19% of this distance is more than 20 m.

Therefore based on real tests can be assumed that the probability that the distance of the place of delivery to the receiving store is more than 5 meters, is:

$$\lambda l > 5 = \frac{\sum_1^n pol > 5}{\sum_1^n po} \tag{3}$$

which in the case the test results gives a value of:

$$\lambda l > 5 = 0{,}51 \tag{4}$$

Therefore it can be assumed that the distance of the point of delivery to the receiver is

$$l = 15\ m \tag{5}$$

Therefore it can be assumed that the duration of delivery time Td is:

$$Td = to1 + n * vpzl10\ kg * 1 + n * vp * 1 + n * to2 + tzd \tag{6}$$

where:
$to1$—the time of the carrier to the customer, checking invoices, an indication of the view loads in the store or in front of him, $to1 = 2$ min

n—number of complete cycles of cargo transfer from the car to the store, assuming that the mass delivery charge is 250 kg and the load is divided on the packaging of mass 10 kg, we get

$$n = \frac{md}{mlop} = \frac{250}{10} = 25 \tag{7}$$

$vpzl10\ kg$—the speed of the human walking distance with a load of 10 kg

$$vpzl10\ kg = 0{,}01\ min/m, \tag{8}$$

data obtained from observation
vp—a man walking distance speed without load

$$vp = 0{,}015\ min/m, \tag{9}$$

data obtained from observation
l—distance between the place of delivery to the point of receiving

$$l = 15\ m \tag{10}$$

$to2$—shutter load box car, retrieve the cargo, and the closure of the cargo box $to2 = 0.5$ min
tzd—time to close the door load box van after delivery of the last batch, checking documentation, the passage of the carrier to the cab driver, take a seat behind the steering wheel to check the next journey, setting driving directions, start the engine.

$$tzd = 3\ min \tag{11}$$

Therefore substituting into the formula we get that the duration of delivery time Td a mass 250 kg with only manual work is:

$$Td = 2 + 25 * 0{,}01 * 15 + 25 * 0{,}015 * 15 + 25 * 0{,}5 + 3 = 26{,}875\ min \tag{12}$$

If the weight of the load supply is higher, the time will be extended. Therefore the probability of keep delivery time is a reference a model delivery time, a priori, to the calculated on the basis of the real studies. Assuming that the probability of satisfactory delivery time deemed made as technical fitness amounts.

$$\lambda zadtd = \frac{t0}{Td} \tag{13}$$

Therefore (Fig. 3) keeping the delivery time Td recognized as delivered during the pre-specified time, the delivery time $t0$ with the probability recognition $\lambda zadtd \geq 0.75$ can be satisfied only for the supply of up to 200 kg, but not more than

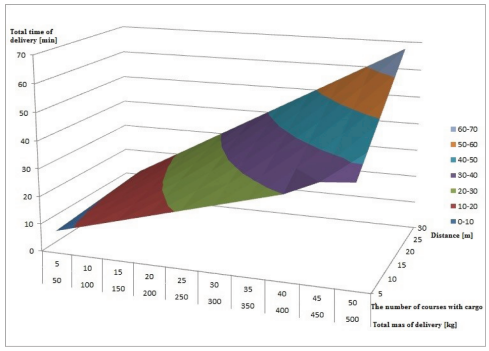

Figure 3. Graph calculation of keep delivery times as technical fitness, case 1. Own work.

10 meters from stopping place to delivery truck from the point of receipt of the delivery, store. Keep in mind that with the driveway to the next point receipt of the delivery may take longer time reloading. This is due to physical fatigue, so that the company's practice with a driver is with the loader. Such practices were observed only in 10% of 900 points.

The probability of recognition to provide delivery at the appointed time at the level of 0.75. In the opinion of owners of trade point the better situation is when who is now managers of logistics were first drivers supplying goods, and late occupied managerial position. Knowledge of reality situation at delivery is very important. According to their opinion, every day of the week are the other conditions of delivery, which also vary depending on the time of day. This is due to of traffic on the roads, and changes in pedestrian traffic on the sidewalks, which is supplied after delivery.

6.2 *We assume that delivery vehicle collected load in the form of packages on pallets of cargo*

Loading is done in such warehouse, and pallets are loads of packages in the form of homogeneous cargo that is on each pallet is the same type of goods, the carrier shall supply realizing completion delivery charge consecutively with each pallet individually (Fig. 4).

This manner the load on the car without is no equipment to self-unloading was observed in 23% of the surveyed points. This necessitates the adoption of that time $to2$—opening time load box on delivery vehicle, retrieve the cargo, and the closure of the cargo box is not $to2 = 0.5$ min, but is larger because is about $to2 = 1.5$ min, due to the additional time spent to choose the load to the contract and move the load box of the car.

Figure 4. View load box overloaded delivery vehicle with of homogeneous cargo (Main Road Transport Inspectorate, 2014).

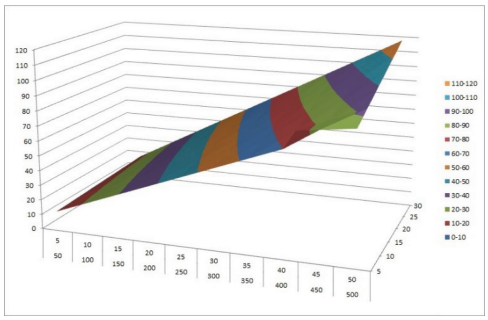

Figure 5. Graph calculation delivery times as technical fitness of, case 2. Own work.

Figure 6a. Carriers with hand truck on a street of Wroclaw. Own work.

Figure 6b. Carrier with hand truck in the street of London. Own work.

Thus (Fig. 5), keeping delivery times *Td* considered as delivered during the pre-specified time, the delivery time *t*0 with the probability of recognition $\lambda zadtd \geq 0.75$ can be satisfied only for the supply of up to 100 kg, but not more than 5 m from stopping place to delivery truck from the point of receipt of the delivery, store.

6.3 *We assume that delivery vehicle collected load in the form of packages on pallets of cargo*

Loading is done in such warehouse, and pallets are loads of packages in the form of homogeneous cargo that is on each pallet is the same type of goods, the carrier realizing supply uses a platform hand truck with a capacity of 150 kg (Figs. 6a and 6b).

This case of delivery was observed in 12% of the surveyed points. Assuming that one hand truck can put a load of 150 kg obtain that the number of cycles for delivery weight 250 kg is 2. This necessitates the adoption of that time *to*2—opening time load box car, retrieve the cargo, and the closure of the cargo box is not *to*2 = 0.5 min, but is larger because is about *to*2 = 4.5 min, due to the additional time spent to choose the load to the contract and move inside of load box of the delivery vehicle. There must also be additional time discharge of hand truck, then 2 * *to*2 = 9 min.

This results from the measurements at 5 points that indicated that the need for about 1.5 minutes load of 50 kg per 10 kg each pieces.

Assuming that one hand truck can put a load of 150 kg obtain that the number of cycles for delivery weight 250 kg is 2. This necessitates the adoption of that time *to*2—opening time load box car, retrieve the cargo, and the closure of the cargo box is not *to*2 = 0.5 min, but is larger because is about *to*2 = 4.5 min, due to the additional time spent to choose the load to the contract and move inside of load box of the delivery vehicle. There must also be additional time discharge of hand truck, then 2 * *to*2 = 9 min. This results from the measurements

at 5 points that indicated that the need for about 1.5 minutes load of 50 kg per 10 kg each pieces.

The formula for the delivery time take the form

$$Td = to1 + n * vjzl150\ kg * 1 + n * vjp * 1 + 2 * n * to2 + tzd \quad (14)$$

vjzl150kg—the speed of the man pushing a the truck with load 150 kg

$$vpzl10kg = 0{,}015\ min/m, \quad (15)$$

data obtained from observation

vjp—the speed of the person drawing an empty the truck

$$vp = 0{,}02\ min/m, \quad (16)$$

data obtained from observation

Thus (Fig. 7), keeping delivery times *Td* considered as delivered during the pre-specified time, the delivery time *t*0 with the probability recognition $\lambda zadtd \geq 0.75$ can be met for the supply of up to 150 kg, but not more than 10 meters from stopping place to delivery truck from the receipt of the delivery, store. Platform hand truck costs about 270 zł. Stability of such a truck is about 5 years. Thus, the monthly cost 4.5 zł per vehicle.

6.4 *We assume that delivery vehicle collected load in the form of packages on pallets of cargo*

Loading is done in such warehouse, and on pallets ie, each pallet is placed in packets for successive orders, the carrier realizing supply uses a mechanical device to self-unloading and hand forktruck for pallets, with or no self-propelled (Fig. 8 and 9). This necessitates the adoption of that time *to*2—opening time load box car, retrieve the cargo, and the closure of the cargo box is not *to*2 = 0.5 min, but is larger because is about *to*2 = 3.5 min.

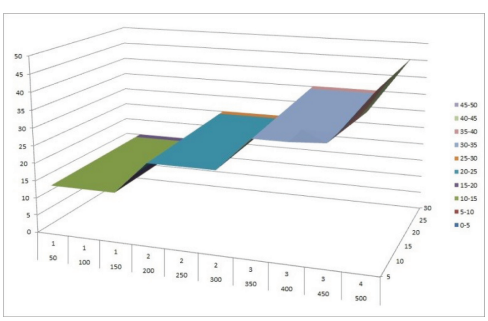

Figure 7. Graph calculation of delivery times as technical fitness of, case 3.

Figure 8. Light self-propelled hand pallet truck (Linde 2011).

Figure 9. Scene before store in Wrocław, Świdnicka street, when the carrier does not wait for unloading pallets. The recipient, store owner participate actively in the implementation of delivery. Own work.

In studies 900 points were identified that 10% of deliveries were used cars the equipment for self-unloading. In the middle of them has been found that the pallet is supplied to the interior of the store through the door and is involved in the unloading. If the carrier does not wait for unloading pallets, leaving realizing the delivery of the remaining points, and then doing reverse course collecting empty pallets.

Assuming that there is a pallet load of 550 kg obtain that number of pallets for delivery by weight 250 kg.

$$Td = to1 + n * vjzl250\ kg * l + n * vjp * l + n * to2 + tzd \quad (17)$$

vjzl250 kg—the speed of the man pushing a the truck with load 250 kg

$$vpzl10\ kg = 0{,}015\ min/m, \quad (18)$$

data obtained from observation

vjp—the speed of the person drawing an empty the truck

$$vjp = 0{,}025\ min/m, \tag{19}$$

data obtained from observation

Thus, keeping delivery times *Td* considered as delivered during the pre-specified time *t*0 the delivery time with the probability recognition $\lambda zadtd \geq 0.75$ can be fulfilled in order all shipments weighing up to 500 kg, but at a distance up to 30 meters from stopping place to delivery truck from the receipt of the delivery, store (Fig. 10).

With the use of equipment to self-unloading as lifting equipment is mandatory periodic inspection of the Office of Technical Inspection. Operation of this equipment without a valid certificate of technical test is punishable by a fine, an administrative and stopping the vehicle registration document. The vehicle is permanently associated with the device. Thus, if it is a taillift, it blocks the possibility of using a load box vehicle.

Price of hand pallet truck is about 1200 zł without self-propelled, and self-propelled about 7000 zł. Thus, the cost per month for 5 years is respectively 20 and 117 zł. The cost of using the side hopper is about 500 zł per month. In return, however, is to shorten the delivery time of delivery.

6.5 *We assume that delivery vehicle collected load in the form of packages on pallets of cargo*

Loading is done in such warehouse, and on pallets ie, each pallet is placed in packets for successive orders, the carrier realizing supply uses a mechanical device to self-unloading. Upon delivery to the stores it turns out that the pallet load will not enter the door stores, and the recipient, store owner, does not participate actively in the implementation of delivery, only controls. The carrier is obliged to charge transfer across the threshold of the store. It is related to the liability of the load (Fig. 11).

This necessitates the adoption of that time $to2 = 3.5$ min. Such cases were found in half of the 10% of the supply of 900 points, where they were used cars the equipment for self-unloading. Pallet is not supplied to the interior of the store through the door, because they are too narrow, store personnel not involved at unloading. In this situation, the carrier substitutes palette under the door of the store and brings the goods to the interior making it in the place indicated by the staff.

Then the formula for the delivery take the form

$$Td = to1 + n * vjzl250\ kg * l + n * vjp * l + n * to2 + tzd + troz\ palety \tag{20}$$

troz pallets—the pallet unloading time at the threshold of the store. Is the transfer distance of 5 m from the relationship can be used as for Case 1 (11).

Thus, keeping delivery times *Td* considered as delivered during the pre-specified time, the delivery time *t*0 with the probability recognition $\lambda zadtd \geq 0.75$ can be satisfied only for delivery to the 100 kg weight and distance of 5 meters from stopping place delivery truck from the receipt of the delivery store (Fig. 12).

If we want to calculate total delivery time, we should know what kind of vehicle we want to use. In centers of cities are use two main kinds of delivery vehicles. with maximal total mass to 3,5 ton:

– car equipment with buildings inside the cargo space, if the shelf goods before delivery must be spread, if not, the goods can be loaded directly onto pallets as long as the floor is equal to over the entire width and length,

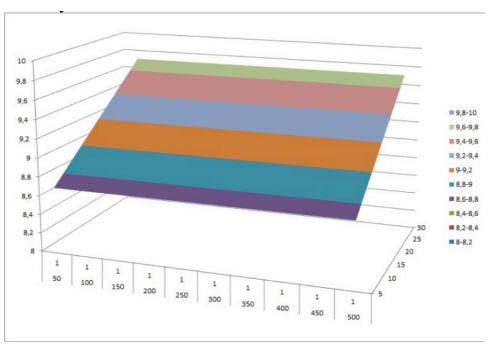

Figure 10. Graph calculation of delivery times as technical fitness of, case 4. Own work.

Figure 11. Pallet on the threshold of the storestore. Own work.

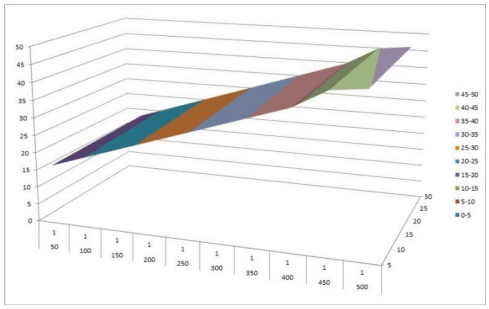

Figure 12. Graph calculation of delivery times as technical fitness, case 5. Own work.

Figure 13. Delivery vehicle equipment with buildings inside the cargo space (Femi 2014).

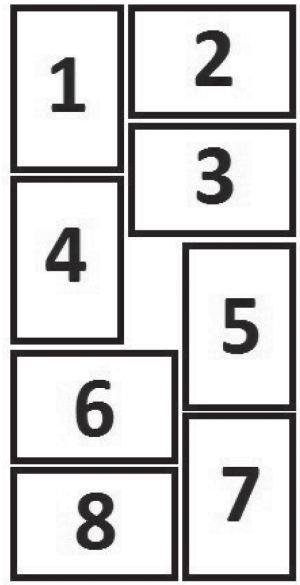

Figure 14. Location of pallets inside delivery vehicle unless than 3,5 tons (Equipment 2014).

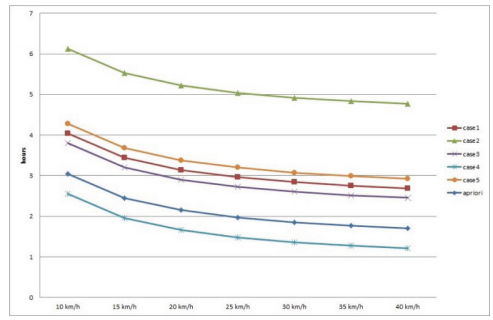

Figure 15. Time of delivery depends on cases of real situation of delivery and road speed. Own work.

– car with floor equal to over the entire width and length,
– isn't equipped with a self-unloading device,
– is equipped with a self-unloading device, taillift or crane HDS.

If we had a delivery car with a floor equal to over the entire width and length, they could carrying total 8 EUR pallets and taillift (Figs. 13 and 14).

We assume that delivery vehicle has do delivery for 5 points. This example is known from *Operations research*. Solution thus use insertion algorithms 1, 2, 3, 5, 4, 1 = 18 km.

We change parameters speed under road traffic, since 10 to 40 km/h, and ceases of delivery from case 1 to 5, all we compare to theoretical time of delivery $t0$ in trade point is 15 minutes.

$$\begin{Bmatrix} \infty & 2 & 4 & 7 & 3 \\ 2 & \infty & 4 & 5 & 7 \\ 8 & 4 & \infty & 7 & 3 \\ 5 & 9 & 2 & \infty & 7 \\ 4 & 8 & 1 & 4 & \infty \end{Bmatrix} \tag{21}$$

When will be change only case of delivery and speed of road traffic we can see that reliability of the delivery in the last 100 meters depends from

Table 1. Unloading times Td in each cases [min].

	Case 1	Case 2	Case 3	Case 4	Case 5
Best	8,125	13,125	14,175	8,7	16,825
Worst	67,5	117,5	45,2	9,7	45,95

a conditions of delivery vehicle and speed under road traffic (Fig. 15).

7 DISCUSSION

To calculate $t0$—pre-specified time we can use results of the shortest and longest time of unloading Td (Table 1).

To calculate a $t0$ time I suggest as the sum total of the products of the frequency of the cases examined (expressed in %) and half sum of the total time for the best and worst examined cases.

Thus this we have $t0$—pre-specified time limit.

$$t0 = 41{,}41 \text{ min} \approx 40 \text{ min}. \quad (22)$$

This values of pre-specified time limit is permitted for a maximum of 40 minutes if loading is observed in London city (London Councils 2014).

8 SUMMARY

Reliability of delivery in the last 100 meters depends on real type of delivery vehicle and from cases of real situation of delivery. The easiest and cheapest solution to keep pre-specified delivery time *t0* within 15 minutes and designated horizontal recognition of 0.75 is the purchase of a platform hand truck for 270 zł. The second opportunity to shorten the time of to provide supplies is to buy a pallet. It is more expensive, but significantly reduces the time to provide the goods. Therefore, to promote at use of auxiliary unloading devices in the course of delivery of supplies. Note, however, that the possibility of the use of pallets in the delivery of the goods may depend on the geometric store the recipient, if there's a narrow door opening. Better to provide planning delivery at the appointed time is that logistics managers are who were first drivers supplying goods, and later occupied managerial positions.

Research the real conditions the supply relationship should be considered as a basis for modeling and simulation. Because the one who wants to write a mathematical model should ask yourself whether creating a simulation model, which is a multi-program computer, creating a functional computer with a compatible sort of simulator, allowing the generation of system states modeled (Korzeń Z., 1998)—thus not associated with the reality but with the virtual city, eg. SIMCITY or model imitating the real operation processes/systems occurring in real-time (Hailala J., 1999), for example in Poznań. If you create mathematical notation only without testing reality it arises only theoretical simulation, which has no relation to reality, and therefore no practical application.

Article submitted data for calculation of $t0$—pre-specified time of supply in the real world.

Risk analytics within high-precision dental tool manufacturing: Multidimensional failure probabilities and validation

S. Bracke & M. Pospiech
Chair of Safety Engineering and Risk Management, University of Wuppertal, Wuppertal, Germany

ABSTRACT: Manufacturing processes of technically complex products require highly standardised methods to fulfil technical/customer specifications and minimise risks. One method for estimation of manufacturing risks is the univariate Process Capability Index (PCI). The determination of state-of-the-art PCI allows visualisation of risk with one indicator and failure probability regarding one product characteristic. Therefore the focus of the research work is the development of an approach to determine a multidimensional PCI (MPCI) as an analogon to the common, univariate PCI. The goal is the analysis of risks, the determination of risk indicator MPCI and failure probabilities with regard to complex manufacturing processes based on multivariate product characteristics. This paper presents a method for the determination of a multidimensional process capability index with the help of a case study 'dental drill'. The method considers the risk analysis of a set of functional important characteristics, the determination of a capability indicator as well as a failure probability.

PCI: Process capability index
USL: Upper specification limit
LSL: Lower specification limit

1 INTRODUCTION

Manufacturing processes of technically complex products require highly standardised methods to fulfil technical and customer specifications. To accomplish the demanded specifications, various methods, which can be applied at different phases of the product life cycle, have been developed. One of these methods, within the manufacturing phase, is the Process Capability Index (PCI). The determination of the PCI allows the visualisation of risk with one indicator and failure probability with regard to a manufacturing process. State of the art is the univariate calculation of the PCI based on the analysis of one product characteristic. However risks of complex manufacturing processes generally depending on more than one product characteristic. The analysis of manufacturing processes and the attendant process optimisation actions leads to a reduced amount of production failures and therefore to a reduced manufacturing risk and reliable products.

With decreasing tolerances of demanded component characteristics, the medical technology is one of the major branches of industry, where industrial state-of-the-art methods mustn't be thus sufficient anymore. Furthermore, a basic requirement, especially regarding medical-technical products is the minimisation of product risks and therefore the optimisation of manufacturing processes. The multidimensional PCI is one possibility to verify manufacturing processes of medical-technical products. Previous researches exhibited the successful benefit of such multidimensional process capability indices (Goethals & Cho 2011, Tano & Vännman 2011). Nevertheless a general procedure for industrial manufacturers hasn't been developed yet.

This paper presents a method for the determination of a multidimensional process capability index with the help of a case study 'dental drill'. The method considers the risk analysis of a set of functional important characteristics and the determination of a capability indicator as well as a failure probability. The presented case study uses a synthetic data set with simulated data and tolerance regions. The characteristics of the synthetic data set are close to observed reality effects.

2 FOCUS AND GOAL OF THE RESEARCH WORK

The focus of the research work is the development of an approach to determine a Multidimensional PCI (MPCI) as an analogon to the common, univariate PCI. Precondition for the determination of

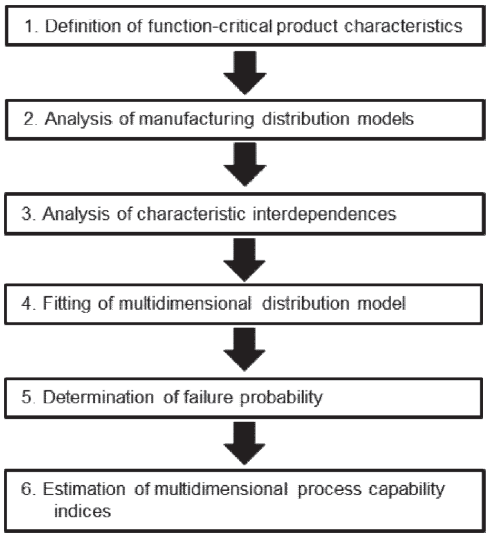

Figure 1. Overview of the approach for determination of Multivariate Process Capability Indices (MPCI).

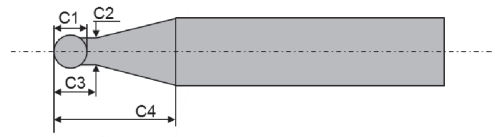

Figure 2. Important characteristics of a dental drill: head-diameter (C1), neck-diameter (C2), head-length (C3) and head-neck-length (C4).

Table 1. Comparison of the drill characteristics C1–C4 with their individual tolerance areas, nominal value and the estimated process parameters (statistical) $\hat{\mu}$ (mean) and $\hat{\sigma}$ (scattering) regarding the manufacturing process.

	Tolerances	Nominal value	$\hat{\mu}$	$\hat{\sigma}$
C1	0.8–0.85	0.80	0.840	0.01224
C2	0.53–0.73	0.63	0.646	0.00605
C3	1.65–1.95	1.75	1.821	0.01259
C4	7.5–8.5	8.00	7.934	0.10187

PCI or MPCI are capable measurement systems and machine tools (Pospiech et al. 2013).

The goal is the analysis of risks, determination of MPCI and failure probabilities of manufacturing processes based on multivariate product characteristics. Subsequently, it is possible to ensure optimised manufacturing processes. This paper focuses on one method for the calculation of multidimensional process capability index with an analogy to the state-of-the-art PCI. An overview of the developed method regarding the estimation of Multivariate Process Capability Indices (MPCI) is shown in Figure 1. The method steps are theoretically explained and applied within the case study in the following sections.

3 CASE STUDY DENTAL DRILL: FUNCTION-CRITICAL CHARACTERISTICS

It is very important to fulfil the customer's specifications within high precision manufacturing. The challenge is the fulfilment of the narrow characteristic tolerances. In the presented case study dental drill (Fig. 2), there are four important product characteristics defined (also step 1, Fig. 1): head-diameter (C1), neck-diameter (C2), head-length (C3) and head-neck-length (C4). If these drill characteristics are manufactured outside the required tolerance area, it has serious consequences on the dental drill application area: the dentist uses the drill unconsciously wrong and the patient-centered care—e.g. tooth therapy—is inefficient. The schematic drawing in Figure 2 outlines the four function-critical drill characteristics. It is assumed, that all four characteristics are normal distributed regarding the manufacturing process.

The shown characteristics are based on a real dental drill: For this paper the data set has to be synthesized. The tolerance areas of the drill characteristics as well as their expected normal distributions (step 2, Fig. 1) parameters regarding the manufacturing process are shown in Table 1. The assumption of the expected normal distribution model was verified and confirmed by a Kolmogorov-Smirnov conformance test (Sachs 2002).

4 STATE OF THE ART: PROCESS CAPABILITY INDEX (PCI)

The continuously analysis and control of the manufacturing process is the precondition for the obtaining of excellent products. The two established methods are quality control charts and the relayed process capability indices. Quality Control Charts (QCC) can be used without an exact knowledge of the characteristic distribution model and are useful in the analysis of manufacturing risks. QCCs show the mean and scattering of each product characteristic in relation to the given tolerance areas. Furthermore, alert and intervention limits can be adapted inside QCC, if needed. This method is an industrial standard, further explanations can be found in (Timischl 2002). It is possible

to gain additional information with the Process Capability Indices (PCI) by obtaining a determined distribution. This is also an industrial standard for univariate product characteristic analysis, but mainly used for normally distributed processes (Pfeifer 2002). Current technical literature gives also basic approaches for other fitted distribution models (Dietrich & Schulze 2009).

In general, process capability is divided into two perspectives: process capability and critical process capability: C_p represents the ratio between the given tolerance area and the manufacturing deviations whereas C_{pk} considers the position of the manufacturing's arithmetic mean inside the ratio. This method is mainly established for normal distributed processes. Equation 1 shows the determination of the process capability C_p hereas equation 2 describes the critical process capability C_{pk}.

$$\widehat{C_p} = \frac{USL - LSL}{6\hat{\sigma}} \tag{1}$$

$$\widehat{C_{pk}} = \min\left[\frac{USL - \hat{\mu}}{3\hat{\sigma}}; \frac{\hat{\mu} - LSL}{3\hat{\sigma}}\right] \tag{2}$$

As all characteristics are normally distributed, the process capability indices are determinable by using equation 3, which shows the density function of the normal distribution.

$$f(x,\mu,\sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right) \tag{3}$$

The abbreviations inside the shown equations are as follows:

USL = upper specification limit
LSL = lower specification limit
μ, $\hat{\mu}$ = mean (estimated)
σ, $\hat{\sigma}$ = standard deviation (estimated)

If the process capability index of one product characteristic is below a defined critical value—e.g. state-of-the-art value 1.33—a review of the production process should be done to improve the manufacturing steps and achieve higher capability indices. Depending on the industrial discipline there are also higher capability requirements such as $\widehat{Cp} > 2.0$ and $\widehat{C_{pk}} > 1.67$. An example for a normally distributed characteristic (drill characteristic C1 in Table 1) is shown in Figure 3.

