The Poisson distribution is a special case of a binomial distribution, if the probability of failure p or probability of successes q is very small and the number of experiment n is very large. The conditions under which the Poisson distribution holds are the counts of rare events, all events are independent and the average rate does not change over the period of interest. The Poisson probability function is given as follows:

$$P(X = x) = \frac{\mu^x}{x!} \cdot e^{-\mu}, \tag{4}$$

the expected value $E(x)$ is

$$E(x) = \mu \cdot \sum_{x=1}^{\infty} \frac{\mu^{k-1}}{(k-1)!} \cdot e^{-\mu} = \mu. \tag{5}$$

In a Poisson distribution, only one parameter is needed to determine the probability of an event.

The Weibull distribution is one of the most commonly used distributions in reliability engineering. The Weibull distribution is a continuous distribution. The distribution makes it possible to represent the time dependent failure probabilities $F(t)$ of components. The required data are the failure frequency, number of all components and the failure times of the components. The probability of failure according to the Weibull distribution $F(t)$ is defined as

$$F(t) = W(t; \beta; t_0; T) = 1 - e^{-\left(\frac{t - t_0}{T - t_0}\right)^{\beta}} \tag{6}$$

where $\beta > 0$ is the failure slope or shape parameter and t_0 is the correction parameter. T is the characteristic lifetime or position parameter.

The Weibull distribution so known under the name "Bath tub curve" is divided into three areas. The first phase is an early phase. At the beginning, the failure rate is high. During the early phase, the failure rate decreases. The second phase is the operational use. During the operational phase, the failure rate reaches the minimum. In this phase, the failure rate is constant. The last phase is a wear out phase. During the wear out phase, the failure rate increases, because the components reach their end-off-live time. The Weibull density function is calculated as follows:

$$f\left(\tilde{t}\right) = \lambda \cdot \beta \cdot \left(\lambda \cdot \tilde{t}\right)^{\beta - 1} \cdot e^{-\left(\lambda \cdot \tilde{t}\right)^{\beta}}, \tag{7}$$

where $\tilde{t} = t - t_0$.

3 FUNCTIONAL SAFETY

The standard IEC/EN 61508 shows exemplarily the procedure for determining the probability of hardware failures. First, it specifies the principles and assumptions on which the calculations are based.

For analysing the safety integrity of safety-related systems many methods are possible. Reliability block diagrams and Markov models, however, belong to the most frequently applied. If correctly applied, both methods provide almost the same results. Nevertheless, the Markov models are still more exact (but more difficult) and provide accurate values, even for complex systems.

To determine the safety integrity of safety-related systems (i.e. consisting of several individual systems), the average probability of a failure PFD_{System} or PFH_{System}, is required for the overall system.

To determine the PFD_{System} or PFH_{System} values of a safety-related overall system (i.e. consisting of the sensor system, the logic system and the actuator system), one must add the determined average probabilities for the individual systems:

$$PFD_{System} = PFD_{Sensor} + PFD_{Logic} + PFD_{Actuator} \tag{8}$$

or

$$PFH_{System} = PFH_{Sensor} + PFH_{Logic} + PFH_{Actuator} \tag{9}$$

Table 1. Definition of safety integrity level according to IEC 61508.

SIL	Low demand mode of operation (Average probability of failure to perform its design function on demand)	High demand or continuous mode of operation (Probability of a dangerous failure per hour)
4	$10^{-5} \leq PFD < 10^{-4}$	$10^{-9} \leq PFH < 10^{-8}$
3	$10^{-4} \leq PFD < 10^{-3}$	$10^{-8} \leq PFH < 10^{-7}$
2	$10^{-3} \leq PFD < 10^{-2}$	$10^{-7} \leq PFH < 10^{-6}$
1	$10^{-2} \leq PFD < 10^{-1}$	$10^{-6} \leq PFH < 10^{-5}$

To determine the average probability of failure for each subsystem, following elements must be known:

– The basic architecture
– The diagnostic cover of each channel
– The failure rate of each channel
– The factors β and β_D for common cause failures

The target is to detect common-cause failures as early as possible and to bring the system into a safe state.

The different requirements of the altered Safety Integrity Levels (SIL) are in dependent on the probability of failure and are shown in Table 1. The probability values are defined as a PFD-value (probability of failure on demand), if the system is in a low demand mode and has to execute a safety function. However, if a system is operating in a high demand mode or continuous mode and a safety function has to be executed, then the probability of failure is specified with the PFH (probability of failure per hour). Its dimension or unit is (1/h). (Carsten 2006), (Kainka 1996)

4 IMPLEMENTATION OF A SAFETY FILTERS

In this section the fundamental Basics of the implementation will be discuss.

4.1 *Design of the use FPGA-board*

A Field programmable Gate Array (FPGA) is a semiconductor chip with consists about many logical components. The User can create integrated circuits with the hardware programming languages VHDL ore Verilog. The Integrated circuits can be takes lower complexity like timers ore really higher complexity like microcontrollers. Producer of semiconductors takes this advantage to produce integrated circuits without fails to reduce the development costs. Here are the possibility to create integrated circuits and simulate this circuits until the design have no fails.

How explained in the introduction, a digital filter will be designed on a FPGA-Board. The FPGA-Board which is used here is from the company Digilent and it's known under the name BASYS2.

The operating frequency of the Board is 50 MHz. However it can be operated with higher frequency as 50 MHz. It is possible to operate the board with an extern oscillator. The Board has a base where the oscillator can be assembled. The Board takes the power supply via USB and will be programmed simultaneous via USB. The USB driver and the software tool to program the FPGA can be downloaded over the homepage of Digilent. How in Figure 1 is shown, the FPGA-Board consist other interfaces like 8 switches, 4 push buttons, 4 PMOD interfaces and a 7-Segment display. With this interfaces the user has the possibility to control input and output data. These Interfaces are direct connected with the central processing unit. The central processing unit is the Spartan-3E which is produced from the company XILINX.

4.2 *Digital filters*

Finite Impulse Response (FIR) filters are Systems where the impulse response is finite. These filter structure are non-recursive and have no feedback. The advantage of this structure is that they are always stable. That means that the system does not oscillate from self. The order of the filter is given over the number of the delays. Where X(n) stays for the discrete input samples and Y(n) stays for the discrete output samples.

These filter structures is designed always by delay blocks, additions blocks and multiplier blocks. Different filter structure with different transfer functions can be designed only by changing the filter coefficient. The following filter can be development:

– Low pass filter n-order
– High pass filter n-order
– Band pass filter n-order
– Band stop filter n-order

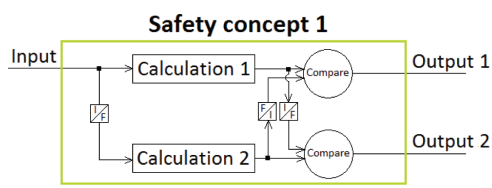

Figure 1. Safety concept 1.

4.3 *Safety concept without limitation*

In this Section a safety concept L1 of the implementation will be described. This safety concept L1 is a low level concept and is shown in Figure 1.

The safety concept will be used on the mathematical blocks. The mathematical blocks like the adder or the multiplications block are necessary for the implementation of the digital filter. The question here is how to make a mathematical function safety. For example the adder block will be designed with the safety concept (shown in Fig. 1). The adder Block has two inputs. The inputs data are represented in fix point arithmetic. The safety concept makes at first the calculation of the two inputs data in fix point arithmetic. In the same time a type converting part change the two inputs in a floating point format. After the type converting an adder makes the same calculation in floating point arithmetic. In the final way the result of the floating point block will be type converted in fix point format to compare the results in fix point arithmetic. In the same time the result of the fix point block will be converted in floating point format. After the conversion the same comparison will be executed in floating point arithmetic. Once the comparisons of both ways are in agreement, the result of the mathematical addition is correct.

5 RESULTS

In this section the results of the measurements will be discussed. For the verification of the results a comparison model will be tacked. The comparison model is the transfer function of the low pass filter which is determined with the software tool Matlab. It will be execute measurements on the low pass filter and compared with result of the theoretical values. At firs the theoretical transfer function of the low pass filter will be plotted. This will be done over the following instruction on the command window of the Matlab tool.

Instructions

- A = [0.25 0.5 0.25];
- Freqz(A);

The Instruction has to type one after another. The instruction gives the transfer function in Figure 2.

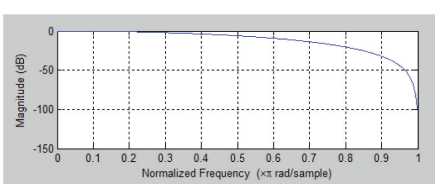

Figure 2. Theoretical transfer function.

Figure 2 shows that the frequency ache is normalized. For the comparison of the results must be considered that $\pi = J_S /$. To compare the practical results with theoretical values, different sinus signals with different frequencies are conveyed over the digital filter on the board. Consequently the attenuation of the signals on the output is measured. The logarithm output attenuation is given with the following equation.

$$A_{dB} = 20 \cdot \log\left(\frac{U_a}{U_e}\right) \tag{10}$$

The following signals will be conveyed over the system.

Input signals

- Sinusoidal signal with f1 = 5 kHz and A = 3.3V
- Sinusoidal signal with f1 = 10 kHz and A = 3.3V

The normalized frequency of 5 kHz is on the 0.21 point. The theoretical attenuation on this point is approximate 0.96 dB (see Fig. 3).

At this attenuation the output signal must be approximate 2.95V by the input signal with the amplitude 3.3V. This can be calculate by equation 11.

$$U_a = 10^{\frac{A_{dB}}{20}} \cdot U_e \tag{11}$$

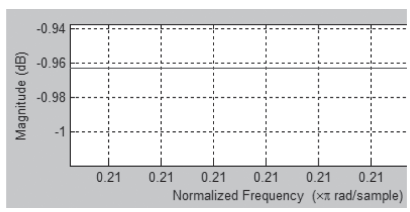

Figure 3. Theoritical tranfer function at the frequency 5 kHz.

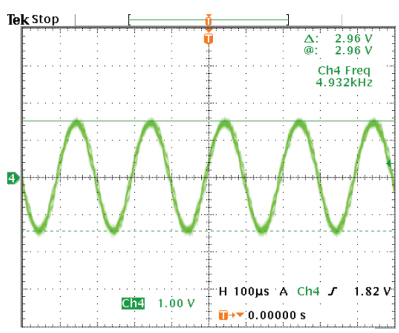

Figure 4. The practical amplitude value at the frequency 5 kHz.

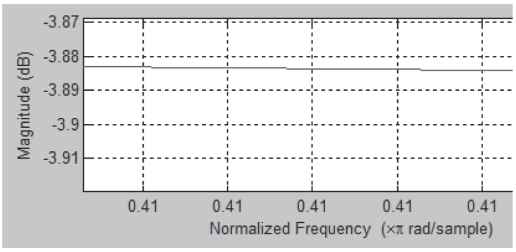

Figure 5. Theoritical tranfer function at the frequency 10 kHz.

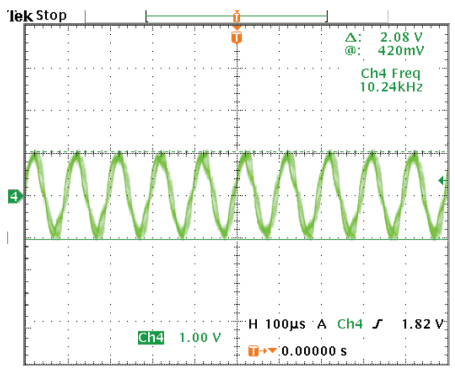

Figure 6. The practical amplitude value at the frequency 10 kHz.

The output signal is 2.95. This can be seen in Figure 4. The theoretical value is equal to the practical value.

Now the second signal with the frequency of 10 kHz is conveyed over the System. The normalized frequency of 10 kHz is on the 0.41 point. The theoretical attenuation on this point is approximate –3.88 dB (see Fig. 5).

At this attenuation the output signal must be approximate 2.11V by the input signal with the amplitude 3.3V. This can be calculating by equation 2. The output signal is approximate 2.11V. This can be seen in Figure 6. The theoretical value is equal to the practical value.

6 CONCLUSION

In this documentation an implementation of a digital filter in a FPGA structure is described. The implementation was done on a FPGA-Board from the company Diligent Inc. The FPGA-Board is known as BAYSIS 2. It was implemented a low pass filter second order. After the implementation the results was discussed. In the final section a safety concept without limitation was described. This safety concept will be a basic principle of the future work. In the future work it will be investigate more time to make the safety concept with limitation and diversity-approach witch are stable and safer. For example with a limitation it can be guaranteed the filter don't work out of range. This limitation will be designed redundant. In addition the limitation will be monitored with a diagnostics concept. This will be described in a next research work.

Heat Supply System reliability management

B. Babiarz
Rzeszow University of Technology, Rzeszow, Poland

ABSTRACT: According to the Polish energetic law act, the aim of heat engineering is to provide an uninterrupted and reliable supply of heat for consumers using commonly available services. One of the heating industry's measures of service is the reliability of this supply, determined by the following requirements, which are: the supply of heat to consumers by means of a heat-carrying agent having the necessary parameters (required quantity, temperature and pressure) in a specific location, under certain operational conditions and timeframe.

Every interruption in the heat supply to consumers indicates a decrease in the heat supply's reliability. Interruptions result in a decrease of the required parameters of a system's elements, which in consequence has an effect on users' discomfort.

Reliability management in Heat Supply System (HSS) requires consideration of their complexity and specific characters. In a heat supply system, three subsystems have been distinguished: subsystem of heat production, subsystem of heat supply and subsystem of heat distribution, which consequently consists of modules, objects and elements. The necessity and possibility of using modern techniques methods in order to improve reliability of elements, objects, subsystems and a whole system have been analysed in this work.

Presenting new methods of heat supply system operation reliability and safety management has been the main purpose of the paper. Application of methods has been showed in example of existing HSS.

1 INTRODUCTION

Heat Supply System (HSS) may be included in relatively complex technical systems. It belongs to energetic systems, being a part of the critical infrastructure, which is necessary to normal functioning of the country.

There are the following targets in the heat supply of the city:

- basic—directed for maintenance of reliability and safety in operation and commonness supply, constituting an element of all the next solutions,
- sustainable development, which follows to possible the lowest costs of energetic services considering environmental costs,
- ecological, which assumes wide scope of state environment improvement,
- social, considering the lowest share of energetic services costs in households.

The basic objective seems to be priority because of the impact on a possibility of realization other targets.

Correct operation of district heating systems gives a possibility to fulfill the requirements of users. Existing infrastructure is very various when it comes to technical and economical view. Technical effectiveness of the district heating sector has an influence on correct and optimal operation of all system.

Heat engineering like any other sector cannot exist nowadays without IT systems. Majority of system heat suppliers use it now or implement modern integrated systems, which is supportive in management enterprise and efficient customer service. Software is however only a tool assisting proper management of a system.

2 STRUCTURE AND SPECIFIC CHARACTER OF HEAT SUPPLY SYSTEM

Heat Supply System (HSS) is one the communal engineering systems consisting of technical infrastructure. At the same time it is one of the youngest and the most interdisciplinary systems connecting many technical fields such as: power engineering, civil engineering, environmental protection, transport etc. There are many features distinguishing district heating sector from of the others. HSS characterises completely local character. The locality of HSS is reflected among other in a lack of heat transfer possibility between cities, which in consequence means that it is not possible

to cover the heat requirements of the country in such a manner that it is possible in the case of electricity or natural gas.

The specific character of HSS involves changeable heat load during the year resulting from external climatic conditioning, in which is our country. The ensemble of climatic condition causes the extraction of a heating season during the whole year which is an established period in which external temperatures don't exceed +10 ^{0}C. During the heating season HSS work for the needs of heating buildings, preparing hot water, ventilation and possible technological needs, however during the after heating season it works with decreased heat load, covering the demand for heat only for hot water and technological ones according to individual production demands. Considerable differentiation of the level of HSS load and its dependence on changing external conditions as well as line functional and structural connections make them different from other technical systems.

Moreover a considerable thermal inertia in supplying the heating medium from the heat source to consumers as well as the need to foresee the sequence of weather changes create considerable difficulties in proper control of heat supply in including reliability in the operation.

Analyzing the issue of Heat Supply System (HSS) reliability requires taking into consideration their complexity and the extent of realization. In the heat supply system we can distinguish three subsystems: Subsystem of Heat Production (SbHP), Subsystem of Heat Supply (SbHS) and Subsystem of Heat Distribution (SbHD), which consequently consists of modules, objects and elements, (Babiarz 2005). There are connections between particular HSS elements and their coherent influence on operational reliability of the whole system. The structure of HSS decomposition into subsystems is presented in Figure 1.

The characteristic feature of heat-supply systems is the occurrence of many operational states of the system at various heat load and efficiency, determined by a range of random factors affecting the demand for heat. From the standpoint of reliability the states are described by a combination of damaged and undamaged elements connected with each other by means of appropriate structures.

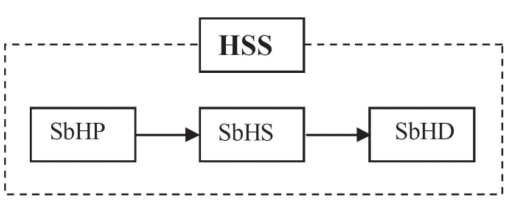

Figure 1. Decomposition of HSS into subsystems.

3 CRITERIA OF HSS RELIABILITY MANAGEMENT

3.1 *Reliability and safety*

Considering HHS as three subsystem set require distinct formulating of the management criteria.

The criteria concern meeting quantity and quality requirements, determined by external conditions. They consider variability in time (fixed variable), space (free and constrained), the nature of interaction (static, dynamic, percussion), causes of failure and above all the possibility of monitoring and control.

Reliability of HSS (REL) is its property which allows it to meet the requirements set, which are the supply of heat to consumers by means of a heat-carrying agent having necessary parameters (required quantity, temperature and pressure) in a specific location, operational conditions and duration of time, (Babiarz 2010).

What is connected with the reliability is safety as a condition of certainty, not occurring threat, the ability of the system to ensure the safety of HSS's users, other systems' users and the environment.

There are many methods using mathematic and simulative tools that can be applied in the evaluation of the reliability and safety in management of various technical systems. More detailed information about it are presented in articles: (Blokus 2006, Rak 2009, Helseth 2008, Ostrowski 2014a,b, Kołowrocki 2013, Todinow 2006, Tracz & Ostrowski 2012). The theory of reliability in heating, ventilation and air conditioning was concentrated in publications (Myrefelt 2004, Peruzzi L. et al. 2014).

Measures of Reliability (Rel) and Safety (S) can be determined according to following relations, (Rak & Babiarz 2001).

Probability of the system reliability provided the non-occurrence of the loss of safety:

$$P(REL/S) = \frac{P(REL) \cdot P(S/REL)}{P(S)} \tag{1}$$

Probability of the system reliability provided the occurrence of the Loss of Safety (LS):

$$P(REL/LS) = \frac{P(REL) \cdot P(LS/REL)}{1 - P(S)} \tag{2}$$

Probability of the system unreliability (UN) provided the non-occurrence of the loss of safety:

$$P(UN/S) = \frac{P(UN/S)}{P(S)} \quad (3)$$

Probability of the system unreliability provided the occurrence of the loss of safety:

$$P(UN/LS) = \frac{P(UN/LS)}{1 - P(S)} \quad (4)$$

3.2 *Quantity parameters*

Flow of heat-carrying agent is the quantity parameter which compliances the level of meeting requirements by the HSS. The flow rate results from thermal power demand (Φ), dependent on atmospheric conditions. Thermal power transmitted by hot water using heating network is changeable during the time (t). Typical trends of changes relative thermal power during the year presents Figure 2—the structured graph of thermal loads.

3.3 *Quality parameters*

Because the biggest influence on medium heat demands have atmospheric conditions, the regulatory graph can be determined for every type of control. Figure 3 presents dependency regulated parameters, such as: flow temperature T_f, return temperature T_r upon external temperature Te.

The regulation graphs are drawn taking into account the structure of the thermal power demand (Wojdyga K., & Niemyjski O. 2012). The example regulation graph for HSS working for heating and hot water preparation demands have been presented in the Figure 3. The correction, determined by the degree of cloudiness and wind speed contain more detailed charts.

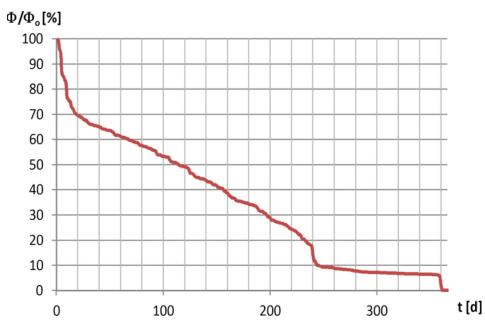

Figure 2. The structured graph of thermal loads.

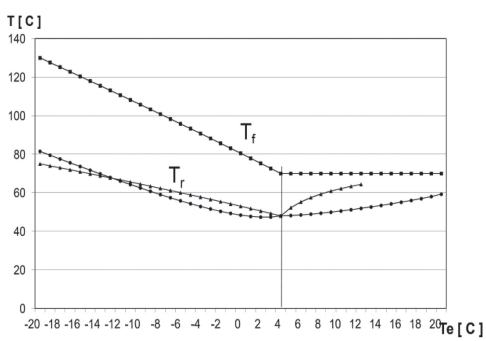

Figure 3. The regulatory graph.

4 METHODS AND TOOLS IN RELIABILITY MANAGEMENT

4.1 *Determinants of reliability management*

Reliability management means change in approach to problems of production, transmission and distribution of thermal energy, taking into account quality of performing services of heat supply. Reliability management should be treated as a complex process containing also safety, (Berg 2008, Rak J.R. 2007, Tchórzewska-Cieślak B. 2009, Tchórzewska-Cieślak B. 2012, Todinov 2006). It covers methods and tools based on experience, in order to identify potential faults or risks at an early stage in the life cycle, (Dou et al. 2011, Vališ & Zając 2010, Vališ et al. 2010).

An admission to introduction more advanced methods of reliability management should be thorough records, control and analysis of operational parameters in the system with reliability and safety evaluation. Proposed schema of reliability and safety of HSS management presents Figure 4.

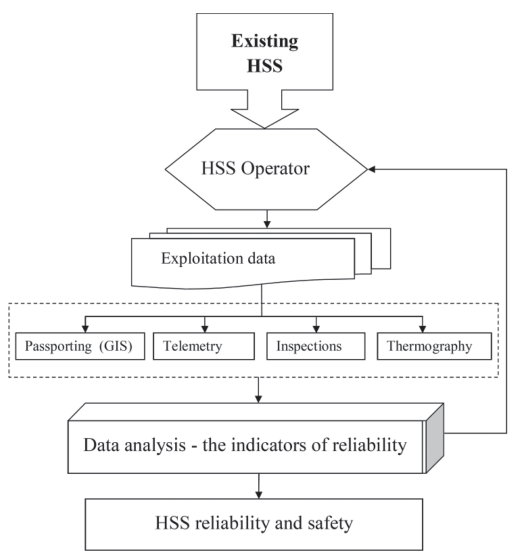

Figure 4. Scheme of HSS reliability and safety management.

In connection with growing competition incomes of enterprises generally decrease. In order to maintain or increase them, it is necessary to maintenance dependability of equipment at the proper level with the lowest costs, so the technical, operational and economical tasks appear.

Technical tasks:

– maintenance the functioning of the equipment and networks required to ensure the required level of heat supply,
– maintenance the operation of equipment to ensure their proper functioning for a long time.

Economical tasks:

– creation a plan to maintain the network and facilities providing the minimum cost of ownership over the "life";
– standardization of equipment maintenance costs;
– retaining proportionality the cost of maintaining the network and devices to the production costs, so that they are a component of variable costs;
– maintaining variable costs at the level specified as a percentage of sales volume of thermal energy;
– planning repairs of networks and devices in order to avoid additional costs associated with the aftermath of damage.

Awareness of the effectiveness of technical resources while maintaining SZC such trends significantly increases. As a result, the reliability can be treated as a commodity, so retaining appropriate level of reliability requires some costs. It should therefore strive to optimize in this area. Particular allowing active actions and decisions in this area is the availability of more and better tools that allow you to collect information about the system during operation, and then use them in the analysis of reliability and safety as well as economic analysis, (Toktasynova et al. 2014, Nowakowski & Werbińska-Wojciechowska 2009, 2010).

4.2 *Network inventory in district heating*

Network inventory of district heating (passporting) networks consisting in electronic records and technical inventory data, together with their description. Course of the network is shown in the available digital maps. Network inventory provides a database of networks for the purpose of exploitation. It helps to carry out the modernization of the network. The system includes a library of basic technical data and symbols of network devices. Network inventory system is based on GIS (Geographic Information System). GIS fulfill a role as a module, that combines other IT systems. This is due to the fact that 80% of the objects, about which information are collected, have a spatial position. Geographic Information System is not only for network inventory, but it also solves real business and technical problems. The main feature of GIS is to provide a mechanism for entering, gathering and storing spatial data, management, providing their integrity and consistency and allowing for their initial verification.

On the basis of the data collected in the system, it is possible to carry out specific analyzes based, among others, on the spatial relationships between objects. The results of spatial analysis and operations characteristic of the programs of base-set may be presented in the descriptive (tabular) or graphic (map, we diagrams, graphs, drawings) form, hence the visualization and sharing of spatial information in the desired form are features of the system.

GIS is a system composed of four inseparable and equivalent elements:

- spatially oriented data;
- hardware and software;
- problems or tasks to be solved;
- people making system and using results of analyzes.

This system provides the following capabilities:

- networks and devices records;
- prediction of heat consumption and thermal power ordered by customers;
- support disaster recovery;
- inventory of assets;
- analysis and statement related to business;
- hydraulic and thermodynamic calculations;
- monitoring of investment and repair activities;
- assist the work of disposal and registration of the network;
- supporting the process of connecting a new recipient;
- integration of the systems in heating enterprise.

4.3 *Telemetry system*

Telemetry system is part of the monitoring, which is used for remote monitoring and controlling district heat network devices. It enables observation of individual elements and objects district heating network in on-line mode. Heat sources, heat exchanger stations and heat chamber are connected to the system. The system allows to control parameters at every point of the city and control of operations carried out currently in the network. It sends periodic inquiries about their status to the devices in the node. It also accepts alarm messages and collects historical information about the node work. Connection of nodes provides transmission equipment through a wired network and the GSM

system. Specialists can watch work of sources and heat networks through a visual representation of the network and its current parameters on monitors. Incoming information are collected in a database server telemetry. This allows to perform detailed analyzes, as well as the aggregation of the data to more general comparisons.

4.4 *Direct maintenance*

Direct inspections are important from the point of view of heat supply security to customers. They require usage of specialized equipment to the location of network failures, leaks and control of a district heating networks. Infrared cameras and other devices, which are part of the resistive pulse or alarm systems, are used to analyze the quality of the insulation of heating networks. They enable ongoing monitoring of the state of the system components to prevent the occurrence of major accidents.

One of the most important system functions for the district heating sector is possibility of remote, automatic reading of heat meters, combined with the collection of measurement results in the so-called repository. Modern IT systems for heat engineering collect information about each device heating infrastructure and also connection between elements of the heating system. The system supports the settlement process with clients, by continuously collecting and analyzing data. It facilitates monitoring of district heating network and also reduces the risk of failure.

4.5 *Remote thermography*

Remote thermography is the analysis of the district heating network by performing "thermal maps of the city"—risk maps. Remote inspection of heat distribution networks is made by overheat path using infrared technology and is a constant element in the palette of mobile procedures for locating leaks. Through remote and comprehensive analysis of the state heating networks with the use of infrared sensors, image data of geometric and thermal high-resolution can be obtained in a short time of measurement and in identical, predefined measurement conditions. This strategy of collecting the data allows to perform comparative analysis of the entire network on the inspected thermal heat supply area. The aim of the investigation is not primarily to locate individual leaks, but large-area assessment of all elements of the heating network and to register and to differentiate all its weak points. This method's target is to direct funds to the priority network failures and to check workmanship on the route sections after repairing or carrying out new project managements. In this way the analysis of the state of the HSS elements is an objective mean of decision-making about planning repairs and inspections.

5 EXAMPLE OF APPROACH TO THE RELIABILITY MANAGEMENT

Reliability management in the existing heat supply system requires continuous improvement and expanding tools of monitoring and control. On the basis of the exploitation data provided by the Municipal Heating Company in Rzeszow city an approach to the management of the reliability in the existing heat supply system have been illustrated. Schema of Rzeszow HSS using the Inventory system is shown in Figure 5.

Inventory system in the HSS of Rzeszow city enables a comprehensive solution to the problem of management of spatial resources. It is based on a foundation consisting of two products:

- *Smallworld*—a universal geographical information system of General Electric company, being the mean of creating specialized GIS systems for asset management, particularly in network industries;
- *EC.GIS*—specialized GIS system for enterprises of thermal energy distribution of Globema company, based on *Smallworld*, composed of a number of functional modules.

Figure 5. Scheme of Rzeszow HSS using the inventory.

Such built system is configured and integrated with other IT systems in Municipal Heating Company in Rzeszow city.

The main functional modules of the system is the *Main Module*, which is used by the following modules:

- *EC.GIS Dispatcher* module—for switching the stroke and analyzes the state of the network;
- *EC.GIS Operation* module—support exploitation activities on the network;
- *EC.GIS Failures* module—to register of failure and failure analysis;
- *EC.GIS Calculations* module—for the hydraulic and thermodynamic calculations;
- *EC.GIS Investments* module—to support investment planning processes;
- *EC.GIS Net* module—to share data on the web/intranet.
- *Smallworld Spatial Intelligence* module—for business analysis and reporting.

In addition, distinguished interfaces for integration with: Komadres and Telemetry system.

Telemetry system in the HSS of Rzeszow city has 39 points on the network. The current system is a telemetry monitoring system only allows observation of individual objects on—line. Current synoptic image of investigated HSS is shown in Figure 6.

All information read on the premises is sent to disposable centers, where it is converted into a user-friendly visualization program WIZCON by 8.20.

The dispatching centers DC-1, DC-2, DC-3 system user (dispatcher) has the ability to:

- control the operating parameters of a heat source (Fig. 7);

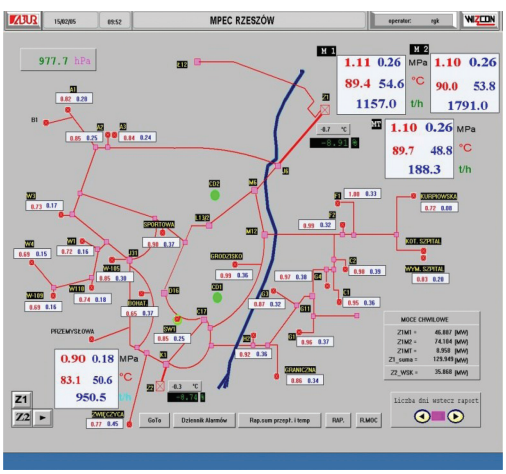

Figure 6. Synoptic image of HSS city of Rzeszow.

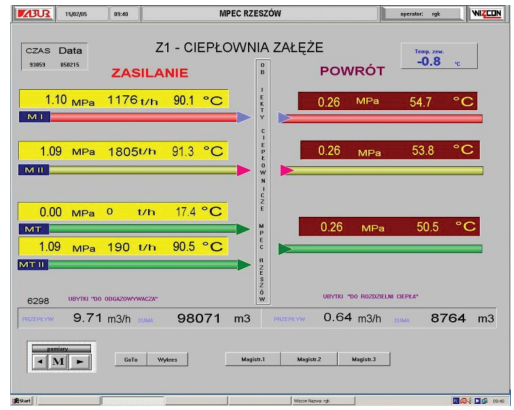

Figure 7. Control of parameters in the heat source.

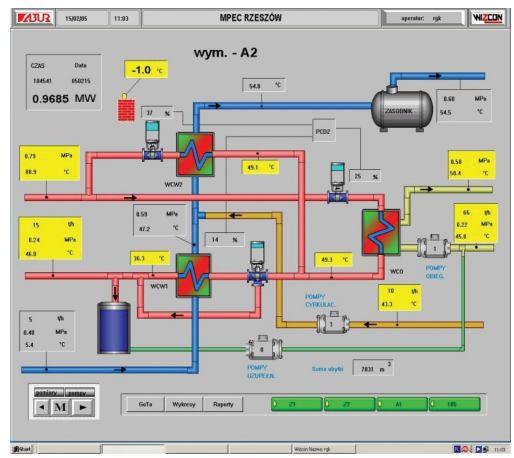

Figure 8. Control of parameters in the heat exchanger station.

- control the operating parameters of the heat exchanger stations and the individual components: pumps, valves (Figs. 8–9);
- control of the level of thermal power usage;
- monitor the carrier losses in heat sources and heat nodes which allows to detect and locate failure in the short-time (Fig. 10);
- control the work and read the level of heat and water meters;
- response immediately to emergency conditions that are reported by the system;
- compile reports concerning operation of individual objects;
- data archive;
- create graphical images of work for performing analysis.

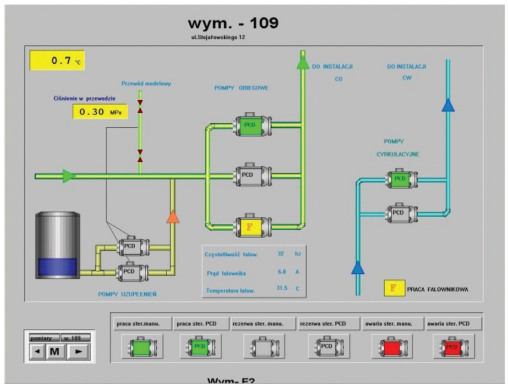

Figure 9. Synoptic image of the pumps control in a heat exchanger station.

Figure 10. Control of water losses in the heating network.

The parameters collected by the system in the form of HTML files, synoptic images, charts, the reports are made available through a network of computers to other users for further analysis.

One of the effects of the use of the possibilities offered by HSS telemetry is to reduce the heat losses and the heat transfer losses to a minimum.

There are many benefits from using Telemetry system, such as:

- conscious management of heat source operation, district heating network and thermal nodes through a solid, all-day control parameters of objects' work;
- disciplining operation of heat sources—enforcement of necessary parameters, the control of the heat carrier losses;
- raising the quality standards of the delivered heat to the customers—supplying adequate thermal power at the right time;
- optimization of nodes' work (number of pumps, pressure, flow—inverters, the level of thermal power usage, thermal comfort recipient);
- rapid detection and minimizing the effects of network's and nodes' failures;
- control of the indication of the measurement systems in heat exchanger and monitored stations;
- continuous monitoring of the heat carrier losses in heat sources and district heating substations;
- possibility of data archiving with the aim of pursuing analysis: daily, monthly, annual, triennial and different ones;
- the ability to verify and adjust the theoretical hydraulic calculations with real data.

Currently telemetry system is still being modernized and developed as well as new facilities are being connected.

6 SUMMARY

Optimal exploitation of HSS, directed to the proper reliability management, determines its proper operation. The variety of devices operating under extensive district heating system requires the support from modern IT systems. In order to maintain the reliability and security of heat supply to the customers, it is necessary to continuously improve and develop of monitoring and control tools, together with application of operating costs optimization.

Consideration of the indicated monitoring and control systems of operating parameters HSS together with reliable records of operational data is required for the proper management of reliability and security of the system. It allows to minimize or completely eliminate the risk of failure to supply heat to the customers.

Uncertainty in the regulation systems of temporary organizations: A challenge for improving the organizational reliability

F. Mazzorana-Kremer, C. Martin & J.L. Wybo
Mines Paristech/CRC, Sophia-Antipolis, France

ABSTRACT: Mainstream economic and sociological theories tend to analyse organizations as permanent entities. However, industry provides many examples of organizations that are not permanent: construction projects, maintenance tasks, crisis management units, the decommissioning of nuclear plants, etc. In addition, classical theories that argue organizations should be long-lasting are inherited from the industrial revolution. Today, many organizations are becoming less rigid and are moving towards more flexible structures oriented to the short-term.

Temporary organizations differ from permanent organizations in that they are designed to have a short lifespan. They are generally created with a specific goal in mind and dissolved once this goal is reached. Different market players interact in these structures: they include distinct legal entities, freelancers or consultants who coordinate their work on a single site or from different geographic areas. Typically the temporary organization is linked to a permanent organization. In other cases, it is fully independent and those involved do not expect to work together once their objectives have been achieved. The unsustainable dimension of these organizations raises many issues in terms of risk and uncertainty.

This paper provides a better understanding of temporary organizations, their coordination, their regulatory systems and their links with the permanent parent organization (if there is one). The research described in this paper is based on a literature review. It provides a typology of temporary organizations and analyses their coordination, regulatory systems and reliability issues.

1 INTRODUCTION

The literature shows that a new trend has emerged in recent years: the increasingly widespread phenomenon of using temporary projects or organizations to perform some tasks or implement new services (Turner and Keegan, 2001; Lundin et al., 2003; Roy and Audet, 2002; Lundin and Söderholm, 1994; Whitley, 2006; Turner and Müller, 2003). This led to an increasing number of new, so-called temporary forms of organization. At the same time, most organizations have been subject to permanent and constant change (Bahrami, 1992; Lundin et al., 2003) which increased their reliance on ad-hoc temporary structures.

There are various kinds of temporary organizations in the industry (e.g. construction sites, periodic maintenance projects and crisis management units). They are defined by their ephemeral nature and modes of cooperation between actors which are different from the usual relationships found in traditional organizations. Often embedded into permanent organizations (particularly for large construction projects and periodic maintenance in complex socio-technical systems), these organizations show a high degree of autonomy and are subject to forms of internal and external regulation that are currently poorly understood.

With respect to safety culture, the autonomy and regulation modes found in temporary organizations can lead to divergence from the objectives of the parent organization.

Risk prevention research has so far shown little interest in the parent/temporary organization relationship (Bourrier, 1999) and in the impact of these relationships on organizational reliability. The purpose of this article is to present a typology of temporary organizations, based on a literature review, and to characterize the relationships between their organizational characteristics and the reliability of socio-technical systems.

In the first part of this article we define the temporary organization. In the second part we present the principal characteristics of this type of organization. Finally, we present an initial attempt to link these characteristics and organizational reliability.

2 UNDERSTANDING TEMPORARY ORGANIZATIONS

This section begins with a sample of definitions of temporary and project-based organizations.

Then we propose a definition of the temporary organization and summarize its main characteristics with respect to permanent structures.

2.1 *Definition*

Before discussing safety concerns and organizational characteristics, it is essential to first define what a temporary organization is.

Temporary organizations are, as the wording suggests, organizations that have the particular characteristic of being "temporary". Organizations are more commonly seen as social entities that have a collective goal; they often are characterized by actors, tasks, formal and informal governance rules, regulations and their environment. In this context, temporary organizations can be seen as collective structures, focused on a specific goal—like any other organization—but with a "temporary" dimension. This temporary dimension can be related to its ephemeral nature or because their duration appears to be much shorter than the average lifetime of traditional organizations. Their temporary nature means that they are set up to meet a specific goal and are dissolved once this goal is achieved.

Compared to research on traditional organizations, there is little current literature on temporary organizations. However, a certain degree of consensus exists on the characteristics of projects, which can be seen as a particular form of temporary organization. Therefore, in order to refine and improve our definition of the temporary organization, our review included articles related to projects.

Some definitions of temporary organizations and projects are presented in the Table 1.

Most of these definitions are global and implicit. We consider the Goodman definition as one of the most explicit. In practice, most researchers have explored the characteristics of temporary organizations rather than provided simple definitions.

From these definitions, we argue that a temporary organization is a collective and social entity set up for a limited period of time, in order to achieve a specific goal, and dissolved when the goal is reached.

In the next section, we review a selection of relevant articles in order to determine the main characteristics of temporary organizations with respect to permanent structures.

2.2 *Main characteristics of project-based and temporary organizations*

Turner and Müller (2003) offer some insight into the definition of a project as a temporary

Table 1. Definitions.

Reference	Definition of project/temporary organization
Goodman and Goodman (1976)	Temporary organizations involve "a set of diversely skilled people working together on a complex task over a limited period of time."
Keith (1978)	"Temporary systems are structures of limited duration that operate within and between permanent organizations."
Cleland and Kerzner (1985)	A project is "a combination of human and non-human resources pulled together into a temporary organization to achieve a specified purpose."
Turner (1990)	A project is "an endeavor in which human, material and financial resources are organized in a novel way, to undertake a unique scope of work, of given specification, within constraints of cost and time, so as to achieve beneficial change defined by quantitative and qualitative objectives."
Lundin and Söderholm (1994)	"Temporary organizations are almost always motivated by a need to perform specific actions in order to achieve immediate goals."
Packendorff (1995)	A project is "a given, plannable and unique task, limited in time, complex in its implementation and subject to evaluation."
Lundin et al. (2003)	"A project has a beginning and an end, and has none of the aspired continuity of the ordinary organization." "A project tends to pass through a series of phases during its lifetime." "Projects generally have two very characteristic features: they have been designed for a purpose so their existence is delimited in time from the moment of their creation, and they are focused on one primary task."
Turner and Müller (2003)	"A project is a temporary organization to which resources are assigned to undertake a unique, novel and transient endeavour managing the inherent uncertainty and need for integration in order to deliver beneficial objectives of change."
Janowicz-Panjaitan et al. (2009)	Projects are "one of many tangible manifestations of temporary organizations." According to the authors, "despite the great diversity of forms and activities temporary organizations undertake (…) temporariness is the only factor that is unique to TOs, while others are simply consequences or correlates thereof."

organization. They argue that projects are unique, special forms of organization, found in businesses that use innovative and transient processes. They view the project as an organization with a production function, a temporary organization and as an agency created to guide change, use resources and manage uncertainty.

In 1994, Lundin and Söderholm, in their theory of temporary organizations, presented action as the main concept of temporary organizations. They argue that temporary organizations are almost always "motivated by the need to perform specific actions to achieve immediate goals". They defined the temporary organization in terms of the contrast with permanent organizations and highlighted the following characteristics:

– it has a limited lifespan, which is established at the outset;
– typically, the creation of a temporary organization is motivated by a task that must be accomplished;
– it consists of a team that is put in place for a known, limited period. The skills and expectations of team members provide the commitment and motivation that will enable the organization to function and accomplish its task;
– it enables transition, a change.

These characteristics highlight that the temporary organization, or an internal project, is defined by its temporality and a task to be accomplished.

However, if the temporary organization is completely assimilated to the project, there is a risk of overlooking the collective dimension of the organization. In practice, 'organization' usually refers to a set of individuals and resources that are coordinated in order to meet a shared goal (Simon, 1983). The organization is therefore often characterized by resources, individuals, the rules governing their relationships and their behaviour in order to maximize the chances of achieving the collective goal.

From this point of view, the concept of the temporary organization refers to the collective nature of action. Here, the approach put forward by Packendorff (2002) differs significantly from others and is a useful addition to our argument. The author reminds us that the literature usually defines the project as focused on a given task, which is unique, follows a set timetable, is time limited, complex to implement and evaluated. Packendorff argues that projects are often seen as tools. Little attention is given to the motivation of the individuals who participate in them; although in practice they suffer from the same dysfunctions as other organizations. He therefore suggests that "Projects should be researched in terms of culture, conceptions, relations to the environment, longitudinal processes, etc., rather than simply as goal-fulfilling

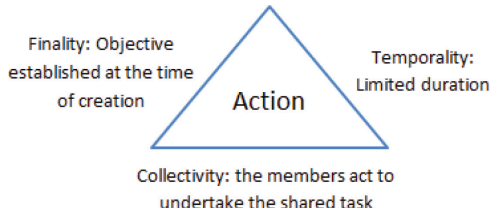

Figure 1. The key dimensions of temporary organizations.

subsystems whose *raison d'être* is provided by a decisive and strategically aware super-system."

According to Packendorff (2002), the project is a temporary organization. However, while a project is generally seen as a "tool" and only implies a user perspective, a temporary organization is constantly embodied by individuals who are continually learning from their experience and who expect to learn more. This suggests that research into temporary organizations should focus more on the actors, their expectations, their actions and what they learn.

This last point underlines the need to understand the collective dimension of this type of organization. We argue that the context for the temporary organization is unstable and that its existence coincides with the achievement of an action. Specifically, it is defined by three fundamental characteristics that distinguish it from the permanent organization or project: its temporality, its predetermined time-sensitive objectives and the collective nature of the action.

The analysis of a temporary organization as an organization and not as a project invites us to also examine its actors, their expectations, and the problems of leadership, control and coordination.

In the next section we focus on the relationship that a temporary organization has with a permanent organization that is responsible for its creation.

2.3 *The relationship between temporary organizations and the permanent parent organization*

It is reasonable to ask what motivates the creation of a temporary organization. Some researchers, such as Modig (2007), highlight the stronger or weaker relationships that may exist between a temporary organization and the permanent organization responsible for its creation. Others (Turner and Keegan, 2001; Turner and Müller, 2003) analyse the temporary organization in terms of a project and see it as a way for a permanent organization to assume a production function while managing the

uncertainty of change. It can also be the genesis of an organization (Lundin and Söderholm, 1994); for example the result of an entrepreneurial effort.

In the case where a permanent organization is responsible for creating a temporary organization, the latter generally pursues objectives that are in the interests of, and in line with those of the parent company.

In the case where a temporary organization fully independant is created, typically in response to an identified need, one or more individuals form its nucleus. In this case, the time-limited nature of the organization is more dependent on the positive motivation of its instigators. This is particularly the case with start-ups and organizations that are designed to make a short-term capital gain or profit.

We note that if a temporary organization is linked to a permanent parent organization, its collective objectives are likely to be linked to the interests of the parent organization. If this is not the case, collective objectives will have been set by one or more individuals before the temporary organisation was created and will correspond to their expectations or interests (financial added value, sporting or artistic events, humanitarian commitments, etc.).

In the next section we analyse its modes of operation as an organization.

3 THE CHARACTERISTICS OF THE TEMPORARY ORGANIZATION

As the temporary organization is a form of organization, it is interesting to analyse how it implements collective action and what issues arise related to decision-making, control, coordination and conflicts.

In this section, we look at how the temporary organization operates (particularly collectively) and we aim at highlighting the characteristics that make it different from the permanent organization, in order to understand the risks and uncertainties specific to this type of structure.

The temporary organization is, as an organization, in part defined by its objectives and the tasks to be accomplished to meet these objectives, which are assigned to people at different levels of the hierarchy (Simon, 1983). Many conditions are necessary to achieve these collective goals. Here we look in more detail at the following:

- The bond of individuals with the organization. The activities of a group of people are only organized to the extent that they allow their bond with the organization to control their decisions and behaviour (Simon, 1983, p.99): this bond is possible only when "directly or indirectly their activity within it contributes to achieving their own goals."
- The definition and coordination of tasks, which makes it possible to centralise decisions, define the roles of members of the organization and achieve the collective goal.
- The exercise and respect for authority, which ensures the necessary coordination between actors and tasks.
- Communication, which enables the transmission and processing of the information necessary for decision-making and for the execution of tasks within the organization.

In the following sections, we analyse to what extent these conditions are met in a temporary organization.

3.1 *Individual bonds with the organization*

For an organization to function according to its initial objectives, these objectives must be compatible with those of the individuals and the objectives of the individuals must also be compatible with the organization's limited timeframe.

In practice, when members of a temporary organization are linked to or employed by its parent organization(s), they are likely to support the project if it improves their remuneration or promotion prospects. A permanent organization that prospers and grows rapidly can offer greater prestige and promotion opportunities (Simon, 1983, p.105). This means that an individual seconded by the permanent organization is likely to value the positive impact it may have on its career, once the collective goal has been met.

However, in cases where individuals working in the temporary organization are not seconded by a permanent structure, their commitment to the goals of the organization will probably depend on the potential beneficial effect on their future career, once the structure has been dissolved. In this case, their motivation may be shaped by substantial financial benefits related to the achievement of collective goals or the hope of better employability in future structures. This is only possible if their work has had high visibility *vis-à-vis* external actors. This idea has been put forward by Modig (2007) and Packendorff (2002) in particular, who argue that the duration of the involvement of actors and their relationship with a permanent parent organization, if any, will influence their behaviour. People who are hired for a limited time by a temporary structure will be more loyal to their network or other potential professional partners than members of the organization. This is explained by the fact that they seek to secure future employment or contracts. "There is a risk that employees whose future work opportunities or position in an organization are dependent on their visibility in earlier projects […], will act opportunistically" (Modig, 2007, p. 810).

In this section we have shown that the bond that individuals form with a temporary organization is not the same as that found in a permanent organization. We also have seen that the members of the organization have a different motivation when they are employed by a permanent parent structure than when they are completely independent; the latter case can present a risk of opportunism and departure from collective goals.

We now examine issues related to the definition and coordination of tasks in temporary organizations.

3.2 *The definition and coordination of tasks*

According to Simon (1983, p. 124), the purpose of coordination is that all members of the group adopt the same decision or, more specifically, take consistent decisions, which when combined, achieve the intended goal. According to the same author, there are two types of organizational coordination: "form", which defines the domain of competence and the limits of the authority of each worker and "substance", which specifies the nature of the task for the individual (e.g. drawing up strategy).

According to some authors (Modig, 2007; Oerlemans et al., 2009), the definition of rules and tasks in a temporary organization depends on the role and involvement of the parent company(s) that it is linked to. In particular, research carried out by Modig (2007), although conducted on a small sample, suggests that, "the more involved a stationary 'parent' organization is in a project, the more guidelines are given as to how the temporary organization is to perform its task." However, according to the author, "Temporary organizations that are 'pure' or virtually 'pure' instead have to develop routines and procedures internally."

Modig adds that, "If work roles, relations and required skills and competencies are well defined, this can reduce the risk for rivalry and conflicts in temporary organizations and facilitate the training of new employees." It also allows the transfer of accumulated knowledge from one project to another, with the advantage of making organizations more competitive and mistakes more easily avoidable. The counterpart is that when rules are predefined, then an element of flexibility and creativity in the organization is lost. In this case, "members of temporary organizations might be more restrained than helped in their work by predefined work processes, as these can hinder them from using their knowledge and skills to develop work routines that match the unique project conditions." Modig (2007).

Oerlemans et al. (2009, p. 36) looked at collaborative temporary organizations in several German Small- and Medium-sized Enterprises (SMEs). Based on a survey of 1,500 SMEs having participated in collaborative programs, the analysis focused on the management style chosen by the organization and founded, on the basis of four case studies, that they were managed in different ways (Table 2).

Other work (Janowicz-Panjaitan et al., 2007) focuses on the literature concerning project coordination or temporary organizations. The authors argue that temporary organizations are generally less formal and normative than permanent organizations. In addition, they have fewer hierarchical processes and bureaucracy and make greater use of interpersonal coordination. However, one example of interpersonal coordination is trust, and it can be difficult to build trust in a context where

Table 2. Characteristics of temporary organizations highlighted by Oerlermans et al. (2009).

	No further collaboration once the project has ended	Ongoing collaboration between companies once the project has ended
Collaborative project under 36 months (average)	Case 1: film production Coordination is provided by a specific role such as a "director" or "general contractor". Hierarchical roles Work takes places in a specific timeframe with contractual deadlines that are fixed according to the phases of the project Personal relationships are only important for a few key players	Case 3: network alliances Coordination is provided by the lead company that provides products and services Deadlines and roles contractually defined Work takes place according to the phases of the project Relationships between partners continue from one project to another
Collaborative project over 36 months (average)	Case 2: crisis management Coordination is provided by a third party Hierarchical roles Working patterns are learned and respond to the needs of the crisis Little priority is given to personal relationships	Case 4: major construcion project Coordination is handled by the lead company or the government agency Work takes place according to the phases of the project

time is limited. To explain this, the authors refer to the work of Ness and Haugland (2005), which shows that even in a short-term collaboration, relational norms and trust develop. According to the authors, "while hierarchical control mechanisms can supply the necessary confidence level, the trust that is necessary to assure sufficient information sharing for problem solving does evolve despite the temporary nature of a project".

The examples cited above lead us to the following conclusions:

The definition of the roles and tasks in a temporary organization is often carried out upstream by the permanent parent organization(s) if there is one, and when there are strong links with it (Modig, 2007). However, if this is not the case, it is carried internally, by the temporary organization itself;

When a collaboration implemented by the temporary organization must be renewed after its dissolution, the lead parent company usually coordinates tasks and actors (Oerlemans et al., 2009). On the other hand, in cases where it is unlikely that the collaboration will be renewed, coordination is undertaken by a dedicated person or group belonging to the temporary organization.

Finally, temporary organizations generally have fewer formal coordination and bureaucratic processes and rely more on the interpersonal skills of their members. These informal processes require a minimum level of trust to ensure collaboration and the resolution of problems.

In the next section, we analyse the different management styles that are implemented, which make it possible for this type of organization to successfully meet its objectives.

3.3 *The managerial dimension of the temporary organization*

In an organization, management and authority are necessary to ensure respect and the coordination of tasks. Authority, according to Simon (1983, p. 119) is the relationship that coordinates the behaviour of a group by subordinating the decisions of an individual to those that are communicated by others. Individuals particularly respect authority under the following conditions: when the person who gives the orders (typically the project manager or the director of the temporary organization) is recognized as competent by peers and subordinates; when the individuals who receive the orders are responsible and naturally accept authority; when the person giving the orders has the power to sanction; when authority does not come from several persons giving contradictory orders; when the given tasks are consistent with the personal goals of the individual.

These criteria raise the question of the coexistence of several management teams. If the temporary organization does not have its own management structure, including a command unit, there is a risk of conflicts or problems with authority.

Research by Oerlemans et al. (2009) highlighted three management configurations in temporary collaborative organizations in German SMEs: co-management by several parent organizations, management by one of the parent organizations, or management by a dedicated, project-specific team. In general, each of the three cases occurs equally often. The exception is collaborative projects with few parent organizations, in which case co-management by parent organizations is found more often.

According to Turner and Keegan (2001), uncertainty about the product and process is greater in the project context than in a classical organization or business. Simple routine management by the permanent parent organization, when there is one, may not be sufficient for the project; it may prove unsuitable and raise the risk of error, opportunism and lack of customer satisfaction.

Turner and Keegan highlight that such projects need a governance interface between them and routine operations, beyond the normal hierarchy. They argue that, in addition to the project manager who manages the project's processes, the governance structure is based on two key roles: the broker and the steward. The role of the broker is to maintain and monitor the relationship(s) with the client(s): they ensure that deliverables and products meet the expectations and needs of customers. The steward "puts together the network of resources to deliver the project, ensuring that the right people are in the right place at the right time to ensure it happens."

For the authors, depending on the type of project organization (if they manage one or multiple projects, or one or many clients), the roles of the broker and the steward will be more or less important and may be partially assumed, or not, by the project manager. In all cases, the authors note that these roles should be separate and this is what is seen in practice. There is a psychological explanation, "the broker must align with the culture of the client, whereas the steward must align with the culture of the competence pools." "The broker is essentially an extrovert, entrepreneurial role, whereas the steward is essentially an introvert, intrapreneurial[1] role."

The examples cited above lead us to the following conclusions concerning the management and governance of temporary organizations or projects:

- There are three types of management in temporary organizations: co-management by many

[1] a person who while remaining within a larger organization uses entrepreneurial skills to develop a new product or line of business as a subsidiary of the organization.

permanent parent organizations, management by one of the parent organizations, or management by a dedicated, project-specific team. (Oerlemans et al., 2009). When there are parent organizations, there is no real trend; the exception is where there are few of them, in which case it is more often that case that management is exercised by the parent organization(s).

- Whatever type of management is in place, authority must not emanate from several hierarchical superiors who manage the same tasks and may give contradictory orders.
- When there is a permanent parent organization there should be an interface between the governance of the parent organization and that of the temporary organization (Turner and Keegan, 2001). Three key roles make this possible:
  - Theprojectmanager, who manages all of the project's processes.
  - The broker, who checks that the services or products meet the client's expectations and constraints.
  - The steward, who organizes and mobilizes the human and technical resources necessary to obtain the services and products defined or re-defined by the broker.

The latter two roles make it possible to manage on the one hand the bilateral dependency between the client (which may be the parent organization) and the project team and, on the other hand, uncertainty surrounding the product or service undertaken.

The question of authority and management is therefore important in a temporary organization as, very often, several independent individuals or structures coexist. When different control structures are shared, it is essential that they ensure the efficient coordination of tasks within the timeframe and budget constraints initially set. The next section is dedicated to another key parameter for the proper functioning of the organization: communication.

3.4 *Communication in the temporary organization*

Communication is another key element in the organization as it enables it to carry out its objectives collectively. In particular, it enables the transmission and processing of information necessary for decision-making and the execution of tasks within the organization.

According to Simon (1983), there are two types of communication in an organization: formal and informal. The formal communication system is implemented notably by discussions, letters, circulars, reports and should, according to the author, be sufficiently well organized and robust to ensure that actors and their personal interests cannot weaken the organization. The informal communication system "is built around the social relations of the organization's employees." This latter type of relationship is created spontaneously by individuals to advance their personal goals or collectively to establish their power within the organization, "it could be said that the weakness of the formal system of communication and the ensuing lack of coordination appears to encourage the formation of cliques" (Simon, 1983, p. 143). Here, cliques mean a group of individuals united by a common interest that differs or even goes against the collective interest of the organization.

Therefore, the question that arises in a temporary organization concerns the robustness of the formal communication system, which is necessary to avoid the formation of cliques that may divert the organization from its objectives. However, the limited duration of such an organization is likely to make it difficult to set up a formal communication system if it is not inherited from a permanent parent organization.

Some of the research mentioned above sheds light on the functioning of communication and the exchange of information in temporary organizations. According to Modig (2007), "All organizations need a variety of resources to perform their activities. Thus, easy access to key resources such as skilled professionals, vehicles, tools and suppliers facilitates project work considerably." The author also points out that in a temporary organization there is insufficient time and above all, a shared history to be able to implement channels for the dissemination of knowledge and information. Generally, a permanent parent organization that has a strong influence on the temporary organization will ensure that its actors have access to the resources and information necessary to meet their objectives.

For Turner and Keegan (2001), communication issues are closely related to issues of governance, which defines and provides the means to achieve a project's objectives (Müller, 2009; Turner, 2009). Communication is thus one of the problems of governance. Turner and Keegan (2001) argue that communication within a project structure is made possible and efficient through the roles of the broker and steward defined above. In order to analyse the internal and external communication needs of projects, the authors define four types of project-oriented organization: multiple small projects with a few large clients; multiple projects with multiple clients; major projects with a few large clients; and finally the start-up (comparable, according to the authors to a project associated with multiple clients).

The authors conclude that in the case of organizations managing multiple small projects with a few large clients, the role of the broker is extremely

significant. In this scenario project teams are often relatively independent and it is important that communication is maintained at the interface between them and clients to ensure that the product and the service develop according to the needs of the client. In the case of a multiple projects with multiple clients, the role of the broker is as important as in the previous case but must be complemented by a strong steward who works with the broker to ensure that project teams receive the right resources in order to deliver the expected service or product. In the case of major projects with a few large clients, they note that the project manager has a direct relationship with the client and plays the role of broker. However, in the start-up case they suggest the opposite: the director (who is usually the originator of their product) plays the role of steward and ensures both internal communication and communication with suppliers in order to carry out tasks and deploy resources, while they rely on a broker for external communication.

This research suggests that communication is a key element in the temporary organization due to uncertainty about its services or products; the behaviour of actors makes it increasingly necessary to put in place functions that ensure communication between the permanent parent organization, the client (or the recipient of the goods or services), and the organization's actors.

There is less risk of cliques being created in organizations if actors' roles are defined and there is (for example through the permanent parent organization) a formal structure to ensure communication at the interface between external actors (the client) and organizational resources (suppliers and employees).

3.5 *Conclusions concerning the characteristics of temporary organizations and their regulatory systems*

Our review of the literature shows that various authors (Whitley, 2006, p.79; Lundin and Söderholm, 1994; Turner and Cochrane, 1993; Oerlemans et al., 2009, p.36; Turner and Keegan, 2001; Modig, 2007) have drawn up typologies of temporary organizations, showing that they can be distinguished from each other based on their proximity to the parent organization, the repetitive nature of their objectives, their intra or inter-organizational nature, or the tasks performed (a project to be developed, a new product or market, etc.).

A temporary organization thus appears to be a complex system composed of individuals that are independent or dependent of permanent structures and who interact with each other (whether they are employees of the same company or not), external actors, their network, clients and other businesses.

In these organizations, coordination and communication will naturally orient the behaviour of actors. However, we have seen that these measures, because of the temporary nature of the organization, are often informal and different to the relationships usually found in permanent organizations.

Returning to the work of Turner and Keegan (2001), temporary organizations operate through the action of a few key players: the project manager, the broker and steward, who are responsible for integration and coordination. Other studies (Modig 2007; Oerlemans et al., 2009; Turner et Cochrane, 1993) show that coordination, authority and communication, which contribute to the regulation of these atypical systems, are also conditioned by external systems such as the permanent parent organization, which is linked to the temporary organization.

Therefore, there is a great uncertainty with respect to the ways in which the actors and subsystems of these organizations regulate themselves in order to reconcile interests, individual behaviours and collective goals.

4 TEMPORARY ORGANIZATIONS AND RELIABILITY ISSUES

In this section, we examine two types of risk: risks created when the temporary organization is conceived and risks associated with the temporary nature of this type of organization.

4.1 *Risks insufficiently taken into account in the design phase*

The analysis of the characteristics of temporary organizations has shown that tasks can be organized upstream, by the permanent organization or the temporary organization itself (if it is semi-independent). However, most of the time, as is the case for temporary organizations established for infrastructure projects (power plants, construction sites) or decommissioning (end-of-life oil fields, nuclear power plant decommissioning or waste treatment installations, etc.), operating budgets are often set in advance. This predetermined factor makes it difficult to assess the technical and financial risks once the temporary organization has been established and its tasks have been defined. Safety issues often appear after the design of a project has been fixed and its budgets determined by the various companies involved (Koppenjan, 2001), "Since finding a balance between various interests is a delicate matter, such a disturbance may even jeopardize the realization of the project." This issue raises two fundamental problems: first, when the temporary organization is initiated, there is a need to define and anticipate risk upstream so that

the project's budget and its capacity are correctly assessed; second, the interests of key individuals in the organization must not be an obstacle to the communication of any difficulties encountered as the project progresses—even if this jeopardises the entire project and raises questions about the personal interests of individual stakeholders.

Similarly, the flexibility of temporary organizations, which is based on good interpersonal communication (that is more informal than formal) raises ethical issues. In particular, how is it possible to ensure that project managers and other key individuals will communicate with each other and disclose safety issues that appear once the structure is in place, if their personal interest is limited to their role in the temporary structure and the achievement of objectives? We argue that there is currently insufficient research into the methods and formal systems (both in terms of communication and governance), which should be implemented upstream in temporary organizations to ensure that technical and human risks and divergences from objectives are given sufficient weight. Serious care should be taken to the control modes of actors, which take into account the risks incurred during and after the lifespan of the temporary organization.

4.2 *Risks related to the temporary nature of the organization*

As we have shown, definitions of temporary organizations highlight their limited duration, task orientation and uncertainty. We argue that these criteria lead to specific risks.

First, one of the most important features of temporary organizations is their limited duration. This short lifetime, according Janowicz-Panjaitan et al. (2009) leads to several problems including: lack of time to develop a relevant shared knowledge base, to plan organisational change and to develop trusting long-term interpersonal relations. Furthermore, the author refers to the work of Weick (1993, p. 644) to highlight the fact that the organization, when viewed in the short term, prevents its members from developing goals that transcend their personal interests.

On the other hand, Janowicz-Panjaitan et al. (2009) suggest that when time limitations and the date or the conditions for the dissolution of the organization are known by its members from the beginning, they will feel under greater time pressure than in classical organizations. The work may become more pressurised and is therefore more likely to lead to deviations or errors than in conventional organizations.

Similarly, the uncertainty inherent to temporary organizations may pose more problems than in permanent organizations. Team members have less shared task knowledge; collective learning is lacking and the uncertainties faced by members of the organization must be managed, starting from their ability to communicate and identify problems.

The task-oriented character of temporary organisations makes their members more focused on getting the work done, which can lead to improved performance. On the other hand, they will be less influenced by other factors; the environment and potential risks are not likely to be priorities, due notably to the "emergency" requirement to achieve objectives.

Finally, the time-limited and task-oriented nature of the temporary organization raises issues of psychosocial risk and organizational reliability. Individuals in these organizations are likely to be under more pressure; in addition they are less likely to be loyal to an organization that is doomed to be quickly dissolved than a permanent organization.

5 DISCUSSION

Based on a literature review, our research consisted in describing temporary organizations that we first defined as "collective and social entities set up for a limited period of time, in order to achieve a specific goal". It appears to us that key features of such organizations are their temporariness, their set-in-advance objectives as well as their collective nature. They also are often linked to permanent parent structures and such link can naturally impact the nature of their tasks and goals.

We have highlighted some of the characteristics of temporary organizations: they generally have fewer formal coordination and bureaucratic processes; they rely more on the interpersonal skills of their members; they need specific roles—between their working staff and their external environment—in order to ensure an efficient communication and a proper completion of their tasks.

Thus, our analysis leads us to see them as atypical and complex structures. Such complexity, associated with a high level of autonomy, seem to raise many issues in terms of risk and reliability. First of all, it is obvious that the limited duration of temporary organizations can represent a stressful environment for individuals. It also let little time for the creation of a common knowledge necessary for the successful completion of the collective tasks and goals. Secondly, because the tasks, objectives and financial budgets of such organizations are often determined in advance, an afterwards emerging risk might endanger their survival much more than in a permanent organization. For these reasons, when they are linked to a permanent parent company, project managers, or some other key players, may be reluctant to communicate problems if

these ones endanger the survival of the temporary organization they are involved in.

Therefore, the issue of the reliability of temporary organizations with respect to the parent organization needs more research founded in organizational theory and oriented towards the energy sector where this type of organizations is widespread and the safety stakes are high.

Solutions and safety barriers: The holistic approach to risk-reducing measures

A. Sevcik & O.T. Gudmestad
University of Stavanger, Norway

ABSTRACT: Currently in the offshore industry on the Norwegian Continental Shelf (NCS), there is much discussion about barriers and the interactions between them. This discussion is fostered to a large extent by the Norwegian Petroleum Safety Authority's (PSA) emphasis on safety barriers. The term 'safety barriers' refers to the measures used to reduce the likelihood and limit the consequences of major accidents. However, the question is whether safety barriers are the only measures for risk reduction. This paper will describe the process model of an accident and discuss risk-reducing measures following ISO 17776 and national regulations such as the Management Regulations from the Petroleum Safety Authority Norway (PSA). Two main groups of risk-reducing measures are distinguished: (1) technical, operational and organizational solutions applied to the critical systems and (2) safety barriers. The main focus in this paper is the demand from the Norwegian offshore industry for clarification of the term 'safety barrier'.

1 INTRODUCTION

Generally, risk treatment may be seen as a process which ensures that an acceptable risk level is achieved and maintained. To align with the Norwegian Petroleum Safety Authority regulations, Sections 4 & 5 of the Management Regulations are followed (PSA 2014a & PSA 2014b):

- In reducing risk […] the responsible party shall select technical, operational and organizational solutions that reduce the probability that harm, errors and hazard and accident situations occur.
- Furthermore, barriers as mentioned in Section 5 shall be established. The solutions and barriers that have the greatest risk-reducing effect shall be chosen […].
- Barriers shall be established that:
  - reduce the probability of failures and hazard and accident situations developing,
  - limit possible harm and disadvantages.

Two main groups of risk-reducing measures are named: risk-reducing solutions and safety barriers (Sevcik & Gudmestad 2014).

On further assessment of the definitions provided, it may be stated that risk-reducing solutions are the measures to reduce the likelihood of errors, hazards and accident situations occurring, i.e. preventing hazards (potential source of harm) from being realized. In other words, the solutions are used to reduce the likelihood of such deviations which could initiate (trigger) an unwanted chain of events. Systems that are primary targets of these solutions may be seen as Safety Critical Systems (SCS) and will be discussed further in the paper.

Safety barriers are the measures which are selected after the risk-reducing solutions have been established, with the purpose of reducing the likelihood of failures and hazards, preventing accident situations from developing and limiting the possible harm caused by an unwanted chain of events. Safety barriers are established to reduce the likelihood of the development of an unwanted chain of events when an initiating (triggering) event has already occurred, i.e. a hazard scenario has already started. The main and only function of a barrier is a safety function that is required on demand.

While we make a distinction between the risk-reducing solutions and safety barriers, it is important to see both of them as one entity designed to reduce the risk within performed activities.

2 RISK-REDUCING MEASURES IN AN ACCIDENT MODEL

2.1 *Generic accident model*

In line with ISO 17776 (2000) and its general hierarchy of risk-reducing measures, this work will propose the following risk-reducing phases as generic safety functions: Prevention, Detection, Control, Mitigation and Emergency Response. These functionalities act in the same sequence when placed on the chain of accident development (Fig. 1).

The term 'prevention' can be used with several meanings. In line with ISO 13702 (1999), prevention means a reduction of the likelihood of a

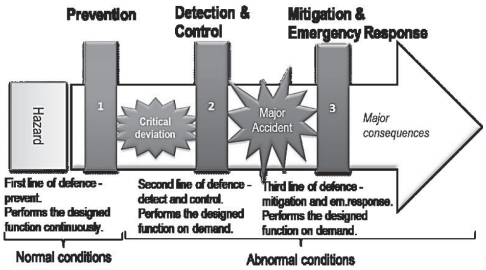

Figure 1. General accident model with safety functions.

hazardous event, and a further specified definition is used in this paper: to prevent means *to reduce the likelihood that a critical deviation occurs,* where critical deviation is seen as an initiating event of an unwanted chain of events.

While the term 'detection function' is commonly understood, the term 'control function' has several different interpretations. ISO 13702 defines control as the limitation of the extent and/or duration of a hazardous event. In this paper we further specify the term and state that control means *to reduce the likelihood that a critical deviation will develop into a major accident once it occurs*, i.e. to stop the unwanted chain of events when critical deviation occurs.

A major accident is the result of the failure of the safety-related solutions (prevention) and detecting/controlling barrier systems. In order to limit or reduce the consequences of an accident, mitigating barrier systems are established together with emergency response measures. The successful functioning of these systems will ensure the lowest feasible harm by stopping the accident escalation as soon as possible. If the mitigation and emergency response barrier systems function poorly, the accident may develop to its full potential and cause maximal damage.

2.2 *Risk reducing measures as systems*

Currently the industry uses the term 'Safety Critical Element (SCE)' to define all the elements that are "such parts of the installation […] which could cause and contribute substantially to a major accident or a purpose of which is to prevent or limit the effect of a major accident" (Dhar 2011). According to the concept presented in this paper, the boundaries of the SCE would embrace parts of the installation which could cause or contribute to a major accident (Fig. 2).

A Safety Critical System (SCS) is described as a system with applied technical, operational and organizational solutions designed to prevent the realization of a potential source of harm inherent

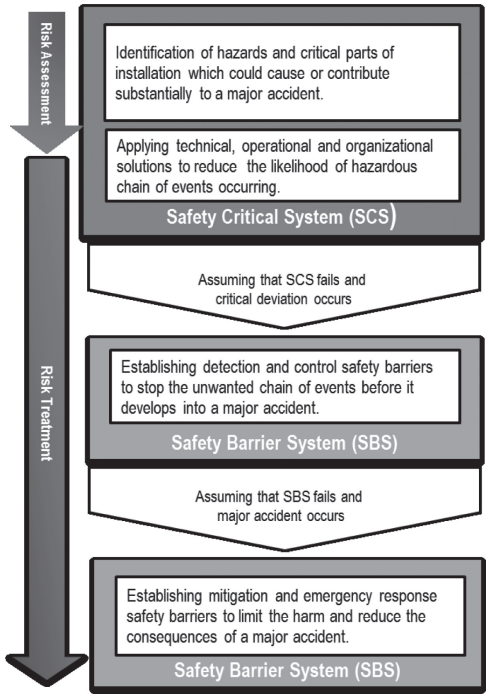

Figure 2. Establishing SCS and SBS of an installation.

in the activities. The requirement to perform is constant. In the case of a system failure, a critical deviation will occur and start the development of an unwanted chain of events (Fig. 3).

The Safety Barrier System—SBS—will embrace the elements of independent safety systems that are installed only for the safety function and in the case of failure will stop the accident's development or limit the effect of an accident (Figs. 4–5).

It is important to see a barrier as an actually established measure that is able to prevent or stop the unwanted chain of events once the initiating event is triggered. Safety principles for nuclear power plants distinguish barriers as physical measures only, while other types of protection are recognized but not defined as barriers (IAEA 1999). Organizational safety measures, such as procedures, strategies, guidelines, requirements, etc., can be seen as part of a regulatory basis that is used to establish the barriers, but they are not barriers in themselves. There is considerable eagerness are a lot of intentions to name them as organizational barriers; however, they cannot be seen as actual barriers that would be able to perform in the case of need. Either physical equipment—a technical barrier—or human actions—an operational barrier—can actually stop the unwanted chain of events that has already started due to the specific

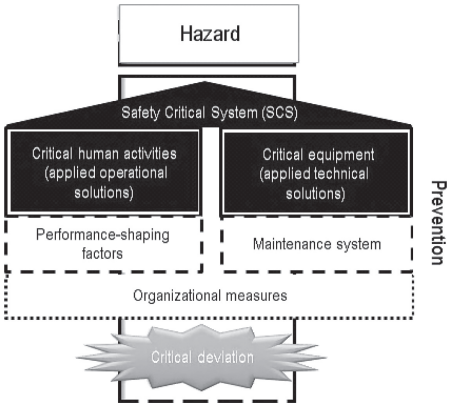

Figure 3. SCS for prevention.

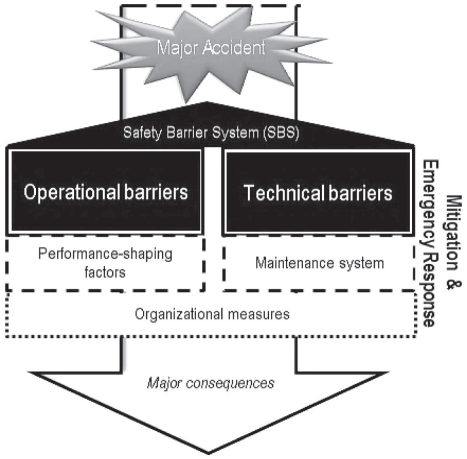

Figure 5. SBS for mitigation and emergency response.

Table 1. SCS and SBS comparison.

Safety Critical System (SCS)	Safety Barrier System (SBS)
Technical, operational and org. solutions applied to process, utilities, structural, etc. elements to reduce risk.	Independent system designed only for risk-reducing functions.
Reduces the likelihood of critical conditions occurring.	Reduces the likelihood of critical conditions developing and limits the harm.
Requirement to perform—constant (normal conditions).	Requirement to perform—on demand (abnormal conditions).
Cannot be removed without affecting process.	Can be removed without affecting process.

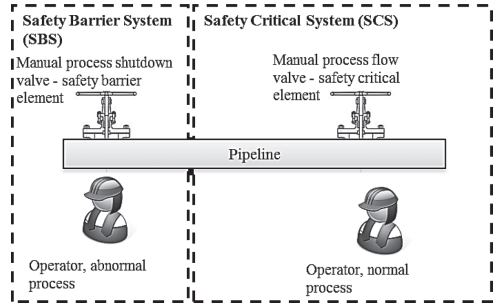

Figure 6. SCS and SBS comparison—generic example.

critical deviation or mitigate the consequences of it.

The differences between SCS and SBS are summarized in Table 1 and Figure 6.

3 SAFETY-RELATED ORGANIZATIONAL MEASURES

Safety-related organizational measures embrace the application of principles that ensure inherent Health, Safety and Environment (HSE) qualities related to the design and technical basis of the facility. The examples of such principles could be the principle of an Inherently Safer Design (ISD) (Mannan 2014), that involves the concept of reducing (avoiding, eliminating) rather than preventing or controlling hazards. The ISD principles should be applied during the general design and layout of the facility. Best Available Techniques (BAT) is another principle, which states that technology and the way it is used in the installations should be "most effective in achieving a high general level of protection of the environment as a whole" (EU Directive 1996); it

is similar to the As Low As Reasonably Practicable (ALARP) principle that adapts a best common practice for judgment of the balance of risk and benefit (HSE 2014). Furthermore, Samarakoon and Gudmestad (2011) have extended the BAT principle to include Qualification: Best Available Qualified Technology (BAQT).

In general, safety-related organizational measures may be seen as a foundational basis for safety-related systems including the design, technology and operational activities.

4 TECHNICAL SOLUTIONS AND BARRIERS

4.1 *Technical solutions*

Technical solutions are applied to the main process and related auxiliary equipment as a derivation of the safety-related principles mentioned in the third section above. The purpose of these solutions is to prevent a critical deviation from occurring and to sustain the normal designed conditions. For example, the thickness of a particular pipeline could be 10 mm if process-needs alone (i.e. pressure or flow rate) are taken into the account, but for safety reasons (i.e. estimated corrosion allowance, etc.) the pipeline is designed with 15 mm walls. Another example could be the selection of process control equipment, preferring modern technology to an obsolete version. The idea of technical safety-related solutions is to decrease the risk within the associated equipment and so it differs from the general design of the facility, which is focused on the process needs. Once applied, technical solutions cannot be removed from the installation without interrupting the functions of the facility for which the solutions were designed.

4.2 *Technical barriers*

A technical barrier is a physical element that is established to perform safety functions related to stopping the unwanted chain of events once it has started: detection, control, mitigation or emergency response. It is designed to perform once prevention fails and abnormal conditions occur and to stop the development of a chain of unwanted events, or to limit the harm of these unwanted events. Examples of technical barriers are: a firewall that is designed to perform if fire breaks out; an Emergency Shutdown (ESD) system that is activated if process control is lost; the fire detection and deluge systems installed to fight the fire. Technical barriers do not perform constantly and may be removed from the installation without interrupting the main process functions for which the facility was designed.

4.3 *Maintenance system*

To ensure the required functionality of critical equipment and technical barriers, maintenance and follow-up activities should be performed by establishing a maintenance system (PSA 2014c). For example, the automatic safety system is one of the main technical barriers; therefore function testing and demand monitoring should be established (IEC:61511-1 2004). Technical barriers should be analyzed, the criticality and failure/fault modes of their elements determined and appropriate maintenance activities undertaken. All critical equipment and technical barrier elements should be tagged and marked accordingly in the general maintenance system of the facilities. In addition, the maintenance system should incorporate an analysis of the human factors and the performance-shaping factors of the operational maintenance activities. Industry examples show that a maintenance system may be enabled through the creation of performance standards—the functional requirement list of each barrier system (Firing *et al.* 2011). The performance standards may serve as a link between technical safety and maintenance disciplines (Fig. 7).

The importance of a well-performing maintenance system is recognized, but industry examples show that implementation often struggles in practice. For example, the accident report on the *Deepwater Horizon* case concludes that "maintenance was inadequate", work orders issued by the maintenance system were "disorganized, erroneous, or irrelevant to individual rig crews" and the "maintenance system was not understood by the crew" (Chief Counsels Report 2011). The challenges facing the maintenance management are indicated in the report on trends in risk level in the petroleum activity (RNNP) process prepared by the Petroleum Safety Authority (PSA) Norway (PSA 2012), which describes the existing difficulties fulfilling regulatory requirements for maintenance management: "tagging and classification of equipment, backlogs of preventive maintenance and outstanding corrective maintenance, including HSE-critical maintenance".

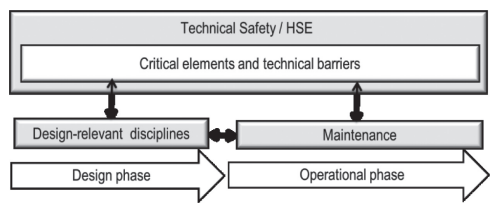

Figure 7. Links between design-relevant disciplines and maintenance.

The authors of this paper believe that one of the main reasons for such a situation is the missing links between the maintenance discipline and other disciplines, especially technical safety. The various analyses done by safety and maintenance engineers often do not have clear linkage and can hardly be implemented in the practical sense. Moreover, a general inconsistency in Computerized Maintenance Management Systems (CMMS) may often be observed due to the overlapping data of maintenance criticality analysis and technical safety analysis.

5 OPERATIONAL SOLUTIONS AND BARRIERS

5.1 *Operational solutions*

Similarly to technical solutions, operational solutions are derived from safety-related organizational principles and are applied to the main operational activities. For example, an operator could do his job in a very cost-efficient way, but, after a risk analysis is performed, a safety-related operational solution—the way the technology is used—will be applied to the job in order to reduce the risk. A safety checklist before an activity may also be seen as an operational solution, as it is an additional activity with a focus on preventing any abnormalities during the operation. The safety checklist may be seen as a part of safety-critical activities, but it is not a barrier by itself.

5.2 *Operational barriers*

An operational barrier can be seen as a determined specific action that shall be carried out in the case of critical deviation to prevent or to stop the development of an unwanted chain of events. A manual shutdown valve is often treated as a technical barrier element; however, it will not perform the barrier function unless somebody activates it on demand. This action is an operational barrier element.

Operational barriers are the part of the Safety Barrier System (SBS) that involves specific human actions related to the barrier function: detection, control, mitigation or emergency shutdown. Examples of operational barriers could be a manual activation of emergency shutdown systems, firefighting and evacuation. A specific lookout or visual check of an operator that is performed only for safety reasons may be seen as an operational detecting barrier.

5.3 *Performance-Shaping Factors (PSF)*

The UK Health and Safety Executive defines human factors as "environmental, organizational and job factors, and human and individual characteristics which influence behavior at work in a way which can affect health and safety" (HSG48 2009). Explicitly defined, human factors may be seen as Performance-Shaping Factors (PSF) and are used to model human behavior as the underlying causes of abnormal performance (El-Ladan and Turan 2012). It must be noted that PSF are explicitly used to describe the influence on human performance (Musharraf *et al.* 2013) and should not be directly referred to as the performance of technical equipment. Technical equipment is affected by maintenance actions which are again influenced by PSF (Toriizuka 2001). However, the PSF of maintenance activities should be seen as an integral part of the maintenance system, and maintenance activities should be distinguished from the operational safety barrier concept that embraces specified safety actions in the case of abnormal situations.

PSF may be characterized as internal and external (Boring *et al.* 2007). Internal PSF influence individual attributes such as mood, fitness, stress level, etc. External PSF exert influence in the situation or environment that affects the individual, such as temperature, noise, work practices, etc. The performance of operational activities is directly affected by PSF, so they must be taken into consideration when SCS or SBS are designed.

6 MANAGEMENT SYSTEM

6.1 *Workflow*

The general steps for establishing the management system for risk-reducing measures is shown in Figure 8. It may be seen as an interpretation of ISO31000 (2009) and the PSA regulations, Section 17 of the Management Regulations (PSA 2014a).

The context is seen directly or indirectly as acting factors that may be important in the risk-reduction process. It includes not only requirements, standards, guidelines, acting regulations and policies, but also general experience, expert knowledge, engineering judgment, etc. The risk analysis is intended to identify, analyze and evaluate the hazards in the activities performed. By understanding the nature of the hazard, the possible scenarios can be laid out and the corresponding safety measures can be discussed accordingly. The required safety-related solutions and barrier functions should be derived as a result of this process. Further steps are the actual identification of system functions and corresponding systems up to the equipment tag level to include them into the maintenance system. Finally, visualization and monitoring tool should be created specifically for SCS & SBS.

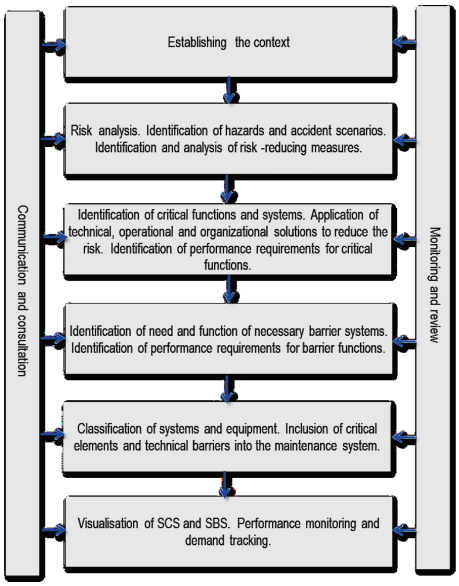

Figure 8. Managing the risk-reducing measures.

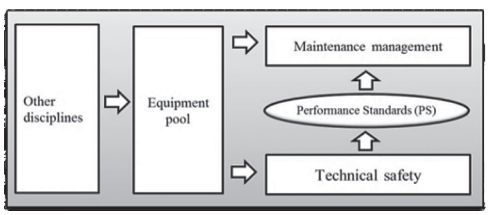

Figure 9. PS as a link between technical safety and maintenance.

6.2 *Challenges facing maintenance management*

The audit activities often find deficiencies in the completion of maintenance activities and missing links between equipment and the safety barriers (Ratnayake *et al.* 2012). It is essential to know the links and interconnections between maintenance and technical safety disciplines. The safety analyses and identification of safety functions should be transferred to the maintenance engineers in order to classify specific equipment accordingly. Results of safety-related analyses performed by technical safety engineers should be prioritized over results of maintenance criticality analyses. Clear links should be established in order to ensure that one discipline's output can be used as input for other disciplines. The mandatory Performance Standards (PS) required by the PSA may be seen as a potential major link between safety and maintenance disciplines (Fig. 9).

For example, the equipment tags of the Safety Instrumented Systems (SIS) should be specified in the Safety Requirement Specification (SRS), a live document made specifically for every installation (GL-070 2004 & IEC:61508 2010). The PS should contain links to such relevant documentation. In addition to specific requirements for safety critical and barrier functions, the PS should have a clear description of equipment groups that are considered as part of the SCS/SBS. A properly created PS will allow the correct identification of critical equipment tags and the implementation of data into the CMMS.

6.3 *Visualization of system*

The integrity status of SCS/SBS should be visualized. From the point of view of ergonomics and human factors, it is important that only the required data and information should be provided; it should not overflow, but be sufficient, unambiguous and non-misleading (Wong and Ceng 2002). Industry examples show how the visualization of safety systems is being implemented (Johansen and Toennessen 2002 & Firing *et al.* 2011). The purpose of this paper is not to evaluate the current achievement but to provide additional insights to the discussions and further development of these systems.

The visualization system should not only show the integrity status of technical parts of the SCE/SBS, but contain the names and duties of responsible personnel in the case of abnormal process conditions. Specific human activities are seen as operational barriers and as an integral part of the safety system. Automatic systems such as Safety Instrumented Systems (SIS) are an exception and may be seen as an SBS without an operational barrier element. The proposed concept of the visualization system is based on the generic accident model shown in Figure 1 and separates SCS and SBS (Fig. 10).

A status color code can be used as an indication of the general status. There may be various selections, for example, three levels of status: green, yellow, and red. The green would indicate that SCS/SBS integrity meets performance requirements, the yellow would demand attention and possible actions to be taken, while a red status would mean that the SCS/SBS is not performing and the risk is increased. The integrity status may be derived from the results of a system function test, preventive/corrective maintenance reports, etc.

By visualizing the status of the safety-related systems, an overview of the integrity status can be made available for operators and managers. This information is essential when evaluating work permits, the bypass of safety systems for maintenance,

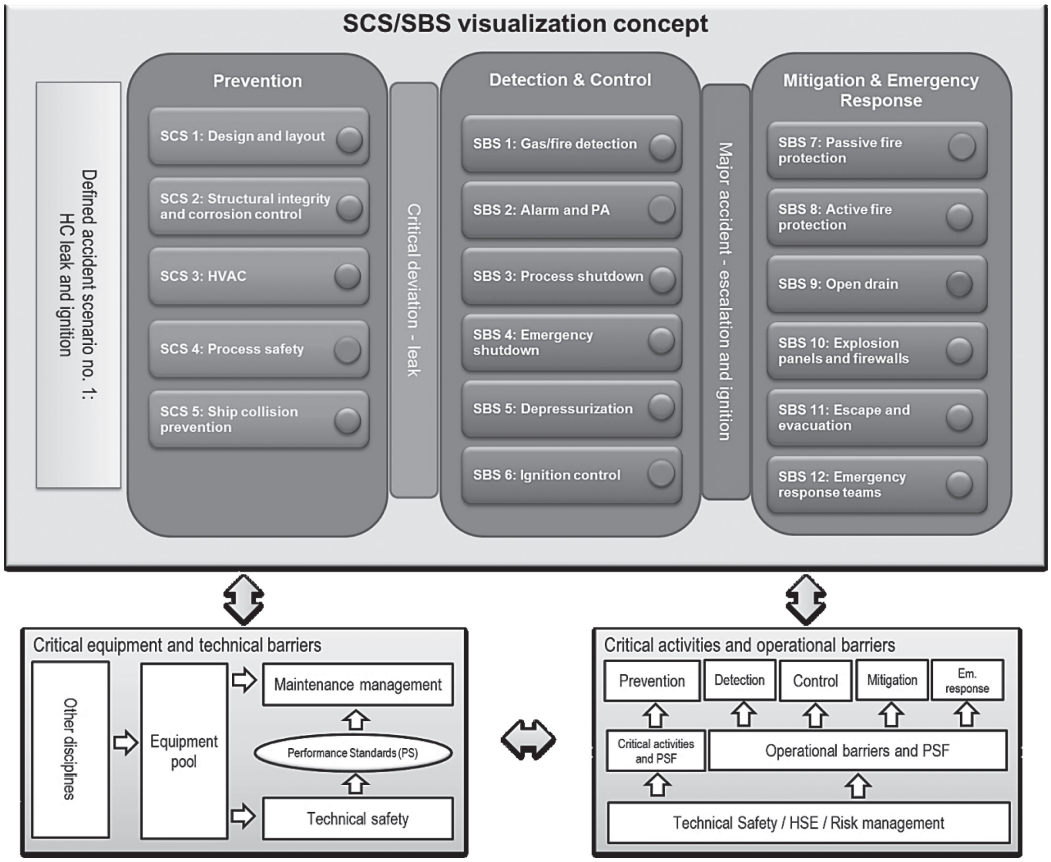

Figure 10. Generic example of visualization of SCS/SBS.

and increased levels of activities. Easy and user-friendly access to the information would facilitate good practices of safety management (Johansen and Toennessen 2002).

7 SUMMARY

Based on the synthesis of ISO 17776, the PSA regulations and common features of the terms found in the scientific literature, the concepts of Safety-Critical Systems (SCS) and Safety Barrier Systems (SBS) are proposed as a basis for further discussion of risk-reducing measures in industrial activities.

Correspondingly, prevention, detection/control, and mitigation/emergency response systems have been introduced and described. Aligning with the PSA regulations, safety-related solutions and corresponding critical systems have been separated from safety barriers and described. Links between technical, operational and organizational elements have been suggested, incorporating maintenance activities and performance-shaping factors. The presented accident chain model (Fig. 1) may be used as a tool for a broader communication about the safety barriers and their role in arresting the accident's escalation.

This may be valuable in risk communication, where the model's simplicity could be well-accepted by non-technical safety personnel.

Furthermore, some important issues regarding the management of safety systems have been discussed with a focus on maintenance and its links with other disciplines. Generic examples of conceptual workflow and system visualization have been proposed and described.

Today the industry has a challenge to link technical and operational elements into a united system. A conceptual framework of systems consisting of technical and operational elements has been discussed in the manuscript.

Further studies are required to enable a synergy of separate work processes that would ensure

adequate maintenance and follow-up of risk-reducing measures during their lifecycle.

A multi-criteria decision model to mitigate the operational risks of offshore wind infrastructures

Mahmood Shafiee
Institute for Energy and Resource Technology, School of Applied Sciences, Cranfield University, Bedfordshire, UK

Athanasios Kolios
Energy and Power Division, School of Engineering, Cranfield University, Bedfordshire, UK

ABSTRACT: For many power generation systems, it is extremely important to control the likelihood as well as the consequences of potential risks during actual operation. Operational risks may result in substantial costs of repair or replacement, significant losses of power production, and catastrophic safety hazards to personnel or infrastructure. The selection of an appropriate strategy to mitigate the operational risks is a very complex and critical task for the offshore wind energy sector. In recent years, Multi-Criteria Decision Making (MCDM) approaches have gained momentum in this field. The aim of this paper is to propose a decision model based on Analytic Network Process (ANP) technique in order to select the best "risk mitigation strategy" for offshore wind infrastructures. The proposed model consists of a number of alternatives (e.g., variation of offshore site layout, improvement of maintenance services, upgrading the control and monitoring systems, and modification in design of wind turbine sub-assemblies) among which the decision maker has to select, on the basis of a finite set of criteria (e.g., safety, added value, cost, and feasibility). The model developed is applied to an offshore wind farm consisting of 30 wind turbines of 2 MW. Our findings indicate that "improving the repair and maintenance services" is chosen to be the most cost-effective approach for mitigating the operational risks of offshore wind infrastructures.

1 INTRODUCTION

Offshore wind energy industry has grown very rapidly over the last years. The cumulative installed capacity of offshore wind power in the EU has increased from 532 MW in the year 2003 to 6.6 GW in the end of 2013, which represents an annual growth of about 29% (European 2014). Along with the growth of the market for offshore wind energy, particular attention should be focused on Operation and Maintenance (O&M) as well as reliability and availability of the installed wind power systems.

Analyses of field failure data collected from various databases like Elforsk in Sweden (Elforsk.se) show that the availability of onshore wind power plants is typically between 95% to 99%, while it is evaluated to be in the range of 60% to 70% for offshore plants. Moreover, offshore wind turbines suffer from a higher failure rate compared to the wind turbines located onshore (Tavner 2012). The main reason might be that offshore wind power generation systems are typically subject to a wider range of *operational* risks, hazards, or damages.

In general, the operational risks within offshore wind farms involve two major categories: (i) the risks of system failures (e.g., asset breakdowns) and (ii) the environmental risks (e.g., natural catastrophes, ship collisions) (Wilson 2013). The former is generally caused by system/component degradation, whereas the latter results from extreme weather conditions and harsh marine environments (see Fig. 1).

Any of the mentioned hazards can potentially have a negative impact on plant profitability if it is not prevented in an efficient way. Random failures result in substantial costs of repair or replacement, and significant losses of power production, and

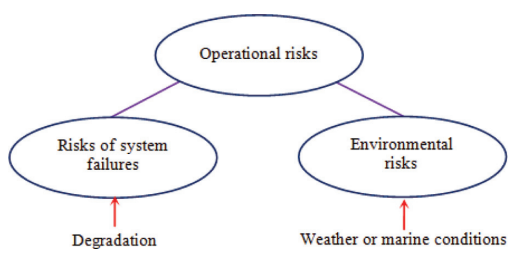

Figure 1. Operational risks within offshore wind power plants.

nature events lead to catastrophic safety hazards to personnel or infrastructure (e.g., grid disconnection). Therefore, there is a critical need to control the likelihood as well as consequences of potential risks during actual operation. For this purpose, a risk management plan should be developed and implemented for the existing offshore wind power plants.

Risk management is a process focusing on the identification and elimination of hazards that could adversely affect asset performance. This process normally includes several steps like identification, assessment, evaluation, control and monitoring, and mitigation of risks resulting from a certain hazard (Aven 2007). Among them, the risk identification and assessment area has received a reasonable attention in the wind energy sector. To this end, the following studies are identified:

Tavner *et al.* (Tavner 2010) and Arabian-Hoseynabadi *et al.* (Hoseynabadi 2010) propose a Failure Mode and Effects Analysis (FMEA) methodology for prioritization of failure modes in a 2-MW wind turbine system. Kahrobaee and Asgarpoor (Kahrobaee 2011) develop a risk-based FMEA approach for wind turbine systems, in which the criticality of a failure is determined on the basis of failure probability and the incurred costs. Das *et al.* (Das 2011) implement the tarditional FMEA methodology on a 2-MW variable speed wind turbine system. Dinmohammadi and Shafiee (Dinmohammadi 2013) develop a fuzzy-FMEA approach for risk and failure mode analysis in offshore wind turbines when the failure data is unavailable or unreliable. Sunder and Kesavan (Sunder 2013) studied the implementation of an FMEA methodology for wind turbines located in uncertain wind environments. Shafiee and Dinmohammadi (Shafiee 2014) propose a mathematical tool for risk and failure mode analysis of wind turbine systems (both onshore and offshore). The proposed tool combines the aspects of the FMEA methodology in (Hoseynabadi 2010) with some economic considerations like power production losses and the costs of logistics and transportation.

In spite of the vast research on risk identification and assessment, only a few methods exist in the literature for mitigating the operational risks within offshore wind farms. A recently published report by the U.S. Department of Energy (The U.S. Department of Energy 2008) recommends enhancing the wind turbine reliability (through prototype testing of components before deployment) to mitigate the failure risks in offshore wind power plants. Sjodin *et al.* (Griffin 2012) and Griffin (Griffin 2014) introduce the variation of offshore site placement/layout as a way of reducing the weather-related risks. Even though this strategy might be non-practical or even not feasible for many offshore farms, it can be cost-effective for some small projects.

In this paper, we propose a Multi Criteria Decision Making (MCDM) approach based on the Analytic Network Process (ANP) technique to select the best risk mitigation strategy for offshore wind infrastructures. The proposed model consists of a number of alternatives (e.g., variation of offshore site layout, improvement of maintenance services, upgrading the control and monitoring systems, and modification in design of wind turbine sub-assemblies) among which the decision maker has to select or rank, on the basis of a finite set of criteria (e.g., safety, added value, cost, and feasibility). Our findings indicate that improving the repair and maintenance services is chosen to be the most cost-effective approach for mitigating the operational risks of offshore wind infrastructures.

This paper is organized as follows: (i) first, a brief overview of the risk mitigation strategy selection and ANP technique is given so as to set the background for the main contribution of the paper, (ii) second, a decision model is proposed for risk mitigation strategy selection in offshore wind farms, and (iii) finally, the implementation of proposed model is presented and the results are discussed.

2 RESEARCH BACKGROUND

2.1 *Risk mitigation strategy selection as a complex MCDM problem*

The selection of a suitable risk mitigation strategy is a very complex and critical task. An appropriate risk mitigation strategy not only reduces the probability of failure occurrence but also improves the assets' operating conditions, which eventually result in higher Operating expenses (Opex). On the other side, an improper selection of strategies may adversely affect the operating budget and thereby reducing productivity as well as profitability.

Risk mitigation strategy selection is considered as a typical MCDM problem. In this problem, the decision-maker (i.e., plant managers or stakeholders) must decide on the best strategy among a set of possible alternatives to mitigate operational risks. Moreover, in the decision making process, many goals or comparing criteria must be taken into consideration (e.g. the investment required, safety aspects, environmental issues). These criteria cannot fulfilled simultaneously, i.e., according to a criterion, a given alternative is the best one, while according to another criterion, other alternatives score higher. Thus, each alternative is evaluated with respect to each criterion and then, the evaluation ratings are aggregated to obtain a global evaluation. Last, the alternatives are prioritized from the best (optimal) to the worst.

In recent years, the MCDM approach has gained momentum in selection of the best risk mitigation strategy within a wide range of industries including oil and gas, construction, and transport. In contrast, to the best of the author's knowledge, there is no presented work dealing with the problem for wind farms.

2.2 *Analytic Network Process (ANP)*

Among the several existing MCDM techniques, the Analytic Hierarchy Process (AHP) and Analytic Network Process (ANP) are the most widely used in solving decision-making problems. In AHP technique, the problem is modeled in a hierarchical structure showing the relationships between various components, namely, goal, criteria (and any sub-criteria) and alternatives [16]. So, the components of decision problem are connected top-to-bottom in a way that the upper level node does not depend on the lower levels, and the elements presented in a node are independent of each other. This one-sided network fails to capture the complex interactions and feedbacks which might be present in the system. To overcome this limitation, the ANP technique was introduced by Saaty in 1996 (Saaty 1994).

In ANP, the goal, criteria and alternatives are modelled in the form of clusters, and all possible interactions between the clusters and elements within a cluster are considered. In fact, the ANP technique provides a general framework to deal with decisions without making assumptions about the independence of higher level elements from lower level elements and about the independence of the elements within a level. So, ANP is a coupling of two parts: the first part consists of a control hierarchy or network of criteria and sub-criteria that control the interactions, and the second part is a network of influences among the elements and clusters.

A brief review of the literature shows that ANP technique has been applied to various fields including economics, engineering, education, health, political and social science, and technology management. Readers can refer to a recently published book by Saaty and Vargas (Saaty 2013) for a thorough review on ANP applications.

3 PROPOSED METHODOLOGY

In this Section, we propose a methodology for selecting an appropriate risk mitigation strategy in offshore wind farms. The eight main steps of our methodology are described as follows.

3.1 *Step 1. Form a group of decision makers*

First, a project team must be established to determine and examine the operational hazards and their potential impact on the wind farm operation. The team is often composed of key plant managers (i.e., power generation manager, head of safety and risk, and project finance director) as well as some practitioners in operation and maintenance.

3.2 *Step 2. Determine the alternative risk mitigation strategies*

Several alternatives can be taken into account in selection of the best risk mitigation strategy, but some of them might be non-applicable to offshore wind industry. In this paper, four alternative risk mitigation strategies are considered: variation of offshore site layout, improvement of maintenance services, upgrading the control and monitoring systems, and modification in design of wind turbine sub-assemblies. These alternatives are briefly described below.

3.2.1 *A.1. Variation of offshore site layout*

The 'layout' of an offshore wind farm is one of the critical elements influencing the risks associated with natural events (i.e., environmental risks) [19]. It is expected that, in general, the potential risks become more likely to happen for wind farms located in ultra deep waters far offshore compared to installation in shallow waters near shore. Therefore, any improvement in offshore site layout will have a substantial impact on likelihood as well as consequences of environmental risks on offshore wind infrastructures.

3.2.2 *A.2. Improvement of maintenance services*

Current practice in offshore wind farms for maintenance is reactive response (or failure-based). Under this policy, the maintenance actions are undertaken when a failure is detected. According to various studies (see, e.g., (Musial 2006)), using the reactive response policy in offshore farms results in high repair costs, frequent unplanned outages, lengthy waiting and maintenance times, and trouble shooting problems. For this reason, Preventive Maintenance (PM) policies (including periodic inspections, risk-based, condition-based, and predictive) are extensively used to control the rate of asset degradation and avoid costly failures (Andrawus 2008). A well-planned and optimized maintenance policy can effectively reduce the costs associated with operating and repairing wind turbines.

3.2.3 *A.3. Upgrading the control and monitoring systems*

One effective way to reduce the likelihood of operational risks in offshore wind farms is improving the fault detection capability. This improvement can be achieved by installing a number of

high quality and technically advanced sensors at specified locations as well as using new monitoring techniques (such as acoustic emission, ultrasonic testing, strain measurement, radiographic inspection, thermography, and signal processing methods) (Yang 2012).

3.2.4 *A.4. Modification in design of wind turbine sub-assemblies*

The operational risks in offshore wind farms can be reduced by enhancing the reliability of wind turbines through design modification. The aim of design modification is to minimise the number of failure experienced in wind turbines, which results in enormous savings in maintenance and energy costs. The modifications could involve reliability growth testing, or adding redundancy to critical components in order to increase the Mean Time Between Failures (MTBF).

3.3 *Step 3. Determine the decision criteria*

In order to evaluate and prioritize the mitigation actions, the project team must specify a set of criteria. Different decision-makers may have different objectives. In this paper, the criteria for risk mitigation strategy selection are determined based on the review of literature and semi-structured interviews undertaken with key managers. The criteria considered can be divided into four categories as follows.

3.3.1 *C.1. Safety*

A high safety level is required for many offshore wind power plants, especially for the ones which are connected to the grid in series. The relevant factors describing safety are:

- *Technicians safety*: A failure of a wind turbine and/or an environment event may lead to serious damages to personnel/technicians working on site.
- *Power grid safety*: A failure of a wind turbine and/or an environment event has a negative impact to the grid-connection equipment and thereby disconnects the power plant from electric grid.

3.3.2 *C.2. Added value*

The added-value criterion deals with the benefits that may be gained from implementing a particular risk mitigation strategy. This criterion includes the improvements in terms of power production and fault detection.

- *Power production*: A failure of a wind turbine and/or an environment event often leads to a substantial production loss. Selecting a suitable strategy for risk mitigation can potentially enhance the power produced by offshore wind farms.
- *Fault detection*: Fault diagnostic and prognostic techniques aim to quickly alert the maintenance engineers where and why faults occur. As a result, the maintenance lead-times are shortened, and the availability of wind farms will be improved.

3.3.3 *C.3. Cost*

Different risk mitigation actions have different expenditure of hardware, software, and personnel training.

- *Hardware cost*: For implementation of risk mitigation strategies, a number of service vessels, support facilities, maintenance tools, monitoring and prognostic sensors should be acquired.
- *Software cost*: More expensive and advanced software are needed if decided to upgrade the control and monitoring systems or modify the design of sub-assemblies.
- *Training cost*: Risk mitigation actions in offshore wind farms should be initiated only after sufficient training.

3.3.4 *C.4. Feasibility*

The feasibility of risk mitigation strategies is divided into acceptance by stakeholders and acceptance by plant managers.

- *Acceptance by stakeholders:* Successful implementation of a risk mitigation action needs the support and participation of wind farm stakeholders (i.e., financial institutions, insurance companies, owners, and regulatory authorities).
- *Acceptance by plant managers:* Plant managers often prefer the strategies that yield more Return On Investment (ROI) and are easier to implement. So, the variation of plant layout and modification of the design of wind turbines might be suitable alternatives for long-term investments.

3.4 *Step 4. Construct a network model*

Using criteria, sub-criteria and alternatives, a network model is constructed. The relationship among criteria and sub-criteria are also determined and reflected in the network model.

Figure 2 shows a network model for the decision problem of risk mitigation strategy selection in offshore wind farms. As can be seen, the proposed network includes three clusters. The first cluster represents the ultimate goal of the problem (i.e., selection of the best risk mitigation strategy). The second cluster consists of four main criteria, namely, safety, added value, cost, and feasibility.

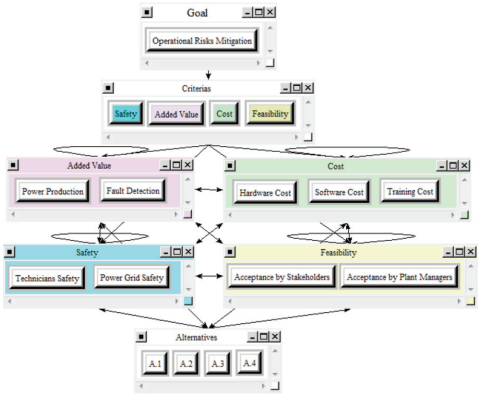

Figure 2. A network model for risk mitigation strategy selection in offshore wind power plants.

Table 1. Pair-wise comparison scheme [16].

Value of rating judgments	Verbal judgments
$a_{ij} = 1$	The tow parameters are equally important
3	Parameter *i* is weakly more important than parameter *j*
5	Parameter *i* is strongly more important than parameter *j*
7	Parameter *i* is very strongly more important than parameter *j*
9	Parameter *i* is absolutely more important than parameter *j*
2, 4, 6, 8	Interval values between two adjacent choices

The criteria are decomposed into various sub-criteria as discussed. Finally, the third cluster of the network represents the alternative strategies.

3.5 *Step 5. Pair wise comparison among criteria and sub-criteria*

Pair wise comparisons are done among related criteria and sub-criteria following the scale suggested by Saaty [16] in Table 1. A questionnaire form is used to complete the pair-wise comparison matrix.

3.6 *Step 6. Calculating local priority vector and testing the consistency*

Once the pairwise comparisons are completed, the local priority vector is computed as the unique solution to:

$$Aw = \lambda_{\max} w, \tag{1}$$

where A is the matrix of pairwise comparison, w is the eigenvector, and $\lambda_{\max}$ is the largest eigenvalue of A. The Consistency Index (CI) and Consistency Ratio (CR) are used to measure the consistency of the pair-wise comparison matrix. The CI and CR values are defined as follows:

$$CI = \frac{\lambda_{\max} - n}{n-1}, \tag{2}$$

$$CR = \frac{CI}{RI}, \tag{3}$$

where n is the number of elements and RI denotes the average consistency index for numerous random entries of same order reciprocal matrices. If $CR \leq 0.1$, then the pairwise comparison matrix is consistent; otherwise, a new comparison matrix is solicited until $CR \leq 0.1$.

3.7 *Step 7. Super-matrix and limit super matrix formation*

The impact of the elements in network on the other elements can be represented in a super-matrix. The super-matrix is actually a partitioned matrix where each matrix segment represents a relationship between two clusters in the network. The local priority vectors, obtained in Step 6, are grouped and placed in proper columns of the super-matrix based on the flow of influence from one cluster to another, or from a cluster to itself, as in the loop.

Since there is usually dependency among clusters in a network, the aggregate of the column vectors of a super matrix may sum to more than one. In this case, the super matrix must be modified so that each column of the matrix sums to unity. To achieve a convergence on a long-term stable set of weights, the weighted super matrix is raised to the power of $2k + 1$, where k is an arbitrarily large number, and the new matrix is called the limit super matrix.

3.8 *Step 8. Selection of the best strategy*

Desirability index (D_i) is used to determine the best alternative. The equation for D_i is defined by (Saaty 1994):

$$D_i = \sum C_i M_i A_i, \tag{4}$$

where C_i is the relative importance of each category metric, M_i is the relative importance of each measure, and A_i is the relative importance of an alternative for a measure. The alternative with the largest desirability index is selected as the best strategy.

4 APPLICATION AND RESULTS

In this Section, the proposed methodology is applied to an offshore wind farm located approximately 5 miles off the coast, and consist of 30 wind turbines of 2 MW (see Fig. 3). The wind plant generates on average 200 GW of electricity per year hours, which it provides about 40,000 households' electricity needs.

Computer software based on the ANP technique, 'Super Decisions' has been utilized for the evaluation and analyses (for more see (Super Decision)). First of all, the priority weights of four criteria with respect to the overall goal are obtained using a pairwise comparison matrix. The exact ratios of the obtained weights of four main criteria are given as follows:

Figure 3. Offshore wind farm considered for this study.

$w_1 = 0.345$ (Safety); $w_2 = 0.202$ (Added value); $w_3 = 0.329$ (Cost); $w_4 = 0.124$ (Feasibility).

As can be seen, in evaluation of the risk mitigation strategies for offshore wind power plants, the greatest weight is given to the safety criterion. This is perhaps in due consideration of the huge impact of operational hazards on grid safety.

Next, all sub-criteria are compared at the second level in terms of corresponding main criteria, and the related comparison matrixes are constructed. The priority weights for sub-criteria with respect to the main criterion are given as follows:

$w_{11} = 0.207$ (Technicians safety); $w_{12} = 0.138$ (Grid safety); $w_{21} = 0.155$ (Power production); $w_{22} = 0.047$ (Fault detection); $w_{31} = 0.149$ (Hardware cost); $w_{32} = 0.107$ (Software cost); $w_{33} = 0.073$ (Training cost); $w_{41} = 0.086$ (Acceptance by stakeholders); $w_{42} = 0.038$ (Acceptance by plant managers).

In addition, the amount of interdependency among sub-criteria or in fact the amount of sub-criteria impacts on each other is measured from the

Table 2. Importance weights among sub-criteria.

answers to questionnaire. The priority weights of sub-criteria against each other are addressed in Table 2.

Afterwards, the priority weights for the alternative risk mitigation strategies with respect to sub-criteria are obtained. These estimated priority weights are shown in Table 3.

Finally, the priority weights for the sub-criteria regarding maintenance alternatives are determined. Table 4 represents the estimated priority weights of each sub-criterion against four risk mitigation strategies.

The priority vectors obtained through paired comparisons are placed in the appropriate columns to form the super-matrix. The zero elements in the super-matrix show the independency among the variables in the rows and columns. The global weights of sub-criteria against the overall goal (determining the appropriate maintenance strategy) were obtained by multiplying the weight of main criterion with the local weight of sub-criteria, and are entered in to column 'goal'.

Later, the super-matrix is transformed into a weighted matrix. The transformation process involves multiplying the super-matrix by the cluster matrix, so that the priorities of the clusters can be taken into account in the decision making process. Finally, the weighted super-matrix is transformed into the limit super-matrix to make the distribution of the vector values meaningful to decision makers. The limit super-matrix is shown in Table 5.

The final priority of the four risk mitigation alternatives is represented in Table 6.

As shown, "improvement of maintenance services" is chosen as the best risk mitigation strategy within the offshore wind power plant.

Modification in design of wind turbine sub-assemblies	0.178
Variation of offshore site layout	0.145

5 CONCLUSIONS AND TOPICS FOR FUTURE RESEARCH

Selection of an appropriate strategy to mitigate the operational risks is a very complex and critical task. In this paper, an MCDM approach was proposed based on the ANP technique to select the best risk mitigation strategy for offshore wind farms. The reason that ANP technique has been used is to overcome the limitation of AHP to take into account the possible dependencies among various components. For instance, the relationship between two criteria 'safety' and 'cost' could be such that an alternative with low risks to technicians as well as power grid would probably be expensive. So, compared to AHP, the proposed methodology is better able to deal with real world problems. The model was applied to an offshore wind farm consisting of 30 wind turbines of 2 MW, and finally, 'improvement of maintenance services' was found to be the most effective alternative for risk mitigation.

There is a wide scope for future research in the area of risk mitigation strategy selection within wind power sector (either onshore or offshore). In this study, we confined the analysis to only four alternatives. However, other alternatives such as outsourcing the operation and repair services of plants could be involved. Also, some other MCDM techniques (such as ANP-TOPSIS) could be applied to study this problem.

Evaluation of operational reliability of the supply chain in terms of the control and management of logistics processes

I. Jacyna-Gołda
Institute of Organization of Production Systems, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: The paper presents an approach reliability of the supply chain in terms of the control and management of logistics processes. Determination of reliability of complex systems of this type should take into account wide range of issues. The article poses the thesis that based on studies of supply chain model concerning speed and reliability it is possible to determine whether the relationships in the supply chain have a high enough reliability factor or not. In order to investigate the supply chain for a company was used the SCOR model. This model is a useful tool for analyzing supply chains and allows you to measure, control and manage processes throughout the supply chain, including all participants (producers, transport companies, distributors, consumers).

1 INTRODUCTION

Modern logistics is primarily a method of managing the flow of goods from suppliers to customers in such a way that the flow proceeds without interference. Logistics, which is engaged in thempumpkins activities related to supplying customers with products and services is defined as the distribution logistics (Barnes et al. 2003, Brzeziński 2006, Ghazanfari & Fatholla 2006, Korzeń 2001, Pfohl 1998, Witkowski 2000). In contrast, supply logistics is a system of managing the flow of materials from suppliers to production areas at the right price, in the right quantity, at the right time, quality and location.

Purchase the product by the end user causes a whole string of earlier events in the supply network, resulting from orders placed to suppliers (Sołtysik 2000). Re-stocking distributor, in turn, affects the supply from the manufacturer, therefore, affect the implementation of production processes, and thus supplies. Logistics supply chain manufacturing company is becoming more complex as companies expand their economic cooperation.

According to Barnes et al. (2003) structure containing a supply warehouse at production (Fig. 1), allows for the delivery of material requirements for a manufacturing plant in Just-In-Time (JIT).

Presented supply chain includes all activities related to the processing of materials and replacement goods from the raw material stage to the stage of delivery to the end user, as well as information and financial processes associated with them, as well as coordinated and integrated management (Shafia et al. 2008).

In a broader sense, the supply chain consists of two or more organizations, which may be the production company parts, components and final products or may also include the supply and distribute service providers or end-customer (SCC 2008). The most important determinant of effective supply chain management is the credibility and confidence in the relationship between partners in the chain. Therefore, in the development of any integrated supply chain, increase trust among partners and creating for them reliability are key factors to achieve sustained success (Ghazanfari & Fatholla 2006). One of the measures of confidence assessment for the project is its reliability.

Numerous studies on the problems of reliability of supply chains (Ball 1979, Barnes et al. 2003, Brzeziński 2006), treat primarily on the reduction of system performance and load changes in

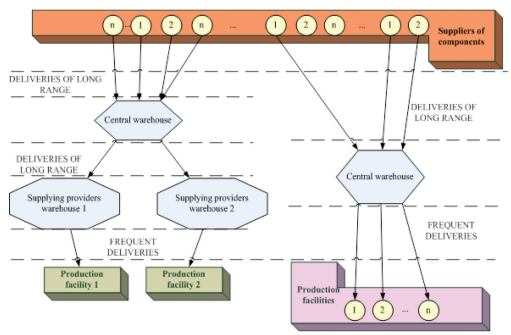

Figure 1. The concept of supply chain with and without considering the providers warehouses.

the network of transport routes (Rutkowski 2009, Seidler 1994). Analyzing the literature, reliability modeling of the logistics system or performance degradation is rarely undertaken topics.

Earlier studies (Chen et al. 1999 Dandamudi & Lu 1994) concerning the reliability of the network connections are addressed primarily to the connectivity and reliability during the trip. Logistics systems described by the authors include the transport of goods, energy, water and information on places of origin to the final consumer in terms of economic prosperity of each country. This approach, however, has limited use in planning at the level of the whole system, such as logistics network design to satisfy the requirements of reliability and supply chain costs and time rating decision.

Pierskalla & Voelker (1976) in their work took care of the problems of reliability theory of technical objects. Authors investigated discrete time vs. continuous time maintenance models, later updated by Valdez-Flores & Feldman (1989).

Improved approach propose Magott, Nowakowski, Skrobanek i Werbińska (2007), where has been taken also a problem of the influence of a spare provisioning policy on the maintenance policy. The authors have attempted to clarify the problem of providing an adequate and efficient supply of spare parts, in support of maintenance and repair of operational systems.

Werbińska-Wojciechowska (2010) in her work analized reliability of complex transportation systems. Author compared the models of systems, on the one hand, integrated, where all the components should be considered in a single model, on the other hand models, in which maintenance, replacement and inventory decisions should be considered separately.

Another approach in terms of reliability of supply chains is a Fault Trees Analysis (FTA) (1990), which is probabilistic approach to safety, reliability, and risk analysis. Traditional fault trees contain Boolean gates to represent how component failures combine to produce system failures. These fault trees are now called static. Dugan et al. (1992, 1993) in their papers presented Dynamic Fault Trees (DFTs). They suggested that Gates of DFTs can express the following features:

– dynamic replacement of failed components from pools of spares,
– failures can occur only in a predefined order.

Bobbio & Codetta (1994), extended DFTs by repair boxes. These boxes can express a repair time of components. In this paper, transformations of different gates and repair boxes into Stochastic High Level Colored Petri Net are given.

In the literature (Bobbio & Codetta 1994, Dugan et al. 1992, 1993, Magott et al. 2008, Montani 2008) can be found a number of issues dealing with the reliability of the network associated with the gates of dynamic fault trees. In most of them in calculation of probabilistic characteristics of systems using DFTs, the following formalisms are used: Markov models, Petri nets and Bayesian networks.

Magott et al. (2008), Montani et al. (2009), Mazuruk & Rzepka (2006) have modified the previous gate of dynamic fault trees. In the analyzed transportation system beyond repair and lead time, also taken into account time consuming replacement process and time resource. Through such a modification the DFT method become increasingly constrained in the expression of the time dependence in a quantitative way. Therefore, the method now as a Fault Tree with Time Dependencies method (FTTD) are not sufficient to represent the transportation system, but provides an interesting solution for non-deterministic models.

Another approach was proposed by Bobyr et al. (2008). Authors in their work in contrast to the analytic approaches they used Monte Carlo simulation. However, Monte Carlo simulation is time-consuming because of the intensive computations. This is because an extremely large number of simulated samples may be needed to estimate the reliability parameters at a high level of confidence

In summary, the available literature for the study on the reliability of supply chains can be classified according to various criteria, such as:

– relationship between the availability of information and object states (Nowakowski 2000, Seidler 1994),
– range of variability of the data relating to the subject (Du et al. 2010, Green 1995, Nowakowski 2000),
– theory (general informations) (Bukowski 2006).

2 RELIABILITY IN SUPPLY CHAINS

Term supply network exists in the literature in terms of the subject, logistical and institutional level and in terms of functional and organizational management view. In the first case, the material flows between suppliers and production companies and products between producers and final consumers (Sołtysik 2000). In the second, as a set of cooperating with each other entities (companies, firms or institutions) (Pfohl 1998, Rutkowski 2009, Witkowski 2000). However, in functional terms as a string of successive links (companies, institutions), which are involved in the shipment of products (Brzeziński 2006), and in terms of organizational managerial processes as integrated management of the flow of materials from suppliers up to final customers (Stephens 2001).

Supply network includes all activities associated with the flow of goods (Fig. 2), from sourcing of basic raw materials and ending with the sale the final product to the final customer and dispose what becomes of this product after use (Beier & Rutkowski 2000, Brzeziński 2006, Daganzo 1996, Ghazanfari & Fatholla 2006, Korzeń 2001). At every stage movement may appear phrases, or materials rejected by the next company in the chain or wastes that require disposal.

Modern supply chains are becoming more complex, increasing thus their exposure to noise and danger. Growing importance of risk management in this type of logistics structures. The supply chain is cooperating in various functional areas of mining companies, manufacturers, retailers, service providers and their customers, between which streams flow of products, information and funds. The interpretation of the structural—the personal supply chain can be (Fig. 2):

– single companies (internal supply chain);
– pair or chain of companies that are in relationships: supplier—customer;
– network, or a group of cooperating and/or competing companies.

An enterprise may be a link several supply chains at the same time; then belongs to the so-called logistics network, and one of the effects of such membership may be conflicts between the requirements of the logistics chains of adjacent cells, and the possibilities of the company.

It seems that the decomposition of the chain-link joint logistics system and logistics tasks are appropriate "levels" in reliability and risk modeling supply chains. Therefore, one should speak about the reliability of cells logistics and logistics task risk, where the insufficient reliability of the results

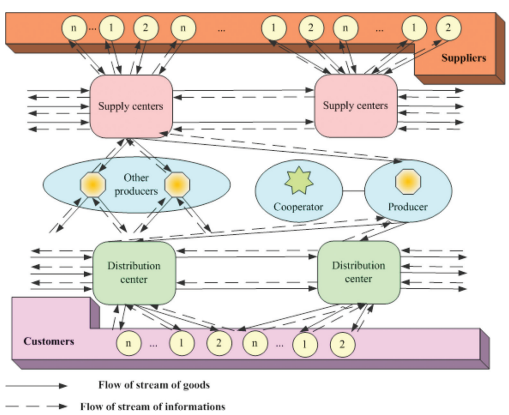

Figure 2. The general model of an integrated management of logistics network.

in a loss, you have to analyze both characteristics. As you know, determinants of reliability and risk in supply chains are "weak links"; therefore simplified reliability analysis and risk supply chains boiled down to, in particular, the analysis of these cells and logistical tasks that have been identified to as the "weak points" chain or logistics system.

According to the standards PN-82/N-04001 & PN-93/N-50191, the reliability of the system (technical object) is defined as a set of properties that describe the object and the willingness affecting it reliability, maintainability and maintenance support. Term dependability is used only for general not numerical technical description of the properties of the object.

To clarify the definition of the reliability should first introduce the importance of availability, which in accordance with the technical recognition PN-82/N-04001 means the ability of an object to remain in condition for fulfilling the required function under given conditions at a given moment or in a given time interval, assuming that there are delivered required external resources. Furthermore Villemeur (1992) assume that external funds other than funds service do not affect the availability of the object. The basic measure of availability is the availability function $Kg\ (t)$ - the probability that the i-th object is able to be in working condition (state of belonging to the set of states S^+), in given conditions, at a given time t, assuming that were delivered required external funds, the form of:

$$Kg(t) = \sum_{i \in S^+} P_i(t) \tag{1}$$

Availability is defined as a measure of the degree of the object reside in the state of functional worthiness and possibility of commencement of operation, which start time is a random variable. From the point of view of the user, the availability is a function of the frequency of occurrence of damage and related necessity to perform a repairs, the frequency of preventive handlings, time period of preventive handlings and the time period of logistics delays affecting the object.

Reliability is understood as the ability of an object to the correct operation is not interrupted with damage. Therefore means the ability of the i-th object to fulfill the required function under given conditions, in a given time interval [0, t]. Distinction is made between operational reliability (missionary) and logistics. It is assumed that at the beginning of time interval object is the state of worthiness—can properly function. Most often reliability is expressed by the probability:

$$R(t) = \sum_{i \in S^+} P_i[0,t] \tag{2}$$

Maintainability, it is the ability of an object to maintain or restore the given conditions in the state in which it can fulfill the required functions, with the assumption that the service is carried out while maintaining accepted conditions and procedures determined for each level of service.

The basic measure of the maintainability is the probability of service $M(t)$—the probability of making within a fixed time interval $[0, t]$ active service of the object exploited under certain conditions, with the assumption that the service is carried out under specified conditions with the use of specific methods and instrumentalities (Nowakowski 1999).

$$M(t) = P_t[0,t] \tag{3}$$

Referring to the logistics system there is no unambiguous definition of system reliability. According to the authors (Magott et al. 2007, Nowakowski 2000) reliability is one of the unquantifiable factors taken into account while designing logistics systems and:

- measure of the operational reliability are the interferences or the degree of performance degradation,
- is taken into account the flexibility of the system (the ability to adapt and change the area of operation) and expandability—extending the area.

The term reliability of the supply chain mostly is limited to the delivery process. Delivery service, as the output of the logistics system consists of elements such as delivery time, delivery reliability, readiness to provide the supply, quality and flexibility of supply. Delivery cycle determines the period between the filing of the order by the customer and the receipt of the goods. It consists of various components of time (time of transport, development time of the order, order-picking and preparation time), which should be taken into account.

Reliability of supply (Twaróg 2003) is determined by the ratio of orders delivered on time to the total number of demands. Quality of supply can be measured by the ratio of the number of complaints and the total number of demands. Flexibility of supply (the ability to adapt to the specific needs of customers) may be specified by the ratio of the number of fulfilled wishes to the number of these special wishes. Readiness to provide supplies may be expressed by the ratio of the number of demands realized from the warehouse to the total number of demands.

The reliability of the supply chain in discussed article will therefore mean among others (Nowakowski 2004):

- term undertake the task
- complete execution of the order,
- receipt and delivery of the goods without any damage.

Thus, an important aspect is the designation of the probability of faultless operation of the system will be the implementation of the service according with the expectation of the members of a supply chain.

3 MAPPING OF THE SUPPLY CHAIN STRUCTURE

Assume, that the structure of supply chain $\boldsymbol{S}$ can be defined as:

$$S = \langle \boldsymbol{V}, \boldsymbol{L} \rangle \tag{4}$$

where $\boldsymbol{V}$—set of numbers of elements of the supply chain of interpretation as suppliers, production companies as customers and storage facilities, $\boldsymbol{L}$—set of transport links occured between elements of the supply chain.

According to the interpretation of the supply chain, the set of its elements are the suppliers (other companies production or extraction), storage facilities and production companies. The model assumes that only the storage facilities are place of transformations performed on streams of loads.

Relationship between the elements (relations) will be transport links existing in the actual transport network.

Considering the above, the structure of the supply chain, understood as a set of elements and a set of relationships between network elements can be represented as a graph. For the purposes of the logistics network model, we assume that the network elements will be numbered with index of v. Thus $\boldsymbol{V}$ will be a set of numbers of elements of the supply chain as a:

$$V = \{v : v = 1,2, \ldots, v', \ldots, V\} \tag{5}$$

wherein V is cardinality of $\boldsymbol{V}$ set.

We assume that, in the set $\boldsymbol{V}$, distinguishes three types of subsets, i.e. set $\boldsymbol{A}$ of numbers of suppliers, which are sources of streams of goods (origin point), set $\boldsymbol{B}$ of numbers of production companies, which are the mouths of streams of goods (collection points) and a set of $\boldsymbol{M}$ of numbers of points in which material flow transformation is done (storage facilities).

Finally, the symbol $\boldsymbol{V}$ indicates a set of numbers of elements of the supply chain, i.e. the set of numbers of sources, outlets and intermediate points, which are involved in the movement of stream of loads, wherein:

$$\boldsymbol{V} = \boldsymbol{A} \cup \boldsymbol{M} \cup \boldsymbol{B} \tag{6}$$

where $\boldsymbol{V}$—set of numbers of elements of the supply chain, $\boldsymbol{V} = \{1,2, a, \ldots, m, \ldots, v, v', \ldots, b, \ldots, V\}$,

$\boldsymbol{A}$—set of numbers of sources of goods, $\boldsymbol{A} = \{v: \alpha(v) = 0,\ v \in \boldsymbol{V}\}$, $\boldsymbol{B}$—set of numbers of collection points, $\boldsymbol{B} = \{v: \alpha(v) = 1,\ v \in \boldsymbol{V}\}$, $\boldsymbol{M}$—set of numbers in which material flow transformation is done, $\boldsymbol{M} = \{v: \alpha(v) = 2,\ v \in \boldsymbol{V}\}$.

The symbol $\alpha(v)$ represents the elements of assigning functions to disjoint subsets $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{M}$ of set $\boldsymbol{V}$, $v \in \boldsymbol{V}$, wherein $\alpha(v) = 0$ when the element is the point of origin, $\alpha(v) = 1$ when the element is the point of reception, and $\alpha(v) = 2$ when the element is the point at which there is a stream of loads transforming.

Geographically elements $v \in \boldsymbol{A}$ and $v' \in \boldsymbol{B}$ in a particular case may overlap but they differ in the role they perform in the supply chain, so they are different. We assume that the division of the logistics network nodes into sets $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{M}$ is exhaustive and disjoint, i.e.:

$$\boldsymbol{A} \cap \boldsymbol{B} = \varnothing; \quad \boldsymbol{A} \cap \boldsymbol{M} = \varnothing; \quad \boldsymbol{B} \cap \boldsymbol{M} = \varnothing$$
$$\text{and } \boldsymbol{A} = \boldsymbol{V} \setminus (\boldsymbol{B} \cup \boldsymbol{M}); \quad \boldsymbol{B} = \boldsymbol{V} \setminus (\boldsymbol{A} \cup \boldsymbol{M});$$
$$\boldsymbol{M} = \boldsymbol{V} \setminus (\boldsymbol{A} \cup \boldsymbol{B}).$$

Furthermore, we assume the following assumption regarding the interpretation of logistics service providers, i.e.:

- services in the area of transport of goods are realized with the use of arcs (v, v') $v \in \boldsymbol{A}$, $v' \in \boldsymbol{B}$ of the supply chain,
- suppliers who are mapped of intermediate nodes of the logistics network $v \in \boldsymbol{M}$ realize services in the form of admission, demoulding, storage, formation and preparation of loads.

In addition, it is assumed that are possible direct transport links between the different elements of the chain, i.e. links that exist between:

- points of sources of goods and points in which material flow transformation is done;
- points of sources of goods and collection points;
- different points in which material flow transformation is done;
- points in which material flow transformation is done and collection points.

It was also assumed, that on Cartesian ratio $\boldsymbol{V} \times \boldsymbol{V}$ mapping is done ϕ conducting elements of the product in the set $\{0, 1\}$, i.e.:

$$\phi: \boldsymbol{V} \times \boldsymbol{V} \to \{0,1\} \tag{7}$$

wherein if $\phi(v,v') = 1$, then between nodes v and $v' \neq v$ there is a direct transport link, otherwise $\phi(v,v') = 0$.

We assume that $\boldsymbol{L}$ would be a set of transport links, tj.:

$$\boldsymbol{L} = \{(v,v'): \phi(v,v') = 1, \text{ for } v \neq v' \wedge v,v' \in \boldsymbol{V}\} \tag{8}$$

whose elements have the interpretation of direct transport links existing in the actual transport network.

It was assumed that set $\boldsymbol{L}$ can be decomposed into four pair wise disjoint sets. Considering the above assumptions, we assume therefore that $\boldsymbol{L}^{A,M}$ is a set of direct transport links between points of sources of goods and points in which material flow transformation is done, i.e.:

$$\boldsymbol{L}^{A,M} \subset \boldsymbol{L} \text{ and } \boldsymbol{L}^{A,M} = \{(v,v'): v \in \boldsymbol{A} \wedge v' \in \boldsymbol{M}\} \tag{9}$$

We assume that $\boldsymbol{L}^{A,B}$ is a set of direct transport links between points of sources of goods and collection points, i.e, tj.:

$$\boldsymbol{L}^{A,B} \subset \boldsymbol{L} \text{ and } \boldsymbol{L}^{A,B} = \{(v,v'): v \in \boldsymbol{A} \wedge v' \in \boldsymbol{B}\} \tag{10}$$

We assume that $\boldsymbol{L}^{M,M}$ is a set of direct transport links between different points in which material flow transformation is done, i.e.:

$$\boldsymbol{L}^{M,M} \subset \boldsymbol{L} \text{ and } \boldsymbol{L}^{M,M} = \{(v,v'): v \neq v' \wedge v,\ v' \in \boldsymbol{M}\} \tag{11}$$

We assume that $\boldsymbol{L}^{M,B}$ is a set of direct transport links between points in which material flow transformation is done and collection points, i.e.:

$$\boldsymbol{L}^{M,B} \subset \boldsymbol{L} \text{ and } \boldsymbol{L}^{M,B} = \{(v,v'): v \in \boldsymbol{M} \wedge v' \in \boldsymbol{B}\} \tag{12}$$

Considering above assumptions, it can be assumed that the supply chain network can be described by a pair $\langle \boldsymbol{V}, \boldsymbol{L} \rangle$, where $\boldsymbol{V}$ and $\boldsymbol{L}$ are respectively the non-empty sets of nodes and arcs. In order to describe the reliability of the network as a model of supply chain with regard to its independence can be used the following nomenclature:

- network consists of $\boldsymbol{V}$ nodes and $\boldsymbol{L}$ arcs,
- each element v represents respectively element of the set $\boldsymbol{V}$ (i.e. $v \in \boldsymbol{A}$, $v \in \boldsymbol{M}$ or $v \in \boldsymbol{B}$),
- each element (v, v') represents arc of the set $\boldsymbol{L}$ (wherein (v, v') belongs to the set $\boldsymbol{L}^{A,M}$, $\boldsymbol{L}^{A,B}$, $\boldsymbol{L}^{M,M}$ or $\boldsymbol{L}^{M,B}$),
- with each node v and the arc (v,v') are related the reliability of the probabilities respectively of the node $r(v)$ and the arc $r(v,v')$.

4 CRITERIA FOR EVALUATION OF OPERATIONAL EFFECTIVENESS OF THE SUPPLY CHAIN

As is apparent from the research all elements of the supply chain must fulfill their own separate performance expectations. This means that the elements in the chain may be considered as whole series of system reliability. The unreliability of one or more elements translates into a failure

of the whole chain. Conversely, the reliability of individual elements of the supply chain, makes it can meet the performance expectations in all markets in their environment. Hence, for the entire system, according to Nahmias (1989) reliability of the chain can be represented as:

$$R(\boldsymbol{V}, \boldsymbol{L}) = \prod_{v \in V:\,(v,v') \in L} \left(r(v) - r(v,v') \right) \tag{13}$$

Taking into account the above to assess the effective functioning of the entire supply chain can be a criterion of the degree of utilization of both its components and the whole system. The degree of use of the whole supply chain can be assessed as the ratio of the total time required for the transition of ordered materials for production through the supply chain in relation supplier-company to a maximum total duration of stay of vehicles in the chain.

Assuming we know moments $\theta\rho_v^{pk_n} : \theta\rho_v^{pk_n} \in \boldsymbol{T}$ of the appearance of the n-th vehicle of class pk ($pk \in \boldsymbol{S}$, $\boldsymbol{S}$-set of classes of vehicles, $pk_n \in \boldsymbol{N}(pk)$, $\boldsymbol{N}(pk)$-a set of vehicles of the class pk) in the nodes $v \in \boldsymbol{V}$ of the supply chain and exit times $\theta\kappa_v^{pk_n} : \theta\kappa_v^{pk_n} \in \boldsymbol{T}$ of the chain is the total time required to move the ordered raw production and supplied by the vehicles through the supply chain in relation supplier-company we write in the form of:

$$\sum_{v \in \boldsymbol{V}} \sum_{pk \in \boldsymbol{S}} \sum_{pk_n \in \boldsymbol{N}(pk)} \left(\begin{array}{l} \left(\theta\kappa_v^{pk_n} - \theta\rho_v^{pk_n} \right) \\ + \sum\limits_{v':\,(v,v') \in \boldsymbol{L}} \left(\theta\rho_{v'}^{pk_n} - \theta\kappa_v^{pk_n} \right) \end{array} \right) \tag{14}$$

With knowledge of the maximum capacity (number of vehicles) $\zeta^{max}(v)$ for each v-th element of the supply chain and the maximum capacity (number of vehicles) $\eta^{max}(v,v')$ of each (v,v')-th arc of the network, and assuming that we know the expected value $E(TO(v, (v,\tau), nk(v,\tau), pk))$ of service time of pk-th class of vehicle to the service station number of $nk(v,\tau)$ (charging device, discharging, etc.) in the time interval τ and the expected value $E(TO(v, v', \tau, pk))$ of service time of pk-class of vehicle to the service station number $nk(v,\tau)$ (charging device, discharging, etc.) passing the arc of the supply networks to fix a maximum total period of stay of vehicles in the supply chain by using the equation:

$$\sum_{pk \in \boldsymbol{S}} \sum_{pk_n \in \boldsymbol{N}(pk)} \left(\begin{array}{l} \sum\limits_{v \in V} \zeta^{max}(v) \mathrm{E}(c) \\ + \sum\limits_{v \in \boldsymbol{V}} \sum\limits_{v':(v,v') \in \boldsymbol{L}} \eta^{max}(v,v') \mathrm{E}(d) \end{array} \right) \tag{15}$$

where $c = \mathrm{TO}(v,(v,\tau),nk(v,\tau),pk)$, $d = \mathrm{TO}(v, v', \tau, pk)$.

Thus, the criterion of maximizing the average use of all elements of the chain can be saved the following relation, i.e.:

$$F1(\boldsymbol{\theta P}, \boldsymbol{\theta K}) = \left(\begin{array}{l} \dfrac{\sum\limits_{v \in V} \sum\limits_{pk \in \boldsymbol{S}} \sum\limits_{pk_n \in \boldsymbol{N}(pk)} \left(\theta\kappa_v^{pk_n} - \theta\rho_v^{pk_n} \right)}{\sum\limits_{pk \in \boldsymbol{S}} \sum\limits_{pk_n \in \boldsymbol{N}(pk)} \sum\limits_{v \in \boldsymbol{V}} \left(\begin{array}{l} \zeta^{max}(v) \mathrm{E}(c) + \\ \sum\limits_{v':(v,v') \in \boldsymbol{L}} \eta^{max}(v,v') \mathrm{E}(d) \end{array} \right)} \\ + \dfrac{\sum\limits_{v \in \boldsymbol{V}} \sum\limits_{pk \in \boldsymbol{S}} \sum\limits_{pk_n \in \boldsymbol{N}(pk)} \sum\limits_{v':(v,v') \in \boldsymbol{L}} \left(\theta\rho_{v'}^{pk_n} - \theta\kappa_v^{pk_n} \right)}{\sum\limits_{pk \in \boldsymbol{S}} \sum\limits_{pk_n \in \boldsymbol{N}(pk)} \sum\limits_{v \in \boldsymbol{V}} \left(\begin{array}{l} \zeta^{max}(v) \mathrm{E}(c) + \\ \sum\limits_{v':(v,v') \in \boldsymbol{L}} \eta^{max}(v,v') \mathrm{E}(d) \end{array} \right)} \end{array} \right) \to \max \tag{16}$$

where $c = \mathrm{TO}(v,(v,\tau),nk(v,\tau),pk)$, $d = \mathrm{TO}(v, v', \tau, pk)$.

A very important from the point of view of the effectiveness to the functioning degree of utilization of all elements of the supply chain. Decision variables take the form of $z_{v,nk(v,\tau)}^{t,pk_n} \in \{0,1\}$ defining assignment of vehicles pk-th class at the service station with the number $nk(v,\tau)$ in the v-th element of the chain, we can evaluate effectiveness to the functioning of the supply chain from the point of view of average use of all elements of the point of the supply chain, i.e.:

$$F2(\mathrm{Z}) = \frac{\sum\limits_{v \in V} \sum\limits_{pk \in \boldsymbol{S}} \sum\limits_{pk_n \in \boldsymbol{N}(pk)} \left(\begin{array}{l} \mathrm{E}(c) \\ \mathrm{sgn} \sum\limits_{t \in \boldsymbol{T}} z_{v,nk(v,\tau)}^{t,pk_n} \end{array} \right)}{\sum\limits_{v \in V} \zeta^{max}(v) \left(\theta\kappa_v^{pk_n} - \theta\rho_v^{pk_n} \right)} \to \min \tag{17}$$

where $c = \mathrm{TO}(v,(v,\tau),nk(v,\tau),pk)$.