The visualisation in Figure 3 shows, that the distribution model of C1 is not completely inside the tolerance area, therefore the related manufacturing process step has to be improved.

In case of risk analyses of technically complex manufacturing processes, possible interdependences

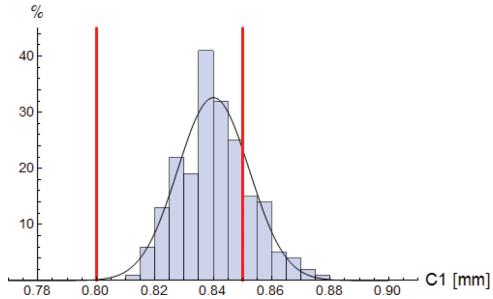

Figure 3. Classified data of C1 fitted with a normal distribution density function within the given tolerance area. The PCI C_p is the ratio between scattering and tolerance area, The PCI C_{pk} considers the mean of the density functions.

of different product characteristics have to be considered. Therefore, the correlation and regression analysis (step 3, Fig. 1) is the subsequent step and the base of operations for the multivariate PCI.

5 CORRELATIONS OF THE CHARACTERISTICS

State-of-the-art calculations for correlations analysis are based on Bravais-Pearson (precondition: bivariate normal distributed characteristics), Spearman and Kendall (rank based analysis; independent of characteristic distribution models), explanation in (Sachs 2002). The results of the application of these correlation analyses show the interdependences of the product characteristics (step 3, Fig. 1). For this case study Spearman correlation, shown in equation 4, was used.

$$r_s = \frac{\sum_{i=1}^{n}\left((R(x_i) - \overline{R(x)})(R(y_i) - \overline{R(y)})\right)}{\sqrt{\sum_{i=1}^{n}(R(x_i) - \overline{R(x)})^2 \sum_{i=1}^{n}(R(y_i) - \overline{R(y)})^2}} \tag{4}$$

Abbreviations:
$R(x_i)$ = rank of x_i
$\overline{R(x)}$ = mean rank of x
$R(y_i)$ = rank of y_i
$\overline{R(y)}$ = mean rank of y

The result of this formula can be between ± 1, where 1 means full positive correlation and −1 means full negative correlation. Values near 0 indicate that the data does not correlate. If there are correlations between the product characteristics, it has an impact regarding the analysed multidimensional tolerance area and therefore for the estimated failure probability (Fig. 3). Furthermore, it has an impact on the manufacturing process

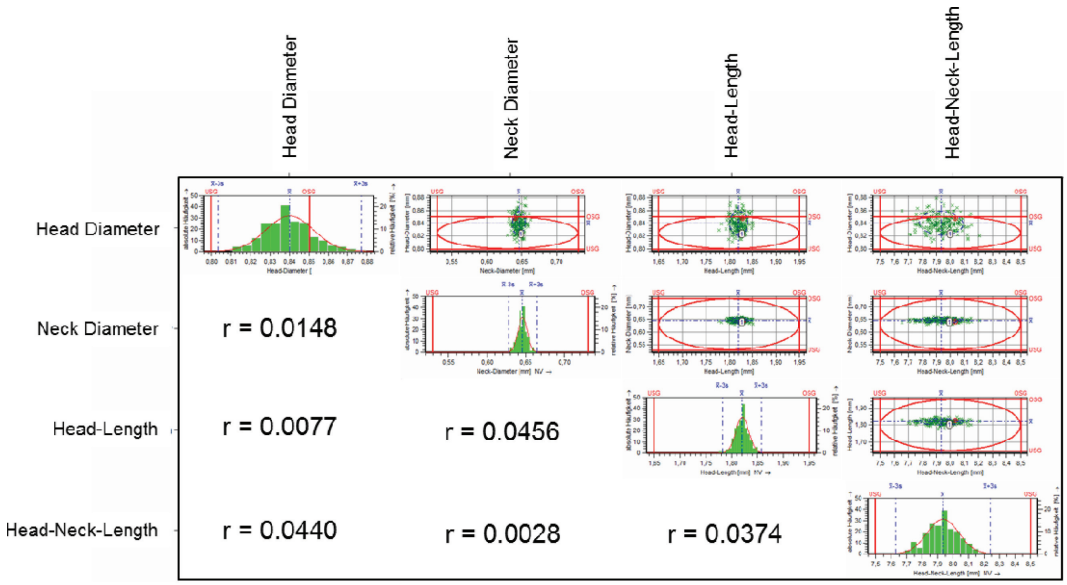

Figure 4. Comparision of the important dental drill characteristics and their correlation influences on each other determined with Spearman's rank correlation coefficient (schematic visualisation).

control. The results of the correlations analysis within the case study dental drill are shown within a correlation matrix in Figure 4. Rows and columns show the important characteristics of the dental drill (also Fig. 2); the crossing shows the fitted distribution models—based on measurement samples—of the proper manufacturing process steps. The graphics top right show the visualised correlations; the equations down left show the estimated correlation coefficients.

Obviously, the values of the estimated Spearman correlation coefficients equal nearly 0. That means that there are no detectable interdependences between the important dental drill characteristics. This leads also to non-depending tolerances zones. This is one precondition for the presented method of MPCI regarding the analysed multidimensional tolerance area.

6 MULTIDIMENSIONAL PROCESS ANALYSIS: DISTRIBUTION AND FAILURE PROBABILITY

As a matter of principle, there are two possible approaches to estimate a MPCI based on multidimensional analysis regarding to product characteristics:

a. Base of operations for the estimation of a MPCI is the fit of a multidimensional distribution model (Fig. 1, step 4), which is explained with the help of the case study in section 6.1. Afterwards, the ratio of the fitted distribution model and the multidimensional tolerance area leads to the failure probability (Fig. 1, step 5) and subsequently to the estimation of the MPCI (analogon C_{pk}; (section 6.2)). This approach is feasible regarding dependent or independent characteristics.
b. Base of operations is the individual estimation of the failure probabilities for each characteristic. Afterwards the composition of the failure probabilities in due consideration of Boolean algebra leads to a comprehensive product failure probability. Precondition is the independency of the analysed characteristics.

This paper focuses on the estimation of the MPCI using the first outlined approach by using multidimensional distribution models.

6.1 *Application of multidimensional distribution models within the case study*

The proper multidimensional distribution model depends on the distribution of the several analysed product characteristics (step 4, Fig. 1). Within the case study dental drill, the analysed important characteristics are normally distributed. If two (or more) characteristics are normally distributed their combination should be also normally distributed. Therefore, the multidimensional approach regarding normally distributed characteristics

can be used, equation 5 (Genz & Bretz 2009). The parameters of the distribution were estimated with the Maximum-Likelihood function (Sachs 2002).

$$f_x(x_1, \ldots, x_k) = \frac{1}{\sqrt{(2\pi)^k \mid \Sigma \mid}} \exp\left(-\frac{1}{2}(x-\mu)^T \Sigma^{-1} * (x-\mu) \right) \quad (5)$$

Abbreviations:
μ = mean vector
$\sum$ = covariance matrix

In comparison with equation 3, μ is a vector and σ a matrix ($\sum$ in (3)). The multinormal-distribution of two characteristics leads to a bivariate vector μ and a bivariate matrix $\sum$. It is possible to visualise this distribution together with the tolerance areas of each characteristic. The non-correlation is a basic condition regarding this approach: There is no impact based on characteristic interdependences. Within the analysed drill characteristics of the case study, there are no characteristic correlations (section 5). This leads to a tolerance zone in form of a rectangle. Otherwise the tolerance zone could be ellipse shaped, which would lead to a different integration form. An example of two dental drill characteristics C3 and C4 (Fig. 2), which are multinormal-distributed, within the resulting tolerance zone is shown in Figure 5.

The graphical interpretation of this example should indicate, that any calculation of separate C_p or C_{pk} should lead to a positive result. Furthermore, the combination of a two-dimensional normally-distributed approach allows the conclusion, that its peak is near to the centre of the tolerance area conducted by a small scattering. Another example is shown in Figure 6.

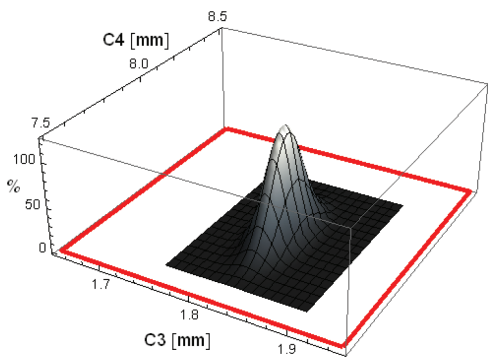

Figure 5. Combination of drill characteristics C3 and C4 (Fig. 2), visualised with the help of a two-dimensional normal distribution density function within the given tolerance area.

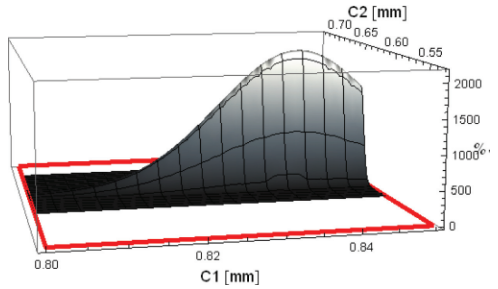

Figure 6. Combination of dental drill characteristics C1 and C2 (Fig. 2), shown with the help of a two-dimensional normal distribution density function within the given tolerance area.

The graphical interpretation shows that the multinormal-distribution of the characteristics C1 and C2 is not completely inside the tolerance area: C1 is located within the tolerance zone, contrary to C2. The application of this approach is also possible for more than two product characteristics: Within the case study, the dental drill has four important product characteristics (Fig. 2). The combination of C1–C4 leads two a four-dimensional normally distributed approach (based on eq. (5)), which obviously cannot be visualised.

6.2 *Failure probability based on multidimensional approaches*

Based on the fitted multidimensional density function, the calculation of the failure probability regarding the given tolerance areas is feasible (step 5, Fig. 1). The integration of the multidimensional density functions by using the tolerance areas as integral limits (equation 6) leads to the probability of manufactured products within the combined tolerance zone. The complement (equation 7) leads to the failure probability.

$$P_{IT} = \int_{x_1 LSL}^{x_1 USL} \int_{x_2 LSL}^{x_2 USL} \int_{x_3 LSL}^{x_3 USL} \int_{x_4 LSL}^{x_4 USL} f_x(x_1, x_2, x_3, x_4) = \int_{0.8}^{0.85} \int_{0.53}^{0.73} \int_{1.65}^{1.95} \int_{7.5}^{8.5} \frac{1}{\sqrt{(2\pi)^4 \mid \Sigma \mid}} \times \exp\left(-\frac{1}{2}(x-)^T \Sigma^{-1} * (x-\mu) \right) dx_1 dx_2 dx_3 dx_4 \quad (6)$$

$$P_F = 1 - P_{IT} \quad (7)$$

Abbreviations:
P_F = Probability failure
P_{IT} = Probability inside tolerance

Therefore, this approach is independent of the amount of combined variables and therefore

Table 2. Comparison of different combinations of the functional-important characteristics C1–C4 (multinormal-distributed).

	Integral of the tolerance zones	ppm
C1/C2	0.791243	208757
C3/C4	0.999999	1
C1/C2/C3/C4	0.791236	208764

independent of the graphical visualisation (Figs. 5 and 6). With regard to the shown case study, several integrals are presented in Table 2. The first two rows show the two-dimensional analysis of drill characteristic combinations C1/C2 and C3/C4. The third row shows the combination of all important drill characteristics C1–C4 with the goal of a comprehensive estimated Product Failure Probability. The probability is expressed in unit Parts Per Million (PPM), which is the base of operations regarding the estimation of the multidimensional process capability index MPCI (section 7).

7 LINK BETWEEN PPM AND C_{pk}

The next step for MPCI is the link between PPM and the common state-of-the-art one-dimensional capability index C_{pk} (section 4; also step 6, Fig. 1). Based on the ratio of process scattering and tolerance area (eq (1) and (2)), the determination of the failure probability is feasible (integration of (3) by using tolerance area as limits). Therefore, each one-dimensional C_{pk} value belongs to a failure probability PPM-value. The relationship between one-dimensional C_{pk} value and PPM value is shown in Figure 7.

In addition to the graphical visualisation, a non-linear regression has been calculated using the Equation 8.

$$y = \beta_0 \, exp \, (\beta_1 \exp(x)) \tag{8}$$

with $\beta_0 = 4.61153 * 10^7$ and $\beta_1 = -3.54913$.

The expression allows the direct conversion of an estimated failure probability into a C_{pk} value. Based on this conversion (direct link), the estimation of a multivariate process capability index MPCI is feasible: The estimation of the expected failure probability with regard to the combination of two or more important product characteristics is shown in section 6.2, Table 2.

The failure probability (unit [ppm]) of the multidimensional analysis leads now directly to the MPCI, as an analogon to the direct conversion of ppm into C_{pk} (Fig. 7 and eq. (6)): The results are

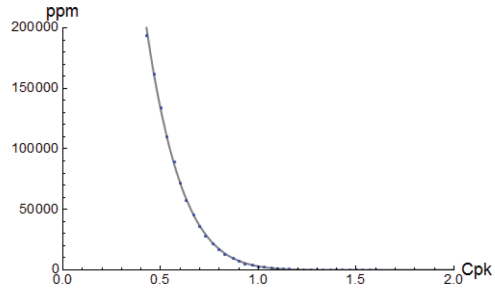

Figure 7. Non-linear regression of the relationship between failure probability ppm and C_{pk}.

Table 3. Expected failure probability (ppm) based on multidimensional process analysis and conversion into MPCI as an analogon to one-dimensional C_{pk} (Fig. 7) within the case study dental drill.

	ppm	MC_{pk}
C1/C2	208757	0,42
C3/C4	1	1,6
C1/C2/C3/C4	208764	0,42

shown in Table 3. E.g. the expected failure probability regarding the analysis of the four important dental drill characteristics C1–C4 (208764 ppm; Table 2) leads to a MPCI value of 0.42.

8 CONCLUSION

This paper outlines a method for multidimensional process analyses and the estimation of multidimensional process capability indices inside the manufacturing phase. The presented results were established within a case study 'dental drill' and were calculated due to simulated data. The procedure of this method was subdivided into three parts.

The first part was focussing on the manufacturing phase by analysing the data. Each characteristic is normal distributed and there are no interdependences between them. This leads to non-related tolerance zones. It was also shown, that within the case study three important dental drill characteristics (C2, C3 and C4) conformed to given tolerance specifications, whereas the important drill characteristic C1 led to non-conforming manufacturing results. The second part was focussing on advanced manufacturing analysis: Multidimensional analysis methods were visualised and possible interactions were explained. Therefore, the multinormal distri-

bution formula was used for several characteristic combinations and the expected failure probability by calculation of the integrals of these multinormal-distributions. The third and concluding part was the analogy of ppm and C_{pk}, which leads to a MPCI. With this linkage it is possible to determine a MPCI of the previous calculated integrals using the equation 6.

With the application of all three parts together, an approach for estimation of MPCI has been shown. With the help of this approach, the multivariate validation of a set of important product characteristics by using one capability index (therefore one risk indicator)—as an analogon to the univariate case—is feasible.

In this context it is important to underline the comparison between one-dimensional SPC methods (state-of-the-art) and the approach of Multidimensional Process Capability Indices (MPCI): For example QCC and PCI—as important parts of SPC—are included in this paper. The added value of the shown MPCI approach is the combination of known SPC methods to detect a risky manufacturing process. Subsequently, by choosing proper process improvement actions, it is possible, to ensure a reliable production process. The output of the method combination is the base of a MPCI. The MPCI enables the validation and supervising of a production line; furthermore the evaluation of the production process by the use of one risk indicator. The separate application of single SPC methods examines only excerpts of production aspects, such as a specific production process step or measurement process. Therefore, the presented approach of this paper extends the reliability of the whole production process.

The presented method will be implemented in future manufacturing process lines of different medical instruments. Furthermore, the mathematical formula will be improved by using different kinds of distribution models regarding different product characteristics (e.g. Weibull and Log-normal). Thus, future results should lead to a precise description of the manufacturing influences by multidimensional process capability indices.

A unified model of systems dependability and process continuity for complex supply chains

L.A. Bukowski
Academy of Business in Dąbrowa Górnicza, Poland

J. Feliks
AGH Academy of Science and Technology, Krakow, Poland

ABSTRACT: Nowadays the manufacturing and logistic systems, and especially global supply networks, become more and more complex, sophisticated and expensive. They operate in an environment of dynamic changes, disturbances, disruptions threats and uncertainty that is related to market behaviour. The typical methods of lean management, based on traditional policies, under this risky work conditions, are for those systems not sufficient and the rules of crises management are not efficient enough. The objective of this paper is to come up with a new unified concept of systems dependability and process continuity management for complex supply chains and especially for global supply networks. The core idea of the overall concept is based on the experiences gained in the area of so called dependable computing, as well as that in the field of the resilience engineering.

1 INTRODUCTION

The modern business activity, both real and virtual, meaning capital, is dynamically developing on the global scale. It involves, amongst others, a constant increase in complexity of the systems within which integrated business, production and service processes are realised, as well as the necessity of making key decisions based on imperfect knowledge, burdened with the uncertainty, incompleteness and ambiguity of the available information.

These complex systems also include modern supply chains, which are characterised by a topology of complicated networks realising particular functions consisting in moving goods in space and time, as well as their storage in an efficient and effective way, in the conditions of a changeable and uncertain environment and possible disturbances and threats. The rational management of these processes relies on logistics, an interdisciplinary domain concerned with efficient and effective coordination of flows (moving and storing) of material and immaterial resources (goods, people, transaction, and information connected with them) as a part of supply chains.

Ensuring a high level of quality for logistic services in global networks requires a continuous improvement process with particular consideration of safety and risk aspects. The most important trends in activities improving the modern supply chains include (Straube & Pfohl 2009):

- Improvement of supply networks' safety through decreasing their vulnerability to external threats connected with both acts of nature (natural disasters) and intentional acts of criminal or terrorist groups.
- Increasing the security of supply networks as well as their survivability and resilience in critical conditions.
- Strategic and complex approach to supply chain risk management, as a tool supporting key decision making in logistics.

A complex approach to the supply chains management, with particular emphasis on dependability of logistic systems and the continuity of the processes realised by them is, according to the authors, the key to the success of the actions mentioned above. The aim of this paper is to present a proposition of a unified model encompassing both of these aspects (systems dependability and process continuity) in a constituent and non-contradictory way, as bases for an effective and efficient supply chains management.

2 COMPLEX SUPPLY CHAINS—SYSTEMS APPROACH

Modern supply chains, particularly these of global range, are large scale systems, consisting of many subsystems, which often are autonomous distributed systems. Thus, from the point of

view of systems science they can be considered so-called systems of systems, which are a subject of a new branch of science—system of systems engineering.

System of Systems Engineering (SoSE) methodology is successfully used in U.S. Department of Defence applications, but is increasingly being applied to non-defence related problems such as architectural design of problems in transportation, healthcare, global communication networks, search and rescue, space exploration and many other domains. SoSE deals with planning, analyzing, organizing, and integrating the capabilities of a mix of existing and new systems into a system of systems capability greater than the sum of the capabilities of the constituent parts (Luzeaux et al. 2011). System of systems may deliver capabilities by combining multiple collaborative and autonomous-yet-interacting systems. The mix of systems may include existing, partially developed, and yet-to-be-designed independent systems.

SoSE differs from the classical engineering (engineering of a single system), and should include the following factors (Luzeaux et al. 2011):

- Larger scope and greater complexity of integration efforts,
- Collaborative and dynamic engineering,
- Engineering under the condition of uncertainty,
- Continuing architectural reconfiguration,
- Simultaneous modelling and simulation of emergent systems behaviour,
- Rigorous interface design and management.

The most important features characterizing the differences between the conventional approach to Systems Engineering (SE) and the approach of Systems of Systems Engineering (SoSE) were compiled in Table 1.

It clearly shows that the global supply chains which have:

- network structure of changeable boundaries, set-up with approximation methods (according to the "good enough" principle),
- manifold aims, resulting from the complexity of mutual relations of the chain's "links",
- emergent properties which cannot be predicted with traditional analytical methods, and
- a time-scale considered not as a part of a life cycle, but in the aspect of the continuity of action, can be qualified among Systems of Systems (SoS).

A simplified model of such a system of systems, exampled by a Complex Supply Chain (CSC) is represented in Figure 1.

The task of such system is to purposefully process material and non-material inputs into outputs. A system of systems consists of a structure (in case of CSC, an infrastructure of network character) and a process realised by it (supplying goods to consumers). In real operating conditions a system of systems is affected by common threats and atypical hazards. They can cause a failure of the structure of a system of systems and a disruption of the process the system is realizing. Since ensuring systems' reliability and the continuity of the processes realized by them is one of dependability engineering and resilience engineering tasks, both of these concepts will be discussed in a later part of this work.

Table 1. Comparing the system engineering and system of systems engineering attributes.

Nr.	Attribute	Systems engineering	System of systems engineering
1	Focus	Single complex system	Multiple integrated complex systems
2	Problem	Defined	Emergent
3	Objective	Optimization (best)	Satisfying (good enough)
4	Boundaries	Static (fixed)	Dynamic (variable)
5	Structure	Hierarchy	Network
6	Goal	Unitary	Pluralistic
7	Approach	Process related	Methodology related
8	Timeframe	Life cycle	Continuous
9	Design tools	Many	Few
10	Management standards	Few	Non

3 DEPENDABILITY ENGINEERING—CONCEPT OF FAULT-TOLERANT COMPUTING

There are two perspectives of defining dependability within the IEC Technical Committee 56: dependability as a system property and dependability as cumulative terms of quality. IEC defines dependability in both forms. One dependability description concerns collective forms (IEC 60300-1 (2003-06), IEC 60300-2 (2004)): "Dependability describes the availability performance and its influencing

factors: reliability performance, maintainability performance and maintenance support performance". Dependability is also defined according to IEC 60300-3-15 (2009) as "the ability of a system to perform as and when required to meet specific objectives under given conditions of use".

The contribution from the computer system group is represented in the Laprie's dependability tree. The authors developed the concept of fault-tolerant computing, based on the idea of dependable service delivering (Avizienis et al. 2004). In this work the dependability of a system is understood as the ability to deliver service that can justifiably be trusted. The service delivered by a system is its behaviour as it is perceived by its user(s); a user is another system (physical, human) that interacts with the former at the service interface. The function of a system is what the system is intended for, and is described by the system specification. Dependability is an integrative concept that consists of three parts: the attributes of, the means by, and the threats to which dependability is attained.

Dependability attributes:

- Availability—readiness for correct service;
- Reliability—continuity of correct service;
- Safety—absence of catastrophic consequences on the users and the environment;
- Confidentiality—absence of unauthorized disclosure of information;
- Integrity—absence of improper system state alterations;
- Maintainability—ability to undergo repairs and modifications.

Dependability means:

- Fault prevention how to prevent the occurrence or introduction of faults;
- Fault tolerance—how to deliver correct service in the presence of faults (e.g. Redundancy);
- Fault removal—how to reduce the number or severity of faults (e.g. Corrective or preventive maintenance);
- Fault forecasting—how to estimate the present number, the future incidence, and the likely consequences of faults.

Dependability threats:

- Faults
- Errors
- Failures

Security is the concurrent existence of:

- availability for authorized users only,
- confidentiality, and
- integrity with 'improper' meaning 'unauthorized'.

Correct service is delivered when the service implements the system function. A failure is an event that occurs when the delivered service deviates from correct service. A system may fail either because it does not comply with the specification, or because the specification did not adequately describe its function. A failure is a transition from correct service to incorrect service, i.e., to not implementing the system function. A transition from incorrect service to correct service is service restoration. The time interval during which incorrect service is delivered is a service outage. An error is that part of the system state that may cause a subsequent failure: a failure occurs when an error reaches the service interface and alters the service. A fault is the adjudged or hypothesized cause of an error. A fault is active when it produces an error, otherwise it is dormant. A system can fail in the different ways—failure modes.

A system consists of a set of interacting components, therefore the system state is the set of its component states. A fault originally causes an error within the state of its components. An error is detected if its presence in the system is indicated by an error message or error signal that originates within the system. Faults and their sources are very diverse.

The concept of fault-tolerant computing became very successful in the area of information technology and computer science, but was not general enough, to cover all types of technical systems, e.g. global production systems and logistics chains, especially in presence of the low frequent and unpredictable hazards.

4 RESILIENCE ENGINEERING—CONCEPT OF DISRUPTION-TOLERANT OPERATION

Resilience Engineering is the latest departure from the popular image in which the typical path to disaster is a single and major failure of a system component—very often the human. The understanding of how accidents happen has undergone a huge development over the last century (AMBER 2009). Accidents were initially viewed as the conclusion of a sequence of events, which involved "human errors" as causes or contributors. This is now being replaced by a systemic view in which accidents emerge from the complexity of people's activities in an organizational and technical context. These activities are typically focused on preventing accidents, but also involve other goals (e.g. effectiveness, throughput, productivity, efficiency, costs) which means that goal conflicts can arise, always under the pressure of limited resources (e.g. time, money, equipment). Accidents emerge from a confluence of conditions and occurrences that are usually associated with the pursuit of success,

but in this combination (each necessary but only jointly sufficient) able to trigger failure instead. The iceberg model proposes that there are a certain number of incidents for each accident, and a certain number of near misses for each incident, and a certain number of unsafe acts for each near miss. The average ratio used is 1 accident for 10 incidents for 30 near misses for 600 unsafe acts (1:10:30:600) (Hollnagel et al. 2006).

The idea of latent failures is an evolution and combination of ideas from preceding theories and models on accident causation, particularly the sequence-of-events model and man-made disasters theory. According to the latent failure model, disasters are characterized by a concatenation of several small failures and contributing events, rather than a single large failure. Multiple contributors are all necessary but individually insufficient for the disaster to occur (Dekker et al. 2008). Latent failures are decisions or other issues whose adverse consequences may lie dormant within the system for a long time, only becoming evident when they combine with other factors to breach the system's defences. Some of the factors that serve as "triggers" may be active failures, technical faults, or atypical system states. According to the latent failure model, we understand of accident potential in terms of organizational processes, task and environmental conditions, individual unsafe acts, and failed defences. A safety-critical system is surrounded by defences-in-depth (as depicted by the various layers between hazards and the object or process to be protected in the figure). Defences are measures or mechanisms that protect against hazards or lessen the consequences of malfunctions or erroneous actions. None of these layers are perfect, however, and the "holes" in them represent those imperfections. According to the latent failure model, accidents happen when all of the layers are penetrated, and when all their imperfections or "holes" line up. Incidents happen when the accident progression is stopped by a layer of defence somewhere along the way. This idea is carried over from the earlier sequence-of-events model, as is the linear depiction of a failure progression.