Another indicator that can be used to assess effectiveness to the functioning of the supply chain is to minimize time loss occurring during logistical processes. It can be determined as the difference between the total length of stay of load in the supply chain (raw materials for production or finished goods to customers in the supply chain) and the expectation time, namely:

$$F3(\mathbf{Y},\boldsymbol{\theta}\mathbf{P},\boldsymbol{\theta}\mathbf{K})$$

$$= \left(\begin{array}{l} \left(\sum\limits_{v\in V}\sum\limits_{pk\in S}\sum\limits_{pk_n\in N(pk)} \left(\theta\kappa_v^{pk_n} - \theta\rho_v^{pk_n}\right) \right. \\ + \sum\limits_{v\in V}\sum\limits_{v':(v,v')\in L}\sum\limits_{pk\in S}\sum\limits_{pk_n\in N(pk)} \left(\theta\rho_v^{pk_n} - \theta\kappa_v^{pk_n}\right) \\ - \sum\limits_{v\in V}\sum\limits_{nk(v,\tau)\in NK(v,\tau)}\sum\limits_{(v,\tau)\in T(v)}\sum\limits_{pk\in S}\sum\limits_{pk_n\in N(pk)} \\ \left(\begin{array}{l} \mathrm{E}(c) \\ \max\limits_{t\in\left[t_\tau^v,\ t_{\tau+1}^v\right]} \left\{ z_{v,\mathrm{nk}(v,\tau)}^{t,\ pk_n} \right\} \end{array} \right) \\ - \sum\limits_{v\in V}\sum\limits_{v':(v,v')\in L(v,\tau)\in T(v)}\sum\limits_{pk\in S}\sum\limits_{pk_n\in N(pk)} \\ \left. \left(\begin{array}{l} \mathrm{E}(d) \\ \max\limits_{t\in\left[t_\tau^v,\ t_{\tau+1}^v\right]} \left\{ y_{v,v'}^{t,\ pk_n} \right\} \end{array} \right) \right) \end{array} \right) \rightarrow \min \tag{18}$$

where $c = \mathrm{TO}(v,(v,\tau),nk(v,\tau),pk)$, $d = \mathrm{TO}\ (v,\ v',\ \tau,\ pk)$.

The proposed approach to the research of the logistics process in the supply chain allows the assessment of operational reliability of the supply chain under different boundary conditions and constraints defining the equipment of the chain and for various tasks i.e. different stream of notifications of orders into the system.

5 SUPPLY CHAIN OPERATION REFERENCE MODEL AS A TOOL FOR CONTROLLING AND MANAGEMENT OF THE PROCESSES IN THE SUPPLY CHAIN

Analyzed in the article discussion concerns the supply chain model whose objective is to study the reaction speed and reliability of the chain elements to determine whether the relationships in the supply chain have a high reliability factor or not. In order to investigate the supply chain enterprises use the SCOR model (reference model of the supply chain, called Supply Chain Operation Reference-model), published by the SCC (Supply-Chain Council), which is used to describe and comprehensive analysis of the supply chain (Haj 2002, Mazuruk & Rzepka 2006, Stephens 2001, Stephan & Badr 2007). This model is a valuable tool for the analysis of the supply chain, have been used.

SCOR model allows for measurement, control and management processes throughout the supply chain-pond, covering all participants (manufacturers, transport companies, distributors, consumers). It is based on five main by processes SCM (Supply Chain Management) (Haj 2002, Stephens 2001, Stephan & Badr 2007):

- "Plan"—covers the planning and allocation of resources, capacity and trade rules along the supply chain and aims to streamline procurement processes, production and supply in terms of resources and demand,
- "Source"—includes the processes of sourcing, purchasing goods and services and the management of the sources of supply,
- "Make"—includes the planning and implementation of the transformation processes that convert the available goods and services in the ordered goods,
- "Deliver"—includes the management of the orders, storage, transportation and installation of goods or commercial goods,
- "Return"—these processes include the organization and execution of shipments of returnable defective products cases, warranty and unnecessary resources to suppliers or customers,

SCOR model supports the operating indicators for the evaluation on four levels (Haj 2002, Stephens 2001).

- "Top Level": by assigning the main processes allows a clear view of the supply chain.
- "Configuration Level": at this level, there is a total of 21 categories of processes for the processes of the first level, by means of which the supply chain can be configured. For each executive process Source, Make, Deliver shared is a variant-oriented warehouse (MTS), in order (MTO) and structure (ECA).
- "Process Element Level": here distributes selected at level 2 categories on the process chains processes and individual elements of the transaction. These elements are closer to the process defined on the basis of input and Output documentation, good examples, support systems and process indicators.
- "Implementation Level": this level is specific to the company and is not part of the reference model. Using the SCOR model processes must be transferred at least to the fourth level, to be able to introduction standardized waveforms in the company.

SCOR model, through the defined process components, allows for modeling, measuring of the description and evaluation of the entire supply chain. It can also serve the restructuring process

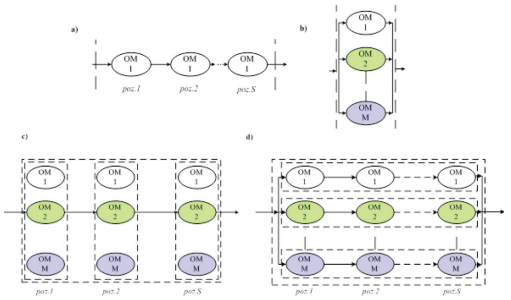

Figure 3. Reliability structures on the example of of supply chains storage facilities (OM) in the system: a) series, b) parallel, c) series-parallel, d) parallel-series.

or construction of a new business area or product line (Mazuruk & Rzepka 2006, Stephens 2001, Stephan & Badr 2007).

Measures from the first level approach to supply chain management in order to assess, and the relevant parameters from the second and third contain more specific and detailed criteria for the categories and components processes. Indicators of the level of the first SSC (2006) divided into five operational criteria, of which three, reliability, flexibility and speed of response, are directed to the attributes of the client, and the other two, expenses and assets are used to measure inside the company. Each of these measures is further divided into small ratios at lower levels.

According to sources in the literature (Stephan & Badr 2007) the level of reliability of the supply chain of the first level can be assessed and measured by SCOR metrics superior orders, and at the other by a metric superior orders, deliveries in a timely manner, with appropriate documentation and excellent quality delivered the goods to the customers.

On the third and fourth level supply chain by SCOR model can be seen small, but more detailed metrics for the evaluation of these measures. It is possible to calculate the level of reliability in each loop chain wide variety of pre-selected time periods. In order to measure the speed of the reliability of the entire supply chain in a certain period of time (Haj 2002) proposes that the first step is to determine the type of supply chain, which can be placed in one of five possible structures of reliability (Fig. 3), i.e., serial, parallel, series-parallel or a parallel—serial, and then, on the basis of a formula related reliability of the system, it is possible to calculate the reliability of the whole system during that period.

6 CONCLUSIONS

The proper functioning of all elements of the supply chain significantly affect the quality of the final product, and hence on:

– meeting customer requirements, which translates into the realization of business objectives,
– greater chance of further contracts, and thus the development of the entire supply chain,
– enhancing ties customer-supplier-subcontractor throughout the life cycle of the product.

The efficiency of the supply chain is a cumulative characteristics of quality of functioning of the entire supply chain, which can be expressed by means of specific characteristics. It determines the effectiveness of expenditure incurred for the useful effects, such as reducing time loss of implementation of a logistics process in the supply chain.

Thus, the proposed indicators to assess effectiveness to the functioning of the chain can be a feature of the system, measurable and useful when comparing supply chains of the same class, expressing different aspects of the different compartments depending on their purpose and conditions of use.

The effective functioning of supply chains is very important not only for companies but also for logistics operators and transport companies, largely because it affects the level of service provided by these companies.

The supply chain will be effective when provided implementation of the agreed tasks at the required level of quality at a reasonable use of the equipment of the whole chain. Thus, analysis of supply chain efficiency should be based on its graduation from global ratings to the partial assessments concerning overall resource efficiency of the chain and the cost of tasks realization.

ABSTRACT: The paper presents the problem of the effectiveness of the national transport system in terms of the cost of emissions. It sets out the general principles of research methodology, taking into account actual emissions from vehicles. The paper formalized effectiveness indicators for road transport modeling of such systems. Transport effectiveness is characterized by significant difficulties in the study due to the large scale of the system as well as many of the entities involved and the need to take into account their interests. Transport is a very important sector of the economy contributing to its development and the development of societies. In view of the above, the paper also presents an example of research on the identification of Polish areas with increased emissions in a macro scale. This article is the result of works done in the project EMITRANSYS funded by the National Centre for Research and Development in Poland.

1 INTRODUCTION

1.1 *General assumptions*

Road transport is the dominant mode of transport in the European Union and is responsible for environmental pollution (Przybyłowski 2011). In turn rail transport is the second most popular mode of transport, but it involves other environmental threats than road. Both modes are included in the national transport systems. The European Union is taking actions to reduce harmful effects of transport through the integration of transport policy with environmental policy, which is to lead to the formation of environmentally friendly transport system (Ambroziak et al. 2013).

Road transport pollution spreads in close proximity to human settlements at high concentrations at low altitudes (Danklefsen 2011) and depends on many factors such as fuel composition, engine type, vehicle maintenance, type and basic characteristics of the vehicle, deployment of infrastructure, speed patterns, routing, congestion, etc. Research on the analysis of emissions under real conditions indicate that certain toxic components of exhaust gases are as much as several hundred percent larger than from non-transport sources for both gaseous compounds (see Engeljerhinger 2011, Merkisz et al. 2014a,b, Merkisz & Pielecha 2014) and particle matter (see Merkisz & Pielecha 2014, Steiningier 2009). Harmful components of exhaust gases are divided into: harmful for living creatures and regulated by Euro standards (carbon monoxide, hydrocarbons, nitrogen oxides, nitrogen oxides) and non-regulated (nitrogen dioxide, sulfur oxide, non-methane HC) and harmful for environment i.e. carbon dioxide, CO_2 equivalent, ammonia, nitrous oxide, methane (REGULATION EC No 715/2007).

National transport system embraces all transport infrastructures and supports all types of vehicles and all types of loading forms. It is based mostly on road transport network—a source of pollutants, which closely cooperates with railway transport, so effect of comodality can be a significant factor creating total pollution patterns on national level.

National transport system should be constantly designed and controlled with regard to different aspects of its activity including environment degradation, economic and social needs. Proper designing and controlling mean right usage of resources reflected in relation between expenditures and

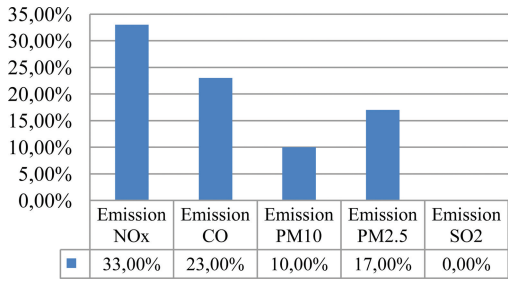

Figure 1. Share of air pollutants from road transport in Poland in 2011. Source: based on KOBiZE 2013.

effects. The effect of particular importance is environment degradation expressed by costs of emission correlated to means of transport, especially road transport.

Effectiveness of transport system embraces different aspects. Individual users perceive differently advantages and costs of transport. In the assessment process it is essential to have possibility of selection of options of infrastructure adjustment to perform transport tasks. The complexes of decisions affect the effectiveness of integrated transport systems (Leontiadis et al. 2011).

1.2 *Road transport emission*

In addition to road transport the sources of air pollutions are (KOBiZE 2013): production processes, energy transformation (coal to electricity), non-industry combustion processes, waste management, agriculture. Figure 1 presents emission levels of basic pollutants from road transport in Poland in 2011.

Against the background of the national emissions, road transport produces 33.18% of nitrogen oxides (NO_x), 23.15% of carbon monoxide (CO), 10.36% and 17.18% of particulate matter (respectively PM10 and $PM_{2,5}$). Emission of sulfur dioxide (SO_2) is 0.15%, and nowadays is not considered as important pollutant. The road infrastructure in Poland is around 3% of the country, but within the direct impact of transport pollution is about 50% of the Poland (Ambroziak et al. 2013).

2 ROAD TRANSPORT EFFECTIVENESS

Efficiency of large scale transport systems is difficult to define and measure because of system complexity and range. According to definition, efficiency is a result of undertaken actions, described by relation of gained effects to expenditures (Leontiadism et al. 2011). Efficiency is correlated to: performance; taking right actions, and efficacy; assessment of fairness of method adopted to the planned goals.

Most commonly the inputs for effectiveness calculation are the costs of actions, and the effects in the form of mass of transported goods and number of conveyed passengers or the transport performance measurements like tonne-km and passenger-km.

Effectiveness of transport system in terms of sustainable economy means minimization of external costs at the least possible increase in direct costs of transport. Presented paper limits discussion to the external cost resulting from emission.

The basic measures of effectiveness of national transport system are economic and ecological (Delucchi & McCubbin 2011). If the emission is considered as effect of transport activity, then following economic measures are used:

– Difference between the costs incurred by society for treatment of diseases and saving the natural environment arising due to air pollution and expenditures greening of the transport system:

$$\sum_{s\in S} kz(s) - \sum_{r\in R} n(r) \tag{1}$$

where:

$kz(s)$—costs of prevention of harmful effects of s-th compound of exhaust gases; $n(r)$—expenditures to increase environmental friendliness of r-th mode of transport.

– Quotient of the costs incurred by society for treatment of diseases and saving the environment due to the expenditures increasing environmental performance of the transport system.

$$\sum_{s\in S} kz(s) \Big/ \sum_{r\in R} n(r) \tag{2}$$

– The quotient of the difference between the costs incurred by society for treatment of diseases and saving the environment in the following two years and expenditures increasing environmental performance of the transport system.

$$\left(\sum_{s\in S} kz(s,t) - \sum_{s\in S} kz(s,t-1)\right) \Big/ \sum_{r\in R} n(r,t) \tag{3}$$

The ecological measures are then:

– The quotient of the number of vehicles with the highest EURO standard to the total number of vehicles in the country:

$$\exists neu \quad \sum_{st\in ST} l(st,neu) \Big/ \sum_{neu\in Neu} \sum_{st\in ST} l(st,neu) \tag{4}$$

where: $l(st,neu)$—numer of st-th type vehicles keeping neu-th EURO standard.

– The quotient of volume of transport done by low-emission modes (eg. inland, rail) to transport volume done by all modes of transport.

$$\sum_{r\in R_e} q(r) \Big/ \sum_{r\in R} q(r) \tag{5}$$

where: $q(r)$—transport volume done by r-th mode, R_e—set of low emission modes $R_e \subset R$.

From an economic point of view, the criterion of the transport system performance evaluation is the direct cost of transportation (Mashayekh et al. 2011). Taking into account previously formulated markings; criterion can be given as follows:

$$\sum_{neu\in Neu}\sum_{st\in ST} l(st,neu)\cdot c(st)\cdot d(st) \longrightarrow \min \tag{6}$$

where: $c(st)$—unit costs of transport by st-th type of vehicle; $d(st)$—the average distance covered by st-th type of vehicle.

3 EFFECTIVENESS FORMALIZATION

3.1 *General remarks*

Estimation of ecological efficiency of national transport system requires formal model of this system to represent its complexity and its features significant for the purpose of research (Jacyna 2012).

Considering tasks realized by national transport system, the model developed to estimate emission and ecological interactions must include following elements:

– Structure of the system representing real transport connections between its elements,
– Characteristics mapping real features of system structural elements important for proper flows distribution that minimize emission of harmful compounds, including technical, organizational and economical characteristics,
– Transport tasks defined as material and passenger streams between points of origin and destinations,
– Organization of flows in the system representing the ways of usage of elements of transport infrastructure.

The model of proecological transport system (MEST) is then given as follows (Jacyna et al. 2013, Jachimowski et al. 2013):

$$\mathbf{MEST} = <\boldsymbol{GE}, \boldsymbol{FE}, \boldsymbol{QE}, \boldsymbol{OE}, \boldsymbol{IE}> \tag{7}$$

where: $\boldsymbol{GE}$—graph of system structure; $\boldsymbol{FE}$—set of characteristics representing real features of system elements; $\boldsymbol{QE}$—transportation tasks performed by system representing all material and passenger flows given as origin-destination matrixes; $\boldsymbol{OE}$—organization—the way of realizing transportation tasks by system with regard to emission of harmful compounds—apportion of material and passenger flows on transportation network; $\boldsymbol{IE}$—databases and information systems.

Organization of material flow determines desired way of transport tasks realization by transport system. So, the load of transport links by vehicles of different types according to different segments of demand for freight and passenger transport is sought. The load of elements of transport network results from directing means of transport to the routes identified in particular transport relations (Farmer 2013, Sivilevičius 2011).

3.2 *Structure and characteristics of the model*

The infrastructure has basic meaning for realization of transport tasks:

– Line; existing transport links (road, rail),
– Point; logistics infrastructure for material handling and passenger servicing;
– Information; processing data, security.

as well as superstructure embracing means of transport fitted to different tasks and types of infrastructure.

In formal way the structure of national transport system is modelled by a graph $\boldsymbol{GE} = <\boldsymbol{WE}, \boldsymbol{LE}>$ where $\boldsymbol{WE} = \{1, \ldots, a, \ldots, b, \ldots, i, \ldots, i', \ldots, WE\}$ is a set of transport nodes including origin and destination points, $\boldsymbol{LE}$ is a set of transport links between nodes of transport representing different modes of transport and different possibilities of movement.

The set $\boldsymbol{WE}$ is divided into three subsets: the set of origins of material and passenger flows $\boldsymbol{N}$, the set of destinations of material and passenger flows $\boldsymbol{O}$, and set of intermediate (transition) points $\boldsymbol{P}$.

For each pair of nodes $(a,b)\in \boldsymbol{E}$, $a\in \boldsymbol{N}$, $b\in \boldsymbol{O}$ the transport relation can be set. For each relation, a set of potential transport paths $\boldsymbol{P}^{ab}$ is known. A single path in a given relation (a, b) is numbered with index p, where $p\in \boldsymbol{P}^{ab}$ so $\forall(a,b)\in \boldsymbol{E} \quad \exists p \in \boldsymbol{P}^{ab}$. Moreover $\boldsymbol{P}_{ii'}^{ab}$ is a set of paths in relation (a, b) passing the (i, i')-th transport link.

Numbers of nodes in set $\boldsymbol{P}$ represent real transport nodes of different types like crossroads, stops, stations, airports, terminals, and other points where characteristics of infrastructure change. Nodes in sets $\boldsymbol{N}$ and $\boldsymbol{O}$ represent areas generating demand for transportation.

Transport links are characterized by assigned types of vehicles to move on $\boldsymbol{ST}'(i, i')$, assigned

EURO standards to enter $\boldsymbol{NEU}(i, i')$, lengths $l(i, i')$, entering costs $k_d(i, i')$, speed limits $v^{max}(i, i')$, capacity $d(i, i')$, loading capacity $DMC(i, i')$, axle load limits $Qosi(i, i')$, horizontal gauge $B(i, i')$ vertical gauge $H(i, i')$, area type $\boldsymbol{OB}(i, i')$, as well as relevant for estimating the dispersion: longitudinal inclination, the occurrence of road noise barriers or plantings, most frequent wind direction and the location of the section in the plan (its direction).

Due to the purpose of the research significant characteristics of means of transport related to the capacity and utilization, operating costs and function of emission according to speed and mileage (the effect of heating up the engine) are noted. For the purpose of research it was assumed that $\boldsymbol{S} = \{1, \ldots, s, \ldots, S\}$ is a set of harmful compounds of exhaust gases. Then characteristics of means of transport are as follows:

- maximal loading capacity of $n(st)$-th vehicle of st-tego type, $q_{max}(n(st), st)$,
- permissible load of $n(st)$-th vehicle of st-th type, $q_{dop}(n(st), st)$,
- cubic capacity of number of passengers of $n(st)$-th vehicle of st-th type, $p(n(st), st)$,
- permissible weight of $n(st)$-th vehicle of st-th type, $DMC(n(st), st)$,
- permissible axle loads of $n(st)$-th vehicle of st-th type, $qosi(n(st), st)$,
- emission standard kept by $n(st)$-th vehicle of st-th type, $nes(n(st), st)$,
- height of $n(st)$-th vehicle of st-th type, $h(n(st), st)$,
- width of $n(st)$-th vehicle of st-th type, $b(n(st), st)$,
- coefficient of average fulfilment of st-th type of vehicle when conveying materials of spt-th demand segment, $Ct(st, spt)$,
- average capacity utilization coefficient of st-th type of vehicle when conveying passengers of spp-th segment of demand, $Cp(st, spp)$,
- average exploitation cost of st-th type vehicle dependent on mileage, $k_l(st)$,
- average exploitation cost of st-th type vehicle dependent on work time, $k_h(st)$,
- level of unit emission of s-th compound identified for st-th type of vehicle, driven by engine of $rsp(st)$-th type, keeping $neu(st)$-th emission standard and moving on (i, i')-th segment of transport network, $em(s, st, neu(st), rsp(st), i, i')$,
- the rate of the effect of the route mileage on unit emission of s-th compound identified for st-th type of vehicle, driven by engine of $rsp(st)$-th type, keeping $neu(st)$-th emission standard and moving on relation (a, b) on p-th route, $\psi(s, st, neu(st), rsp(st), p, a, b)$,
- the number of available st-th type vehicles with $rsp(st)$-th type of engine and keeping $neu(st)$-th EURO standard, $lp^{max}(st, neu(st), rsp(st))$.

Above characteristics are necessary because particular vehicles are different according to usage, type of engine, fuel, capacity etc.

3.3 *Selected criteria for emission estimation*

The problem is reduced to seting values of decision variables:

- number of freight vehicles $xt(p,a,b,st)$ of st-th type moving through p-th path in relation (a,b),
- number of passenger vehicles $xp(p,a,b,st)$ of st-th type moving through p-th path in relation (a,b),

to extremize values of criteria of effectiveness of national transport system in relation to emission of harmful compounds. According to the nature of the problem criteria functions describe the level of emission of different compounds while the transportation process is performed (Kok et al. 2011). For optimal solution these criteria will take possibli lowest values. Criterion describing level of emission is as follows $\forall s \in \boldsymbol{S}$:

$$\sum_{st\in\boldsymbol{ST}}\sum_{(i,i')\in\boldsymbol{LE}}\sum_{(a,b)\in\boldsymbol{E}}\sum_{p\in\boldsymbol{P}^{ab}_{i,i'}}\left[xt(p,a,b,st)+xp(p,a,b,st)\right]\cdot l(i,i')\cdot ema(s,st,i,i')\cdot\psi a(s,st,p,a,b)\longrightarrow\min \tag{8}$$

where coefficients of unit emission $ema(s,st,i,i')$ and $\psi a(s,st,p,a,b)$ are set by formulas (9) i (10):

$$\forall s\in\boldsymbol{S}\ \ \forall st\in\boldsymbol{ST}\ \ \forall(i,i')\in\boldsymbol{LE}^{\boldsymbol{PP}}\quad ema(s,st,i,i) = \frac{\sum\limits_{\substack{rsp(st)\\ \in\mathbf{RSP}(st)}}\ \sum\limits_{\substack{neu(st)\\ \in\mathbf{NEU}(st)\\ \cap\mathbf{NEU}(i,i')}} \begin{pmatrix} em(s,st,neu(st),rsp(st),i,i') \\ \cdot lp^{max}(st,neu(st),rsp(st)) \end{pmatrix}}{\sum\limits_{\substack{rsp(st)\\ \in\mathbf{RSP}(st)}}\ \sum\limits_{\substack{neu(st)\\ \in\mathbf{NEU}(st)\\ \cap\mathbf{NEU}(i,i')}} lp^{max}(st,neu(st),rsp(st))} \tag{9}$$

$$\forall s\in\boldsymbol{S}\ \ \forall st\in\boldsymbol{ST}\ \ \forall(a,b)\in\boldsymbol{E}\ \ \forall p\in\boldsymbol{P}^{\mathbf{ab}}\quad \psi a(s,st,p,a,b) = \frac{\sum\limits_{\substack{neu(st)\\ \in\mathbf{NEU}(st)}}\ \sum\limits_{\substack{rsp(st)\\ \in\mathbf{RSP}(st)}} \begin{pmatrix} \psi(s,st,neu(st),rsp(st),p,a,b) \\ \cdot lp^{max}(st,neu(st),rsp(st)) \end{pmatrix}}{\sum\limits_{\substack{neu(st)\\ \in\mathbf{NEU}(st)}}\ \sum\limits_{\substack{rsp(st)\\ \in\mathbf{RSP}(st)}} lp^{max}(st,neu(st),rsp(st))} \tag{10}$$

From an economic point of view, the criterion of performance evaluation of the transport system

is the direct cost of transportation. Taking into account previously formulated markings, criterion can be ascribed as follows:

$$\sum_{\substack{st \\ \in \boldsymbol{ST}}} \sum_{\substack{(i,i') \\ \in \boldsymbol{LE}}} \sum_{\substack{(a,b) \\ \in \boldsymbol{E}}} \sum_{\substack{p \\ \in \boldsymbol{P}_{i,i'}^{ab}}} \left[\begin{matrix} xt(p,a,b,st) \\ + xp(p,a,b,st) \end{matrix} \right] \cdot c(st,i,i') \longrightarrow \min \tag{11}$$

where: costs $c(st,i,i')$ of entering particular types of transport links by means of transport are set from formula (12):

$$\forall st \in \boldsymbol{ST} \;\; \forall (i,i') \in LE^{\boldsymbol{PP}}$$
$$c(st,i,i') = k_l(st) \cdot l(i,i') + \frac{k_h(st) \cdot l(i,i')}{v(i,i',\mathbf{X}^*)} + k_d(i,i') \tag{12}$$

where: ($k_l(st)$ and $kh(st)$) are cost characteristic of means of transport, $v(i,i',\mathbf{X}^*)$—average velocity of traffic on given transport link dependent on cargo and passenger distribution $\mathbf{X}^*$.

Of course solutions are sought under appropriate conditions and restrictions touching among others; range of variability, exceeding capacity, or limiting acsess to certain areas or sections of roads, etc (Sen et al. 2010).

4 EXEMPLARY AREAS OF POLAND WITH HIGHER CONCENTRATION OF SELECTED COMPOUNDS

Considerations presented below have been compiled basis on the researches included in Ambroziak et al. 2013 that have been conducted for the EMITRANSYS project. Chief Inspectorate of Environmental Protection in Poland on the basis of regional data provides an annual assessment of air quality in specific areas of Poland (GIOŚ 2011, GIOŚ 2012). Assessment has been carried out taking into account two criteria: protection of human health (criterion f_1), protection of plants (criterion f_2). Effectiveness of national transport system according to pollution can be presented on examples of areas contaminated by harmful compounds of fumes arising from road transport. Railway transport is not included because its indirect air pollution share.

The first criterion bases on sulfur dioxide, nitrogen dioxide, carbon monoxide, benzene, ozone, particulate matter PM10, lead, arsenic, cadmium, nickel and benzo(a)pyrene contained in PM10, particulate matter PM2,5. Second criterion uses: sulfur dioxide, nitrogen oxides and ozone. Highlighted substances are emitted by means of transport and measurements are performed in relation to areas (zones), comprising:

- agglomerations with a population of over 250 thousand inhabitants,
- cities (non-urban area) with a population of over 100 thousand inhabitants,
- remaining areas of the voivodships, not forming part of the agglomeration and city with over 100 thousand inhabitants.

The area can be assigned to one of the classes depending on concentration level of harmful compounds: A—concentrations not exceeding the permissible level, B—concentration above the permissible level, but not exceeding the permissible level plus the margin of tolerance, C—concentration above the permissible level plus the margin of tolerance, D1—concentrations not exceeding the level of the long-term target, D2—concentration above the level of long-term target.

Figures 2 and 3 show the areas contaminated by nitrogen oxides (NO_x) emitted by means of transport too.

Assessing areas for safety of human health the level above the permissible for nitrogen dioxide was recorded in five areas: in the agglomeration of Warsaw and Krakow and in the Silesian conurbation and in Czestochowa and Wroclaw. Due to the criterion of plant protection in the whole country the level of concentrations of nitrogen oxides did not exceed permissible level. The share of road transport in total emissions of nitrogen dioxide is high and is at the level 33.18%. Based on the preliminary analysis carried out and the data available

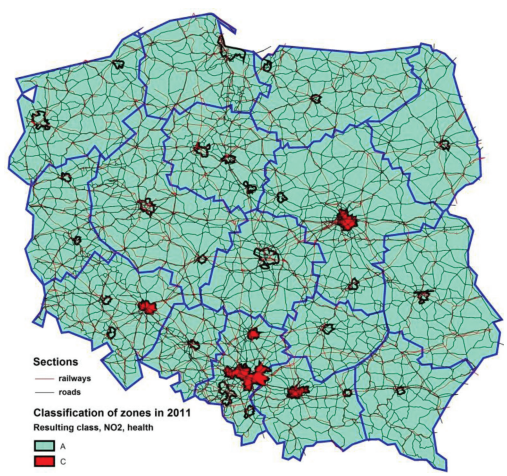

Figure 2. Classification of areas in Poland according to NO_2 emission in 2011 (criterion f_1). Source: own research based on GIOŚ 2011, GIOŚ 2012.

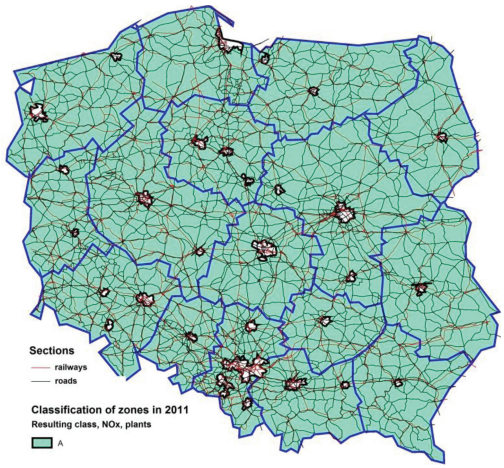

Figure 3. Classification of areas in Poland according to NO_x emission in 2011 (criterion f_2). Source: own research based on GIOŚ 2011, GIOŚ 2012.

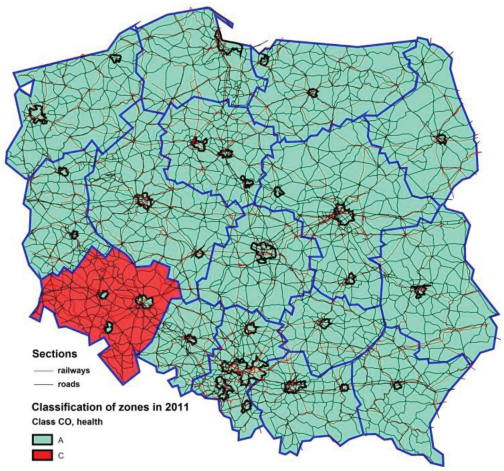

Figure 4. Classification of areas in Poland according to CO emission in 2011 (criterion f_1). Source: own research based on GIOŚ 2011, GIOŚ 2012.

in the study (GIOŚ 2011) it can be concluded that one of the reasons for exceeding the allowable concentration is intense traffic in city centres and in the agglomeration. The analysis shows that it should be included in the model national transport system restrictions on movement of vehicles in these area.

Figure 4 shows the classification of the areas due to air pollution by carbon monoxide (CO), and Figure 5 due to contamination with lead. Both substances were analysed only by the criterion of human health protection.

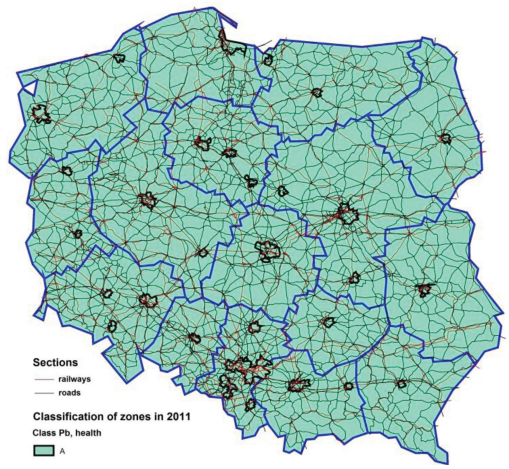

Figure 5. Classification of areas in Poland according to Pb emission in 2011 (criterion f_1). Source: own research based on GIOŚ 2011, GIOŚ 2012.

Maximum concentration of carbon monoxide has been exceeded in one area (Lower Silesia), due to the excess concentration in the health-resort Cieplice-Zdroj (near the Jelenia Gora). It should be noted that the concentrations of the standards for health resorts are much more stringent than for other areas. As can be seen from the data shown in Figure 1 the share of road transport in total emissions of this compound is high and the value is at the level 23.15%. Due to the location of the health resort area in the neighbourhood of major road transport routes with heavy traffic the sphere of road transport can cause excess of the limit.

Figure 6 presents the classification of areas for air pollution by particulates matter classified into a fraction PM_{10}, and $PM_{2,5}$ (Fig. 7). Both substances were analysed only by the criterion of human health protection.

From the point of view of criterion f_1 (human health) for PM_{10} air pollution in only four areas the acceptable level of concentration has not been exceeded (cities of Elblag, Koszalin, Olsztyn and Zielona Góra). In other cities, and in all voivodships permissible concentration has been exceeded. As can be seen from the data shown in Figure 2 share of road transport in total emissions of particulate matter PM_{10} fraction is at the level 10.36%. It can be concluded that one of the reasons for exceeding the limit value can thus be heavy traffic, especially in cities and towns over 100 thousand inhabitants. This reason is not dominant because the engines of new cars must comply with ever higher emission standards Euro.

Air pollution by particulates matter $PM_{2,5}$ fraction has qualified for three classes: A, B and C.

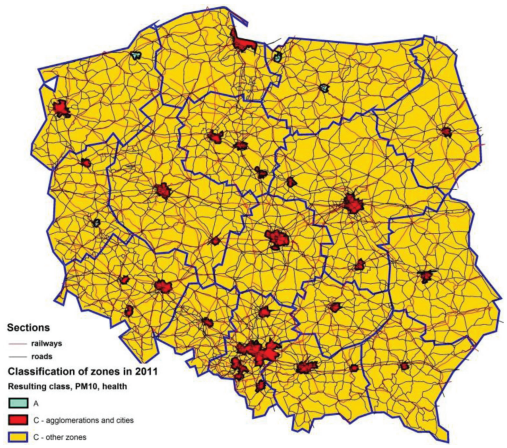

Figure 6. Classification of areas in Poland according to PM_{10} emission in 2011 (criterion f_1). Source: own research based on GIOŚ 2011, GIOŚ 2012.

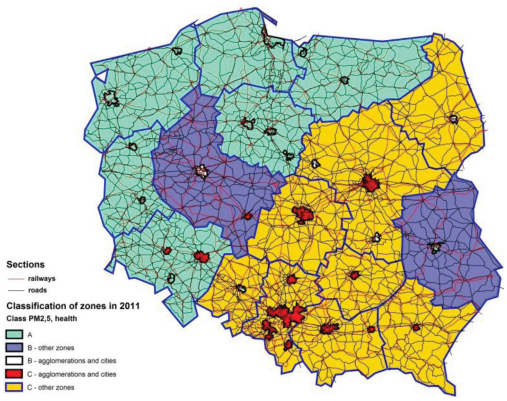

Figure 7. Classification of areas in Poland according to $PM_{2,5}$ emission in 2011 (criterion f_1). Source: own research based on GIOŚ 2011, GIOŚ 2012.

To the class A, where does not exceed the limits, classified North-western area of the Poland and the city Lublin. In five voivodships all areas classified into the class A (Pomorskie, Warminsko Mazurskie, Zachodniopomorskie, Kujawsko-Pomorskie and Lubuskie). To the class B, which has been exceeded a limit value for particulate matter $PM_{2,5}$, but within the limits of tolerance, qualified six zones: Lubelskie and the Wielkopolskie voivodships and the cities Bialystok, Plock, Radom and Poznan. Southeastern Voivodships are an areas where the permissible parameter value has been greatly exceeded. To the class C classified all areas in the voivodships: Lodzkie

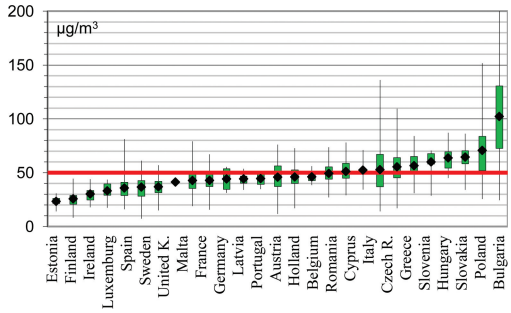

Figure 8. Daily limits of PM_{10} in 2011 in European countries. Source: EEA 2013.

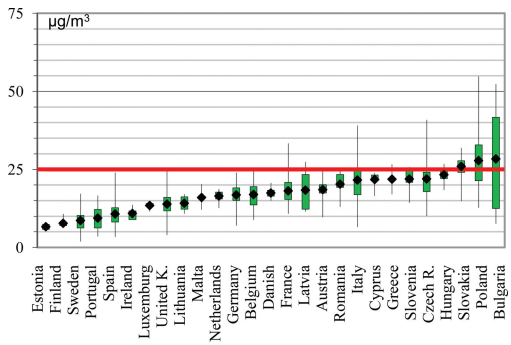

Figure 9. Daily limits of $PM_{2,5}$ in 2011 in European countries. Source: EEA 2013.

Malopolskie, Podkarpackie, Silesian and Swietokrzyskie. The share of road transport in total emissions particulate matter $PM_{2,5}$ is at the level 17,18%.

Basing on EEA data at Figures 8 and 9 daily limits for PM_{10} and $PM_{2,5}$ in 2011 are presented.

5 CONCLUSIONS

The article presents selected issues of effectiveness of transport system in terms of costs of the functioning. Presented research is based on economic and environmental criteria relating to the community and pollution problems. Presented mathematical model takes into account criteria of efficiency in terms of emission and costs as a discriminants of proecological transport system.

The effectiveness of the functioning in terms of ecology is made on the basis of quantitative and qualitative indicators. For the study, it was assumed that both quantitative and qualitative indicators are measurable and only those were analyzed.

Implementation of the work indicates that the designing environmentally friendly transport system should take into account:

- reducing emissions of nitrogen dioxide (NO_2) in large towns and cities by minimizing the movement of vehicles on the road/in the fields;
- reducing emissions of carbon monoxide (CO) in the spa areas by reducing the traffic around and in the zone,
- reducing emissions of particulate matter (PM_{10}) throughout the country, especially in urban areas and agglomerations,
- reducing emissions of particulate matter ($PM_{2,5}$) in the central and south-west areas of Poland, which is quite complicated, as the share of road transport in total emissions is significant, and one of the factors affecting the emission of the terrain.

Therefore, in these areas, it is proposed to introduce the low emission zones or areas which it is possible to enter only by vehicles that meet certain emission standards or charging for entry depending on EURO standards.

The introduction of such zones will serve the improvement of air quality and increasing motivation to buy more environmentally friendly vehicles. The good test area for such a restriction could be established in spa town of Teplice—Zdroj in Lower Silesia because of exceeded allowable concentration of carbon monoxide (CO).

Category of effectiveness embraces many different issues characteristic for transport systems, especially of large scale systems. This also applies to decision making in transport enterprises. Decision-makers in transport enterprises by analyzing the current solutions in the area of transport organization, must consider possible impact of their actions on the environment.

Proposed mathematical model implemented into PTV Visum environment bases on representation of full railway and road transport network of Poland with appropriate transition points. Model uses complete ODO matrixes for segments of demand for freight transport and uses full structure of vehicles for both modes. These elements allow for testing efficiency of transport system of Poland according to different aspects, like environmentally friendliness resulting from emission patterns. Emission levels are implemented into the model as functional dependences gained from on-board surveys (Merkisz et al. 2014, Mierkish & Pielecha 2014).

Above research allows for the development of guidelines to design proecological transport systems. This will lead to long-wave effects allow for reducing pollutant emissions.

ACKNOWLEDGEMENTS

Article was prepared as a part of research project "Proecological transport system designing" (EMITRANSYS), funded by the National Centre for Research and Development in Poland.

ABSTRACT: Currently, the focus of reliability engineering has been extended from product design quality to product service, which drives the research on Prognostics and Health Management (PHM) methodology to provide timely and reliable service information about the health status of product. However, traditional PHM technique mainly concentrates on usage information which leads to the shortcomings of prediction modelling problems, especially for high-reliability and long-life products. This paper proposed an experiment-based PHM life cycle framework, aiming to integrate information from the in-field development phase to provide usage-oriented life prediction model set. When the on-line monitoring data is available, model set can be updated to acquire accurate prediction results and ensure effectively maintenance activity. In this paper, the life cycle is divided into seven stages and related modelling processes are given with specific case studies.

1 INTRODUCTION

Prognostics and Health Management (PHM) technique is to manage product health status through utilizing monitor information, do decision-making before failure happens and avoid catastrophe events, while reducing life cycle cost. The development of PHM represents that the focus of current reliability engineering has come into a new stage extended from quality-centered to service-centered, which can provide customers timely and reliable health information about their products and manage them properly. Among the service indexes, customers are mainly concerned about the Remaining Useful Life (RUL) which is to answer how much time is left for products to perform well. This demand promotes the deeper research on RUL prediction during the past decades, which is widely used in prognostics and maintenance scheduling for machinery, electronics and other products. The core of RUL research is to set up life prediction model whose accuracy will definitely affect the follow-up maintenance activity.

Traditional PHM extracts performance degradation pattern from real-time monitoring signal data or acquire degradation parameter data directly. Based on that information, life prediction model can be given according to the nature of data or the generalization capability of the selected models to capture the time-varying performance. However, it is difficult to verify whether the model itself is reasonable accuracy which will definitely increase the potential risk of product operation. Meanwhile, the advanced technology promotes the emergence of high-reliability and long-life products, which make it even harder to collect sufficient data for capturing the degradation process of such products in a limited time, especially for newly ones. Thus, traditional PHM technique faces the problem of life prediction modelling for the new generations which is high risky and less cost effective.

This paper at first reviews the existing research of traditional PHM in life prediction aspect and proposes an experiment-based PHM framework to overcome the abovementioned shortcomings. The usage-oriented life prediction model set is given at the in-field development phase and integrated with operational data to do health evaluation and maintenance decision-making. The rest of this paper is organized as follows. In Section 2, the research status of life prediction methods is analyzed and the existing problems are pointed out. The new framework is presented in Section 3 and three stages are mainly introduces, i.e. pre-design, after-design and field use, with related research contents for life prediction modelling. The flexibility of the framework is verified by case studies in Section 4. Section 5 concludes this paper.

2 REVIEW OF LIFE PREDICTION METHODS FOR PHM METHODOLOGY

RUL represents the length of time when product performance degrades below failure threshold or cannot meet the requirements, which is the key research of Condition Based Maintenance (CBM) and PHM (Jardine et al. 2006, Si et al. 2011). The RUL prediction methods can be divided into three categories: model-based (also called physical-based), data-driven and hybrid modelling (Heng et al. 2009, Zhou et al. 2013). Nevertheless, model-based methods require that the failure mechanism is known or degradation process can be analytical expressed, which cannot be applied for complex products, while data-driven methods is widely used since there is no need to know about the physical property. However, the prediction accuracy highly depends on the generalization capability of the selected models. The hybrid models integrate the strengths of both model-based and data-driven methods, which still cannot ensure the prediction accuracy.

The present research of RUL prediction in PHM technique mainly concentrates on product usage information. For the high-reliability and long-life products, the existing prediction methods have the following two problems:

- *Data:* How to collect sufficient monitoring data for the purpose of capturing the degradation process in a limited time?
- *Model:* How to establish reasonable life prediction models and simultaneously verify them for new products?

For the data problem, some research integrates expert knowledge or historical information with monitoring usage data. Zio & Di Maio (2010) proposed a similarity-based RUL prediction approach which utilizes the fuzzy similarity between system measurements with the reference failure trajectory patterns by giving related weights. Similar research refers to Wang (2011). Vaidya & Rausand (2011) studied the life extension problems of the equipment in offshore oil and gas industry which considers the influence of expert judgment, operational and environmental conditions, initial system state, etc. on RUL prediction. Chen & Tsui (2013) proposed a two-phase modelling method based on degradation signals which combines historical data with real-time monitor data to improve the RUL prediction results through Bayes theorem. Considering that in-field experiments, like Accelerated Testing, can shorten the test time effectively and gather performance degradation information rapidly for life prediction. Liao & Tian (2013) researched degradation modelling based on drift Brownian Motion and used Accelerated Degradation Testing (ADT) data to do model validation and parameters' evaluation, then the results are used as prior information for product RUL prediction under time-varying operational conditions. Similarly, Li et al. (2013) proposed an approach to build life prediction model based on degradation data under accelerated stress levels and the evaluated parameter results are used as prior information for RUL prediction in normal stress level. The case study shows that the proposed approach has a satisfactory prediction results even under the condition that field monitoring data is insufficient.

As for the model problem, researchers mainly do model comparison or combination to get the applicable prediction model. Saha et al. (2009a) compared several typical algorithms for battery RUL prediction, like Autoregressive Integrated Moving Average (ARIMA), Support Vector Machine (SVM), Relevance Vector Machine (RVM), etc. and results shows that integrated Bayesian regression and estimation methods, like SVM-PF, has significant prognostic advantage than traditional ARIMA and Extended Kalman Filter (EKF) methods. Then, Saha et al. (2009b) furthered this study. Caesarendra et al. (2010) studied the prognosis of complex devices based on sequential Mento Carlo method which shows a potential capability to predict trend data. Zio & Peloni (2011) proposed a RUL prediction method for non-linear component based on particle filtering (PF). Liu et al. (2012) proposed a data-model-fusion framework to improve the accuracy of long-term system state prediction results. Similarly, Zhao et al. (2013) offered a reliability prediction method which integrates PF and Support Vector Regression (SVR). Details about the hybrid prognosis algorithms in engineered system, readers are referred to Liao & Kottig (2014).

The above research papers partially answer the questions on both data and model for life prediction of high-reliability and long-life products. However, as described in Lee et al. (2014), explanation documents about the reason why select some specific prognosis algorithms still lack, which constrain the RUL prediction research into practical applications. Meanwhile, if we choose them blindly without reasonable basis, future life prediction activities will be extremely dangerous.

In order to solve those problems, we transfer the line of sight to the process before product put into market which is called the in-field development phase. In this phase, many experiments are conducted to ensure the requirement of high reliable and long life, among which reliability tests are the most important part. Through repeating the process of test-failure-fix, product life and reliability levels can be guaranteed to meet the design requirements (Collins et al. 2013). Meanwhile, this phase

will accumulate a wealth of important information, such as failure mechanism, key components, accelerated testing data, etc. If those information can be properly utilized to build usage-oriented prediction model set, the life prediction problems for current PHM technique will be solved. Hence, an experiment-based PHM framework is proposed to make up the shortcomings for high-reliability and long-life products. The usage-oriented model set will also be verified at the in-field phase. When field monitoring data is available, the model will be updated and improved correspondingly to ensure the accuracy of life prediction results and maintenance activities.

3 THE EXPERIMENT-BASED PHM LIFE CYCLE FRAMEWORK

For the purpose of solving existing life prediction problems in PHM, the experiment-based life cycle framework is proposed by integrating testing techniques at the in-field develop phase, including seven different stages which are pre-design, final-design, trial, manufacturing, field use, re-manufacturing and cycling, as shown in Figure 1. It should be mentioned that not all products experience these stages.

With the main line of life cycle stages, we introduce the interdependent relationship of the data and model under this framework, and provide their support for life prediction modelling.

In pre-design stage, which is also called concept demonstration phase, the feasible way is to carry out simulation test. According to the historical or similar product information and user requirements, we can acquire the material, geometric and other attributes. Then, product degradation behavior simulation can be undertaken based on Physics of Failure (PoF) model. This process covers from the determination of the degradation mechanism in component level to the degradation behavior modelling in system level, producing the weakest link of the design and assessing the life and reliability of products. Therefore, the design will be improved

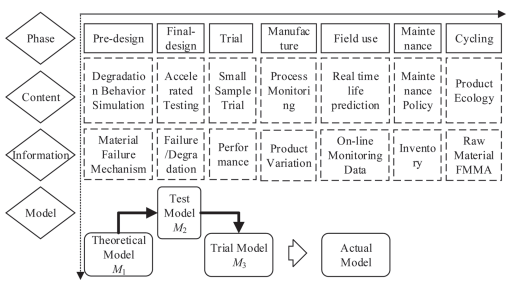

Figure 1. The experiment-based PHM life cycle framework.

until the specific requirements are satisfied. Hence, this stage will set up the relationship among performance parameters, time and the stresses which is the theoretical life prediction model M_1.

$$M_1 : \begin{cases} P = f(t, M, S_{sim}) \\ T = g(P, S_{sim}, D) \end{cases} \tag{1}$$

where M represents product material information; S_{sim} represents the specific operational conditions; D is the failure threshold. f represents the relationship among stresses, material and performance parameters, i.e. P, with time t, while g for stresses, performance parameters, threshold and product life T.

This relationship can be either analytical expression or data-driven models in accordance with the system complexity.

In final-design stage, in order to assess and verify the life and reliability level of product in a limited time, life prediction modelling based on accelerated testing will be carried out. With the input accelerated model M_1 from simulation test, ADT or ALT (Accelerated Life Testing) will be conducted to acquire accelerated data of product. When modelling the degradation data, both the models from M_1 and newly algorithms can be used and the most suitable model set, i.e. M_2, will be chosen for life prediction.

$$M_2 : \begin{bmatrix} M_{1\to 2} \\ M_{0\to 2} \end{bmatrix} \tag{2}$$

where $M_{1\to 2}$ represents the models inherited from M_1, while $M_{0\to 2}$ for the new ones.

Field trial can be arranged into different stages according to different purpose. For example, the trial is normally arranged into the middle of the development phase to reveal the early defect of product design, while after the final-design to assess if the reliability indexes satisfy the general requirements. No matter which stage that is, the field trial can appraise the actual performance level of product although that is not exactly the same one for future use. In this stage, initial PHM prediction module can be set up based on model set $[M_1, M_2]^T$, including sensor layout, data acquisition system and life prediction algorithms, etc. With the data from typical operational conditions, the most suitable prediction sets for field use are selected, M_3, which is the usage-oriented model set.

$$M_3 : \begin{bmatrix} M_1' & M_2' \end{bmatrix}^T = \begin{bmatrix} M_{11}', M_{12}', \ldots, M_{21}', M_{22}', \ldots \end{bmatrix}^T \tag{3}$$

where the symbol $'$ represents model updating.

In manufacturing, the consistency of production quality will be controlled by process monitoring, random sampling, etc. However, it is inevitable to introduce product variation which should be taken into consideration in future life prediction activity.

The above all stages is called the in-field development phase which utilizes the sub-stage data and models to provide usage-oriented prediction model set M_3. The contained models are verified through simulation, testing and trial. Therefore, the prediction results can be reasonable and accurate to avoid the prediction modelling problems in field actual use.

In field use, the monitoring data, like performance degradation, life and failure data, etc. is under actual operational and environmental conditions. Thus, the best prediction models or model combination, M_4, can be selected by ranking or assigning weights according to the prediction accuracy of M_3. Apparently, M_4 is a subset of M_3 but not a null set since the modelling process integrates all the information related to product.

$$M_4 : \left\{ \left(M_4 \in M_3 \right) \cap \left(M_4 \neq \varnothing \right) \right\} \tag{4}$$

At the end of field use, the product performance degrades nearly to the threshold and maintenance policy based on RUL should be carried out, like keep use after repair, replacement, etc. which can effectively prolong its life cycle and enhance system safety (You & Meng 2013). Just take battery as an example. The maintenance policy can provide battery manufacturing scheme, inventory and other information. If the battery completely scrap, it will be into the cycling stage to collect the raw materials and do Failure Mode and Mechanism Analysis (FMMA), which can be compared with the results of simulation test to adjust model set M_1. This improvement will be feedback to the battery design of next generation, thus to achieve the ecological life cycle management.

Overall, the proposed experiment-based PHM framework can utilize all the information from the in-field development phase to provide usage-oriented life prediction set and verify it simultaneously, specifically the life and reliability tests before products are put into use. This overcomes the shortcomings of traditional PHM technique on model selection and data acquisition in the aspect of life prediction. The framework is applicable to the new products which have high-reliability and long-life properties, providing technical support for the new reliability engineering area which centers in intelligent service. Therefore, it has practical engineering value and broad development prospects for the implement of PHM system in engineering applications.

The specific modelling process for several typical stages are given below.

3.1 *Product degradation behavior simulation based on PoF models*

The goal of product degradation behavior simulation is to acquire performance data varying with time under specific conditions and find out the weakest link of product design.

This process uses historical and similar product information, and expert knowledge as inputs. The output is the theoretical life prediction model set M_1 (Fig. 2).

Conventional layer classification is the first step for product analysis. Then, the related failure mode and mechanism, environmental and load conditions, and other information should be determined to conduct performance simulation in component level. Through the transfer function between system and component levels, performance simulation in system level can be carried out, collecting simulated performance data varying with time under specific conditions. Finally, modelling the degradation process with consideration of the failure threshold is to produce the model set M_1. Noting that theoretically physical model can be established for product with simple failure mechanism, while modern engineering tools should be used for complicated products. Thus, the model set M_1 can be analytical functions or data-driven models.

The selected models are applicable to describe the properties of product performance which, however, are under many assumptions, like boundary conditions, etc. which may not be suitable for real applications. Therefore, more test data is needed to verify the feasibility of M_1.

3.2 *Life prediction modelling based on accelerated testing*

For high-reliability and long-life products, accelerated tests are normally used to evaluate its life

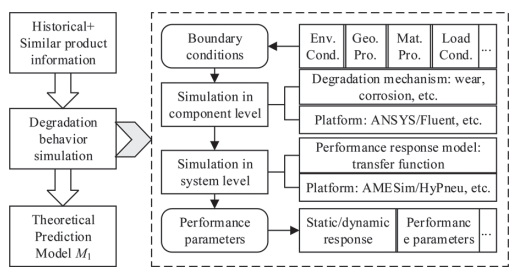

Figure 2. Degradation behavior simulation based on PoF models.

and reliability by experiencing severe stress levels than that in normal conditions to accelerate product failure or degradation process. Thus, sufficient data will be obtained in a short period of time and used for life prediction modelling. This process is dependent on the basis of accelerated model from simulation test, i.e. M_1, and the sensitive stress to conduct accelerated test. Then, suitable models will be selected from M_2 based on the test data, see Figure 3.

This stage is usually first carry out the qualitative accelerated tests, such as High Accelerated Life Test (HALT), etc. to obtain the stress limit where product can still function well. Then, with the input from simulation test, quantitative accelerated tests will be carried out, such as ALT, ADT, etc. including test plan design (Tseng et al. 2009, Liu & Tang 2010) and data proceeding (Meeker et al. 1998, Escobar & Meeker 2006). For the proceeding of accelerated test data, the models from M_1 should be verified and eliminated the unreasonable ones, while new models can be introduced. Therefore, the new level prediction model set is achieved, i.e. M_2.

Being similar to the selected procedure in simulation stage, the models in this stage still need further screening process since there are still exist many assumptions, like stress simplification, ignoring multi-degradation mechanism, etc.

3.3 *On-line predictive maintenance through PHM*

Traditional PHM technique mainly focus on field use information by which to evaluate product health status and offer maintenance policy, i.e. CBM (Niu et al. 2010, Meng & You 2011). However, this technique has its limitations when applying to high-reliability and long-life products. On the contrary, the experiment-based PHM framework provides alternative prediction model sets M_1, M_2 and (or) M_3 at the in-field development phase, which can be used for field life prediction. Figure 4 illustrates this process.

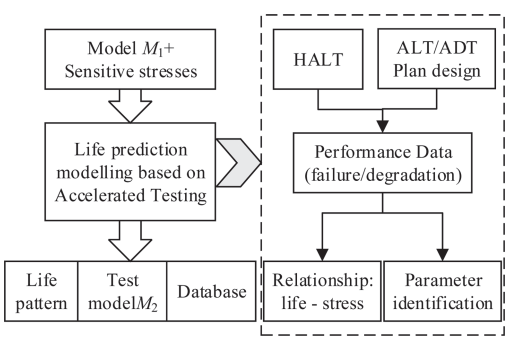

Figure 3. Life prediction modelling based on accelerated tests.

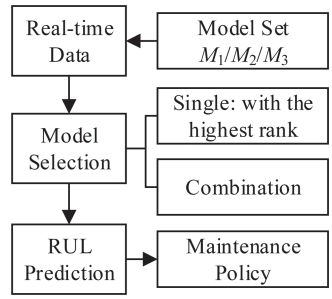

Figure 4. On-line Life predictive maintenance through PHM.

When field monitoring data is available, life prediction can be accomplished by either single model with the highest rank or combined models with their weights according to the prediction accuracy. Its procedure is significant different from the traditional selection method without criteria and it can achieve reasonable RUL prediction results and ensure the effectiveness of maintenance decision-making.

4 CASE STUDIES

The below several cases are used for describing the field RUL prediction modelling based on the information from each life cycle stage under the experiment-based framework. It should be noted that partially tests are carried out for the specific applications at some stages, but all the information collected from this tests do help modelling the RUL prediction for field use.

4.1 *Life prediction modelling for Double nozzle flapper electro-hydraulic servo valve*

Electro-hydraulic servo valve is a key control unit widely used in modern aircraft. In practical application, servo valve is susceptible to the effect of the oil particle pollution which affects its performance, causing the wear of the valve core and sleeve edge. The influence mainly includes pressure gain, inner leakage, etc.

For the purpose of evaluating the life and reliability indexes of servo valve, both simulation test and accelerated test are conducted before that is put into use. The information obtained from the two tests are used for life prediction modelling according to the procedure in Section 3.1 and 3.2. The results are shown in Figure 5. At first, the wear of nozzle flapper and sliding valve under the influence of oil pollution is simulated through

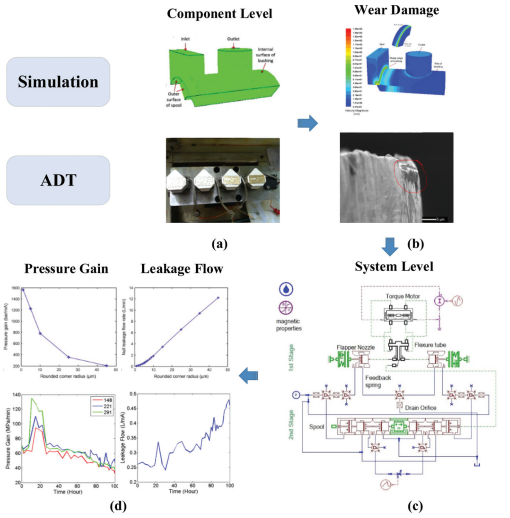

Figure 5. Life prediction modelling for Double nozzle flapper electro-hydraulic servo valve.

FLUENT software in component level, acquiring the wear degradation process of structure parameters varying with time (Fig. 5a, 5b). Then, the data is used as input for system level simulation through transfer function which shows the link between components and system (Fig. 5c) using AMEsim software. Finally, the degradation behavior of system performance is obtained which shows that the pressure gain reduces with time, while leakage flow increases. After the simulation test, the collected data is also used for designing accelerated plan. The optimal plan is Step Stress ADT (SSADT) with 5 stress levels (oil pollution degree) and 3 samples. The monitor interval is 2 hours and the performance parameters are pressure gain and leakage flow, see Figure 5d. After the test, the edges of valve core wear severely.

Based on the degradation data from simulation and accelerated tests, the life prediction models M_1 (Quadratic or linear function) and M_2 (drift Brownian Motion) can be given by integrating with the failure thresholds (25% initial pressure gain and 10% rated flow-rate). Details are referred to Zhang et al. (2014) and Wang et al. (2014). The model set then will be used for field life prediction. This modelling procedure is also applicable to other products by building usage-oriented prediction models and being verified for field use, which can definitely guarantee the accuracy of prediction results.

4.2 *Life prediction modelling and on-line updating for super luminescent diode*

Super Luminescent Diode (SLD) is a kind of one-way light amplification devices which has excellent properties, like wide spectrum, high power. Light SLD is one of the key functional modules of fiber optic gyroscope, experiencing temperature stress in practical use. The inner components degrade with time and that decrease the output optical power.

SLD belongs to high-reliability and long-life product which should be in use for several years. If the life prediction modelling only rely on field use data, sufficient data is needed to capture the degradation process which, however, is hard to acquire even for a long time. Thus, the models based on this data cannot ensure the prediction results. Before SLD is put into market, ADT was carried out at the in-field phase. According the procedure from Section 3.2, eight samples and four temperature stress levels were used in the SSADT (Fig. 6a, 6b). The monitoring parameter is the output optical power which is shown in Figure 6c. Therefore, the life prediction model M_2 (drift Brownian Motion, etc.) can be built based on the ADT data. When on-line data is available (Fig. 6d), the model is updating with time through Bayesian approach. The prediction results show that this method has higher accuracy than the traditional regression method which only uses the field data. Meanwhile, monitoring data in a limited time is enough for modelling the degradation process for this kind of product (Li et al. 2013).

4.3 *Life prediction based on combined algorithms*

This case is to describe how to use the usage-oriented model sets to conduct field RUL prediction. Commonly used method is single prediction model or combined models with associated weights according to their prediction accuracy. Here, we only consider the combined model for life prediction.

As shown in Section 3.3, the input is the model sets, M_1, M_2 and (or) M_3 which are BP neural

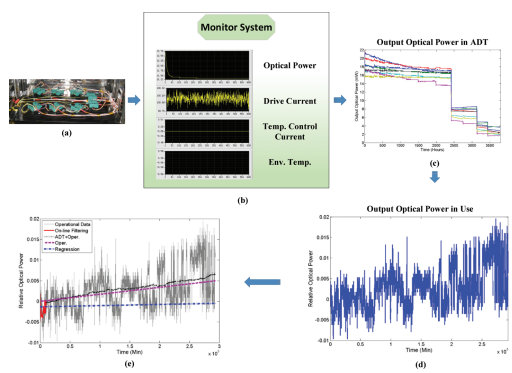

Figure 6. Life prediction modelling based on ADT data and on-line updating through Bayesian approach for super luminescent diode.

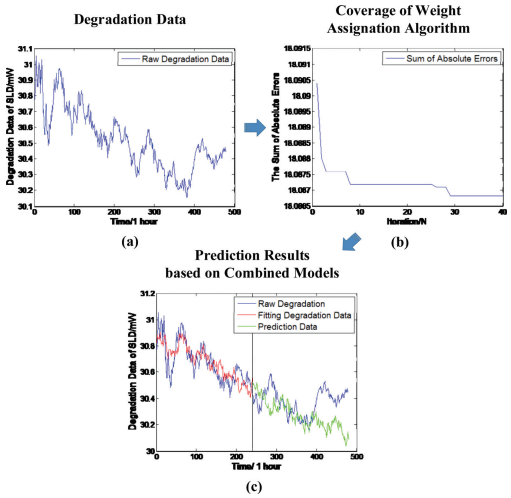

Figure 7. Life prediction based on combined algorithms.

network (f_1), drift Brownian Motion (f_2), time series model (f_3) and particle filtering model (f_4). Degradation data for the particular optical device was collected in field use for 480 hours (Fig. 7a). The first half is used for model training, while the rest for validation. Then, training data is fitted by each single model and encompassment test is conducted to do model selection. The ranking result based on their prediction accuracy is $f_3 > f_2 > f_1 > f_4$ and the encompassment test rejects model f1. Thus, the other three models are combined for RUL prediction in the following process. Combinatorial optimization algorithm, like the Particle Swarm Optimization with Immunity Algorithms (IA-PSO), is used to assign weights for the three models (Fig. 7b) which are 0.288, 0.712 and 0, respectively. Finally, we use the rest data to verify the prediction accuracy and the result is $f_{com} > f_3 > f_2$. Hence, the combined model perform better than the single forecasting models (Fig. 7c). Details are referred to Feng et al. (2014).

The experiment-based PHM framework can provide usage-oriented prediction model at the in-field development phase for field RUL prediction, which is superior to the traditional methods that mainly rely on field monitoring data.

5 CONCLUSIONS

Nowadays, the PHM technique has been applied in rotating machinery, batteries and other complicated equipment, providing on-line health evaluation results of the product to users and saving maintenance cost (Sikorska et al. 2011, Zhang et al. 2011, Lee et al. 2014). However, traditional PHM technique mainly focus on the monitoring data from field use to undertake RUL prediction modelling, which has shortcomings on both data and model for high-reliability and long-life products. Therefore, this paper proposed the experiment-based framework to integrate all the information from in-field phase to do life prediction modelling from the perspective of total life cycle. The prediction model sets keep updating with the information accumulating to ensure the effeteness of prediction activity. At the viewpoint of reliability engineering, this is also a new development of reliability growth program. The usage-oriented life prediction model set is given and verified at the in-field development phase, which definitely ensure the accuracy of prediction results.

The values of the experiment-based PHM technique are on:

- Integrating the idea of prognosis and acceleration to enrich the connotation of reliability engineering.
- Supporting the total life cycle management of product with the further development of reliability platform, which can be widely used in aerospace, automotive, energy and other fields.
- Shortening the product development time by improving product reliability and life expectancy, realizing intelligent maintenance to ensure its safety and economy, achieving green product ecology.

The development of high-reliability and long-life products promotes new requirements for current reliability engineering systems. The proposed experiment-based framework integrates diagnostics, prognosis and health management with reliability testing methods, providing a feasible idea to achieve total life cycle management.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Kun Zhang, Dr. Jin-Yong Yao and Dr. Xiao-Hong Wang for their contribution to this paper. The authors would also like to express their gratitude to the anonymous reviewers for their valuable suggestions. Effects of external audits on safety management systems: A case study of the Norwegian-managed maritime industry

J.F. Aae, A.K. Sydnes & C. Heggøy
University of Tromsø—The Arctic University of Norway, Norway

ABSTRACT: The maritime industry is subject to an enforced self-regulation regime based on the 1993 international code for the safe operations of ships and for pollution prevention. Companies in the maritime industry are required to establish Safety Management Systems (SMS) that are subject to external audits. This study examines the effects of external audits on vessel SMS, based on a series of interviews from the Norwegian-managed offshore supply vessel and dry bulk segments. First, it outlines how external audits are conducted, as mandatory and as industry-driven. Second, it finds that companies largely perceive the incentives for complying with regulations and external audits to be based on the threat of sanctions. Third, external audits are associated with both positive and negative effects on a vessel's SMS. This depends on the type of audit, where the flag state is seen as most beneficial for promoting safety.

1 INTRODUCTION

This paper examines how external audits affect the Safety Management Systems (SMS) of merchant vessels: specifically, Norwegian-managed Offshore Supply Vessels (OSV) and dry bulk vessels. Vessels in these segments operate under the 1993 International Code for the Safe Operations of Ships and for Pollution Prevention (ISM Code) established by the International Maritime Organization (IMO). The ISM Code requires companies to develop, implement and maintain SMS (IMO 2002: 7). However, it is largely left to the companies to design cost-effective SMS to meet their specific circumstances (Anderson 2003). To ensure that companies and their vessels comply with the ISM Code and other relevant rules and standards, the ISM Code, Part B, requires the use of internal and external audits, to be conducted by flag or port states, classification societies, and other safety or technical audits (IMO 2002: 7). Thus, the regime is based on 'enforced self-regulation' (Kristiansen 2005). We explore how the 'enforced' component, as represented by various external audits, affects the 'self-regulation' component, as represented by the company SMS. We do so through a series of more specific research questions: First, what practices have been established for the Norwegian OSV and dry bulk segments regarding external vessel audits? Second, how do companies perceive the need or incentives for complying with external vessel audits? Third, how do external vessel audits affect the SMS on board the vessels?

2 METHODS AND DATA

Our main data source is a series of semi-structured interviews conducted during the first half of 2013 (Heggøy & Aae 2013). We have selected two somewhat different maritime segments as cases for exploring the research topics in this study. The first is the offshore supply segment specialized in offshore supply vessels, aimed at the offshore petroleum industry. The second is shipping companies that operate deep-sea dry bulk carriers. These are vessels that carry homogeneous cargo worldwide in bulk, such as grain and minerals, stored in large cargo holds. Vessels from these two segments have different operational patterns, designs and technologies, but both are subject to the ISM Code and the regime it establishes for safety management. The companies included in the study are all well-established in the Norwegian shipping industry, varying in size from relatively small to large global companies. In total, six Health, Safety, Environment and Quality (HSEQ) managers and five vessel captains were interviewed (Table 1). Informants were selected on the basis of their involvement in on-board vessel audits. All interviews have been anonymized as regards both personal and company information. Interviews with HSEQ managers and captains from the two segments were conducted in person or by telephone. The data were then transcribed and categorized analytically.

Table 1. Informants, by company code and position.

Code	A OSV	B OSV	C OSV	D DB	E DB	F DB	G DB
HSEQ	A1	B1	C1	D1	E1	F1	
Captain	A2, A3	B2		D2			G1

3 MARITIME SAFETY REGULATIONS

3.1 *Safety regulation*

In recent decades, safety regulation has shifted from the use of detailed prescriptive regulations towards the use of functional requirements and self-regulation (Power 2000). This transfers greater responsibility to the company for establishing and maintaining an SMS that complies with established safety objectives (Reason 1997). The role of the regulator is, on the one hand, to establish the overall levels of safety or other goals to be achieved, and, on the other, to audit whether the company's safety management system complies with current safety legislation (Baldwin et al. 2010).

Enforced self-regulation implies that companies are required to establish a management system that takes into account all identified risks, and to continuously evaluate and improve the system (Gilad 2010). State agencies (or other mandated actors) then conduct systematic checks of the organization's activities and arrangements, to determine whether it is complying with the required standards (Blewett & O'Keffe 2011). These systematic checks are referred to as audits, defined as *"systematic, independent and documented process for obtaining audit evidence, and evaluating it objectively to determine the extent to which the audit criteria are fulfilled"* (ISO 2011).

The ISM Code was introduced in response to a series of serious accidents in the 1980s and early 1990s (Anderson 2003). In contrast to earlier safety measures, the ISM Code is based on an enforced self-regulating strategy, taking a step away from more traditional descriptive legislations (Kristiansen 2005). Despite the intentions of promoting a safer shipping industry, the effects of the ISM Code have been debated, within the industry, in the academic literature and by policy-makers (Anderson 2005; Batalden & Sydnes 2014).

The ISM Code has been made mandatory through the IMO convention SOLAS, but legal enforcement is delegated to the flag state—the state where the vessel is registered (Kristiansen 2005; Oltedal 2010). Additionally, safety audits are also conducted by many other actors within the shipping industry (Kristiansen 2005; Vorbach 2010). According to Gunningham et al. (1999) professional industry bodies, industry associations, trading partners and supply chains can provide an external pressure on companies to comply with market-based or branch requirements. Such audits complement traditional flag- or port state sanctions—such as fines, detentions and certificate withdrawal (Anderson 2005). Commercial and reputational concerns are particularly prevalent (Van Erp 2008).

3.2 *Safety management systems*

A safety management system can be seen as a systematic process for achieving and maintaining a safety level in accordance with the organization's goals (Aven & Vinnhem 2004). The ISM Code defines a safety management system as "*a structured and documented system enabling Company personnel to implement effectively the Company safety and environmental protection policy*" (Section 1.1.4). Adherence to functional requirements is to be developed, implemented and maintained by the company's SMS as defined above; a safety and environmental-protection policy; instructions and procedures to ensure safe operation of ships and protection of the environment in compliance with relevant international and flag state legislation; defined levels of authority and lines of communication between and among shore and shipboard personnel; procedures for reporting accidents and non-conformities with the provisions of the Code; procedures for preparing for and responding to emergency situations; and procedures for internal audits and management reviews (ISM Code, Section 1.4). As Anderson (2003) points out, these requirements represent the *minimum* features of an acceptable safety management system.