The word resilience means the tendency or ability to spring back (bouncing back), and thus the ability of a body to recover its normal size and shape after being pushed or pulled out of shape, and general any ability to recover to normality after a disturbance. It means to being able to withstand shocks and deviations from the intended state and go back to a desirable or acceptable, state. The authors of ReSIST document (ReSIST 2009) concluded that a useful meaning to apply to resilience for current and future systems is ability to deliver, maintain and improve service when facing threats and evolutionary changes. Their concern is often one of balance, as they see excessive emphasis on static means for achieving safety, designed in response to accidents, while they see a need for a culture of self-awareness, learning how things really work in the organization (real processes may be very different from the designed procedures), taking advantage of the experience in dealing with anomalies, paying attention to the potential for unforeseen risks, fostering fresh views and criticism of an organization's own model of risk.

A limitation of maximum tolerable disturbance measures is that we may well be interested in characterizing how well a system rebounds from smaller disturbances. For instance, given a form of fault tolerance that allows for some degradation of service, we may then want to measure not just how far the system can be pushed before failing altogether, but the relationship between the size of disturbances and the degradation of performance.

Since for most systems of interest the resilient behavior is non-deterministic in practice, we are no longer interested in whether the system will rebound from a disturbance but in the probability of it successfully rebounding; or the distribution of the time needed for it to return to a desired state. Thus in fault-tolerant computing we talk about the "coverage" factor of a fault-tolerant mechanism, and we can talk about the distribution of the latency (time to detection) of a component fault or data error (Avizienis et al. 2004).

A concern in the resilience engineering literature is that measures of outcomes may lack predictive power: success in the past is no guarantee of success in the future). Thus a search for leading indicators that can be used to assess future resilience has begun. Leading indicators sets should be based on: Management commitment, Just culture, Learning culture, Opacity, Awareness, Preparedness and Flexibility. Examples of indicators related to preparedness is "crisis training beyond minimum requirements" and to management commitment is "percentage of overtime" (Avizienis et al. 2004). Another approach based on organizational resilience focuses on Commitment, Competence, and Cognizance—"three C's". Sometimes these three C's' are combined with "four P's": Principles, Policies, Procedures, and Practice (O'Rourke et al. 2007).

Sum up, one is simply the recognition of the multidimensionality of resilience. For instance, Westrum (Westrum 2006) writes: "Resilience is a family of related ideas, not a single thing. The various situations that we have sketched offer different levels of challenge, and may well be met by different organizational mechanisms. A resilient organization under Situation I will not necessarily be resilient under Situation II (these situations are defined as having different degrees of predictabil-

ity). Similarly, because an organization is good at recovery, this does not mean that the organization is good at foresight".

5 CONCEPT OF THE UNIFIED MODEL OF SYSTEMS DEPENDABILITY AND PROCESS CONTINUITY FOR COMPLEX SUPPLY CHAINS

The concepts discussed briefly in points 3 and 4 are different in many ways, but can be considered mutually complementary. However, as of yet, in spite of huge and constantly growing interest in the issue of resilience engineering (particularly in the field of logistics), there still is no complex quantitative model of resilience, compatible with other related fields of study (ex. dependability engineering). Thus, a proposition has appeared to build a resilience model on the basis of an analogy with the dependability model, in compliance with the specificity of the process perspective dominant in the resilience approach.

Dependability of the supply chains is understood as the ability to deliver correct service that is available and safe under normal (ordinary) work conditions in a given time interval.

Dependability (D) is also the 2-dimentional vector

$$D = \{AV, SA\} \quad (1)$$

with:

- Availability (AV):
  - Reliability (REL),
  - Maintainability (MAI),
  - Maintenance Support Performance (MSP),
- Safety (SA):
  - Absence of Critical Damages (ACD)—active actions,
  - Protecting the environment against the effects of any potential critical damages (PRO)—passive actions.

Resilience of the supply chains is the ability to assure the service delivery with an acceptable discontinuity under abnormal (uncommon, hazardous) working conditions and situations (e.g. disruptions, attacks, accidences, disasters).

So we understand resilience (R) as the 3-dimentional vector

$$R = \{SE, SU, RE\} \quad (2)$$

with:

- Security (SE)—protection of a system from malicious intent, is displayed by
  - Confidentiality (CON) of information to unauthorized users,
  - Integrity (INT)—impossibility of introducing changes into the system by unauthorized users, and
  - Accessibility (ACC) for authorized users only.
- Survivability (SU)—the capability of a system to fulfil its mission, in a timely manner, in the presence of attacks, failures, or accidents, is described by
  - Detectability (DET)—early threats recognition, supervision and monitoring,
  - Robustness (ROB)—resistance and redundancy,
  - Adaptability (ADA)—flexibility, agility, fault tolerance.
- Recovery (RE)—failure removal (restoration) in acceptable time and costs, is divided into
  - Susceptibility to repair (SUS) and
  - Availability of Repair Resources (ARR).

The framework for evaluation of technical systems dependability with the use of fuzzy logic and experts' knowledge was developed and published by authors in (Bukowski & Feliks 2011).

The resilience model proposed in this work is based on a typical course of a service delivering process, interrupted by an occurrence of a threat leading to a disruption of the process continuity. An example of such a course as a function of time is represented in Figure 2, on which three fundamental phases can be distinguished:

- A phase of normal work, interrupted only by slight disturbances and rare cases of more serious hazards, which were recognized sufficiently early and "parried" (thwarted), thanks to a properly functioning security system
- A phase of process continuity disruption, directly after an occurrence of a hazard, which has not been effectively blocked by the security system. During this phase, the system's survivability is its decisive feature, which is measured by the levels of performance: DPL and PPL, as well as time t_s
- A phase of process recovery to an acceptable level of APL performance after the continuity's disruption, characterized by time t_r.

After the removal of the effects of the process continuity disruption, a process of improvement can begin, consisting in an adaptation of the system to new working condition and a possible increase in the level of performance.

This model is algorithmically illustrated in Figure 3.

External sources of risk generate disruptions and hazards which encounter security barriers.

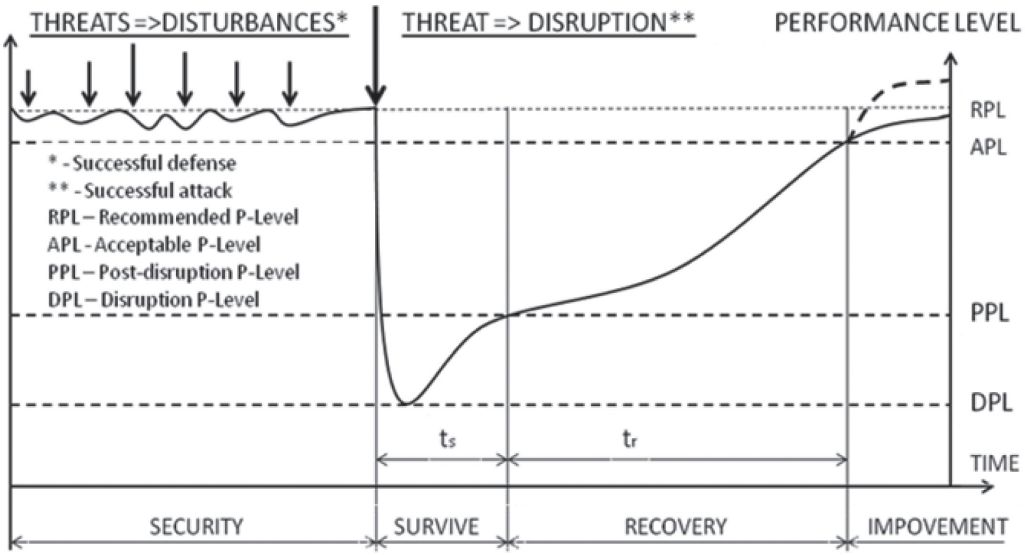

Figure 2. Typical disruption time history.

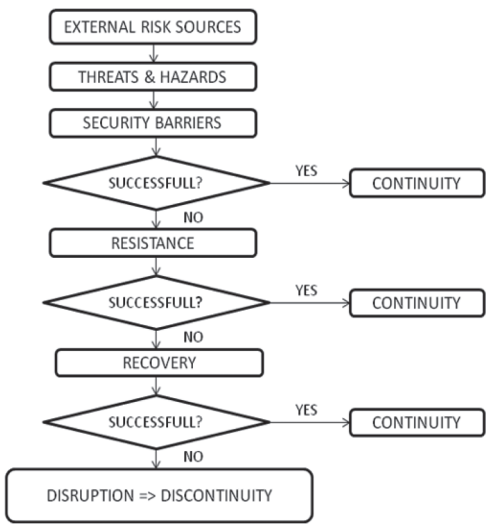

Figure 3. Disruption model flowchart.

Table 2. Comparing the dependability engineering and resilience engineering attributes.

Nr.	Attribute	Dependability engineering	Resilience engineering
1	Focus	System related	Process related
2	Desirable state	Availability	Continuity
3	Undesirable state	Fault	Interrupting
4	Undesirable event	Failure	Disruption
5	Activity after undesirable event	Renewal	Recovery
6	Desired abilities	Reliability robustness maintainability	Survivability resistance recoverability
7	Measures in time dimension	MTBF MTTFF MUT MDT	ETBD ETTFD ECT EDT

As long as these barriers fulfil their roles, the system realizes the required functions in a continuous way. If the barriers turn out to be insufficient to protect a given system, the system must defend itself with its internal resistance. In a case in which the resistance is too weak in relation to the working hazard (to absorb disruption impact and to withstand disruption shock), the system goes into the "recovery" state, which encompasses the stages of damage removing, as well as repair and restoration. If this stage also ends in failure, a total interruption of the process continuity will occur, resulting in the need of reengineering (redesign of structure and processes).

Basic characteristics of the accepted dependability and resilience models have been compiled in Table 2, together with the measures of the time indicators describing them quantitatively.

Thus, the MTBF (mean time between failures) indicator corresponds with ETBD (expected time between disruptions), the MTTFF (mean time to first failure) indicator corresponds with ETTFD (expected time to first disruptions), the MUT (mean up time) indicator corresponds with ECT (expected continuity time), while the MDT (mean down time) indicator corresponds with EDT (expected disruption time). Differences result mainly from the fact that while in the case of dependability the indicators are generally assessed through statistical methods, in the case of resilience, due to very infrequent events threatening to disrupt the process continuity, generally only expert methods are available. Such a method, with the use of artificial intelligence methods, is proposed by the authors of this paper.

The application of fuzzy sets theory in this case is reasonable because expert's knowledge can be used to build a suitable rule base (Bukowski & Feliks 2005). Expert knowledge on the impact of the various parameters on result is expressed in the form of "if … then" rules. The knowledge encoded in a rule base is derived from human experience and intuition as well as on the basis of theoretical and practical understanding of the properties of the studied object. The main task of this deduction system is to calculate the approximate value of the output variable based on the share of each rule from the rule base with an appropriate factor determining the "validity" of the rule. Fuzzy logic based systems are a kind of expert system built on a knowledge base that contains inference algorithms in the form of a rule base. What distinguishes fuzzy inference in terms of concept from conventional inference is the lack of an analytical description. The approximate inference mechanism transforms knowledge from the rule base into a non-fuzzy form. The non-fuzzy form of the result is obtained in the process of defuzzification. Defuzzification is interpreting the membership degrees of fuzzy sets into a real value. The correctness of selection of rules as well as the shape and ranges of the membership function is verified with a rules viewer and simulation. The rules viewer displays a roadmap of the whole fuzzy inference process.

The software WinFACT® (WinFACT—User Guide 2003) was used for building a system for evaluating resilience level. WinFACT® provides FLOP (Fuzzy Logic Operating Program) tools for creating and editing fuzzy inference systems or integrating our fuzzy systems into simulations with BORIS (Block Oriented Simulation). An example of the application of this idea is shown in the Figures 4 and 5.

The evaluation system of supply chain resilience is a hierarchical structure. In the first sequence the Security (SE), Survivability (SU) and Recovery (RE), were evaluated, and the information about them can be represented by the membership function of fuzzy system. Trapezium membership functions are associated with the numerical value RE, SU, SE. Each of these parameters was divided in to three categories—Low, Moderate and High from range 0 to 1. Level of resilience (R) is an output of

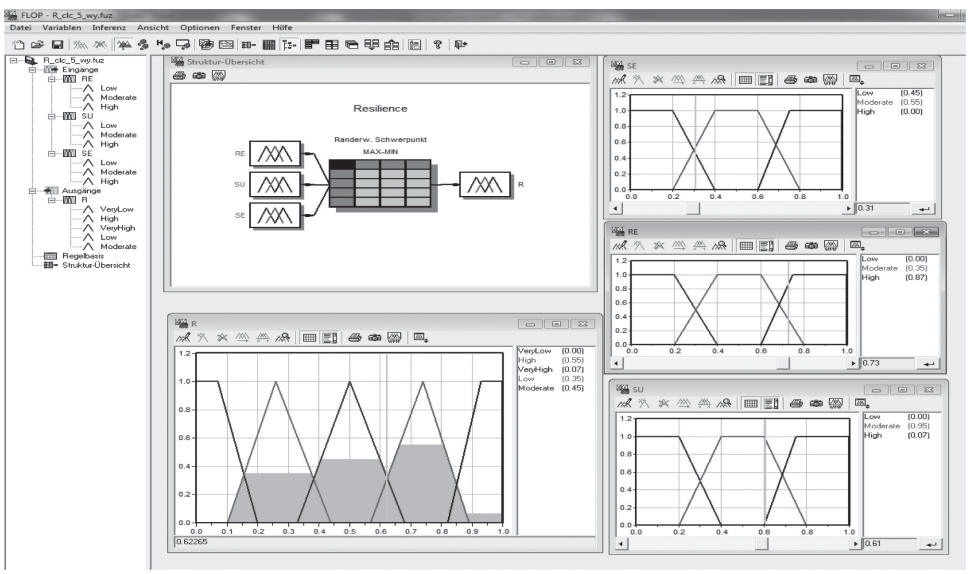

Figure 4. Screen shot of resilience fuzzy model.

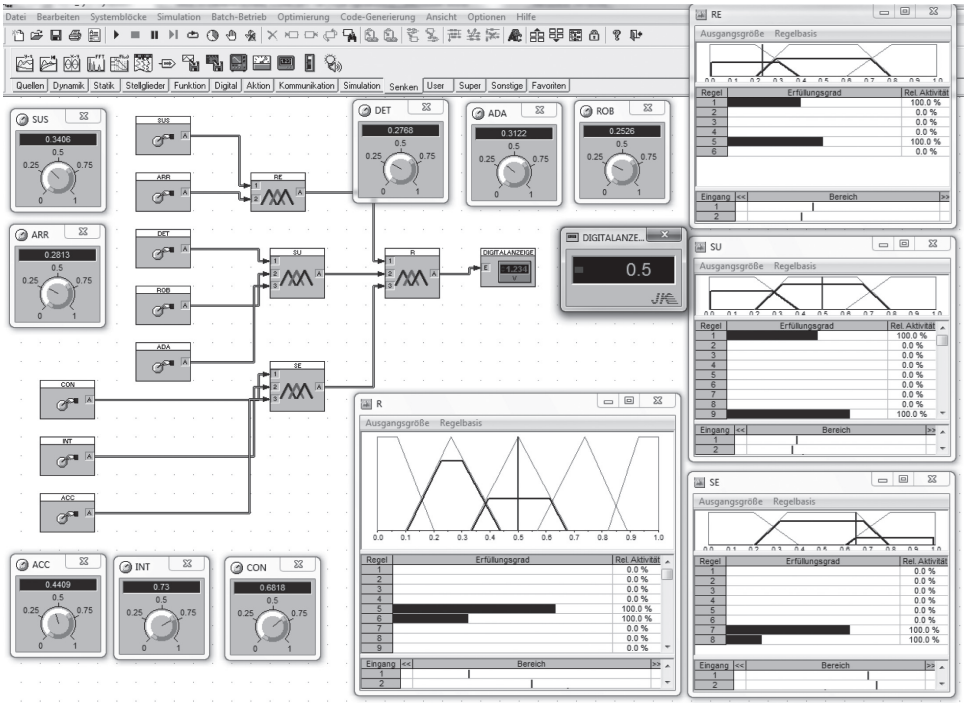

Figure 5. Screen shot of simulation fuzzy model.

this system and it is depends on the value of inputs and on the "knowledge" which is implemented in the rules base in a fuzzy system. In the case of using trapezoidal membership function models for linguistic variables, one may assume that that the measure of uncertainty in quantitative estimates is the angle of inclination of the sides of the. So slope of each input variables could be interpreted as an uncertainty of input parameter estimation.

6 CONCLUSIONS

The unified model of systems dependability and process resilience proposed in this paper is a universal, "shell" type tool, that can be applied to verifying and validating the vulnerability of complex systems, especially for complex supply chains.

Adapting this model to the needs of a particular type of system or a specific practical case requires the estimation of numerical values (or ranges) corresponding to each parameter class.

The measure of uncertainty in this model is the inclination angle of the triangles or trapezoids sides (the smaller the angle, the larger the uncertainty).

Using quantitative stochastic model checking tool to increase safety and improve efficiency in production processes

L. Herbert
DTU Compute, The Technical University of Denmark, Lyngby, Denmark

Z.N.L. Hansen & P. Jacobsen
Department of Management Engineering, The Technical University of Denmark, Lyngby, Denmark

ABSTRACT: This paper shows how quantitative stochastic model checking can be employed in an evolutionary algorithm to automatically reconfigure a production process to improve the efficiency of production while observing freely defined safety constraints. Our approach is based on a formalized subset of the modelling language Business Process Modelling and Notation (BPMN). This language is extended with annotations, which capture the associated consumption of resources (e.g. time, cost or consumption of materials) and which allow for stocastic behaviour. We employ Probabilistic Temporal Logic (PCTL) to specify safety constraints and to determine the quatative properties of the workflow. We procced to present an evolutionary algorithm to search through possible reconfigurations of a production process to meet the required safety constraints while observing safety constraints specfied in PCTL. The ideas in this paper are implemented in SBOAT, a prototype software tool which is employed in a case study in the baked goods industry. Applied to the case study SBOAT is able to optimize a production process such that production time of baked goods is improved while safety constrints are observed, thereby reducing the costs associated with production faults while maintaining a defined level of safety.

1 INTRODUCTION

Historically, Frank Gilbreth is credited with developing the first method for documenting process flow (Gilbreth & Gilbreth 1921), and since then many different abstract representations of business processes have been proposed. Today, two modelling languages have come to dominate modern business process modelling: the *Business Process Model and Notation* (BPMN) language (Object Management Group 2011a) and the *Unified Modelling Language* (UML) (Object Management Group 2011b). Both of these are visual languages which has allowed them to be used by practitioners with little formal training. However, the rapid adoption and development of these languages has come at the expense of an imprecise and incomplete semantic definition, preventing analysis by formal means (Börger 2012, Recker, Indulska, Rosemann, & Green 2005).

1.1 *Efficiency gains in production processes*

Modern enterprises exist within complex networks which must adapt to constantly changing environments. The architecture of an enterprise is the organizing logic of the individual business processes which make up its operations (Ross, Weill, & Robertson 2006). For industries which create complex products or provide complex services, their strategy and business processes often exhibit a high degree of complexity. In these environments creating dependable, yet efficient, business processes poses a significant challenge. Requirements for process models can be divided into the following categories, although a specific requirement may belong in more than one category (Vergidis, Tiwari, & Majeed 2008):

- **Validation properties:** testing whether the business process behaves as expected in a given context; e.g., does this financial process comply with the Sarbanes–Oxley act?
- **Performance properties:** evaluating the ability to meet requirements for throughput times, service levels, and other quantitative factors; e.g., how long does it take to deliver a package?
- **Stochastic properties:** evaluating the probability of behaviour within the system; e.g., is there a greater than 98% chance the package will be delivered in three days?

The predominant approach to developing business processes is first to develop conceptual process models, which are used for development of

an implementation, typically involving a mix of automated and manual processes. There is substantial evidence (Gallaher & Kropp 2002, White, O'Connor, & Rowe 2004) that being able to determine such properties and their exact quantitative values early in their design phase can result in smoother integration, accurate provisioning to meet service level agreements, and significant cost savings. In particular, safety critical processes frequently combine the need for certainty that safety properties are not violated while simultaneously requiring a specific performance profile.

In this paper we present a mathematical approach to analysing production processes in order to optimise them for greater efficiency and safety. We do this by employing quantitative stochastic model checking. We show the practical applicability of this approach by applying our software tool SBOAT (*Stochastic BPMN Optimisation and Analysis Tool*), to an small example from the baked goods industry. Combined this approach provides a practical technique for business process architects a means to automatically test and redesign production processes according to given constraints (e.g. safety, cost, time).

1.2 *Related work*

In general by performing model checking to determine quantitative and qualitative properties of BPMN models, this work draws a comparison with a number of other BPMN analysis techniques outlined below. The selection of analyses discussed is not exhaustive, but covers the main approaches which have been widely referenced in the literature. They can broadly be defined as functional analyses, non-functional analyses and stochastic analyses.

In terms of the analysis of functional qualitative properties a wide range of approaches have been developed for BPMN. These are predominantly focused on the analysis limited sets of functional properties, such as proving the absence of deadlocks. The work of Ouyang et al. (Ouyang, Dumas, ter Hofstede, & van der Aalst 2006, Ouyang, Dumas, & Hofstede 2007) is the closest match to the type of translation approach taken in this paper. Here, translation of BPMN models is done directly into the web-services orientated Business Process Execution Language (BPEL) (Organization for the Advancement of Structured Information Standards (OASIS) 2007) by means of an algorithm similar to what is presented in this thesis. However, the approach by Ouyang et al. is intended to support simulation through execution of the BPEL services with all the limitations that a simulation approach entails. Limitations are for example that statistical simulation can explore some situations, but cannot observe all behaviours. Safety properties which guarantee that specific behaviour will always, or, can never, occur need to be evaluated under all possible situations which simply cannot be achieved by the simulation method. The other key limitation is that simulations need to be executed for a certain amount of time.

A number of different approaches have been developed to analyse non-functional properties of BPMN models. In particular there has been a focus on determining timing properties of BPMN models, but little work on general quantitative properties.

Work by Ling and Schmidt in 2000 (Ling & Schmidt 2000) present a time interval extension of the workflow nets of van der Aalst (Aalst 1997) in terms of timed Petri-nets (Peterson 1981). Their extension introduces a notion of safety in time which is analogous to the notion of boundedness in Petri nets (Peterson 1981), using this notion they basically preserve the original soundness theorems of workflows and the liveness theorems of Petri nets in their timed workflow nets. However, their work only provides for placing bounds on the total execution time for a processes and do not allow for analysis of time intervals on a per state basic. Further, treatment of other quantitative properties associated with a business process are only dealt with to a limited degree and due to need to consider completion run times, and may not readily extendible to other quantitative properties of interest.

Work by Wong and Gibbons (Wong & Gibbons 2009) complements their previous work developing a Communicating Sequential Processes (CSP) (Hoare 1983) based semantics for BPMN. By employing an extension of CSP which accounts for processes *responsiveness*, and an analysis technique that addresses the of timing of processes in such a fashion that a formal automated analysis is still possible. This impressive work allows for extensive analysis of BPMN models, but still does not cover arbitrary quantitative properties or stochastic behaviour.

Analysis of BPMN models extended with stochastic properties has seen limited development with only two approaches identified of dealing with general models which exhibit both probabilistic and non-deterministic transitions. Prandi et al. (Prandi, Quaglia, & Zannone 2008) have identified Probabilistic Symbolic Model Checker (PRISM) (Kwiatkowska, Norman, & Parker 2011) as ideally suited to the analysis of stochastic PRISM business processes. This effort involves conversion of PRISM models into a model expressed in the Calculus for Orchestration of Web Services (COWS) (Pugliese & Tiezzi 2012), which in turn is converted into a model that can be analysed using PRISM (Kwiatkowska, Norman, & Parker

2011). This approach adds unnecessary complexity in that it is possible to convert the notation of BPMN directly into the PRISM modelling language, and then allow PRISM to impose a semantic interpretation without the additional semantic restrictions of going via COWS. Further, the translations PRISM to COWS and in particular from COWS to PRISM is loosely defined and, in the form described by the authors, not amenable to algorithmic translation. This approach, however, does allow the use of rewards. Consequently, the PRISM model checker is potentially able to perform analysis of both quantitative and stochastic properties of a business process. However, details of how such properties will be included in the original BPMN models is not described.

1.3 *Core BPMN*

We will begin by constructing a formalized restricted subset of BPMN for the purpose of illustrating the application of model checking methods to business process optimisation. This subset seeks to be simple enough to allow for relatively straightforward analysis while still having sufficient expressivity to capture a wide range of workflows. Often called the *core* subset of BPMN, it consists of the eight elements found to be most commonly used in a large survey of real-world BPMN usage (Muehlen & Recker 2008); indeed more than 70% of models surveyed consisted only of these elements. The graphical elements of core BPMN are shown in Figure 1 and described below.

The process of modelling a workflow in BPMN involves composing a number of BPMN elements into a Business Process Digram (BPD). The intention is that a business process diagram captures the complete workflow of a business process, with separate sub-components of a workflow organised into separate pools. A BPD is formally defined

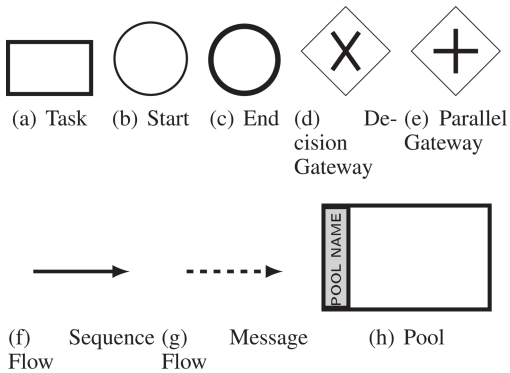

Figure 1. Core BPMN elements.

here as simple partitions of a process graph with synchronisation arcs as defined in definition 1, with the straightforward addition of a function to capture pools.