We consider SMS as a process that can be divided analytically into four stages which in sum meet the functional requirements presented above: 1) *safety target and policy,* 2) *risk management,* 3) *internal audit,* and 4) *monitoring and learning* (Stolzer et al. 2008). This can be considered as an action-cycle, based on Deming's Plan–Do–Check–Act model (Reason 1997). In the first stage the overall safety and environmental policy is established, determining which objectives will be met. The second stage involves risk identification, management and execution of the scheduled tasks. In the third stage the company should conduct regular internal audits to ensure that the safety objectives have

been met. Stage four, monitoring and learning, requires the company to follow up on the information from the previous stages, and implement corrective measures if necessary (Stolzer et al. 2008; Reason 1997). In this fourth stage, the company can also draw on results from external vessel audits as a source of information (Stolzer 2008). Further, SMS is a circular process which demands continuous holistic improvements to the system (Aven & Vinnem 2007).

4 EXTERNAL VESSEL AUDITS

Here we present the main external audits that are conducted on board vessels within the two segments of our study (see Table 2). We will also present our findings as to how informants perceive the relative importance of complying with requirements of external audits.

The ISM Code establishes a series of mandatory audits to be conducted by the flag state (or classification society on its behalf) in addition to internal audits. In order to operate a vessel, the owner or operator must initially have a Document of Compliance. This is a document issued on the basis of flag state audits, verifying that an SMS consistent with the ISM Code is in place (IMO 2010). A vessel must also carry a Safety Management Certificate, verifying that the key elements of the ISM Code are in place (Anderson 2003). Further, external audits are conducted to ensure the effectiveness of the SMS in meeting the objectives of the ISM Code (IMO 2010). When a vessel enters port, it can also be subjected to port state control. The port state does not have the authority to suspend or withdraw the document of compliance for vessels issued by the flag state. However, it has the right to impose sanctions, for example by fines or detaining a vessel in port (Anderson 2005).

In addition to the mandatory audits established by the ISM Code, various non-mandatory, or industry-driven, audits are conducted (Knapp 2007). Importantly, industry-driven audits serve as databases where cargo owners and charterers can get information about a vessel's safety standard. Results from the audits, or vettings (as these types of audits often are called), are made available in online databases, where vessels also are given safety rankings (Knapp 2007). In the Norwegian OSV segment, two industry-driven audits have predominated. First, the Common Marine Inspection Document (CMID), aimed at improving technical standards and reducing the number of inspections, by providing a common industry format (IMCA 2009). Second, the Offshore Vessel Inspection Database (OVID), which aims to establish an internationally accepted assessment tool to be applied as a basis for selection during vetting and assurance of OSVs (OCIMF 2010). In addition come other industry-driven audits, or "spot audits," generally more limited in scope. An example of such audits can be "falls from heights audit" (A2). However, as our informants saw these as less important to the main research topics addressed here, they are not addressed in detail. From the sample of cases from the Norwegian OSV segment, it is clear that industry-driven audits play an important role as an addition to the mandatory audits established by the ISM Code. All three companies are subject to OVID and CMID audits on a regular basis. In addition, there are spot audits initiated by contractors or the vessel-companies themselves.

Table 2. External audits, OSV and dry bulk segments.

Audit segment type	OSV	Dry bulk
Mandatory	Flag state	Flag state
	Port state	Port state
Industry-driven	CMID	Rightship
	OVID	Spot audit
	Spot audit	

In the dry bulk segment, Rightship has been established as an international, industry-driven audit and ranking system. Rightship combines information from various sources, such as vetting inspections, port state controls, casualties and owner information (Knapp 2007). Based on this, it provides an information system where vessels are ranked from 1 to 5. Rightship inspections primarily concern dry bulk carriers (Rightship 2014). Industry-driven audits have a less prominent role in the dry bulk segment. Only company D has Rightship auditing its vessels. As one HSEQ manager noted regarding Rightship, "*The oil companies have practiced this vetting form for a while now, and seem to have benefited a lot from it, so now we also have started. Earlier we just had to show our papers, now we have to show that we actually work according to the papers*" (D1). Vessels from company D, E and F are occasionally subject to spot audits from cargo owners, but none of the informants indicated that this occurs regularly. According to one informant, "*The customers do not really have any concerns regarding safety on board the vessel*" (F). Though only company D is currently audited by Rightship, all companies are aware of its existence. It is not unlikely that industry-driven auditing will become more prevalent in the Norwegian dry bulk segment over time.

4.1 *Complying with external audits*

In general the informants in this study, within both the dry bulk and OSV segments, noted the need

for external audits to be conducted, and felt that these audits have a positive effect on safety management. However, we wish to understand what kind of external pressure external audits put to bear on companies to comply with regulations and standards as part of their safety management on board vessels. Being audited provides external pressure on companies in the dry bulk and OSV segments in several ways, two of which will be examined here. First, vessels need to meet the formal requirements established by the ISM Code and other regulations through mandatory audits. Second, the maritime industry is known for being driven by international competition (Vorbach 2010). Safety management is an important aspect in this regard as well. As explained by one captain, and one HSEQ manager, from the OSV segment: *"One side is more of a commercial importance, while the other side is important for simply being a shipping company"* (B2). Also, *"When we submit an offer for a job, safety is a big part of the competition"* (A2). Compliance and scoring during audits are commercially important for gaining commercial contracts. For example, results from the industry-driven CMID and OVID audits are used as a basis for decision-making and risk management when negotiating contracts in the offshore supply segment. While several informants in the OSV segment (A2, B2, C1) considered the audits themselves to be a burden due to the time and resources required, they nevertheless recognized the importance of performing well during audits.

In the dry bulk segment, industry-driven Rightship audits have a more limited role. The mandatory flag- and port state controls seem to be of greater concern, as regards both the costs of being detained or getting non-conformities, and the commercial consequences of negative publicity and loss of reputation (D2, G1, E1, F1). However, several informants saw limited safety benefits of port state controls (D1, D2, E1, F1). The main challenge concerns the varying interpretations of legislation applied by port states; *"The worst thing about port state control is that they don't even have similar interpretations of the law. What can be accepted in England you might risk to get a deficiency on in the Netherlands"* (E1).

In summary, within both the dry bulk and the OSV segments, compliance is primarily related to sanction costs that may follow as a consequence of poor audit results. This leads to a more limited focus on auditing and compliance as measures for improving the safe management of operations.

5 EFFECTS OF EXTERNAL AUDITS ON VESSELS SMS

Here we present our findings regarding the effects of external audits on the SMS on board the vessels in the study. The results are arranged according to the four stages of a SMS: safety policy, risk management, internal audit, and monitoring and learning (Reason 1997; Stolzer et al. 2008).

The overall objective of an SMS is defined in a safety and environmental protection policy, and is a mandatory part of the system according to the ISM Code (Section 1.4.1). However, auditing safety policy, though important for companies and vessels SMS, is part of the onshore company audit, not the vessel audits. Consequently it lies beyond the scope of this study and the data we have gathered.

5.1 *Risk management*

Risk management includes risk identification, assessment and the conduct of shipboard operations (Stolzer 2009; Reason 1997). Informants gave statements concerning both positive and negative impacts on risk management on board dry bulk and offshore supply vessels. The results of vessel audits can be considered as a source of proactive information (Anderson 2005), or a type of information that enables companies to implement measures before accidents occur (Rausand & Utne 2009). In general all informants from both segments saw external vessel audits as a proactive measure (A1, A2, A3, B2, C1, D2, G1, E1, F2). External audits provide an independent view of the system on board (A1, A3, B2, G1, F1). As one captain in the OSV explained, *"Working on board a vessel is like living in a small closed community; when you're audited you get an independent view on how you work"* (A3). However, one captain from the OSV notes, *"External audits must not turn in to a false sense of safety, you still have to exercise caution constantly"* (B2).

High-quality information can enable a company to predict an accident (Turner 1976). There are differences in the value of information the various types of audits provide about the SMS. In the OSV segment, industry-driven audits were seen as being less relevant (A1, A2, B2, C1). Informants from the dry bulk segment felt that port state controls did not always provide information useful for improving vessel SMS (D1, E1, F2, G1). As one informant from the dry bulk segment explained, *"During audits we get a good discussion and dialog, where they provide suggestions, and thereby help to improve our system, but this is mainly the [flag state audits], port state control doesn't make such a contribution"* (F1). Port state audits are seen as less useful due to the diverging interpretations of legislation and requirements between different port states (D1, D2, E1, F1, G1). One captain noted, *"Sometimes I get quite astonished when I see some of the vessels that certain port states let pass, but maybe they are*

better than they look from the outside. I don't know, but sometimes is seems that the threshold for detaining a vessel is quite high" (G1).

In the OSV segment, concerns relate mainly to the industry-driven audits OVID and CMID. Here our informants shared a common concern regarding what one informant referred to as *"audit overkill"* (C1). External vessel audits from OVID and CMID seem to be conducted very frequently, which leads to considerable time being spent on satisfying the auditors (A1, A2, A3, B2, C1). A shared consideration among our informants was that the OVID system does not function as intended (A1, A3, B2, C1). As one captain explained, *"The idea was that you were supposed to have one OVID every 12 months. The charterer then could see the results in a database, but what happens is that every charterer requires their own OVID audit. The regime that was supposed to make things easier does not work"* (B2). Moreover a HSEQ manager noted: *"OVID was supposed to replace CMID, nevertheless they exist in parallel"* (A1).

Vessel audits require involvement from the crew on board. This is identified as a common challenge as informants from both segments expressed concerns regarding how external audits consume time when the vessel is in port, where time already is short (A1, A2, A3, B2, C1, D2, E1, F1). Two captains, one from the OSV and one from the dry bulk segment, said that the extra work external audits entail can come the expense of rest-hour regulations (B2, D2). As one captain said, *"To operate a vessel you have to be sharp. But when I've been busy all day with an audit, in addition to all the other things we have to do in port, then I am not fit to maneuver the vessel, and accidents may happen"* (D2).

These findings show that our informants are generally positive to the effects of external audits on risk management. However, the effects depend on the audit. Here, flag state audit was regarded most positively. The OSV and dry bulk segments consider industry-driven and port state audits, respectively, to have more limited positive effects. A common challenge noted was the time required for conducting external audits.

5.2 *Internal audits*

Internal audits are a measure for the company to evaluate the effectiveness of the SMS in accordance with established procedures (ISM Code, Section 12.2). All informants from both segments say that internal audits of their vessels' SMS are performed at least once a year, as per the ISM Code, Section 12.1. As required in Section 12.4, internal vessel audits are conducted by HSEQ personnel who are working on the companies' onshore staff. All informants felt that these internal vessel audits were important, and that, due to the presence of external audits, the internal audits become even more important (A1, A2, A3, B1, B2, C1, D2, E1, F1, G1). It was commonly held that it is better to discover deficiencies internally than have them found by external auditors. This triggers a self-critical view on the system when internal audits are conducted. This was a consideration shared by all informants in our study. One captain from the dry bulk segment explained, *"I bring my biggest magnifying glass and tell the crew that it's better that I find something than someone else does. We probably could be better, but I clamp down on every little thing I find"* (D2).

A prominent view among informants was that internal audits are a tool for ensuring good results on external audits (A1, A2, A3, B1, B2, C1, D2, E1, F1, G1). As one HSEQ manager said, *"For us it means that we have to be ahead of those who audit us, there are small margins in the industry today, and we have to be out in front and proactive regarding the regulations"* (E1).

The OSV segment appears to be subject to extensive industry initiated auditing compared to the dry bulk segment, and informants were preoccupied with scoring high on these audits. This is because the results also are associated with commercial aspects (A1, A2, A3, B1, B2, C1). *"It is a lot better to find things internally, because than it does not lead to any economic consequences"* (A1). Another informant said, *"Results from an OVID are available for the whole industry in 12 months. If you have several deficiencies, you've shot yourself in the foot"* (B2). The same motivation for conducting industry-driven audits was, naturally enough, not expressed by informants from the dry bulk segment. This being said, one company had the commercial actor Rightship auditing their vessels, which added commercial interests to having good scores on these audits, as we saw in the OSV segment (D1, D2). *"Rightship is a big actor in the dry bulk segment, you can compare them with BP and Shell, and so they have a lot of influence. Even when we are in line with international requirements, Rightship can tell us that we still aren't good enough"* (D2).

In general, internal audits are seen as an important measure for evaluating and improving vessel SMS. A main motivation for internal auditing is to avoid non-conformities during external audits.

5.3 *Monitoring and learning*

We have seen how external audits contribute to monitoring the vessels' SMS to varying degrees. Below we focus on how external audits contribute to system learning. According to our informants, find-

ings from external audits can sometimes contribute to learning and development on board vessels. All companies represented in this study have systems for transfer of experience, enabling all vessels in the fleet to benefit from the results of an external audit.

Findings from external audits do not always serve as a source of learning. Informants raised concerns as to the port state controls performed in the dry bulk segment and industry-driven audits in the OSV segment (A1, A2, B2, C1, D1, E1, F2, G1). They said that the following factors affect the learning value from information generated from external vessel audits: type of audit, experience and knowledge of the auditor, and the auditor's intentions.

Most informants felt that flag state audits bring the most learning value about the system, mainly because the auditors are familiar with the vessel and often are experienced (A1, B2, C1, D2, E1, F1, G1). In contrast, informants from the dry bulk segment all held that port state controls were too unpredictable, making it difficult to update the system in accordance with various auditors' interpretations of the regulations (D1, E1, F2, G1). One HSEQ manager put it like this: *"Port state is very unpredictable, you cannot update the vessels according to all deficiencies"* (E1).

In the OSV segment, customer-initiated audits as a whole were subject to criticism regarding learning value, but the examples provided by informants mainly concerned the OVID audit. We were given various examples that indicated that OVID was less beneficial as a source of learning. As one captain remarked, *"They search for errors just so that they can write something. Once on an OVID vetting we got a deficiency because the chef's hat was the wrong color"* (B2). Another point made was that the OVID audit is not fully adapted the OSV segment. *"They seem to have copied and pasted a lot from the tanker segment and this does not necessarily fit a supply vessel"* (A3). A third criticism was that the OVID audit is too superficial, *"It's based on yes/no questions, so you actually end up not gaining any more knowledge"* (A1).

To summarize, there seems to be a clear connection between how informants consider the relevance and quality of the external audit and to what extent they perceive it as providing a basis for learning. Again flag state-audits are considered to have the greatest learning effect as regards SMS. In the dry bulk segment, the port state audits score lower, while for the OSV segment OVID in particular was regarded as having a more limited effect on learning.

6 DISCUSSION

In this study we have examined how external safety audits affect the SMS on board OSVs and dry bulk vessels. In 1998 the ISM Code became mandatory for all vessels, and required companies to establish a SMS on their vessels. The ISM Code is implemented through the use of enforced self-regulation, which makes the company responsible for establishing a system that ensures safety at sea (ISM Code 1.2.1), including both human life and damage to the environment. The performance of this system is then audited through external mandatory and industry driven audits, in addition to internal audits.

The Norwegian dry bulk and OSV segments are both subject to mandatory audits established by the ISM Code and international requirements. Our focus here has been on flag- and port state audits. These audits are frequently conducted by classification societies acting on behalf of the states as "recognized organizations" (IMO 2010). In addition come established, industry-driven audits within both segments, albeit far more prevalent in the OSV segment, where CMID and OVID, in addition to various spot audits, are well established. In the dry bulk segment Rightship has been established to perform a similar function as CMID and OVID, but has not yet achieved the same widespread recognition and use. According to Lindøe et al. (2011), these differences may be explained partly on the basis of the regulators associated with the offshore petroleum industry and maritime bulk transport. The Norwegian petroleum industry aims to be a world leader in safety. This pervades the whole industry, including shipping companies (Lindøe et al. 2011). As opposed to bulk transport, the petroleum industry has close connections between contractors and suppliers, often resulting in strong industrial relations (Oltedal & Engen 2010). This is also evident in our study. Rightship is a fairly new actor in the Norwegian setting, but informants note that it is becoming more prevalent in the dry bulk segment and may contribute to strengthened industry-driven auditing practice over time.

Stronger industry involvement may also entail challenges. As Baldwin et al. (2012) emphasize, with a multitude of audits and regulators, coordination is necessary. Our data from the OSV segment indicate that audits, especially industry-driven ones, are not well-coordinated. While the intention was to reduce the number of audits, CMID and OVID audits are conducted in parallel and more frequently than expected. This has also been found in studies of other industries (Blewett & O'Keffe 2011). Therefore, greater industry involvement in auditing may not always lead to safer practices.

Our study also found that compliance is generally driven by the costs related to potential sanctions. In the dry bulk segment, port state audits were seen as most 'risky' in terms of the sanctions that could be imposed and their consequences. The OSV segment focused more on the financial costs of poor scores or ratings on publicly available industry-driven audits. These were considered to have implications

on the tendering process. Thus, both legal and non-legal sanctions prove to have an effect on compliance (Van Erp 2008). At present their relative effect depends largely on the characteristics of the audits and the industry (Oltedal & Engen 2010). As Vorbach (2010) notes, audits need to be coordinated, to increase the desired effects on safety management.

6.1 *Effects on SMS*

The final question raised in this paper was how informants assessed the effect of external audits on a vessel's SMS. External audits seem to have two main effects on a vessel's SMS. The first is related to the tangible feedback that an external audit provides about the SMS. The second concerns the external pressure the audits place on companies to establish and maintain their vessels' SMS. We find that external vessel audits have both positive and negative effect on a vessel's SMS. In particular flag state audits are seen as making positive contributions to a vessel's SMS, in contrast to industry-initiated audits in the OSV segment and port state controls in the dry bulk segment. In the following we discuss our findings regarding the stages of the SMS: risk management, internal audit, and monitoring and learning (Reason 1997; Stolzer et al. 2008).

In general, accidents occur when hazards accumulate unnoticed in the system (Turner 1976; Reason 1997). Detecting these and acting accordingly is therefore crucial for a vessel's SMS. As a contribution to risk management, external audits stimulate companies to be more proactive, and the audits provide a fresh view of the system on board. In this regard we can argue that external vessel audits provide a positive contribution to a vessel's SMS. However, according to our informants, this is mainly the case for flag state audits.

We also found that external audits are often seen as more of a burden than a measure for promoting safety. In both segments, external audits place an extra workload on the crew on board, especially in the OSV segment, where industry-driven audits seem to be conducted quite frequently. In consequence, the crew has less time for conducting other shipboard operations. Moreover, as also indicated by Knapp (2007), rest-hour regulations may suffer. This is disturbing, stress and fatigue are known to increase the risk of accidents (Sneddon et al. 2013).

All companies are required to establish procedures for internal audits, according to Section 1.4.6 of the ISM Code. Our informants consider this arrangement to be of great importance, noting in particular that internal audits provide an opportunity to discover non-conformities and deviations ahead of the external audits. This is an incentive for companies to conduct internal audits, to ensure compliance with established requirements and positive results on external audits. On the other hand, internal audits risk having a stronger focus on scoring on external audits and complying with established standards, than focusing on work-safety on board (Bhattacharya 2009). This is a well-known pitfall from internal auditing in enforced self-regulatory regimes (Blewett & O'Keffe 2011; Hohnen & Hasle 2011). Focusing on external requirements and audits rather than applying a risk-based approach based on the vessels may lead to a false sense of security (Batalden & Sydnes 2014b forthcoming). Disasters like the Longford explosion (1998) and the Piper Alpha (1988) have showed that external audits may be of little value in detecting hazards and avoiding accidents (Hopkins 2000). This underscores the need for thorough internal audits and risk management.

Monitoring and learning is the last stage of the SMS as defined in this paper. Our informants mentioned that external audits often provide inputs that fail to result in improved SMS. This is primarily related to industry-driven audits in the OSV segment and port state audits in the dry bulk segment. Again this has been shown in other studies of auditing (Blewett & O'Keffe 2011). Both the scope of the audits and the competence of auditors are important for understanding the extent to which audits may provide valuable inputs to SMS (Bhattacharya 2009; Batalden & Sydnes 2014b forthcoming). Also our informants highlighted these factors to explain why flag state audits are seen as providing positive inputs as sources of learning.

7 CONCLUDING REMARKS

This study first outlined how the OSV and dry bulk segments are subject to a series of mandatory and industry-driven external audits. What effects these audits have will depend largely on the characteristics of the individual audits and the maritime segments. However, we find that, in both cases, compliance is driven by the costs of sanctions, legal and commercial, related to the different audits.

We have also seen that external audits are important for the continuous focus on SMS on board both dry bulk and OSV vessels. However, not all external audits contribute equally to enhancing safety on board vessels. Here we find the flag state audits to be of greatest importance. They are regarded as having the most competent auditors and most relevant scope. Other audits discussed here, such as industry-driven and port state audits, do not have the same positive effect in promoting safe practices and learning in the SMS.

Internal audits seem to be a tool for ensuring good results on external audits and avoiding sanctions. However, that also entails the risk of losing the focus on a risk-based and self-regulatory approach to SMS.

In sum, our study has shown that the maritime industry still faces challenges in achieving the aims of the ISM Code. Nevertheless, external audits do put pressure on companies to comply with established requirements, and are thus part of the solution in addressing these challenges.

Our findings largely echo those of previous studies of auditing in the maritime industry. However, there is need for more extensive studies covering a broader range of cases sampled. There is also a need for further in-depth studies of how the characteristics of audits (design, conduct and sanctions) affect how companies respond to them. This would contribute to our knowledge on the effects of external audits on safety management.

Review of acceptable risk levels of bridge collapse in respect of ships collisions

L. Gucma
Maritime University of Szczecin, Poland

ABSTRACT: The bridge collapse due to ship collision is supposed to be the cause of almost half of the bridge catastrophes. The paper intention is to gather the existing methods of risk acceptable level and compare them. The paper presents also selected problems of accident probability assessment in respect of ship collisions with bridges. Accident statistics in Poland and around the world are presented. Wide discussion on bridge collapse risk acceptance criteria have been carried out. Finally to different case studies of probability assessment taking into account both horizontal and vertical clearances. Two case studies partly covering discussed aspects are presented.

1 THE ACCIDENT STATISTICS AND THE PROBLEMS OF SHIPS COLLISIONS WITH BRIDGES

Bridges situated on sea and inland waterway areas belong is the particularly sensitive infrastructure from three the major causes:

1. create restrictions of not only in the vertical water area but also in horizontal;
2. they create the threat to its users in the case of ship-bridge collision and bridge collapse,
3. the cost of the bridge is usually considerably larger then the cost of the ship itself.

He the ground analyses of the literature [Scheer, 2010; Radomski, 2011] it is clear that the collisions with ship is they of the major causes of bridges disasters and they can be even 30% of all reasons of whole bridge catastrophes. In years 2003–2013 the scientific the team of the marine traffic engineering of Maritime University of Szczecin executed the row of analyses of the safety of bridges in this [Gucma L., 2013]:

– the railway bridge in Szczecin (2003),
– two locations of foot bridges in Elbląg (2008),
– foot bridges to the Ołowianka Island in Gdańsk (2009),
– two bridges on the Motława in Gdańsk (2009),
– the bridge to the Ostrów Brdowski Island in Szczecin (2013).

The problems of ships collisions with bridges comes from years 60, when is in the result of the height of the intensity of the traffic and dimensions of ships followed the scale of events and disasters. First, sizable studies were done in the year 1980 after the allision of the ship Summit Venture with the bridge Sunshine Skyway. In monograph [Gucma L., 2013] it is presented the composition of several collisions of ships with bridges since the year 1980 together with results and reasons of collisions, the death rate and the name of the ship. One can notice (Fig. 1) that averagely in the world it appear 2 serious collisions of ships with bridges per year, and every 2 years it appears the event with catastrophic results causing the destruction of the bridge, the loss of the ship or the fatalities.

American statistics [USCG, 2003] brought to light that the large part of collisions of ships with bridges caused however comparatively not large scale losses. In years 1992–2001 one noted together 2692 collisions. Only 61 from them (2,2%) caused greater losses then 0,5 millions USD. The 1702 events (63%) of them was incidents in which the damage were not significant and the repairs of the bridge was not necessary. In the inland area administered by RZGW in Szczecin there was average one collision of the inland unit with the bridge per year. Most destructive was the collision

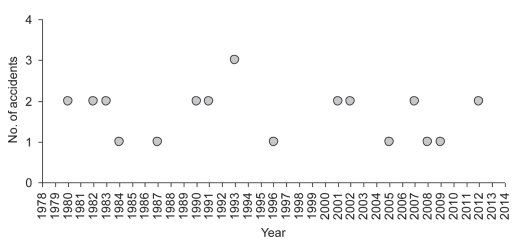

Figure 1. The yearly number of ships collisions with bridges serious in results in the world.

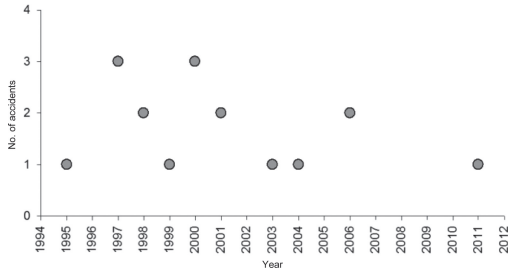

Figure 2. The number of events with bridges in the region administered by RZGW in Szczecin [Gucma L., 2013].

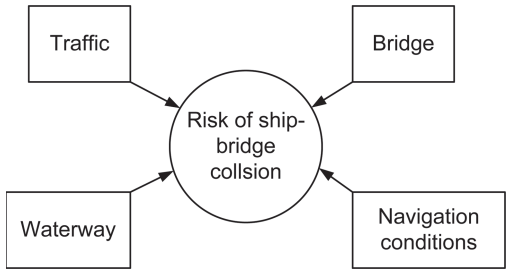

Figure 3. Factors of the risk of collisions of ships with bridges.

in 2001 when the guides of the railway bridge in Szczecin was destroyed, what caused the necessity of their exchange. In the region administered by RZGW all cases of collisions of inland units with bridges Szczecin are presented in Figure 2. It was recorded 17 cases within analysed of 16 years. Happily, it never arrived to fatalities in people. Events due to error of the navigator dominates, they happens with the frequency approx. 90%, what confirm world statistics. Alarming is also the large participation of collisions with bridge spans which amounts around 65%. The part from them ended with bulky damages of the ship. Such collisions result most often due errors in the planning phase of navigational passage under the bridge, mostly from the ignorance about the current clearance of the bridge or the height of the air-draught of ship.

2 THE RISK MANAGEMENT IN THE ASPECT OF THE COLLISION WITH SHIPS IN THE BRIDGES AREA

The creation of the rational risk management system before the delivery of engineering construction, especially, when such object could attract possible fatalities, are nowadays the standard in many countries. In this chapter some theoretical and practical aspects of the risk management are presented. The important are the measures of the risk assessment what ties in with the settlement of levels of its acceptance. Figure 3 presents the four main factors influent on collisions of ships with bridges. To navigational conditions need to be also considered.

The risk of the collision of ships with bridges one can divide on five main categories:

1. the risk for the owner of the bridge connected with necessity of its repair or the loss of profits after the break of the bridge passage;
2. the risk for users of the bridge connected with the possibility of the loss life, health's or the monetary values during the passage;

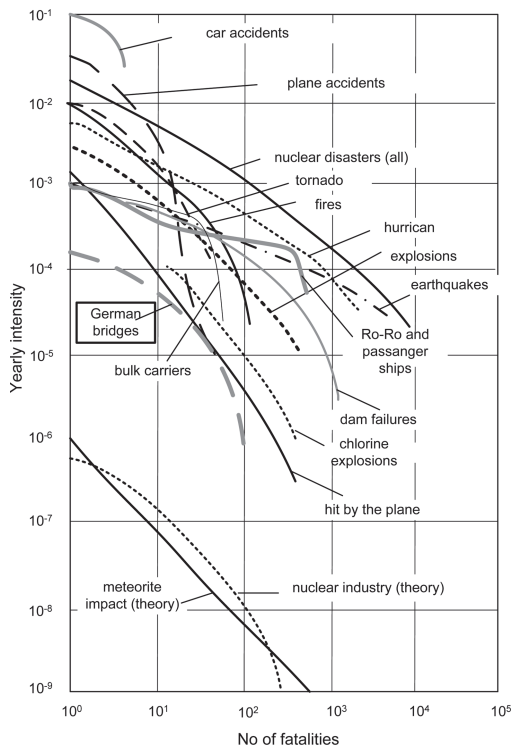

Figure 4. Example FN curves for different activities together with FN estimated for German historical bridges [Gucma L., 2013].

3. the risk for third parties which do not draw any advantages from the bridge. It refers also ships, in case, when the bridge causes the threat with relation to of the state before construction of the bridge;
4. the risk concerning of results socioeconomic because of the break of the passage;
5. the risk environmentally as result of pollution with the overflow or with the liberation of toxic gases.

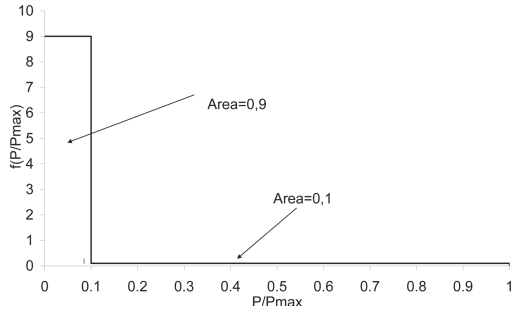

Figure 5. Density function of bridge collapse due to ship collision (AASHTO [1991]).

The procedure of the risk management is the multistage rational method, targeting increasing of the safety of the shipping throughout the protection of lives and health's of people, environments and properties [Gucma L., 2009]. The procedure consists of the risk analysis (estimation), the assessment of the risk which requires of the decision about his acceptability and his temporary inspection. It consists of four following stages:

1. The identification of hazards.
2. Risk analyses (the estimation of the risk on the basis of data possessed without taking into account of changes in analysed area) which consists of assessing of the probabilities of the threats (probability assessment) and the qualification of consequences (consequence analysis).
3. Evaluation of the risks (the comparison of the risk with criteria values, to meet the acceptable level).
4. Risk managements (with the regard of methods of the risk reduction and its temporal control).

It is the risk analysis of ship-bridge collisions the measures of the societal risk described by FN (frequency—number) are widely used (Fig. 5).

3 ACCEPTABLE LEVELS OF BRIDGE COLLAPSE AS RESULT OF THE SHIPS COLLISION—COMPARISON OF CRITERIA VALUES

Acceptability criteria of break of the bridge connection risk is set up due to following factors:

– possible number of fatalities in the case of the traffic on the bridge,
– the degree of the importance of the bridge for the society or/and defence of the country,
– costs of the restoration and costs of the operation as result of the break of the bridge passage, qualified most often by means of CBA analyses.

Taking into account international and local regulations, the acceptability of the risk of the critical bridge by trespassing ships are varied in different designs of the bridge in the world. When risk acceptability criteria does not exists it is necessary to perform wide relations to the existing projects or to natural threats in the investigated region.

The probability applied for bridge failure in codes and international standards differs from 0,0001 to 0,001 for 100 year (10^{-6} to 10^{-5} per year). Analysing the accessible literature shown in [Gucma L. 2013] within the range of the risk acceptability of the bridge destruction as result of the collision with ship, following conclusions could be drawn:

1. For the project of the bridge through Great Belt the criterion of the bridge serious collision with ship was 1 per 10 000 years, that gives the probability of the bridge collapse 0.02 on 100 years (2.0 10^{-4} per year).
2. Given in 1985 the recommendation of the Louisiana State divide bridges on 2 categories. For deep water bridges (ships up to 13 m of the draught) the admissible probability of the destruction of the bridge as result of the ship is 0,01 on 100 years (10^{-4} a year).
3. The ISO standard puts limit probabilities of the destruction of the bridge as result of the collision with ship on level of 0.01 per 50 years, what gives value of 0.02 per 100 years (2.0 10^{-4} a year).
4. J.B. Menzies proposes to apply the acceptable risk of bridges destruction on level 2.0 10^{-6} which then the value seems to be nearing to norms quoted in Eurocode 1 EN1990:2002. It is worth of notice that this author ascertains, that in the past above the half of all destructions of bridges was due to event relied with the ship collision or the erosion the bottom at the pier as result of the flood.
5. Recommendations of the American Association of State Highway and Transportation Officials (AASHTO) assumes the probabilities of the bridge destructions on level from 0.1 and 0.01 per 100 years (10^{-3} and 10^{-4} a year) consecutively for standard- and critical bridges.
6. According to L.J. Vincentsena and S. Spangenberga in changed project of the bridge and the tunnel through Great Belt the accepted levels of the bridge road- and of railway link break simultaneously is set to 0.02 on 100 years, and bridge or railway alternatively as 0.1 per 100 years.
7. According to the report 63 of Construction Industry Research and Information Association the risk of the destruction of the construction can be definite as $P_z = (10^{-4}/n_r)K_s n_d$, where

P_z is a probability of the destruction of the construction due to any reason within a period of its operation n_d, n_r is a number of persons threatened in the accident and K_s is the coefficient dependent of values related with class of the building: places of public meetings, dams—0.005; the household activity, the office, the trade or the industry—0.05; bridges—0.5; towers, masts and sea-constructions—5. This criterion has became put-upon to the designing of the second bridge trough Severn river and brought the acceptability level to value of less than 4,0 10^{-7} per a year.

8. *Nordic Committee for Safety of Structures* gives legitimate values of the probability of the one year's damage as 10^{-3} to 10^{-7} for serious results or very serious.
9. JCSS gives criteria values on level 10^{-3} to 10^{-6} for damages with serious results.
10. AASHTO use the so called return periods. For the erosion the bottom at the pier as result of the flood it apply 100 and 500 years return-period adequately for regular and critical bridges (0,01 and 0.02 in the year), for earthquakes 475- and 2500-the years return-period (0.02 and 0.004) period and for the collision with ships 1000- and 10 000-years (0.001 and 0.0001 per year).

It should be noticed that criteria of the risk acceptance in Europe are created usually for cumulative all possibly events such as: seismic, fires, the bottom erosion at piers and the influence of ice etc. US criteria are built rather for single events. The above-analysis shows that the lack is generally accepted acceptability criteria of the risk. Guidelines have a considerable spread of the criteria values. The probability of the break of the bridge connection varies widely from 10^{-3} to 10^{-6}, can be accepted as the enter average value to further analyses.

The US analysis of ship—bridge collisions [USCG, 2003] reveals that only 2% events ends with events of considerable consequences, which could be the reason of high resistances of bridge supports for collisions and the fact that these studies embraced majority of inland units. AASHTO [1991] proposed method of density function creation of the bridge collapse probability composed of two uniform distributions (Fig. 6):

$$f(P/P_{\max}) = \begin{cases} 0,9 & for\ \ 0 \le P/P_{\max} < 0,1 \\ 0,1 & for\ \ 0,1 \le P/P_{\max} \le 1 \end{cases}$$

where:

P/P_{max}—the relation of the load from the ship collision (P) to the peak load (P_{max}), which can be transferred to the bridge pier.

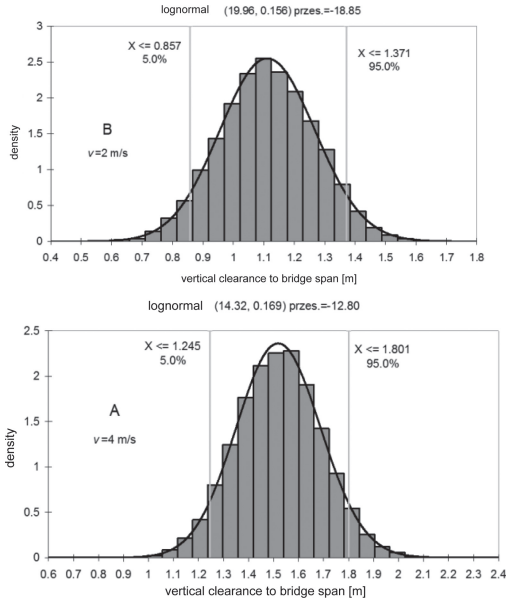

Figure 6. The distribution of the vertical clearance of the height over the ship to the span for two speeds of ships: A—8 kn (abt. 4 m/s) and B—4 kn (abt. 2 m/s).

4 SELECTED CASE STUDIES OF THE SAFETY ANALYSIS WITH ACCIDENT PROBABILITY ESTIMATION OF THE SHIPS PASSAGE UNDER THE BRIDGES

Two example analyses concerning the quantifying of the risk of the ship passages under bridges thet restricts water area both concerning the horizontal and vertical area.

4.1 *The collision with the span: Qualifying of horizontal clearance with the methods of the statistical simulation*

The Monte Carlo based model was built of the clearance between ships and the span. The random variables and their parameters were estimated he the base results obtained in the project: "The creation of the method of dynamic and probabilistic underkeel clearance estimation" [L. Gucma, 2008d]. To build example solution the example bridge on the fairway Szczecin–Świnoujście with the height above water level of H = 36 m have been chosen. The maximum ship, which can enter to Szczecin now is ship with following parameters: L = 160 m, T = 9,15 m, and A = 35 m. The horizontal clearance have been calculated for two ship speeds 8 and 4 kn. Input data to the model one are presented in the Table 1. Monte Carlo simulations

Table 1. The random distributions of variables accepted to the Monte Carlo simulation of horizontal clearance to the bridge and their parameters.

Variable	Symbol	The accepted average value	Distribution of errors	Parameters of given distribution
Bridge height [m]	H	36	Uniform	(0; –0,05)
Draught [m]	T	9, 15	Normal cut	(0; 0,1; 0,2)
Ships air draught [m]	A	35	Based on T	a.a.
Squat [m]	O	4 models	*Bootstrap*	
Water level [m]	p_{wa}	0	Normal cut	(0; 0,1, 0,15)
Breadth [m]	B	35	Uniform	(35; 40)
Speed of the ship [in]	v	8 and 4	Normal	(0, 0,5)

were executed by means of the @Risk software, the number of samples equals 100 000, what gave the suitable statistical convergence of obtained results. The best fit of the clearance of the height to the span of the bridge gives the log-normal distribution with relatively low asymmetry. In further step it is possible to qualify the probability of the collision of the ship into the span of the bridge. From graphs presented in Figure 6 it is apparently visible that 5% ships will keep a smaller than: 1,24 m and 0,86 m for investigated speeds 4 and 2 m/s It was confirmed also the argument about the relationship of the reserve of the height over by ship to the span with her speed, what results from the squat phenomenon.

4.2 *The collision with pier: The bridge Great Belt—the traffic analysis of ships by means of AIS*

The AIS system could be a very useful tool to the traffic analysis of ships and their safeties also in the bridges area. It should be noted that the possibility exists of the GPS satellites signal reception difficulties and consecutive loss of ships position during the passage under bridge due to its shadowing effect. The traffic analyses of ships during the passage under the greatest European bridge Great Belt Western is presented. The traffic under the bridge is two-way. As an input data unprocessed signal from the AIS Baltic countries exchange network (AIS HELCOM) was applied. The number of registered passages was about 6500 ships per year in one direction. Research embraced the year 2011. Registered chosen passages of ships are showed in Figure 7. It is visible that some ships passed vary close to the pier of the bridge.

In the next step the distributions of density probability of the position of registered positions of ships during the passage under the bridge have been analysed. The CDF of ships positions moving north is presented in Figure 8. The logistic

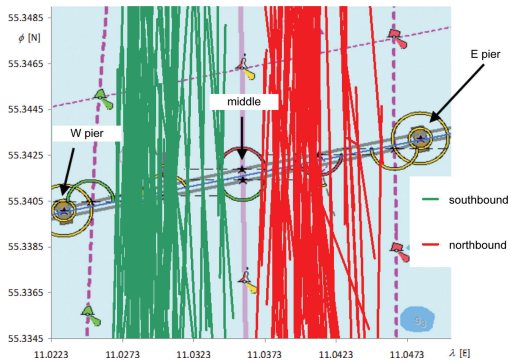

Figure 7. Registered routes of ships in the region of the Bridge Great Belt Eastern.

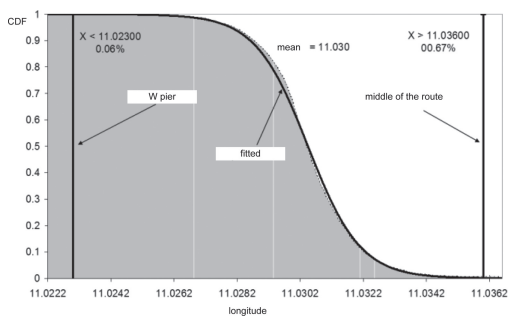

Figure 8. Cumulative distribution function of positions of ships under the bridge (the western route).

distribution with parameters of a = 11,03 and b = 8,32 showed good fit to given empirical (the Kołmogorowv–Smirnow tests was applied). It is visible that the probability of the collision with the western pier of the bridge lead to values of $6 \cdot 10^{-4}$, so shows the large agreement with the values meet in the literature. The probability of the exit outside the given route and intrusion to opposite traffic lane is higher and quails: $6{,}4 \cdot 10^{-3}$.

5 CONCLUSIONS

It was shown that the problem of collisions of ships with bridges in Poland and in around the world is serious, also on inland waterways. Additionally the fact of the considerable degradation of the infrastructure contributes to his deepening. There exists the row of methods of the valuation of the risk from which two were described.

The designing of new locations of bridges should be supported by individual risk analyses, because as it was showed norms and guidelines are sometimes inconsistent and not always assure optimum-foundations to their designing.

It is necessary to carry out of the deeper discussion in the matter of the safety of the location of bridges in the respect of collisions with ships in Poland especially that possible disasters can entail deadly sacrifices.

A new approach for evaluating the disruption risks of a seaport system

A. John, R. Riahi, D. Paraskevadakis, A. Bury, Z. Yang & J. Wang
Liverpool John Moores University, UK

ABSTRACT: Much of the available data associated with seaport operations is uncertain and ambiguous, requiring an approach capable of handling both quantitative and qualitative information. Conventional risk modelling approaches are considered to be inadequate in many circumstances due to the lack of flexibility and an inappropriate structure for addressing the system's risks. This paper proposes a flexible risk assessment approach to facilitating the treatment of uncertainties in seaport operations in a systematic manner. The methodology consists of a fuzzy analytical hierarchy process, an Evidential Reasoning (ER) approach, and fuzzy set theory. The fuzzy analytical hierarchy process is used to analyse the complex structure of seaport operations and determine the weights of significant risk factors while ER is used to synthesise them. The methodology provides a framework for collaborative modelling of the system and allows for a step by step analysis. It could provide managers and infrastructure analysts with a flexible tool in order to enhance the resilience of the seaport system.

1 INTRODUCTION

Safety Critical Maritime Infrastructure (SCMI) systems, which are defined as ports, waterways, vessels and their intermodal connections, are the foundation of world economic growth. Due to the interaction and interdependence among their components and subcomponents, the systems are vulnerable to various risks in their field of operations.

As a result of multiplicity of stakeholders and the operational complexity in SCMI systems, high levels of operational uncertainty exist in the systems (Mansouri *et al.*, 2010). Given that the world's trade is mainly carried out by sea transportation, the global economy is heavily dependent on the effective operation of these systems, disruptions at any point could potentially result in catastrophic and disastrous consequences.

Building resilience in maritime operations requires creating capabilities and a sustained engagement from the stakeholders involved in these operations. In order to optimise the protective capability of the system, it is essential to constantly revise and update the risks that are associated with the system in such a way that it would recover to a desired level of functionality when facing adverse operational constraints. The complexity of a SCMI system is caused by the integration of technical, organisational, operational and security issues into its routine operations.

Conventional techniques such as Fault Tree Analysis (FTA), Event Tree Analysis (ETA), Failure Mode, Effects and Criticality Analysis (FMECA) and Bow-Tie (BT) have been widely used in analysis of critical systems and have contributed greatly to the literature of risk analysis. The aforementioned approaches have some drawbacks which affect their applications. The use of traditional risk assessment approaches to deal with newly arising hazards and threats (e.g. potential terrorist attacks) to maritime infrastructure reveals two major challenges: i) the lack of capability to process diverse data suitable for input into a risk inference mechanism, and ii) the lack of capability to analyse the interactive dependence between risk factors (Yang *et al.*, 2009).

One realistic way to analyse a system with unavailable data is to employ subjective assessment using the combination of fuzzy logic and Evidential Reasoning (ER). Compared to the traditional fuzzy inference mechanism (i.e. max-min fuzzy operations), an ER approach has the advantage of avoiding the loss of useful information in its inference processes; hence, it can be suitable for modelling complex systems.

The insufficiency of quantitative risk assessment in the maritime-related literature together with the vision to establish a secure and resilient SCMI system has resulted in a need for an integrated risk assessment methodology capable of tackling the uncertainties associated with a system's operation (John, 2013).

This paper is organised as follows. Section 2 reviews the existing literature on SCMI systems, and discusses the major risk factors associated with seaport operations. Sections 3 and 4 highlight the decision making techniques that are used for

the analysis. Section 5 presents the methodology of the study. Section 6 provides a numerical example to demonstrate the applicability of the proposed methodology. Section 7 concludes the study.

2 LITERATURE REVIEW

SCMI systems are complex due to the dynamic interactions among their interrelated components. The level of interdependences and complexity of the system's operations can be acknowledged through its description by the US Department of Homeland Security "as all areas and things of, on, under, relating to, adjacent to, or bordering on a sea, ocean, or other navigable waterways, including all maritime related activities, infrastructure, people, cargo, vessels and other conveyances" (Moteff and Parfomak, 2004). Analysing the disruption risks of a CMI system's operation will: i) improve security, ii) increase the resilience of the system, and iii) reduce its susceptibility to hazards.

Modern seaports as an important component of SCMI systems focus their operations on continuous handling of flows and efficient transport. Experience has shown that operation of a seaport has progressed from performing cargo handling, stacking and distribution functions to a complex transportation hub in a logistic chain. Comprehensive analysis of maritime infrastructure revealed that a seaport system is entailed with: i) the infrastructure (i.e. assets that are capable of an intended service delivery, such as access channels, turning basins, quay walls, jetties, navigational aids, breakwaters, pilots, tugs and stacking areas), ii) the superstructure (i.e. logistics, ICT, handling equipment, warehouses, *etc*.), iii) the operating procedures, iv) management practices, v) complex interactions with the society to facilitate trade, and vi) the transfer of goods and services for economic development (Taneja *et al.*, 2010).

The flexibility in the flows of vessels and large amounts of bulk cargoes has created a huge amount of concerns about the integrity of the infrastructure because of the numerous opportunities for them to be tampered with for terrorism-related acts and sabotage. Additionally, their operations can be hampered by several organisational and environmental risks that range from natural to man-made disasters, with disruption likelihood that can potentially result in a large amount of direct and indirect financial losses (Hultin *et al.*, 2004; Nilchiani and Mostashari 2008).

When studying the safety aspects of a seaport system, a logical approach is to break down the system into its functional entities comprising components and subcomponents. Safety modelling of these functional entities can be carried out to fit such a logical structure, then the interrelationships can be examined and a system safety model can be formulated for risk-based decision making in all phases of the system's activity, from its conception and design to its operation, maintenance and decommission.

The risks associated with seaport operations are multifaceted. Risk factors are presented in Table 1 (Nair *et al.*, 2010; Handley-Schachler and Navare, 2010; Moktari *et al.*, 2011; Slatter and Force, 1999).

Each main risk factor, as shown in Table 1, is broken down to its associated root causes. These causes are chosen because they are regarded as the most significant ones associated with major disruption of seaport activities. The selection of such disruption risks and causes is conducted based on extensive discussions with experts and a robust literature review (John, 2013).

2.1 *Operational risk factors*

The evolution of large vessels for maritime transportations has necessitated the need to optimise terminal infrastructures to systematise the management of risk in loading and unloading operations in ports and maximise the possibility of controlling incident/accident cases effectively.

Table 1. Causes of seaport disruption.

Main risk type	Associated cause
Operational risk factors (R1)	Port equipment failures
	Vessel accident/grounding
	Cargo spillage
	Human errors
	Sabotage
Security risk factors (R2)	Terrorism attacks
	Surveillance system failures
	Arson
Technical risk factors (R3)	Lack of equipment maintenance
	Lack of navigational aid maintenance
	Lack of IT system maintenance
	Lack of dredging maintenance
	Labour unrest
	Dispute with regulatory bodies
Organisational risk factors (R4)	Berth congestion
	Gate congestion
	Storage area congestion
Natural risk factors (R5)	Geologic/seismic
	Hydrologic
	Atmospheric

The operational risk factors that cause disruption of maritime activities are due to port equipment failures, vessels accident/grounding, human error and cargo spillage (John, 2013).

2.2 *Security risk factors*

Since the 9/11 attacks, security experts have shown serious concerns over the efficiency and robustness of SCMI systems, with regard to their possible exploitation by terrorists, who could cause a disaster in the system either through the sinking of a large vessel in a port channel or by attacking a port's physical infrastructure facilities (Bichou, 2008 and Fritelli, 2005).

Experience has shown that decision makers have invested significant resources on sophisticated security measures in order to ensure smooth flows of trade. The effective performance of security systems or measures can be built based on a robust modelling of the system (John, 2013).

2.3 *Technical risk factors*

SCMI systems can be categorised as: i) marine constructions, ii) port maintenance, iii) port operations, and iv) logistics. Because ports are open facilities with multiple means of access by both land and sea routes, they involve multiple modes and each is managed by a different entity within the system. For smooth operations of maritime systems, events such as the lack of equipment, navigational aid, IT systems and dredging maintenance are identified as significant issues leading to disruption of the systems with long-term financial consequences (Moktari *et al.*, 2011).

2.4 *Organisational risk factors*

Events such as labour unrest, dispute with regulatory bodies, breakdown in organisational communications leading to berth congestion, incompatible management goals leading to gate congestion, and poor management procedures leading to storage-area congestion are major factors mentioned in the current literature which lead to the disruption of seaport operations (John, 2013; Mansouri *et al.*, 2010). There is a widespread agreement among safety researchers that the key means of tackling the human element contribution to disruptions will be via the incorporation of resilience into the operations of the system (Mostashari *et al.,* 2011).

2.5 *Natural risk factors*

The dynamics of the natural environment affect the entirety of seaports' operations. The most important hazards due to natural factors are hydrological, atmospheric and geological ones (Kroger, 2008). The impacts of these hazards have consistently added more cost to management of seaports in the form of maintenance, reconstruction and preparedness.

Heavy rainfall, flooding and snow are important examples of hydrological hazards; tsunamis and earthquakes are categorised as geological or seismic hazards; hurricanes and cyclones are classed as atmospheric hazards.

3 EVIDENTIAL REASONING ALGORITHM

The theory of evidence was first generated by Dempster (1968) and further developed by Shafer (1976). It is often referred to as the Dempster-Shafer theory of evidence or D-S theory. The D-S theory was originally used for information aggregation in expert systems as an approximate reasoning tool (Mantaras, 1990). Subsequently, it has been used in decision making under uncertainty (Yager, 2004).

Due to the ever-changing environment and the multiple criteria decision-making problems having a degree of uncertainty, the ER algorithm was developed (Yang and Xu, 2002).

The major advantages of ER are listed as follows:

- It is capable of handling incomplete, uncertain and vague as well as complete and precise data.
- It is capable of providing its users with a greater flexibility by allowing them to express their judgements both subjectively and quantitatively.
- It is capable of accommodating or representing the uncertainty and risk that is inherent in decision analysis.
- As a hierarchical evaluation process, it is capable of offering a rational and reproducible methodology to aggregate the data assessed.
- It is capable of obtaining the assessment output using mature computing software, Intelligent Decision System (IDS) (Yang and Xu, 2002).

4 THE EXPECTED UTILITY

The concept of expected utility is utilised to generate numerical values equivalent to the distributed assessment of the top-level criterion or goal of each alternative for ranking in order to obtain the probable risk level of disruption for decision making.

In light of the above, let the utility value of an evaluation grade H_n be denoted as $u(H_n)$ and $u(H_{n+1}) > u(H_n)$ if H_{n+1} is preferred to H_n (Yang, 2001). It is worth mentioning that $u(H_n)$ represents

utility values of each linguistic term and can be determined using the decision makers' preference. If there is no preference information available, it could be presumed that the utilities of the evaluation grades are equidistantly distributed in a normalised utility space. The utilities of evaluation grades that are equidistantly distributed in a normalised utility space are calculated as follows:

$$u(H_n) = \frac{V_n - V_{\min}}{V_{\max} - V_{\min}} \quad (1)$$

V_n stands for the ranking value of the linguistic term that has been considered (H_n), V_{max} is the ranking value of the most preferred linguistic term (H_N), and V_{min} is the ranking value of the least preferred linguistic term (H_1). The utility of the top-level or general criterion $S(E)$ is denoted by $u(S(E))$. If $\beta_H \neq 0$ (i.e. the assessment is incomplete, $\beta_H = 1 - \sum_{n=1}^{N} \beta_n$ where β_n is a belief degree to which $S(E)$ is assessed to H_n) there is a belief interval $[\beta_n, (\beta_n + \beta_H)]$, which provides the likelihood that $S(E)$ is assessed to H_n.

Without loss of generality, suppose the least preferred linguistic term having the lowest utility is denoted by $\mu(H_1)$ and the most preferred linguistic term having the highest utility is denoted by $\mu(H_N)$. Then the minimum, maximum and average utilities of $S(E)$ are defined as follows (Yang, 2001):

$$u_{\min}(S(E)) = \sum_{n=2}^{N} \beta_n u(H_n) + (\beta_1 + \beta_H) u(H_1)$$
$$u_{\max}(S(E)) = \sum_{n=1}^{N-1} \beta_n u(H_n) + (\beta_N + \beta_H) u(H_N) \quad (2)$$
$$u_{average}(S(E)) = \frac{u_{\min}(S(E)) + u_{\max}(S(E))}{2}$$

Obviously, if all the assessments are complete, then $\beta_H = 0$ and the maximum, minimum and average utilities of $S(E)$ will be the same. Therefore, $u(S(E))$ can be calculated as follows:

$$u(S(E)) = \sum_{n=1}^{N} \beta_n u(H_n) \quad (3)$$

5 METHODOLOGY

The aim of this paper is to develop a decision-making model for evaluating the diverse risks of a seaport system in a systematic manner. The methodology in a stepwise order is explained as follows:

1. Identifying the risk factors associated with seaport operations.
2. Developing a model with a hierarchical structure for evaluating the risk of disruption to seaport operations.
3. Assigning a weight to each different criterion by using Fuzzy Analytical Hierarchy Process (FAHP).
4. Assessing the risk level of a hazardous event using triangular fuzzy numbers.
5. Aggregating the input data using an evidential reasoning algorithm.
6. Determining a crisp value for a risk level in terms of expected utilities.

6 A NUMERICAL EXAMPLE

A numerical example is used in this section to show how the proposed approach can be implemented for the assessment of the various risk factors and their impact on the smooth operations of a seaport.

6.1 *Identification of risk factors associated with disruption of a seaport operation* (*step 1*)

Based on the literature review, risk factors associated with disruption of a seaport's activities are identified and presented in Table 1. Each risk factor is investigated based on its associated causes. These causes are chosen because they are regarded as the most significant factors associated with major disruption of a seaport activity.

6.2 *Development of a model for evaluating the risk of disruption to seaport operations* (*step 2*)

Based on the risk factors identified in Section 2, as shown in Figure 1, a model with hierarchical structure is developed. Following a review of Wang *et al*. (1995) for effective information processing of a safety expression, linguistic terms need to be in the range of four to seven. As a result, within this paper five linguistic terms are defined to evaluate the likelihood and consequence of each identified risk factor, as shown in Table 2.

6.3 *Assigning a weight to each different criterion by using FAHP (step 3)*

Questionnaires were designed and possible values were assigned through meetings with experts. Weights were assigned to all criteria by using FAHP (An *et al*., 2007). These weights are presented in Table 3.

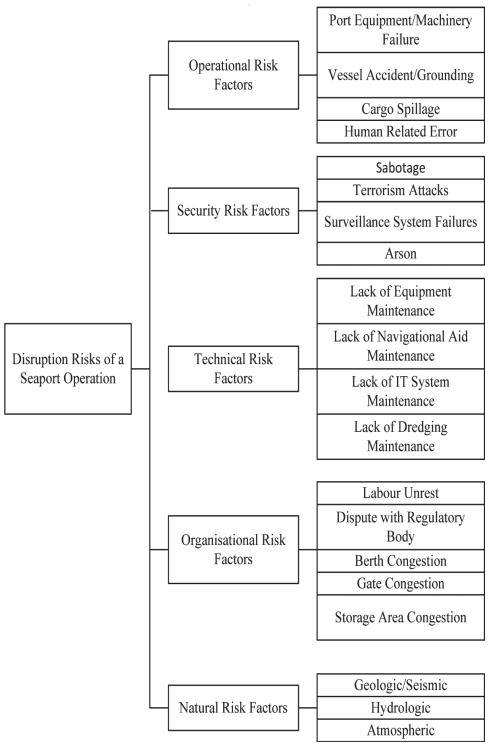

Figure 1. Model for disruption of a seaport system.

Table 2. Triangular fuzzy numbers for likelihood and severity.

Grade	Occurrence likelihood (L)	Consequence severity (S)	Triangular fuzzy numbers
1	Very low	Negligible	(0, 0, 0.25)
2	Low	Moderate	(0, 0.25, 0.5)
3	Medium	Serious	(0.25, 0.5, 0.75)
4	High	Very serious	(0.5, 0.75, 1.0)
5	Very high	Disastrous	(0.75, 1.0, 1.0)

6.4 *Assessing the risk level of a hazardous event using triangular fuzzy number (step 4)*

When the occurrence Likelihood (L) of a hazard and its consequence Severity (S) are assumed to be mutually independent, their combination is equal to the product of the two. Hence, under the same assumption, the product of the two triangular fuzzy numbers denoted by $TFN_L = (a_L, b_L, c_L)$ and $TFN_s = (a_s, b_s, c_s)$ as presented in Equation 4 is equal to the risk level of a hazardous event under investigation.

$$TFN_{LS} = TFN_L \otimes TFN_S = (a_L \otimes a_S, b_L \otimes b_S, c_L \otimes c_S) \quad (4)$$

Table 3. Weights of risk parameters.

Risk parameters	Abbreviation	Weights
Port equipment failures	R11	0.510
Vessels collision/grounding	R12	0.083
Cargoes spillage	R13	0.258
Human related error	R14	0.149
Sabotage	R21	0.481
Terrorism attacks	R22	0.306
Surveillance system failure	R23	0.124
Arson	R24	0.089
Lack of equipment maintenance	R31	0.490
Lack of navigational maintenance	R32	0.076
Lack of IT system maintenance	R33	0.283
Lack of dredging maintenance	R34	0.150
Labour unrest	R41	0.475
Dispute with regulatory bodies	R42	0.054
Berth congestion	R43	0.081
Gate congestion	R44	0.114
Storage area congestion	R45	0.275
Geologic	R51	0.35
Hydrologic	R52	0.325
Atmospheric	R53	0.325
Operational risk factors	R1	0.246
Security risk factors	R2	0.291
Technical risk factors	R3	0.188
Organisational risk factors	R4	0.153
Natural risk factors	R5	0.122

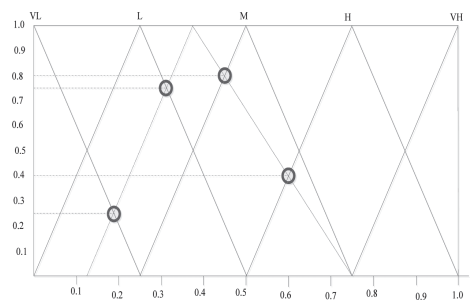

Figure 2. Converting a triangular fuzzy number to a set with five linguistic grades.

TFN_L stands for the triangular fuzzy number for likelihood and TFN_S stands for the triangular fuzzy number for severity and TFN_{LS} stands for the triangular fuzzy number for the risk level of a hazardous event under investigation.

As an example and based on Table 3, if a risk has an occurrence Likelihood (L) of Medium (0.25, 0.5, 0.75) and consequence Severity (S) of Very Serious

(0.5, 0.75, 1), based on the Equation 4, the corresponding triangular fuzzy number for the risk level of a hazardous event under investigation (i.e. TFN_{LS}) is evaluated as (0.125, 0.375, 0.75). To obtain a risk set with five linguistic terms, as shown in Figure 2, TFN_{LS} is mapped over the membership functions of a risk with five uniformly distributed grades (Very Low (VL), Low (L), Medium (M), High (H) and Very High (VH)) (Moktari *et al.*, 2011).

As shown in Figure 2, a point where the TFN_{LS} intersects a linguistic term is circled and the corresponding degree of membership (i.e. Z_P) is presented in Table 4. As illustrated in Table 4, Z_P is normalised to obtain Z (i.e. linguistic variables; linguistic terms with their membership degrees).

Based on Equation 4, the risk level of a hazardous event can be evaluated as follows:

$$\begin{aligned} TFN_{LS(VeryLow)} &= TFN_{L(VeryLow)} \otimes TFN_{S(Negligible)} \\ TFN_{LS(Low)} &= TFN_{L(Low)} \otimes TFN_{S(Moderate)} \\ TFN_{LS(Medium)} &= TFN_{L(Medium)} \otimes TFN_{S(Serious)} \\ TFN_{LS(High)} &= TFN_{L(High)} \otimes TFN_{S(VerySerious)} \\ TFN_{LS(VeryHigh)} &= TFN_{L(VeryHigh)} \otimes TFN_{S(Disastrous)} \end{aligned} \quad (5)$$

Table 5 presents the triangular fuzzy numbers for the risk levels based on Equation 5. K is the risk level value used for the grouping of a triangular number (a_1, a_2 and a_3) and is obtained as follows:

$$K = \frac{1}{2(a_1 + a_2 + a_3)} \quad (6)$$

Table 4. Example of mapping FTN_{LS} into five grades.

FTN_{LS}	0.125, 0.375, 0.75
Grade	VL L M H VH
Z_P	0.25, 0.75, 0.80, 0.40 0
Z	0.10, 0.34, 0.36, 0.20 0

6.5 *Aggregation of input data using evidential reasoning algorithm (step 5)*

Based on the demonstrated techniques in Section 6.4 the linguistic variables (Z) for all risk factors, as shown in Table 6, are evaluated. By using the evidential reasoning algorithm the risk factors are aggregated and the linguistic variables for main criteria, as shown in Table 7, are assessed.

By using the ER algorithm the linguistic variables for main criteria are aggregated and the linguistic variables for disruption risks of a seaport operation (DR) are assessed (Table 7).

6.6 *Evaluation of a crisp value for a risk level using the expected utility approach (step 6)*

Quantitative assessment based on a single value is much easier and is a more realistic tool for a decision maker to rank the risk factors. In view of the fact that the linguistic variables for the disruption risks of a seaport operation (DR) was characterised by five linguistic terms, the highest preference is given to the "Very High" linguistic term and the lowest preference is given to the "Very Low" linguistic term.

By using Equations 1–3, the DR value was evaluated as: = (0.2349 × 0) + (0.461 × 0.25) + (0.2348 × 0.5) + (0.0693 × 0.75) + (0 × 1) = 0.285 or 25.8%. This value represents the disruption risks of a seaport operation under investigation.

Based on Table 5, it is close to the class of significant risk category. This value means that the risk must be reduced if practicable. It can be used to benchmark the safety performance among different ports or in the same port at different periods of time.

Such a result can be used to help port safety analysts to carry out formal safety assessment of a port, and to initiate safety audit and review of key performance indicators of various port departments for enhanced operation. The result of the analysis could also help analysts to propose various

Table 5. Definition of linguistic variables used for risk evaluation and risk levels based on TFNs.

Risk level	Description of risk evaluation variables	Triangular fuzzy numbers	Centroid values (Risk levels) K
Very low: Risk is acceptable	If likelihood is very low and severity is negligible	(0, 0, 0.0625)	0.020
Low: Risk is tolerable but should be reduced if it is cost effective	If likelihood is low and severity is moderate	(0, 0.0625, 0.25)	0.104
Medium or significant: Risk must be reduced if it is practicable	If likelihood is medium and severity is serious	(0.0625, 0.25, 0.5625)	0.292
High: Risk must be reduced	If likelihood is high and severity is very serious	(0.25, 0.5625, 1.0)	0.604
Very High: Risk must be reduced and controlled	If likelihood is very high and severity is disastrous	(0.5625, 1.0, 1.0)	0.854

Table 6. Linguistic terms with their membership degrees (Z) for risk factors.

Risks factors	Z				
	VL	L	M	H	VH

DR	0.2349	0.4610	0.2348	0.0693	0.0000

layers of protection or measures to optimise the robustness of the system. This approach may provide a viable approach where there is a lack of objective or statistical data in such an assessment for the port under investigation.

7 CONCLUSION

This paper proposes a methodology for evaluating the risk of disruption to seaport operations, in order to optimize the operational efficiency of the system.

In the risk-based modelling approach presented in this paper, input data are expressed by linguistic terms with their membership degrees. This approach presents a flexible framework for use when precise data is not available. The approach has the following advantages:

- It provides managerial insights to analysts in a rational, reliable and transparent manner for collaborative modelling of complex systems with a group of experts under situations of high uncertainties in data.
- It provides researchers with an effective tool to make full use of the information generated at the lowest level in design to evaluate the safety of the whole system for resilience improvement of its operations.
- It has been shown to be flexible in application, and can be useful in safety analysis and synthesis in many industrial environments.

It is envisaged that the proposed approach could provide risk managers and infrastructure analysts with a flexible tool for use in understanding the importance of developing organisational strategy in order to increase the resilience of the system to unforeseen operational uncertainties in a transparent manner.

Methodology for evaluation of barriers for rig move operations

E. Okstad, S. Hauge & B.A. Mostue
SINTEF Technology and Society, Safety Research, Trondheim, Norway

H. Skår
Statoil ASA, Bergen, Norway

ABSTRACT: This paper presents a methodology for evaluation of safety barriers against major accidents in rig-move operations. A stepwise approach is suggested, which was identified and adopted in cooperation with marine experts from Statoil with partners. Barriers were identified on basis of a documentation review followed by workshops. The strength and shortages of technical, operational and organizational barriers have been focused. The novelty of the suggested approach lies in the way barrier information in rig-move operations are collected and assessed, and secondly, the way stakeholders and system experts are involved in the evaluation of the critical safety barriers. Of the most important learnings were the effective identification of measures for strengthening the existing barriers, and the process of identifying supplementary barriers.

1 INTRODUCTION

1.1 *Background*

Failures or weakening of barriers are frequent causes of undesirable incidents in the petroleum sector. The Petroleum Safety Authority in Norway therefore states in the Management Regulations that the relationship between risk assessments and barrier management must be clarified by the industry (PSA, 2010). This relationship is essential for the successful risk management of operations.

Marine operations and rig-move operations in particular, are lacking risk models that cover, or describe in an appropriate way, important barrier functions and systems. Therefore, Statoil suggested an evaluation of important barriers to be carried out according to the following three steps:

- Identify hazards and situations that may result in undesirable events
- Identify technical, operational and organizational barriers that exist, or are missing in order to prevent major accidents and serious incidents
- Assess the quality of technical, operational and organizational barriers as basis for suggesting safety improvements.

The current paper presents generic results from the above barrier evaluation and is based on project collaboration between SINTEF/MARINTEK and Statoil.

1.2 *Objectives*

The main objective of the paper is to present the methodical approach applied for evaluation of safety barriers in rig move operations. The methodology should focus on work laid down by oil companies in preventing major accidents and serious incidents associated with rig move operations. Hence, the approach should support work processes aimed at identifying and strengthening the most important safety barriers in this area of marine operations. The important questions are:

- What are the main barriers against incidents and major accidents in rig move operations?
- In what way can these safety barriers be identified and further strengthened?

2 RIG-MOVE OPERATIONS

2.1 *System descriptions*

The suggested methodology considers normal work processes in rig-move operations and the measures that are implemented to prevent associated accidents. Included are activities from the

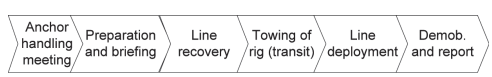

Figure 1. Phases of a rig move project.

early anchor handling meeting, through the operational phases until demobilisation, debriefing, and reporting.

2.2 *Requirements*

Different sources of information were applied to obtain an overview of the requirements related to rig-move operations. General information regarding work processes, activities and roles and responsibilities in rig move operations have been taken from the NWEA—Guidelines (NWEA, 2012). The guideline incorporate best practice and procedures from North Sea operating companies, logistics companies, ship owners, shippers and lessons from the appropriate national safety forums. The guideline does not supersede flag- and other legal requirements.

Internal procedures of the operating company might also describe the main structure of tasks, roles and responsibilities for a given assessment case. Finally, the operational requirements, limitations and constraints for a specific rig move operation are utilised as described in the respective Scope-of-Work document (SoW). The main reason is that much of the SoW descriptions typically are considered as formal requirements to each specific rig move operation.

2.3 *Interpreting the barrier concept*

As mentioned in the background section, barrier management has been highly focused in the Norwegian petroleum industry lately. Safety barriers are implemented to avoid hazards or accidents. When several barriers are in place to prevent an undesirable event or accident, this is often referred to as "defence in depth". The principles apply to safety in rig move operations as well. Several barriers must fail simultaneously in order for an accident to occur. This is often illustrated by the "Swiss cheese model" (Reason, 1997). The following barrier definitions are based on the memo "Principles for barrier management in the petroleum industry" (PSA, 2013):

2.3.1 *Barrier*

Barriers are technical, operational and organisational elements which are intended individually or collectively to reduce possibility for a specific error, hazard or accident to occur, or which limit its harm/disadvantages.

2.3.2 *Barrier Function (BF)*

A barrier function describes the task or role of the barrier. Examples include preventing leaks or ignition, reducing fire loads, ensuring acceptable evacuation and preventing hearing damage.

2.3.3 *Barrier Element (BE)*

Barrier elements are technical, operational or organisational measures or solutions which play a part in realising a barrier function.

2.3.4 *Performance Influencing Factor (PIF)*

Performance influencing factors are significant conditions for the ability of barrier functions and elements to perform as intended.

The following interpretation to rig move operations has been applied as to what could be identified as a barrier or a barrier element:

> *Barriers are measures that are implemented to oppose an undesirable chain of events occurring.*

In planning of risky operations or activities, it is often argued that the risk analysis in itself should be defined as a safety barrier. This implies that a Safe Job Analysis (SJA) before a specific anchor handling operation could be defined as a barrier. Our interpretation of the barrier concept does not open for this definition. Risk analysis including SJA is considered as a performance influencing factor in the way that it affects the quality (with respect to safety) of a work process, or planned operational activities. This is also in line with the PSA's interpretation of the barrier definition (PSA, 2013).

3 BARRIER EVALUATION APPROACH

3.1 *The six-step methodology*

A six-step methodology is suggested for the barrier evaluation. It describes the process for collection, systemization, visualization and evaluation of safety information related to rig move operations. The main activities were the document reviews and meetings with operational personnel of the company under study. Clarification of the system limits and a correct interpretation of rig move operations were important initial activities to ensure an appropriate basis for the barrier evaluation. Main input to the evaluation was requirements, procedures and reports covering relevant incidents and accidents as well as the operational knowledge of the involved experts.