Definition 1 (Core BPD). A core BPD is an *extended process graph tuple* $BPD = (\mathbf{N}, \mathcal{F}, \mathbf{P}, \text{pool}, \mathbf{L}, \text{lab})$ *where* $\mathbf{N} \subseteq \mathbf{T} \cup \mathbf{E} \cup \mathbf{G}$*, is a set of nodes composed of the following disjoint sets:*

- *Tasks* $\mathbf{T}$*, are the basic actions performed as part of a business process.*
- *Events* $\mathbf{E} \subseteq \mathbf{E}^{\mathbf{S}} \cup \mathbf{E}^{\mathbf{E}}$*, where the disjoint sets* $\mathbf{E}^{\mathbf{S}}$ *and* $\mathbf{E}^{\mathbf{E}}$ *respectively represent start and end events.*
- *Gateways* $\mathbf{G} \subseteq \mathbf{G}^{\mathbf{D}} \cup \mathbf{G}^{\mathbf{F}} \cup \mathbf{G}^{\mathbf{M}}$*, where the disjoint sets* $\mathbf{G}^{\mathbf{D}}$, $\mathbf{G}^{\mathbf{F}}$ *and* $\mathbf{G}^{\mathbf{M}}$ *respectively represent exclusive decision gateways, parallel fork gateways, and parallel merge gateways.*

$\mathcal{F} \subseteq \mathcal{S} \cup \mathcal{M}$ *is a set of flow relations, where sequence flows* $\mathcal{S} \subseteq \mathbf{N} \times \mathbf{N}$ *relate nodes to each other and message passing* $\mathcal{M} \subseteq \mathbf{T} \times \mathbf{G}^{\mathbf{M}}$ *is a relation between tasks and parallel merge gateways.* $\mathbf{P} \subset \mathfrak{P}(\mathbf{N})$ *is a set of disjoint pools and pool* $: \mathbf{N} \to \mathbf{P}$ *maps nodes to a pool* $p \in \mathbf{P}$*.* $\mathbf{L}$ *is a set of unique labels and* $\text{lab} : \mathcal{F} \to \mathbf{L}$ *is a labelling function which assigns labels to flows.*

The definition of a BPD given in definition 1 models business processes by using elements of $\mathcal{F}$ to define a directed graph with nodes which are elements of $\mathbf{N}$. However, definition 1 allows for graphs which are unconnected, do not have start or end elements, and are free from various other properties which place them outside what is implied to be permitted in standard BPMN models. To ensure that a BPD describes a meaningful business process we have developed a set of structural semantics (well-formedness) rules (Herbert & Sharp 2012) which enforce restrictions on connecting elements, pool boundaries, and message passing.

When performing quantitative analysis of a graph based process language we choose structural semantic rules such that they impose the minimum semantic interpretation necessary to determine the control flow of a model. In the case of a BPMN BPD, it adds no more semantic interpretation than implied by the standard (Object Management Group 2011a). In the case of BPMN, when we have imposed restrictions they have been made only for simplicity and are discussed at length in previous work (Herbert & Sharp 2012).

It should be noted that by combining several Core BPMN elements most elements of the entire BPMN language can be simulated, although a few constructs pose more complex issues. Of particular note are inclusive gateways which pose a challenge as the specification of their semantics

include a non-trivial and non-local backwards search of the flow graph of the BPD. However, these can be addressed through the work of Christiansen, Carbone and Hildebrandt (Christiansen, Carbone, & Hildebrandt 2011) who present a method to translate this construct, in a large number of cases, into other BPMN processes with some restructuring of the overall BPD. In general, most elements of the full BPMN language can be incorporated by simply including a preprocessing step in the analysis of BPMN which translates non-core BPMN elements to core BPMN elements.

1.4 *Extending core BPMN*

We will extend our modelling formalism to better accommodate real-world processes which add further complexity, in that the processes may interact with elements outside the processes' control and whose behaviour is unknown. This motivates the need for probabilistic decision points in the modelling of business processes, because the outcomes of complex decisions within a process can appear random and/or not possible to predict. In such a stochastic system, characterizing properties such as the number of items that remain in a queue or the resources consumed per job done will require answers in terms of probabilities.

BPMN makes use of external conditions on decision gateways to select the outgoing flow from a decision point. These decisions are modelled by the set $\mathbf{L}$ and assigned to specific flows by the function *lab* introduced in definition 1. In practice, decision points in a business process will have outcomes which depend on some inherent property of the task or on outside factors. The idea is that at a decision point an active choice is made, and then that choice results in a number of different possible outcomes.

This behaviour, which is similar to a Markov Decision Process (MDP) (White 1993), where we wish to preserve the intention of actors in a process and still enable probabilistic behaviour, can be effectively captured by annotating the possible outcomes of specific decisions with pairs of labels and probabilities (l, p). We employ the following function to ensure meaningful assignment of these intention preserving probabilistic annotations.

Definition 2 (BPD Gateway Flow Probability Function). *Given a BPD, a decision gateway probability function is a partial function* $\mathcal{P} : \mathcal{S} \times \mathbf{L} \to [0,1]$ *which for a node* $g \in \mathbf{G}^{\mathbf{D}}$ *and label* $l \in \mathbf{L}$*, assigns probabilities to all outgoing sequence flows* (g, x)*, such that for a given* l*:*

$$\sum_{\forall x \in out(g)} \mathcal{P}((g,x),l) = 1$$

Definition 2 ensures that all decision gateways have an associated probability and that the sum of all probabilities for a given label l is 1.

Furthermore, many business processes make use of various limited resources such as stock levels, time, or available liquidity, and the accurate provisioning of these resources is the key to their safe and efficient execution. An essential activity in developing business processes that integrate well with their environments is accounting for these resources during their, frequently complex, execution. To enable quantitative analysis of business processes we add numerical data to our models by using the following function which associates positive real numbers with tasks in a BPD.

Definition 3 (BPD Task Reward Function). *For a BPD a reward function for a task* $t \in \mathbf{T}$ *is a partial function* $\mathcal{R} : \mathbf{T} \to \mathbb{R}_{\geq 0}$.

This function captures the notion that certain nodes have some reward or cost associated with the task. The term *reward* is somewhat misleading: there is no practical distinction between costs and rewards, and we can use these annotated values to keep track of whichever quantities may be of interest in a process. We may associate as many reward structures as we wish with a given BPD, so that a single task may have multiple different numerical properties which are incremented when the task is performed. The only restriction is that each reward structure is monotonic.

Further, within our implementation of these ideas: SBOAT, we allow some reward structures to be parametrised, allowing us to model limited resources involved in a process. In this case a reward has an associated upper and lower bound.

Note that the stochastic branching annotations and reward structures presented here are simple additions to the BPMN language, or other graph based process languages, and do not alter the implied semantics of the language.

2 QUANTITATIVE STOCHASTIC MODEL CHECKING

Current approaches to business process analysis are overwhelmingly manual and require time-consuming inspection by an expert. The focus is almost exclusively on qualitative properties and frequently quantitative properties are first examined only when the process has been implemented. Attempts to improve this have mostly focused on simulation, where sets of specific actions in a business process are explored in a stochastic fashion by performing simulation experiments to better understand the effects of running that process. A number of simulation approaches and corresponding tools,

such as (Tumay 1995), ARIS (Scheer & Nüttgens 2000), and FileNet (Netjes, Reijers, & van der Aalst 2000) have been developed. However these approaches have some fundamental differences from formal mathematical analysis.

The most prominent distinction between simulation-based verification and formal verification is that the former requires input vectors and the latter does not. The approach in simulation-based verification is first to generate input vectors, and then to derive reference outputs. The thinking process is reversed in the formal verification process. The user states what output behavior is desirable (without considering input stimuli), and then lets the formal checker prove or disprove it.

Although statistical simulation can be useful in some cases, only formal verification is complete, in the sense that it does not miss any point in the input space of a problem. Statistical simulation can explore some situations, but cannot observe all behaviors. Safety properties which guarantee that specific behavior will always, or, can never, occur need to be evaluated under all possible situations that simply cannot be achieved by the simulation method. The other key limitation is that simulations need to be executed for a certain amount of time whereas verification by model checking is typically unbounded, and can reason about the properties of infinite runs of a system.

Therefore, our approach makes use of formal verification in the form of model checking. The goal of this work is to make it possible to automatically transform a BPMN model of a production process into a form which can be formally analysed. This allows all possible execution paths through the production process to be efficiently examined. This is achieved by transforming the BPMN model into a MDP (White 1993) which is amenable to formal statespace analysis (i.e. mathematical analysis of the set of possible values the process can take during execution). These states represent possible configurations of the system being modelled with probabilistic state transitions being combined with non-deterministic choices between several discrete probability distributions over successor states. Model checking allows for the efficient exploration of the entirety of this space with a temporal logic employed to select sets of states of interest, and offers the possibility of verifying many properties of a system.

Performing model checking of Core BPMN is done by means of the state-of-the-art PRISM tool. This translation of BPMN models to a format that can be analysed by PRISM is detailed in (Herbert & Sharp 2012). The central issue in this translation is addressing parallelism. This is fundamentally accounted for by generating appropriately named PRISM *actions* that enforce synchronisation between modules. An illustration of this process for a simple pair of parallel fork and merge gateways and the resulting three guarded PRISM modules are shown in Figure 2. It should be noted that while this synchronisation between sub modules is performed by means of PRISM action labels, these are ultimately converted, due to the semantics imposed by PRISM, into additional system module variables which impose synchronisation be means of dedicated state variables.

The overall design of the analysis framework for analysing production processes via quantitative stochastic model checking is shown in Figure 4. The main idea is to convert formalized BPMN models into PRISM code and thereby perform Probabilistic Computational Tree Logic (PCTL) model checking of business processes. The only inputs required are the specification of a BPMN model annotated with probabilities and reward structures where required, and a PCTL query (highlighted in grey).

A key consequence of this approach to statespace generation is that in the semantics imposed by PRISM, concurrent elements of a business process do not execute synchronously, instead these transitions are instead arbitrarily interleaved in time (in the style of CSP (Hoare 1983) parallel composition). PRISM will generate all possible interleavings, as dictated by message passing, of separate BPDs and all possible interleavings within each BPD of all Core BPMN elements between parallel fork and merge gateways. An illustration of this interleaving behaviour for the concurrent part of the Core BPMN example process given in Figure 10 is shown in Figure 3.

Note how the possible paths from the *[fork]* gateway to the *[merge]* gateway cover all possible allowed interleavings of assessing and then scanning a patient, and examining the patient's medical

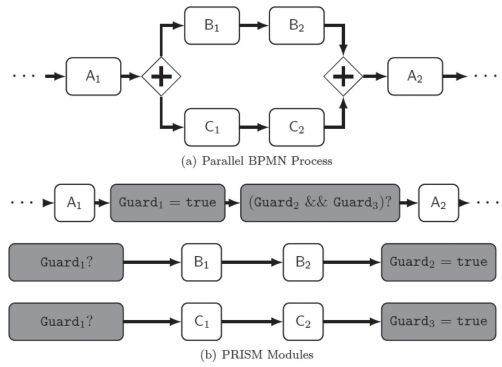

Figure 2. The BPMN to PRISM approach to handling parallelism in a Core BPMN model. Tasks B_1, B_2, C_1, C_2 will be executed after A_1 in all possible interleavings and then followed by the execution of $thsfA_2$.

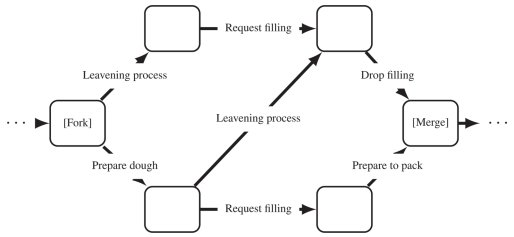

Figure 3. Illustration of interleaving semantics imposed by the PRISM model checker (extract of the statespace of the parallel processes of from Fig.10).

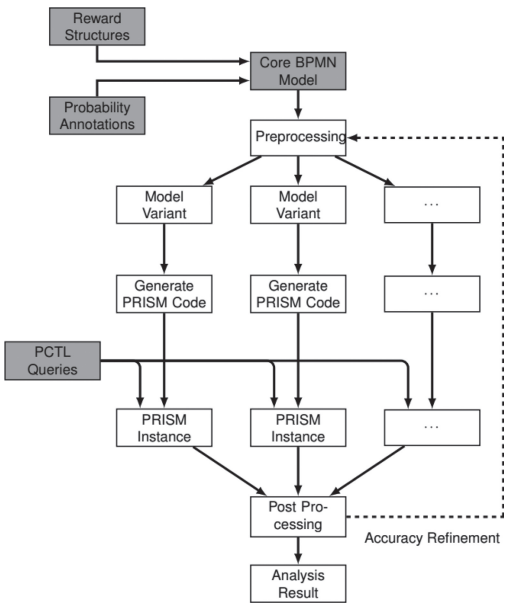

Figure 4. The overall approach taken to automated business process analysis.

record. This maximal interleaving ensures that all possible execution paths are explored, but does not capture so called "true concurrency". This semantic distinction is expressed by Baeten (Baeten 1993) by means of the *the total order assumption* which requires, for the assumption to hold that "all execution sequences of observable actions or events are totally ordered by precedence". This assumption is shown by Baeten (Baier & Katoen 2008) to be well suited to cases when an execution sequence is totally ordered by time and a totally ordered set, such as the non-negative real numbers is employed to model the time domain. Furthermore, when business processes are managed by BPM software, this multitasking, or multiprocessing, is enabled by a software or hardware scheduler. In this type of scheduling the actual execution semantics of a business process will have the total order assumption imposed upon their execution. This assumption ensures all execution sequences that will be possible in practice are present in a model generated by PRISM. Therefore verification of a system under the total order assumption closely matches its actual real world behaviour and verification of systems under the total order assumption provides a strong guarantee of their safety properties.

However, it is this interleaving behaviour which leads to the requirement that, when evaluating performance properties in the form of probability and reward queries, only upper or lower bounds on the expected values can be determined. Note that in a system where there is no non-determinism and only probabilistic behaviour, no interleaving behaviour is present and the bounds will converge, as this case, in essence, reduces to Discrete Time Markov Chain (DTMC) model checking (Baier & Katoen 2008).

This approach is implemented in our SBOAT tool as shown in Section 3.

2.1 *Stochastic model checking*

The central idea of this approach is to be able to perform stochastic model checking of BPMN models. We will employ the property specification language PCTL (Kwiatkowska, Norman, & Parker 2011) based on classical continuous stochastic logic (Hansson & Jonsson 1994) extended to probabilistic quantification of described properties, to define properties of interest. This logic allows us to reason about properties relating to: timing, occurrence and ordering of events, reward values, transient and steady-state probabilities, and best- and worst-case scenarios. An implementation of the PCTL logic is employed by the PRISM model checker in its property specification language and has the following basic elements.

First developed by David Parker as part of his PhD thesis (Parker 2003), the PRISM tool has seen extensive development and has grown to be a very capable model checker. PRISM is an open-source software tool which accepts probabilistic models written in a textual PRISM modeling language based on *Reactive Modules* (Alur & Henzinger 1999), a state-based language using guarded commands. Where properties for their analysis can be specified using the PRISM specification language, which implements the probabilistic temporal logics, PCTL, LTL, and PCTL*. PRISM includes multiple model checking engines, several of which are based on symbolic implementations (using binary decision diagrams and their extensions). These can enable the probabilistic verification of models of up to 10^{10} states (Kwiatkowska, Norman, & Parker 2011);

however, the tool achieves optimal performance on models in the range of 10^4 to 10^8 states.

The key constructs in the PRISM property specification language, as it applies to Markov decision processes, are the *P* and *R* operators. The *P* operator refers to the probability of an event occurring, more precisely, the probability that the observed execution of the model satisfies a given specification. The *R* operator is used to express properties that relate to rewards (more precisely, the expected value of a random variable, associated with particular reward structure) and since a model will often be decorated with multiple reward structures, we augment the *R* operator with a label. For example, to determine the mean time to exhaust the supply of cake filler we would specify the following property:

$$R_{time} =_? [F^{[0,\infty]} filler_empty] \quad (1)$$

In this property (eq. (1)) we employ the time-bounded operator F^I, where $I \in [t_1, t_2] \in \mathbb{R}^2$, to describe if a subsequent boolean variable becomes true, it remains true. Other operators allowed include, the operator U^I which allow for specification of execution paths where one boolean variable holds until another is true, and G^I, which can be seen as the dual of F^I: expresses the fact that a condition remains, rather than becomes, true. Note that these operators can be combined in arithmetic expressions, allowing more complex measures to be expressed.

2.2 *Quantitative properties*

For quantitative analysis of business processes we add numerical data to our models by using a reward function reward function which associates positive real numbers with tasks in a BPD.

Definition 4. (BPD Task Reward Function). *For a BPD a reward function for a task* $t \in \mathbf{T}$ *is a partial function* $\mathcal{R} : \mathbf{T} \to \mathbb{R}_{\geq 0}$.

$\mathcal{R}$ captures the notion that certain nodes have some reward or cost associated with the task. In practice there is no practical distinction between costs and rewards, and we use these annotated values to keep track of whichever quantities may be of interest in a business process, such as execution time or power usage. We may associate as many reward structures as we wish with a given BPD, so that a single task may have multiple different numerical properties which are incremented when the task is performed.

Note that the sequence flow probabilities, message flow probabilities, and reward structures presented here are simple additions to the BPMN language and do not alter its implied semantics.

3 SBOAT

SBOAT is a *Stochastic BPMN Optimisation and Analysis Tool*, which allows a user to model, and annotate with rewards and stochastic branching, a business processes as a BPMN BPD. Analysis is specified using a PRISM style PCTL query and depending on the nature of the query one or number of results are calculated. At the core of SBOAT is the PRISM model checker (Kwiatkowska, Norman, & Parker 2011) which performs analysis of individual models generated by the SBOAT. An overview of the design of SBOAT is shown in Figure 5.

Designing a BPMN model and adding annotations to a model is done in the modeller, shown in Figure 6. Within SBOAT we employ an *adjacency list* (Cormen, Leiserson, Rivest, & Stein 2009) data

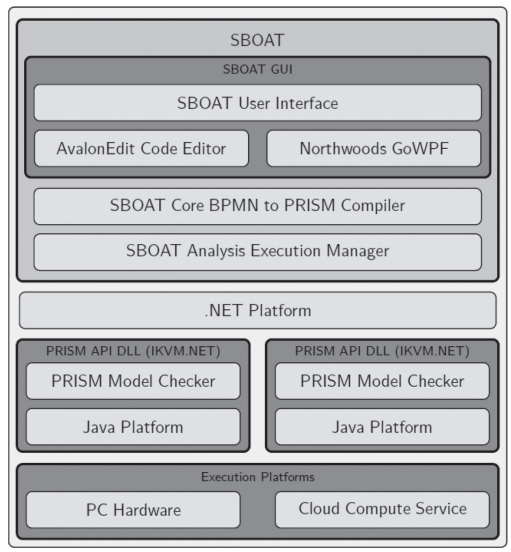

Figure 5. Overall design of SBOAT.

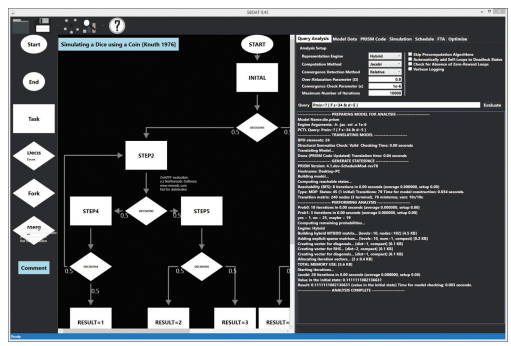

Figure 6. SBOAT 2.0 User Interface.

structure to store the modelled BPD as a directed graph.

This implementation approach allows nodes and edges to be of any data type, where edges implement a simple interface that defines connections to nodes. This flexibility also supports almost any type of reward annotation to be stored in nodes or edges. Further, the data structure is mutable and cloneable making it possible to build a suitable data structure for a wide range of possible graph based process languages. Internally, the data structure keeps a dictionary from nodes to a unordered list of edge elements.

The data structure used is serializable allowing for generation of XML files to store models. In the case of BPMN models, we emit files that comply with the XML based BPMN file format (Object Management Group 2011a), using the annotation features inherent in the BPMN file format to store rewards and stochastic branching probabilities. When importing data files we parse the BPMN XML and at that stage checks for the structural semantic rules of the model are made as new nodes and edges are added.

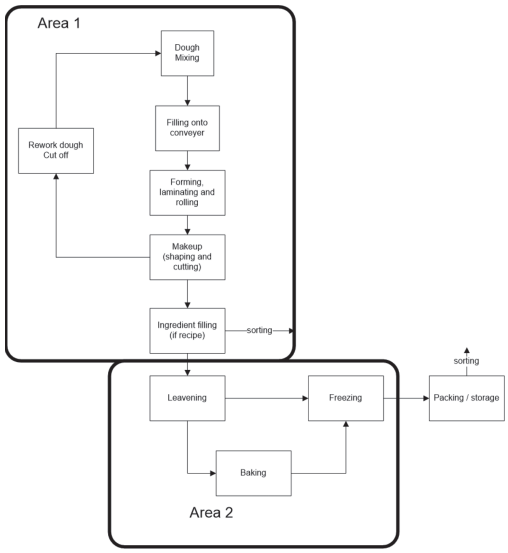

Figure 7. The production process at Baked Goods A/S.

4 CASE STUDY

Baked Goods A/S has two production lines. Line 1 develops cakes and pastries and line 2 develops baked goods like sausage rolls and pizzas. The company has an approximate overall waste of 20% for all products during the whole production cycle. The waste is calculated at different places on the production line, but currently it is only possible to get the overall waste percentage of a product. The production process is shown in Figure 7. The dough is prepared, then the product, for example a cake, is prepared and made, then baked or frozen, followed by packaging and then shipment. Dough leftover during production is reused in the preparation of new dough. Quality checks take place during and after production as well as after freezing where defective products are discarded.

Depending on the line and product, the packaging is either automatic or manual and either controlled for number of pieces and weight or just number of pieces.

The processing steps are as follows;

1. Dough mixing. The ingredients for the dough are mixed in vats with a screw-hook mixer. Water and flour are delivered automatically through transport tubes, all other ingredients are manually added including ice.
2. Lamination. If specified the dough is laminated, meaning folded in on itself and rolled out. This takes place continually. Dough is supplied into a dispensing system. The dough is split into two sheets of continues length, and if specified, a layer of fat is supplied in between these layers. The lamination step can be skipped by using the second dispensing machine situated further up the production line.
3. Make-up and filling. Make-up refers to cutting the shapes out from the dough carpet. The product can also be filled with creams etc.
4. Leavening. This is done to induce a faster rising of the product in order to achieve the wanted volume of the product. This is done by raising the temperature and having a high humidity. This will promote the growth of yeast producing gas and the humidity will counteract surface drying allow for the dough to expand without generating stress cracks etc.
5. Baking. A baking step can be used after leavening.
6. Freezing. Some products are frozen instead of baked and then baked at the customer site.
7. Packing. Products are packed in bags, sealed and packaged for shipping to the customer.

5 ANALYSIS OF CASE EXAMPLE

To illustrate an application of this method we will consider a specific example of a simple production process inspired from the baked goods case study involving bread production. To employ the method, one begins by building a BPD model of an existing production process. Figure 8 is an example of such a process which is annotated with rewards

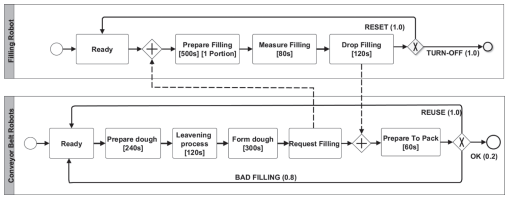

Figure 8. BPD model of a baking workflow process before optimization.

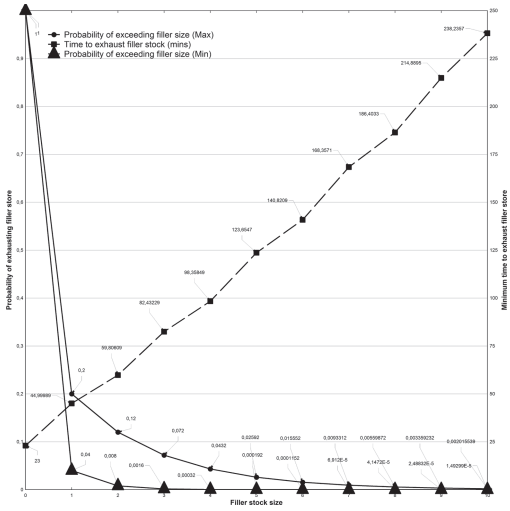

Figure 9. Quantitative safety analysis of the filling process for filler store sizes in the range 0–10.

and information about its stochastic behaviour. This naively-designed production process consists of two processes, Conveyor Belt modelling the actions of the machines on a conveyor belt, and Filling Robot which models the actions of robot which fills the dough with cream, or similar fillings, when needed.

In Figure 9 an analysis of the effect of allocating various amounts of resources to a business process is presented. This provides an assessment of both the probability bounds that a given resource level will lead to resource exhaustion, but also analysis of the non-functional property of the expected amount of time taken to reach such states. This type of provisioning analysis is frequently part of regulatory requirements for the introduction of new technologies (e.g. in the medical field (International Organization for Standardization 2003)) and the ability to perform this in an exact and automated fashion has been of considerable value to the project's industrial partner.

For the production process described in Figure 8 it would be desirable to see an improvement in the time taken for a conveyor belt machine to complete baking a cake. This is in other words the optimisation goal. Further, it would also be desirable that the rate of filling consumption and the consequent probability, given a specific filling stock size, of running out of the filling is kept as low as possible. This is the second optimisation goal.

In addition to the optimisation goals, a number of functional requirements exist for this process (formally expressed using the temporal logic PCTL in SBOAT). These requirements describe the sequences the steps the process have to be in:

1. The baking of the dough should take place before the leaving process of the dough.
2. All dough making, leaving, cut and filling, must take place before a cake is packed.
3. The conveyor belt machine cannot pack the cake before it has received filling.
4. The Filling Robot must ensure that a filling has been prepared and measured before it is sent to the conveyor belt.
5. When the conveyor belt determines that a bad dose of filling has been received it must immediately request a new dose.

Note that the final functional requirement (item 5) is not currently satisfied by the initial *BPD* shown in Figure 8.

Figure 10 illustrates one possible outcome of applying our optimisation methods to the BPD shown in Figure 8. Specifically, this is the outcome of 28 generational improvements of population size 500 of the process. Note that the new functional requirement (item 5) is now satisfied. In the case of this example the rates for sequencing and parallelising are set so that the Mutate function ensures that considerably more re-sequencing modifications are performed than parallelisation modifications.

In this run of our optimisation method we have identified two opportunities to parallelize actions. Within the Filling Robot process, the filling can be prepared and measured at the same time. In the conveyor belt process, it is possible to prepare

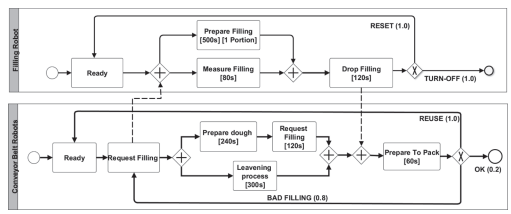

Figure 10. BPD model of a baking system after 28 generations of optimisations with a population size of 500.

dough and cut it while the dough simultaneously leaves. In both cases this saves time, as when performing actions in parallel only the path with the slowest behaviour is counted towards the parallel sections contribution to the reward value.

We have also determined that, in this simplified example, the conveyor belt process always orders filling to finish the cakes but the conveyor belt machines must wait while the *Filling Robot* performs its operations and then returns the filling. As the filling will inevitably be needed, and only the packing of the cake needs to be done after the dough has been made, it is within the functional requirements for the process, and results in a considerable time saving to order the filling immediately before even preparing the dough. This ensures that there will be no delay imposed on the *Conveyor Belt* process by the actions of the *Filling Robot* process. This simplified optimisation example does not violate the functional requirements and results in a significant reduction of the time taken for the execution of the production process.

Existing languages for the modelling of business processes such as BPMN or UML activity diagrams lack a formalised semantic basis (Börger 2012, Recker, Indulska, Rosemann, & Green 2005) which would enable formal analysis and subsequent automated scheduling. Further, these languages do not allow for modelling stochastic behaviour or provide mechanisms to effectively track the consumption of resources during execution. These aspects are therefore the key strengths of this optimisation method as no other method, to our knowledge, has all these features. Further, it should be noted that our method by employing the PRISM tool calculates exact values. However, this need for precision also means that a disadvantage of our approach is that it requires detailed knowledge of the workflow processes being optimised. Another disadvantage of our method is that to use the optimisation schedule in practice great computing power is needed which can be both expensive and time-consuming. However, our method allows for automatic optimal scheduling with mathematical precision and within specific parameters which can help organisations limit waste of, for example, energy or material as well as optimise production with regard to parameters such as time, human resources and cost.

6 SBOAT PERFORMANCE

In line with PCTL model checking theory, the model checking problem is polynomial in the size of the system statespace S. Furthermore, the translation of BPDs to PRISM models while subject to polynomial growth, constitutes only a small fraction of the time taken to perform model checking. Testing of the SBOAT tool, where the largest model explored has a million BPD elements and exhibits on average 1.5 two-way message exchange between BPD pools and features at most three parallel regions within each pool. This level of parallelism seem to reflects a scaled up version of the typical business processes encountered by the industrial partner.

As is common for evolutionary algorithms the time taken to perform each optimisation search is highly unpredictable, the focus in the design of SBOAT is on doing several optimisation searches in parallel, limited by the complexity of each individual model checking run. As the individual searches are completed, their results are compared, and if no significant improvement is being discovered, the pathologically slow searches are terminated. A plot of the average time taken to perform analysis at each generation along with the associated average statespace size is shown in Figure 11.

It is clear from Figure 11 that the analysis times are highly unpredictable, and as subsequent generations are constructed the variance of the model checking time increases. The linear growth in the upper bound of the model checking time taken for each variant implies a linear growth in the computational resources required to perform this analysis. For example, production of the plot in Figure 11 required the use of 512 CPU cores on the Microsoft Azure cloud platform. In addition, the analysis was set up so that when 80% of the cause checking a given population had fallen idle, generation of that population was terminated.

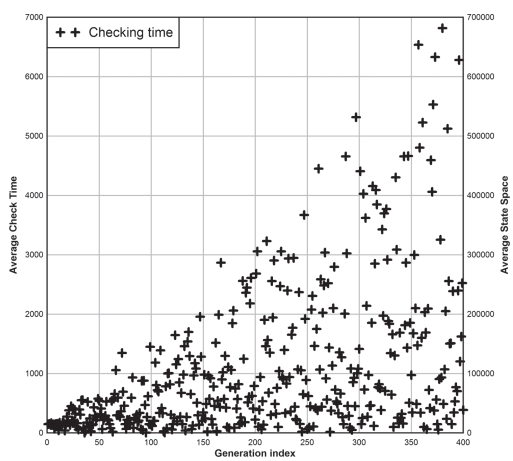

Figure 11. Optimisation analysis performance for a standard BPD with 1000 elements and a population size of 512 per generation. This plot is produced over combined analysis runs where $r_{resequence} \in [0.25, 0.65]$ and values of $r_{parallelize} \in [0.1, 0.2]$.

The focus of efforts to obtain more reliable performance from the optimisation approach is to employ *parallelisation* of individual model checking runs. In particular, the number of evolutionary generations produced and the population size of each generation dictate the average run time. Tuning these values to closely match the available computational resources in terms of parallel processing units (e.g. CPU cores) available provides significant speed up if all processing units can be kept busy. Experimentally extending child generation runs such that they terminate when a threshold fraction of parallel processing units become idle leads to overall reductions in run time at the expense of greater variance in convergence time. This approach leads to generally better results, both in terms of convergence and degree of improvement, than the naive alternative where, as fitness checking of each individual variant in a generation are completed, results are compared, and if significant improvement is not discovered, the pathologically slow searches are terminated. This seems to be due to the fact that while obviously incorrect models can quickly be determined to be incorrect, an individual long model checking run is a sign that no property violation has yet been found and may likely be a good candidate process for the next generation.

In practical use once an optimisation run has been completed, in the SBOAT tool, the final optimal BPD is rendered and displayed to the user.

7 CONCLUSIONS

In this paper we have presented an approach to analyse, enhance the safety of and optimise production processes using the software tool SBOAT. This tool presents an automated approach to restructuring of processes and allows practitioners to create processes which are safer and more efficient, based on the input they give to the tool. For a business practitioner, this input involves defining a model of a business process in the Core BPMN language, annotating the model with the resource consumption of each task, and choosing goals for the optimised derivative of the original process. The practical utility of this approach is demonstrated by means of a case study. The case showed that the framework could be used to reduce the risk of exhausting resources during production, and the impact in quantitative terms, of reaching these critical states (e.g. when a production stop occurs).

The key strength of this approach is the mathematical foundation for designing, analysing and improving production processes in a single unified framework. The SBOAT tool produces processes which are safer and more efficient given an initial process, quantitative properties and a goal for the final process. This is a fully automated approach, where the main constraint is the computational resources available to determine possible future configurations.

Further research will focus on refining the analysis framework and the software tool, SBOAT. Specific focus areas are the refinement of the evolutionary algorithm and extending SBOAT to include other graph-based languages.

Research on information system and its impact on distribution process of supply chain

E. Pawlak
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: Present economic development, growing competition on the logistic services' market as well as the fast pace of life and work of people lead to numerous problems emerging at all stages of the distribution system. This paper presents a new approach to the problem of organization and maintenance of distribution processes in state of reliability in the context of the accompanying information system. Considerations were carried out on the basis of real logistics system consisting of 13 points, dealing with all logistics services. Detailed study involved national groupage service and the quality and quantity of concluded contract of carriage in terms of an offer made to the client. Moreover focus was put on the analysis of types of defects, reasons of their occurrence and their consequences in the system. Results of the research will be used to develop procedures for conduct of damaged shipments in the sense of the information.

1 INTRODUCTION

Nowadays, when determining the level of logistics service the majority of attention is focused on price and quality of service. The subject and the range of research were determined based on own experiences and observation during the several years of work in logistics companies and after studying many publications from the logistics field.

The subject for observation and reflection are the actions—operating processes occurring inside the elements of the logistics system which are in the logistics and distributions companies. To the research adopted the concept of system in which it is treated as the internally correlated arrangement of the elements, which have a specific structure of the actions, a collection of methods of operation and rules of the organization, which fulfill a specific function and which are isolated from the environment for a specific purpose (Nowakowski 2011). As well to the research was adopted the main standard for company's services according to Mr. Christopher's definition—the main standard of service, what should be pursued in the company, is one hundred percent compliance with customer expectations.

The above assumptions and maintenance the system of capable of reliability is a goal to be achieved in the operation of objects and processes in the logistics system. In the literature can find many definitions of reliability referring to the technical objects and to carrying out operations and processes.

Adequate to the tests carried out, is the definition of according to which system reliability it is the ability of the system to undisturbed continuing implementation of tasks in support of the processes within the supply, transportation, maintenance and operation of infrastructure (Nowakowski 2011).

Equally important to the conducted research is the definition formulated in 1994 by L. Johansson, according to which maintenance the system of capable of reliability requires that all participants in the supply chain are adequately informed.

Should remember that points of contact and the information flow between different cells of supply chain are critical elements for the final results of operation in supply chain management (Rutkowski 2004).

Although issues regarding to the distribution network are treated in the literature very broadly was discovered the absence of full studies and research on the information system and its significant role in the network. Another reason for interest in the subject was to determine the absence of a comprehensive, dedicated tools to assess the quality and quantity of information in the system, despite the many existing and functioning market solutions.

2 RESEARCH AND ANALYSIS

The studies included actual distribution systems of logistics operator 3 PL which is involved in the logistics services, warehousing and distribution of goods nationwide. The study proved to be laborious

and time-consuming, because the test object consisted of 13 elements—local branches—with different degrees of automation, abundance of staff, object class, technical equipment and sequence of use and the validity in the structure of the whole logistics system. It has been observed that in each of the surveyed local branches which are obliged to maintain the designated level of reliability, are serviced from a dozen to several dozen commercial customers who have different requirements for the level of quality limit, efficiency, productivity and service efficiency and even in some cases they have the different, dedicated price lists.

In each object point of the distribution network there are different processes based on one of the computer systems. It has been observed that the service inside the terminal looks different at different logistic points due to the level of technological development of the object, i.e. the type and number of discharge gates, object class, the means of internal transport, the agreed method of aggregation data, the number of personnel needed to handle the stream of cargo both to the processes of loading and handling as well as to realise administrative and customer services. Also were observed different staff work schedules which are determined depending on the number of supported orders. These problems have not been undertaken because dimensioning and shaping logistics facilities were not be the purpose of research.

Detailed study covered included handling of groupage services and the quality/reliability of the national product in logistics network relative to an comercial service offer for the client. The study took into account only domestic groupage network system so only the parcels or consignments whose size do not exceed the permissible total weight of 4500 kg and the total number of cargo to 8 pallet (pallet space is defined as an field about the basis 1.2×0.8 m).

To the tested distribution network was developed diagram of a cargo flow (Fig. 1), which shows the fixed connections between successive points of the network, which are called the linehaul connections, and the two-stage linehaul connections, i.e. cargo flow lines with a double transhipment. Number of linehaul connections is the result of the economic viability specified for each linehaul, which is determined on the basis of fulfillment of vehicles, the transport distance, numbers of operations on the cargo, destination, cargo volume sended by external customers and their location.

Each of the points of the network—terminal—has its own local distribution area, territorially limited to a designated zone around its location. Distribution in this zone corresponds to a closed set of postal codes assigned to the network. Zones for network points are separable.

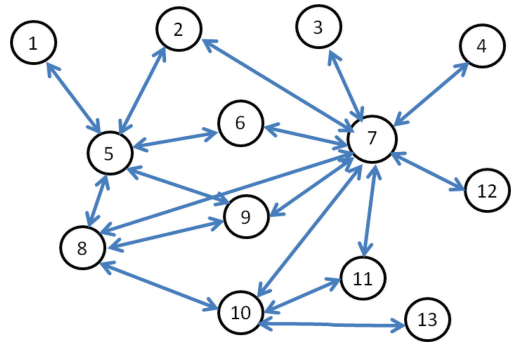

Figure 1. Diagram of a cargo flow for studied distribution network.

The customers are the sources of the flow of cargo. For the logistics terminal were defined sources dependent of the client location and kind of client loads:

- External—load derived from "its" customers located geographically close to the location of the point of logistics network.
- Internal—generated by the other points' customers to distribute in the local area.
- Storage i.e. customer of storage/load storage—loads from one's own area of high storage to distribute.

How to handle shipments and transmission of information depends on the type of customer and contractual requirements. The study included external and internal customers.

Tested, observed and compared the internal processes at each point of the logistic network, keeping in mind that a properly designed internal processes are affecting for reduction of time of cargo handling, the use of a smaller number of technical and human resources and, consequently, for reduce the costs of the whole logistic system and thus for increase the profitability of point-objects. From the made observations the conclusion was drawn, that the internal organisation of each points of logistic network should be constantly monitored and depending on the changing needs, it should be improved to minimize the losses of orders and congestions of internal movements. Also should remember about impact the reliability of individual points on the reliability of the entire logistics system.

Based on many hours of interviews and observations at the time of the collection of information on the operation and organization of the company, the study of literature developed a number of models, with particular emphasis on modeling information system. Starting the modular modeling of

the logistic system, which include the information system, was taken into account that it has an hierarchical structure. In the beginning the system was shown as a black box—Figure 2.

Delving into the layers can reach the information units constituting the information/messages which are transmitted in the system regardless of the media. The following presents only three selected representations of the developed few-layers model of the information process accompanying the distribution processes in the logistic and transport company. This process is part of the enterprise information system. Because all aspects of the business profile of organization did not lay in the area of interest in research, was applied simplification—have been omitted penetrating steps between the general model of an information system of the studied company (Fig. 2), the information system model of the tested logistic object (Fig. 3) and model of an information subsystem of the service of groupage distributions (Fig. 4).

It was considered that the model shown in Figure 4 can be regarded as a universal model of information process accompanying the implementation of groupage transport service in terms of the transaction, because they do not take account of the specific organizational structure of the company and only her functionality. When determining of the model's modules were taken into account only the consecutive points/stages/units as stages chain of transfer of informations. They were described only by slogans. It was considered that the customer for a company which provides logistic and transport services LCL is the sender (client) of consignment/load. He is the one who

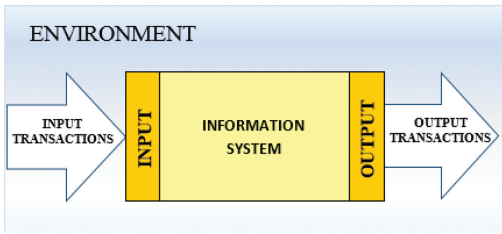

Figure 2. The general model of an information system of the studied company.

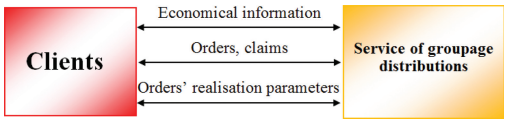

Figure 3. Model of information system of the tested logistic object.

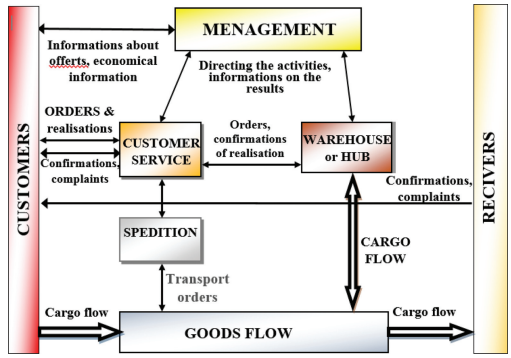

Figure 4. The structure of the object "Service of groupage distribution".

sets the needed conditions of logistic service and with whom is carried out the final financial settlement. For the tested subsystem of information the customer (sender) is as the initiating unit which initiates sending information and a whole process. For a presented model were developed graphically models of its modular components. After the development of the modular model of the system to the desired level of detail it was possible to start next step of analysis.

During the 6—months studies collected detailed data on the customer service for 980 clients in the form of an extensive database. Hundreds of thousands of data were collected for supported consignments and related with them processes and customers, inter alia were collected data on 143 978 consignments. After research the data were subjected to treatment. Work was begun from ordering of data, their selection and appropriate aggregation, and then were prepared the systematized results needed for further analysis in the form of an extensive database. Table presented below is an example of obtained results carried out at this stage of work. The fragment of database (Table 1) contains aggregated and sorted data on the number and type of errors observed in the selected time period—e.g. during 1 month.

Upon completion of this phase of work were started analyzing the examined objects and processes focusing on information system and his proper functioning, the used tools and the system's operators (the people). An additional effect the 6-month's studies of the distribution network was to design and develop a set of reports for qualitative research and quantitative distribution system. Were classified the most common errors in implemented services with their assessment of the cost—Table 2.

Based on the results of research on a sample of 24,913 orders in one month classified and specified

Table 1. Number and type of errors during 1 month.

	Wrong classification of pallets	No dock. transport and/or WZ	Incomplete information from the customer	Incorrect shipment dimension	Inadequacies of the system	Errors during emergency procedures	Unrealized service	Responsibility of distribution	Others responsibility	Shipments
OD1	23	32	47	64	178	13	70	28	42	3372

the actual error participation in the flow of information in the consecutive paragraphs of network OD1-OD13 what shown on the graphs (Figs. 5–6).

For the analysis of errors in the system and evaluate the system reliability were used the event trees, which are the graphical cause-and-effect relationships models occurring during the solving problems and are built from the initiating events. Trees represent all the possible sequences of events that are initiating events consequence and allow to specify the probability of an adverse event.

In the researches were used them both for qualitative analysis to understand the situation which affected reliability problem, and for quantitative analysis to determine the probability of sequences of events. It is noted and accepted as an assumption for research, that although the observed processes and their service in each of the objects may vary, criteria relevant to the reliability of the information system are the same. From the analysis of the research presented in Figures 5–6 shows that the biggest distribution network problems are the incorrect data in the system generated by both external customers (data input to the operator system via the internet) and employees of the operator (direct manual data input to the system via computer workstation).

Conducted qualitative analysis of the information system allowed for define the cause-and-effect relationship of the system, identify the forcing factors and excess and deficiency of functional information that can lead to transition the system into a state of temporary or total inadequacy of the system.

On the basis of observations and studies were shown that compliance with procedures, regulations and technical specifications by a single element of the system does not ensure safety process as a whole. Permit on the occurrence of an adverse event in the flow of information accompanying to the groupage system, can lead to economic and structural losses.

During the research of the information system of the test object were developed and analyzed event tree of accompanying the flow of information during the execution of the contract for the transport of cargo groupage service. Figure 7 shows the idea (tree) of the system. Then were developed some of its components, i.e., tree branches, which in the figure are in the form of complex event symbols. For the study assumed 100% reliability of customer service module, forwardings module, warehouse and transportation services module, which means that they not generate their own's errors, which affect the reliability of the whole system. The probability of errors appearing on their outputs is only as result from processing incorrect data input put into the individual modules. In the analysis the basic events were data from the offers and price lists.

Table 2. Costs of errors occurred.

Classification of errors associated with the direct transfer of information:	Implications for the logistics chain	Cost of errors occurred
Lack information transferred between branches	Perfunctory information in the system	Decrease KPI/freight cost/ contractual penalty
Wrong information given—bad tracking number, wrong time of monitory note, supplying incorrect data	Incorrect execution of the service	Decrease KPI/freight cost/ contractual penalty
Missing or incorrect information transmitted from the driver	Incorrect execution of the services giving rise to the complaint	Decrease KPI/freight cost/ contractual penalty
Lack information on the fate of the consignment (omission consignment in the verification process of cargo flow)	Failure to perform the services	Decrease KPI/freight cost/ contractual penalty
Lack confirmation of delivery consignment in the system (loading terminals, recipient)	Re-verification of information	5 PLN/event
No information about the problems in distribution—damage, theft, loss of shipment delays	Re-verification of data and recovery of documents confirming the execution of the service	Decrease KPI/freight cost/ contractual penalty/costs of complaint proceeding
Transmission of incorrect dimensions of the shipment by all subsequent chain links	Re-labeling and specify appropriate dimensions, enter correct data into the system	Re planning and transport of the consignment

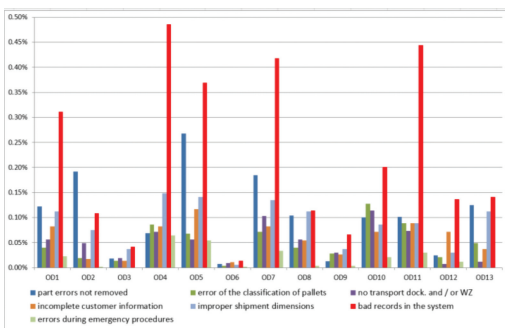

Figure 5. The number of the classified errors broken down on the points of the distribution network.

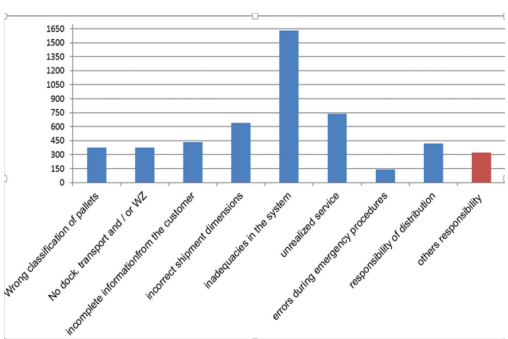

Figure 6. The monthly number of classified errors in the tested groupage network.

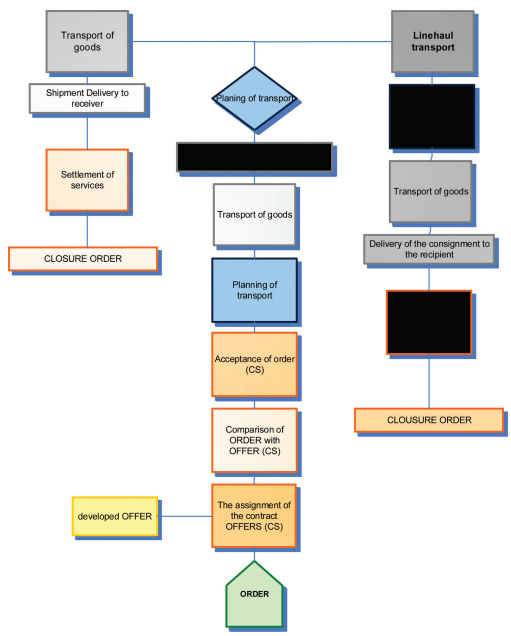

Figure 7. Event tree of information flow accompanying to the handling of the order of groupage service.

The task of a good sales representative is to prepare the satisfactory offer for the customer. But not only. The offer must be done on time and must guarantee a high quality of service, but also make a profit to the company. Disorders in achiev-

ing the above purposes are treated as a system failure. Each Offer should be carefully calculated and refined in detail. The ideal would be automatical create individual offers and service pricing.

Pricing dedicated for the Customer should include: the prices for transport services in accordance with the assumptions and broken down into areas of distribution (unit prices on 100 kg/m^3/ palete), the prices for additional services, price for redelivery of the Customer's fault, the cost of shipment canceled before issuing a driver, fuel surcharge and Viatoll. For the system study, it was assumed that the price list is optimal, and the proposed prices include all costs and founded profit. In the future the process of developing price list should optimize to create it in electronic/system version so that will be possible its processing in TMS (Transportation Menagement System) and CRM (Customer Relationship Manage-ment). Every time must be check the compatibility of each order received from the Customer to his the specific offer/contract. Lack of verification may result in the financial losses of a logistics operator and result in reduction in quality and thereby lead to the unreliability of the system.

Example of the process of verification the information in the contract with the information from OFFER shows Figure 8. It is process comparing information about the correct type of transported goods. All subtrees illustrating the processes dedicated comparing the other informations in the Contract with the corresponding informations from the Offer looks like the event tree on Figure 8.

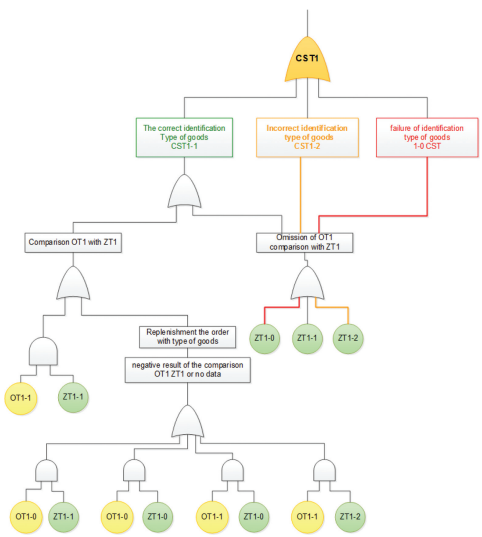

Figure 8. Process of comparing information about the correct type of goods (comparing ZT1 z OT1).

The operational staff of transport departments of (freight forwarders and dispatchers) is interested in:

- freight route—attributed to the location of pick up the shipment and where is to be further forwarded, other the next point of transshipment, or for distribution,
- Physical size of the freight—size and weight of the cargo in order to choose means of transportation and planning its fulfillment

Only on the basis of the above information may be chosen the means of transport, to plan his route, loading and transport to the recipient. The more detailed the data it is the higher the quality of service and lower costs associated with its implementation. Outline of the processing information for the freight forwarding is shown in Figure 9. The explanation to the symbols shown in Table 3.

After made the analysis of qualitative information system and studies the actual parcel distribution system made it possible to carry out quantitative analysis to determine the probability of adverse events resulting in a decrease in quality of service. Only on this basis can be shown that the accurate and timely flow of basic information (the offer and contract) has a significant impact on the maintenance of the system in the state of reliability.

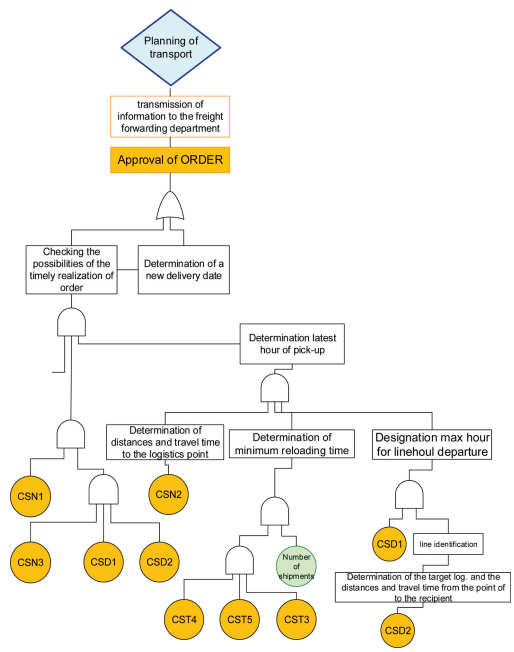

Figure 9. Tree of the processing information for the freight forwarding.

Table 3. The symbols—the information necessary for further processing.

Output	Information on the output
CST1	Type of good
CST2	Temperature conditions
CST3	Type of pallet
CST4	Height of the load unit
CST5	Weight of the load unit
CSN1	Time of order
CSN2	Place of pick-up
CSN3	Date and time of pick-up load
CSD1	Date and time of delivery loads
CSD2	Place of delivery

The analyzes carried out were the next step in the study of the role and importance of information flow in distribution groupage transport service networks. Through its research and analysis has become possible to carry out and to identification the initiating factors and to diagnostic the shortage and the excess of informational-functional in the information system. They could cause the element of logistics system could pass in a state of temporary or total disablement from the point of view of the tasks and logistics processes and organizational problems measured in terms of the customer expectations levels. The work has begun on the next stage, which will be to develop methods of assessment information system and its computer's implementation to the knowledge base of the expert system.

After final completion of the work will be possible to identify tools that streamline and improve the flow of information.

3 RESUME

The research and analysis made it possible to draw the general conclusion, that the reliability of the distribution system could be achieved through the elimination or significant reduction of errors in the information system. The qualitative studies demonstrated directly proportional information system status impact on the status of distribution groupage system.

Therefore it was concluded that the reduction of errors in the functioning distribution systems can be achieved by reducing the occurrence of errors in the information system. In order to improve the reliability of the system should be determined categories of the most common errors in it, their causes and the areas in which occurs and carry out an analysis qualitative and quantitative, to diagnose the causes and effects of errors in the information system.

Define them, and then to monitor and react to current changes have a significant impact on the reliability and quality of groupage transport services. In fact the well done analysis of errors in information system make it much easier to identify needs and areas for intervention, reorganization and formalization. In a word, such an analysis is a tool for management, significantly affects the growth of service quality, and consequently on the achieved economic results of the company and customer satisfaction, i.e. affects the economic situation of the company and its market position.