3.1.1 *Step-1 Review of accidental events*

The rig-move study for Statoil was based on a total of 151 reports of experienced incidents. It spans from simple Synergi reports of minor incidents and near misses, to investigated in-depth studies of more serious events. Near-miss incidents (approximately 30 reports) were excluded from the review, mainly due to the minor risk potential (personnel injuries), but also project resource limitations.

Through the initial mapping, it was early identified that the main part of incidents with a major accident potential could be grouped into:

– Positioning failure incidents, and
– Anchor handling incidents.

By positioning failures we include incidents that relate to wrong navigation in rig move operations, either caused by missing navigation resources, technical failures on navigation equipment, or wrong configuration of such.

Anchor handling incidents include collisions with vessels involved in rig move operations and the anchor handling on deck. The main part of collision incidents are minor impacts occurring during operations at the field. Historically, the anchor handling incidents on deck were the most serious ones with respect to personnel injuries and harm to operating personnel.

Most of the events reported in Synergi are incidents more than accidents. For incidents, the Synergi database utilizes the following categorization:

– *Near misses*—Incidents that nearly have caused a more serious accident
– *Discrepancies*—The work as done deviates from written procedures or requirements
– *Conditions (technical or not)*—Vital characteristics or condition of important equipment or work practice is outside accepted limits

The above categorization is important in order to learn from reported incidents and understand the underlying causes.

Table 1 gives an overview of the received reports indicating the type of activity, type of documentation and category, year of occurrence, and number of events within each event category.

Of the positioning records there are four near misses, eight discrepancies and two conditions. The most frequent cause is wrong info in maps and positioning failures (six) and errors related to navigation equipment (four).

Of the anchor handling incidents, eight were investigated in-depth. Four of these caused personnel injuries, and three incidents had potential for such consequences. Concerning the other 99 anchor handling incidents, personnel injury was registered as a consequence in 15 of them. For the rest, damage to equipment and material was the typical result. Three of these incidents also resulted in delay in work progress and one resulted in spill to the environment.

Table 1. Number of reported incidents and events.

Activity	Category	Year	Number
Positioning (incidents)	Near misses	2004–2012	4
	Discrepancies	2005–2009	8
	Conditions	2008	2
Anchor handling	Investigated in-depth study	2008–2011	8
	Incidents	2011	50
		2012	43
		2013	6
	Near miss	2011	17
		2012	12
		2013	1
		SUM	151

3.1.2 *Step-2 Mapping of events*

The STEP-diagram method (Passmore, 1988) was used to map the work processes involved in the experienced incidents/events. Figure 2 illustrates an extract of such a mapping for the "Line recovery" phase at the field. Activities in the main work process are linked with solid lines in Figure 2, whereas actors indirectly involved are linked with dashed vertical lines to the core activities. The actors involved in rig move operations are specified to the left in the STEP diagram.

The following six different phases of a rig move project were covered in order to identify the most safety-relevant activities:

– Anchor handling meeting
– Preparation and briefing
– Line recovery at current location
– Towing of rig (or transportation) from the current location to new location
– Line deployment at new location
– Demobilisation and report

The experienced incidents and accidents were linked to the typical project phases and activities. Historical incidents being mapped are shown in

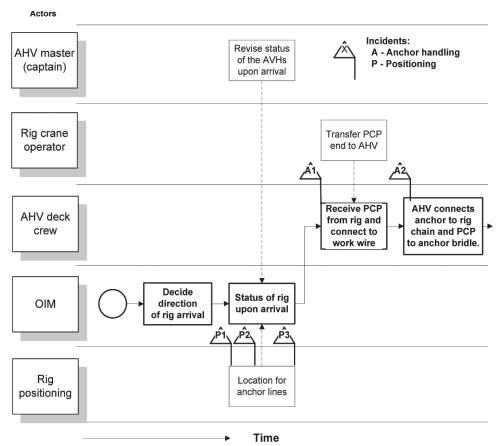

Figure 2. Extract of a STEP diagram: Line recovery.

"A" and "P" triangles for the anchor handling and positioning failures, respectively.

As indicated in Figure 2, clusters of reported incidents could be related to specific activity sequences in operation.

3.1.3 *Step-3 Scenario identification*

To facilitate the barrier analysis from an accident sequence perspective, the Bow-tie method (CGE, 2014) was used prior to and during a workshop (WS) with marine experts. The bow-tie diagram is a particularly suitable tool for visualizing barriers in safety critical operations, and is readily understood by non-specialists. Figure 3 shows an extract of a bow-tie diagram with some of the relevant barriers. The TOP event, representing loss of control, is indicated in the middle. To the left is what could cause the TOP event to occur, i.e. the initiating events or threats, and their associated preventing barriers. To the right are potential consequences and the mitigating barriers.

As background information for the scenario identification, PSA's RNNP project was used (PSA, 2012). Table 2 outlines the set of hazard and accident situations (Norwegian DFUs) that could lead to severe damage and loss of life in petroleum production.

Identification of possible accident scenarios and TOP events was based on the above DFU list. Events No. 5–9 were considered most relevant for rig move operations.

A list of six generic scenarios was defined and is shown below with the relevant DFU attached in brackets:

A. Collision between the anchor handling vessel and rig when the vessel arrives at the location from where the rig will be moved (DFU 5).
B. The tow line breaks during towing of rig from the current position to the new position when it passes close to another installation (DFU 6).

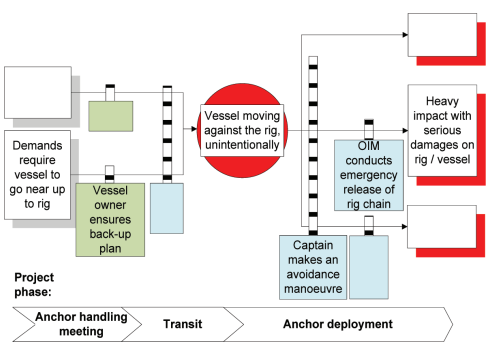

Figure 3. Extract of a Bow-tie diagram: Close to rig operation.

Table 2. DFUs according to RNNP (PSA, 2012).

No.	DFU
1.	Non-ignited hydrocarbon leaks
2.	Ignited hydrocarbon (HC) leakages
3.	Well incidents/loss of well control (well control events)
4.	Fire or explosion in other areas, not HC
5.	Ship on collision course (against the facility)
6.	Drifting object (against the facility)
7.	Collision with field-related vessel/installation/ shuttle tanker
8.	Damage to the device structure/stability/ anchoring/positioning errors
9.	Leakage from underwater production installation, pipeline/risers, buoy, and discharge hoses, etc.
10.	Damage to subsea production equipment/pipeline systems/diving equipment caused by fishing
11.	Evacuation (precautionary/emergency evacuation)
12.	Helicopter incident

C. An anchor handling vessel moves unintentionally against the rig in connection with the anchor handling operation for that rig (DFU 7).
D. Positioning errors with serious consequences resulting from errors in maps or lack of navigational equipment or resources, and the errors might not be detected during late planning and execution of the operation (DFU 8).
E. Severe loss of stability during execution of an anchor recovery operation (DFU 8).
F. The anchor is landed at wrong position because it did not engage correctly at the intended position and was dragged over existing production facilities/pipelines nearby (DFU 9).

The adapted scenario descriptions were made on basis of documented events and incidents, in addition to general experience/knowledge within the project group. Scenario A and C were again combined into a single collision scenario making the barrier analysis more effective. In addition, scenario D was selected to cover the positioning failures. As mentioned, the basis for selecting these scenarios was the mapping of incidents and events in the STEP diagram. The major-accident potential from the different types of events was also considered. According to the above grouping, the following three accident scenarios were chosen for further analysis:

– Scenario 1: Positioning failure prior to "grappling" (to retrieve anchor at current location)
– Scenario 2: Collision during close to rig operation
– Scenario 3: Collision due to operational/technical failure

The three scenarios above were visualized in preliminary bow-tie diagrams as preparation for further analysis. The respective TOP events were then:

– Grappling at wrong position (Scenario 1)
– Anchor handling vessel moving against the rig unintentionally (Scenario 2 and 3)

3.1.4 *Step-4 Identification of barriers*

Barrier identification and analyses were conducted in a Workshop (WS) with marine experts from Statoil and partners. Results from the WS were documented in the prepared STEP diagrams, preliminary Bow-tie diagrams and work sheets for further analysis. Only scenarios with end consequences implying a major accident potential were focused.

The WS was carried out in three steps:

1. Identification of possible initiating events and causes given the TOP event
2. Identification of accidental scenarios and possible consequences of the TOP event
3. Identification of frequency reducing barriers that may prevent the TOP event from occurring, and consequence reducing barriers that may prevent the TOP event from developing/escalating into a major accident

In the subsequent analysis the most important barriers were identified in revised bow-tie diagrams for the respective positioning failure- and collision scenarios. Color codes were applied to better differentiate between onshore and offshore barriers (activities) in the Bow-tie figures.

Each barrier function with the related barrier elements were discussed in assessment tables based on the revised bow-ties. Separate tables were made for the Initiating Events (IE) and End Consequences (EC), respectively. Table 3 and Table 4 below illustrate two extracts of such with a few examples of barrier functions and barrier elements. The single initiating event and end consequence been used are:

– IE1: Operational demands require vessel to go near up to the rig

Table 3. BF: Avoid a too short distance to rig.

No.	Barrier elements	PIF (examples)	Comments/ quality
IE1	Vessel owner who ensures back-up plan	SJA Team work MoC	A specific SJA is required
	QC marine operation who intervenes	Communication Competence Culture	–

Table 4. BF: Avoid serious damages from an impact.

No.	Barrier elements	PIF (examples)	Comments/ quality
EC1	Captain who makes an avoidance maneuver	Attention Competence HMI	The rig may cut mooring lines and drive off
	OIM who conducts emergency release of rig chain	Emergency response Design	–

– EC1: Heavy impact with serious structural damages on rig/vessel

Similarly Table 4 shows two barrier elements for the end consequence EC1.

Factors that could effect on the quality and effectiveness of barriers were identified thereafter. The notation Performance Influencing Factors (PIF) was applied to these factors. PIFs were identified for the barrier elements based on judgments in the WS, and further supplied by the project group afterwards. In the same process, comments to quality of the respective barrier elements were stated.

3.1.5 *Step-5 Evaluation of barriers*

Following the barrier assessments, the qualities of existing barriers are evaluated as basis for recommendations. Improvement measures for the existing barrier elements, or supplementary barrier elements were suggested. Barrier elements subject for recommendations were marked in the assessment tables. Measures could be related to the whole barrier function, or to single barrier elements only. The following three criteria were used to assess the quality of the barriers:

1. *Quality:* The extent to which the barrier functions as intended, e.g. contributes in preventing collisions?
2. *Actual use:* To what extent the barrier is actually in use to prevent, e.g. collisions?
3. *Vulnerability/resilience:* To what extent is the barrier function vulnerable to the influence of surroundings? If so, what are possibly the most important factors that influence the barrier function?

The above evaluation criteria are based on previous research (Hollnagel, 2008, Sklet, 2006). The same criteria were used in another relevant study on barriers against ship collisions (Kongsvik et al., 2012). Here the focus was also on barriers against collisions between vessels and offshore installations.

However, the criteria were adapted and simplified to fit offshore service vessels and related barriers against ship collisions.

3.1.6 *Step-6 Reporting and dissemination of results*

The study results were documented in a (restricted) technical report summarizing the most important barriers with recommendations for Statoil. One important result from the study was that of a total of 40 barrier elements that were identified, only five were technical barriers and the rest operational/organizational barriers. This seems to be typical for this kind of marine operations. Thus, when presenting the improvement measures we distinguished between the recommendations given to the technical and the operational/organizational barrier elements.

Following the report, a presentation of main results was prepared for internal dissemination in the company. Following the summary report, main results were presented in a HSE seminar held by Statoil, where leaders from the contracted ship owners participated. Finally, the study results with recommendations were discussed in a dissemination workshop with personnel from Statoil's rig move department.

3.2 *Evaluation of the approach*

The suggested approach involved relevant personnel from the company with its partners through participation in meetings and the WS. SINTEF/MARINTEK facilitated the WS with an interdisciplinary team of researchers. In addition to facilitating the WS, SINTEF/MARINTEK also contributed with knowledge within barrier management and marine systems.

The analysis of historical events and the preparation of STEP diagrams, bow-ties and work sheets were done in forehand. Although the approach as a whole has not been applied earlier, well defined methods were combined to form the whole methodology both during the preparation phase and accomplishment of the WS. A natural part of the process was thus to adjust the approach continuously based on findings and experiences, as well as feedback from the customer throughout the process.

The following describes some of the pros and cons with the applied approach, mostly seen from the facilitator's point of view. This may be a basis for improvements for similar projects in the future.

3.2.1 *Information*

The collected information prior to the barrier evaluation mainly included data documenting accidents and incidents related to rig move operations. An advantage is that most of the incidents in marine operations are reported in Synergi. However, when comparing the two mentioned groups of events (positioning and anchor handling failures), only the anchor handling incidents are typically investigated in depth. This could be due to the more extensive exposure of personnel on deck during anchor handling operations. Still, both categories appear to have major accident potential. Anyway, the different focus might lead to a distorted view of the risk. More information is typically found in investigation reports compared to "simple" Synergi reports. However, the discussions with the operating company and the WS are perceived to compensate for possible distortions and direct focus on the real safety issues.

3.2.2 *Study limitations/definition*

For the current case the definition of actual work processes and activities to cover was rather clear. Reference was made to process diagrams found in governing documents of the operating company. By using this in addition to scope of work descriptions for specific operations, a good overview was obtained. The conditions for defining an appropriate study basis were thus present.

3.2.3 *Methods applied*

As mentioned, bow-tie diagrams were used in the WS to visualize potential accident scenarios in order to identify the safety barriers. A challenge is that the bow-tie method does not visualise the actual sequences of potential accidental events. The existence of accidental sequences, their realism and knowledge to such must therefore to some degree be handled outside the bow-ties. Also the bow-tie approach does not illustrate the importance of the barriers, in terms of whether the barrier is sufficient to stop a developing event or must function together with other barriers. In that respect, the mapping of incidents and events in STEP diagrams was one of the tools for identifying scenarios. Through the STEP visualization, relevant project phases and activities could be viewed against the incidents. Then, it was easier to relate historical data of incidents to possible deficiencies or failure causes of "rig move operations" itself, and thereof, identification of scenarios.

The *top event*, interpreted as "loss of control" lead to the identification of *initial events* and possible *end consequences.* From this stage the bow-tie models functioned more as a tool for identifying failure causes and thus, the barrier elements against accidental sequences. Both preventive and mitigating barriers were highlighted.

Another constrain is that the bow-tie models may grow too large and become disordered. One

reason for this being that the bow-tie methodology in itself seems to lack a clear and consistent definition and limitation of what is a barrier. Therefore, one must constantly focus on what are barriers and what are performance influencing factors. For this purpose clear definitions must be available, and the group discussions need to be somewhat controlled. This is important simply to avoid ending up with "everything" being identified as barriers and a false impression of an extensive defense-in-depth system that is not real.

3.2.4 *Suggested measures—follow-up*

The recommendations resulting from the evaluation will obviously depend on company specific conditions and priorities. Several of the suggested measures are of operational and organisational character. The prevailing situation with significant turnover of experienced staff both within the rig fleet and ship owners *can* lead to lack of knowledge and experience. In particular this may result in inadequate knowledge concerning local conditions and systems at the offshore fields. It is therefore recommended to examine potential effects of such on the risk related to rig move operations (risk handling).

One of the recommended measures for improved safety in rig move operations is to implement greater degree of joint training of the crews on rigs and vessels. This kind of training might be one step to remedy the above mentioned trend.

4 DISCUSSION

4.1 *Implications of results*

The suggested approach encourages involvement from relevant stakeholders in a way that hopefully ensures participation and ownership to the results and recommendations. The quality of safety barriers for each of the scenarios and suggestions for improvements are discussed in relation to the most relevant project phases and activities. Comprehensive descriptions of barriers and their quality will be obtained. Secondly, by following the six-step methodology, a clarification of ownership and knowledge to the existing safety barriers are achieved, both within the oil company and its partners.

4.2 *Further research*

Since there are generally no physical obstacles to prevent a collision between a vessel and a rig, safety during rig move operations relies heavily upon operational and organizational measures. This implies that competence, motivation and training of the personnel involved become paramount. As part of the barrier management, PSA Norway states that performance requirements shall be developed also for operational and organizational barrier elements (PSA, 2013). Further work to increase safety in rig move operations should therefore include development of specific and verifiable competence, training and certification requirements to key personnel involved in the operations.

Joint training of crews on rigs and vessels was pointed out as an improvement measure. Research on state-of-the art within training and how to prepare for more joint training of the crews are therefore highly relevant. Important success criteria for such should be identified in near collaboration with the industry.

Another topic is whether to apply more safety-performance methods during the WS and discussions with the operating company, as supplement to the data-based scenario identification. As commented in the evaluation, the historical data of incidents and events may not reflect the whole risk picture. Positioning failures are less investigated even though they represent major accident potential. Risk based approaches (Øien, 2001) and safety performance based approaches (HSE, 2006, Sklet et al., 2010) could here be a supplement to the barrier and indicator identification.

5 CONCLUSION

A methodology for evaluation of safety barriers against major accidents in rig-move operations has been presented. Important input to the evaluation was requirements, procedures and reports covering relevant incidents and accidents as well as the operational knowledge of the experts involved in workshop discussions.

Clarification of system limits and interpretation of requirements to rig move operations also provided input for identifying and evaluating the barriers present during rig-move operations.

The review of historical incidents and events, along with mapping in STEP diagrams gave a good basis for the scenario identification. However, other approaches may also apply to this step as discussed in the previous section. Additionally, the bow-tie method for scenario analysis was valuable in sense of providing fruitful WS discussions. It also provided a good platform for the barrier evaluations and visualization of the main results.

The work is based on close cooperation between researchers and marine experts from the companies involved in rig-move operations. The work done and the suggested approach are contributions to the continuous work of limiting risk and reducing accidents during these operations. In this respect the suggested approach was a contribution

to their improvement processes. It is the authors believe that the generic approach could be useful for similar projects, or further research.

ACKNOWLEDGEMENTS

The authors also like to acknowledge the support from Statoil marine operations both in terms of contributions in writing the present paper, for the project collaboration, and for providing documentation and facilitating the necessary meetings and workshops.

Performance of skimmers in the Arctic offshore oil spills

M. Naseri & J. Barabady
Department of Engineering and Safety, UiT The Arctic University of Norway, Tromsø, Norway

ABSTRACT: Oil spill removal techniques have been developed as passive barriers to reduce the severity of adverse impacts of oil spills on the environment. Among different oil spill removal methods, combination of skimmers and booms are more preferable environmentally, as they can recover the spilt oil from sea permanently. However, a number of factors such as harsh Arctic climatic conditions, presence of sea ice, remote distances, poor visibility, and less developed infrastructure threaten the overall performance of skimmers. Therefore, identifying such influencing parameters and evaluating their impacts on the overall performance of skimmers is of the utmost importance. In this study, the overall performance of skimmers in the Arctic offshore is discussed from the viewpoints of effectiveness and availability performance. Several operational conditions and their impacts on the availability performance of skimmers and their effectiveness in the Arctic offshore are further reviewed and discussed. Changes in physical and chemical properties of spilt oil and their contribution to the window-of-opportunity for a successful skimming operation are described, taking into account the severe Arctic climatic conditions.

1 INTRODUCTION

The increasing trend of oil and gas activities in the Arctic offshore has raised major concerns about oil spills and their impacts on the Arctic's ecologically sensitive environment. To decrease the severity of such impacts, oil spill clean-up technologies are developed as passive barriers to oil spills. Various techniques are available for removal of offshore oil spills, such as in-situ burning, use of dispersants, and mechanical methods. Oil skimmers are one of the essential categories of mechanical recovery methods that generally are used in combination with containment booms (Fingas 2011, Potter et al. 2012).

There are different types of skimmers that vary in different aspects such as size, working principle, and performance criteria. To plan an oil spill removal operation using mechanical methods, it is essential to estimate the amount of oil that can be recovered by a specific type of skimmer during a given period of time. To determine if a specific skimmer performs as per design, its effectiveness can be evaluated based on three measures stated by the manufacturer (Jensen & Mullin 2003, Schulze 1998):

- *Recovery Efficiency:* the ratio of oil to the recovered mixture, expressed as a per cent;
- *Throughput Efficiency:* the ratio of oil recovered to the encountered oil, expressed as a per cent;
- *Oil Recovery Rate:* the rate at which pure oil is being recovered in barrels per hour (or in cubic meters per hour).

These measures vary based on the type of skimmer type, its characteristics, and are defined for a known range of operational conditions. However, in practice, a skimmer may not recover oil as it is stated by the manufacturer. In other words, the amount of oil that a skimmer can recover with a given period of time depends not only on its working principle, type, size, and performance criteria, but also on a number of operational conditions such as physical and chemical properties of spilt oil, weather conditions, personnel skill, and sea state (Broje & Keller 2006, Broje & Keller 2007, Fingas 2011, Jensen & Mullin 2003, Nordvik 1995). Concept of system effectiveness then may be utilized to evaluate the extent, to which a system meets the planned objectives or the objectives stated by the by the manufacturers (ISO 2005). In this regard, the operational conditions and their impacts on the throughput efficiency, recovery efficiency and oil recovery rate of skimmers are discussed in the context of the *effectiveness of skimmers*.

Availability performance of skimmers is another factor that must be assessed carefully in order to plan the type and the number of required skimmers for a specific oil spill removal operation. Availability can be simply defined as "the item's capability of being used over a period of time" (Stapelberg 2009). In other words, one needs to ensure that skimmers are able to fulfil their function (i.e. skimming of oil from water surface) within a given period of time, and if they fail, they can be restored to their functioning state within a minimum time interval. Moreover, to have a sustain-

able skimming operation, performance of pumps, connections, separation facilities, and storage and transportation systems must be also evaluated and improved accordingly. However, the focus of this study is mainly on the skimmers' performance.

Considering the operational conditions in the Arctic offshore, there are various parameters, which may give rise to the probability of failure of different systems utilized. For example, low Arctic temperatures may increase the failure rate of the systems due to their adverse effects on the material properties such as metals and plastics (Singh 2013). Therefore understanding the key operational conditions and their effects on the various aspects of the performance of skimmers play crucial roles in every skimming operation.

The aim of this paper is to review and discuss the various aspects of the performance of skimmers in the Arctic offshore. The key operational conditions and their effects on the performance of oil skimmers are also reviewed and discussed.

Section 2 describes the main types of skimmers and their working principles. Section 3 is devoted to a general discussion on the skimming operations in the Arctic offshore. Sections 4 and 5, discuss various key operational conditions that can affect the availability performance of skimmers and their effectiveness, respectively. In section 6, the effect of the weathering processes on the skimming operations are discussed from the viewpoint of window-of-opportunity. Conclusions are given in section 7.

2 SKIMMERS

Skimmers are mechanical devices designed to skim the spilt oil from water surface. There are various types of skimmers categories based on different parameters, such as size, working principle, recovery efficiency, oil viscosity range, oil recovery rate, throughput efficiency. Skimmers can operate in either a stationary or a mobile (advancing) mode. Some of them are equipped with storage tanks and water/oil separation facilities, while some other types pump the recovered mixture into external storage and separation facilities (Broje & Keller 2006, Fingas 2011, ITOPF 2012, Jensen & Mullin 2003, NOAA 2010). One of the most efficient ways of using skimmers in open waters is to combine them with containment booms. Booms can contain the oil and increase the thickness of oil slick, so that and the skimmer can skim the oil with a higher recovery rate. A typical configuration of a skimmer combined with containment booms is depicted in Figure 1.

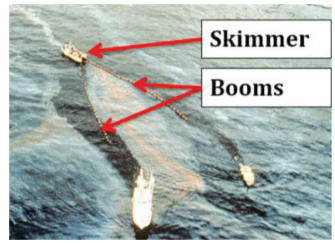

Figure 1. V-configuration of booms combined with a skimmer that is located at the apex of the two booms (Fingas 2011).

Based on their working principles, skimmers can be classified into two main categories: *oleophilic or sorbent surface and non-oleophilic surface skimmers*.

Oleophilic surface skimmers use a surface, to which oil can adhere, and thus be removed from water surface. A wiper blade or a pressure roller then removes the oil from skimmer surface and deposits it into an onboard container. The output mixture of the skimmer may also be directly pumped into storage and separation facilities on a barge. Various types of oleophilic surface skimmers are available based on the process of oil adsorption, including: disk; drum; brush; belt; and rope skimmers.

Non-oleophilic surface skimmers mainly include weir, suction and elevating skimmers. *Weir skimmers* are submerged holding tanks, equipped with a suction pump, recovering oil from water surface based on the gravity difference of oil and water. *Suction or vacuum skimmers* use a vacuum or slight differential pressure to skim the oil from the water surface. In *elevating skimmers*, a paddle belt, wheel or a conveyor belt with ridges is adjusted to the top of the water layer. Oil is then moved up the recovery device into the storage tank (Fingas 2011, Potter et al. 2012, Schulze 1998, Ventikos et al. 2004).

Various skimmers have different performance criteria. Accordingly, selection of the appropriate type of skimmer needs an adequate evaluation of several parameters, such as operational conditions (i.e. wave height, wind and current speed, properties of spilt oil, etc.); effect of such conditions on the effectiveness of skimmers; availability performance of the skimmers under severe climatic conditions; regulations; and requirements defined by the stakeholders.

3 SKIMMING OPERATION IN THE ARCTIC OFFSHORE

To evaluate the overall performance of a skimming operation in the Arctic offshore, at first one must determine how much oil is available to be

skimmed by the skimmer (i.e. oil encounter rate). Spill rate, the degree that oil has spread, containment efficiency of booms, the sweeping area of the skimmer, winds, and characteristics of waves and currents are the main parameters that determine the oil encounter rate (Fingas 2011, ITOPF 2012, Jensen & Mullin 2003). The use of booms improves the oil encounter rate by containing the spilt oil and increasing the thickness of oil slick. Boom efficiency itself is a function of spill rate, weather conditions, currents and waves characteristics (Fingas 2011, Jensen & Mullin 2003, Lee & Kang 1997, Nordvik 1995).

Especially in open waters, due to the fluctuations in the water/oil interface and the working principle of the skimmer itself, some water will be always skimmed together with oil. Accordingly, the output of skimmer will be a mixture of oil/water that must be later separated. Such mixture is then pumped into storage tanks and separation facilities. Separation and storage generally takes place on the barge, especially in the offshore oil spill removal operations. In some cases, the recovered mixture is transported off-site for further separation. Recovered oil and produced wastes are then transported for final disposal, recycle or reuse (Fingas 2011, ITOPF 2012, Jensen & Mullin 2003, Nordvik et al. 1996). These steps are illustrated in Figure 2.

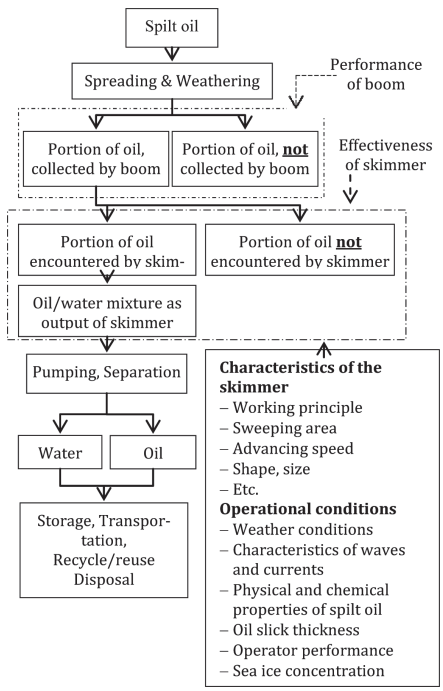

Figure 2. Illustration of offshore oil spill removal process using skimmers combined with booms.

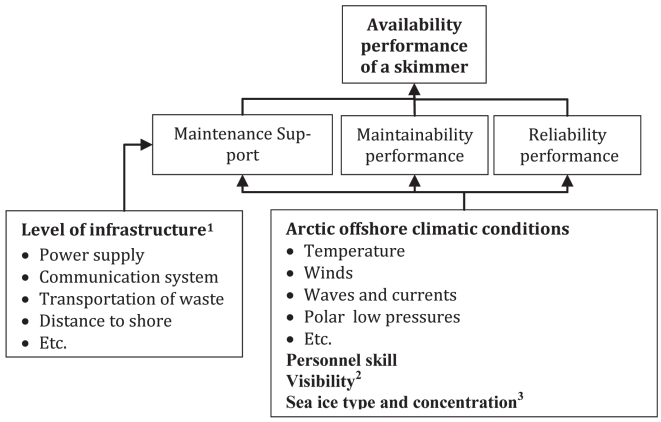
Therefore, to have a sustainable skimming operation, in addition to the performance of skimmers, the overall performance of all the processes of containment by booms, storage, separation, and transportation, must be assessed, as well. The overall performance of the systems can be discussed from two prospective as in the following:



First, the system must be in working state. In other words, it must be able to function as per designed, and if it fails one must ensure that the system can be resorted to the working state within a minimum period of time. These concepts are discussed in the context of availability performance (Barabady et al. 2010, Stapelberg 2009).

Second, while the system is in working state, it must be able to deliver, produce, or recover as per design. For instance, pumps must have the ability to pump the recovered mixture into the separation facilities with a rate determined by the manufacturer. As another example, skimmers must be able to skim the oil from water surface as per designed rate. These concepts are discussed from the viewpoint of system effectiveness.

Although there are a large number of different systems being used in every skimming operation, this study mainly discusses the overall performance of skimmers. Both availability performance of skimmers and their effectiveness are affected by a series of operational conditions such as severe climatic conditions of the Arctic offshore, waves, currents, etc. These sets of conditions must be identified and their effects on the overall performance of skimmers must be assessed accordingly.

4 PARAMETERS THAT AFFECT THE AVAILABILITY PERFORMANCE OF SKIMMERS

To evaluate the availability performance of a skimmer, at first one needs to focus on its elements: *reliability performance, maintainability performance, and maintenance support performance* (Barabady et al. 2010). Reliability of a system is defined as "the probability that a system will perform a specified function within prescribed limits, under given environmental conditions, for a specified time" (Stapelberg 2009). In other words, the failure rate of a skimmer depends on a number of parameters including environmental (operational) conditions. Low ambient temperature, wave height, current speed, sea ice concentration, and wind speed are some examples of operational conditions in the Arctic offshore. Figure 3 depicts some of the operational conditions that may affect the availability performance of the skimmers intended to be used in the Arctic offshore.

Comments: 1- Available waste disposal/recycle/reuse options plays a crucial role in the whole oil spill removal operations
2- Visibility may be limited because of fog, snow storm, rain, and seasonal darkness
3- Sea ice type and concentration may affect the maintenance support performance

Figure 3. Key operational conditions that influence the availability performance of a skimmer in the Arctic offshore.

For instance, plastics and metals develop brittleness and lose their flexibility at low Arctic temperatures (Dutta 1988, Singh 2013). As another example, low Arctic temperature together with waves, currents, and winds increase the viscosity of crude oils drastically through some weathering processes such as emulsification and evaporation (Brandvik & Faksness 2009, Fingas 2011, Fitt-Rasmussen et al. 2012, Nordvik 1995). Pumping of highly viscous oils may lead to mechanical failures in pumps and connections (Fig. 4) (NOAA 2010).

Clogging of skimmers with some pieces of sea ice is another example, which can result in a failure in a skimmer being operated in the Arctic offshore (Schulze 1998, Shum & Borst 1985). Moreover, in low Arctic temperatures, splash of water on skimmers and connections can cause spray icing. The skimmed water may also freeze inside the hoses, connections, separation and storage facilities (Potter et al. 2012).

Maintainability performance is another element of availability performance of a system. When a skimmer fails, the crew must be able to repair the failed component or to provide a new one. The required time to bring the failed component/system back to the operating state is known as *repair time* and is a measure of system maintainability; the lower the repair time, the higher the maintainability performance (Stapelberg 2009). Weather conditions, such as rain, snow, storms, low ambient temperature, etc. are important factors that may increase the repair time and consequently the operation downtime. Performance of the maintenance crew is also a crucial parameter that may affect the repair time and thus maintainability and availability of the skimmer.

Figure 4. Burst hose as a result of excessive pressure from pumping highly viscous oil (NOAA 2010).

To avoid excess downtime, it must be ensured that required resources such as maintenance crew and required spare parts and tools must be available upon request under given conditions and a maintenance policy (Barabady et al. 2010). This is known as maintenance support performance, which is the third element of the availability performance of a system. Harsh climatic conditions of the Arctic offshore, less developed infrastructure in the Arctic regions, and remoteness may cause unpredicted delays in the provision of spare parts, which consequently results in an additional increase in operation downtimes.

Therefore, it is of the utmost importance to determine the conditions under which a skimmer is intended to be used. The effects of such conditions

on various elements of the availability performance of the skimmers must also be evaluated accordingly. Various failure modes of skimmers in severe climatic conditions of the Arctic offshore must be identified and evaluated accordingly. Accordingly, some modifications to the skimmers may need to be done in the design phase. For instance, selection of appropriate materials that are tolerable for extremely low temperatures can significantly increase the reliability performance of the skimmers. In the planning phase, one also needs to evaluate the compatibility of the skimmer with sea ice type and concentration. Adequate heating systems must be implemented to avoid spray ice on the facilities and also to prevent the skimmed water from freezing inside skimmers, pumps, or other facilities utilized in skimming operation.

Required spare parts, tools, and skilled maintenance crew must be available upon request. Maintenance support must be planned taking into account the uncertainties in the prediction of severe weather conditions. Adequate working conditions must be provided for the operators and maintenance crew. For example, they must be equipped with appropriate clothing to withstand the low Arctic temperatures and be able to perform their job.

5 PARAMETERS THAT AFFECT THE EFFECTIVENESS OF SKIMMERS

To evaluate the effectiveness of skimmers, at the first step, one must identify the rate at which oil becomes available to the skimmers (also known as oil encounter rate) (ITOPF 2012). Further, it is crucial to identify how much water will be skimmed together with oil. This determines the basis for further separation, storage, and transportation of the recovered mixture. There are various factors that may affect the oil encounter rate, including: characteristics of waves and currents; sea ice type and concentration, performance of containment booms; characteristics of skimmers (i.e. shape, size, tow speed, operation mode, sweeping area, etc.) (Fig. 2) (Fingas 2011, ITOPF 2012, Schulze 1998).

Some of these parameters make it difficult to achieve the designed efficiency and oil and recovery rate of skimmers in real oil spills (Schulze 1998). For instance, it is quite challenging to simulate the exact characteristics of open-water waves, currents, and winds in tank tests where performance of skimmers is tested by manufacturers. Therefore, it is of the utmost importance to identify the operational conditions, and assess their impacts on the effectiveness of skimmers. This provides a basis to estimate the number and type of required skimmers, booms, and the time that the additional skimmers need to be available on-site. In the following, the key parameters that influence the effectiveness of skimmers are described in more details.

5.1 *Oil slick thickness*

Slick thickness is the most important factor to determine the effectiveness of the skimming operations; the thinner the oil slick, the lower the oil encounter rate (Schulze 1998). The degree that oil spreads on the water surface is highly influenced by winds, waves, and currents. Additionally, oil slick thickness may vary with physical and chemical properties of spilt oil, such as viscosity, density and interfacial tension (Castro et al. 2010, NOAA 2010). Such properties change over time due to the effects of the weathering processes (Fingas 2011, Fritt-Rasmussen et al. 2012, NOAA 2010, Payne & McNabb 1991). Use of containment booms can prevent further spreading of the spilt oil and thus significantly increase its thickness.

5.2 *Oil viscosity*

Various types of hydrocarbon oils have different viscosities. Other factors such as weathering processes can contribute to the changes in viscosity of oil. For instance, viscosity of spilt oil can rise from a few centipoise to more than 160,000 centipoise (cP) due to the effects of weathering processes (Andrade et al. 2013). Based on the various factors such as working principle of skimmers, their size, and shape, an increase in oil viscosity may either increase or decrease the final oil recovery rate (Broje & Keller 2006, Broje & Keller 2007, Fingas 2011, ITOPF 2012). Figure 5 shows oil recovery rate of smooth and grooved drum skimmers with respect to the viscosity of oil. As shown in this figure, different types of smooth and grooved disk skimmers have various trends of oil recovery rate with an increase in oil viscosity.

5.3 *Operator performance*

Human error is an inevitable part of any operation. The influence of human performance becomes crucial in cases where operators directly guide the skimmers through the oil slick. Human performance itself is adversely affected by the severe climatic conditions in the Arctic region. Low ambient temperature, combined with winds can decrease the felt temperature by operators (i.e. wind chill effect) (Bluestein & Quayle 2003, Osczevski & Bluestein 2005). Extremely cold weather may cause some health issues for the operators and thus deteriorate their performance.

Poor visibility due to foggy weather, and seasonal darkness periods in the Arctic offshore are

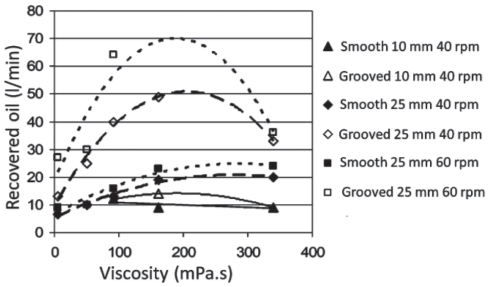


Figure 5. Effect of oil viscosity on the net recovery efficiency of smooth and grooved drum skimmer with different geometrical properties (1 mPa·s = 1 cP) (the viscosities given here, are just some examples to show the various trends of oil recovery rate versus viscosity; the viscosity of weathered oils may be quite larger than these values) (Broje & Keller 2006).

other factors that may reduce the efficiency of human performance. This consequently reduces the efficiency of the skimming operation, as operators need to monitor the spilt oil layer and its probable loss from booms and skimmers.

Therefore, to improve the human performance in skimming operations, adequate clothing is required to provide better working conditions for the operators. Especial cameras and artificial lighting are also required to help the operators to distinguish the spilt oil.

5.4 *Climatic conditions*

Weather conditions may influence the effectiveness of skimmers in various ways. They may alter physical properties of spilt oil through weathering processes. The degree at which the oil spreads on water surface is also a function of climatic conditions, and characteristics of waves and currents.

Winds and waves, in general decrease the effectiveness of skimmers (Fingas 2011, Schulze 1998, Ventikos et al. 2004). This is mainly due to the splash of oil over skimmers, and also because rough waters move the skimmer collection mechanism away from the oil layer on the water surface. However, there are some types of skimmer, such as rope skimmers, whose performance is less affected by waves (Fingas 2011, ITOPF 2012, Potter et al. 2012, Schulze 1998).

Currents also contribute to the effectiveness of skimmers by reducing the oil encounter rate. Fast currents can cause the oil to escape under the collection booms (Al-Majed et al. 2012, Castro et al. 2010, Schulze 1998). Currents may also swamp intakes or cause surface oil to move across the collection element so fast that it cannot be effectively recovered. To have a more efficient skimmer in fast currents, skimmers must be equipped with a collection element, which is able to move with a zero relative velocity to the currents (Schulze 1998).

5.5 *Sea ice concentration*

Performance of skimmers in ice-infested waters depends not only on the weather conditions, waves and currents, but also on the sea ice type and concentration. Sea ice can affect the effectiveness of skimmer in different ways. Ice pieces can clog skimmers their hoses, storage tanks and pumps, especially if there are considerable amount of brush ice (Broje & Keller 2006, Schulze 1998, Shum & Borst 1985).

High concentration of sea ice, on the other hand, may benefit the overall skimming operations by reducing the spreading of spilt oil (Brandvik & Faksness 2009, NOAA 2010, Potter et al. 2012) as spilt oil can be entrapped in pools surrounded by ice. Moreover, presence of ice floes can damp the wave energy and thus benefit the skimmer performance by providing calm water situations (Fritt-Rasmussen et al. 2012, NOAA 2010).

Sea ice also affects both the rate and extent of the changes in the physical and chemical properties of the spilt oil through its effects on the weathering processes (Brandvik & Faksness 2009, Fritt-Rasmussen et al. 2012, Ornitz & Champ 2002). Weathering processes have different rates and extents, depending on sea ice concentration. Among different weathering processes, water uptake by spilt oil (i.e. emulsification) and oil evaporation are the most important ones (Díez et al. 2007). The rate of these processes decreases at high concentrations of sea ice (e.g. 70–90% ice concentration) because oil film is thicker and has a smaller surface area (Brandvik & Faksness 2009, Fritt-Rasmussen et al. 2012, Potter et al. 2012). Both the rate and extent of weathering processes affect the viscosity of spilt oil and thus the response efficiency of the skimmers. Table 1 presents the oil water content of a specific crude oil after 2.5 days in different sea ice conditions. The original crude oil viscosity at 13 °C was about 7 cP. As stated in this table, sea ice only affects the oil water content and viscosity of weathered oil when its concentration is high.

Table 1. Effect of sea ice concentration on the viscosity of a specific crude oil and its water uptake (Brandvik & Faksness 2009).

Sea ice coverage	Oil water content	Dynamic viscosity, cP
Open water	38–41%	4000
30%	38–41%	3500
90%	20%	1500

Therefore, to select skimmers, pumps, connections, etc., one must consider mixed effects of sea ice concentrations and weathering processes on the viscosity of spilt oil, as efficiencies and performance of skimmers and pumps vary based on oil viscosity.

6 WEATHERING PROCESSES AND WINDOW-OF-OPPORTUNITY

Immediately after that an oil spill occurs, a series of transformation processes take place, whereby the physical and chemical properties of spilt oil change. Such processes are known as weathering processes that include for instance evaporation and emulsification. Both the rate and extent of weathering processes mainly depend on the weather conditions, time, and the chemical composition of the spilt oil (Boehm et al. 2008, Díez et al. 2007, Fingas 2011, Nordvik 1995).

Evaporation of lighter components of the spilt oil causes the remaining oil to have a significantly higher viscosity compared to the original spilt oil (Al-Majed et al. 2012, NOAA 2010, Prince et al. 2002). For instance, the results of a field study showed that the viscosity of a 3-day weathered oil increased from 22 cP at 5 °C to about 2000 cP for a light crude oil from the Barents Sea (Fritt-Rasmussen et al. 2012). Additionally, evaporation of the lighter components increases wax content as well as the portion of heavier molecules in the residual oil, resulting in a huge increase in oil pour point (i.e. the temperature where the oil does not flow freely anymore) (Brandvik & Faksness 2009, Potter et al. 2012). An increase in oil pour point may adversely affect the whole skimming operation by reducing the pumping efficiency.

Emulsification (i.e. dispersion of one liquid into another one in the form of small droplets) (Fingas 2011, Nordvik 1995) may occur due to the mixing effect of waves and currents. Viscosity of an emulsified oil increases due to the presence of water droplets in the continuous oil phase (Brandvik & Faksness 2009, Fingas 2011, Ornitz & Champ 2002). Increased oil viscosity due to emulsification can be as high as 500 to 800 times than the original oil (Fingas 2011).

Therefore, considering the spreading of oil and the changes in its physical and chemical properties, one should define a time-frame during which a specific response action (e.g. skimming operation) is viable. Such time-frame is known as window-of-opportunity (Nordvik 1999, Ornitz & Champ 2002). Establishing the appropriate window-of-opportunity depends on the working principles of skimmers and probable changes in the properties of the spilt oil. This should take into account the effect of climatic conditions, waves, currents, etc. on the weathering processes and spreading of oil. Spill rate and duration is another parameter that affects the number of skimmers, booms separation and storage facilities, etc. (Nordvik 1995, Nordvik 1999, Ornitz & Champ 2002, Potter et al. 2012).

One also needs to consider the uncertainties in prediction the climatic conditions in the Arctic offshore. Unpredicted downtimes contribute to extensive changes in the properties of spilt oil through weathering processes. Improving availability performance of skimmers, pumps, connections, and other required facilities greatly reduces the operational downtimes. Additionally, it must be noted that the operational conditions in the Arctic offshore are far different from those in test tanks. Various types of sea ice, storms, high waves, strong currents, snow, rain, etc. are common parameters in open waters while they may not be considered in test tanks. This increases the level of uncertainties in planning the skimming operations.

7 CONCLUSION

To increase the efficiency of an oil spill removal operation, one needs to improve the performance of oil skimmers by ensuring that they are in working state upon request. Furthermore, to increase the clean-up rate, skimmers must have high efficiency and recovery rate. In other words, both the rate and portion of the recovered oil in the oil/water mixture must be as high as practically possible.

High levels of recovery rate and efficiency cannot be achieved without accounting for the effects of operational conditions on both of the availability performance of the skimmers and their effectiveness.

The key operational conditions in the Arctic offshore include severe climatic conditions; seasonal darkness; poor visibility; remoteness; lack of well-developed infrastructure; sea ice; etc.

On the other hand, with regards to the changes in physical and chemical properties of spilt oil over time, the skimming operation must be done within an appropriate time-frame, known as window-of-opportunity. In this regard, failures of the skimmers and other machinery, as well as the uncertainties in the prediction of weather condition must be taken into account accordingly.

To have a sustainable skimming operation, it is vital to assess the performance of all the involved systems and facilities such as pumps, connections, hoses, separation facilities, and storage and transportation systems. Such assessments must be performed taking into account the impacts of operational conditions in the Arctic offshore.

ABSTRACT: The management of safety is marked by strong procedural features and permanent adjustments of social actors to situations. Focusing on these two noticeable aspects of its operational reality, we propose to go hunting for new food for thought: rethinking safety management in the light of the meta-concept of injunction.

In order to understand the nature of safety injunction, we will analyze it through two approaches: a scientific one and a philosophical one. As a mass communication device triggering heteronomy to its receivers, safety injunction appears as a basis for safety management concepts. So one can note that safety injunction is a meta-concept to talk about safety.

But philosophy and sciences do not insist on the same aspects of this meta-concept. Philosophy analysis leads us to think that safety injunction is linked to a model and introduce new elements in it through experience while a scientific point of view is more focused on safety injunction output with some cause-effect pathways dealing with struggles for power at organizational and social scales.

However, as scientific safety injunction analysis also implies normativity and subjects' perceptions issues in its scale tension showing the difficulty to master safety injunction. That is why; one can conclude that safety injunction cannot be separated either from practice or experience. This interesting result not only helps to define safety injunction but is also an important parameter to be considered in the design of an appropriate methodology.

In order to deploy and animate risk prevention measures, the nuclear industry mainly uses injunctions for safety which are practically based on the rise of expectations projected on to a unit from outside (Boussard, Demazière & Milburn 2010). The aim of this article is to define injunction as a meta-concept for safety management, that is to say a concept aiming to provide the firm grounds to a language attempting to talk about scientific concepts while discovering their meaning (Lacour 2005).

First, we will define injunction around safety through a scientific and philosophical approach. Then we will analyze its impacts at a social and organizational level and the consequences lead on safety management in high risk organizations. On the one hand this will lead to notice the interest to consider injunction as a meta-concept for safety management, but, on the other hand, this will underline the necessity not to reify injunction that is to say disregarding the role of its experience in the field provided.

1 WHAT IS SAFETY INJUNCTION?

1.1 *Injunction as a meta-concept for safety*

To master safety, high risk industries follow a general trend of "normalization of social interactions and practices, leading to the bureaucratization of everyday life, a phenomenon long envisioned by Max Weber and regularly reassessed and commented by sociologists" (Bieder & Bourrier 2013). The existence of rules and the integration of these observations into a symbolic universe (in a large sense) allow us to state that we are before the presence of a human fact (Granger 1992).

This human fact can be scientifically cut-up and analyzed to draw its meaning, revealing a structure referring to a "cybernetic" model in which "energetic"[1]

[1]A one-plan model in which organizations receive an input and transform it into an output like a machine (Granger 1992).

organization is regulated at an informational level, in a flow of information through a network. But this scientific approach of the human fact disregards how humans experience toward a safety injunction since it only focuses on its structures.

If safety is an output of an injunction produced by social actors, then injunction would be a meta-concept for safety, thus a concept on which the language of safety relies on to make meaning through experienced actions.

Reducing the safety injunction to a mechanism of cause and effect suppresses the possibility to inquire about what really is at stake: the heteronomous[2] tension that it applies on individuals. For this reason, we will also propose to set up a philosophical scaffold around the organization of this experience with the purpose to understand safety injunction.

1.2 *Safety injunction in philosophy*

Neo-classic philosophy, the historical mainstream of contemporary thinking, reduces individual behaviour and collective functioning to the *homo œconomicus* model, whose vices would lead to the general interest. A classic example is given to us by Adam Smith, who wrote that "it is not from the benevolence of the butcher, the brewer, or the baker, that we expect our dinner, but from the attention they pay to their own interest. We address ourselves, not to their humanity but to their egoism; and we don't talk to them about our needs but always about their advantages" (Smith 1776)[3].

Even if this model is rather closed, loops would exist opening the way to the positivist modernization front started by the Enlightenment (Latour 2012). In this world portrait, injunction would inject in the autonomous and rational individual the necessary elements to perpetuate his or her capacity to make the "right" choices, just as it would inject into society the necessary elements to go on with the course of civilization. Briefly said, injunction would be the meta-concept "opening" and adjusting our understanding of the world along with the knowledge production progress. Injunction as a meta-concept would be hence defined as a heteronomous device at the service of a neo-classic instrumental rationality. Furthermore, the hypothesis of transparency of information inherent to the instrumental rationality ideal is an assumption far away from concrete action, just as the pure and perfect competition principle in economics. As for recruitment, the decision to join a firm is more complex than suggested by classic Supply and Demand Theories. The desirability of a movement is related to a lot of subjective variables. "Whether dissatisfaction with the organization leads to withdrawal depends on whether the participant perceives the "employment contract" as given or as subject to change. Where the contract is viewed as unchangeable, the only options are to "accept" or to "reject". Where the contract can be changed, participation by no means precludes internal conflicts and bargaining" (March & Simon 1993).

1.3 *Safety injunction in sciences*

Injunction, as a meta-concept for safety, looks like mass communication triggering heteronomy on its individual receivers. At a large scale, individuals would introject the content of a message. As a result the content of the message would become their own subjective meaning, making of this message the source of their motives to take any action, instead of looking for those motives in themselves.

At the Oak Ridge National Laboratory in 1947, safety injunction took shape concretely through preventive posters warning the staff of the Manhattan Project of radiation risks.

Figure 1. Radiation risk prevention poster in Oak Ridge (USA).

[2]Heteronomy: when one does not follow its own rules by looking after his reasons to act in external things. Heteronomy is opposed to autonomy.

[3]Tough Adam Smith is not a neo-classic but a classic economist, neo-classic theory is based on his "invisible hand" metaphor.

As the poster suggests, individuals are the particular dispositions of the safety injunction hence their subjectivities are more or less called upon, depending on the practices linked to the injunction. In the case of an order, the compliance of individuals is weaker than it would be through a message diffusing an ISO norm relying on a participatory basis.

In the case of the preventive poster mentioned above and presented below, the staff members are called upon twice. They must learn to be aware of an invisible hazard and develop the proper discipline to work in a radioactive environment at the same time.

2 HOW DOES THE SCIENTIFIC CONCEPT OF INJUNCTION ON SAFETY WORK?

Scientific analysis of injunction on safety as a meta-concept on the field shows a double mechanism: injunction as a flux and instrumentalized injunction, at social and organizational levels respectively.

2.1 *Injunction as a flux*

Injunction on safety comes from the desire to respect our society values such as life, leisure or work. As a consequence, individuals want to stick to moral (to put it in a nutshell: value aggregation) as those values are important to them. When it comes to action, social actors expect a form of ethics (an applicable moral) from each other that suits social values. Not only the social actors find normal or acceptable a practice that matches their ethics but they also expect others to behave according to the same ethics.

Injunction as a flux is a support that transports permeable expectancies that appear for action. Injunction on safety as a support diffuses expectancies though a network crossing society. There is no determined reaction due to injunction diffusion.

Expectancies that feed the flux come from all kind of human and non-human network-actors. They have no determined origin. As Egyptian mosquitoes, hardly definable targets that "forge links and arouse chain reactions" (Callon 2006), injunction as a flux does not structure society but crosses it, transmitting what it brings.

The example of the Oak Ridge Laboratory poster on which an operator pays his respects to a radioactive source in a zone with a "Radiation, Danger, Keep away" sign illustrated with two sentences "Radiation need to be feared … but it must command your respect", directly shows injunction as a flux. Indeed, "Radiation need to be feared" is a general message. One must be afraid of radiations as they have an impact on health. One should not brave the danger as it could be interpreted as an insult to life keeping.

2.2 *Instrumentalized injunction*

In organizations, applying injunction as a flux implies a contextualization of it in order to reach a goal. For instance, to be authorized to produce for the nuclear industry. The decision-maker selects in the flux the closest expectancies toward the actual action processes.

When organizations seek for some particular elements, injunction is applied as a medium to get it. In other words, injunction is instrumentalized to fulfil objectives. In an analysis based on the actor-network theory, organizations involve their stakeholders by using points and arguments referring to economics or social depending on those actors position toward organizational goals. As one can see "it is clear […] that stakeholders mobilization thus their concrete implication in the action plan goes through a problematization phase to build a sense to action that can be accepted by all" (El Abboubi & Cornet 2010). This is precisely in this step that organizations can associate stakeholders which can be quite hostile at first glance. In this move, organizations absorb their position in the action plan which was their initial goal. Then, they can submit workers mass to legitimate policies. Instrumentalized injunction has been derived from the flux to serve action for the firm sake.

In the risk prevention campaign of Oak Ridge, the intended effect is the modification of operators' behaviours facing a risk through a visual support. Operators are encouraged to discipline and to command respect as one can note with the character attitude. Indeed, he placed his cap on his chest, as soldiers does to show respect toward important people.

3 INJUNCTION ON SAFETY AND NORMATIVITY

Uniformisation of perceptions and practices due to injunction on safety and safety apprehension as a social value lead to constraint individuals. How can we understand this normativity?

3.1 *Safety in society*

Scientific analysis of injunction on safety as a meta-concept implies at the same time a reduction of normativity to an object and an objective representation of normativity. For centuries the sovereign power had the privilege to "make one die or let one live" (Foucault 1976), but in the Classic Age, the sampling mechanisms needed to defend and

maintain the sovereign tend not to be the major form of power exercise anymore. Sampling mechanisms become "a piece among others that has incentive functions, that reinforce, control, supervise, arise and organize the forces they submit: a power made to produce forces, to increase and order them instead of preventing, breaking or destroying them" (Foucault 1976).

This "biopouvoir" as modern power over life supposes universalist human well-being conceptions and the end of some practices judged as unethical by stakeholders such as dose management (high exposure to radiations during short periods of time coupled with high team turn-over to maintain or increase nuclear industry production). At the same time, sensibilisation to rules work is encouraged by decision-makers considering that it is important to protect workers by making them aware of their workplace risks.

Injunction on safety tend to neutralize spoilers that justify its existence rather than to ensure the appropriate behaviour according to its standards. The use of injunction in safety management tends to stamp out and alleviate life roughness.

But this way to proceed fails to recognise the interpretation and normativity reorganizations in other normativity signification systems. Indeed, no one can really anticipate operators' receptions and feelings towards the poster campaign and its collective effect. But, this recognition defines our relationship with phenomenological experience that is to say how facts appear to me in my own subjectivity. We will now analyze injunction on safety psychological effects.

3.2 *Injunction on safety psychological effects*

Injunction on safety is not made to equilibrate the communication relationship between transmitter and receiver. It demonstrates power relationships and a social order in which we are all involved. This struggle for power and influence on the receiver is part of injunction authoritarian character. Not following the path is a potential threat toward the social group cohesion.

So, "statistically, threat becomes a moderator variable instead of a direct predictor: an interaction model" (Feldman 2013). "In brief, this model posits that the underlying basis of authoritarianism is the conflict between the values of autonomy/independence and social conformity. People who are predisposed toward authoritarianism value social conformity over autonomy because they believe that strongly held and rigorously enforced norms and values are needed to maintain social cohesion and order" (Ibid).

Radiation threats brought by the "Radiation need to be feared … but it must command your respect" poster remind the reader of the rule. This imperative is due to the serious aspect of the subject. Beyond danger and risk, operators have to be professionals in their attitude by wearing equipment and being focused. As a consequence, the operator designed on the poster does not smile but appears as responsible.

This example illustrates that what is invested in our safety apprehension "is less reality than a particular knowledge of what is real […]. The knowledge contained in the mythical concept[4] is a confuse knowledge, formed by smooth and unlimited associations. This open character of the concept must be stressed; this is absolutely not an abstract and purified essence; it is a non-formed, instable, unclear condensation which unit and coherence particularly depend of its function. In this sense, one can say that the fundamental character of the mythical concept is to be appropriated" (Barthes 1957). The real image of safety is deleted for injunction on safety meta-concept which is a system in a system dealing with sense and interpretation.

Making the operators aware of danger by using fear mechanisms is an incentive to make them actors of their own safety by protecting themselves. But such a safety management also triggers numerous tensions in organizations as the whole is not the sum of its parts.

4 INJUNCTION ON SAFETY META-CONCEPT IMPACT ON SAFETY MANAGEMENT IN ORGANIZATIONS

4.1 *A scale tension between autonomy and heteronomy*

A philosophical approach of injunction on safety shows a tension between subjects' autonomy and injunction heteronomy process. Organizational objectives and values were "initially […] imposed on the individual by the exercise of authority over him; but to a large extent the values gradually become 'internalized' and are incorporated into the psychology and attitudes of the individual participant." (Simon 2000). So, an operator in a zone exposed to radiations that has incorporated Oak Ridge poster to his representations can possibly prevent a colleague from staying too long in front of a radioactive source were sieverts are released in important quantity.

However, when the receiver catches injunction on safety message, he internalizes to his representations and practices. The heteronomous mechanism addressed to individuals does not

[4]Or meta-concept in the present article.

impede individuals from overcoming what is being imposed. Although "events are directed from outside to inside" (Horkheimer 1936), one can also note that the internalized message of injunction changes due to its appropriation by social actors.

As injunction on safety message tends to be diffused at large scale, the number of people with their own and changing representations is multiplied. This individual process becomes a collective fact influencing collective representations guiding the decision-maker. In other words, injunction as a flux and instrumentalized injunction can be combined. As a matter of fact, one can see that safety expertise power is balanced with the necessity for workers mass to integrate safety in their job. While expertise is stuck to support functions, its general knowledge is aspired, modified and adapted to the core functions of the firm, in operators' job descriptions. Furthermore, to be funded, expertise is also led to develop its knowledge depending on operational needs.

4.2 *The injunction mastering impossibility*

The slip of injunction on safety message creates some unexpected and unpredictable effects for the decision-maker. Indeed, validating a risk prevention campaign does not mean that the decision-maker masters all operators' reactions (indifference, careful reading or contempt).

When action representation is linear and derived from a decision coming from a reflexion, it is implied that there is intentionality in the process. But, one cannot control all his acts (Reason 1990) or all his communication effects (Adorno 1954).

In the perspective of a Reflexion-Decision-Action model, a decision-maker that cannot obtain the result he wanted would have taken the wrong decision. Combining injunction on safety as a meta-concept and a philosophical approach allows us to imagine that a decision-maker would gather information on factors that could influence his action result, such as federation or separation of social groups or an informal leader's sensitivity.

Decision-maker's goal would be to limit the gap between his result and what was expected. Decision would not be good or bad. What would be at stake would be its normal appearance to the largest number of people who might be concerned by it (Alter 2009).

The risk prevention poster lets the operator act in the most suitable way for him by delegating to him his risk evaluation. While fixing a normative horizon, injunction let the operator determine what to do and what adjustments are necessary in his practice. In the end, the decision-maker has to believe in his influence skills but also in operators' work.

5 INJUNCTION AS A META-CONCEPT TO UNDERSTAND SAFETY?

Understanding injunction on safety meta-concept inscription in safety management has led us to consider it with a scientific analysis but also to balance it with a philosophical approach.

Injunction on safety meta-concept, as a concept to provide basis to a language aiming to talk about scientific concepts by finding their signification (Lacour 2005), is quite interesting as we can formulate and give a sense to human facts. The notion of meta-concept gives order to a conceptual system so it is reflexive.

However, capturing injunction on safety with a meta-concept reifies it and conducts to a paradox: the loss of its reference. Injunction on safety is also an experience-based element, it is a phenomenological manifestation.

Injunction on safety is the meta-concept through which one can understand safety in action and its management. But it is also by its prism that we crystallize expectancies toward our existence.

Concerning methological issues, one should first analyze empirically injunction on safety by observing actors possibly submitted to injunction in their experience before reshaping the meta-concept.

6 CONCLUSION

Injunction on safety allows us a glimpse on operational safety by its apprehension as a meta-concept. But it also makes underlying and structuring safety logics appear under the condition to be kept in experience field too.

Using IRIDM & VTA to support the risk management of the research reactor Maria

M. Borysiewicz, K. Kowal & S. Potempski
National Centre for Nuclear Research (NCBJ), Otwock-Świerk, Poland

ABSTRACT: The aim of this article is to present how to integrate safety, security and economic issues in the risk management process of the nuclear reactors based on operating experience of the research reactor Maria, operated by National Centre for Nuclear Research (NCBJ). According to the recommendation of International Atomic Energy Agency (IAEA) the risk management of nuclear facilities should be performed by usage of the Integrated Risk Informed Decision Making (IRIDM) methodology. In this work the IRIDM approach has been improved by application of the Value Tree Analysis methods in order to support decision making process on the reactor fuel conversion.

1 INTRODUCTION

The relationship between the main stakeholders of the nuclear industry is similar all over the world. Especially, there is always a regulatory body established to enforce the nuclear law and to control if that law is obeyed by the facility operators in order to ensure appropriate level of safety for the people. If non-compliance with the regulations is demonstrated the regulatory body applies appropriate sanctions against the operator, including cancelation of the license for nuclear activity. Therefore the decision making on nuclear installations should be performed in balanced and comprehensive manner that brings transparency and auditability of that process. Then the regulatory body is able to verify how the implementation of particular decision would affect the risk associated with the facility operation (IAEA 2001).

Until now, the commonly applied approach to the decision-making on nuclear facilities was based on Deterministic Safety Assessment (DSA), where a set of rules and requirements has been defined in order to ensure a high level of safety. This was done by applying the defense in depth principles and adequate criteria for safety margins (IAEA 2009).

Nowadays, the standard approach is based on combining the insights from both the DSA and Probabilistic Safety Assessment (PSA). The PSA provides estimation of the probability and consequences of all accident scenarios possibly leading to the core melt and radiological releases (IAEA 2010).

However, the decision making on nuclear facilities require much more inputs than only the DSA and PSA insights. Beyond the safety goals there are also financial indicators, organizational aspects, security systems, social doubts etc. The consideration of such a wide range of issues is a complex multi-attribute process. In order to meet this challenge it is recommended to implement the model of Integrated Risk Informed Decision Making (IRIDM) developed by International Atomic Energy Agency (IAEA) and United States Nuclear Regulatory Commission (U.S. NRC) (IAEA 2010, US NRC 2009).

IRIDM is a process where a number of qualitatively different inputs, corresponding to different types of risk, are jointly taken into account in the decision making. Relative importance of the IRIDM inputs depend upon the decision to be made and should be weighted quantitatively. The weights assigning, however, is quite subjective and bases mainly on the engineering judgment. This is the main disadvantage of that process which can be improved by application of the Value Tree Analysis (VTA) methods as it was described in this article.

The aim of this work is to present the possibility of practical implementation of IRDM and VTA in the decision making process on fuel conversion of the research reactor Maria. The conversion means giving up of High Enriched Uranium fuel (HEU) containing 36% of U-235 and replacing it with Low Enriched Uranium fuel (LEU) with only 19.7% U-235. The decision on the fuel conversion was dictated by the security reasons with accordance to the Global Threat Reduction Initiative (GTRI) recommendations. However, since the decision has been made, it became necessary to determine how to perform this process in an optimal manner. Basic criterion was to maintain the previous operating parameters of the reactor while meeting all safety requirements after the conversion (Borysiewicz et al. 2013).

2 THE IRIDM APPROACH

According to the basic framework of the Integrated Risk Informed Decision Making process, consideration must be given to the requirements of both regulatory body and operator in order to draft a preliminary set of options that potentially could solve the analyzed issue (Fig. 1).

However, to make the final decision and choose one from the preliminary set of options, specified inputs must be established, namely the standards and good practices, operating experience, deterministic and probabilistic considerations, organizational and security systems and other factors such as research or economic insights. Relative importance of each element depends upon the decision to be made and should be weighted qualitatively. This process leads to evaluation and reduction the preliminary set of options. Finally one of them should be chosen, implemented and monitored. Moreover, if the performance of just implemented decision is not satisfactory corrective actions should be undertaken and the list of option needs to be redefined (IAEA 2011).

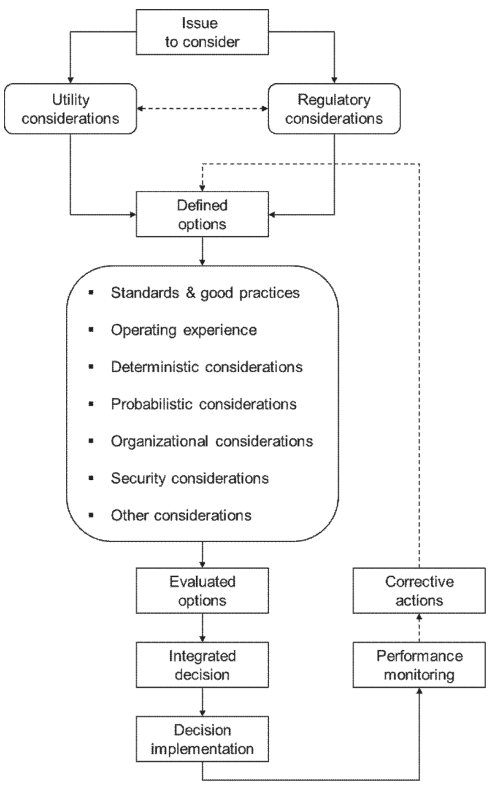

Figure 1. Organizational framework and key elements of the IRIDM process (IAEA 2011).

3 THE VTA METHODS

While the IRIDM framework itself seems to be very well organized its practical implementation may be difficult due to the problem with the inputs prioritization. It is because the weights assignment process is quite subjective, based on engineering judgment and dependent on particular issue being addressed. This is the main disadvantage of that process which can be improved by application of the Value Tree Analysis (VTA) methods (Borysiewicz, in press).

The VTA approach can be applied in the IRIDM inputs prioritization and the decision options evaluation by usage of several techniques. The most important ones are the following:

- SMART (Simple Multi-Attribute Rating Technique)—a two-way process: first the worst attribute is selected, then the others are scored by the ratio related to it (Edwards 1977).
- SWING (SMART with Swing Weighting)—the process starts from choosing the most important attribute then the other weights are defined by making relations to it (Edwards et al. 1994).
- SMARTER (SMART Exploiting Ranks)—first, ranking of attributes is made, then the weight W_i is determined for i-th input according to the formula (Edwards et al. 1994):

$$W_i = \frac{1}{N}\sum_{n=i}^{N}\frac{1}{n}, \tag{1}$$

where N number of attributes.

- Value function *val* that has the following properties: if $x \sim y$ then $val(x) = val(y)$, i.e. if two attributes give the same impact then their weights are equal, and if $x < y$ then $val(x) < val(y)$, i.e. if attribute x is less important than y then the value of y is higher than the one of x. The key point here is the shape of the function: linearity reflects simple mapping of the parameter values, while, for example, a concave exponential curve means that any changes in the lower region of the parameter space are more important than the changes of the same size in the upper region; for a convex function the situation is opposite.
- AHP (Analytical Hierarchy Process)—a pairwise comparison matrix A is first created, where a_{ij} is the estimated ratio of weights W_i and W_j, i.e. $a_{ij} = W_i/W_j$ (consequently $a_{ji} = 1/a_{ij}$). If the matrix is consistent (i.e. $a_{ij} = a_{ik} \cdot a_{kj}$) then the method can be reduced to simple weighting. However, this is not always true because the judgements of decision makers does not have to be consistent. For consistent matrix it can be seen that all eigenvalues are ones, except the highest one equals to N, i.e. $AW = NW$. For inconsistent case one wants

to be in accordance with the consistent one—therefore, the vector of weights is found as an eigenvector of maximal eigenvalue: $AW = \lambda_{max} W$ (Saaty 1980, Saaty 1980, Salo et al. 1992).

4 CONVERSION OF MARIA REACTOR CORE

The research reactor Maria is a multi-purpose, high flux, pool type reactor, moderated with water and beryllium with graphite reflector and pressurized channels consisting of 22 concentric six-tube assemblies of fuel elements. The active length of the fuel assemblies is 1 m. The reactor was designed with a high degree of application flexibility and it has been using the high enriched uranium fuel (UO_2-Al alloy) with aluminium cladding since it began the operation. The fuel channels are situated in a matrix containing beryllium blocks and enclosed in a lateral reflector made of graphite blocks in aluminium cans. Maria is equipped with vertical channels for irradiation of target materials, a rabbit system for short irradiations and 7 horizontal neutron beam channels. The nominal reactor's power is 30 MW_t while thermal neutron flux density is $4.0 \cdot 10^{14}$ n/cm^2 s. This reactor is suitable for testing of fuel and materials for the nuclear power engineering, neutron studies (radiography, activation analysis and transmutation doping) and for the scientific research in the field of condensed matter physics. However, its main application is the radioisotopes production. Maria is one of the few reactors able to produce Mo-99 which is essential for the diagnosis of cancer in medical centers all over the world.

Ensuring the continuity of molybdenum supplies excludes the long term shutdown of the reactor and requires to maintain approximately the same thermal power after the core conversion. Therefore, since the conversion leads to decrease of U-235 enrichment the volume of fuel itself has to be increased. For that reason the present fuel channel configuration—that bases on 6 concentric tubes (Fig. 2)—will be replaced with a new one, which consists of 5 tubes but with different diameters and thicknesses.

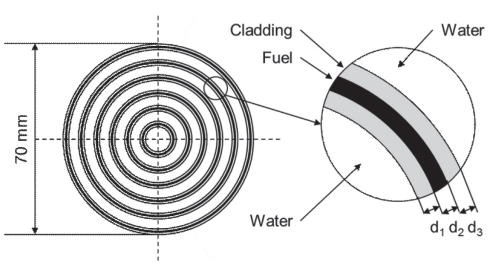

Figure 2. Horizontal cross section of the high enriched uranium fuel element of the research reactor Maria (Borysiewicz 2013).

The thermal hydraulic analysis showed that the cladding temperature for both types of fuel elements are almost the same, e.g. maximum cladding temperature on the internal surface of the tube is 425 K and 426 K for LEU and HEU respectively. However, the maximum heat flux on the external wall of the fuel tube is 2,61 MW/m^2 and 2,04 MW/m^2 for the LEU and HEU fuel respectively. Moreover, the data acquired from the performed measurements point out that the coefficient of hydraulic resistance for LEU fuel elements exceeds by around 30% the resistance coefficient for the HEU fuel (Dorosz et al. 2009).

The required coolant flow rate through the new LEU fuel channel is at least 30 m^3/h while in the HEU fuel it is equal to 25 m^3/h. This difference implies the necessity of increasing the mass flow in the new channels up to 120% of previous nominal flow. However, since the existing infrastructure is not sufficient to increase the mass flow, this process requires replacement of the primary cooling channel pumps. It complicates the whole procedure and makes the fuel conversion much more expensive than it was expected. Therefore, the implementation of IRIDM has been proposed in order to determine the best solution of the problem.

5 IRIDM & VTA METHODS APPLICATION

The IRIDM process has been organized in a form of facilitated workshop with representatives of the regulatory body (National Atomic Energy Agency) and utility (National Centre for Nuclear Research). The stakeholders considered a possibility of initiating the partial conversion process before modernization of the pump system. In such a case the whole procedure would be performed in a gradual way and the most burned-up HEU fuel would be unloaded first. Thus, the following options has been defined:

- Option 1: Partial core conversion before change of the pumps (with higher flow rate) without any additional criteria.
- Option 2: Partial core conversion before change of the pumps (with higher flow rate) but with additional criteria.
- Option 3: Rejection of partial core conversion before change of the pumps

When the consensus has been obtained that the results from DSA, PSA and economic analysis will have the highest impact on the final decision, the ranking of these inputs was performed. The highest priority was given to the deterministic

aspects (max. clad temp., max. heat flux and the hydraulic resistance). This choice comes from the fact that during the operation of reactor, it is necessary to maintain safety limits and requirements of defense in depth methodology. Probabilistic aspects in general should stay in conjunction with the deterministic results. Moreover, the proposed changes in the reactor fuel and the cooling system requirements could have an impact on the safety systems reliability, core damage probability, and radioactivity releases frequency. Thus, the Probabilistic Aspects (PSA) has been assigned at the medium weight. Obviously, the economic issues have a lower importance when compared to the safety aspects. However, the decisions on nuclear facilities are often somehow motivated by economics. In this case it was considered what are the costs of core conversion, what part of these costs may be covered from own resources, and what is the payback period of the investments.

When a compromise was reached in the process of prioritisation of the IRIDM inputs, a relative importance of *i*-th of them was expressed by W_i. Within each input the appropriate attributes were identified and the prioritisation of these attributes was made by assigning weight A_{ij} for each *j*-th attribute of the *i*-th input. For assessment of both W_i and A_{ij} the SMART method could be used. However, this approach involves a degree of subjectivity due to the necessity of the relative weights determination. In order to remedy these difficult the SMARTER method, reduced only to the rank order criteria, was applied.

Then, the s_{ikj} factor describing how the implementation of option *k*-th would affect the attribute *j* of input *i*, was calculated by usage of the concave function $val(\alpha)$, with α given by the following formula:

$$\alpha_x = \frac{x^a - x^f}{x^a - x^i}, \tag{2}$$

where x^a is the acceptable value of the parameter x which cannot be exceeded because of the official regulations, safety goals or internal policy of the operator. Variables x^i and x^f describe the initial (actual) value of the parameter and its final value (after implementation of *k*-th decision option), respectively.

Once when the values of all attributes for each input were determined, there was a possibility to calculate a final score *S* for each option via the formula:

$$S_k = \sum_i W_i \sum_i A_{ij} \cdot s_{ijk}. \tag{3}$$

In such a way a value tree diagram was constructed which is shown in Figure 3.

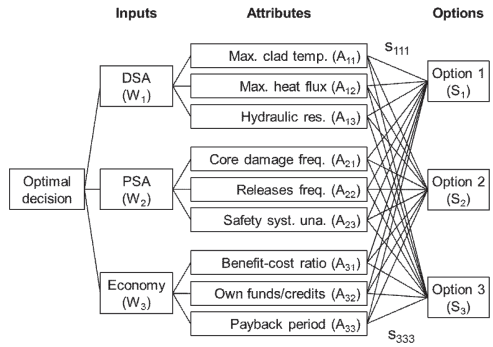

Figure 3. The value tree diagram developed to support decision-making on Maria reactor fuel conversion.

6 RESULTS AND CONCLUSIONS

Option 1 (conversion before change of the pumps without additional criteria) has been recognised as the best solution from the economic point of view. The radioisotopes can be produced continuously and no additional changes in the organizational system are needed. However, this option has an overall negative impact on both DSA and PSA. This is because the primary cooling channel pumps are not efficient enough to provide appropriate mass flow after conversion. Consequently the safety margins cannot be maintained. Therefore, this option was rejected due to the highest negative impact on the safety aspects.

Option 3 (replacement of the pumps before fuel conversion) was the best solution in terms of safety. However, this option assumes a long-term shutdown of the reactor. This generates significant economic losses associated with interruption of the isotopes production. Additionally, it needs some changes in the organizational system at the time of the replacement process. These are the main reasons why option 3 was rejected as well.

Option 2 (partial core conversion before change of the pumps starting from the most burned-up HEU fuel) has been chosen even though that there is slightly negative impact on both safety and economic aspects. Moreover, the additional requirements meaning criteria on power limits have been proposed. Due to the power limits slightly lower production of isotopes is expected. However, the economic losses are not as high as in option 3. Thus the option 2 is much safer than the first one and still very attractive economically. This is also the most balanced solution in the terms of risk distribution between different IRIDM inputs.

ABSTRACT: This paper focuses on the incorporation of not only equipment ageing but also maintenance and surveillance management programs explicitly into PSA (Probabilistic Safety Assessment) models and data. Thus, a new kind of Ageing PSA (APSA) modelling is proposed to be considered in the framework of the Risk Informed Decision Making according to R.G. 1.174 (USNRC, 2011) published by the US Nuclear Regulatory Commission (US NRC), which is intended to be used to support risk-informed decisions on the improvement of asset management programs and technical specification requirements of critical equipment of Nuclear Power Plants (NPP). An example of application is also presented in this paper that centers on critical equipment of a Nuclear Power Plant in order to evaluate the risk impact of considering the combined effect of equipment ageing and maintenance and surveillance management programs along design life operation of NPP (equipment design life management) and beyond along the extended period after receiving approval eventually for the NPP long term operation (equipment extended life management). The impact of several alternatives proposed is also discussed.

1 INTRODUCTION

One of the main challenges for 2020 horizon is to maintain fission technologies competitiveness by research and technological development necessary in order to allow a safe Long Term Operation (LTO) of the nuclear reactors in operation nowadays (GEN II and III).

For example, in 2020 most of the Nuclear Power Plants (NPP) in Spain, which are Light Water Reactor (LWR) type, would be operating for around 40 years, which is the plant design life, and they will face the Periodic Safety Review (PSR) to obtain, eventually, life extension approval for the LTO from the regulatory body (usually 10 years).

During the design life, licensee of NPP must perform the necessary activities for ageing management of Structures, Systems and Components (SSCs), which include considering measures for monitoring, control and mitigation of the mechanisms of physical ageing of SSC adopting the necessary maintenance and surveillance activities in scope of asset management programs.

An important part of PSR involves the evaluation of risk impact of how current equipment ageing and maintenance and testing programs management would jeopardize NPPs safety for the extended period and, eventually, adoption of an ageing management plan and reformulation of current operational requirements such as surveillance requirements.

Probabilistic Safety Analysis (PSA) is an essential tool for assessing, maintaining, assuring and improving the nuclear power plant safety. It is an essential and efficient tool for evaluation of risk impact in the framework of the Risk Informed Decision Making according to R.G. 1.174 (USNRC, 2011), which is adopted by many regulatory bodies. Often, neither the effect of equipment ageing nor maintenance and testing programs are explicitly considered in PSA models and data, e.g. adoption of constant failure rate instead of age dependent failure rates.

This approach of consideration of the ageing contribution will most likely result in underestimation of component unavailability and cost, particularly for an aged one. So, unavailability and cost models integrating component ageing and the effects of test and maintenance activities must be considered. However, the current standard PSA do not adequately address important ageing issues, which could have a significant impact on the conclusions drawn from PSA studies and applications where plants are operated at an advanced age or long term. In addition, all NPP have a large variety of testing, maintenance and inspection programs,

which can mitigate more or less the effects of ageing, it is obvious that the extent to which the components are susceptible to ageing degradation differ considerably. The ageing effects can be seen at the component level, at system level or at the plant level.

Nowadays, different approaches to develop Ageing PSA (APSA) are being proposed to account for equipment ageing (Nitoi et al., 2010; Volkanovsky, 2012). In these approaches, different methods for prioritization of the NPP components considering the implication of their ageing on the core damage frequency of the NPP for different test and replacement intervals are shown.

In this respect, lessons learned on ageing assessment, modeling and management of SSC of NPP in the framework of international programs and initiatives (GALL, IGALL, ….) should be fully integrated within advanced PSA models and data (USNRC, 1991; USNRC, 1991; IAEA, 2013).

In this paper, a new kind of Ageing PSA (APSA) modelling is proposed, which incorporates the impact of not only equipment ageing but also maintenance and testing management explicitly into PSA models and data, which is intended to be considered in the framework of the Risk Informed Decision Making according to R.G. 1.174 (USNRC, 2011) published by the US Nuclear Regulatory Commission (US NRC). This APSA could be used to support risk-informed decisions on the improvement of asset management programs and technical specification requirements of critical equipment of Nuclear Power Plants (NPP).

An example of application is presented that focusses on critical equipment of a Nuclear Power Plant in order to evaluate the risk impact of considering the combined effect of equipment ageing and several alternatives of maintenance and surveillance management programs along design life operation of NPP (equipment design life management) and beyond along the extended period after receiving approval eventually for the NPP long term operation (equipment extended life management).

2 MODELING RISK IMPACT OF EQUIPMENT AGEING CONSIDERING MAINTENANCE AND TESTING

2.1 *Failure rate model. Ageing and imperfect maintenance incorporation*

Traditionally, in the Probabilistic Safety Analysis (PSA) in Nuclear Power Plants (NPPs) it is assumed a constant standby failure rate, $\lambda(t) = \lambda_0$.

In this paper, reliability models at component level are reformulated using age-dependent models to estimate the effect of ageing on the unavailability PSA models.

Different models of age-dependent reliability have been proposed in the literature (Kim et al., 1992; Kim et al., 1994). The selection of the most adequate model depends on aspects such as component type, its operation mode, the ageing mechanisms considered or maintenance and surveillance testing programs performed.

Effective Preventive Maintenance (PM) programs are essential for ensuring acceptable operational reliability throughout the service life of nuclear power plants. The role of PM are to detect and mitigate component degradation managing of ageing effects.

To ensure effectiveness of PM programs, they should be periodically reviewed and modified on the basis of operating experience. Consequently, the age of the component is a function of maintenance activities performed during its design life and its effectiveness. So, it is necessary to include the effect of maintenance on the age of the component and on its reliability.

An imperfect maintenance model has been adopted with the aim of include the effect of maintenance on the age of the component. Maintenance imperfect models consider that each activity improves the state of the component by some degree, depending on its effectiveness.

Among the different models of imperfect maintenance that exists, in this paper the "Age Proportional Reduction" (PAR) model, proposed by (Martorell et al., 1999) is adopted. In the PAR approach, each maintenance activity is assumed to reduce proportionally the age gained from the previous maintenance. In this model, the effect of the maintenance is introduced by using an effectiveness parameter, ε, ranged in the interval [0, 1]. If ε = 0, the previous models simply reduces to an "as bad as old" situation, while if ε = 1 they are reduced to an "as good as new" situation.

Assuming that the time during which a component is out of service as a result of maintenance activity is negligible compared to the time between two consecutive maintenance, age of the component in the period m+1 between m and m +1-maintenance activity is given by:

$$w_{m+1}(t) = w_m^+ + (t - t_m) \tag{1}$$

where w_m^+ is the age of the component immediately after the maintenance number m, t is the chronological time and t_m is the time which the m-activity maintenance is performed. Using the expression of w_m^+, formulated in the reference (Martorell et al., 1999) age of the component in the period m+1 between m and m+1-maintenance activity is given by:

$$w_{m+1}(t) = t - \varepsilon \cdot t_m \tag{2}$$

In the literature, different ageing models are considered being the most common used the linear model, Exponential, Weibull… (Vesely et al., 1990).

In this paper, the linear ageing failure has been considered being this the simplest dependent model. This model assumes that the failure rate has a linear increase with the time, which can be expressed as (USNRC, 1992):

$$\lambda(w(t)) = \lambda_0 + \alpha \cdot w(t) \tag{3}$$

where α represents the linear ageing factor and $w(t)$ is the component's age which depends on the preventive maintenance applied to the component and $w(t)$ is the age of the component at a chronological time. So, the linear failure rate model shown above assumes that the total failure rate is the sum of random failures, λ_0, and ageing, $\alpha \cdot w(t)$.

Using Equation 1, Equation 2 and Equation 3, induced failure rate after m-maintenance is obtained as follow:

$$\lambda_{m+1}(t) = \lambda_0 + \alpha \cdot (t - \varepsilon \cdot t_m) \tag{4}$$

Then, it is formulated the average failure rate, λ^*_{m+1}, over the period between two consecutive maintenance activities, m and m+1 using the following expression:

$$\lambda^*_{m+1} = \frac{1}{t_{m+1} - t_m} \int_{t_m}^{t_{m+1}} \lambda_{m+1}(t) dt \tag{5}$$

Equation 5 represents an average failure rate between two consecutive maintenance activities which includes the effect of the ageing using a linear model, and the effect of the preventive maintenance performed on the component modelled as a PAR model.

2.2 *Risk impact*

PSA is a method of estimating mathematically the likelihood and consequences of potential accidents at Nuclear Power Plants (NPPs). The major advantage of PSA is the possibility of in-depth qualitative and quantitative analysis of NPP actual configuration with definition of factors characterizing of contribution to the general risk of reactor core damage.

The evaluation of ageing performed using PSA applications can allow to evaluate the component ageing impact to the unavailability of the safety systems, to show an increasing of core damage frequency due to the ageing of safety important components and structures, and to propose optimal test and preventive maintenance intervals. It should be noted that the core damage frequency could increase significantly due to the ageing degradation of components (Vesely et al., 1990).

In order to characterize the risk impact of component ageing and service wear effects, it is necessary to characterize the age dependent nature of the change in plant risk to incorporate into PSA models the degradation of the components due to ageing and the maintenance and surveillance program.

RG 1.174 (USNRC, 2011) establishes two risk metrics for evaluating the risk impact of whatever change to the licensing basis (Martorell et al., 2014), which are herein adapted to address the risk impact of equipment ageing.

Using a level 1 PSA, the required risk metrics for the evaluation of ageing are the annual average baseline CDF before ageing (named herein CDF_b) and the change in the annual average baseline CDF due to equipment ageing, which can be formulated as follows:

$$\Delta CDF = CDF_a - CDF_b \tag{6}$$

where CDF_b and CDF_a are the CDF before (b) and after (a) considering the ageing effect, respectively.

3 EVALUATION OF RISK IMPACT OF AGEING

In this paper, the three steps based approach for the evaluation of risk impact of ageing addressing identification, treatment and analysis of uncertainties in an integrated manner is adopted as proposed in Ref. (Martorell et al., 2014). The approach proposed is based on the use of the Ageing PSA and consist of: 1) modeling of risk impact including identification of ageing and other uncertainty sources, 2) assessment of risk impact including uncertainty treatment and 3) analysis of risk impact including importance and uncertainty analysis. The approach is coherent with the general principles of risk-informed decision-making framework.

What concerns risk modeling, it uses the APSA modeling introduced in section 2 and emphasizing the identification of not only the usually addressed sources of uncertainty linked to PSA models and data but also the sources of model and parameter uncertainties associated with the assumptions in maintenance and testing modeling. Random and parametric uncertainties are built into the structure of the PSA model itself. It is this aspect of uncertainty that gives PSA the probabilistic part of its name. They are typically characterized by establishing probability distributions on the parameter values. However, there may be different options or alternatives on how the models should be formulated. Examples include approach to modeling

human performance, common-cause failures, ageing, maintenance effectiveness, etc.

Risk assessment is proposed by formulating the usual risk metrics for analyzing Surveillance Requirement changes in the literature, as introduced in section 2.3. It is proposed treatment of model and parameter uncertainties based on traditional sensitivity studies and uncertainty assessment respectively, the latter based of the probabilistic approach for uncertainty formulation and propagation by standard Monte Carlo Sampling (MCS) technique.

Risk analysis is based on the well-established comparison of the assessment of risk impact of the change including treatment of uncertainties with acceptance guidelines. Thus, the numerical acceptance guidelines are given in RG 1.174 in terms of regions defined in the space of values $\{CDF_b, \Delta CDF\}$ where the results of the impact on risk are placed (see RG 1.174 (USNRC, 2011) for a more detailed description of such regions). The decision on the acceptability of the change must be based on a full understanding of the contributors to the PSA based results and the impacts of the uncertainties, both those that are explicitly accounted for in the results and those that are not. Therefore, the different regions of the acceptance guidelines introduced in RG 1.174 require different depths of analysis. Thus, when the results {CDF, ΔCDF} obtained are well away from the criteria boundaries, any concerns about the impact of a potential bias caused by the uncertainty tends to be a lesser concern. However, when the result of anyone is close to the boundary, then the appropriate representation of the uncertainty could make the difference between being above or below the boundary. In addition, it is proposed also the use of both traditional importance measures and uncertainty importance measures (sensitivity analysis) in order to analyze respectively how basic events and parameter uncertainties influence the risk impact of the change proposed and its uncertainty. The former helps to identify the main risk contributors and eventually the chance for adopting compensatory measures in order to the make NPP ageing acceptable. Uncertainty importance measures help to identify which of uncertain parameters are most significant contributors to risk impact uncertainty and eventually the need of limiting the impact of the effect of particular uncertainties.

4 APPLICATION CASE

4.1 *Problem description*

This section presents a simple example of application that focusses on analyzing the influence of considering the effect of ageing of a single critical component of a NPP depending on several maintenance and surveillance programs alternatives along the operational NPP design life (equipment design life management) and beyond along the extended period for the NPP long term operation (equipment extended life management).

In this work, a Motor-Operated Valve (MOV) of the Auxiliary Feed Water System (AFWS) has been selected based on several arguments. First, the basic event representing MOV "fails to remain open" is one of the most important contributors to the CDF based on the standard PSA available. Second, equipment aging, preventive maintenance and surveillance requirements are meaningful for this MOV. This basic event is modelled as a standby-related failure. This valve is normally open and its function is to control the flow from AFWS until Steam Generators on the secondary of a typical Pressurized Water Reactor (PWR) NPP.

4.2 *Risk modelling and data*

A level 1 standard PSA at power considering internal events only is available, i.e. allowing obtaining the CDF as risk metric. The level 1 PSA used has been developed at component level, so that, the level of detail is appropriate to support the analysis of equipment ageing addressing maintenance and testing. Consequently, there is a need of refining the level 1 PSA modeling only to address equipment ageing, i.e. to obtain the APSA, by replacing the standard failure rates and equipment unreliability models by the new ones proposed in section 2.

For sake of simplicity in the problem formulation and discussion of results, only the MOV of the AFWS is considered in order to formulate the APSA for this simple example of application. Table 1 shows data used for modelling the MOV basic event into the level 1 APSA, including description of parameters and corresponding constant value or probability distribution function (pdf). In the same way as in the standard PSA, all variables except motor-operated failure rate have been considered constant, i.e. mean values have been used. MOV failure rate has been modeled as a random variable assuming a Gamma probability distribution.

In Table 1, the value of the linear ageing factor (α) has been obtained from a generic data base, which is known as TIRGALEX (Levi et al., 1998). TIRGALEX considers that the value of α in the case of motor-operated valves is equal to $4.11 \cdot 10^{-11}$ h^{-2}. Furthermore, the value of Test interval (T) is taken from current Surveillance Requirements in Technical Specifications, which impose an operational test of this MOV at least

Table 1. Reliability, maintenance and surveillance data of basic event.

Parameter	Description	Parameter type	Parameter/value
λ_0 (h^{-1})	Motor operated valves initial failure rate	Random variable	Gamma ($4.45 \cdot 10^{-08}$, 0.5, $11 \cdot 10^{06}$)
T (h)	Test interval	Constant	13140
α (h^{-2})	Ageing factor	Constant	$4.11 \cdot 10^{-10}$
M (h)	Maintenance interval	Constant	4320
ε	Maintenance effectiveness	Constant	0.8
L_D (yr)	Remain design life period	Constant	10
L_E (yr)	Life extension period	Constant	10

every plant shutdown for refuelling. In addition, time-directed preventive maintenance, with periodicity M and corresponding effectiveness ε, given in Table 1 is based on current practice at NPP.

As it has been mentioned in the introduction, in 2020 most of the Nuclear Power Plants (NPPs) in Spain would be operating for around 40 years, which is the plant design life, and they will face the Periodic Safety Review (PSR) to obtain, eventually, life extension approval for the LTO from the regulatory body. So, in this paper, two points of time are considered: a) remaining design life period (L_D), i.e. 10 years, and b) life extension period (L_E), i.e. 10 more years after the remaining design life.

4.3 *Assessment of risk impact*

In this section, the CDF has been assessed using the APSA modelling developed from the standard PSA modeling and data available and with the additional data in Table 1, as described in the previous section. The conditional values have been derived as usual, e.g. as proposed in (Martorell et al., 2014), using now the APSA. In addition, the values of CDF_b and ΔCDF have been obtained using Equation 6 as proposed in section 2.3.

Tables 2 and 3 show the results for the current surveillance and maintenance policies as compared to several sensitivity analyses. In particular, Table 3 summarizes the results of a number of simulations performed in order to evaluate the risk impact of equipment ageing and testing and maintenance for the design life operation under current maintenance and testing policies (Case 1) and for the design life operation and the LTO of the NPP under alternative maintenance and/or testing policies (Case 2 to 5). Table 2 provides de CDF_b which is common for all cases.

4.4 *Analysis of risk impact*

In this section, risk assessment results are compared against acceptance guidelines in RG 1.174.

Table 2. Results of CFD_b for all cases (CDF with no ageing, current CDF).

Study (L_D;L_E;M;ε;T)	CDF_1 ($year^{-1}$)		
	Mean	5% perc.	95% perc.
Base case (10;0; 4320; 0.5; 4616)	1.03E-05	3.06E-06	2.43E-05

Couples of values {CDF_b. ΔCDF} are used to evaluate the risk impact of equipment ageing under current (Case 1) and alternative (Case 2 to 5) maintenance and testing policies. According to RG 1.174, the appropriate numerical measures to use in the comparison of the PSA results to the acceptance guidelines are mean values. Those mean values refer to the means of the probability distributions that result from the propagation of the uncertainties on the input parameters and those model uncertainties explicitly represented in the model (middle point for each couple in Figs. 1 and 2).

In this paper, two different contexts are studied. The first one corresponds to design life management (Case 1 vs 2), see results in Figure 1, and the second one focuses on a possible NPP life extension for LTO (Case 3 against 4 and 5), i.e. extended life management, see Figure 2. These contexts are explained in detail in the next sext subsections and the numerical results are shown in the Tables 2 and 3.

4.4.1 *Design life management period*

A key aspect of NPP life management in a RIDM context is to evaluate the risk impact of existing maintenance and testing programs in managing aging of systems, structures and components. The effectiveness of existing maintenance and testing practices are herein evaluated, using the proposed methodology, in terms of the risk impact of equipment ageing because of the implementation of such practices.

Table 3. Results of CFD_a and ΔCDF for each case (ageing scenario and different maintenance and testing periods).

Study (L_D;L_E;M;ε;T)	CDF_1 (year^{-1})			ΔCDF (year^{-1})		
	Mean	5% perc.	95% perc.	Mean	5% perc.	95% perc.
Case 1 (10;0;4320;0.8;4616)	1.03E-05	3.46E-06	2.43E-05	1.04E-06	4.75E-07	2.66E-06
Case 2 (10;0;2160;0.8;4616)	1.01E-05	3.70E-06	2.32E-05	8.56E-07	7.14E-07	1.61E-06
Case 3 (10;10;2160;0.8;4616)	1.05E-05	3.57E-06	2.47E-05	1.26E-06	5.89E-07	3.12E-06
Case 4 (10;10;720;0.8;4616)	1.02E-05	3.67E-06	2.33E-05	9.56E-07	6.87E-07	1.71E-06
Case 5 (10;10;2160;0.8;2160)	1.00E-05	3.38E-06	2.38E-05	7.57E-07	3.98E-07	2.25E-06

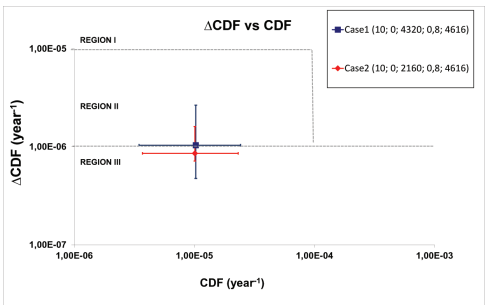

Figure 1. Couples {CDF_b. ΔCDF} of the Case1 and 2 in the context of life management considering (L_D;L_E;M;ε;T).

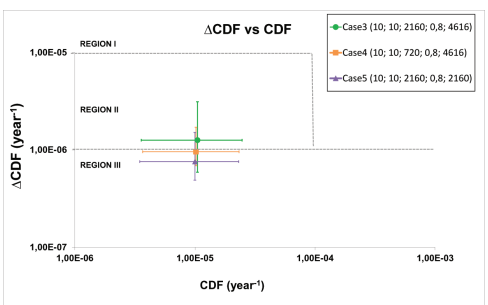

Figure 2. Couples {CDFb. ΔCDF} of the Case 3 to 5 in the context of life extension management considering (L_D;L_E;M;ε;T).

In this context, two cases have been considered, which are summarized in Figure 1. First, in Case 1, CDF_a has been calculated at the end of the design life (10 years from now) considering current maintenance and testing programs, where preventive maintenance interval equals to 4320 hours. Thus, the objective of this case is to determine the ΔCDF at the end of the design life for the current life management of this particular MOV. In Figure 1, one can realize couple {CDF_b, ΔCDF} is placed in the Region II according to RG 1.174. In this region, as established in this Regulatory Guide, improvements should be proposed in order to move the couple from this region to Region III. Therefore, it seems appropriate to implement some kind of compensatory measure for ageing management. Thus, Case 2 is considered that focuses on analysing the effect of the maintenance interval on the risk level. Consequently, the maintenance interval, M, is reduced to be 2160 hours. By repeating the calculation of the same couple for the new maintenance interval, keeping the other parameters at the same values, one can observe in Figure 1 that the new point representing Case 2 confirm that the change in the maintenance interval during its remaining design life period moves it to Region III.

4.4.2 *Extend life management period*

An important part of a PSR close to the end of the design life of the NPP should involve the evaluation of risk impact of how current equipment ageing and maintenance and testing program would jeopardize NPPs safety for the extended period. Eventually, if compensatory measures are necessary to managing ageing in an appropriate way, it should include also assessment of the effectiveness of managing equipment ageing by adopting alternative maintenance management programs and/or reformulation of current operational requirements such as surveillance requirements for the extended life period.

Case 3 to 5 have been formulated to show simple examples of the evaluations of the risk impact of MOV ageing along the extended life period under different maintenance and testing strategies. The results are represented in Figure 2. Thus, Case 3 considers the improved design life management of the MOV (Case 2) remains the same for the extended life period. For Case 3, the point {CDF_b, ΔCDF} moves to Region II again, which means that some kind of compensatory measure for ageing management would be welcome for the extended life. Two

alternatives have been considered in order to manage the ageing of the component. First alternative (Case 4) consists of a change in the preventive maintenance interval for the extended life period, which is reduced to be 720 hours from the previous 2160 hours for the design life period. Second alternative (Case 5) consist of a change in the surveillance test interval for the extended life period, which is reduced to be 2160 hours from the original 4616 hours for the design life period. Both compensatory measures move the result couple from Region II to Region III.

5 CONCLUDING REMARKS

Most NPP in Spain, which are Light Water Reactor (LWR) type, would be operating for around 40 years in approximately ten years from now, which is the plant design life, and they will face the Periodic Safety Review to obtain, eventually, life extension approval for the LTO from the regulatory body (usually for 10 more years). This PSR will require specific requirements related to evaluation of ageing, maintenance and surveillance programs for not only the design life but also for the extended life.

This paper presents new kind of Ageing PSA (APSA) modelling to be considered in the framework of the Risk Informed Decision Making according to R.G. 1.174, which is intended to be used to support risk-informed decisions on the effectiveness of asset management programs and technical specification requirements of critical equipment of Nuclear Power Plants (NPP). This APSA can help in performing the Periodic Safety Review to support risk-informed decisions required to obtain approval from the regulatory body for continuing NPP operation. This APSA incorporates not only equipment ageing but also maintenance and surveillance testing requirements explicitly into APSA models and data as compared to previous APSA.

The results obtained from the different example of application cases developed show how the risk impact of ageing depends on not only ageing of critical equipment but also on maintenance and testing practices. This way, the APSA allows addressing explicitly the role of compensatory measures in terms of improved maintenance and surveillance requirements programs in satisfying safety criteria as imposed by current NPP regulation.

The CDF evaluation has been developed using age-dependent reliability, availability and risk models and data, which allows obtaining results that are more realistic. The results are analysed in the framework of risk-informed decision-making established in RG 1.174.

Finally, this paper presents a preliminary study in which only one critical component has been considered into the APSA. Future work should consider at least all critical components and use plant-specific ageing data in order to obtain plant-specific robust results.

Warsaw Railway Institute, Warsaw, Poland

ABSTRACT: Radio-communication as a transmission media for the railway control command systems has to ensure appropriate safety and reliability. Lowering transmission safety and reliability cause whole system safety lowering. European Train Control System (ETCS) which is a modern control command systems is currently being installed on many railway lines in Europe and in many countries outside Europe. ETCS can be installed in two basic configurations—ETCS level 1. and ETCS level 2. ETCS level 2 use railway mobile radio-communication (GSM-R) as a basic transmission media for transmission of the Movement Authorities which define limits for safety movements of the trains (ETCS). Therefore RAMS of ETCS and of the GSM-R are crucial for safety of the railway transportation. However RAMS requirements for ETCS are defined (UIS 1998) while RAMS requirements for GSM-R are practically not defined. Transposing ETCS RAMS requirements to GSM-R is possible only partly.

As a result we are facing necessity to define GSM-R RAMS requirements which will be taken into account during ETCS installation and commissioning. This article analyse associated challenges taking into account implementation possibilities as well as their influence on construction and exploitation of the GSM-R layers. Article includes also proposed solutions to be taken into account during installation and exploitation which are seen as appropriate by authors.

1 INTRODUCTION

GSM-R digital networks are used by many European and non-European railway infrastructure managers and corresponding railway undertaking. The underlying concept of the International Railway Association UIC (French abbreviation *Union Internationale des Chemins de fer*) was to ensure uniform European communication system based on the results of the collective dedicated project named EIRENE (*European Integrated Railway radio Enhanced Network*) (International 2006, UIC 1998). Implementation of the GSM-R communication system ensures calculable financial results for railway transport as a whole transport system (Pawlik 2007). Railway lines capacity is growing, border disruptions between railway systems of the neighbouring countries is lowering—additional traction units and additional tracks for shunting disappear, necessity of the different drives and different equipment in traction units is strongly minimised and as a result time needed to pass borders is limited significantly (Sameni 2012). Border disruptions starts to be comparable with other transport media. Additionally railway undertaking gain unified transmission media which can be used e.g. for transport monitoring or failures quick detection.

GSM-R is a mobile digital cellular phone system which is based on public GSM however offers wider range of functionalities. Its infrastructure namely transmission antennas are situated along the railway lines. In some cases GSM-R is crucial for the railway traffic control command solutions. Precisely the *European Rail Traffic Management System* (ERTMS) comprising:

- *European Train Control System* (ETCS) which is a modern control command systems ensuring transmission and collection of the crucial data relating to the train running like running speed, position, running mode, etc.,
- *Global System for Mobile Communication—Rail* (GSM-R) which is as a basic transmission media for ETCS in one of its basic configurations named ETCS level 2 passing Movement Authorities which define limits for safe movements of the trains.

superior significantly vitality of the GSM-R as a safe transmission provider (Pawlik 2010).

Trains due to extremely big masses (up to over 3 000 tones) and relatively high speeds (up to over 200 km/h) gain high kinetic energy having at the same time adhesive coefficient about eight times lower than road vehicles. As a result braking distance for trains are long and each accident appearing inconsiderable may cause catastrophic consequences (Pawlik 2010). This is why railway movements are regulated by signalling systems ensuring meeting following safety related functionalities:

- keeping safe distances between trains running on the tracks between stations—train spacing management,
- preventing setting conflicting train routs for the trains running in to and out from the stations—train routing management,
- locking of the mobile elements of the switches for entire train in correct positions—preventing derailments caused by switch movements under trains,
- protection of the level crossings constituting by the roads and railway lines one level—ensuring automatic level crossing protection as well as putting appropriate signs on the rail and road side,
- enabling safe incorporation of additional trains from the branches, sidings, industrial tracks etc. without creating disturbances—train movement start-up procedures.

Pointed functionalities require trackside as well as on-board (mobile) equipment which should be analysed separately. This article is focusing on the GSM-R trackside safety challenges taking into account applicable specific conditions.

2 STATE OF THE ART ARCHITECTURE AND FUNCTIONALITIES

Presently all ERTMS considerations related to both ETCS level 1 and ETCS level 2 assume independency of ETCS and GSM-R. It can be seen not only in technical document but even in legal resolutions of the European Community up to independent verifications of conformity with European requirements.

The safety of the ETCS system is defined in (UIS 1998) by respective level (SIL4 as defined in EN 50 129). Safety of the GSM-R system is not defined by documents. The same situation take place for all RAMS requirements. As a result it is not possible to verify directly whether transmission is adequate from the safety point of view or require undertaking special additional means by enhancing reliability and availability (Pawlik 2013). Whereas safety is a must, high reliability and availability are very important as means supporting safety and not directly by themselves. Therefore reliability and availability have to be analysed also from the operational and economical point of view (Anderson 2013). Such analyse requires understanding of the architecture, functionalities and data transmission principles.

2.1 *GSM-R architecture*

Depending on the railway line GSM-R ensures voice and/or data transmission using cellular digital mobile system. BTS base stations along the railway lines as well as architecture of the connectivity are function dependent—transmission safety, reliability, availability—voice, data transmission. As a result locations of the BTS base stations as well as connectivity principle have to be determined line by line taking into account class and purpose of the line, required capacity and required safety measures (Pawlik 2007).

GSM-R is based on phase 2 of the public GSM, including both GSM basic functions and GSM 2+ additional services (broadcasting, group calls, GPRS, priority calls).

2.2 *GSM-R basic functionalities—voice*

GSM-R offers for the railway infrastructure managers and railway undertakings following services and functionalities:

- VBS (*Voice Broadcast Service*)—voice information is transposed to many predefined users which cannot answer. Predefined groups can be modified automatically depending on time or manually in emergency,
- VGCS (*Voice Group Call Service*)—voice information is transposed bi-directionally with many predefined users which can answer. Every user can activate and dis-activate its own participation in information exchange. Teleconference ends on initiator request or system dispatcher or by barren time limit which is predefined on SIM card,
- eMLPP (*enhanced Multi-Level Precedence and Preemption*)—priority is given to limited number of users ensuring quick voice information exchange in emergency situations. Call setting time for priority calls has to be below 2 seconds including disconnecting of the on-going calls (International 2006),
- FA (*Functional Addressing*)—numbers are given to railway employees based on their operational functions instead of using terminal numbers Operational functional numbers are given by

local leading station or by dispatcher dedicated authorised to define, change and delete numbers linked to certain terminals,
- LDA (*Location Dependent Addressing*)—voice communication with railway employees fulfilling certain operational functions which is changing in relation to train localisation or dedicated calling area. Location is mainly defined by cellular identity however to ensure better location dependent addressing additional information can be used as on-board localisation systems, trackside information e.g. from ETCS balises or other fixed installation,
- GPRS (*General Packet Radio Service*)—is intended for ETCS track-train transmission of vital data in at large stations and density areas,
- eREC (*enhanced Railway Emergency Call*)—emergency calls for train drivers, dispatchers and other dedicated crucial personnel in critical situations which require suspend of the operation in certain area or undertaking other action. Railway Emergency Call for trains must be delivered to all train drivers and all respective dispatchers.

2.3 *GSM-R additional functionalities—data*

GSM-R also ensures data exchange for:

- track-train data communication which to ensures correct functioning of the control command and signalling systems. For instance for ETCS to ensure safe communication between Radio block Centre and on-board main vital computing equipment,
- transmission of informative text messages as well as text messages which require driver confirmation. Lack of confirmation automatically causes train braking,
- transmission of data in other applications for railway operation e.g. supervision of train movements to support logistic chains and networks, collection of trackside and on-board diagnostic data to lower maintenance costs and for passengers e.g. ensuring accessibility of time schedules and connections of the trains, weather predictions, possibly internet based on package GPRS or EDGE transmission,
- fax data transmission.
- Both track-train data for control command and text messages can be send point-point as well as using broadcasting functionality.

As all other telecommunication systems GSM-R has to ensure data transmission in predefined time and predefined error rate. Both must be adequate to required high safety and high reliability in the railway environment. This is crucial for infrastructure managers and railway undertaking as it influences directly safety and fluid traffic flow.

3 GSM-R SAFETY

3.1 *GSM-R safety related transmission*

Increasing safety is ensured by using for GSM-R frequency band other than for public GSM. Railway dedicated GSM-R works in the band 876–880 MHz (uplink) and 921–925 MHz (downlink), while public GSM works in the band 890–915 MHz and 935–960 MHz ensuring safe band independency. Additional increase of data transmission reliability is ensured by appropriate radio coverage along railway lines which depend on train speeds. For line speeds below 220 km/h (train speeds below line speed) radio coverage has to be equal or higher than –95 dBm. For line speeds over 280 km/h (train speeds below line speed) radio coverage has to be equal or higher than −92 dBm. Radio coverage for lines with only voice transmission is lowered by 3 dB. Lines should be covered with those radio coverage with probability equal or higher than 95% on each 100 meters of the railway line, while handover between neighbouring cellular areas should be achieved in normal conditions not less than 99,5%.

Additional important parameter which shows GSM-R operating correctness is the Quality of Service (QoS) which is composed by probability of the incorrect connections, data transmission delays, limited jiter and predefined failure rates (European 2005).

3.2 *GSM-R safety related architecture*

Telecommunication safety is a set of procedures and processes which ensure high availability and reliability due to appropriate system structure namely by redundancies and fail-safe transmission backbone. GSM-R architecture must be designed in a way ensuring minimising operational disruptions in case of failures of one or many elements. Serious damage (disaster) of the GSM-R means interruption of service on entire network which last longer than predefined maximal recovery time. That requires procedures and processes ensuring *Disaster Recovery.* Those processes and procedures together with resetting of the applications, data, equipment and transmission compose overall plan ensuring continues operation. Such plan is based on scenarios which assume failures of the components. Base on scenarios bottlenecks in safe system operation are being find and can be mitigated (Siergiejczyk 2012). Most common and popular way to enhance safety, reliability and availability is adding redundancies both in relation to data and in relation to equipment which can be multiplied base on different principles e.g. n+1, 1+1, 1:n (Siergiejczyk 2013). Operation

of such elements can assume hot or cold reserve. Redundancy may affect:

– whole system,
– some subsystems e.g. BSS, NSS, OMC,
– some elements e.g. MSC, HLR, VLR,
– some components e.g. processing boards known as internal redundancy.

Recovery time depend on configuration and complexity of the network. For GSM-R it always below four hours, however building new NSS may need even some months.

UIC documents (International 2006, International 2006, UIC 1998) suggest doubling radio coverage for lines equipped with ETCS level 2 by doubling BTS base stations (collocated or alternated) and appropriate construction of the BSS (redundant BSC base stations controllers which are also connected to different MSCs). More redundancies mean higher system cost and to some extend lower disturbances of operation however switching times have to be taken into account.

Redundancy is also important in fixed transmission systems. Using self-recovering structures SDH, ensuring double optical cables constitute important elements influencing GSM-R safety and reliability. It is described in details by 'L. Pushparatnam—T. Taylor GSM-R Implementation and Procurement Guide 15.03.2009 Paris' (Pushpartnam 2009) which as an example in point 6.6.3.5 states *'For information and only as an example, here below we are presenting as a return of experience in the case of an operational network—the availability* figures *for 2008, kindly offered by ProRail:*

Overall network availability: 99, 97%
Dispatcher systems availability: 99, 91%
GSM-R for ETCS network availability: 99,999%

According this document safety of the GSM-R cannot be defined by SIL4 as definition of 'critical failure' depends on line (long, short, high speed, suburban dens traffic).

Document UIC ERTMS Users Group dated 30/09/98 „ERTMS/ETCS RAMS Requirements Specification Chapter 2—RAM" (UIC 1998) ETCS hardware availability under certain conditions was calculated on the level of A = 0,99985. Italian railways (RFI) assumed for ERTMS availability calculations for high speed network the same availability for ETCS and GSM-R (together with trackside transmission):

$$A_{ERTMS} = A_{ETCS} \cap \cdot A_{GSMR} \quad (1)$$

As a result un-accessibility of the GSM-R in a year is about 79 minutes. In theoretical calculations (Ding 2010), assuming certain availability of the GSM-R subsystems (NSS, BSS, transmission system (optical cables and SDH equipment) and different configurations received un-accessibility times are:

– for single equipment (NSS, BSS) availability 99,962386% un-accessibility time 198 min/year,
– doubled equipment (NSS, BSS) availability 99,999945% un-accessibility time 0,29 min/year.

Base on this calculations it has to be assumed that un-accessibility 79 min/year cannot be reached with single GSM-R equipment (NSS and BSS).

It has to be pointed in recapitulation that direct data regarding availability and un-accessibility of the GSM-R are not available. 'Annex A to the Commission Decision dated 25 January 2012 on the technical specification for interoperability relating to the control-command and signalling subsystems of the trans-European rail system (2012/88/UE)' specification defining reliability and availability requirements has status 'reserved' which shows that European Commission see the need for such requirements but it is still not available.

4 PRESENT GSM-R SAFETY ASSURANCE

In the 'GSM-R Implementation and Procurement Guide' (Pushparatnam 2009) chapter 6.5.3.2 points that However, several of the railways of the Member States, as well as the UIC Safety Committee have stated that the GSM-R system itself does not possess any safety requirements. The basis of this assertion is as follows:

– telecommunications services are used to support safety-related railway applications. However, safety is assured by means of applications external to the telecommunications bearer, or by means of operational procedures. Telecommunications are simply used as a non-safety-related bearer service;
– in order to ensure adequate safety of those applications which use telecommunications services, the telecommunications systems themselves have certain dependability requirements (in terms of reliability, availability and maintainability) but no specific safety requirements as such;
– the GSM-R system is no exception to this rule. It has no specific safety requirements and need not therefore be associated with a specific Safety Integrity Level (SIL);
– certification will however be required for certain GSM-R system elements. For example:
– compliance with ETSI norms, assurance of transmission and frequency aspects, health and safety of individual persons, etc;
– certification of railway-specific elements such as EMC, interoperable functions, ability to be used in a railway environment and supplementary national functions. Certification requirements

are likely to be identified either by European Norms (CENELEC, CEN) or by UIC rules (UIC leaflet 751-4 etc).

5 NEW PROPOSED GSM-R SAFETY ASSURANCE

We do not agree with some of the above arguments. Ascertain putting practically equal sign between requirements for public GSM and railway dedicated GSM-R is not acceptable due to vital role of GSM-R in the ERTMS system. GSM-R system has to ensure:

- transmission of safety related data for ETCS namely movement authorities defining speed and distance limitations which can be used by trains for safe movements,
- vital generating and vital receiving railway emergency calls REC,
- redundant architecture as suggested in UIC documents (International 2006, UIC 1998, Pawlik 2007) (double radio coverage, double NSS). This principle is used for GSM-R In contradiction public GSM networks do not have such suggestions and public operator using 100% redundant network is hard to find.

In the 'GSM-R Implementation and Procurement Guide' (Pushparatnam 2009) chapter 6.5.3.3 states 'In order to interpret the assertion that no safety requirements are to be placed upon GSM-R, it is important for each railway to identify exactly which applications are being referred to. In particular:

- there are many applications external to GSM-R (e.g. ETCS) which will make use of GSM-R as a bearer service;
- there are also several applications internal to GSM-R (e.g. railway emergency calls, driver-controller calls, DSD messages) which are provided by the GSM-R telecommunications service and which use a GSM network as a radio bearer.'

Therefore it is understandable why there are no safety requirements for GSM-R and at the same time puts obligation to keep above mentioned radio coverage level in relation to line speed ensuring probability equal or higher than 95% on each 100 meters of the railway line. It can be expressed by following notation:

$$L_z = \sum_{i=1}^{n} lz \leq 5\ m \tag{2}$$

where:

Lz—sum of the length of the sections with reduced radio coverage,

l_z—length of the i-ted section with reduced radio coverage.

Length of the "radio hole" in GSM-R which can cause transmission errors for ETCS is 5 m.[1]

Time (T)during which radio-modem is in the "radio hole" depends on the length of the hole (lz) *and from speed of the traction unit* (v).

$$T = \frac{lz}{v} \tag{3}$$

As an example time when radio-modem is in a hole when train is moving with the speed of 250 km/h and the hole length is 5 m is 72 ms (in a hole of 01 m—1,44 ms)[2].

Document (European 2005) states that in normal operational conditions overall time used for single data transmission between interlocking and ETCS on-board via Radio Block Centre (RBC) on high speed lines is about 4 s.

Taking that into account together with other above statements it is questionable why many documents suggest multiplying GSM-R infrastructure to ensure high redundancy. A simple answer is that redundancies increase safety, reliability and availability of the GSM-R. Unfortunately basic data are not available and have to be determined by infrastructure managers.

In accordance with 'Commission Decision dated 25 January 2012 on the technical specification for interoperability relating to the control-command and signalling subsystems of the trans-European rail system (2012/88/UE) chapter 2.3' "a train equipped with Class A on-board train protection for level 1 need not be equipped with a GSM-R data radio but must already implement all level 2 functions so as to ensure that the mere connection of a GSM-R data radio at a later stage will ensure it is equipped for level 2". Therefore it can be assumed that:

- ETCS level 1 can be seen as a solution for transition period,
- GSM-R trackside should be constructed in configurations enabling future operation of the ETCS level 2,
- ETCS level 1 can operate with analogue voice communication systems VHF,
- ETCS level 2 cannot operate without GSM-R therefore ETCS level 2/3 constitute with GSM-R integrated system named ERTMS,
- it has to be analysed whether GSM-R and ETCS are independent or dependent from reliability and availability point of view. For this

[1]That requires measurement samples collected every 10 cm (some countries are using 7,5 cm or even 4 cm).

[2]In accordance with above equation when l_z *is constant* and $v \to 0$ in result $T \to \infty$; longer time means higher probability of the failure causing emergency braking (e.g. data transmission long lack) causing possibly derivative train stopping in a radio hole.

article it is assumed that GSM-R and ETCS are independent as ETCS failure do not influence GSM-R operation and GSM-R failure influences ETCS operation however it can be neglected.

As a result relation between ETCS and GSM-R in ERTMS can be noted as following:

$$\text{ERTMS} = \text{ETCS} \cap \text{GSM-R} \tag{4}$$

Future analyse will be done with most restrictive requirements for GSM-R system namely for data transmission services, which are used for the safe rail transport management based on ETCS level 2/3. For other GSM-R services e.g. *Voice* reliability and availability requirements are less restrictive. GSM-R system has a network character both hardware and software dimension (Network-Centric Systems) and therefore traditional equation is:

$$A = \frac{MBTF}{MBTF + MTTR} \tag{5}$$

which for availability of GSM-R means masking of system reliability. Systems with high availability can be very reliable—especially regarding software errors e.g. system standstills or bags which are removed by diagnostic and watchdog programs. Additionally as a result of internal redundancy time needed for failure removal can be very short—counted in miliseconds or a few seconds. Some publications expression "reliability" for hardware-software systems should be possibly replaced by expression "dependability", which is better defines states of such systems.

GSM-R system infrastructure is composed from a few subsystems e.g. BSS, NSS OMC etc. Failures within some subsystem do not influence safety of the rail traffic.

Incidents which can happen in GSM-R system can be subdivided in following groups:

– critical e.g. losing data transmission,
– important e.g. losing redundancy, keeping data transmission,
– less important e.g. opening BTS base station door without authorisation, keeping data transmission.

Moreover incidents may happen presently and in the future in different places influencing big areas or limited areas, for instance:

– losing data transmission in NSS subsystem cause failure in the whole area covered by such NSS (practically on all railway lines which are served by such NSS),
– losing data transmission in BSC base stations controller do not cause negative consequences on lines which are served by other controllers,
– losing data transmission in BTS base station cause negative consequences only on the area served by this basic transmission station (practically on about 7 km of the railway line) and only if at the same time there is a train at this section (terminal EDOR).

GSM-R system dependability depends mainly from critical failures e.g. long lack of data transmission which can possibly cause emergency braking. In case of BTS base stations the length of the time window with failure is also important. Probability of critical failure on the section served by basic station is a function of the time the train is on such section, time window with failure and frequency and length of the telegrams which are exchanged.

$$P_{ki} = f(t_p, t_o) = f(v_t, l_c, t_o, \omega, w) \tag{6}$$

where:
t_p—time window when train is in single cellular area
t_o—failure time
v_t—train sped
l_c—length of the single cellular area
ω—frequency of telegrams exchange between $\text{ETCS}_{\text{trackside}}$ and $\text{ETCS}_{\text{on-board}}$
w—length of the telegrams in bits

According ETCS SRS recommendations frequency of telegrams exchange by ETCS is between 1 and 255 seconds while the length of the telegrams are up to 960 bits. Therefore time when the train is in the area served by one BTS base station can be expressed as:

$$t_p = l_c / v_t \tag{7}$$

Time when all the trains are in the time unit in the area served by one BTS base station can be expressed as:

$$T_o = \sum_1^n \frac{1}{v} \tag{8}$$

where:
T_o—time window when trains are in single BTS base station area
n—number of trains in time window
l—length of the railway line served by chosen BTS base station area
v—train speed in chosen BTS base station area

Assuming that basic station is serving 7 km long section of the railway line and the speed of the trains is 250 km/h, we can calculate time window when the train is in single cellular area

as a bit over 100 s. As a result on a line with 30 pars of trains daily within one basic station all the trains together will remain cumulatively 6000s which is around 7% of the day, which means that 93% of time even critical failures in a BTS base stations may have no influence on railway traffic safety. This means also that MTBF is composed by two elements which are: system working time and system readiness time and therefore availability of the BTS base station can be expressed as:

$$A = \frac{Operating\ Time + Operable\ Time}{Operating\ Time + Operable\ Time + Downtime} \quad (9)$$

When failure occurs within sending or receiving of the telegram from Radio Block Centre to the train or vice versa and last long enough to cause losing data transmission between RBC and train it leads up to train emergency brake. As shown on the Figure 1. below such transmission is additionally protected by Euroradio coding/decoding layer separately operating trackside and on-board. If as a result of a failure time window without data transmission is short enough that it does not cause emergency brake of the train then ETCS does not see lack of data transmission. Re-establishing connection means first synchronization of the equipment and then data transmission related to safe train traffic management reaching speed appropriate for the section (energy losing and train delay as braking is more intense e.g. 0,5 m/s^2 than acceleration e.g. only 0,3 m/s^2).

Similar analyse should be done for BSC base stations controller. In practice BSC base stations have big hardware and software redundancy and their reliability is at least on the level of 99,999% (BSC base stations controller unavailability is at average 3 min per year).

Similar analyse should also be done for other subsystems of the GSM-R system taking into account:

– dimension of the influence area,
– time for removing critical errors,
– failure mischievousness and
– influence from occurrence of fires, lightning, floods, etc.,

for the working dependability of a whole GSM-R system.

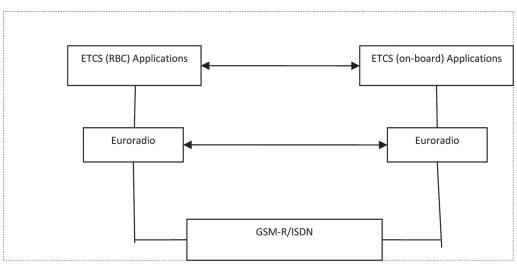

Figure 1. Communication between ETCS trackside and on-boars equipment (Europen 2005).

6 CONCLUSIONS

Findings show that practically:

– GSM-R voice transmission is not critical for ERTMS safety, reliability and availability while data transmission is critical,
– redundancies within BSS subsystem as well as multiplying whole BSS are inefficient and therefore economically questionable however technically possible,
– redundancies within NSS subsystem as well as multiplying whole NSS significantly influences GSM-R and ERTMS safety, reliability and availability. NSS installations are serving large areas and therefore both fate and regular failures may affect railway transport even of a whole country. Therefore NSS subsystem strongly requires redundancies. Proposed solution is a whole subsystem redundancy 1+1 composed by whole set of equipment located in two different cities powered by different large area public power stations.
– Necessity for following works:
– It is necessary to elaborate mathematical model verifying independency assumption ERTMS = ETCS ∩ GSM-R,
– GSM-R Safety, reliability and availability should be defined by countable values,
– It is necessary to define 'critical failure' including time correlation between failure and train location,
– Dedicated analyse has to be done to find how long time trains can be in radio hole without effective influence on train running safety.

All swept up: An initial classification of NSA surveillance technology

M. Cayford, C. van Gulijk & P.H.A.J.M. van Gelder
Delft University of Technology, Delft, The Netherlands

ABSTRACT: The study was initiated as part of the FP7 SURVEILLE project commissioned by the European Commission. The goal is to examine the mass surveillance technology used by the NSA in the programs revealed by the Snowden leaks. This paper forms the basis from which to study the effectiveness of these surveillance technologies. Novelty: While there have been a lot of headlines regarding what the NSA is purportedly doing, discussion of the technology used to do this is scarce to nonexistent. There is also the problem of different programs being revealed via different media sources, thus making it difficult to know and follow the information being revealed regarding NSA programs. This paper attempts to bring the NSA programs and methods into one place, categorize those that are similar, and analyze the probable surveillance systems used. Relevance: This work is the beginning of developing a method of evaluating the effectiveness of surveillance technologies, the lack of which is notable in government oversight mechanisms. Methods and findings: The methods for this research begin with a review and analysis of the leaked NSA information and documents. Further, a study of articles delving deeper into the NSA programs is conducted. Lastly, the research focuses on a technical understanding of the technology involved through readings and interviews with experts. It is found that these numerous programs can be classified in a few categories of surveillance technology. This initial study forms for the basis for evaluation of the effectiveness of these technologies.

1 INTRODUCTION

Many types of surveillance (phone tapping, collecting metadata, intercepting mail) used by the NSA are not new to the world of espionage. What is new in surveillance, thanks to huge advances in technology, is mass surveillance. In the digital age in which everyone's communication and information is stored and transmitted online it is now possible to gather massive amounts of information rather easily. What formerly would have required a laborious process of monitoring physical mail, tracking targets' movements, and entering homes or offices to gain information about a target's activities, contacts, financial information, etc., can now be done largely by monitoring their online activity. And in a post-9/11 era where terrorism is a primary concern of governments, all this information can be swept up not just about one person, but about thousands, potentially even everyone, in the event that this information may prove useful later, and in the interest of identifying and apprehending terrorists before they are able to act.

The objective of this paper is to gather information about technical systems that the NSA uses to perform mass surveillance to be able to later analyze their effectiveness to determine to what extent and at what cost these systems achieve their objectives as stated by the NSA. The analysis was performed from the perspective of risk control. That is to say, the assessment focuses on an integral analysis of the system rather than on computer science aspects.

This paper will provide an initial classification of NSA surveillance technologies as they have been revealed in the recent Snowden leaks. The classification aims to group the technology behind the confusing array of NSA operations and programs, and to rate it on a scale of mass to targeted surveillance. The following surveillance technology categories are examined: wiretaps (2.1), PRISM (2.2), decryption (2.3), exploitation (2.4), analysis tools and databases (2.5). We then classify these technologies as they relate to mass or targeted surveillance (3).

Two factors have influenced our research. One is that what kind of surveillance technology the NSA uses and how it works is all classified information. Therefore much of our examination and explanation is educated guessing based on recent leaks, previous revelations, and an understanding of what methods and devices are available. Secondly, the stories on the Snowden leaks have been published in a multitude of media sources in various countries. This renders it more difficult to gather pertinent information into a meaningful ensemble. Further, these leaks continue and information on these systems may consequently change. There-

fore these are initial steps to understand NSA surveillance technology and will be updated and improved as necessary.

2 NSA SURVEILLANCE TECHNOLOGIES

2.1 *Wiretaps*

Wiretaps on fiber-optic cables are likely the means by which the NSA accesses and captures vast amounts of internet data. This would provide the basis for it to analyze and map the information, identify specific targets, and deploy malware attacks. The conclusion that the NSA is tapping fiber-optic cables is based on three things: 1) According to an NSA slide, "Upstream" is "the collection of communications on fiber cables and infrastructure as data flows past." 2) The GCHQ operation TEMPORA is known to be tapping into fiber-optic cables and to be working with the following telecom companies: BT, Verizon Business, Vodafone Cable, Global Crossing, Level 3, Viatel, and Interoute. (Ball et al. 2013) 3) A 2006 court case against AT&T, which disclosed that the NSA was wire-tapping fiber-optic cables at AT&T's internet exchange point in San Francisco.

2.1.1 *Fiber-optic cables*

Fiber-optic cables carry the world's communications across the globe. More than 550,000 miles of these undersea cables connect our world, (Fulghum 2010) carrying 99 percent of the world's intercontinental data (Timberg & Nakashima 2013).

Standard fiber-optic cables over land consist of 144 individual glass fibers; those undersea consist of only 8 individual glass fibers. Each fiber carries 40–160 light wave signals and each of these signals handles 10–40 gigabits of traffic. (Fulghum 2010) The data is turned into "ultra-short flashes of light. These flashes represent the zeros and ones that all digital information is comprised of. A photodiode at the end of the cable turns the light flashes back into electrical signals." (Schmidt 2013) The signals, however, have to be re-amplified with a regenerator about every 80 kilometers otherwise they will drop. Each fiber optic has to be to re-amplified separately, so the fiber optics must be laid out separately rather than bundled together. If a cable was to be secretly tapped this is the weak point at which it could be more easily done (Schmidt 2013).

2.1.2 *Fiber-optic splitters*

An even easier way to tap fiber-optic cables is to have the consent of the telecommunications company to split the wires. This was the case with AT&T—the company allowed the NSA to tap its cables.

To intercept AT&T's signal at 611 Folsom St. in San Francisco, the NSA installed splitters. A splitter is a piece of equipment that physically splits the cable and sends the signal in two different directions. The simplest form of splitter is a "T" which has one signal coming in and two signals going out. The NSA splitters used in this case were 50/50 splitters—of the signal that came in, 50% of it went out one fiber and 50% went out the other. This does not refer to 50% of the data, but to 50% of the signal. That is, the signal is split in half, making it weaker, but 100% of the data is sent through each of the two signals. Essentially this means that a copy of the data is being made. The data is then sent on its way to its original destination through one signal, and a copy of this data is sent into another cable owned and operated by the NSA. (See Fig. 1.)

Effectively, these splitters were installed at an Internet Exchange Point. At the San Francisco facility AT&T exchanged internet traffic with 16 companies with which it had peering arrangements. The splitters diverted traffic related to AT&T's Common Backbone, the network that provides internet access (as opposed to telephone traffic). It is believed that all, or substantially all of AT&T's peering traffic was diverted through the splitters, but that its own traffic was not. The splitters were placed on the fiber-optic cables belonging to these 16 ISPs before they reached the AT&T Common Backbone. Thus, their traffic was copied, but AT&T's own traffic was not (Marcus 2006).

2.1.3 *Deep packet inspection*

After passing through the splitters, the copied data was sent into a secure room at the San Francisco facility where it was processed by Narus equipment.

Narus is Deep Packet Inspection (DPI) technology. DPI is the inspection and analysis of internet traffic in real time. It extracts basic protocol information, such as source and destination IP

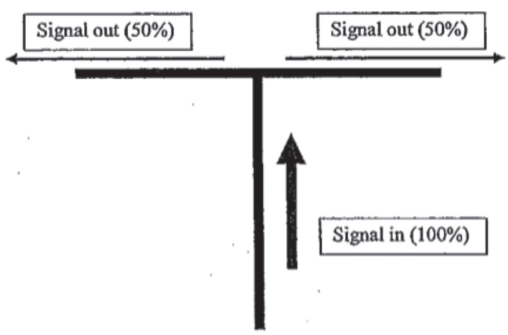

Figure 1. 50/50 splitter (Source: *Declaration of J. Scott Marcus*, p. 13).

addresses, as well as the deeper layers of the traffic, which consist of the actual content of the traffic.

DPI was designed by engineers for Internet Service Providers (ISPs) to optimize their networks. "The primary technical capability underlying DPI is the ability to recognize. DPI has been developed to detect, for example, applications, protocols, media content, viruses or data in a specific format, such as credit card numbers." (Asghari et al. 2012) Once data is recognized the ISP can manipulate it, for example, by blocking or prioritizing certain traffic. It can also carry out notification actions, such as "generating reports, alarms or billing incidents." (Asghari et al. 2012) Using DPI, ISPs can prioritize applications like VoIP to improve service or identify illegal downloads. In other words, ISPs use DPI to look at the internet activity of their customers and act upon it.

The Narus system at the AT&T San Francisco facility consisted of two parts—the Narus Semantic Traffic Analyzer (STA) 6400 and the Narus Logic Server. Part one of the system—the STA 6400—monitors data packets for metadata that matches "key pairs," such as "a specific IP address or a range of IP addresses, a keyword within a Web browser request, or a pattern identifying a certain type of traffic such as a VPN or Tor connection." (Gallagher 2013) The matching packets are put into the second part of the system, the Narus Logic Server. This second part consists of analytic processing systems that re-assemble the network sessions of the matching packets, mine them for "metadata, file attachments, and other application data" then index and deposit the data into a database. (Gallagher 2013) Narus is capable of processing huge volumes of data and of storing the traffic that it captures.

The amount of internet traffic that Narus can handle monitoring is directly related to how many rules have been loaded into the machine watching the metadata flow past (part 1 of the system). The more rules, or pre-configured filters, turned on, "the more compute power burned and memory consumed per packet, and the fewer packets that can be handled simultaneously." (Gallagher 2013) In the Narus system, if all the pre-configured filters are turned on then the system can monitor 12 gigabits out of 20 (on a two-way 10 gigabit Ethernet connection). To make the system more efficient and able to monitor more of the 20 gigabits flowing past, some of these filters have to be turned off. "In other words, to handle really big volumes of data and not miss anything with a traffic analyzer, you have to widen the scope of what you collect" (Gallagher 2013).

Also present at the AT&T facility was what was referred to as the "SG3 backbone." This was a private backbone network, separate from AT&T's backbone. It was believed that this indicated that after the Narus equipment collected and processed data of interest, the data was sent via the SG3 backbone to central locations for further analysis. (Marcus 2006).

2.1.4 *Possible additional locations of NSA splitters*

AT&T staff revealed that besides San Francisco, NSA surveillance sites also existed in Atlanta, Los Angeles, San Diego, San Jose, and Seattle. Using criteria based on the assumption that the NSA would want to intercept the most data with the fewest number of splitter sites, researchers at the University of Toronto have identified another 12 cities that likely host NSA splitters. Of 1,319 U.S.-only internet data traffic routes in the researchers' database, only seven did not pass through one of these 18 cities suspected to have NSA surveillance sites. That means that with splitters at these locations the NSA could intercept 99% of U.S.-only traceroutes (Clement 2013).

2.1.5 *Concluding remarks on fiber-optic cable tapping*

The splitters at the AT&T San Francisco location were never known to be removed. The aforementioned NSA "Upstream" slide mentions several code names in relation to the Upstream program—FAIRVIEW, STORMBREW, BLARNEY, OAKSTAR. These code names reportedly refer to specific telecommunications companies such as A&T. (Cohn 2013) It seems likely that the NSA surveillance technology being employed in Upstream are splitters placed on the fiber-optic cables along with DPI technology. The program, MUSCULAR, in which the NSA exploits the data links connecting Yahoo and Google data centers, could also be using splitters and DPI to tap the fiber-optic cables connecting the data centers.

Deploying splitters on fiber-optic cables is clearly mass surveillance since a copy of all data is made. And in this instance DPI would also qualify as mass surveillance since the parameters are set wide to capture as much data as possible.

2.2 *PRISM*

The Guardian article revealing the PRISM program reported that this program gave the NSA direct access to the servers of major internet providers such as Google, Apple, Skype, and Yahoo. The slide speaks of PRISM "collection directly from the servers" of nine U.S. internet services providers. The interpretation by *The Guardian* and *The Washington Post* was that this meant these companies were collaborating with the NSA to give it a direct connection to their servers, to

"unilaterally seize" all manner of communications from them. (Greenwald & MacAskill 2013) This proved, however, to be erroneous.

The "direct access" described here is access to a particular foreign account through a court order for that particular account, not a wholesale sucking up of all the information on the company's users. The court order gives the NSA access to the targeted account as well as to the accounts it is in contact with. This follows in the same principle of a court order on a phone number yielding the phone numbers the targeted phone has communicated with (with the obvious difference of a Facebook page containing content, while phone metadata does not). The NSA and the attorney general serve a court order on one of these companies for one or more foreign accounts, say for example, several Facebook accounts in Pakistan. Those accounts are then monitored and their activity is sent back to the NSA. This is where "direct access" fits in—the NSA has access to the account in real time. (Soar 2013) Marc Ambinder, writing in *The Week*, speaks of a 'mirror' of the accounts that the company somehow creates and only the NSA has access to. When the selected account is updated the Facebook server and the mirrored server are both updated in real-time. PRISM is the tool that allows the analyst to monitor and analyze this data and all the data on foreign targets provided to the NSA by internet companies in the U.S. (Ambinder 2013).

PRISM, then, is a targeted technology used to access court ordered foreign internet accounts.

2.3 *Decryption, or circumventing encryption*

One of the NSA's core missions is to decipher and break codes. Interestingly, however, the leaks have shown that the majority of the NSA's decryption efforts do not involve actually breaking codes, but exploiting human elements and implementation software to circumvent encryption. Further, while mass surveillance programs aid in identifying machines to exploit, the actual decryption—or circumventing of encryption—is done on a targeted, rather than mass surveillance scale.

BULLRUN is the NSA's program dealing with defeating encryption. The Classification Guide for Project BULLRUN states that the NSA has "some capabilities" against encryption in HTTPS, VoIP, Secure Sockets Layer (SSL; used for online banking), VPNs, SSH, and Webmail. The Guide also make explicit that "capabilities against a technology' does not necessarily equate to decryption."

The NSA has various methods for defeating encryption—obtaining encryption keys, backdoors, influencing encryption standards, and brute force. To obtain encryption keys the agency issues court orders requiring companies to turn over keys; hacks into companies to obtain the keys; or secures companies' willing collaboration. The agency reportedly maintains of database of the keys it collects. (Simonite Sept. 6, 2013) The NSA has also persuaded or coerced companies into installing backdoors into their security systems. It can then get around the encryption by using these backdoors.

The agency purportedly influences encryption key standards. This would probably be done through the National Institute for Standards and Technology (NIST) "which sets U.S. cryptography standards and is influential worldwide." (Simonite Sept. 9, 2013) The MIT Technology Review's IT editor for hardware and software argues that it is unlikely that the NSA compromised many of these most widely used standards because there were developed by open groups outside the U.S. The one standard it did play a significant role in developing is part of a cryptography toolkit—Suite B—used by the U.S. government and its contractors. "Introducing backdoors into that would seem counterproductive to the NSA" (Simonite Sept. 9, 2013).

The NSA also uses brute computer force to break weak encryption. Therefore, although there is not yet evidence that the NSA has cracked SSL, experts have long warned that the keys typically used with SSL are not long enough. A government agency or a large company with significant resources could break the 1,024 bits long keys that most sites use for SSL. Longer keys are necessary to protect against this kind of attack, but few companies use them. (Google and Facebook are just this year switching to longer keys. Google's key will be 2,048 bit.) (Simonite Sept. 9, 2013).

The NSA capabilities under BULLRUN are interesting because they show the limits of its abilities. The agency cannot break encryption. Its attacks against encryption use must be done on a case-by-case basis. However, it also illustrates its ability (and potential) to bring more data under its surveillance by bypassing encryption. Obtaining each individual key or backdoor access is targeted; what this yields could be targeted or mass surveillance (e.g. it could read all the traffic of a company once it has the encryption key). Where on the mass-targeted scale decryption falls is therefore somewhat variable. We have chosen to place it towards the mass end of the scale but not fully in the mass surveillance category since encryption keys and backdoors can give it access to non-target data, but the agency does not have the capability to unilaterally bypass all encryption.

2.4 *Exploitation*

To exploit—hack into—computers and other devices the NSA utilizes its secret servers and software and hardware implants.

2.4.1 *Secret servers*

The NSA's attacks using FOXACID are a good example of both its exploitation techniques and how it circumvents encryption. FOXACID is a Computer Network Exploitation system that matches potential targets with prepared attacks. It is a modular system that allows exploits to be changed if discovered and only launches certain attacks against certain targets. FOXACID is used to perform all kinds of attacks. One example is attacks against Tor users (Schneier Oct. 4, 2013).

Tor—The Onion Router—is an online anonymity network. It is a problem for law enforcement because criminals use it for communication and it makes identification of the user, hence, the criminal, excessively more difficult. Tor works by routing data packets through multiple nodes, or relays, rather than taking the most direct path. Each relay only knows the relay the data came from and the next relay it is going to. To the websites visited, the location of the Tor user appears random.

To execute an attack, the first step is to identify Tor users on the internet. This is easy for the NSA to do because the characteristics that make Tor anonymous also make all Tor users look the same on the internet. However, the user's identity and location remain unknown. "The NSA creates 'fingerprints' that detect http requests from the Tor network to particular servers." (Schneier Oct. 4, 2013) The fingerprints are then put into a database and data analysis tools are used to sort through all the internet traffic the NSA monitors to identify Tor connections.

Once a Tor user is identified the NSA uses its secret servers on the internet backbone, codenamed QUANTUM, to redirect those users to other secret servers, codenamed FOXACID. Because QUANTUM servers are at key locations on the internet backbone, they can react faster than other websites and thus impersonate the website the user is wanting to access. They can respond to the request before the actual website can and they look the same as the actual website. The target's browser is thereby fooled into contacting the FOXACID server. These kinds of attacks are a sort of race and are hard for anyone besides the NSA to execute because they depend on "a privileged position on the internet backbone" (Schneier Oct. 4, 2013). This is known as a man-on-the-side attack.