Availability and reliability of resources in an agile manufacturing systems

A. Stachowiak
Poznan University of Technology, Poznań, Poland

ABSTRACT: Agility is strategy that allows to cope successfully with dynamics and complexity of contemporary market and to respond to global customers' needs and requirements efficiently and economically. It is based on the idea that a company should respond to customers' needs providing them with products fitting their specific requirements. One of the most important and difficult decisions connected with agile strategy is definition of resources necessary to run various processes and if necessary develop products from the very beginning. After the resources are defined it is necessary to provide their availability and reliability. The aim of the paper is to identify strategy for technical resources management.

Agile approach is discussed in literature, and importance of human factor is stressed, while technical aspects are presented usually in a general way. The research starts with development of methodology for identification of structure of technical resources and their status (own/shared).

Reliability and availability (the scope of the conference) of resources seems to be crucial for ability to run customer-driven processes efficiently.

The expert system is to be designed for resources definition, and based on that reliability-providing strategy is to be suggested.

1 INTRODUCTION

Companies nowadays are facing numerous problems emerging from globalization, advance in technology and communication techniques and more and more sophisticated requirements of customers. These phenomena however are not only sources of risk but also of competitive advantage. Businesses capable of turning dynamics and complexity of contemporary markets into opportunities are potential winners.

Agility is strategy that allows companies to cope successfully with dynamics and complexity of contemporary market and to respond to global customers' needs and requirements efficiently and economically. It is based on the idea that a company should respond to customers' needs providing them with products fitting their specific requirements. One of the most important and difficult decisions connected with agile strategy is definition of resources necessary to run various processes and if necessary develop products from the very beginning. The resources definition is complex and demanding process as resources to be considered are of various character i.e. technical resources, human resources, knowledge, experience, know-how, environment etc. The hereby paper is to present an approach to resources definition to be used for agile manufacturing systems based on pull logic and enabling manufacturing on demand. Such definition of goals and constraints makes the decision model developed useful for companies running unique processes, providing unique or customized products and responding to specific requirements of customers to gain competitive advantage. Resources definition will be followed with capacity analysis and discussion on required level of capacity and costs it generates. Hence, the model is supported with maintenance strategy based on contemporary approach to the field. The tool applied for the final solution is an expert system as AI support seems to be crucial for complex and unique/individual project—author believes that agile manufacturing meets the criteria.

The structure of the paper is the following: the first part includes brief presentation of terms and approaches applied in the model, namely agile manufacturing systems, resources definition, reliability and availability aspects and expert systems brief presentation. The second part is presentation of the model developed with its main assumptions, while the third presents discussion on results obtained, concluding it and introducing further research perspectives.

2 RESEARCH FRAMEWORK

The model to be developed is based on agility paradigm (2.1. *Agile manufacturing*). To achieve

agility, the most important is to manage resources well, and all categories of resources necessary for processes performance should be considered and properly defined (2.2. *Agile resources definition*). To benefit from resources composition, high level of availability and reliability is expected, provided by application of adequate maintenance strategy (2.3. *Availability and reliability*), and finally decisions concerning resources and capacity identification, as well as maintenance profile definition, require support, benefiting from contemporary tools and techniques (*2.4. Expert systems*). The research framework presented briefly shows theoretical assumptions for the model developed.

2.1 *Agile manufacturing*

In their report on 21st century manufacturing enterprise strategy introduced in 1991 at Leigh university (Gunasekaran *et al.* 2002, Emigh 1999) the authors suggest that various production resources, including people, funds, technology and facilities should be integrated and managed as a whole; thus optimizing the utilization of resources and taking full advantage of advanced manufacturing technology and computers. As a result agile manufacture based on dynamic alliance is coming into being so that enterprises can remain competitive in a constantly changing business environment and is becoming a main competitive paradigm in the international market. It is defined as the ability to thrive in an environment of continuous and unpredictable change and profit from rapidly changing, global markets for customized customer-driven products and services.

Since its introduction agility, which has basically two meanings: flexibility and reconfigurability, has become a very important characteristics of a modern manufacturing enterprise. Generally, flexibility aspect refers to ability to make adjustments according to customers' needs, while reconfigurabiliy is the ability to meet changing demands (Li 2009).

Agile manufacturing through flexibility and reconfigurability emphasizes high customization of production, and is viewed as a breakthrough of traditional mass production. An agile corporation is adaptable, and capable of rapid reconfiguration to satisfy quickly changing market demands. Agile manufacturing crosses company borders. Core competencies of organizations can be pooled to satisfy various customer demands and reduce the time to market. One way to establish an agile manufacturing system is to employ agile manufacturing cells as building blocks to take advantage of cellular manufacturing's quick response and ability to accommodate changes in product mix. Cellular manufacturing can produce medium-volume/medium-variety part types more economically than other types of manufacturing systems and surveys affirm that many benefits have been gained from CM implementation including shorter manufacturing lead time and customer response time. This makes CM a logical choice for firms whose strategy is time-based competitive manufacturing.

Each agile manufacturing cell in the agile manufacturing system is capable of manufacturing a part family, and is connected via the internet with other agile cells from different enterprises to seek temporary market opportunities and accomplish manufacturing tasks cooperatively. Manufacturing can take place across organizational and geographic boundaries to exploit distributed resources from different partners in dynamic teams that can be formed quickly in response to rapidly changing market demands. Internet technology is a key to enable distributed agile cells to cooperate with each other by extending traditional information systems and eliminating barriers to integration (Yu *et al.* 2004).

The most distinctive characteristics of agile manufacturing systems include (Devadasan *et al.* 2005, Towill 2002, Golsby 2006)

- human resources characteristics, i.e.:
  - work assigned to multi-skilled, multi-functional and self-committed employees (achieved thanks to continuous, life-long learning,
  - involved employees, giving ideas and knowledge to be utilized in processes, fully empowered,
- management system characteristics, i.e.:
  - flattened, team-managed organization and structure,
  - devolution of authority based on integration and autonomy, learning approach to organization and management,
  - open organization based on partnership with suppliers,
  - responsive and dynamic profile,
  - based on simplified and shortened information flows,
  - providing customer delight,
- technical resources characteristics, i.e.:
  - application of flexible manufacturing systems, with possibility of automation application,
  - enabling flexible and easily collapsible set-ups, resulting in quick response to changes,
  - increasing productivity,
- manufacturing process characteristics, i.e.:
  - dominated by main assembly, following external manufacturing and procurement,
  - based on just-in-time purchase and short delivery cycles,
  - efficient, continuously improving,
  - economical.

There are numerous differences between traditional and agile manufacturing systems. Analysis

of requirements and expectations towards agile systems leads to the conclusion that they can be met only with predefined set of resources at required level of capacity (Stachowiak 2013).

2.2 *Agile resources and capacity*

Resources definition is quite simple—they enable performance, which makes the term broad. Resources to be taken into consideration at this stage of research are: machines and tools, space they need, people, their skill and knowledge.

Traditionally, machines to be used by a company are determined by processes the company is to perform. Analysis of technology applied for products manufacturing (operations, machines, performance and set-up times) allows to define a list of machines needed and their number. As people operate machines, their number is determined by number of machines and work organization (shifts etc).

However, the most important characteristic of a contemporary company is lack of precise data concerning products and technologies. Nowadays demands are difficult to define and that is why it is difficult or even impossible to define resources using traditional procedures. The new approach to resources definition is necessary. The basic assumption of the new approach is that resources are not dependent on demands when modeling a company (Stachowiak 2013). They constitute agile manufacturing system, however their definition is based mostly on strategic assumptions taken when founding a company (Fig. 1).

Agile resources definition is the process in which the most important aspect is definition of corporate strategy including rough identification of scope and range of business activity. Human resources definition should cover all the capabilities potentially necessary to perform company's processes, while technical resources should be defined in a way providing synergy between human and technical elements of the system.

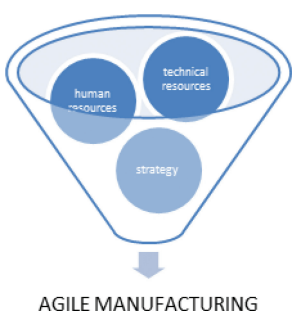

Figure 1. Agile resources definition.
Source: own work.

In a contemporary/agile manufacturing systems products and technologies definition is the first stage of manufacturing process as according to agile manufacturing definition the most important is meeting customers' demands, which results in treating customers as the first and the most important party in manufacturing process. Such cooperation is one of the main assumptions of agility and its consequence is that customers are no longer outside the company—they are integral part of it. They create product with the company and therefore the demands are impossible to forecast—they emerge too late. The beginning of manufacturing process is moved back—from making an order by a customer to stage of understanding the need of the customer. And that is why the demands cannot be the basis to define company's resources. The very first stage of resources definition should be considering ability to perform various processes in order to meet customers' requirements. Thus the kinds of machines should be chosen so that they performed as many processes as possible. The solution then is using either universal machines or as many special/of specific use as budget allows. Either idea is good as the most important resource are not machines but people and their skills.

Defining resources for contemporary company is mostly defining capabilities crucial for company's performance.

Capacity is the size of resources, hence it is traditionally referred only to tangible aspects of resources. As mentioned above it is impossible to define demand in terms of quantity and quality, which results in difficulties with definition of size and type if resources. The approach which can be applied here is definition of capacity based on strategic assumptions and constraints.

Capacity is the sum of human and technical resources:

$$C = \sum_{i=1}^{n} R_{hi} * c_{hi} + \sum_{i=1}^{m} R_{ti} * f_{ti} \quad (1)$$

where:

C	capacity
$i = 1 .. n$	number of employees
Rhi	human resources (employee i)
chi	capabilities of human resources (employee i)
$j = 1 .. m$	number of machines
Rtj	technical resources (machine i)
ftj	functions of technical resources (machine j)

while:

$$\sum_{i=1}^{n} k_{hi} * R_{hi} + \sum_{i=1}^{m} k_{ti} * R_{ti} \leq R_f \quad (2)$$

where:

Rf	financial resources of a company

khi cost of human resources (employee i)
ktj cost of technical resources (machine i)

Setting the capacity at the predefined level requires precise definition of available financial resources as this is the only constraint set. The cost of financial and human resources is defined basing on acquirement cost, maintenance cost, disposal cost and all the aspects applicable (the formula is general).

The formula presented refers capacity to economic and social aspects as capabilities of human resources and costs are considered (Stachowiak 2013).

2.3 *Reliability and availability of resources*

Reliability and availability of resources depends on implementation of proper maintenance strategy.

Availability of the resources depends primarily, on their selection (choosing resources respondent to company's goal and scope) and number, but also on their condition—hence they need to be well maintained so that they were available whenever needed. In agile manufacturing conditions it is especially important as manufacturing jobs are difficult to forecast and plan because of demands volatility and customer-orientation.

Reliability of resources mostly depends on their technical condition resulting in great importance of maintenance operations providing high level of reliability.

According to Narayan (2012), maintenance concerns the combination of all technical, administrative, and managerial actions during the life cycle of an item, intended to retain it in, or restore it to, a state in which it can perform the required function. The conclusion from the presented definition is the following: maintenance is not only technical tasks, such as disassembly and replacement of spare parts, lubrication, and repair. In practice, maintenance has a much wider spectrum involving numerous additional tasks (Jasiulewicz 2013).

The maintenance process is dynamic, as it has strong connotations to manufacturing process, and together with manufacturing process it has been changing over the years. Throughout the years several approaches to enhance the maintenance management have been developed and applied to a wide variety of organizations and systems, (Loska 2012).

The period up to around the 1950s (the end of WWII) was referred to as the "first generation" in maintenance. The feature characteristic for that period was taking up repairs or replacing machines and technical devices only after breakdown happened (so called reactive maintenance). The next generation of maintenance was initiated with the industrialization process. An increased number of machines and devices in companies, and their value, caused an increased interest for managers in lengthening exploitation periods of technical objects. Plans and schedules of preventive actions (e.g., inspections, services, general repairs) were being developed for each company. This generation is now referred to as preventive maintenance. From the beginning of the 1970s, new options for maintenance realization appeared with the development of diagnostic tools and new approaches to corporate management. Particularly, global striving for inventory management based on the Just In Time paradigm, the continuous improvement idea according to Total Quality Management philosophy, and waste elimination according to the Lean Manufacturing approach resulted in changing the approach to the role of maintenance in achieving corporate goals. The term "waste" was crucial for process performance in companies. Including a lean category to maintenance operations resulted in development of the Lean Total Productive Maintenance or Lean Maintenance approach described in literature (McCarthy & Rich 2004, Smith & Hawkins 2004). A combination of the classic approach of Total Productive Maintenance with Lean Manufacturing, as described by Nakajima (1988), enables achievement of predefined results (e.g., higher availability and reliability of equipment, repeatability of production) with a lower requirement for resources (spare parts, tools, energy, human labor) (Jasiulewicz 2013).

One of the latest approaches in maintenance is RCM. Moubray (1997) defines RCM as "a process used to determine what must be done to ensure that any physical asset continues to do what its users want it to do in its present operating context", characterizing RCM as a process to establish the safe minimum levels of maintenance, hence, the objective of maintenance should be to keep the equipment doing whatever its users want it to do, rather than to prevent failures for the sake of preventing failures (Jasiulewicz 2013). This makes the methodology crucial for providing reliability and availability of resources.

RCM methodology (Moubray, 1997) has three major goals:

- to increase safety and reliability of systems by focusing on the most significant functions (RCM is concerned mainly with what we want the equipment to do, not what it actually does);
- to prevent or to mitigate the consequences of failures, not to prevent the failures themselves (the consequences of a failure disagree depending on where and how items are installed and operated);
- to decrease maintenance costs by escaping or removing maintenance actions that are not strictly necessary.

Hence, determining the operating context and what the user wants the equipment to do is the starting point for the RCM process, which is applied by asking and answering the following seven questions (Moubray, 1997):

- What are the functions and associated performance standards of the machine in its present operating context?
- In what way does it fail to fulfil its functions?
- What causes each functional failure?
- What happens when each failure occurs?
- In what way does each failure matter in respect of the environment, human safety, losses, and expenses?
- What can be done to predict or prevent each failure?
- What should be done if a suitable proactive task cannot be found?

These main maintenance policies, rather than being applied independently, are integrated to take advantage of their respective strengths in order to maximize facility and equipment reliability while minimizing life-cycle costs (Jasiulewicz 2013).

2.4 *Expert systems*

There are numerous definitions of artificial intelligence, some more precise and others less. Some of the definitions are focused at psychological approach, while the others suggest that machines perform tasks more efficiently than humans or they are not able to mimic human behavior in an exact way (Rich *et al.* (1991), (Russel *et al.* 1995). In the following paper, the definition by Z. Bubnicki is used. According to this definition, artificial intelligence is a field of computer science, which deals with algorithmization and formalization of processes of thinking and concluding, as well as these of learning, perception, recognition etc. (Bubnicki 1993). As human intelligence is a capability, which allows to process information, solve problems, adjust to new tasks and situations, as well as understand, compare and contrast facts, learn and remember, develop thesis, theories and conclusions, analyze and think creatively (Rutkowski 2006) authors believe, that the definition mentioned above is the one presenting the idea in the best way possible.

The basic methods of artificial intelligence are: expert systems, genetic algorithms (Coley 1991), (Goldberg *et al*. 2003), (Man 1999), neural networks (Kosinski *et al.* (2007)), fuzzy sets (Yen (1998)). Expert Systems (ES) are a discipline of artificial intelligence, which gained numerous practical applications as the first on from the above list (Zielinski 1991). However, practically, hybrid systems are often used, as they benefit from combination of two or more types of systems. What is an expert system then? It is an "intelligent" computer program, which uses knowledge and concluding procedures to solve problems requiring human (expert) experience earned by long-lasting activity in a predefined field (Rutkowski 1991). Hence, the starting point for developing expert system is analysis of the problem to be solved. Undoubtedly, role of an expert (person who knows the field well enough to take efficient actions) at the stage of general design cannot be overestimated.

Expert systems work is based on realizing three basic, independent though cooperating modes i.e. knowledge base, concluding machine (concluding mechanism) and user's interface (Bubnicki 1993). However its structure may vary. It mostly depends on its application (Knosala 2007). Generally, expert system works thanks to implementing expert's knowledge to the knowledge base, defining concluding mechanism based on information available and designing user's interface to enable communication (Rutkowski 1991). Knowledge base of an expert system includes facts and rules and while facts information which is accepted and can be used by an expert, rules are logic phrases, which lead to new facts definition and enable solving problems defined.

Application of ES leads to numerous benefits for an enterprise (Pawłyszyn *et al.* 2010), (Pendersen *et al.* 1997). which makes them really popular managerial tool (Chwiałkowska *et al.* 1991) as they provide companies with much cheaper expertise comparing to "real" experts; they work much faster than experts, which results in cost and labor savings; they improve quality of expertise thanks to consequent concluding and smaller number of made mistakes; they provide higher flexibility of production and customer service and reduce time of work, which is expensive; they usually react faster than experts, especially when the problem solving requires operating with large quantities of data; they enable solving complex problems, too difficult for an individual or requiring knowledge larger than that of one man.

Expert systems are used in almost every area of human activity (Chwiałkowska *et al.* 1991), performing lots of activities supporting human activities. However, each area requires different, individual and often unique expert system, which should be constructed by analysis and gathering data in the predefined field, choice and application of proper concluding methods (concluding machine) and, in the end stage, designing an interface to enable communication between users and computers. More detailed description of stages of expert system construction can be found in (Hayes-Roth *et al.* 1993).

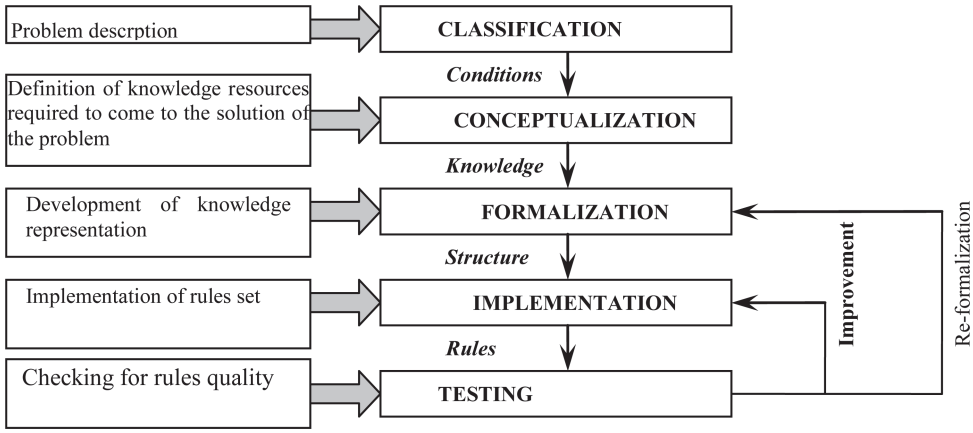

Figure 2. Stages of an expert system development process.
Source: (Knosala *et al*. 2002).

Construction of expert systems usually begins with definition of the problem to be solved, the range the problem should considered in and the way it should be solved (requirements, which should be met when searching for solutions of the problem, assessment of alternative solutions etc.). Construction of expert system is usually performed in the process including the staged presented in the figure below (Fig. 2).

More detailed description of stages of expert system construction can be found in (Hayes-Roth *et al*. 1983; Zieliński, 1999; Knosala *et al*. 2002).

Practically, there are many expert systems, and the most well-known and often used are: Dendral, Prospector, Mycin, XCON and many others (Shim, *et al*. 1999; Chromiec, Strzemieczna, 1994; Hayes-Roth *et al*. 1983), and the basic language used to record and perform logic operations is the one used in Prolog (Bubnicki, 1993; Bratko, 2001; Puppe, 1993).

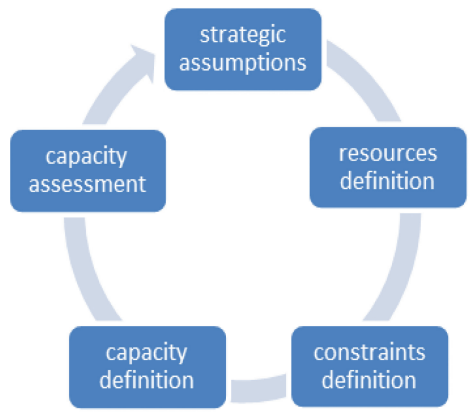

Figure 3. Sustainable approach to agile capacity planning.
Source: own work.

3 MODEL FRAMEWORK

Providing availability and reliability of resources in agile manufacturing system is a multi-stage procedure. It starts at strategic level of management providing identification of the general business rationale, identifying types of resources to be applied. The next step is identification of constraints and definition of capacity—decisions made at tactic level and followed by capacity assessment and providing with suitable maintenance actions.

Combination of resources definition, capacity definition and availability assessment results in the following model of approach to capacity planning in agile manufacturing systems, as presented in the following scheme (Fig. 3).

The model is organized as a cycle and is meant to mimic the idea of continuous improvement cycle, leading to self-learning and self-improving agile organization.

The first stage and initiation of the cycle is an idea to start a business and definition of preliminary strategic assumptions including branch, range and scope of processes to be realized.

The second stage is resources definition based on processes within the branch considered. Some flexibility is advised in this stage to provide agility at the highest rate possible.

The third stage is constraints definition and financial resources seem to be the most often

considered at this stage, however some legal, geographical or cultural aspects are in some circumstances under consideration as well.

The fourth stage needs data input from the previous ones (strategy, resources and constraints) and results in definition of company's physical structure.

The fifth stage is assessment of the structure developed in terms of predefined criteria and their optimization to reach predefined availability and reliability. The conclusion and results are used to redefine strategic assumptions and strive for excellence.

The model requires making numerous decisions, based on knowledge of the market, its trends, technologies, processes, products. The decisions are to be taken on repetitive basis, as in agile manufacturing systems customers' demand change. To cope with their complexity and high requirements concerning knowledge and experience, expert system was developed, providing reasonability of decisions and accuracy of actions. The structure of the system is the following:

Problem is described as definition of optimal composition of resources provided at required level of availability and reliability (capacity definition) for a given product or a potential customer.

Necessary knowledge resources include market data, description of techniques and technologies available, machines performing known operations and their parameters and maintenance profiles.

Knowledge is represented in databases linked and related with rules sets based on pre-identified relations and interdependencies. The stage requires thorough knowledge of the branch and processes.

The research is focused on one branch and the present stage comprises of identification and verification of rules for capacity and availability definition. Quality of decisions is to assessed with Delphi methodology during the next stage of the research, after carrying simulation experiments.

4 CONCLUSION

In contemporary/agile company products and processes definition is the first stage of manufacturing process, as according to agile manufacturing definition, the most important is meeting customers demand, which results in treating customers as an important stakeholder of manufacturing process. Such cooperation is one of the main assumptions of agility and its consequence is that they become a part of a company.

The very first stage of resources definition should be considering ability to perform various processes in order to meet customer requirements. Thus, the kinds of machines should be chosen so that they perform as many processes as possible. The solution then is using either universal machines, or as many specific as budget allows. Providing their ability and reliability then seems to be the key issue, together with careful appointing people and their skills to meet requirements of process.

The decisions made within the area are complex and based on numerous determinants, what is more they generate high risk, as their consequences are investments and changes in process organization. Hence quality of decisions is crucial, what makes AI support specially important and useful.

The research introduced in the paper is a part of general research conducted by the author and comprising various aspects of resources management in agile environment.

Initial FMEA analysis of the container transport chain

M. Zając & J. Świeboda
Wroclaw University of Technology, Poland

ABSTRACT: Intermodal transport is more and more popular mode of transport. There is stable increase of intermodal operation. Today the biggest container port operate more than 34 M TEUs. The complexity of the issues often results in a very selective analysis of the elements of supply chains in the context of the processes of logistics, as well as machine components, systems of traffic, so the issues related to technology. The purpose of this article is to present preliminary estimates of the causes and effects of risks occurring in the international intermodal transport, as well as evaluation of possibilities to avoid potential risks.

1 INTRODUCTION

Intermodal transport, in brief, is the freight transport using more than one means of transport at integrated loading unit (container or swap-body semi-trailer). The most important advantage of this type of transportation is overcoming high distances in respect of customs service. Intermodal transport is very complex way of cargo transportation, the cargo handling operations and components, important in the transport of hazardous materials. Table 1 shows the biggest ports in the world in 2012 and 2013, the order was determined by the amount of transhipped containers million TEUs.

From Table 1 it can be seen that the largest port is Shanghai, which reloaded in 2012, 32.5 million TEUs in the next year increased the amount of nearly million TEU. The next place is the port of Singapore, which reloads by 1 million TEU less than container port in Shanghai. Port, which is in third place reloads already 10 million TEU less than the port, which is the first in the ranking. Port of Ningbo, is on site 6, but among the top 10 ports, he had the biggest increase in container handling in 2013. Compared to 2012, it is up 7.1%. For the last places were the ports of Dubai and Tianjin. In 2013, largest ports transhipped total 204.1 million TEUs, an increase of 2.9% a year earlier. Intermodal freight market is dominated by China, because there are many major ports, only 3 other ports in Singapore, Busan and Dubai are located in other countries. The biggest container port in Europe is Rotterdam, which in turn in 2012 and 2013. reloaded nearly 12 million TEU. The next position is the Port of Hamburg, which reloaded around 9 million TEUs in 2013. was up 5% increase compared to 2012. Port of Piraeus, is in 8th place, but among the top ten ports in Europe, he recorded an increase in container handling by 15.3%. Ports dominant in Europe are in the Netherlands, Germany and Italy. In 2013, ports transhipped 56.31 million TEU in total, compared to ports in the world (204.1 million TEU), it is almost 160 million TEU less.

So much interest in intermodal transport requires a response in the area of technological logistics cargo handling. On operations in intermodal transport is known to many studies. These relate to issues of effectiveness or efficiency of the chain container. These publications taking risk issues (Vališ & Zajac, 2013 and Kierzkowski A. & M. Zajac 2012a).

Table 1. The largest ports in 2012 and 2013 (in million TEUs).

No.	Port	Country	2012	2013	2013/2012
1	Shanghai	China	32.5	33.6	3.30%
2	Singapur	Singapur	31.7	32.6	3.00%
3	Shenzhen	China	22.9	23.3	1.50%
4	Hong Kong	China	23.1	22.3	–3.60%
5	Busan	South Korea	17	17.6	3.30%
6	Ningbo	China	16.2	17.3	7.70%
7	Qingado	China	14.5	15.5	7.00%
8	Guangzhou	China	14.7	15.3	3.80%
9	Dubai	UAE	13.3	13.6	2.30%
10	Tianjin	China	12.3	13	5.70%
			198.3	204.1	2.90%

The complexity of the issues often results in a very selective analysis of the elements of supply chains in the context of the processes of logistics, as well as machine components, systems of traffic, so the issues related to technology (Nowakowski & Werbinska-Wojciechowska, 2012). Issues related to the readiness of the lifts were included in the several publications (Vališ & Zak & Humility 2014). Methods applied to issues of intermodal transport are included, among others, is the (Kierzkowski 2010 and Kierzkowski & Zajac 2012B and Vališ & Koucký & Žák 2012).