"By the time the NSA tricks a target into visiting one of those servers, it already knows exactly who that target is, who wants him eavesdropped on, and the expected value of the data it hopes to receive." (Schneier, Oct. 15, 2013) Based on this, FOXACID automatically determines which exploits are best to serve against the particular target. It performs a risk-benefit analysis, considering factors such as the technical sophistication of the target, the value gained from a successful attack, the risk of discovery, the value and rarity of the exploit, etc. (Schneier, Oct. 15, 2013) In the case of Tor, FOXACID attacks through the Tor browser bundle (a group of programs designed to make the installation and use of Tor software easier), exploiting vulnerabilities in the Firefox web browser. Once an attack has been successfully executed, the infected computer calls back to the FOXACID server, which then further infects the computer, compromising it long-term and providing the NSA with ongoing information (Schneier Oct. 4, 2013).

Note that although the NSA can execute these attacks against Tor it cannot do so on a large scale. Nor can it do so on demand. These are targeted attacks against individual users, not blanket attacks against all Tor users. According to 2012 NSA PowerPoint slides, the agency "will never be able to deanonymize all Tor users all the time." It has had success de-anonymizing "a **very small fraction** of Tor users" with manual analysis, but has had no success in de-anonymizing a Tor user on demand. (Bold in original document.)

This is apparently the same kind of attack that the GCHQ used against Belgacom. When targeted employees visited their LinkedIn profiles a secret served responded with a fake page that infected their computer with malware. (*Spiegel Online* staff 2013)

2.4.2 *Software and hardware implants*

In December 2013 *Der Spiegel* published a leaked document of a sort of catalog of NSA spy technology. It included both software and hardware implants for exploiting mobile phones and their networks, computers, routers, and servers, among others. To give a couple of examples: SOMBERKNAVE, a software implant for Windows XP, uses the computer's unused wireless device to contact the NSA remote operations center and makes the targeted device controllable remotely. When the target is using the wireless card, SOMBERKNAVE is inactive. RAGEMASTER is a hardware implant hidden in the monitor cable that allows the NSA to see whatever appears on the monitor of the targeted computer.

Like the attacks performed by the secret servers, these implants are targeted surveillance, being targeted at specific devices. In some cases, however, they could move along the scale towards mass depending on how they are used. For example, the implants for professional routers could potentially gather information on non-targets, depending on whether the organization itself or someone within the organization using the router is the NSA's target. It has also been reported by some sources that at least one of these systems—NIGHTSTAND—has been used from drones to target certain geographical

areas. (Appelbaum 2013) For this reason we classify exploitation on the targeted end of the scale, but not completely in the targeted category.

2.5 *Analysis tools and databases*

NSA has a myriad of data analysis tools and databases to process the data it collects. XKEYSCORE is both an analytical tool and database. We have chosen to focus on this system as an example of NSA databases, as it is often mentioned in reporting on NSA leaks, and is at the same time, perhaps, the most complex and difficult to understand.

After the attacks of 9/11 the NSA needed a quick way to increase its internet surveillance. It accomplished this by purchasing "off-the-shelf" systems such as Narus. The result was that a lot of data was collected. The problem for the NSA was where to store it and how to get it there. "Even when you store just the cream skimmed off the top of the 129.6 terabytes per day that can be collected from a 10-gigabit network tap, you're still faced with at least tens of terabytes of data per tap that need to be written to a database." (Gallagher 2013) It was physically impossible for the NSA to get all that information back to its central database. So it created XKEYSCORE. XKEYSCORE solves the problem by storing the data packets in local caches rather than sending it back to a central database. Since the advent of XKEYSCORE the agency can now store 3 days worth of raw packet data and 30 days worth of metadata in the local caches.

XKEYSCORE *is not* the system that actually captures the data via the fiber-optic cable tap. The system that captures data packets from NSA wire taps is code-named TURMOIL. XKEYSCORE processes the data that TURMOIL brings in.

It processes it by running plug-ins, analysis engines that look for specific content in the captured data packets. XKEYSCORE has plug-ins for email addresses, phone numbers, webmail and chat activity, and extracted files, among others. "For selected traffic, XKEYSCORE can also generate a full replay of a network session between two Internet addresses." (Gallagher 2013) The plug-ins extract the metadata from each internet session and index it into tables. XKEYSCORE can track, cross-index, and search any kind of metadata that can be extracted from an internet session—log ins, email addresses, the use of encryption, language use, IP address geolocation, etc.

There are approximately 150 XKEYSCORE sites around the world. These sites include wiretaps at telecommunications companies' peering sites (such as the AT&T case), systems connected to friendly foreign intelligence agencies' collection sites, and mid-ocean fiber-optic cable taps (executed by F6, the joint CIA-NSA Special Collections Service). Only information that is related to specific cases is sent back to the NSA's central database. The data in the local caches is available to analysts through federated search while it is being stored (Gallagher 2013).

To perform a search request an NSA analyst creates a query. This query is sent to all the XKEYSCORE sites. Analysts can search by hard selectors (e.g. email addresses) or soft selectors (e.g. language). So if an analyst does not have a hard selector, such as an email address or phone number for a known target, he/she can do a search for a category of information, such as all encrypted Word documents or all VPN (virtual private network) startups in a given country. (NSA XKEYSCORE slides 2008) Any kind of query can be created as long as the plugin exists. XKEYSCORE combines and returns all the responses to the query.

Using XKEYSCORE is apparently how the NSA can identify Tor users—this is a category that can be queried. Another category that can be searched is exploitable machines—"Show me all exploitable machines in country X." (NSA XKEYSCORE slides 2008) When the NSA's Tailored Access Operations (TAO) identifies a computer as a target it loads its fingerprints, or unique identifiers, into XKEYSCORE's fingerprint ID engine. In the case of Microsoft system crashes XKEYSCORE identifies these error reports and sends an automatic notification, enabling TAO to exploit the machine. (Spiegel staff 2013)

Like Narus, XKEYSCORE performs best when it 'goes shallow,' that is, fewer filters are applied to determine which data packets are captured. This means that a lot of information is collected, including, undoubtedly, information unrelated to NSA targets. XKEYSCORE, therefore, classifies as mass surveillance technology.

3 FINDINGS

Based on information currently available on the above NSA surveillance technologies, we have given them an initial and basic rating on a mass to targeted surveillance scale (See Fig. 2.)

The NSA's use of splitters on the fiber-optic cables of companies like AT&T is clearly mass surveillance. This surveillance technology indiscriminately copies all data, sweeping up vast amounts of data belonging to non-targets.

PRISM, by contrast, is a targeted surveillance method and is therefore placed at the other end of the scale.

The NSA's decryption program is a little less clear cut. The NSA does not have the capability to unilaterally bypass all encryption. However, once it does have an encryption key or a backdoor, for

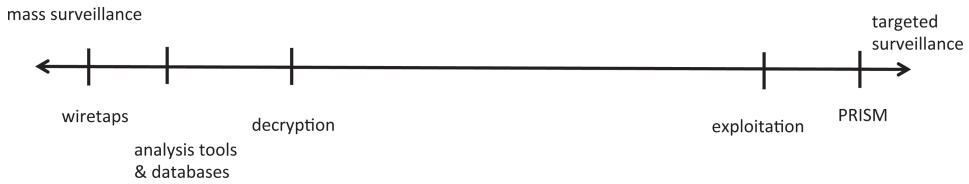

Figure 2. Classification of NSA surveillance technology.

example, it can have access to far more data than just that belonging to specific targets. For this reason we have classified it as one step down from the mass surveillance of wiretaps.

The surveillance technology used for exploitation is targeted. However, as previously stated, in some cases it may be aimed at groups of people, which include non-target subjects. Therefore we have classified exploitation as targeted surveillance but not completely in the category of targeted.

Whether or not analysis tools and databases are mass or targeted surveillance is dependent upon the data that is put into them. Examining all databases is beyond the scope of this paper. We have taken XKEYSCORE as an example, and found that because it sorts and stores volumes of data obtained via mass surveillance methods, it is also mass surveillance technology.

4 CONCLUSION

This paper aimed to create some structure for the many NSA surveillance programs recently revealed in the Snowden leaks. It was an initial step to classify the surveillance technologies and rate them according to mass and targeted surveillance. We found that in most cases (PRISM being the exception) several programs could be classified under one technology category. Further, while some of these programs have been portrayed as mass surveillance, they are, in fact, targeted. Lastly, further research is needed to determine if these technologies are effective.

Future work will examine subsequently leaked NSA programs, adding to and/ or adjusting the categories of surveillance technology as needed. This will form the basis from which to analyze the effectiveness of the NSA surveillance technology; to what extent and at what cost does it achieve its goals.

Study of the security of processes running in computer operating systems

I.J. Jóźwiak
Faculty Informatics and Management, Wrocław University of Technology, Wrocław, Poland

A. Szleszyński
General Tadeusz Kościuszko Military Academy of Land Forces, Wrocław, Poland

ABSTRACT: A process is the main part of a computer operating system. Its role is to fulfil its task(s). But if it contains errors it may disrupt the proper work of the host computer operating system. Any disruption affects host computer operating system security. In this paper, the authors evaluated behaviour of a test process and its influence on the increasing use of operating memory, which is the element of the host computer operating system efficiency. Then an interaction between processes was evaluated.

1 INTRODUCTION

Nowadays, operating systems are used in multitasking environment. This means that it is possible to support multiple processes that share their operating memory, Central Processor Unit (CPU) time, and input and output devices. This activity is related to the switching processes coordinated by a special program called scheduler. An initiation of a new process in an operating system means that a user has necessary privileges to do that. For an operating system security it means that at least one of the safeguards is omitted.

From this moment the process receives an access to operating system functions and to computer hardware controlled by an operating system. So, if the program was written in such a way, it may initiate numerous malicious actions such as: observing a user to find out personal passwords, attempting to transfer illegal data transfers, encrypting available data or disturbing the work of host computer operating system. The last activity may be possible due to improper requests operating system's kernel functions (Tannenbaum & all, 2006).

The goal of this paper is to study the way the processes may interact with each other, what kind of disturbance may be expected in case of malicious activity in one or more processes? The authors have not found answers to those questions in the available literature on the subject.

The answer is derived from the experiment conducted on some operating systems used by business and education organisations. During the research authors used their own software written in Object Pascal programming language. The Object Pascal belongs to a group of high level and object oriented programming languages. It does not offer the possibility to manipulate a value of specified operating memory cell. All of those operations are executed by using operating system Application Programming Interface (API). The Pascal programming language was not created with the purpose to build the new operating system[1] so it does not offer the functionality and flexibility such as Assembly or C programming languages. Because its functionality is limited, the attempt to create any malicious software requires special techniques to achieve effects similar to those using Assembly or C programming languages. It is similar situation to that of using the script programming languages[2] running on commercial and non-commercial operating systems.

2 PROBLEM IDENTIFICATION

The aim of this work is to find out the answers for three questions "How a single process, run on operating system, can violate an operating system security?", "How the single process influence on operating system performance?", "How to measure the extent of damages resulting from such action?".

The choice of the availability attribute depends on the information technology system providing

[1]Different as C programming language which was used to create the Unix operating system.
[2]i.e. Visual Basic Script from Windows operating system or Perl Script Programming Language for Linux.

the data necessary to make decisions. The lack of necessary information on time for a decision maker means that there is no information at all (Michalski, 2007). In addition, the information make 70 per cent of the value of manufactured goods and services (Michalski, 2007).

The main goal of the information technology system is to deliver reliable and well addressed information to right people at the right time according to the 'need to know' rather than 'nice to know' rule. The same requirement is true for information technology systems in which a human-to-machine interaction or just machine-to-machine interaction exist.

The issue of process security is vital because running of the process in operating system means that the operating system security subsystem is omitted. It is so because only the authorized user may run a process. Moreover, working on operating system process gives an access to all computer resources allocated to the user in accordance with the security settings.

3 EXAMINING OF OPERATING SYSTEM EFFICIENCY

To answer the three questions stated above it would be necessary to conduct the research by using the analysis of influence of the processes on three security attributes such as confidentiality, integrity and availability. The aim of this work is to find what consequences result from the malicious activity of the single process. Then, the next question is to be answered—how destructive this situation could be for other processes running on an operating system?

The mechanism of malicious activity is not well known. The literature available to the authors do not describe the exact mechanisms of malicious code. One of the possible reasons is that the analysis of malicious code operation requires a lot of technical knowledge. The specialized software is necessary to test malicious behaviour. It is difficult to examine the structure and behaviour of malicious codes. Some of them have a built-in self-protection mechanism against the software structure and behaviour analysis.

There is not many information about the influence of the malicious software on stability of an operating system performance. This results from the operating systems manufacturers not interested in detailed description of the methods used to exploit vulnerabilities of their products.

The authors are going to study the behaviour of processes running on an operating system. At the beginning, the authors decided to check the possibility of the availability attribute violation. To measure the system performance there was a simple application created. The application makes an addition of two integers. That activity is repeated forty times in a program loop. The result of the operation is written to memo component, subsequently those data is used to derive all necessary calculation and statistics. The results of the experiment would be used to calculate a mean time of the process. The mean time of a sequence of actions shows the efficiency of the system. Next parameter is the utilization rate of CPU of the computer by each of the running processes.

Very similar method would be used concerning the data integrity verification.

As the first parameter to examine, an operating memory usage was chosen. During the experiment, the increase of the amount of operating memory for test process was checked. Data in Table 1 shows the increase of used memory allocated to the test processes.

Position 0 shows the amount of memory allocated to the test process after loading it into operating memory before it was run. After the first run of process the amount of operating memory allocated to the processes increased 16 times (from 8.93 MB to 145.39 MB), it is the biggest value. The next growths were much lower than the first one. It means that the first run of a process needs more memory (16 times more). Next runs of the test process need just two times bigger the memory than a previous one. However, the amount of operating memory between positions 0 and 4 runs of the process required 62 times more RAM (Random Access Memory, also called operating memory) than right after loading. At the end, the single run of the test process allocated more than 0.5 GB RAM what was more than 25%[3] (Solomon, 1998) of operating memory allocated to run all the

Table 1. Operating memory usage by test process (source: authors own work).

No. of test process run	RAM memory allocated for test process [MB]	Increase of allocated RAM memory for the test process [MB]
0	8.93	–
1	145.39	136.46

3	497.49	216.13
4	553.30	55.81

[3]Some operating systems divides RAM installed into computer into operating system functions and processes run on it. The half of RAM is reserved for running kernel functions and the second half for processes run.

processes in the operating system. The comparison of proportional increase of allocated RAM, between each run of the test process, is shown in Table 2.

The analysis of the availability of information can be realised by measuring the time of execution of each part of the task. The test process makes the addition of two numbers from 1 to 100 then elements and the result are converted to string value. String value is added to memo control that is inside the main form. The statistical parameters of the results of the test process operation are presented in Table 3.

The mean value for the fourth run of the process is six times longer than it was during the first run of process. An explanation for data shown in Table 3 is that the of increase the amount of RAM influences the execution time. It is because the operating system has to provide the memory management for the rest of operating processes. The jumping increase of the amount of RAM needed to provide for the process results in more frequent use of the virtual memory disc. This kind of disc uses the hard drive to store data needed for switching processes. But the access time to hard disc is 1000 times longer than access time to RAM. That is the reason of the increase of the process operation time. The distribution of execution time for four runs of the test process is shown in Figure 1.

Median [s]	0.507	1.467	2.379	3.355
Maximum value [s]	0.967	1.919	3.089	3.978
Minimum value [s]	0.094	0.998	1.935	2.901
Interval of values [s]	0.873	0.921	1.154	1.077
Most frequent value [s]	0.421	1.326	2.028	3.042

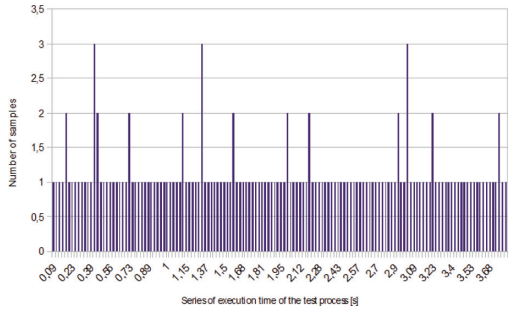

Figure 1. Series of execution time for four run of the test process (source: authors own work).

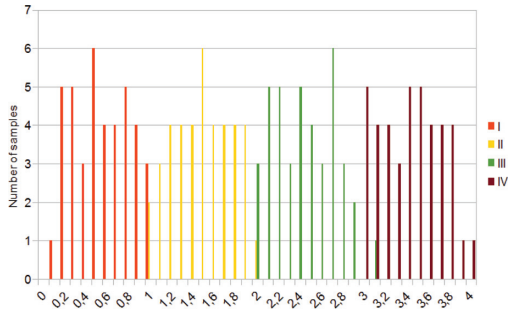

Figure 2. Distribution of execution time for four operations of the test process (source: authors own work).

The data gathered during the experiment were used to present the distribution functions for all four operations of the test process. Data gathered during the experiment were used to present the distribution functions for all four operations of the test process.

It was made in order to compare them to each other. The graph of the distribution functions of the execution time is shown in Figure 2.

The biggest difference in value is observed during the third run of the test process (Fig. 2). This is the result of the highest increase of the amount of RAM allocated for it. During the third process operation 216 MB growth of the amount of RAM is observed. The difference between the lowest and the highest value of the execution time of the test process is 1.154 s. Dynamic change of RAM allocated for the test process force the memory management subsystems to handle other processes and allocate them to the virtual memory if necessary. Computer operating system memory manager has to store information about memory pages, counters of instructions and value of CPU registers at the virtual memory drive. The virtual memory drive is controlled by the computer hard disk drive. Because the virtual memory uses com-

puter hard disk drive, the time needed to access the data is 1000 times longer than in case of RAM.

The lowest scatter of values of the execution time is observed during the first operation of the test process. Although during that action the amount of RAM proportionally rises 16 times (see Table 2), the dynamic increase of the amount of memory has no influence on the scatter of the time of process execution.

Almost all, except the second one, distribution functions of the execution time of the test process shown in Figure 2, show that they are multi-mode. Only the second run of the test process is similar to one-mode distribution. The total interval of the operation time of the test process is between 0.094 s and 3.97 s.

The increase of the amount of RAM for proper operation of one process requires more frequent use of virtual disk. That may imply the longer time of process execution and may result in the lower efficiency of the system. In the worst case scenario, there may be not enough space on the hard disk drive. If computer hard disk drive does not have sufficient space to store all the data related to all working processes, the host computer operating system may break down. Such a situation requires the restoration of the operating system. Unexpected failure may stop computer work for a long time (hours or even days). During that time, information stored on computer hard disk is not available. It is possible that some files stored on hard disk may lose their integrity as a result of a computer failure.

3.1 *Evaluation of the correlation between two independent working processes*

During the next experiment, the influence of one working test processes on the second test process was evaluated. At the beginning, the second process was started-up without the test processes. Then, time of completing the main task was recorded. After that, both processes were run concurrently and the time of completing the main task was recorded. The second process makes only the addition of two integer variables and the result is assigned to third integer variable, but the result of this operation is not sent to an output device such as computer monitor. Values for both test processes measured out during the experiment are shown in Table 4.

The data shows that the influence of any working process on the other working process is negligible. It was not possible to observe any big differences in the time of execution of the second test process. We may conclude, that if a process does not use output devices, the differences in execution time in both experimental cases are negligible.

Table 4. The comparison of the execution time the second test process (source: authors own work).

No of operation the second test process	Without acting test process [s]	With acting test process [s]
1	0.187	0.203
2	0.234	0.265
3	0.234	0.265
4	0.234	0.265
5	0.234	0.234
6	0.218	0.280
7	0.219	0.265
8	0.250	0.249
9	0.250	0.265
10	0.250	0.266
11	0.281	0.265
Average:	0.236	0.257

Time needed to transfer data from computer operating memory to device memory is far longer than in case when all the results are stored into computer operating memory. Because all the results of the second process were stored in computer operating memory, the differences between the execution time are small (Table 4). The difference between the average value of the execution time in each case is 0.021 s.

4 CONCLUSIONS

The evaluation of the efficiency of the host computer operating system shows that it is possible to cope with the rapid increase of the operating memory use. Rapid growth of RAM allocated to a process affects the time of its execution. The test process execution time rose more than 3 times.

During the experiment it was observed that if the process does not use memory-consuming external devices, the increase of the execution time was less than 9% in both test cases. In conclusion, the influence of interaction between two processes is negligible.

Control-in-the-loop Model Based Safety Analysis

P.-Y. Piriou, J.-M. Faure & J.-J. Lesage
Automated Production Research Laboratory, Ecole Normale Superieure, Cachan, France

ABSTRACT: In most cases, Model Based Safety Analysis (MBSA) of critical systems focuses only on the process and not on the control system of this process. For instance, to assess the dependability attributes of power plants, only a model (Fault Tree, Markov chain …) of the physical components of the plant (pumps, steam generator, turbine, alternator …) is used. In this paper, we claim that for repairable and/or phased-mission systems, not only the process but the whole closed-loop system Process/Control must be considered to perform a relevant MBSA. Indeed, a part of the control functions aims to handle the dynamical mechanisms that change the mission phase as well as manage repairs and redundancies in the process. Therefore, the achievement of these mechanisms depends on the functional/dysfunctional status of the control components, on which these functions are implemented. A qualitative or quantitative analysis method which considers both the process and the control provides consequently more realistic results by integrating the failures of the control components that may lead to the non-achievement of these mechanisms. This claim is exemplified on an industrial study case issued from a power plant. The system is modeled by a BDMP (Boolean logic Driven Markov Process), assuming first that the control components are faultless, i.e. only the faults in the process are considered, and afterwards that they may fail. The minimal cut sequences of the system are computed in both cases. The comparison of these two sets of minimal cut sequences shows the benefit of the second approach.

1 INTRODUCTION

Model-Based Safety Analysis (MBSA) can be defined as "an approach in which the system and safety engineers share a common system model created using a model-based development process" (Joshi et al. (2006)). MBSA performed for critical controlled systems are most often applied on a model of the process alone. This is the case for example in Chaux et al. (2012) and Sondermann-Woelke et al. (2012). In particular, the last publication highlights the role of control for the application of redundancies, but does not consider control failures. These approaches take into account mechanisms of reparations and redundancies in the plant but they omit that the functions which manage these mechanisms can fail, as well as the components which support them. Two kinds of control failures can then be distinguished: software and hardware based. This paper does not consider the software failures because they can be avoided (or at least limited) by using one of the numerous existing formal verification techniques, like for instance model checking (more details on this issue may be found in Berard et al. (2001)). But with the increase of the digital components in complex controlled systems, dependability studies performed for these systems cannot underestimate probable failures of the control components. Indeed, even if these components have a good reliability, their failures remain possible, especially when the concerned systems have a long lifespan. Moreover, new studies integrate more and more injuries whose causes are external (fire, flood, terrorist attacks …). These injuries concern the plant components as well as those of the controller without distinction between them. Hence control should be considered in the loop for MBSA practices, and this paper aims to show that this issue carries significant consequences on both the modeling and the results.

Indeed, the more complex the system is the more switching mechanisms appears in the controlled process (due to fault tolerance, mission phase changes, maintenance based on autotest …). These switching mechanisms are handled by functions implemented into components of the control. Therefore, the achievement of these mechanisms depends on the ability of the control components to perform them. Hence, the failure of the control components may lead to the non-achievement of these mechanisms, what may have a significant influence on the results of a qualitative MBSA. Moreover, the formalism for performing MBSA are generally not made for taking into account the loss of these switching mechanisms.

In order to illustrate this issue, the paper considers an industrial controlled system on which a comparison study is performed. First the system failure is represented by a model that complies with the BDMP formalism. Second, the minimal cut sequences are extracted from this model. Section 2 describes the case study and gives the definition of the BDMP formalism. Section 3 applies the MBSA stated above while considering only the process failures. Then a control architecture is described, and added to the model in section 4. For integrating these new failures in the model, three models are proposed and discussed. In the same section, the set of minimal cut sequences is updated, and compared with the previous one. This comparison shows that the control failures have a significant influence on the qualitative analysis of the system. Finally, the last section draws up concluding remarks and outlooks.

2 BACKGROUND

This section introduces the case study used in this paper and recalls the basics of the BDMP formalism.

2.1 *The coolant feeding system*

In order to exemplify our claim, we consider the case study presented in Chaux et al. (2012). It is a coolant feeding system issued from a power plant. Its purpose is to supply cooling fluid to the steam generator. It is composed of two redundant groups of pumps, and a strongly redundant power supply (Fig. 1). The two groups of pumps are series-connected and the first one is powered by the power supply. The power supply of the second group of pump is not considered here.

Six kinds of components can be identified:

- The Grid (Grid) is the source of electricity supply.
- The electric Transformers (Tr1 and Tr2) decrease the voltage (from 400 kV to 6.6 kV).
- The Distribution Boards (DBA1, DBA2, DBB1 and DBB2) transfer the electricity from their inputs to their output.
- The Diesel generators (Diesel1 and Diesel2) are other possible sources of electricity supply.
- The Extraction pumps (Ex1, Ex2 and Ex3) provide a sufficient flow of cooling water.
- The Feeding Turbo Pumps (FTP1 and FTP2) pressurize the cooling water.

All the components may fail and be repaired. The diesel generators and the pumps may fail not only when they are active but also when they are dormant. The system fails when its supply function cannot be achieved. To avoid this general failure, several redundancies are defined:

- An active material redundancy is defined for the group of components (DBB1, DBB2).
- A passive functional redundancy is defined for the groups of components (DBB1, Diesel1) and (DBB2, Diesel2).
- A simple passive material redundancy is defined for the group of components (Tr1, Tr2), (DBA1, DBA2), (FTP1, FTP2).
- A 2 out of 3 passive material redundancy is defined for the group of components (Ex1, Ex2, Ex3). If one of the two primaries pumps fails, the third is activated.

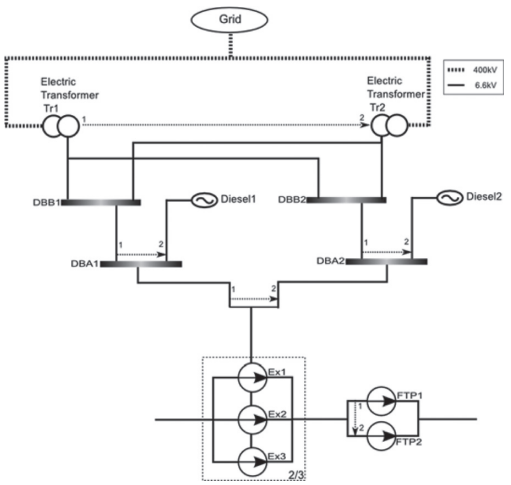

Figure 1. Schema of the coolant feeding system process.

2.2 *Recall on the BDMP formalism*

The BDMP is a formalism defined by Bouissou & Bon (2003) to address the dynamic modeling issues while preserving the structure-expressiveness of tree based formalisms (fault tree approaches). Indeed, a static fault tree model aims to describe the system failure as a combinatorial expression on the failures of its leaves (a leaf model a component). The BDMP formalism keeps the same idea, but the Boolean basic leaves of the tree are replaced by dynamic ones specified by Markov Chains (MC). In particular, repairable components can be considered. Moreover, these MC can consider non dysfunctional events to model switching between different operations modes (active, dormant …). The occurrence of these non-dysfunctional events is managed by triggers. In particular, a passive redundancy mechanism can be modeled by such a trigger. Hence, a BDMP model can be implicitly defined as a multi-top

coherent tree structure whose leafs are triggered MC. Since it is the unique formalism dedicated to the modeling of dynamic repairable systems, it is relevant to model the case study considered in this paper.

Most often, only two kinds of leaves are used and are called *F* and *SF*. The *F* leaves describe components fallible only in active mode, whereas *SF* leaves describe components fallible in both active and dormant modes ($L = L_F \cup L_{SF}$) The behavior of these leaves is specified by the models depicted on Figure 2. Since this paper addresses a qualitative analysis only, the labels of the arcs correspond to events. For performing a quantitative analysis, they should be considered as probability rates. In this figure: the events a-X, d-X, f-X-a, f-X-d and r-X, denote respectively the activation, the deactivation, the failure in active mode, the failure in dormant mode and the reparation of a component X. The two mainly used kinds of logic gates in a BDMP are *AND* and *OR*. But some works use an additional kind: the *PAND* gate. Such a gate expresses a dynamic logic: the failure status of a *PAND* gate is *True*, if and only if the failure status of all its children is *True* and have commuted from *False* to *True* in a predetermined order (generally from left to right in the tree).

Let us call the children of a given node (leaf or gate) the leaves of the sub-tree whose node is the root (if the node is a leaf then it has a single child: itself). Let T_i be a trigger, and ($Orig(T_i)$, $Dest(T_i)$) denoted respectively its origin and destination nodes. While $Orig(T_i)$ is not failed, the children of $Dest(T_i)$ stays in the dormant mode (the children of kind *SF* can still fail). When $Orig(T_i)$ fails, the MC of the children of $Dest(T_i)$ are triggered to the active mode, as soon as $Orig(T_i)$ is repaired. Then, they are put back in the dormant mode. For a better description of the BDMP semantics, see Chaux et al. (2011).

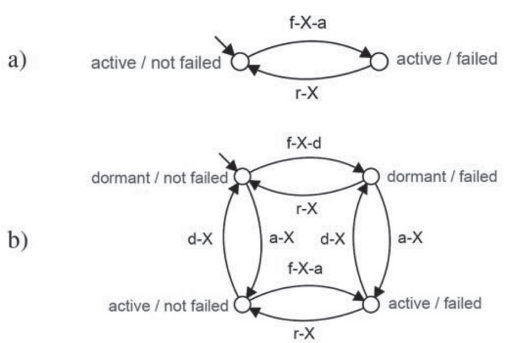

Figure 2. Behavior of the most used BDMP leaves: a) the *F* leaf; b) the *SF* leaf.

3 SAFETY ANALYSIS CONSIDERING ONLY THE PROCESS FAILURES

In this section, a BDMP model of the system is built considering only the failures of the process components. Then a qualitative analysis based on this model is performed.

3.1 *Building the BDMP model of the process*

Figure 3 shows the BDMP model of the coolant feeding system process.

The scenarios implicitly described by this BDMP model can be explicitly represented by the sequences of dysfunctional events that can occur. The next subsection aims to determine among them the shortest sequences which lead to the system failure.

3.2 *Extracting the minimal cut sequences*

In the dependability scope, a qualitative study consists in determining the main weaknesses of a system. This knowledge can be used for easing the qualitative study, what become essential when complexity increases.

For static systems, these analyses consist in determining the *Cut,* which is defined by Birnbaum et al. (1961) as a set of failed components that leads to the system failure. A *Minimal Cut* of a static system has then been defined by Rauzy (2001) as a prime implicant of the related Boolean function which can be modeled using fault trees.

For dynamic systems, the system failure depends not only on the set of failed components but also on the order of occurrences of these components failure events. Then *Cut Sequences* and *Minimal Cut Sequences* have been defined by Tang and Dugan (2004), as respectively *Cuts* and *Minimal Cuts* whose component failures have been ordered.

But when the considered system contains repairable components, the failure events are not sufficient to describe all the possible way to fail. Then a *Cut Sequence* is redefined as a sequence leading to the first system failure. Chaux et al. (2013) proposes a framework to give a formal definition of *Minimal Cut Sequences*. Informally, the set of *Minimal Cut Sequences* (MCS) is the minimal set of sequences of minimal length that are necessary and sufficient to describe the whole set of cut sequences.

In order to extract these MCS, we use the algorithms defined in Chaux et al. (2011) and Chaux et al. (2012). The first one transforms a BDMP model into a finite state automaton and the second one extract the MCS of a finite state automaton. Several MCS limited to the length 5 (selected arbitrary among the 84 existing) extracted

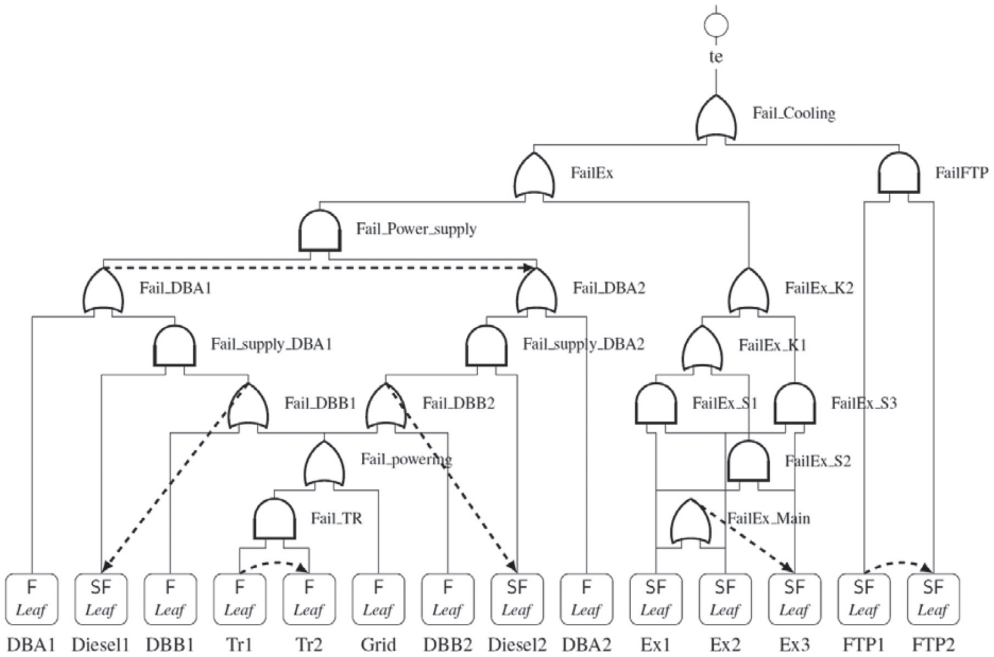

Figure 3. BDMP model of the coolant feeding system process.

Table 1. Examples of MCS of length from 2 to 5 considering only the failures of process components.

Length	Sequences
2	f-DBA1-a,f-DBA2-a
	f-Ex1-a,f-Ex3-a
	f-FTP2-d,f-FTP1-a
	… (6 others)
3	f-Die1-d,f-Die2-d,f-Grid-a
	f-DBA1-a,f-Die2-d,f-DBB2-a
	f-Grid-a,f-Die1-a,f-DBA2-a
	… (16 others)
4	f-DBB1-a,f-Die1-a,f-Die2-d,f-DBB2-a
	f-Tr1-a,f-Die1-d,f-Die2-d,f-Tr2-a
	… (36 others)
5	f-Tr1-a,f-DBB1-a,f-Die2-d,
	f-Die1-a,f-Tr2-a
	f-DBA1-a,f-DBB2-a,r-DBA1,
	f-Die2-d,f-DBA1-a
	… (15 others)

from the BDMP model described by the last subsection (Fig. 3) are sum up on Table 1.

Let us remark that from length 5, the MCS may contain repair events. For instance, the sequence f-DBA1-a → f-DBB2-a → r-DBA1 → f-Diesel2-d → f-DBA1-a, is minimal because the failure in dormant mode of the component Diesel2 may not occur without the previous reparation of the component DBA1. Then there exists no shorter cut sequence to fail by this way.

4 SAFETY ANALYSIS CONSIDERING THE CONTROL IN THE LOOP

In this section, the control system which manages the process components, and in particular the mechanisms of redundancies, is introduced. The modification of a BDMP model containing triggers is discussed. Then the control system failures and reparations are integrated to the BDMP model given in the last section. Finally, the MCS of the complete system are extracted and compared with the previous ones.

4.1 *Description of the control architecture*

A control architecture can be defined as the allocation of the control functions on the control components. In this paper, we focus on the control functions which manage the redundancies defined for the process. Moreover, only the passive redundancies require a switching management. Then among the redundancies defined in the subsection 2.1, only six are concerned. Let R_A, R_B, R_C, R_D and R_E be the functions which manage the switching between respectively (DBB1, Diesel1), (Tr1, Tr2), (DBA1, DBA2), (FTP1, FTP2), (Ex1, Ex2, Ex3). Since the switching between (DBB2, Diesel2) is of the same kind that the one between (DB1, Diesel1), it is also managed by R_A.

Each function R_X (for $X \in \{A, B, C, D, E\}$) is implemented on a couple of redundant PLC (Pro-

grammable Logic Controller): (PLCX1, PLCX2). The PLCs are connected to the process via two redundant buses (BUS1, BUS2). These redundancies are active, that is mean all the components are working, and the information must be treated and carried by at least respectively one PLC and one BUS. The control architecture of the coolant feeding system is depicted on Figure 4.

The loss of a switching function R_X (for $X \in \{A, B, C, D, E\}$) allocated to the components PLCX1 and PLCX2 can be represented by the BDMP model reported in Figure 5.

4.2 *Modeling a switching function in a BDMP model*

In this work, a switching mechanism consists in the transfer of the service achievement from a component (or sub-system) to another. The expected behavior of a passive redundancy can then be defined with two conditional switching mechanisms ("component" can be replaced by "sub-system" below):

- *Replacement switching*: if the main component fails then a switching must occur from the main component to the spare one.
- *Withdrawal switching*: if the main component is repaired then a switching must occur from the spare component to the main one.

Thereby, if the function which manages the redundancy is lost, these switching cannot occur when they should do. In particular, if this function is lost after the failure of the main component but before its reparation, the withdrawal switching cannot occur.

Since the semantics of a BDMP trigger complies with this definition (sub-section 2.2), a passive redundancy can be correctly modeled by such a trigger. Then the loss of the function which manages a redundancy corresponds to the loss of the corresponding trigger in the BDMP model. Figures 6, 7 and 8 show three possible models of the loss of the switching function R_D for the subtree corresponding to the feeding turbo pumps (gate FailFTP and leaves FTP1 and FTP2).

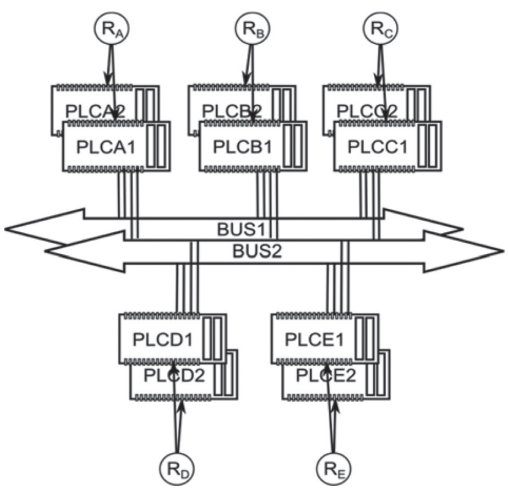

Figure 4. Schema of the control architecture.

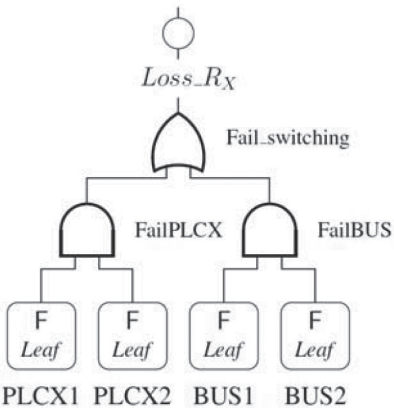

Figure 5. BDMP model representing the loss of a switching.

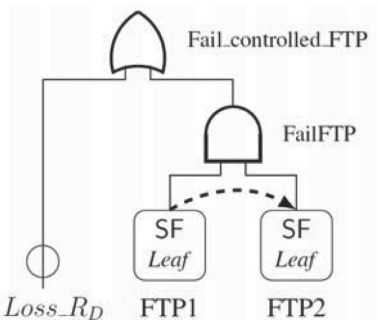

Figure 6. First solution to model the loss of a trigger in a BDMP model.

The first proposition (Fig. 6) expresses that while the switching function is loss, the group of pumps cannot perform its service even if none of them has failed. This model is very pessimistic because the main pump does not need the switching function for working alone. However in the case of a material redundancy, the function that manages a redundancy and the function that control the process components involved in this redundancy, are allocated on the same control components. Indeed, there is no need to be able to switch between two components if it is not possible to control them. In this case, the loss of the switching function occurs as the same manner as the loss of the control function. And this model expresses that when the switching function is loss, the control function is

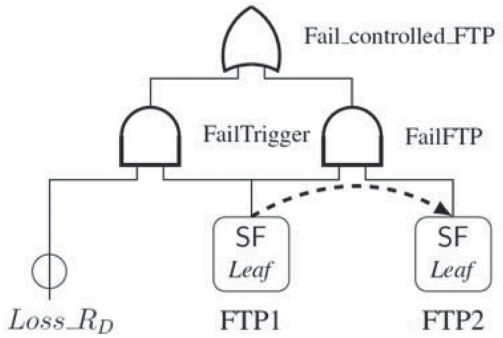

Figure 7. Second solution to model the loss of a trigger in a BDMP model.

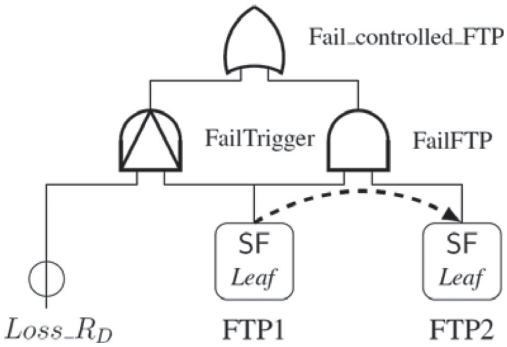

Figure 8. Third solution to model the loss of a trigger in a BDMP model.

also loss; then the group of pumps can actually not perform its service.

The second proposition (Fig. 7) expresses that while the switching function is loss and the main pump failed, the group of pumps cannot perform its service.

The third proposition (Fig. 8) expresses that if the main pump fails after the loss of the switching function, then the group of pumps cannot perform its service (the gate FailTrigger is a PAND).

In order to choose between these three propositions, let us consider the critical sequence: f-FTP1-a → f-Loss RD-a → r-FTP1 → f-FTP2-a. The expected behavior described by this sequence is informally reported below:

1. Initially, the service is provided by FTP1.
2. After the failure of FTP1, the replacement switching occurs (from FTP1 to FTP2) by means of the function R_D.
3. After the loss of R_D, the service is still provided by FTP2.
4. After the reparation of FTP1, the withdrawal switching (from FTP2 to FTP1) cannot occur because of the loss of R_D; then the service is still provided by FTP2.
5. After the failure of FTP2, the service is not provided anymore (even if FTP1 had been repaired).

Let us remark that since this sequence leads to the first failure of this sub-system, it is a cut sequence for this sub-system. Table 2 compares the accuracy of the three models proposed for this sequence. The accuracy criterion is here the conformance between the expected and the modeled behavior. The cells show the pump which provides the service, if any and the symbol Ø otherwise. Let us remark, than the last event is called f-FTP2, because it corresponds to f-FTP-d in the BDMP models, but should be f-FTP2-a in the reality.

Table 2 shows first that none of the models is perfectly accurate. Indeed, a perfectly accurate model would specify exactly the same behavior as the expected one for any sequence. Moreover, the third model is the closest of the reality, but it is not conservative. Indeed, it misses at least the cut sequence considered above. It is also the case for the second model. We are then constrained to choose the first model, because despite its bad accuracy, it is the only one which is conservative. This discussion shows that the BDMP formalism (the unique one which is dedicated to model the repairable dynamic system) has not the semantics required for correctly model the loss of a trigger. More generally, the gates of a BDMP are focused on the failure events and not the repair events. Then the consequences of the reparation of the trigger's origin are fixed by the semantics of a trigger, and cannot be changed by modifying the structure.

4.3 *Integrating the control failures in the BDMP model*

Figure 9 shows the BDMP model of the entire controlled coolant feeding system. This model had been constructed by applying the model chosen in the last subsection for each passive redundancy. The new gates are darkened. The intermediate events of kind $Loss_R_X$ (for $X \in \{A, B, C, D, E\}$) should be replaced by the corresponding sub-tree (see Fig. 5).

4.4 *Comparing the new MCS with the previous one*

Considering the control failures brings many new sequences as can be seen on the Table 3 that sums up several MCS selected arbitrary. Since the process has not been changed, it can still fail as presented in the last section. Then the new MCS includes the previous one. But 94 new sequences are added to the 84 previous ones (for the sequences of length

Table 2. Confrontation of the behavior described by the three models to the expected one on a critical sequence.

Sequence	$1 \xrightarrow{f-FTP1-\alpha} 2$	$\xrightarrow{f-LOSSR_D-\alpha} 3$	$\xrightarrow{r-FTP1} 4$	$\xrightarrow{f-FTP1} 5$	
Expected	FTP1	FTP2	FTP2	FTP2	Ø
1st model	FTP1	FTP2	Ø	Ø	Ø
2nd model	FTP1	FTP2	Ø	FTP1	FTP1
3rd model	FTP1	FTP2	FTP2	FTP1	FTP1

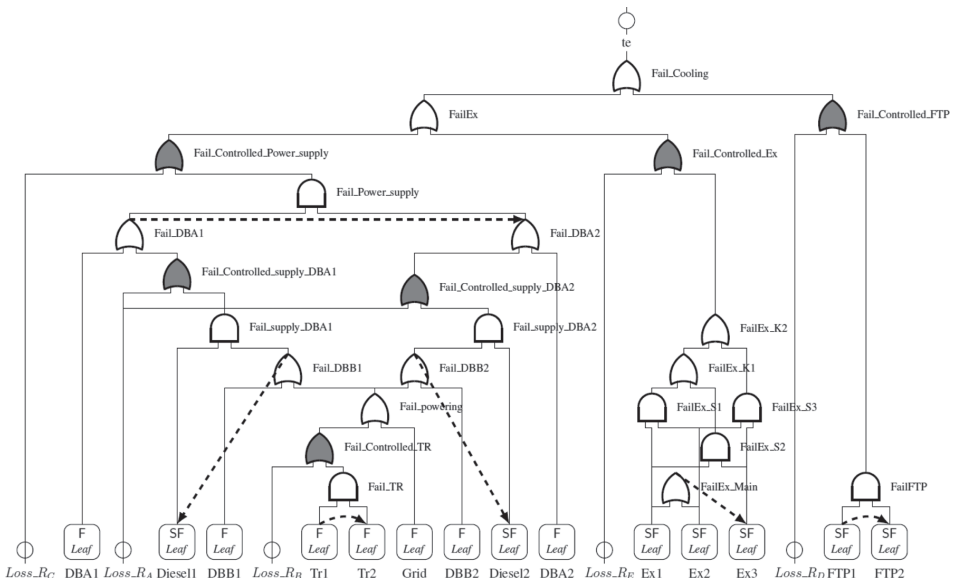

Figure 9. BDMP model of the controlled coolant feeding system.

lower than 5). Among them, 10 new sequences of length 2 show that the buses and the PLC which host the function R_A, R_C, R_D and R_E are very critical. Indeed, the achievement of the system function depends directly on the success of these groups of redundant component. Moreover, 54 new sequences of length 4 and 30 new sequences of length 5 that mix failures of both process and control components appear.

For instance, the sequence f-PLCB2-a → f-Die2-d → f-PLCB1-a → f-DBA1-a describes the behavior informally reported below:

1. Initially, the power supply is performed by the first line (Grid, Tr1, DBB1, DBA1) and the pumping services by Ex1, Ex2 and FTP1.
2. After the failure of PLCB2, nothing happens because it is in active redundancy with PLCB1.
3. After the dormant failure of Diesel2, nothing happens because the power supply is still performed by the first line.
4. After the failure of PLCB1, the controlled transformers are considered unavailable; then DBB1 and DBB2 either. The switching function R_A is not lost then the replacement switching from DBB1 to Diesel1 occurs. The power supply is performed by Diesel1 and DBA1.
5. After the failure of DBA1, the first line cannot supply the power anymore. The switching function R_C is not lost then the replacement switching from the first line to the second one occurs. But DBB2 does not transfer the power supply (because of the failure of the controlled transformers). The switching function R_A is still not lost then the replacement switching from DBB2 to Diesel2 occurs. But Diesel 2 has already failed in dormant mode. Then there is no other way for performing the power supply. Hence the coolant feeding system fails.

This set of MCS is a pessimistic representation of the weaknesses of the system considering both the process and the control. The number of MCS extracted is more than twice bigger when the control is considered. This observation confirms that the control should be taken into account in

Table 3. Examples of MCS of length from 2 to 5 considering the failures of both process and control components.

the MBSA studies for systems that bring many switching mechanisms. Let us remark that the results depend on the architecture choice for the control as well as the process. Then another choice of allocation of the control functions on the control components would lead to different results.

5 CONCLUSIONS

This paper claims that the failures of control components should not be omitted in the MBSA. A comparative study is performed on an industrial example. The system is modeled by a BDMP considering first only the process failures, and then considering also the control failures. The failures of control components may lead to a loss of the switching functions which handle the redundancy mechanisms between the process components. Hence we propose a modification of the model for considering the loss of these switching functions in a BDMP model. The study shows first that the set of MCS extracted is twice bigger from the model of the controlled process than from the model of the process (without taking into account the control). Furthermore, it shows that BDMP formalism is not fully adapted to deal with this issue.

Since this formalism does not allow us to describe correctly the loss of a switching function, ongoing works are aiming to define an extension of this formalism which offers that possibility. Furthermore, the consideration of failures in a closed loop system raises a failure propagation in-the-loop issue that cannot be addressed by a method based on tree formalism like BDMP. Hence, developing a qualitative analysis that deals with this issue is also under investigation.

ABSTRACT: The work permit process offshore is established to maintain control of which activities that are to be carried out on the installation and to manage their risk. This paper reports on the development of a shared information surface which can support the assessment of work permits. Findings from an initial usability study are provided.

1 INTRODUCTION

A field study was conducted on an offshore installation with the aim of studying communication of risk in the planning process and how technology can better support mediation of this through the planning process. The aspects of risk communication and management in the offshore work permit system are reported in (Sarshar et al., 2013) while this paper reports on one application of the technology aspects. The question is what information and knowledge do we recommend to depict on a shared surface to provide situation awareness at a glance. This paper reports on the development of a concept for providing overview of ongoing and planned maintenance activities at an installation, based on learnings from observations and interviews (Skjerve et al., 2011, Sarshar et al., 2013) with personnel involved in assessment of offshore work permits.

Integrated Operation (IO) in the petroleum industry has for many years included distributed collaboration as a key support capability. The technologies used to enable distributed collaboration, e.g. between onshore and offshore, have evolved from phone calls and teleconference to video conferencing rooms, to desktop solutions and lately towards more mobile solutions (Sarshar & Rindahl, 2014). As described by Kaarstad and Rindahl (2011) IO can improve access to information and provide a shared awareness in decision-making. One important feature is the increased availability of real-time data that makes it possible for personnel at different locations to cooperate based on a shared and up-to-date description of the operational situation. Another important enabler of improved decision-making in IO is a shared collaboration surface. A shared collaboration surface can provide a common and coherent representation of goals and activities and what the participants understand to be the agreed decision. Further, using such a collaboration surface, the participants can give their confirmation of the understanding of the decision, and it can be saved for future reference. This increases understanding and commitment within the team, and significantly reduces the risk of later, possibly wrong or vague, interpretations.

Chapter 2 describes in brief the work permit system followed by previous work in chapter 3. The method and approach for the development is described in chapter 4. Chapter 5 describes the interactive surface developed and chapter 6 describes the initial usability study of the tool. Chapter 7 discusses the results from the usability study before conclusions are made in chapter 8.

2 THE WORK PERMIT SYSTEM

Planning of offshore activities can be divided in different time horizons: a main plan has the horizon of several years, a yearly plan spans for one year, operational plan for three months, work order plan for one or two weeks and work permit plan which has the horizon for the next 24 hours.

The work permit system is established to maintain control of which activities are to be carried out on the installation and to manage their risk. Activities that typically require a work permit is maintenance work be it on the process equipment, pipes or structure of the platform. There are two main categories; corrective or preventive maintenance. Work permits are divided in two levels to differentiate between their impacts on risk. High-risk jobs which e.g. require welding are of level 1 while lower risk jobs are of level 2. Jobs that have been identified as no risk activities do not require a work permit

and typically include jobs inside the living quarter, in office spaces or in workshops. We limit our scope to tasks that require a work permit.

There are several technical disciplines offshore including process technicians, instrument technicians, electrical technicians and mechanical technicians. Each discipline goes through the work orders which they are responsible for and divide the task through the week with respect to their priority and available resources.

A work order describes a job package and can normally be divided into subtasks that can be carried out in sequence. Before any of these can be performed, the personnel that shall execute a task must apply for a work permit. The work permit system is established to ensure scrutiny of factors related to HSE (Health, Safety and Environment) before job execution. The work permit for each task is discussed between representatives from the various disciplines in plenum and the job description and related safety measures are evaluated. Examples of such are safety equipment needed to perform the job safely. A general work permit flow is described in (NOG, 2006). After job execution, the job responsible logs feedback from the execution and closes the job in the maintenance management system.

The management systems for work orders and work permits are typically specialized enterprise resource planning ICT tools, like SAP ERP. These are good at managing data related to these activities, but are not normally regarded as best in human-interaction in terms of supporting decision making and providing a good overview.

3 THE IO-MAP PROTOTYPE

The IO-MAP prototype tool (Skjerve et al., 2011) was developed to explore how future technology could enhance collaboration between distributed teams, e.g. onshore and offshore. It was developed to visualize work permits and potential associated risk related to HSE using a graphical map representation. The work permits were given a geographical location and displayed in a map view. The usability study from this prototype shows that there is a huge potential in visualizing and presenting information this way. The project reported on in this paper makes use of learnings from the IO-MAP development and design (Braseth & Sarshar, 2012). Figure 1 illustrates the 2nd version of the IO-MAP tool.

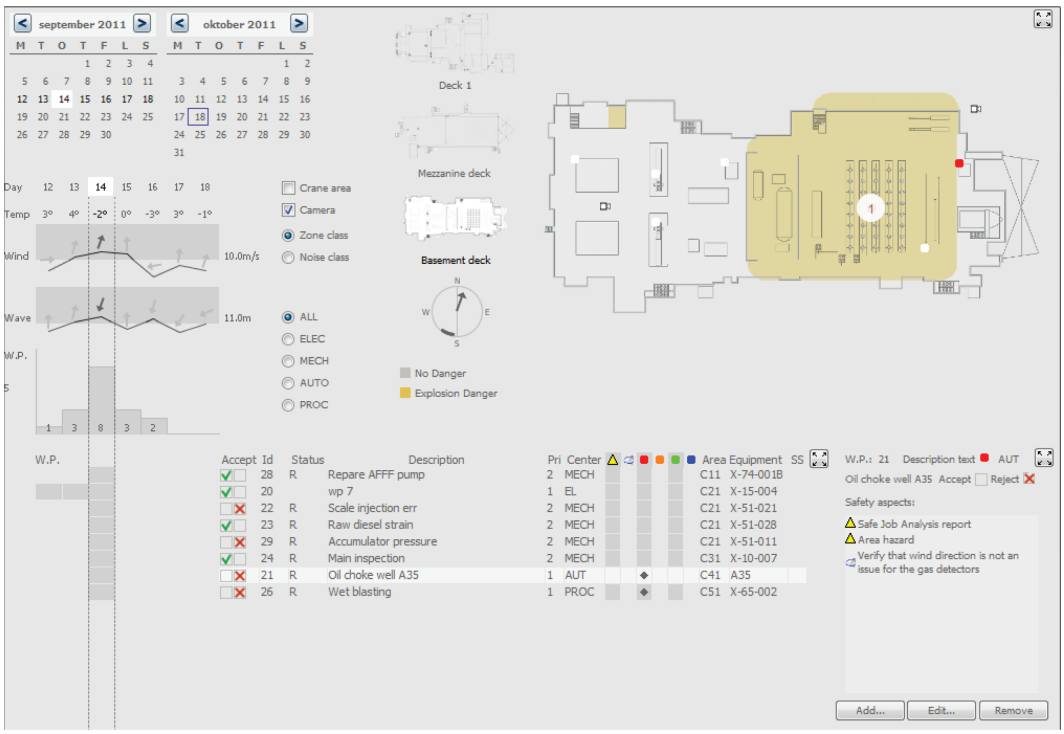

Figure 1. The 2nd version of the IO-MAP tool (Braseth & Sarshar, 2012).

4 METHOD

4.1 *Design rationale*

The focus of the design process was to create a large collaborative touch surface, which facilitated easier collaboration and discussion between technicians offshore. Design choices were therefore made on the background of creating a clear visualization of the current activity level on the installation to improve the decision making process. The design also aimed to create a means for accumulating different observations from different planners, further encouraging a discussion regarding the planned work permits.

4.2 *Iterative process*

The prototype's design was created through an iterative process consisting of several workshops. On two occasions expert evaluations with different interaction designers were conducted. The design phase spanned a total of eight iterations, where each workshop or expert evaluation resulted in a new iteration. After the final iteration, the resulting design was implemented in a high fidelity prototype.

4.3 *Implementation*

The design was implemented using various web technologies, namely JavaScript, SVG, and PHP. The architecture is based on traditional client-server architecture, with a database and client-side scripts on the server side, and scripting on the client-side to handle touch events, changes to the user interface, and calls to the server. The prototype was organized into six modules: Map, legend, activities, news, weather and info. The map module contains an SVG map of a selected deck, and shows activities based on location. Each activity on the map listens to touch events that trigger an "information box" to show and display information about the selected activity. The activity module is implemented as a bar chart using the JavaScript library d3.js, and based on a sorting algorithm that decides the placing of the different activities.

5 THE INTERACTIVE SURFACE

The interface design was based on a literature research on visualization and interaction design. Additionally, the design choices relied on IFE's (Institute for Energy Technology, Halden) expertise and experience with designing user interfaces for industrial control rooms. The design of the IO-MAP tool is the closest project to ours. While the focus when developing the IO-MAP tool was on the planners onshore, the tool developed here focuses on work permits planned to be carried out or under execution on current day.

The developed interactive surface is illustrated in Figure 2. The color scheme of the prototype is

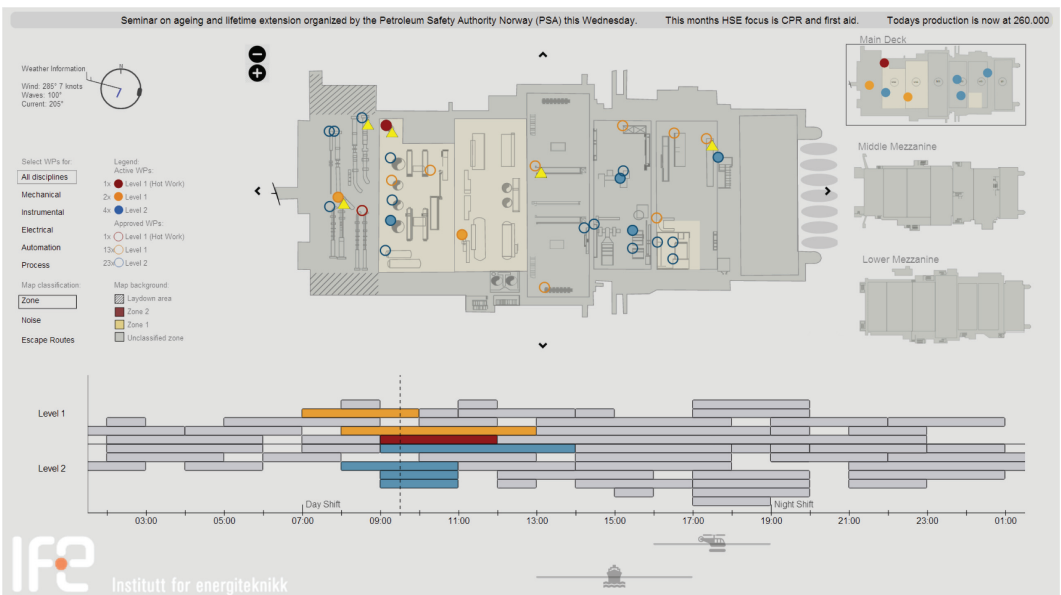

Figure 2. The interactive surface (HIØ, 2013).

muted, and strongly influenced by the IO-MAP prototype. The muted background without hard lines or borders is based on the design principles of Edward Tufte (Tufte, 1990), a design choice also used in several other interfaces created at IFE.

A grey color scheme was used for text and borders in order to avoid hard lines. Additionally, strong colors were avoided, and used deliberately only for warnings and potential hazards.

To maintain a user-friendly interface, the Schneiderman's principles (Schneiderman & Plaisant, 2010) were applied. The principle of consistency was maintained by using the same selection type for the corresponding elements in the prototype. Example of this is selection of decks where selected thumbnails in the map module were marked by a grey frame. Furthermore, active work permits on the map and selected work permits in the graph or map were marked by the same white border.

The prototype consists of six modules: legend, activity, info, weather, news and map. The map module presents the deck of an offshore installation. Thumbnails representing other decks in the installation can be used to change the deck displayed in the map module. An additional feature provided by the map module is the possibility to zoom in on the selected map. When zoomed in one or more levels, the map offers a more detailed view of the deck, displaying smaller equipment not presented in the previous zoom level. When zoomed in, the map can also be "panned" using a drag gesture. In order to maintain overview of the platform, changing deck while zoomed in will retain the zoom and pan placement of the map. This way, looking for dangers in the levels above or below an activity is easier and encouraged.

Work permits are classified using three different colors. Level 1 work permits are colored yellow, and work permits involving hot work are colored red. Level 2 work permits are colored blue. Work permits involving hazards will display warnings in form of a yellow triangle next to the circled work permit on the map. Activities, which are scheduled but not started, are visualized as unfilled circles. When a job is started, the circle is filled using the corresponding color. By selecting an activity on the map using the tap gesture, the information box module is invoked.

The information box module contains information regarding the highlighted activity, in the form of a transparent pop-up box. The information displayed is: Work Permit ID, Equipment ID, Work Permit Level, start and end times, a textual description of the work permit, a hot work tag, discipline tag and a hazard description. This box provides contextual information regarding the selected work permit and is displayed both when interacting with the map module, as well as the activity module.

The activity module consists of work permits of all types visualized as bars. Each work permit bar has a start and stop time which is extracted from a database. The work permits are placed in the graph using a simple algorithm, sorting the jobs by length and work permit type. The work permits, which are not currently active, are displayed as grey. A currently active work permit is displayed using its corresponding color. These colors are explained in the legend module.

Furthermore, the legend module explains the color codes of the different map zones such as "laydown area" as well as a count of currently active and scheduled work permits. The legend allows for filtering both active and scheduled work permits by discipline such as "Mechanical" and "Electrical". These filters could help different planners focus on their discipline and its interaction with others, as they have different backgrounds, experiences and concerns when conducting their planning. This filtering also affects the count of current jobs, in order to allow the users to quickly assess the current activity level on the platform for the chosen discipline. As a final functionality, the map can also be edited to different map classifications, highlighting noise levels, escape routes or the default view presenting the different classification zones of the deck.

The weather module provides the information surface with valuable condition information such as wind force and direction as well as wave and current direction. This weather info may be relevant to leaders and technicians before the work permit is initiated. This module along with the news module works in isolation from the other modules, but serves the surface in providing a better overview of the platform. The news module displays announcements and news, which may be relevant to the execution of planned work permits.

6 USABILITY STUDY

The functional prototype was evaluated in a usability test, by two participant groups. The first group was students with previous IO backgrounds, and the second group was employees at IFE with relevant experience the field of IO or the petroleum industry. The participants were not actual end users.

The main purpose of the usability test was to assess to what extent the prototype facilitates a group of users to perceive an overview of the activity level on a petroleum installation. Another focus of the evaluation was to appraise if the prototype visualizes risk and concurrency conflicts. A final aspiration was to evaluate if the prototype can be useful as a tool for a group of people to

collaborate and discuss the plan and ongoing activities. The usability test was conducted at IFE's Future Laboratory, see Figure 3. Previously, the prototype was prepared and tested to be working on a large touch surface in the Future Laboratory. Although, not all planned features were ready for testing core functionality was implemented. At the time of testing, area selection, equipment selection and the weather module was not implemented, and therefore not tested in the scenarios.

Zooming on the map for greater detail was implemented, however, as there were issues with this functionality; this was also omitted from the scenarios.

The usability test consisted of five phases: Introduction, training session, scenarios, questionnaire and interview. In the introduction the participants were provided a small introduction of the evaluation and the prototype, and were then asked to sign a form of consent. In order to prepare the users for the prototype, there was a small training session in which the users were trained in the functionality of the prototype. A technical assistant was the tutor for this session, and helped the participants navigate and understand the functionality of the prototype. Following the training session, each participant was assigned a fictive role for the scenarios. These roles were based on actual job descriptions for onshore and offshore personnel. Each role had different goals and responsibilities to keep in mind during the testing. The roles included:

- Platform Manager
- Health, Safety and Environment Manager
- Maintenance and Operation Manager
- Leader of Mechanical technicians
- Leader of Electrical technicians

The scenarios were created to be as realistic as possible, and were designed to enable the users to test all the functionality in the prototype. There were a total of six scenarios. The scenarios were created to explore different possibilities of using the prototype to evaluate the work permits of the day plan. The intent of the scenarios was also to find potential conflicting activities, consequences of delayed activities or possible hazards. As each participant had his or her own goals concerning their role, the user test format facilitated discussion surrounding the scenarios. In order to facilitate discussion, the scenarios were made to be approved

Figure 3. Illustration of the interactive surface in use on a large touch screen at IFE's Future Laboratory.

by one point of view, but not another. In addition to the scenarios, there were hidden conflicting work permits and problems in the schedule. These "Easter eggs" were hazards, which would cause problems in carrying out the planned activities.

After the participants had completed the different scenarios, they were asked to fill out a questionnaire. The questionnaire was based on a questionnaire previously used in the usability study to evaluate the IO-MAP (Skjerve et al., 2011). The questionnaire was divided in three parts: participant's background, information—and risk visualization, and usability. The usability test was concluded with a semi-structured group interview, designed to gain further understanding of the participant's experience of the prototype, and to facilitate a group discussion concerning the scenarios and the prototype. Most of the questions in the interview were intended to give an answer to whether or not the prototype fulfilled the research questions. Additional questions were based on observations from the solving of the scenarios.

7 RESULTS

The results from the questionnaire are displayed in Table 1 and Table 2, which are divided in two parts. The first part concerns the scenarios; how easily they could identify risk, and how well the prototype visualized information. The other part consists of statements based on the System Usability Scale (SUS), where every other statement is positive, and the other negative. All statements are ranged from the scale of 1 (strongly disagree) to 7 (strongly agree).

7.1 *Interviews*

What was your overall impression of the prototype? The participants agreed that the overall impression was good. It was stated by one of the participants that the prototype was intuitive and pleasant to use. Another participant stated that "The prototype is a great discussion tool for gathering different domain knowledge in a group", and argued that this was probably the greatest strength of the prototype.

What do you feel worked well? What did not work well? Why? The option to filter on disciplines was regarded as a very useful function, and the fact that all information was displayed in one page was considered to be good, as it was easy to get an overview of the situation without navigating to different pages. The prototype received negative feedback in regards to responsiveness, and the participants felt the hardware did not respond well to the touch gestures. Regarding visualization, it was suggested to add arrows to escape routes. Some participants also felt that it was difficult to locate a specific activity, and suggested adding an ID in addition to the circle representing an activity.

What were your thoughts on solving the different scenarios? The participants thought the task of solving the scenarios went very good, some also said it was fun. The only scenario they agreed were troublesome was the one where they had to find an

activity with the only information given was the ID and the discipline.

Were some of the scenarios more difficult to solve than others? One of the groups had trouble with the scenario where they had to find an activity with crane work that could not be executed while the helicopter was on deck. They explained that they did not know about the expression "laydown-area", which was the clue to discovering this hazard.

How was it working collaboratively on the prototype? Several of the participants felt that this was one of the strengths of the prototype, while one of participant mentioned that while it was good for discussion, simultaneous interaction was not possible.

Do you have any suggestions for improving the prototype? Many of the suggestions for improvement were mentioned earlier in the interview, such as adding IDs to the activities, and adding arrows to the escape routes. Other improvements that had been mentioned earlier were adding crane activities as a discipline, and being able to drag the timeline to a different time, or rearranging the activities. Other suggestions were to visualize the number of workers for each activity, and to display an indication of the duration of an activity on the map.

8 CONCLUSIONS AND FURTHER WORK

The primary objective of the project was to create a prototype of a collaborative interactive surface intended to facilitate discussions concerning the day plan, and to give a clear visualization of the amount of activities on a petroleum installation. Based on the results from the initial usability tests we can conclude that the prototype has achieved the objectives of displaying a clear overview of the activity level, and facilitated a group to collaborate and discuss the day plan. The reason why the prototype could accommodate for such behavior is that an interactive surface which gives a clear visualization of the activities—their location and the surrounding circumstances—allows for more accurate discussion than without the use of visualization. Consequently it is easier for the individuals within the group to imagine the impact of each activity, and share this observation with the rest of the group. By gathering these individuals in front of the interactive surface it is likely that they will identify more potential hazards, errors and inconsistencies of the day plan than they would alone, or without the use of the tool. The systems they have available today are mostly one user desktop software solutions which do not support groups collaborating.

Further work include to test the tool with offshore personnel and other end users to get input for improvements and to better understand the overall objective of how technology can better mediate risk communication in IO.

ABSTRACT: GAMM (Graphical Analysis for Maintenance Management) is a method that supports decision-making in the overall maintenance management through the visualization and graphical analysis of data, which has been developed and published by the authors. In addition, it allows for the identification of anomalous behavior in the equipment analyzed, whether derived from its own operations, maintenance activities, improper use of equipment or even as a result of design errors in the equipment itself. As a basis for analysis, the GAMM method uses a nonparametric estimator of the reliability function using all historical data or, alternatively, part of the history, allowing it to perform an analysis even with limited available data.

However, for successful results are strictly necessary the experience and advanced knowledge about maintenance management process. With regard to the interpretability of GAMM method, a set of basic rules have been developed in this paper. This set of rules aim to help and support to maintenance managers to get a right and objective interpretation, improving the decision making. Typically, engineers have validated intelligent software system performance by running test cases through a system and comparing results against known results or expert opinion. We adopt this method of validation by comparing the results of selected cases by GAMM with the recommendations of HIMOS (Hybrid Intelligent Maintenance Optimization System, University of Salford), which was compared and validated by an expert panel.

1 INTRODUCTION

The importance of the maintenance function management has grown in the past decade as a result of the continuous advancement of industrial organizations towards more efficient operations and improved productivity (Kah 2001). The basic concept leading to the maintenance engineering is the continuous improvement of the maintenance management process by incorporating knowledge, intelligence and analysis. They support the decision-making in the field of maintenance and are designed to enhance the global output of economic and operational result (Barbera 2012).

The development and application of graphical tools supporting decision making in the area of operational reliability (Birolini 2007) is a fundamental task to achieve an accurate and efficient management of assets and resources in an organization, even when there is a large number of devices with functional configuration that is highly complex. To obtain real applications of analytical models, practical, functional, innovative and simple tools must be generated (Barbera 2013). This will help to make tactical and operational decisions easier. Additionally, the development of simple technical tools to facilitate the exercise of analysis and results outcome (Nelson 1969) provides a framework for the control and monitoring of action plans implemented in terms of maintenance activities.