The purpose of this article is to present preliminary estimates of the causes and effects of risks occurring in the international intermodal transport, as well as evaluation of possibilities to avoid potential risks. Structure of the article is as follows: the next section presents logistical operations occurring in the international supply chain. Than the article includes a discussion on the choice of a suitable risk analysis process. Sequentially presented in the table descriptions associated with the FMEA analysis. The last part is a summary and set out the next stages of work.

2 LOGISTICS OPERATION IN INTERMODAL CHAIN

As previously shown, most cargo handling is implemented in a relationship with China, which have up to 3 ports included in the top 10 largest ports. In Figure 1 can be read, that in 2009 the main focus was Asia—Europe, which carried the 11 493 million TEUs, while in the direction of Europe—Asia transported was 5 458 million TEUs. Another relationship is Europe—North America, then Europe—India and the Middle East, and the least used was the direction of Europe—Central and South America. In the tab. 8 are summarized in the order of all logistics processes in the edible Intermodal transport in relation Asia—Europe.

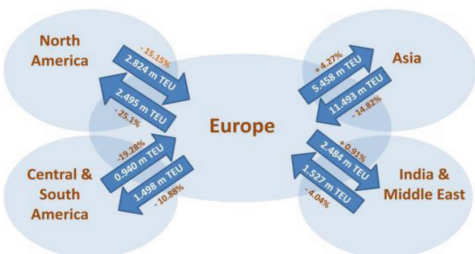

Figure 1. Container traffic at major European relations in 2009.

Figure 2 indicates the processes and operations carried out during the transport container from China to Europe in relation manufacturer—cargo reciver. Identification of the process will hereafter demonstrate risk during this process.

To be able to conduct a hazard analysis for intermodal transport should characterize all processes. It is advisable to know what operations, the operations are performed exactly in the process. In the following section describes the processes that are contained in Table 2.

I. Process 1, 22, 23, 27, 29—loading the container,
II. Process 2, 25, 32—road transport to the port or client,
III. Process 3, 12, 26—goods acceptance (customs service, freight forwarding),
IV. Process 4, 31, 33—unloading the container unit,
V. Process 5, 17, 21, 28—decision about place in a yard,
VI. Process 6, 19, 30—container warehousing in the port or container terminal,
VII. Process 7, 18—internal translocation (download container, transfer to another place, put aside by RTG crane),
VIII. Process 8, 15, 16, 20—translocation before loading,
IX. Process 9, 10, 13, 14—taking load by STS crane,
X. Process 11—ship transport,
XI. Process 24—rail transport.

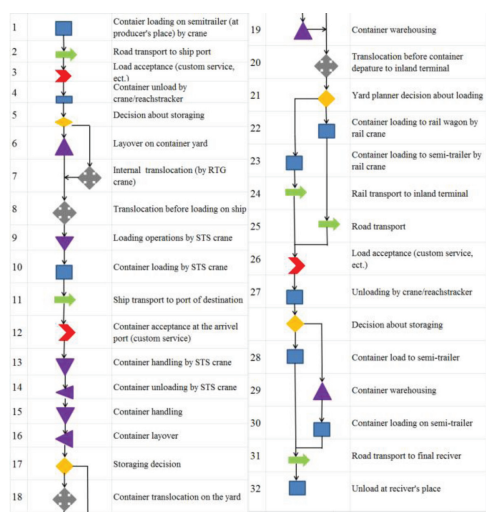

Figure 2. Logistics processes in intermodal transport.

Table 2. Identification of risks, its causes and effects.

Group no.	Process	Risk	Results	Causes
I	Loading the container	– incorrect loading	Impact in: human (penelty), other container (load fail), mean of transport (damage of mean of transport and/or load inside the container), block of containers on yard (damage of container and/or load);	– incorrect manipulation, – lack of experience
			– container falls (damage of container)	– lack of experience – crane overloading
			– breaking roap	– lack of experience – crane overloading – lack of maintenance
II	Road transport to the port or client	– cargo will be not deliver,	– load damage	– road accident
			– penalty of driver or another traffic member	– lack of experience, – lack of skills, – lack of maintenance, – ect.
			– cargo damage	– twist—lock not locked – road accident
			– truck damage	– road accident, – truck/semitrailer overload
III	Goods acceptance (customs service, freight forwarding)	– acceptance of damaged container	– damaged container can't leave the terminal	– incorrect interchange procedures
		– acceptance of container with forbidden goods	– process delay (check goods inside the container)	– intentional activity, – unintentional activity,
		– incorrect documentation service	– lack of documentation	– lack of experience – breaking the low
		– acceptance of incorrect container	– lose of money caused by storaging and sending to proper place	– lack of experience – human fatigue
IV	Unloading the container unit	– incorrect container unload	Impact in: human (penelty), other container (load fail), mean of transport (damage of mean of transport and/or load inside the container), block of containers on yard (damage of container and/or load);	– incorrect cargo manipulation – incorrect driver on the yard – lack of experience – human fatigue
			– container's fall (container and/or cargo damage)	– acceptance of overloaded container

(*Continued*)

Table 2. (*Continued*)

Group no.	Process	Risk	Results	Causes
V	Decision about layover	– container will be not delivered	– human wrong decision	– freight operator mistake – lack of experience
VI	Container warehousing in the port or container terminal	– incorrect container layover	– incorrect warehousing place	– wrong decision about layover place – lack of yard planner experience
			– damage of container by crane	– human factors
			– container fall	– Bad weather conditions
VII	Internal translocation	– damage of container and cargo inside	RTG Vehicle – container falls – broken rope – impact to: vehicle damage human (penelty) container on yard (container and cargo damage)	– lack of experience, – lack of skills, – lack of maintenance, – ect.
VIII	Container translocation before loading	– damage of container	Stradlle carrier Reachstracker – container falls – container impact to: human (penelty) container (cagro damage) mean of transport (mean of transport damage) damage of other containers	– lifting to heavy cargo – incorrect drive on yard
		– incorrect place on yard	– container missing on yard	
IX	Operating by container by STS crane	– cargo damage – deck damage – incorrect handling point	– container or/and cargo damage – ship damage – container missing	– transport system fail
X	Ship transport	– cargo not delivered – cargo loose – ship sinking	– lose of another commision – ship sinking	– storm – incorrect cargo/container bucking
XI	Rail transport	– container damage – train damage	– cargo damage – breaking wagon composition	– incorrect wagon service

3 THE RISK ANALYSIS IN INTERMODAL TRANSPORT

In the case of intermodal transport will be used FMEA process. Its main objective is consistent and systematic process to identify potential hazards and then eliminate or minimize the risks involved. The analysis was performed in order:

1. statement of purpose,
2. identification of defects and their consequences,
3. the importance of risk (R),
4. likelihood of risk (P),
5. detection of defects (W).

The purpose of the analysis is a valuable designation danger and risk of potential effects. Using mapped processes in Figure 2, in the next part of any operation can be described, setting a potential threat, effects and causes.

In the (Swieboda 2014) contains the exact values of the individual parameters, which were determined based on RPN. Table 3 presents the RPN values at each process steps.

Table 3. RPN values in intermodal chain.

No. process	R	P	W	R × P × W
I	10	1	4	40
	6	7	2	84
	7	3	2	42
	8	7	4	224
	8	3	6	144
	9	2	4	72
II	7	6	8	336
	10	7	10	700
	7	1	2	14
	8	7	10	560
III	2	2	6	24
	1	6	2	12
	6	1	2	12
	8	1	2	16
IV	10	1	4	40
	6	7	2	84
	7	3	2	42
	8	7	4	224
	7	3	2	42
V	6	4	2	48
VI	3	6	4	72
	7	7	6	294
	7	6	6	252
VII	8	3	2	48
	8	2	4	64
	7	3	2	42
	10	1	4	40
	8	7	2	112
VIII	8	3	6	144
	10	1	4	40
	6	7	2	84
	7	3	2	42
	8	7	4	224
	1	8	4	32
IX	9	2	4	72
	10	1	2	20
	1	6	4	24
X	7	3	2	42
	10	1	10	100
XI	8	2	4	64
	8	3	10	240

4 CONCLUSIONS

From Table 4 it can be seen that the highest result obtained is the RPN = 700 (group II), and the lowest score is RPN = 12 (group III). In this process group achieved the greatest results RPN. The highest score of 700 is the death of the driver or other participants in the road. This is a situation in which there is a collision of vehicles, vehicle collision with an obstacle, etc. Obvesly, the effect is disastrous, but it can't be forget that the fault does not always have to be on the side of the driver who drives the load; it may be the fault of another road user. The next value is the destruction of the vehicle 560, it may be at the aforementioned. Both of these findings are of high value due to the detection impossible, events on the road are random. The most smaller the RPN is the loss of cargo. It is possible that the driver did not protect the container during loading by a twist locks. It does not happen often, because the occupation operator can recall the driver while driving or notice a minimum loss of control of the vehicle, and then improve your mistake.

On prudent activities in a complex system

I. Årstad
Petroleum Safety Authorities, Norway
University of Stavanger, Norway

T. Aven
University of Stavanger, Norway

ABSTRACT: In this paper we review the concept of "prudent activities" in the context of safety regulations for the Norwegian petroleum activities, the main aim being to assess whether the concept is adequate to reflect ambitious safety objectives in a complex environment. The work is carried out by discussing the suitability and relevancy of the concept in the light of theories and empirical studies addressing the challenges of complexity in the prevention of major accidents, as well as by assessing how initiatives taken by regulatory authorities and the oil and gas industry in recent years address the need to cope with complexity in practice. The paper concludes that, suitably interpreted, the concept of "prudent activities" is adequate for this purpose—what is required is an acknowledgement of some key principles of risk management to confront complexity and uncertainties.

1 INTRODUCTION

In this paper we study the concept of prudence, which is a fundamental concept in the Norwegian petroleum legislation, as it defines the paramount objective of safety related endeavours both for the companies and for the authorities. We are particularly concerned by what prudence entails in complex systems and explore whether the concept is adequate to reflect ambitious safety objectives in a complex environment. We limit the question to what may be relevant for the prevention of *major accidents* and discuss the subject from a safety management point of view, not a legal perspective.

The assessment is deemed necessary, because the concept of prudence has materially remained unchanged for a long time, while the industry has changed and our understanding as to how safety is created and eroded has evolved. As complexity increases, the occurrence and recurrence of major accidents are increasingly linked to how we fail to address complexity in practice. In this context, increasing pressure on current safety regulations to get simpler and clearer, actualizes also the question of what is prudent to simplify.

Thus there is a need to revisit the concept of prudence, and the purpose of the present paper is to provide insights into this concept and its practical use, by linking it to relevant theories and empirical studies, as well as to initiatives taken by regulatory authorities and the oil and gas industry in recent years, e.g. after the Deepwater Horizon accident. *Complexity* is the key issue in these theories, studies and initiatives.

The paper is organized as follows. Firstly in Section 2 we review the basic characteristics of complex systems as well as the necessary perspective to address those in practice. On this basis, we present in Section 3 our assessment of the adequacy of the concept of prudence to convey ambitious safety objectives in complex systems. Then in Section 4 we discuss how some initiatives taken lately by the industry and the authorities reflect the particular needs of complex systems and prudence in practice. Finally, the last section provides our conclusions about how complexity is reflected in the concept of prudence, and some recommendations on how to enhance prudence in complex systems.

2 COMPLEX SYSTEMS

We begin by clarifying the theoretical basis of our assessments. In the present paper, we use the term *major accident* to address acute events with severe consequences and we view major accidents as non-linear phenomena that emerge in a complex system. This view is at the basis of systemic accident models and resilience engineering (Hollnagel et al. 2012), the concepts of system accidents as outlined by Perrow (2011), the drift into failure studied by Dekker (2012) and of the black swans and antifragility concepts analysed by Taleb (2010, 2012).

Systemic approaches refer to *systems*, in the sense summarized by Ackoff (1999): "A system

is a set of two or more elements that satisfies the following three conditions.

- The behavior of each element has an effect on the behavior of the whole.
- The behavior of the elements and their effects on the whole are interdependent.
- However subgroups of the elements are formed, each has an effect on the behavior of the whole and none has an independent effect on it.

The essential properties of a system taken as a whole derive from the interactions of its parts, not their actions taken separately."

The concept of system is generic and can be applied to a technical system (e.g. a BOP), a management system (e.g. a maintenance management system), an organisational entity (a company's drilling department), a company, a group of interrelated companies (e.g. an operating company and contractors involved in the drilling of a well), a national industry etc. In this article, we focus on complex systems, as systemic approaches focus on the importance of understanding complexity to better grasp what contributes to the emergence of major accidents and what may explain their recurrence, and to prevent them more efficiently. Thus, we assess the concept of prudence in relation to the characteristics of a complex system, as described by, i.a., Dekker (2012) and summarized by Snowden & Boone (2007):

- "It involves large numbers of interacting elements.
- The interactions are nonlinear, and minor change can produce disproportionately major consequences.
- The system is dynamic, the whole is greater than the sum of its parts, and solutions can't be imposed; rather, they arise from the circumstances. This is frequently referred to as emergence.
- The system has a history, and the past is integrated with the present; the elements evolve with one another and with the environment; and evolution is irreversible.
- Though a complex system may, in retrospect, appear to be ordered and predictable, hindsight does not lead to foresight because the external conditions and systems constantly change.
- In a complex system the agents and the system constrain one another, especially over time. This means that we cannot forecast or predict what will happen."

Thus, complex systems are open systems, not exhaustively describable and understandable. They are characterized by a multitude of interdependent factors, both within the system itself and between the system and its environment, both punctually and over time. Interactions are non-linear, creating unfamiliar relations between input and output or between an event and its consequences. Minor changes can produce disproportionately major consequences. The outcomes of interactions are not certain and straightforward, as there are positive and negative feed-back-effects reinforcing or suppressing various influences, and many cause-and-effect relationships are unclear.

We focus also on the adequacy of the concept of prudence in the light of the challenges of managing complex systems. A decision that improves the safety in one part of the system may create a safety problem in another part of the system. A decision that is rational and effective at one time might be irrational and destructive at another time. A non-compliance that may be of no consequence 100 times may suddenly be determinant for the emergence of an accident. For complex systems, the outcomes of decisions may not be visible or immediately foreseeable, and measures might create problems while intending to achieve the opposite. This ambiguity is pointed out by, for example, Dekker (2012), when he addresses the dangers of protective structures, by Hollnagel et al. (2012) addressing the increasing complexity induced by measures deemed necessary in the wake of major accidents, and by Taleb (2010, 2012), addressing the dangers of treatment in excess of benefits—fixing past failures is not necessarily positive for future success, and past success is not sufficient information about how to achieve future success.

Complexity causes large uncertainties. And seeing risk as a function of uncertainty (Aven 2013), complex systems represent a higher risk than simpler systems. Complexity is in itself a risk factor, and the ambiguity of complex systems infers that routes to failure are also routes to success. Thus, both major accidents and system safety are emergent phenomena in complex systems (Dekker 2012 p. 158).

Our assessments refer both to complex and simpler systems. The complexity of systems is often explained in comparison to simple and complicated systems (Snowden & Boone 2007), or just in comparison to a complicated system (i.a. Page & Miller 2007). In essence, simpler systems are characterized by their tractability, linear interactions, less volatility, less ambiguity, less uncertainty; thus, they are more predictable and manageable.

Systemic approaches argue that we cannot define and solve all safety issues as though they belonged to a simple or complicated domain, as though complexity could be "simplified away" without consequences. But, systems are not either complex or not, they are both, and the systemic approach forces us to consistently differentiate between the characteristics of the *whole* system and

the characteristics of the *parts*. Complex systems may have simple or complicated parts, but, as a whole, they have the characteristics of complex systems: they are intractable and their interactions and outcomes are emergent, adaptive, volatile and ambiguous. Complex systems are closer to living organisms than to machines. Thus, while we may be able to define, understand predict, plan, design, manage or control simple and complicated parts of the whole, we cannot do the same with the whole. While we may be able to reconstruct what has happened in a simple or complicated part of the whole after an accident, we cannot do the same with the whole. Hindsight may give some foresight for a simple or complicated part of the whole, but not for the whole. Oversight may be achievable for a simple or complicated part of the whole, but not for the whole. Thus, safety for the whole (system safety) cannot be achieved solely by managing safety for the parts taken separately. It requires something more and different. It requires a system thinking approach that forces us to relate to the messiness of "reality", not obliterate or eliminate it. It allows instead for *both* zooming in on simple or complicated sub-systems, addressing important details, and for zooming out on the bigger picture, addressing the context and interdependencies of sub-systems.

3 THE CONCEPT OF PRUDENCE

To address the adequacy of the concept of prudence, we have reviewed the Norwegian petroleum legislation and underlying documents (Draft resolutions and bills) from the perspective of what systemic approaches deem relevant to prevent major accidents. We have assessed whether it conveys a systemic approach and an acknowledgement of complexity, both in the conducting of petroleum activities and in what it takes to achieve prudence. This article being centered on the prevention of major accidents, we have focused on the term of prudence applied to *safety*, defined (Framework regulations 2013 Section 2) as a broad term, centred on prevention—of more or less severe harm, in the shorter or longer term, whoever or whatever may be harmed (people, the environment, assets, production or transport of hydrocarbons).

Demonstrating prudence is the most fundamental regulatory requirement imposed upon the companies when conducting petroleum activities in Norway. The term 'prudence' is used to translate the Norwegian term "forsvarlig", which reflects high ambitions, an internalized sense of responsibility, and also the ability to defend the pertinence of choices and outcomes. All three aspects are found at the core of the concept of prudence in the reviewed legislation and they are seen as particularly well suited to the needs of complex systems.

The concept of prudence is seen to support the view that the system to be managed by the companies is a complex system, and that prudence is the emergent outcome of many interdependent processes and variables. The Petroleum Act (1996) views prudence as the resultant of managing successfully interdependent considerations, such as i.a. good resource management, high safety standards safeguard of the environment, compliance, coexistence with other activities (shipping, fishing, aviation, etc.) or subsea facilities (pipelines, cables, etc.). The Framework regulations (2013) under the Act recognize explicitly the dynamic interaction of offshore and onshore processes and view prudence as dependent on the management of interdependent matters such as safety, health, working environment, pollution control, production and transport regularity. They recognize the need to assess the overall load of individual factors and to not take for granted that what may be good enough locally, individually, punctually or one-dimensionally, may not be good enough when you take into account interdependencies, consider a bigger picture, or a longer time perspective etc. Thus, they recognize the ambiguity inherent in complex systems, where interdependencies can as likely create synergies as conflicting objectives, and where the pursuit of success demands trade-offs which can be at the source of failure. They recognize the volatility of complex systems, as prudence is defined as a moving target, which demands both to be maintained and further developed, in tact with technological and other developments in society. Thus, they acknowledge that prudence for the whole system cannot be limited to prudence for the parts.

Requiring prudence entails to be able to demonstrate or justify that prudence is achieved systematically and deliberately, not by chance, and that what is achieved is in accordance with all applicable regulatory requirements (also the required prudence). Thus, both prudence and compliance are defined as the essential objectives of the necessary management processes. Requiring prudence in addition to compliance expresses the expectation of an internalized sense of responsibility. It recognizes that compliance may not always be sufficient to achieve prudence, and that compliance, in some instances, may even come into conflict with prudence. For example, if new knowledge shows that a previously accepted standard solution is dangerous, the concept of prudence infers that an adequate response must follow, without waiting for the legislation to be updated. Thus, knowingly using a dangerous solution is not compatible with demonstrating prudence. Furthermore, limiting safety issues to legal issues is known to be the driver of a negative

tick-the-box-approach, diverting attention and resources away from what is the desired safety performance, personal responsibilities, continuous vigilance, the need to improve current performance or adapt to changing conditions. Thus, requiring prudence in addition to compliance reinforces the high ambitions attached to the concept of prudence: aiming at doing the right thing is the preferred driver, thus going further than just aiming at doing things right.

The legislation is viewed to convey that prudence and compliance must be contextualized to express high enough safety ambitions in a complex system. Activities in Norwegian petroleum activities are spread over a huge territory with very different geological and environmental conditions, and display a technological and operational diversity reflecting over 40 years of activity and a dynamic internationalized industry. Attempting to specify in regulations all adequate solutions for all possible contexts would not be realistic, nor compatible with the volatility and non-linearity of complex systems. Simplifying complexity away by requiring the same detailed solutions for all activities (if it were possible) would not be prudent either, as such solutions would be prudent to some, but irrelevant, inadequate, ineffective or insufficient for others. Thus, the Norwegian regulations posit that safety solutions must be contextualized and that the same high ambitions must apply for all. Instead of requiring the same specific solutions for all, they require the same safety *functions* for all, regardless of how challenging the context might be. Thus, doing things right, in the sense of being in compliance with the requirement of prudence, implies essentially taking the responsibility to *recognize* what is the right thing to do and *do* the right thing, at all times, thus adapting to changes when necessary.

Overall prudence is seen to rely on efforts in many different areas, and on the integration and contextualization of a wide spectrum of different management processes. Thus, prudence for the whole system cannot be limited to prudence for the parts. We see for example that the Petroleum Act (1996) presents prudence as the central condition for a company's "license to operate". As such, it is also a central objective of a company's corporate management system and corporate risk management system. And as activities are deemed prudent if they are prudent also from a safety point of view, safety management (Framework regulation 2013) is an integral part of a company's corporate management. Safety management has two main objectives: to ensure prudence and compliance with requirements pertaining to safety. In the current regulatory context, a risk management system is required as a means to contextualize important safety management processes and ensure that safety solutions are adapted to the actual needs in each particular case. Barrier management (Management regulations) is furthermore an integral part of the risk management system, as it is an important means to ensure that technical and operational safety measures on the installations take account of accidental scenarios, which are deemed relevant. Prudence requires the contribution of many more management processes, which are important for system safety, e.g. maintenance management, knowledge management, strategic management, change management, etc. Most of those processes are interdependent and linked in a non-linear fashion. It entails that each management process constitutes an important but insufficient contribution towards prudence. For example, barrier management is important but not sufficient to manage the risks that need to be addressed; risk management as here defined is important but not sufficient to manage safety, i.e. achieve prudence and compliance with regulatory safety requirements; and prudence from a safety point of view is important but not sufficient to demonstrate prudence in the sense of the Petroleum Act. Figure 1 illustrates the system boundaries that a company must consider in order to conduct prudent activities in accordance with the current safety legislation. It illustrates also how different management processes contribute to achieving prudence in the sense of high safety standards and compliance with safety regulations (darker areas), and how those are integrated in corporate governance and management systems aiming at ensuring overall prudence as outlined in the Petroleum Act.

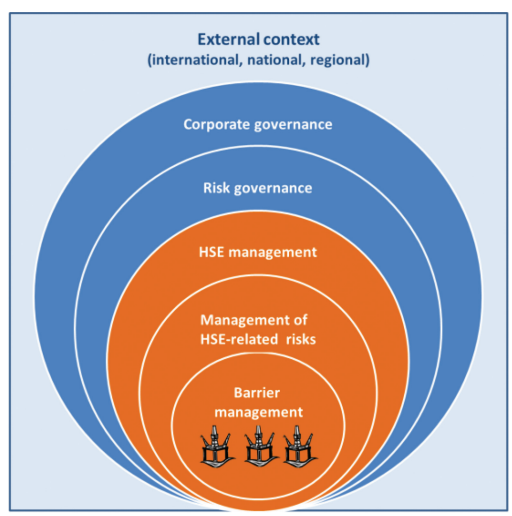

Figure 1. Integration of some management systems—company perspective.

Regulating prudence in a complex system is demanding. We see that the reviewed legislation appears to be in tact with newer management standards, as it bears the marks of their increasing acknowledgement of complexity over time. The legislation itself appears to be a complex system, as it cannot be reduced to a set of independent paragraphs. For example, compliance with one detailed requirement taken individually cannot compromise compliance with a higher standing requirement and the safety of the whole. Detailed paragraphs must be contextualized and understood in conjunction with several central requirements, which apply without being repeated over and over again. The legislation is also the result of processes with the active participation of parties in the industry and many other influences. Thus, the legislation itself functions as a complex system opened both to the environment it regulates and to a wider environment.

Operating in this complex domain is considered demanding. In addition to an ambitious regulatory regime, there is a severe selection process to ensure that license shares or operatorships are granted to companies that are competent and responsible, i.e. with a sustainable risk appetite, compatible with prudent behaviour. Enabling diversity is also viewed as necessary for coping with complexity. To this end, the legislation supports the legitimacy of different stakeholders (licensees, operator, management, workers' representatives, trade unions, any individual in the system) and demands their involvement in safety matters. This is meant to activate different objectives, interests and competences, accommodate for inputs and controls with different perspectives, and stimulate contradictions of assumptions. Thus, the complexity of conducting prudent petroleum activities appears tangibly and consistently acknowledged in the infrastructure put in place to achieve the high safety ambitions it is deemed necessary to convey.

4 PRUDENCE IN PRACTICE

We have seen that the concept of prudence and its regulatory context supports the view that complex systems fail in complex ways, and that prudence depends on all parties acknowledging that complexity. We have also sought to assess whether it is necessary to give more attention to complexity *in practice,* as there are recurrent warnings as to our systematically defining and solving safety issues as though they all belonged to a simpler domain, i.e. as though obliterating complexity was a valid option to cope with complexity. To that end, we have reviewed some of the main initiatives taken, both by the authorities and the industry, after the Deepwater Horizon accident (i.a. OGP 2011, OLF 2012, PSA-N 2011abc, Report to the Ministry of Labour and Social Affairs 2013, Reports to the Ministry of Oil and Energy 2010, 2012, White papers nr. 8, 10, 28), some reports and recommendations following six major accidents (Buncefield 2007, 2008ab, Deepwater Horizon 2011, HSC 2000, 2001, HSE 2000, Montara 2010, 2013, NOU, 2008. 8, The BP U.S. Refineries Independent Safety Review Panel 2007), as well as current practice with regard to risk management. We have looked for what Dekker (2012) refers to as "the language of complexity", i.e. how we demonstrate a system perspective in practice, by what we express through our words and silences, our actions and passivity.

We have seen that investigation reports after major accidents confirm that not taking complexity into account is a relevant system safety issue, as they point at systemic issues, including interdependencies between processes across objectives, functions, organizations, etc., both punctually and over time. Nevertheless, improvements put forward in the wake of those accidents do not often reflect a language of complexity. The focus is mostly on technology, the people and processes at the sharp end of the business, and on more requirements, more controls, more documentation, and more detailed analyses. This stands in contrast to the warnings of systemic models, arguing that limiting ourselves to more "safety by constraints" increases complexity and sustains some important conditions for the emergence of major accidents. Thus, there seems to be a systemic flaw in what we learn in practice: we limit lessons from major accidents to what belongs to the simple and complicated domains, and justify the relevancy and virtue of improvements independently from the complex domain in which they will function.

We have seen that there are still many examples of "undercommunication" of interdependencies between processes and objectives, as though safety issues themselves were in practice a closed system in the simple or complicated domain. Most of the communication concerning system safety is in practice limited to matters concerning the sharp end of the business, i.e. the installations. Thus, in safety matters, everybody may be looking mostly in the same direction, at the installation, and at the same information, about the installation. Thus, there might be a substantial blind spot, where people involved in processes concerning e.g. cost-efficiency, strategy, resource allocation, re-organizing, etc. may not have a sense of ownership of the risks they introduce by their own decisions. There is also recurrent communication about safety regulations being a threat to the expansion and profitability of the industry, as though compliance were a luxury without a bearing on expansion and profitability, as though prudence concerned a closed system independent of

the business itself. Communication about the contribution of such statements on system safety is less common. There are also recurrent demands that regulatory improvement of safety should undergo a formal cost-benefit-analysis, as though there were enough prudence for a while. It is not nearly as common to witness communication about the need for buffering uncertainty to achieve prudence in ever-changing complex/open systems. There is little communication too about how to address externalities, or the benefit of a "dynamic nonevent" (Weick & Sutcliffe 2011) in economic terms, or the benefit of a safety paragraph in isolation from its regulatory or operational context. Demands to reduce the risk of major accidents through "simple" solutions, such as more detailed regulations and more responsibilities transferred to the authorities are much preferred in practice than communication about the dangers of binding more of the authorities' few resources on standardized control activities, or how innovative approaches can improve system resilience through more risk ownership, contextualization, differentiation and diversity.

The "language of complexity" in some risk management practice is not clear either. It is not uncommon to see risk management limited to a compliance-driven exercise, consisting of standardized discrete processes, centred on analytical tools, focusing mostly on one sub-system (the installation), which is assumed to be a closed system, i.e. without safety-significant interdependencies with other parts of the system, or other systems, neither punctually nor over time. Vulnerabilities are limited to one type of consequence (harm to people), all interactions are assumed to be linear, and hindsight is assumed to give sufficient foresight. The resulting probabilistic measures of risk are assumed to embody all significant uncertainties about the context, the design, maintenance and operation of barriers, the competence, discipline and rationality of people, relevant constraints, dilemmas, pressures, paradoxes, etc. Emphasis is put on measuring risk and comparing this measure to an acceptance criterion, not on understanding what contributes to risk and needs attention, and the limits of such understanding. Such processes will often merely confirm the rarity of major accidents, limit the motivation to invest in system safety and comfort complacency in the system.

Not talking the "language of complexity" is apparent in compliance-driven approaches, based on the use of few regulatory requirements, isolated from their context. Limiting risk management to measuring risk and comparing this measure to an acceptance criterion at particular points in time, as mentioned above, is an example. Such an approach makes it possible to justify for example to normalize the evacuation of an installation each time the weather conditions imply that the annual probability of losing a main safety function exceeds 10-4. Over time this could justify building installations that are unsafe under certain weather conditions, and planning to evacuate workers regularly could become a design criterion. This approach would justify the acceptability of the collapse of an installation, as long as it was unmanned, as it is not repeated in each paragraph that the integrity of an installation is required both for the sake of people, the environment, assets and production. Thus, seeking to reduce regulatory compliance to compliance with a few paragraphs separate from the rest of the legislation comes in conflict with the concept of prudence, both punctually and over time.

Not acknowledging complexity in practice is also apparent in the resistance to change existing practices, for example the practice of quantifying accidental risk in a 25-year perspective and in areas as huge as the Barents Sea (1400000 km^2), which inevitably generates the information that the probability of encountering a major accident is low, the consequences potentially huge, and the uncertainties unlimited. Focus on risk quantification diverts all attention away from system safety, and risk measures are instead misused to either justify (irrespective of uncertainty) that there is nothing to worry about, or that the level of uncertainty commands extreme worry, regardless of existing knowledge (White papers nr. 8, 10, Hauge K.H. et al. 2013). Such mechanisms resonate with the safety eroding forces described i.a. by Dekker (2012) in his concept of drift into failure, and by the National Commission on the BP Deepwater Horizon Oil Spill (Deepwater 2011), addressing the dominance of the systemic conflict between environmental and industrial considerations, probabilistic expressions of accidental risk being instrumental as a leverage by both sides in that conflict. This may also be an illustration of the relevancy of Perrows' (2011) focus on the political nature of risk assessment. Thus, we view the shortcomings of the "language of complexity" in themselves as an expression of the complexity of the system.

5 CONCLUSIONS

In this article, we have reviewed the concept of prudence, which is central in the Norwegian petroleum legislation. We have chosen to approach the concept of prudence through the lens of systemic accident models, which link the occurrence of major accidents to complexity and their recurrence to our shortcomings with respect to coping with complexity in practice. We have seen that coping with complexity requires a systems thinking approach in addition to the current analytical approach.

We have shown that demonstrating prudence is the condition for a company's "license to operate" in Norwegian petroleum activities, and that it reflects high ambitions with respect to safety standards, both punctually and over time. Prudence also implies compliance with regulatory requirements, which, in this particular context, means that actual challenges are recognized, safety measures adapted to those challenges, and required safety functions are fulfilled. As the safety legislation itself is a complex system, compliance with the requirement of prudence for the whole system cannot be limited to compliance with each requirement taken separately. Thus, requiring prudence in addition to compliance recognizes the dangers of compliance-driven approaches and detailed requirements. It expresses the expectation of an internalized sense of responsibility, where aiming at doing the right thing is the paramount objective of regulatory compliance, thus going further than just aiming at doing things right. We have seen that both the concept of prudence and its regulatory context are adapted to the challenges inherent to the complexity of the petroleum activities and to the view that safety management belongs to the complex domain. The concept of prudence reflects a consistent acknowledgement of complexity, both of petroleum activities, of the system necessary to manage safety, and of regulating and supervising system safety. There is also compatibility with systemic accident models and systemic approaches to safety management. Thus, both prudence and system accidents are viewed as properties that emerge from a web of adaptive interactions within a company and between a company and its continuously changing environment and the developments of technology, knowledge and society.

Even though the complexity of conducting prudent petroleum activities is recognized through the design of the regulatory infrastructure, we have pointed at the challenge to align the regulatory intentions with prudent practice. We have argued for the relevancy of paying attention to warnings as to our propensity to define and solve safety issues as though they all belonged to a simpler domain, i.e. as though obliterating complexity was a valid option to cope with complexity.

We support the view that systems thinking can support a "language of complexity", which can improve our coping with complexity, thus enhancing prudence in practice. It may contribute to more precise articulation of the choices we make with respect to the boundaries of the sub-systems we consider, and the safety-relevant environment of these sub-systems. This may improve current practices, by enabling greater precision as to the risks we do (and do not) consider, understanding that the risk of a major accident is not tractable, and that what we can address is a more tractable part of a bigger picture, e.g. the risk for personnel on installation X, given an event A, our uncertainty covering i.a. the reasons behind such an event, the reasons why barriers may fail and other types of consequences. Thus it may contribute to a better use of current analytical tools, adapted to zoom in on barriers at the sharp end of the business, and develop other tools to zoom out on what may contribute to the emergence of accidents which render barriers necessary. It may increase our awareness of the limits of our understanding and conclusions, and enable us to better buffer or reduce uncertainties linked to our decisions. It may also expose other risks than those usually in focus and mobilize a wider range of relevant risk owners. It may reveal the safety-relevancy of information which is available today but not currently labelled as safety-relevant. It may foster better attention to our own contribution to risk, while current practice is often centred on others' contribution. It may contribute to more purpose-driven risk management, thus more focus on *recognizing* risk and on the need to generate adequate understanding to practise wisdom (Ackoff 1989), as the concept of prudence commands.

The language of complexity is also useful in that it helps consider current shortcomings concerning our recognition of complexity as a normal expression of the system's complexity itself, i.e. something which will always be there to a certain extent, because it is rooted in many mechanisms which cannot be "fixed". It is something to acknowledge, buffer and adapt to. In exposing the normal "messiness" of "reality", the systemic approach contributes to understanding the forces in action in the system, the fact that actual performance often differs from normative performance, and that it contributes both to the resilience of the system and to the fragility of the dynamic equilibrium that prudence represents. The language of complexity helps us to "get real", reduce naïve illusions about simple solutions, reduce our vain indignations about the messiness of "reality", increase our humility as to what we can know, understand and fix, and how much harm we may do, either unintentionally or by being willing to do good, whatever function we have in the system. Thus, the language of complexity contributes to justifying the high ambitions outlined in the current safety legislation, and the necessity of competent and responsible actors in the whole system, to sustain prudent activities.

Parallel computing for system availability and applications

R. Briš & S. Domesová
Technical University of Ostrava, Czech Republic

ABSTRACT: Rapid development of computer technology recently requires adequate novelties of source codes and appropriate software. New parallel computing technology based on HPC (High Performance Computing) for availability calculation will be demonstrated in this paper. The technology is particularly effective in context with simulation methods, but analytical methods are taken into account as well. Basic algorithms for availability calculations must be improved to achieve better computation efficiency. Parallel processing is executed by two ways, firstly by the use of the MATLAB function parfor and secondly by the use of the CUDA technology. The computation efficiency is compared and demonstrated on selected examples from practice.

1 INTRODUCTION

System is a set of components that work together and form a functional unit. Real systems include technical machines, production lines, computer networks and other devices. In practice, it is often required to model reliability characteristics of such systems. Using models of system availability, system operators are able to assess operational costs, determine how many people are needed to maintain the system, estimate expected yields, etc.

In applications related to availability modelling an important sub-problem is often encountered: The logical structure of the system and availability of each component at a given time $t \in \mathbb{R}$ are known and with this knowledge availability of the whole system at the time $t \in \mathbb{R}$ should be determined, i.e. the probability that the system is operational at the time should be calculated (in some cases the time evolution of the probability is required). This problem was solved in the past by many different algorithms that can be roughly divided into analytical and simulation ones. The simulation approach is employed when analytical techniques have failed to provide a satisfactory mathematical model or defy solution of the problem in closed form or the solution becomes unwieldy. The principle behind the simulation approach is relatively simple and easy to apply. However the common simulation techniques are slow and take a lot of time to provide accurate results. Nevertheless, this technique is the only practical method of carrying out reliability or risk studies, particularly when system is maintained and arbitrary failure and repair distributions are used or some special repair or maintenance strategy is prescribed.

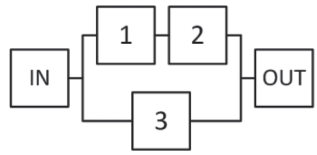
The Monte Carlo (MC) method allows complex systems to be modeled without the need to make unrealistic simplifying assumptions, as is inevitably done when using analytical methods. With the increasing availability of fast computers, MC methods become more and more powerful and feasible (Briš, R. 2008). As they have the potential of obtaining solutions of models which are very close to reality, they can yield relevant and useful results. In the past twenty years, applications of MC simulation methods on a variety of system engineering problems have indicated that such techniques can provide significant improvements in the realistic assessment of reliability and availability of complex systems. Recent reliability analyses of complex systems based on the MC method bring very efficient estimators (Zdráhala, A. & Briš, R. 2011). Finding of an appropriate estimator must be necessarily connected with a variance-reduction technique. There exist efficient techniques that provide significant reduction in variance, when they are correctly applied (Rubinstein, R.Y. & Kroese, D.P. 2008). The application of these techniques gives other potential for optimization of the simulation algorithms solving complex practical reliability problems.

Another problem connected with the application of the MC method is slow convergence. To mitigate this issue, several techniques have been developed such as those based on the importance sampling and other classical methods (Fishman, G.S. 1996). Another possibility to improve the convergence is provided by the so-called conditioning methods which directly modify the modeling or the simulation procedure, as for example in the Petri net approach (Perez, D. et al. 1996, Signoret, J.P., et al. 2013). In spite of

all these advanced techniques, in most practical cases whenever reliability characteristics must be determined exactly and efficiently, the analyst faces computing problems, i.e. slow convergence and large simulation time. That is because systems are more and more complex and demands on reliability are continually growing. For example, NEC producer (Mochizuki, Y. et al. 2006) has offered system components for use in supercomputers in order to support the need for an extremely high performance. The improving reliability will be an essential feature of the products of the next generation.

The above mentioned computing problems are solvable by applying parallel processing of computing algorithms. This new computing technology is possible to put into practice just on assumption that an adequate computing infrastructure exists, which can be used for the HPC (High Performance Computing) calculations. In Technical University of Ostrava such a new supercomputing center is recently built. This paper demonstrates basic approach to the parallel computing for system reliability characteristics. Both analytical and simulation method is discussed in context of computer efficiency.

2 SYSTEM AND ITS REPRESENTATION USING ADJACENCY MATRIX



Consider a system consisting of n components, $n \in \mathbb{N}$. At a given time $t \in \mathbb{R}$ each component is in one of two disjoint states, operational or failed. To the i-th component a state indicator b_i belongs. If the component is operational, $b_i = 1$, otherwise $b_i = 0$. The vector $\mathbf{B} = (b_1, b_2, \ldots b_n)$ is called the state vector of the system. The set of all possible state vectors is called the state space of the system and denoted by V. Since just components with two possible states are considered, the state space has 2^n elements (Dubi, A. 2000).

The system state is determined by the states of its components. The function $S(\mathbf{B}): V \rightarrow \{0,1\}$ defined as:

$$S(\boldsymbol{B}) = \begin{cases} 1 & \ldots \ \textit{system is operational}, \\ 0 & \ldots \ \textit{system is failed}, \end{cases}$$

is called the system function.

The logical structure of systems is often represented using block diagrams. A block diagram is a directed graph with two special vertices (in Figure 1 marked IN and OUT), the remaining vertices symbolize components of the system. A directed edge connecting two vertices indicates that there is a direct path between corresponding system elements in indicated direction. Let's say

	IN	1	2	3	OUT
IN	0	1	0	1	0
1	0	0	1	0	0
2	0	0	0	0	1
3	0	0	0	0	1
OUT	0	0	0	0	0

Figure 1. Block diagram and corresponding adjacency matrix.

that the system is operational if there exists a path between the IN element and the OUT element passing only through functional components. For the system function:

$$S(\boldsymbol{B}) = \begin{cases} 1 & \ldots \ \textit{system is operational}, \\ 0 & \ldots \ \textit{otherwise} \end{cases}$$

holds.

For implementation purposes, it's suitable to represent the block diagram equivalently using the adjacency matrix M of size of $(n+2) \times (n+2)$. The first row and column of the matrix is used for the IN element, the last row and column for the OUT element. The remaining rows and columns represent the components of the system. If a directed edge between elements i and j exists, $(M_{ij}) = 1$, otherwise $(M)_{ij} = 0$.

3 METHODS OF AVAILABILITY QUANTIFICATION

As mentioned above, the following task is solved in this paper:

"A system with n independent components and an appropriate system function $S(\mathbf{B})$ is given. Further availabilities of all components are known. There is necessary to quantify the availability of the system."

The state space of the given system includes 2^n state vectors. By substituing each state vector into the system function, the state space can be divided into two disjoint subsets $V_0 = \{\mathbf{B} \in V | S(\mathbf{B}) = 0\}$, $V_1 = V \setminus V_0$. Let's denote the availability of the i-th component by p_i. Further denote:

$$\beta_i = \begin{cases} p_i & \text{if} \ \ b_i = 1, \\ 1 - p_i & \text{if} \ \ b_i = 0. \end{cases}$$

Therefore the probability $P(\mathbf{B})$, that the system is in state defined by a specific state vector $\mathbf{B} = (b_1, b_2, \ldots, b_n)$ can be calculated as:

$$P(\mathbf{B}) = \prod_{i=1}^{n} \beta_i.$$

At this point both solving methods can be presented, the analytical and the simulation one.

3.1 *Analytical method*

Availability A is the probability that the system is operational at the considered time, i.e. that it is in a state belonging to V_1. This probability can be calculated as the sum of probabilities $P(\mathbf{B}_j)$, that the system is in state $\mathbf{B}_j \in V_1$. Therefore the availability A can be expressed as:

$$A = P\left(S(\mathbf{B}) = 1\right) = \sum_{j=1, \mathbf{B}_j \in V_1}^{2^n} P(\mathbf{B}_j)$$
$$= \sum_{j=1, \mathbf{B}_j \in V_1}^{2^n} \prod_{i=1}^{n} \beta_i^j.$$

Using this formula, the algorithm for the analytical computation of system availability can be easily constructed. Notice that each state vector of the system is evaluated, so it can be expected that the computation time increases exponentially with respect to the number of components.

3.2 *Simulation method*

One of the ways to avoid evaluating the state of the system for each state vector is to solve the problem using the Monte Carlo method. The problem is simulated using appropriate random variable X. Here the following random variable is chosen:

$$X = \begin{cases} 1 \ldots S(\mathbf{B}_j) = 1, \\ 0 \ldots S(\mathbf{B}_j) = 0. \end{cases}$$

It should be verified that the mean value of X equals the availability A. For the mean value:

$$E(X) = \sum_{j=1}^{2^n} X_j \cdot P(\mathbf{B}_j) = \sum_{j=1, \mathbf{B}_j \in V_1}^{2^n} P(\mathbf{B}_j) = A$$

holds, i.e. the random variable X is selected properly.

The experiment consists of generating a random state vector and determining the value of X_j. The vectors are generated according to following rule: The probability that a specific state vector $\mathbf{B}_j$ is generated equals the probability $P(\mathbf{B}_j)$. After N repetitions of this experiment a random sample X_1, X_2, … X_N is obtained. The sample mean $\overline{X}$ of this random sample estimates the mean value of the variable X and therefore the availability A.

3.3 *System state evaluation*

The operation $S(\mathbf{B})$ is an important part of both approaches. It is an algorithm which for a system given by an adjacency matrix and for a given state vector **B,** determines the state of the system, i.e. if the system is operational. The algorithm consists of two primary steps:

- removal of failed components
- deciding if the system is operational

and is defined as follows:

1. Remove rows and columns that belong to failed components from the adjacency matrix.
2. Create three empty sets ACTUAL, AVAILABLE and VISITED. Move system elements that are directly connected to the IN element to the AVAILABLE set.
3. Move elements from AVAILABLE to ACTUAL. Move elements that are directly connected to some of the elements in ACTUAL and that are not in VISITED to AVAILABLE.
4. If AVAILABLE contains the OUT element, terminate the algorithm, system is through.
5. If AVAILABLE is empty, terminate the algorithm, system is not through.
6. Move elements from ACTUAL to VISITED. Continue with step 3).

Considering the estimation of the computation time, notice that steps 3 to 6 are executed at most m times, where m is the number of operational components of the system, $m \leq n$. This means the state of the system is calculated in n iterations at most.

4 PARALLELIZATION

Both the analytical and the simulation algorithm described in the previous section were implemented in the MATLAB language, at first as a sequential application and then both algorithms were parallelized. The principal of the parallelization consists in dividing the task into multiple simultaneous threads, each of them executing a different part of the calculation. The aim is to optimize the algorithms and to reduce the computing time.

The Monte Carlo method is suitable for parallelization, because the experiments are independent and may be realized in different threads. Assume that $M \cdot r$ experiments should be executed in r threads. This means that in the k-th thread M random state vectors are generated and for each of

them the system state is evaluated. The output of the thread is the total number of generated vectors for which the system was operational, denote by S_k. The estimated availability can be easily obtained from the intermediate results as:

$$\bar{X} = \frac{1}{M \cdot r} \sum_{k=1}^{h} S_k .$$

Similarly in case of the analytical algorithm, the state space can be divided into several parts and the state vectors evaluated in different threads.

4.1 *The parfor loop*

MATLAB programming tool allows a simple parallelization of loops with fixed number of recurrences using the "parfor" keyword. In case of the Monte Carlo method, the loop over all the sample size is parallelized and in case of the analytical algorithm it is the loop over the state space. Number of threads in which the calculation is executed equals at most the number of used processor cores.

4.2 *The CUDA technology*

These algorithms can be efficiently parallelized using CUDA (Compute Unified Device Architecture). This technology allows to use the NVIDIA graphics cards for parallel computing. The threads are organized in blocks and the blocks are organized in a grid (CUDA C Programming Guide 2013). In case of the graphics card used in this simulation there can be at most 1024 threads per block and 65535 × 65535 blocks per grid. Furthermore the maximum amount of available memory cannot be exceeded.

In each thread the so called "CUDA kernel" is executed. This special function is written in a file with the ".cu" extension, syntax is similar to the C++ language. There is a possibility to work with these files directly from the MATLAB environment. But first it is needed to create a ".ptx" file (Parallel Thread Execution) using external compiler (NVIDIA CUDA Compiler). From these two files the kernel object can be created in MATLAB.

MATLAB also allows an allocation of arrays on the graphics card, these arrays are used as input and output variables of the kernels. For the realization of experiments, here random state vectors generation, an array of length $n \cdot N$ of random numbers from $U(0,1)$ is pre-allocated on the graphics card (n is number of components, N is number of experiments). To generate the i-th state vector n numbers from this array are used (beginning with the position $i \cdot n$ when indexing from 0).

4.3 *Bitwise operation*

A further optimization of both algorithms can be achieved using bitwise operations. Their proper use results in a reduction of computing time as well as in lower memory requirements, which is especially important when using the CUDA technology.

The state indicator of a component is always zero or unity. To save the state indicator it is thus adequate to use one bit. In this context, simulation variables of data type "unsigned int" are used having the length of 32 bits. The binary code of such variable consists of 32 digits (0/1), each of them represent the state of one component.

In this simulation the bitwise operations are used in the CUDA kernel code. Their use in the pure MATLAB implementation is not suitable, because the bitwise operations are extremely time-consuming.

5 TESTING

For testing purposes the following well-scalable problem is used:

"A system of n component with a serial structure is given. Availability of each component equals 0.999. There is necessary to quantify the availability of the system."

The system with serial structure is represented by the adjacency matrix in Figure 2.

The problem was solved for various values of n using both the analytical and the simulation method. All of the implementations were tested under equal conditions on two processors Intel Sandy Bridge E5-2665, 8 cores each. The CUDA parallelization was tested on the graphics card NVIDIA GT 555M. The results of tests are shown in following tables and graphs.

The analytical algorithm was tested on small systems with 24 components at most. The following Tables 1–3 show that the analytical method is unsuitable for large systems, because (as expected) the computing time increases approximately exponentially with respect to n. However, for small systems, its use is appropriate since exact results are obtained.

The following parallel scalability graph in Figure 3 shows the computation time decreas-

$$M = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & & \vdots \\ 0 & 0 & 0 & \ddots & 0 \\ \vdots & & & & 1 \\ 0 & 0 & 0 & \cdots & 0 \end{pmatrix}.$$

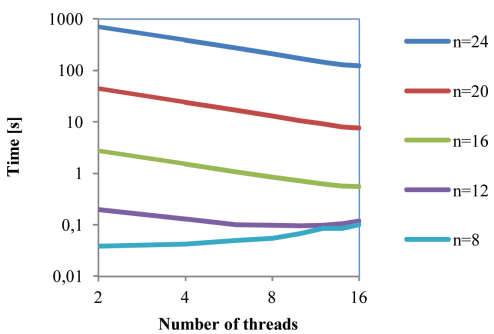

Figure 3. Simulation algorithm using parfor: scalability graph.

ing when the number of threads grows from 2 to 16 threads (note the logarithmic scale of both axes).

In case of the simulation algorithm besides the computation time also the estimated availability $\overline{X}$ and PRSD (percentage relative standard deviation) were recorded, what is demonstrated in Tables 4–6. Random samples of size 10^5 were used. Number of system component was significantly increased as well, to $n = 200$.

Also in case of the Monte Carlo method it has been shown that the computation can be significantly reduced by the use of parallel computing. This fact is illustrated in the following scalability graph in Figure 4, for several sizes of the system. The scale of both axes is logarithmic.

6 INDUSTRIAL EXAMPLE

In this section an example of a concrete engineering problem is presented, for its solution the aforementioned methods are used. The task is to simulate the availability of a fire detector system with independent components, basic motivation see in Rausand & Hoyland (2004). The block diagram is shown in Figure 5, according to it, the corresponding adjacency matrix can be constructed.

Assume that the system is in its useful life period, i.e. the failure rate and the repair rate of each component are constant. Therefore the availability $p_i(t)$ of the i-th component is given by Dubi (2000):

$$p_i(t) = \frac{\mu_i}{\lambda_i + \mu_i} + \frac{\lambda_i}{\lambda_i + \mu_i} e^{-(\lambda_i + \mu_i)t}, \tag{1}$$

where λ_i is the failure rate and μ_i the repair rate of the i-th component, exactly specified in Table 7.

Assume that in time $t_0 = 0[h]$ all of components are operational. The availability of the system is simulated in time, thus an appropriate time discretization should be chosen. Here for example the constant step of 6 hours is chosen. At this point the simulation of the availability course in time can be computed. For each time step, availability of each component is first calculated using formula (1), then the availability of the whole system is calculated using one of the methods presented in sections 3–4. It is convenient to plot the results for each time step into a graph, see Figure 6.

The following Table 8 compares the computation time needed to calculate the availability in 50 time steps (plotted in the graphs in Figures 6–7) by different types of the algorithm.

7 CONCLUSIONS

This paper was aimed at two specific algorithms (one analytical and one simulation) which can be used in applications related to availability modelling of systems represented by the adjacency matrix. The following two ways of implementation of these algorithms into parallel processing were introduced:

– parallelization using the MATLAB parfor loop,
– parallelization using the CUDA technology together with the use of the bitwise operations.

Using these two parallelization techniques, the computation efficiency of both algorithms was successfully enhanced. More significant reduction of the computing time was achieved using the second technique. For instance the practical example presented in Section 6 was computed over a computing time which is 275 times shorter than the computing time used for the original sequential implementation.

The parallel scalability was illustrated on the first of the techniques (the parfor loop). The scalability graphs in Figures 3–4 confirm that the use of parallel computing is always more efficient than the traditional approach using the sequential implementation.

On testing example we showed that the simulation methodology is particularly convenient when the number of system component increases. For instance if the number of system component approaches to $n = 200$, this method gives acceptable results, whereas using the analytical method is impossible.

ACKNOWLEDGEMENT

This paper has been prepared in the framework of the IT4Innovations Centre of Excellence project, reg. no. CZ.1.05/1.1.00/02.0070 supported by Operational Programme 'Research and Development for Innovations' funded by Structural Funds of the European Union and the Government of Czech Republic.

Within the last fifty years the performance requirements for technical objects and systems were supplemented with: customer expectations (quality), abilities to prevent the loss of the object properties in operation time (reliability and maintainability), protection against the effects of undesirable events (safety and security) and the ability to restore performance (resilience). The need to adapt the operation of complex systems in such an uncertain and volatile environment has caused the necessity to formulate new and well established achievements associated with modeling, testing and evaluation of these properties. The concept of a complex system applies not only to the technical ones but also the infrastructure of major importance for social life such as transportation and logistics systems, buildings, power systems, water distribution systems or health services.

Safety and Reliability: Methodology and Applications contains the proceedings of the 24th European Safety and Reliability Conference (ESREL 2014, Wroclaw, Poland, 14-18 September 2014), and discusses theories and methods and their applications in the areas of risk, safety and reliability. The book will be of interest to researchers and practitioners, academics and engineers working in academic, industrial and governmental sectors.