The GAMM (Graphical Analysis for Maintenance Management) (Barbera 2013) method is a graphical tool based on collected data related to the sequence of technical equipment revisions. This method of graphic analysis adds variables with useful information that allows the management to visualize support patterns and make decisions in the overall maintenance management, such as: number of technical revisions performed, type (corrective or preventative), duration, operational failure during the routine service, reliability of the equipment before the service, or the variability of equipment failure over a period of time. Moreover,

GAMM provides a visual representation from a complete or partial historical record of the maintenance work performed, showing different patterns of analysis that provide useful information for decision making and problem solving (Barbera 2013).

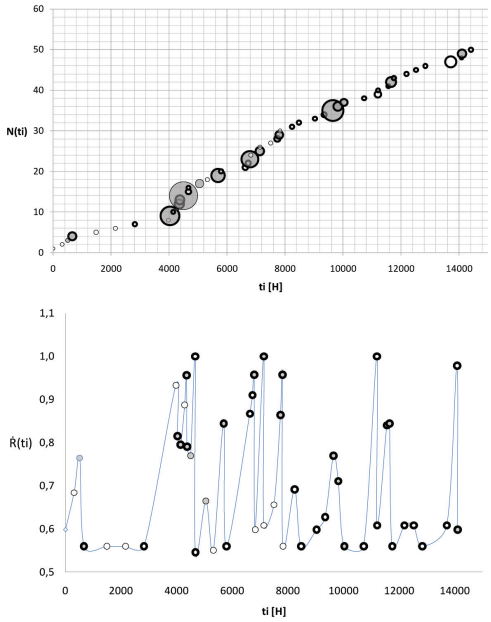
To help maintenance managers to make decision making based on GAMM analysis and interpretation, this article proposes a set of rule-based GAMM for preventive maintenance program evaluation. The maintenance manager will be able to make the best decision making according to some basic rules about the GAMM graphics (Graphic 1, Graphic 2). The set of rules provides easy access to certain variables patterns showing useful information for maintenance management and decision making in the short, medium and long term. This paper is a complementary research of GAMM method, published by Barberá et al. in 2013.

2 PROBLEM STATEMENT AND PURPOSE OF STUDY

GAMM method (Barbera 2013) is a support tool for operational maintenance management and preventive maintenance program evaluation. The tool provides useful information regarding the reliability and maintainability of systems or equipment for analysis when considering variables such as type of intervention, duration of intervention or the existence of a stop during the intervention of the equipment/system. This broadens the spectrum display for maintenance management, acquiring new evaluation parameters and graphically determining possible areas of improvement.

The graphics of GAMM (Graphic 1, Graphic 2) illustrate aspects such as: trend of the interventions, deviation in the frequency of preventive interventions, reliability function, efficiency of maintenance operations, impact by unavailability, quality in the intervention performance, quality in use and operation of equipment by staff responsible of it, among others. Thus, the tool proposed provides information that is useful, clear and easy to interpret.

However, for successful results are strictly necessary the experience and advanced knowledge about maintenance management process. With regard to the interpretability of GAMM method, a set of basic rules have been developed in this paper. This set of rules aim to help and support to maintenance managers to get a right and objective interpretation, improving the decision making. Afterwards, in this paper we adopt the method of validation using data of (Kah 2001), by comparing the results of selected cases by HIMOS with the recommendations of an expert panel and GAMM method.



HIMOS (Hybrid Intelligent Maintenance Optimization System) is a system for decision support in maintenance management. More specifically, HIMOS helps to determine the optimal maintenance policy, essentially the frequency of Preventive Maintenance (PM) which minimizes the sum of down time due to PM and CO (Corrective Maintenance). HIMOS uses an 'intelligent' decision support system to carry out an automated analysis of the maintenance history data. Maintenance data are presented to the system and the most suitable mathematical model from a model-base is identified utilizing a hybrid knowledge/case based system (KBS = CBR) (Kah 2001). Thus initially a rule base is applied to select a model. If no model is matched, the system reverts to its historical case-base to match the current case with a similar case that has been previously modelled. This double reasoning adds to the system's true learning capabilities (intelligence) and increases the rate of success of model selection. The study results include optimal PM intervals for a sample of industrial data sets.

3 REVIEW GAMM METHOD

According to (Barbera 2013), the Graphical Analysis for Maintenance Management (GAMM) is a quantitative and qualitative analysis method that intends to support decision making in maintenance management using the logic of a dispersion diagram and also integrating the following variables: type of intervention, duration of intervention, and state of equipment/system during the intervention. The combination of these new variables with a graphic display (Graphic 1 and 2) of the sequence of interventions generates synergies with regard to the information given by the diagram, thus establishing new sources of analysis.

In addition, GAMM is able to estimate the reliability function, which is calculated using the algorithms on the basis of the nonparametric method of Nelson–Aalen, and evaluated in the time ti, that is, in the moment before the intervention. The estimation method can consider both the historic full data and the censored historical data.

GAMM provides useful information regarding the reliability and maintainability of systems or equipment for analysis. This broadens the spectrum display for maintenance management, acquiring new evaluation parameters and graphically determining possible areas of improvement. The graph-

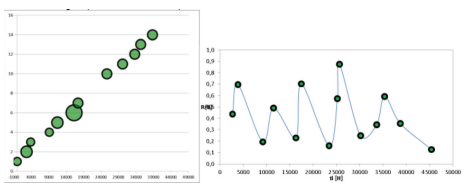
Figures 1 and 2. Examples of the graphs generated by GAMM (Graphic 1, Graphic 2).

ics of GAMM illustrate aspects such as trend of the interventions, deviation in the frequency of preventive interventions, reliability function, efficiency of maintenance operations, impact by unavailability, quality in the intervention performance, quality in use, and operation of equipment by staff responsible of it, among others.

GAMM allows viewing different patterns of analysis that provide useful information to assist decision making at the operational level, for example:

- Trends in the behavior of the interventions.
- Preventive Maintenance (PM) deviation: adding variable analysis as the type of intervention can display the frequency of completion of PM (programmed) and therefore can track and monitor the attainment of the established PM frequencies in the program.
- Quality of operations and/or PM: a graphic display of interventions by type (preventive or corrective) provides the sequence recognition of certain patterns that can define the quality of operation and/or the performing PM activities. This way, by observing corrective interventions within preventive ones, sequences of corrective short term stop pages and accumulation of corrective interventions immediately follow a PM intervention; the existence of problems in the execution of the duties or how the equipment operates is evident.
- Reliability function: GAMM shows the reliability of the equipment/system at preintervention, complementing the analysis of the quality of operation and/or PM. This demonstrates, for example, the existence of corrective interventions in periods of high levels of reliability (this indicate abnormal premature failure).
- Efficiency and quality in the implementation of interventions: the duration of each intervention is represented by the size of the bubble in GAMM (Graphic 1). This variable identifies those interventions that are beyond the average times of intervention, questioning if the schedule of the workload is right or if the deviation in execution times is due to external factors such as lack of tools, waiting for parts, lack of staff training, and so forth.
- Impact on production: the stop variable (Det) determines the status of equipment/system at the time to intervene. The bubbles with hard shaded border represent interventions in which the equipment stops, affecting their individual availability and possibly affecting the overall system availability.

Finally, GAMM is a quantitative and qualitative analysis that intends to support the decision making in the overall maintenance management (Barbera 2013), which helps to reduce the high costs of unavailability of the system or the maintained equipment as well as the costs associated with unforeseen maintenance interventions. The combination of analysis patterns presented provides valuable information to implement action plans to improve the global maintenance management. This specifically included the performance of equipment and, ultimately, to achieve a management that is efficient, effective, and opportunistic, identifying gaps to help determine the root causes thereof.



4 RULE BASE OF GAMM METHOD

In the industrial environment, it requires expertise to choose the most appropriate decision to a situation represented by real world data. To help maintenance managers to make decision making based on GAMM analysis and interpretation, a set of rule-based GAMM for preventive maintenance program evaluation is required. The maintenance manager will be able to make the best decision making according to these set of rules about the GAMM graphics (Graphic 1, Graphic 2). The rules provides easy access to certain variables patterns showing useful information for maintenance management and decision making in the short, medium and long term.

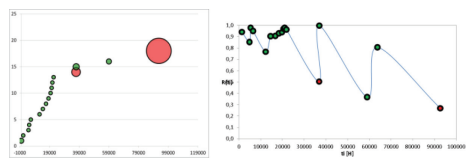


Table 1. Rule base of GAMM method.

Rule 1	If the Graphic 1 shows a line of $N(t_i)$ (number of interventions) vs t (time) which has approximately constant slope and $R(t_i)$ ranging between $R(t_i)$ max = 1.00 and $R(t_i)$ min = 0.70, then you have an acceptable[R1.1] maintenance program. If the line of $N(t_i)$ vs t has not a constant slope or $R(t_i)$ has sudden or large fluctuations, then the maintenance program is not optimal. R1.1: regular number of maintenance events over an increasing operating time which means that a certain average reliability over time is guaranteed thanks to your maintenance activities.
Rule 2	If number of PM[1] interventions > 80% of the total interventions ($N(t_i)$), then it could be considered as an acceptable[R2.1] level of PM. If number of PM interventions > 95%, then increase PM interval could be considered[R2.2]. If number of PM interventions < 80%, then it could be necessary to evaluate the quality and frequency of the PM interventions. Decrease PM interval could be considered[R2.3]. R2.1: according to many industry best practices. However we should check the effects of existing failures and how they are distributed just in case they may become critical (size of the circle). R2.2: Number of PM interventions > 95% could also be a consequence of excessive maintenance to some non-critical failure modes. R2.3: Number of preventive interventions below 80% are scenarios showing room for potential improvement of PM policies.
Rule 3	If there are CO[2] interventions carried out in periods of high reliability ($R(t_i) > 0.85$) or shortly after a PM intervention (less time than the average duration between PM interventions), then the PM task before that CO intervention could be poor (problems in the execution of PM intervention) or the failure could be the result of improper equipment operation, among others, and it is necessary to evaluate it.
Rule 4	If there is a logic/constant pattern of PM durations[R4.1] (downtimes, according to the tasks carried out on each intervention), then the PM program duration shows consistent maintainability. If there is a high variability of PM durations, then deviations in execution time due to external factors (lack of tools, waiting for parts, lack of staff training, accessibility problems, etc.) should be checked. R4.1: However, in some cases there are two or more different patterns of PM duration due to, e.g., overhauls.
Rule 5	If the temporal pattern of time between PM interventions is not constant, then the maintenance program is probably not well scheduled or its fulfillment should be reviewed.

5 VALIDATION OF RULES

Validation aims at substantiating that GAMM performs with an acceptable level of accuracy. In the literature several validation methods are found. In (O'Keefe 1987), there is a review of qualitative and quantitative validation methods for expert systems. In O'Leary 1987), a different framework for system validation is suggested, which includes content validity, criterion validity, objectivity and reliability. Typically, engineers have validated intelligent software system performance by running test cases through a system and comparing results against known results or expert opinion. We adopt this method of validation by comparing the results of selected cases by GAMM with the recommendations of HIMOS, which was compared and validated by an expert panel.

To validate the use of the proposed interpretation rules, GAMM method was applied to analyze a total of 5 sets of historical data, from the petrochemical industry (Kah 2001).

Figures 9 and 10. Graphic 1 and Graphic 2 of GAMM for using data set 4.

Figures 11 and 12. Graphic 1 and Graphic 2 of GAMM for using data set 5.

Table 2. Comparison between HIMOS and GAMM recommendations for 5 data sets.

Data set 1	
HIMOS	Increase PM interval from 135 to 176 days (CBR-Geometric I model)
GAMM	R(ti) has sudden or large fluctuations: **maintenance program is not optimal**. Number of PM interventions > 95%: **increase PM interval could be considered**. There is a logic/constant pattern of PM durations (downtimes, according to the tasks carried out on each intervention): **PM program duration shows consistent maintainability**. The temporal pattern of time between PM interventions is not constant: **maintenance program should be reviewed**.
Data set 2	
HIMOS	Increase PM interval from 177 to 403 days (CBR-RPOW model)
GAMM	The line of N(ti) vs t has not a constant slope and R(ti) has sudden or large fluctuations: **maintenance program is not optimal**. Number of PM interventions > 95%: **increase PM interval could be considered**. There is a logic/constant pattern of PM durations (downtimes, according to the tasks carried out on each intervention): **PM program duration shows consistent maintainability**. The temporal pattern of time between PM interventions is not constant: **maintenance program should be reviewed**.
Data set 3	
HIMOS	Increase PM interval from 159 to 223 days for the first sequence but gradually decrease to 86 days (tenth sequence) (NHPPScoSpm model)
GAMM	R(ti) has sudden or large fluctuations: **maintenance program is not optimal**. Number of PM interventions > 95%: **increase PM interval could be considered**. There are CO interventions carried out in periods of high reliability (R(ti) > 0.85) and also shortly after a PM intervention (less time than the average duration between PM interventions): **PM interventions before that CO interventions could be poor** (problems in the execution of PM intervention) or the failure could be result of improper equipment operation **and it is necessary to evaluate them**. There is a logic/constant pattern of PM durations* (downtimes, according to the tasks carried out on each intervention): **PM program duration shows consistent maintainability**. The temporal pattern of time between PM interventions is not constant: **maintenance program should be reviewed**.
Data set 4	
HIMOS	Increase PM interval from 108 to 140 (first sequence)–117 (tenth sequence) days (RPDWSco)
GAMM	R(ti) has sudden or large fluctuations: **maintenance program is not optimal**. Number of PM interventions > 95%: **increase PM interval could be considered**. There are CO interventions carried out shortly after a PM intervention (less time than the average duration between PM interventions): **PM task before that CO intervention could be poor** (problems in the execution of PM intervention) or the failure could be the result of, improper operation of equipment **and it is necessary to evaluate them**. There is a logic/constant pattern of PM durations* (downtimes): **PM program duration shows consistent maintainability.** The temporal pattern of time between PM interventions is not constant: **maintenance program should be reviewed**.
Data set 5	
HIMOS	Decrease PM interval from 103 to 21 days (Delay-time Model, Weibull distribution, manual selection mode)
GAMM	Graphic 1 shows a line of N(ti) (number of interventions) vs t (time) which has partially constant slope and R(ti) has sudden or large fluctuations: **maintenance program is not optimal**. Number of PM interventions < 80%: **it could be necessary to evaluate the quality and frequency of the PM interventions. Decrease PM interval could be considered**. There are CO interventions carried out in periods of high reliability (R(ti) > 0.85) and shortly after a PM intervention (less time than the average duration between PM interventions): **PM task before that CO intervention could be poor** (problems in the execution of PM intervention) or the failure could be the result of improper operation of equipment **and it is necessary to evaluate them**. There is a high variability of PM durations: **deviations in execution time due to external factors (lack of tools, waiting for parts, lack of staff training, accessibility problems, etc.) should be checked.** The temporal pattern of time between PM interventions is not constant: **maintenance program should be reviewed**.

In (Kah 2001), these data sets were analyzed by an expert panel (five experts in maintenance modeling) and HIMOS with the aim of comparing their recommendations of appropriate maintenance policies for each data set. Table 2 summarises the recommendations of HIMOS and GAMM.

It is interesting that, being the general HIMOS advice is in accord with GAMM, GAMM is able to show additional information considering different variables and using the same data sets.

As can be seen in Table 2, for each data set there was general agreement between the results produced by HIMOS and the recommendations of GAMM. Thus, it was agreed that the proposed rule base is suitable for the right and objective interpretation of GAMM method, improving the decision making based on this method.

This expertise is usually provided in a Knowledge-Based System (KBS) or 'intelligent' DSS (IDSS) by the knowledge subsystem. In GAMM, this expertise concerns the right interpretation of the graphs (performed from a data set) based on the rule base proposed. The rules were developed by looking for patterns in different data sets for different equipments and considering all aspect of GAMM method, such as: relative numbers of CO and PM events, range of PM intervals, intervention durations and reliability before of each intervention, among others. The knowledge base implemented in GAMM consists of the set of 5 rules shown in Table 1.

6 CONCLUSIONS

The aim of this paper was to present and validate a proposed rule base to help and support to maintenance managers to get a right and objective interpretation of the graphs of GAMM method, which has been developed and published by the authors. Additionally, for validation of the proposed interpretation rules, GAMM method was applied to analyze a total of 5 sets of historical data (shown in the appendix) from the petrochemical industry, previously analyzed by HIMOS. Comparing their recommendations, for each data set there was general agreement between the results produced by HIMOS and the recommendations of GAMM.

As a future research line, it is interesting that the joint application of HIMOS and GAMM could be considered as a quantitative and qualitative analysis that intends to support the decision-making in the overall maintenance management and helps to reduce the high costs of unavailability of the system or equipment, as well as the costs associated with unforeseen maintenance interventions. The combination of the different analysis patterns provides valuable information to implement action plans to improve the global maintenance management. This specifically included the performance of equipment/systems by optimization of the PM cycle interval for a repairable system (frequency) and, ultimately, to achieve a management that is efficient, effective and opportunistic, identifying gaps to help determine the root causes thereof. So, the joint application of HIMOS and GAMM could be a support tool for operational maintenance management of short and medium term. They provide useful information, clear and easy to interpret which can be checked with one another in order to determine the optimal maintenance policy (frequency of preventive maintenance). This broadens the spectrum display for maintenance management, acquiring new evaluation parameters and determining possible areas of improvement. This way it could be possible to show quantitative and qualitative maintenance implemented activities and its operational implications on the reliability and maintainability of the equipment or system, within the maintenance management process.

A discussion of the risk-management and the rule-compliance regulation regimes in a security context

S.H. Jore & A. Moen
University of Stavanger, Norway

ABSTRACT: In recent years, the use of risk-management approaches for protecting vital societal functions and critical objects has increased in many countries. In Norway, new object security legislation based on a risk-management approach has been passed, and new standards for security risk analysis have been developed.

Hopkins (2011) has described two different regimes for regulating risk; "the risk-management regime" and "the rule-compliance regime". This paper aims to describe the consequences of these two regimes in a security context, and to discuss some of the challenges of applying a risk management regime within the area of security. We conclude that risk-management and rule-compliance are intertwined and complementary strategies. The issue, therefore, is not to decide between the two; it is to get the balance right.

There are some aspects with security risks that make the application of a risk-management regime challenging; Terrorism is a highly uncertain risk and the political aspect of the threat and how to handle it implies that the risk of terrorism is highly ambiguous. Acts of terrorism are obscure, low-frequency events where strategically calculating human beings are the ones who possess the threat. Terrorists can strike suddenly, without warnings and cause enormous damage. Additionally, often the area of security is just one of several risks an organization has to take into account, and most organizations will have the main focus on safety risks because these will be assessed to have a higher probability of occurring. Furthermore, most organizations in Norway lack security competence, benchmarking is difficult because the area is often classified, and little is known about the effect of counterterrorism measures.

1 INTRODUCTION

While security from intentional acts, such as terrorism, used to be an area of secrecy where the security services played a central part, mitigation and protection from the threat of terrorism has nowadays become an area where citizens, companies and different official bodies have a shared responsibility. This is reflected in the many official strategies against terrorism which have been published in most Western countries in recent years (Aly, 2013; Jore, 2012). In order to manage the risk of terrorism, governments in most Western countries have highlighted risk-management thinking as a tool for protecting critical objects and critical infrastructures against the threat of terrorism, especially after the terrorist attack in the US on September 11th 2001 (9/11) (Office U. S. G. A., 2005).

Traditionally, Norway was seen as a quiet outpost of Europe. However, in the aftermath of the 9/11 terrorist attack the focus on terrorism as a risk against Norwegian society has gradually increased (Jore & Njå, 2008). The bombing of the Norwegian government complex and the shooting massacre on the island of Utøya on 22. July 2011 where totally 77 people were killed (Gjørv, 2012), and the terrorist attack on the Algerian oil facility in In Amanas in January 2013 where 5 Norwegians employees in the Norwegian oil company Statoil were killed (Statoil, 2013), have further increased the focus on protection from the threat of terrorism in Norway. After these two incidents, both evaluation reports concluded that there had not been sufficient focus on security from intentional acts, and that the attack could either have been avoided or the impacts could have been reduced if the companies or official bodies responsible had taken the necessary precautions (Gjørv, 2012; Statoil, 2013). In the aftermath of these events new object security legislation based on a risk-management approach was passed in January 2011 (Forsvarsdepartementet, 2011), and in order to lay a foundation for better risk analysis of intentional acts three standards for protection against intentional acts have either been published or are in progress (Standards Norway 2012; 2014a,b).

Several scholars have over the years discussed and described two different regimes for regulating risk. Different terminologies have been used to describe these two regime (Ayres & Braithwaite, 1992; Gunningham & Rees, 1997; Baldwin & Cave, 1999; Hale et al., 2002; Hood et al., 2001; Lindøe,

2002; Hutter & O'Mahony, 2004; Hutter & Power, 2005; Hutter & Jones, 2007; Braut & Lindøe, 2008; Baldwin et al., 2010; Coglianese & Mendelson, 2010; Baram et al., 2013. Hopkins (2011) refers to these regimes as the "risk-management regime" and the "rule-compliance regime". The distinction and the balance between these two regimes have been extensively discussed, and most regulatory regimes today build on a mixture of these two regimes. However, most of these discussions have been related to the area of safety from non-intentional accidents. The consequences and the balance between the two regulatory regimes have not been discussed in relation to security from intentional crimes. This paper aims to describe the consequences of these two regimes in a security context, and to discuss some of the challenges of applying a risk-management regime within the area of security. In line with Piètre-Cambacédès & Chaudet (2010) we call protection from terrorism or other intentional crimes for security—in contrast to safety risks witch implies protection from non-intentional acts.

We conclude that risk-management and rule-compliance are intertwined and complementary strategies. The issue, therefore, is not to decide between the two; it is to get the balance right. Furthermore, because of the nature of the security risk the risk-management regime is challenging in a security context.

2 THE RULE-COMPLIANCE REGIME

Historically, rule-compliance was the dominating approach for how to regulate hazardous activities. Governmental regulation of HSE was during the first part of the 20th. Century dominated by a top-down command and control-based regulatory model characterized by prescriptive regulations, involving detailed, specific and often technical requirements. During this time period, the authorities met new risks related to technological development by applying more prescriptive regulations. In most industries, such as nuclear and oil and gas, risk management was traditionally based on this prescriptive regulating regime, in which detailed requirements for the design and operations were specified (Lindøe, Kringen, & Braut, 2012). Although this regime is often referred to as the historical regime which today is challenged by the risk-management regime, this regime is still present in many sectors. In the area of security, this is the regime which is applied for example in the post-911 aviation security regime.

2.1 *Advantages with the rule-compliance regime*

In the rule-compliance regime, the authorities set out detailed regulations in order to steer the direction of companies, or others, in their security work. This will lead to a uniform implementation of security measures, meaning that each organization or critical infrastructure covered by a specific regulation will have the same level of security independently of an organization's perception of available resources, threat picture and former experience with the threat of intentional crimes. In a security context, this means that organizations or owners of critical infrastructures will implement the same level of security measures independently of whether a company or an owner of a critical object belong to a sector which has historical experience with acts of intentional crimes or terrorism. The post 9/11 aviation security regime illustrates this point. After the 9/11 terrorist attack, harmonization of airport security was the main goal of the EU regulations. As a consequence, all commercial airports in Europe had to follow the same security regime regardless of national or local threat assessments or previous experiences with acts of terrorism (Engen & Olsvik, 2010; Jore & Njå, 2012). The outcome of this regime was that small airports in rural parts of Norway were bound by the same regulations as giant airports in Europe such as Frankfurt or Heathrow.

The rule-compliance regime might lead to an easier management process within an organization, because the government agencies or supranational official bodies, such as the EU, have set the rules for when and how to implement security measures. The organization itself does not have to invest time and resources in evaluations of whether it should implement security measures or not, and this can make the decision-making process easier for the organization or the owner of a critical infrastructure or object. In aviation, the airports simply follow the regulations dictated by the EU. There is no decision-making process on each airport for deciding whether the airport should implement the measures or not.

It can also be claimed that the rule-compliance regime simplifies the job of the official bodies responsible for inspections since it is easier for official bodies to clarify whether a company has the expected level of security or not (Lindøe et al., 2012; Stålesen, 2011). The task of those who are doing inspections is simply to decide if the rules are followed or not, and not to decide whether the security measures are effective and in line with the threat landscape.

2.2 *Challenges with the rule-compliance regime*

Despite these advantages with the rule–compliance regime, there are also some challenging aspects with this way of managing security risks.

2.2.1 *The rules are in focus*

One challenging aspect with the rule-compliance regime is that it is the rules that are in focus, and not necessarily how to achieve the optimal level of security. Companies and inspectors operating in this security regime will be concerned with whether the rules are followed rather than how to achieve the optimal level of security from intentional crimes. In aviation, the prescriptive and detailed regulation regime offers no opportunity to locally assess and mitigate the risk of terrorism, unless there is an assessment leading to a strengthening of security beyond minimum requirements. Studies of the post-9/11 security regime in aviation have showed that the industry informants have been skeptical about the actual risk-reducing effects of the new security regime. They described several areas where the detailed and stringent regulations were problematic or burdensome or did not make any logical sense (Engen & Olsvik, 2010; Jore & Njå, 2012).

Moreover, if risk management is built on general rules rather than specific threat and vulnerability assessments for each and every organization; many organizations will implement security measures on a higher level than necessary and by this leading to an unnecessary level of costs and inconveniences for the company and its employees.

2.2.2 *A reactive regime*

Another challenging aspect with this approach is that since the process of changing regulation takes time, this security regime does not facilitate for quick changes in the regulations if the threat landscape changes. The rule-compliance approach has a tendency to involve a reactive response from the regulated organizations, meaning that rules are often made because a terrorist attack or a revealed terrorist plot have revealed vulnerabilities of the current security system. In aviation, numerous regulations have been added to the existing regulations because perpetrators have tried or carried through attacks against the system or because of revealed plots; The 2001 "shoe bomber" incident led to the shoe removal and screening policy, the liquid and gel ban policy was instituted after the 2006 plot to blow up planes bound for the United States with liquid explosives, and the 2009 Christmas Day bomber incident, where the perpetrators were carrying explosives in their undergarments, led to the deployment of advanced imaging technologies and pat-downs for all passengers. In all these cases, the changes in the regulations were a direct response to the attempt to commit an intentional crime (Jacobson, 2012). In fact, the whole new security regime in aviation was a direct response to the 9/11 terrorist attacks (Birkland, 2004; Engen & Olsvik, 2010; Salter, 2008).

3 THE RISK-MANAGEMENT REGIME

As mentioned earlier, the authorities traditionally met new challenges of technological development, related to risks and accidents by applying more prescriptive regulations. However, as time went by more detailed regulations were passed. The amount of regulations gradually increased to the point where it was completely unwieldy (Hale, Hopkins, & Kirwan, 2002; Lindøe, 2012). At the end of 1990's a review of the law and management structure in HSE area in Norway, displayed that there was over 60 laws and 1000 regulations governing this area (Lindøe, 2012).

In the 1970's, a new regulatory regime emerged, and the focus changed from detailed governmental control towards an internal control regime (Lindøe, 2012). In most industries the rule-compliance regime gradually was replaced by more goal-oriented regimes, focusing on what to achieve rather than on the means of doing so. Goal orientation and risk characterizations were two major components of this new regime that has been endorsed by international organizations and various industries (Aven & Renn, 2009).

The risk-management regime builds on the assumption that organizations or owners of critical infrastructures have the necessary competence for knowing what type of risks the organization can face in the future, and know the appropriate means for how these threats should be met. Consequently, the assumption is that organizations, because of their knowledge, have the ability to describe what may happen in the future, to assess associated risks and uncertainties and to choose among alternatives. (Aven, 2003). The assumption is that risk assessments should be a part of the decision support in a decision-making process in order to make ideal decisions about how to find the optimal level of security.

3.1 *Security is an organization's responsibility*

In the area of security, the state has traditionally been the one responsible for protecting citizens from acts of terrorism (Jore, 2012). However, the introduction of the new Norwegian object security regulation passed in 2011 (Forsvarsdepartementet, 2011), was based on what Hopkins (2011) refers to as a risk-management regime. This regulation gave the departments the responsibility of pointing out critical objects within its jurisdiction. The object security regulation contains a risk-based approach to how to protect a critical object, and it is the owner of the critical object which is responsible for conducting a risk analysis of valuation of assets, threats and vulnerabilities which will lay the foundation for what measures the organization should

implement. Owners of critical objects are also responsible for the implementation of risk reducing measures and to bear the associated costs.

The implementation of the new object security regulation marked a shift in who bear the responsibility for protecting citizens from acts of terrorism and other intentional crimes. A regulation founded on a risk–management approach entails that the responsibility for security no longer is dictated from the state but is delegated to the organizations that own critical objects or critical infrastructures. This implies a change in the role of the state regarding security related issues. In a rule-compliance regime, the state is a protector of law and the primary task is, by the use of legitimate authority, to force organizations to fulfill their obligation of following laws and regulations within legal binding norms. Anyone violating laws can be sanctioned and punished. In the risk-management regime the role of the state is not to enforce companies to follow certain rules, but to arrange for and assist organizations in finding the optimal level of security. This means that the official bodies responsible for inspection working in this regulation regime, have a different role than the inspectors working in the rule-compliance regime. The role of the official bodies doing inspections in the risk-management regime is to check if the organizations have carried through risk assessments and implemented measures in accordance with the risk assessments. The role of the inspector is, thus, changed from a punisher to an adviser.

3.2 *Flexible and in line with the current threat landscape*

In the risk-management regime the knowledge that an organization has regarding its assets, values, and vulnerabilities and associated threats is in focus. This means that the organizations have more flexibility in how to arrange its security regime, and can direct the security system against the threats that are considered to be most critical to the organization. Consequently, the organization can protect the assets which are assessed to be most valuable, and organizations can change and adapt security measures if the threat landscape changes. Despite these advantages, there are also some challenging aspects with the risk-management regime.

3.2.1 *The risk-management regime is no practical guide*

According to Renn (2008) there are various types of risks. For simple risks, the cause for the risk is well known, the potential negative consequences are obvious, the uncertainty is low and there is hardly any ambiguity with regard to the interpretation of the risk. Simple risks are recurrent and unaffected by ongoing or expected major changes. Consequently, statistics are available and the application of statistics to assess the risks in statistical terms is meaningful.

Renn draws attention to the fact that not all risks are simple: they cannot all be calculated as a function of probability and effect. Such risks are called systemic risks. The term systemic describes the extent to which a risk is embedded in the larger contexts of societal processes. The management of systemic risks, such as terrorism, requires a more holistic approach to hazard identification, risk assessment, and risk management because investigating systemic risks goes beyond the usual agent-consequence analysis. Systemic risks are not confined to national borders or a single sector and do not fit the linear, mono-causal model of risk. They are complex (multi-causal) and surrounded by uncertainty and/or ambiguity (van Asselt & Renn, 2011).

The goal of a terrorist attack is not only to cause damage but also to produce a signal effect of meanings. Thus, terrorism is also a crime against the mind (Burgess, 2007; Crelinsten, 2009; Jackson, Jarvis, Gunning, & Smyth, 2011). Subsequently, activists can gain extensive attention with threats only, and it is hard for society to assess what plans and capability actually are behind the threats. In other words, terrorism is a highly uncertain risk and the political aspect of the threat and how to handle it imply that the risk of terrorism is highly ambiguous. Acts of terrorism are obscure, low-frequency events where strategically calculating human beings are the ones who possess the threat. Terrorists can strike suddenly, without warnings and cause enormous damage to society. In order for a terrorist attack to be effective, the terrorists must keep a low profile; thus, a terrorist threat will be secret by nature and, therefore, to a large degree, not knowable by those who are responsible for the security (Aradau & van Munster, 2007).

What risk means in a security context and how the risk can be expressed and managed, is a contested topic in the scholar literature (Bier & Von Winterfeldt, 2007; Deisler Jr, 2002; Jore & Njå, 2010; Willis, 2007). Traditional quantitative risk analysis calculates risk based on the probability of an incident multiplied with the consequences. Newer perspectives often include uncertainties not captured in the probability or the background knowledge that the traditional risk estimates are based on (Aven, 2011). According to Aven (2013), in the area of security, application of probabilities is commonly avoided; it is said that they are impossible to determine and that they are of little interest as a tool to support the decision making. Often qualitative assessments are performed on the basis of judgments of actors' intentions and capacities, without references to a probability scale.

These views are reflected in the three standards for protection against intentional acts which have either been published or are in progress in Norway (Standards Norway 2012; 2014a,b). In these standards, risk is defined as a combination of valuation of assets, threats and vulnerability (Standards Norway 2012). The definition, thus, differs from the general ISO definition of risk being the "combination of the probability of an event and its consequence (ISO 2002). However, some targets are more attractive than others and as a consequence more likely to become a terrorist target. Even if the probability aspect is removed from the risk analysis the organization, in an actual decision-making context, still has to address this issue because to make decisions concerning risks means to direct the resources at the most likely targets.

Another challenge for organizations responsible for the risk assessment of intentional acts is how to include the relevant range of possible scenarios of intentional acts. The selection of scenarios is often heavily influenced by the last incident or the current understanding of the security landscape (Karlsen & Jore, 2013). After the terrorist attack in Norway 22/7 2001 and the In Amenas attack the commission reports concluded that the people responsible for security had not envisioned the scenarios that materialized.

These are all aspects of the terrorism risk contributes to that a risk management regime cannot provide any clear answers.

3.2.2 *No benchmarking for when to implement security measures*

A risk-management approach is no practical guide; it does not give any clear guidance for what is an appropriate level of security or any benchmarking for when a company has achieved the "right" level of security.

For a company standing in a concrete decision context, the risk level falls somewhere on a continuum from extreme to insignificant; if the threat is extreme, the company needs to eradicate the threat with every possible means. If the threat is insignificant, the organization can invest the money and resources on other things. However, for most organizations that conduct a security risk analysis the risk assessment will fall somewhere in between the risk continuum, and the organization will have to decide whether the risk is so severe that there is a need for implementing security measures or not.

Regulation based on a risk-management regime does not give any clear guidance in the decision-making context. In each case the risk has to be judged as falling on one or the other side of a line: on one side, a certain action is required; on the other, it is not. In other words, the risk continuum must be converted into a dichotomy for the purposes of decision-making. Thus, the risk-management approach does not in general provide much guidance to those faced with these decisions, that is, it does not offer a way of deciding whether the risk is acceptable or not (Hopkins, 2011). In the area of security this gets even more complicated; since most assessments and decisions regarding security measures are classified, an organization will in a concrete decision-making context often lack information about how other organizations have arranged their security system. This could also be a challenge for the directorates responsible for inspection. According to the object security regulation it is the directorate in each sector that is responsible for the inspections within its jurisdiction. Most of these directorates do not have security as their main activity, and will probably lack the experience and the competence on how to deal with security threats.

3.2.3 *Organizations can be tempted to lower the risk assessments to save money*

The purpose of risk management is to ensure that adequate measures are taken to protect people, the environment, and assets from harmful consequences of human activities. The extent to which risk reducing measures are justified depends on the balance between costs and benefits in terms of safety gains (Aven & Renn, 2009).

To handle security risks will for most organizations not be their main activity, and most organizations will probably have other risk related areas that are assessed to have a higher probability of occurring, such as non-intentional accidents.

According to the Norwegian object security regulation it is the organizations themselves that have to pay for the security measures. The consequence of this could be that many companies can be tempted to lower the risk level to save the investments in security system. Thus, trust is a fundamental character of the risk-based regime. Such a regime is based upon a belief about the regulated wanting and pursuing the best solutions available.

3.2.4 *In the risk management regime security becomes an ongoing process*

A risk management regime is challenging for the organizations because it requires that the organizations put lots of efforts into the risk management process. This approach moves the focus from governmental inspections checking compliance with existing rules, towards inspiring the industry to develop their own systems of internal control and management. In this regime, the organizations are forced to evaluate and report upon their own self-regulatory strategies in order to enable the regulatory authority to judge if the objectives of the regulations are met. Thus, the risk management process becomes central. In other words, security in this perspective is not just a check

list that can be completed, but an ongoing process where the organizations continuous have to monitor that the security system is in accordance with the threat assessments.

However, many companies may not fully understand the threat situation or what measures can be implemented in order to reduce the threat. Today, many Norwegian companies operate on an international or global basis. This means that organizations need to be updated on the local security situation and the threats assessments needs to be updated. Still, even for organizations operating solely on the national level in Norway, most organization will not have the necessary competence and mean to conduct meaningful threats assessments. As a consequence the organizations will have to rely on risk assessments done by the authorities or companies that sell risk assessments.

3.2.5 *Organization lacks knowledge of the effect of counterterrorism measures*

The objective of risk-based security management is to identify risks before they materialize in the form of an intentional crime. Once risks have been identified, preventive measures can be taken to eliminate the risks or to reduce the probability of the occurrence of such events. Although this is an attractive idea, little is known about how well security measures actually works. In research, minor attention has been paid to the effectiveness of counterterrorism measures. Lum, Kennedy and Sherley (2006) discovered an almost complete absence of research that evaluated counterterrorism measures. From the evaluations they found, it appeared that some interventions either did not achieve the outcomes sought or sometimes increased the likelihood of a terrorist attack.

LePorte and Frederickson (2002) have demonstrated that it is almost impossible to measure the efficiency of counterterrorism measures because it is impossible to know if the absence of terrorist attacks means that the security measures are effective or whether there never existed a terrorist threat in the first place. This means that organizations will lack knowledge regarding the risk reducing effect of countermeasures and also the means for evaluation whether the measures are effective or not.

4 THE RELATIONSHIP BETWEEN THE TWO RISK REGIMES

In this paper we have presented the risk-management regulation regime as a contrast to the rule-compliance regime. However, Hopkins (2011) claims that these are not mutually exclusive approaches; they are complimentary. This is also the case for the area of security in Norway. Also organizations who work under the rule-compliance regime work under a regime that acknowledges that security risks can be assessed and managed. In order to determine the appropriate rules, most likely a risk assessment is behind that decision. This risk-assessment is just removed one step from the end point decision-maker. In the case of airport security, the risk assessments are done by the European Aviation authorities, and not by national or local assessors.

Furthermore, behind the introduction of a risk-management security regime lays another rule, this time a legislative requirement that risk-assessments should be conducted. Behind the risk-management regime introduced in Norway, lays the Security Act which demands that owners of critical objects need to carry through the risk-management regime. Moreover, the security risk analysis standards that have been developed and are in progress can be seen as a guide for helping companies to interpret and deal with risk-management regulation—because organizations still needs rules to guide them in their security work. From this point of view, risk-management and rule-compliance are intertwined and complementary strategies. The issue, therefore, is not to decide between the two; it is to get the balance right.

One appropriate question to ask is whether the risk management security regime represents a new regime or if it is just a broadening of an already existing regime? Within the area of port security, the introduction of new port security regulations[1] can be interpreted within the trend of moving from prescriptive, detail-oriented regulations towards more flexible, risk-management based regulations. The new Norwegian regulations tend to take a more flexible form while referring to the more detail-oriented demands in international regulations (IMO's International Ship and Port facility Security code, ISPS, and EU-regulation 725/2004 on enhancing ship and port facility security). To what extend the regime has actually changed to a more risk-management based regime is not evident. However, this underline the fact that regulatory regimes hardly ever are purely risk-management based, but often tend to be a hybrid version of the risk-management based and rule-compliance approaches.

A risk management approach offers no clear guidance for what is an appropriate level of security or any benchmarking for when a company has achieved the "right" level of security. In order to support the companies in their decision making of whether action are required or not, detailed guidance standards are often offered for how to

[1]Regulation on Protection of Harbours and Regulations on Protectin of Port Facilities (29 May, 2013) was implemented May 1, 2012, replacing the former Regulations on Protection of Ports and Port Facilities against terrorist attacks, etc. 3 July 2007.

assess risk and whether or not action is required. Such non-legal standards are more easily updated, ensuring the regulations to keep up with the development. Thus, by implementing a set of more detailed standards to support the risk-management based regulations contributes to a better balance between the risk management approach and the rule-compliance approach. This however, requires a robust system for updating of the standards.

5 CONCLUSION

This paper has described the consequences of the rule-compliance and the risk-management regime in a security context, and discussed some challenges of applying a risk management regime within the area of security. We claim that risk-management and rule-compliance are intertwined and complementary strategies. The issue, therefore, is not to decide between the two; it is to get the balance right.

In the rule-compliance regime, the authorities set out detailed regulations in order to steer the direction of companies, or others, in their security work. This will lead to a uniform implementation of security measures, meaning that each organization covered by a specific regulation will have the same level of security independently of an organization's perception of available resources, threat picture and former experience with the threat of intentional crimes. In a security context, this means that organizations or owners of critical infrastructures will implement the same level of security measures independently of whether a company or an owner of a critical object belong to a sector which has historical experience with acts of intentional crimes.

In the risk-management regime the knowledge an organization has regarding its assets, values, and vulnerabilities and associated threats is in focus. This means that an organization has more flexibility in how to arrange its security regime, and can direct the security system against the threats that are considered most critical to the organization. Consequently, the organization can protect the assets which are assessed to be most valuable, and the organization can change and adapt security measures if the threat landscape changes.

Although these aspects with the two security regimes also are present within the area of safety, there are some aspects with security risks that make the application of a risk-management regime more challenging; Terrorism is a highly uncertain risk and the political aspect of the threat and how to handle it imply that the risk of terrorism is highly ambiguous. Acts of terrorism are obscure, low-frequency events where strategically calculating human beings are the ones who possess the threat. Terrorists can strike suddenly, without warnings and cause enormous damage. In order for a terrorist attack to be effective, the terrorists must keep a low profile; thus, a terrorist threat will be secret by nature and, therefore, to a large degree, not knowable by those who are responsible for security. Additionally, often the area of security is just one of several risk issues an organization has to take into account, and safety risks are areas where the organization will have its main focus because many of these risks will be assessed to have a higher probability of occurring. Furthermore, most organizations in Norway lack security competence, benchmarking is difficult because the area is often classified, and little is known about the effect of counterterrorism measures.

Since the risk-management approach is no practical guide and does not give any clear guidance for what is an appropriate level of security, it is reasonable to assume that many organizations in Norway are "struggling" with adapting to this new regime. This is a topic further research should look into.

ABSTRACT: The purpose of this paper is to explore different safety cultures in anchor-handling operations in the Norwegian offshore petroleum industry; how the crew and management cope with both critical and dangerous operations, compared to the periods in-between operations that are characterized by routine work. Between operations, officers function as middle managers fulfilling organizations needs for control, predictability and audit requirements. During operations, dangers and complexity demands full focus and presence towards that specific situation. Thus, the different demands are balanced by actualizing two different safety regimes and work practices. The discussion in the paper is based on two research projects conducted in 2009 and 2013, focusing on safety conditions at anchor-handling vessels.

1 INTRODUCTION

1.1 *Anchor-handling operations*

Anchor-Handling Tug Vessels (AHTVs) perform what is known as *advanced marine operations*, *extreme marine operations*, or simply *anchor-handling operations*. Anchor-handling vessels are an important part of the offshore operations in the production of oil and gas on the Norwegian Continental Shelf (NCS). According to statistics from the Norwegian Shipowners' Association, the offshore industry in Norway consists of approximately 340 vessels, where AHTV and supply vessels are the biggest category. The fleet is the second biggest offshore fleet in the world next to the US. Furthermore, this industry employs more than 12500 people and delivered 24 percent of the total value creation within the Norwegian maritime industry in 2012 (Maritimt Forum 2012). Moreover, in 2011, this industry is said to create values of more than NOK 30 billion, in an industry that creates about 150 billion in total.

The operations on board an AHTV vessel involve many dangerous work situations, which demand a strong focus on safety before and during operations. Seafaring has mortality rates considerably higher than populations ashore (Hansen et al., 2002; Roberts, 2002).

The standard rig move operations are integrated; anchors are recovered to the AHTVs, the rig moved to a new location, and anchors are placed at the new location and connected to the rig—all in one operation. This operation may take 6–10 days and requires a rather stable weather window. Also, it requires tight coordination between the parties; the rig and 2–3 anchor-handling vessels, where one of them has the lead.

1.2 *Rule-based offshore petroleum culture*

The offshore petroleum industry in Norway is controlled by regulations, guidelines, and standardization of operations. In this way, the industry is characterized by a rule-based organizational culture and structure, with normative concepts of behaviour. The aim of a rule-based safety regime is to reduce accidents on board and to develop a safe workplace. The regulating authority for all vessels and movable rigs on the Norwegian Continental Shelf is the Norwegian Maritime Directorate.

The planning of offshore operations has to follow certain guidelines. A "Risk assessment document" is prepared by the operator, the oil company, or a company contracted as Marine Representative. The planning is based on experiences of what could occur or previously have occurred. The guidelines are the NWEA, version 2 regulations.

This is a generic document, which is intended for continuous updating during the preparation period and during operations, in accordance with the incidents occurring. A preparatory meeting is arranged with all parties present. The Guidelines and Risk assessment are presented and discussed. The risk assessment is revised as a result of feedback from that meeting.

When the vessels are hired from the spot marked, there are no vessel representatives at the above meeting. Long-term contracts, however, allow such representation.

At the base during mobilisation, the marine representative arranges a familiarisation meeting for all vessel crew. This is a presentation of scope and a safety brief.

1.3 *Safety culture*

The relation between safety and culture has been one of the main topics of safety research for the last decade (Guldenmund, 2007; Haukelid, 2008; Stiansen, 2009). Research has shown that the cultural aspects of work practice influence safety as much as technology and formal organization structures.

According to Gherardi et al. (1998), safety is strongly linked to the work practice of a community. It is a collective competence that has developed through experience and training of seamanship. This also influences what is considered safe or dangerous behavior during operations on board. The seamen's identity is shaped by what is appropriate within the norms and values of the culture on board, and influence the way they perceive safety rules (Knudsen, 2005). According to Knudsen (2009), good seamanship is a blend of professional knowledge, professional pride, and experience-based common sense.

Safety is also strongly linked to management of safety, where the aim is to control and measure an organization's operational performance. According to Petersen (1978), safety conditions can be identified, predicted and controlled—through the means of defined work processes and procedures. Planning and setting goals are also a part of safety management.

In this paper, we address both these views of safety: 1) the importance of the culture of the seaman crew due to safety and 2) the impact of the offshore control routines concerning safety.

2 METHODS

The collection of data is based on qualitative methodology, involving semi-structured interviews, unstructured conversations and observations onboard AHTVs during operations. One researcher covered integrated operations over a period of one year (2009–2010) and one researcher covered a week's operation during a pre-lay operation in 2013. The main data source from the one-year fieldwork is thus participation on board AHTVs and interaction with crews on these vessels (Røyrvik 2012). In addition to participation and observation, structured and semi-structured interviews from all positions on board were conducted, on board narratives were collected, and operation documents were studied. In addition, the researchers participated in relevant contexts, such as operations planning, pre-operational meetings, AHTV operational and safety procedure simulator training programs and R&D related contexts.

The positions interviewed in the 2013 data collection were: captain, first officer, chief engineer, deck foreman, ROV supervisor, surveyor, mooring supervisors/controllers and marine representative for the operator (oil company). Interviews were transcribed from audio files, as all interviews were recorded. The quotes used in this article are all translated from Norwegian. Observations with conversations in between interviews were conducted over a period of around 14 hours daily. Observational notes were taken at the time the observation was made or shortly thereafter and included in a field log as documentation. As the observations, participation and interviews that form the empirical basis of this article were made and conducted in 2009 and 2013, respectively, comparisons allow for discussion on developments in both operational practices and safety management.

3 RESULTS

Based on the analysis from the fieldwork, we will describe the characteristics of the working and living conditions on board the anchor-handling vessels. Overall, we found that the management and crew of seamen on board both strongly prioritize safety to avoid occupational accidents and major organizational disasters. How this is performed is very much affected by the fact that these vessels are part of a long-standing sailor tradition and a strong industry managerial regime. Thus, the officers are expected to function both as ship officers, focusing on seamanship, yet at the same time as middle managers of the greater corporations. The role as middle manager involves detailed planning and control in an effort to follow safety procedures and routines.

Depending on the organization of the particular operator, the oil company, as many as seven different parties may be involved in an anchor handling and rig move operation. The oil company may

choose to include several of the functions from internal resources or use outsourced resources. The functions or processes involved are: A drilling management responsible for planning and drilling, an offshore marine representative advising the drilling management and operator being the representative on board the senior AHT, a planner function/company, drilling company/rig owner, site survey to confirm the correct site, navigation company to find and document the correct location, weather forecasting company and anchor and mooring handlers.

3.1 *Anchor operations*

The core function of AHTVs is to reposition oil-rigs, floating installations that are anchored to the seabed while they search for oil. In principle, an anchor operation consists of three parts: recover anchors at rig location, tow the rig to new location, and release anchors and reposition them on the seabed according to position data. Traditionally, an anchor operation consists of three main parts: 1) the pulling of an anchor, loosening the rig from the sea bed, 2) tugging the rig to a new position, and 3) anchoring the rig in place at that new position. Such operations involve coordinating four AHTVs and one rig. Furthermore, an operation typically involves recovering and repositioning eight anchors, with each vessel working with and taking on board two anchors and their anchor systems.

The new pre-lay type operation consists of one recovery and pre-lay operation and one concerted (4–5 days) rig move (1–2 days). This requires two sets of anchor mooring spreads, one owned by the mooring equipment supplier and the other often owned by the rig company. The spread is left on the seabed from a previous rig move about 2 weeks prior. Anchors (usually 8) are all recovered and brought to the new location and spread according to a spread plan and buoyed with light buoys. On the rig moving day, the anchors at the "old" location are all buoyed, the rig is moved with the help of two AHTVs, wires are recovered and the rig connected.

Prior to any operation, a decision has to be made whether to carry it out as a pre-lay or integrated operation. There are advantages and disadvantages to both types of operations, and they both involve comprehensive planning: mooring analysis and equipment, vessel requirements, additional personnel, logistics, notification of others parties of location, and various risk assessments, such as Safe Job Analysis (SJA).

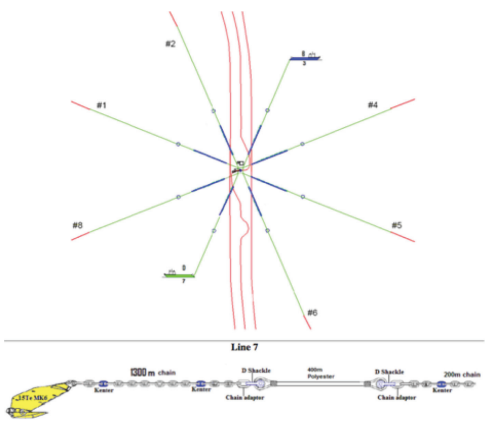

Figure 1. Map of an anchor system—and specifications of anchor # 7.

3.2 *AHTV vessels*

The AHTVs vary in terms of hull design, and there are different kinds of propulsion systems, as well as anchor handling systems. Some of the more modern AHTVs are equipped with an ROV (Remotely Controlled Vehicle) to inspect the seabed and recover the anchor lines. This significantly reduces the need for grappling functions (see section below). Nevertheless, there are some characteristic similarities between all AHTV vessels, like the positioning of the living quarters and bridge afore, the long working deck at sea level and the large winches mounted to the living quarters facing the work deck. The dual work chairs of the coxswain and the winch operator are another special feature of AHTVs. During operations, their work positions are at the bridge, overlooking the work deck. Independent of the type of AHTV, the positions on board are highly specialized, from the bridge and deck to the engine department.

Figure 2. An AHTV docked at Kristiansund.

The vessel is built specifically for towing and oilrig anchoring. Towing implies towing a rig from one location to another, and oilrig anchoring means anchoring the rig so it sits steadily in the water. To achieve this, four or five vessels must collaborate to stretch and tighten the enormous wires or chains, and anchor them to the ocean floor. The anchor is sometimes a kilometer away from the rig, so the thick wires are bound to be very heavy.

To cope with the great forces of the wire or chain, as well as nature, the vessels are very powerful and thus very demanding on resources. As the operations also take place some distance from shore, the vessels usually spend weeks offshore to get as much work done as possible on each trip. Each vessel can be considered to be a complete and integrated organization, because of the limited physical frames the crew live and work within over some time. The crew all have different tasks, qualifications and responsibilities, and everyone and every task is necessary in order to be able to stay offshore for such extended periods of time every trip. Some are responsible for food, some for cleaning, and some for maintenance of the vessel.

3.3 *Positions on board*

The crew consists of a minimum of 13: four on the bridge, four on deck, four in the engine room and one cook. Usually though, cadets and apprentices join the crew in training to become officers or able seamen, and it is common that the size of the crew varies between 15 to 20.

The four people working regularly on the bridge hold positions of captain, chief officer and first and second mate (sometimes two first mates). These four work closely together. During operations, the captain and one mate work on one shift together, and the chief officer and the other mate work the second shift. The shifts rotate—six hours of work and six hours of sleep, which implies that for twelve hours a day, two of the officers sit next to each other on the bridge collaborating on controlling the tension of the anchor systems, coordinating the work on deck to minimize risk, and making sure that the vessel is working properly. Between operations, they are also working and living closely together, and although other aspects, such as age and different personalities, influence the way the crew interact with each other, it is clear that "the bridge" defines both work and social roles and relations.

This is true also for the other positions on board. The able seamen, also working in pairs during operations, have their own work areas—the work deck—and resting area—the dirty mess, which allows for the seamen to rest and wait for orders still in their work outfits.

The work carried out in the engine room is considered a bit more separate than the other tasks on board. As with the other positions, they work in pairs (and depending on the engine, there may be a daytime electrician as well), monitoring the systems on board the ship, tinkering with the engine and spending their working hours mostly without having to coordinate their work much with anyone other than the captain.

As a crew works closely together, a collective practice of both work and social interaction develops. This is true both for those working in similar positions as well as for those working at similar times. During operations, the same ABs and officers will collaborate around the clock, as well as eat and sleep at the same times. As a result, although conducting the same work, crew on different vessels, as well as different shifts and the different positions on board may both work and socialize differently.

Figure 3. In between anchor operations: cargo-run.

3.4 *In between operations*

Anchor operations must be performed during specific *weather windows*. A weather window in this context means predicted weather conditions that are defined as safe enough for the time it takes to carry out the operation. The technical definition of a weather window, in this context, is when the *significant wave height* is predicted to be less than 3.5 meters 1.5 times the predicted operational time (DNV rules for marine operations). A typical operation may last for many days. Therefore, in the North Sea, and especially during the winter months, anchor-handling involves a lot of waiting around and working in-between operations.

If the weather forecasts predict an extended waiting period, the crews will stop working shifts and work on maintenance during the day, perhaps washing down or painting the vessel, fixing tools,

checking the electrical systems and so on. As hiring an AHTV is expensive for operators, they may decide to use the vessel in other types of operations, if the waiting period is predicted to last long. These operations, such as cargo runs, are considered to be considerably less difficult and dangerous, and, as a consequence, the atmosphere on board during such operations is more relaxed, and the crew is more sociable and talkative.

The workday is also very much characterized by paperwork and safety management. Most tasks performed on board include some type of risk, either from being performed in an exposed environment (such as outside in high waves, or high up somewhere), from involving heat (such as welding work), or from working with hazardours substances (like paint or gasses) or closed environments.

In these cases, and many others, permissions are required in order to perform the tasks. SJAs are performed, and an officer, together with the one who performs the task, must sign that they have performed the analysis and that they have taken every safety precaution required.

3.5 *Advanced operations*

The first step of an operation is to lower the grapple in to the sea. The able seamen have prepared and positioned the grapple at the back of the ramp on the work deck. Grappling means fishing with the grappling hook, for a wire located on the seabed, which is connected to the anchor at one end. This process may take some time, and can't be carried out by the bridge alone, so, depending on the time of day, it is common for the rest of the crew to come and observe the grapple being lowered and the grappling to begin. It is a bit of a competition between the vessels to see who is the first to recover the wire/chain and bring it on board, and so the atmosphere on the bridge is slightly excited and easy. As soon as the wire/chain is on board though, it is secured by the so-called "shark jaw" (a device that locks the wire and later chain in position), and it is time for the sailors to go out on the work deck and connect the wire to the vessel's winch, and for the bridge to apply tension to the system.

From the moment that the wire is connected to the vessel and tension is applied to the system, the situation, and thus also the atmosphere, change dramatically. Now, if something goes wrong, simply sailing away is no longer an option (as the vessel is connected to an external system), and the energy that could be released if anything were to happen is potentially catastrophic due to the tension of the system. As a consequence, everyone, and the vessel itself as a collective entity, goes in to a focused state of mind. Silent concentration falls over all aspects of the boat and crew; all interaction is reduced to carrying out the operation, like a purposive bubble of extreme presence.

The majority of the hours during an operation, are spent "driving the chain". In the North Sea, depending on the depth, an anchor may lay a kilometer or so from the rig. And when the chain between the rig and the anchor is either recovered or put down into the sea, the winches that either pull or release propel the vessel—while the propellers or thrusters are used to maintain position or a specific heading. This work goes on for hours and hours, in a monotonous and, at first glance, seemingly routine way.

Although this seems like a routine part of the operation, it has proven to be very dangerous work. Every chain link weighs about 20 kg, and handling and controlling a one-kilometer chain is thus highly demanding on both equipment and crew. The incident involving Bourbon Dolphin showed the consequences of losing control of such forces; the currents affected the chain, which in turn dragged the vessel out of position. The crew and the vessel fought the forces that pulled them off course for hours, but a fatal turn of events, after

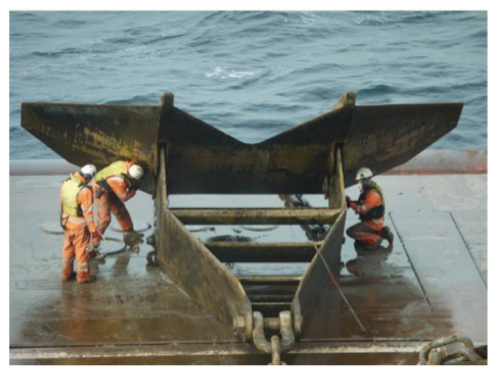

Figure 4. On-deck personnel working on an anchor.

Figure 5. The bridge—winch is handled from the left chair, the vessel from the right.

hours of fighting, caused the ship to suddenly capsize. This final and tragic event happened very fast, as the weight of the chain made the pull direction drag from the port side after a maneuver intended to ease tension and increase the maneuverability.

It is literally a matter of life and death for the bridge crew to maintain their focus and control the situation in order to follow the precise line of motion that ensures the tension and pull, keeping the vessel in the right position. When anchors are set, they are tested for tension. The anchors are pulled with a set force, called bollard pull, in order to test if the anchor is able to hold its position in the seabed during a calculated 100 years worth of impact from weather conditions. During the test, the bridge is mostly silent. Everyone is waiting for the moment of truth; will the anchor hold or break? Thumbs up if the test is successful and the anchor is holding within the seabed. If not, the process has to be repeated all over again, and the operation is redone.

The great tension of the anchor systems poses a considerable danger, not just for capsizing the vessel. More often, accidents or so-called near-miss-incidents endanger the sailors working on deck. The wires recovered from the seabed might be twisted, releasing energy stored by the twist when they are pulled up. If a wire snaps, the backlash would seriously hurt anyone being hit. The entire system of activities is potentially dangerous, and at the same time, the work conducted out on deck is both physically demanding and conducted in harsh environments. Therefore, it is of great importance that there are no misunderstandings, that the deck is clear when tension is released on the system, that a bolt is not left inside or not fastened when it should not, and so on. The bridge and the deck crew therefore depend on knowing that the others involved knows every situation as well as they do themselves.

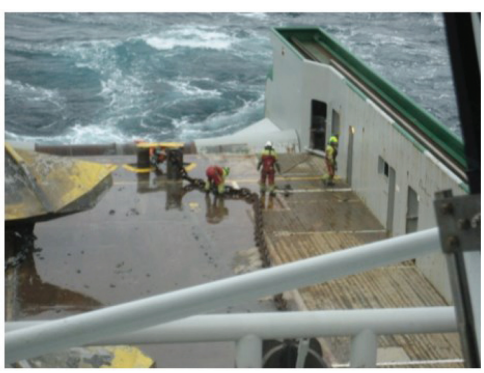

Figure 6. On-deck work during an operation—seen from the bridge.

4 DISCUSSION

This paper explores the safety culture at two levels: 1) the culture and work practice among the seamen on board performing the operations (occupational culture), and 2) the organizational culture of the offshore petroleum industry in Norway, i.e. safety management systems/regimes that involve detailed planning and control of operations. These two organizational cultures have different ways of perceiving and performing safety.

4.1 *Two modes of work*

The two safety cultures described above are reminiscent of how Pool (1997) and Weick & Sutcliffe (2007) describe so-called High Reliability Organizations (HROs), exemplified by a nuclear aircraft carrier from the US Navy and Diablo Canyon nuclear power plant in California. A central issue in Pool's discussion focuses on how certain organizations can be strictly hierarchal, with factors such as rank and routine, and being more dynamic in character on the other. The latter mode is of crucial importance when the organization is facing stress, for example during the launching and recovering of planes on board an aircraft carrier. The gear engaged "when things heat up", is distinguished by a focus on communication and expertise, rather than rank, stability, predictability and thick manuals. The success of high reliability organizations lies in their ability to include, request and balance these two "modes of operation" within their organization. This requires, for example, involvement from everyone in the organization. One should, on board the aircraft carrier, be able to achieve a situation where "the welfare of the ship and crew is [seen as] everyone's responsibility" (1997:261). Pool continues by stating that: "Besides communication, high reliability organizations also emphasize active learning, not simply the memorization of procedures. Employees should not only know why the procedures are written as they are, but should be able to challenge them and look for ways to improve them" (1997:266). Being part of this process of active learning, the rotation of crews is portrayed as an advantage for the organization rather than an obstacle. As Pool argues: "The collision of fresh, sometimes naïve approaches with a conservative institutional memory produces a creative tension that keeps safety and reliability from degenerating into a mechanical following the rules" (1997:261). This argument shows both the existence of two modes of work, and how safe work practices stems from the co-existence of these.

On board an AHTV, the transition between the two modes is very noticeable. First, there are structural changes in how the crews organize

and conduct their work. They begin working six hour shifts at their respective work positions, not allowing for any non-work related social interaction except during meals. Second, there are very noticeable changes in the atmosphere on board. The crewmembers' presence changes very much—they are quietly focused on the tasks they conduct. Words exchanged are work-related, information-redundant messages such as "clear deck" or "release tension". The atmosphere mirrors the tension of the anchor system, when the weak link is broken, the crew ease out.

4.2 *Occupational culture*

The social organization of a ship is often characterized as a "total institution" (Goffman, 1961). To enter into a total institution is to leave a multitude behind and instead be surrounded by and eventually be part of a universe, which is "something more than a formal organization, but […] something less than a community" (Goffman 1961:103).

Total institution refers to the fact that a ship is not divided into isolated arenas for interaction, but instead represents a collapse in that respect, in the sense that the seafarers on board spend 24 hours a day in the same place, and the activities they engage in—both related to work and leisure—are carried out simultaneously and with the same people. The seafarers on board are there to make sure the operation goes smoothly and on schedule. In other words, a ship is first and foremost a place for work.

We found that during anchor handling operations, it is much more important to "have control" than to control and audit the job. In order to manage having control among the seamen, one important assumption is competence, training, work experience and autonomous tasks on board. The findings from the interviews illustrate this, as one of the seamen on deck experienced the importance of autonomous tasks: *"If the foremen is giving orders all time on deck, you may feel unsecure about the work tasks. Then things may go wrong. Luckily, our manager doesn't tell us what to do in detail."* Being a good seaman seems to have much to do with working autonomously, without having someone telling you what to do, and to deal with unforeseen events as they arise.

We found management style to be essential in the effort to empower crewmembers. Based on our findings, the management on board holds the belief that crewmembers learn what to do by performing work tasks. As one of the deck foremen stated: *"When new seamen arrive on board, I think it's very important to let them know what's happening on the vessel. It's important to be hands-on and allow the new seamen to be actively involved in the operations. This is how they learn."* This is another example of how the management on board is involving the crew*: "I'm not a kind of manager that tells the seamen what to do. Here, we plan and do the operations together, and it works well."* We find that the managers on board empower the crew to develop practical skills and being able to perform as a team.

This is in accordance to one of the five principles of HRO; deference to expertise, established by Weick & Sutcliffe (2007), focusing on the respect of the HRO for the expertise held by the operator. Decisions regarding how to perform are made at the front end of the operation, rather at the top. This recognizes and takes care of the knowledge held by front end operators. In anchor handling operations the expertise on how to best perform safely stays with the deck team as a team. The Captain is in charge of what to do according to the scope of work, but he mostly leave to the team how to perform. The effectiveness of knowledge and experience sharing in a team will, however, depend upon the openness and trust established (Jonassen, 2014).

4.3 *Balancing regimes*

Within the oil and gas industry in Norway, major companies have largely standardized the work processes on board in an effort to control and measure operations. Safety management systems (regulations, procedures, work processes) may influence safety on board in a positive way, such as carrying out necessary operations planning.

In the case from 2013, we found that a new position had been included on board the AHTV. The mooring equipment, such as anchors, links and buoys, is often hired from a mooring company for pre-lay operations. The company will then supply and control the complete logistical chain, including control work on board. Controllers are positioned on board to control, in detail, all the mooring equipment and register all the numbers on individual pieces. They socialize with the crew, as they spend time together in the dirty mess while waiting in between operations. In addition to other possible gains, this position may be seen as serving the needs of both the organization (by auditing the work, registering and reporting) and the situation (as the controller is not disturbing the performance or presence of the sea farers). Although the formal reason for this position is to serve the control function, their presence is socially accepted by the added on board value they provide and their position among and with the ABs in the dirty mess. Ideally then, this type of resource both adds to the structure and standardization (needs of the organization) and contributes to on board flexibility.

From the example above, the addition of the controller function seems to contribute to a stronger focus on controlling safety on board. Making sure work processes comply with strict safety requirements and routines, leads to more administrative work on board, compared to earlier. According to Knudsen (2009) and Antonsen (2009), the seamen seem to have an aversion against the introduction of new rules and requirements by written procedures. They don't consider this very useful for operations. The seamen perceive it as traditional ideals of seamanship being under attack by attempts to regulate work by formal regulations and more paperwork.

There appears to be a great deal of inconsistency between the informal ideals for work performance and the formal ideals conveyed by safety procedures (Antonsen, 2009). Formal work requirements seek to standardize work processes. Standards can be seen as formalized rules that serve to prescribe and document efficiency and control within and across organizations. According to Mintzberg (1988), there are four different forms of standardization: standardization of work processes (specification of how worked is to be performed), outputs (what is to be done), skills (education and certification of competence) and norms (share a common set of beliefs).

Another effect of standardization is simplification, which is a two-edged sword. On the one side it helps people to better understand and remember. On the other it covers the fact that a complex structure or organization actually is complex. Imposing an image of simplicity may lead to dangerous situations. The reluctance to simplify is another of Weick & Sutcliffe's principles of HROs. Standardization reflects the experiences of past and may represent a hindrance to solve or prevent future problems. As Hollnagel argues: "Safety cannot genuinely be improved only by looking to the past and taking precautions against accidents that have happened. Safety must also look to the future. It must be proactive" (Hollnagel, 2008).

Standardization may be contrasted with improvisation. Improvisation refers to what is not planned for and involves a low degree of predefined structures. The weakness of standardization may be less room for improvisation (Antonsen, Skarholt and Ringstad, 2012). According to Antonsen et al. (2012), improvisation skills are necessary when unforeseen situations occur on board. In such situations, the management and crew have to quickly find solutions that have not been planned for and for which no procedures exist. The ability to improvise is very much dependent on the empowerment and autonomy among the crewmembers, in addition to knowledge of each other's experience and competence. This kind of expertise develops in a strong community where seafarers share norms and identities. Leadership practices influence the crew's ability to act in such situations.

5 CONCLUSIONS

The aim of this article was to discuss how a rule-based safety management culture and an occupational culture influence safety on board. On board anchor handling vessels, cultural traits of both industrial management and experience-based seamanship is present. Between operations, officers function as middle managers, filling the organization's needs for control, predictability and audit requirements. During operations, danger and complexity demand complete focus on and presence in that specific situation. The different demands are thus balanced by actualizing two different safety regimes and work practices.

We found that the seafarer's skills, experience and close collaboration are strengths in terms of safety on board. Safety is, to a great extent, a matter of maintaining control over work carried out within an organization. In this paper, we have discussed how control is gained through good seamanship characterized by a culture of empowerment, responsibility, experience, and, not least, a strong focus on safe conduct during the operations.

We conclude that rule-based safety and the work practice among the crew on board are mutually dependent. Safety management systems (regulations, procedures, work processes) influence safety on board in a positive way, for example by requiring necessary operations planning. However, the need for control in the offshore oil and gas industry seems to increase, as seen for example through the new control position and function on board. In the future, the challenge thus becomes maintaining what is considered to be good seamanship; professional knowledge, professional pride, and experience-based common sense.

Safety and environmental control of industrial activities in France: A negotiated relationship

V. Sanseverino-Godfrin
Center for Research on Risks and Crises (CRC), Mines-ParisTech, PSL Research University, Sophia-Antipolis, France

ABSTRACT: Environmental regulation aims to ensure that industrial activities cause the least possible damage. In France, this includes checks of regulatory compliance by environmental inspectors. In cases of non—or partial compliance, the Environmental Code gives inspectors the power to impose sanctions: fines and/or imprisonment. In theory, the relationship between the "inspector" and the "inspected" refers to a person with powers similar to those of the police who can punish all kinds of non-compliance, and another person considered to be an "offender". In reality, the objective of environmental inspectors is not to apply sanctions, but to promote economic development, by finding solutions that enable compliance with environment protection and safety regulations.

1 INTRODUCTION

The inspection of industrial activities is a necessity. Mainly it is a question of sustainability—to protect the environment and natural resources from damage caused by these activities—but it also concerns the safety of people, evidenced by the many victims of major industrial accidents (Bhopal in India, Enscheda in the Netherlands, BP Texas City in the United States, and AZF in France, etc.). Environmental regulation aims to ensure that industrial activities cause the least possible damage. For instance, the operators of industrial plants in the European Union must comply with Seveso Directive regulations preventing pollution and risks. But it is not enough to provide regulations, it is also necessary to check that the regulations are correctly applied. In France, the risk of pollution caused by certain industrial plants (*Installations Classées pour la Protection de l'Environnement*) means that environmental inspectors (*Inspection des installations classées)* regulatory check their compliance with a special juridical framework. In cases of non—or partial compliance, the French Environmental Code gives inspectors the power to impose sanctions: fines and/or imprisonment. In theory, the relationship between the "inspector" and the "inspected" (a private or public person, or a business) refers to a person with powers similar to those of the police who can punish all kinds of non-compliance, and another person considered to be an "offender". However, in reality the objective of environmental inspectors is not to apply sanctions, but to promote economic development, by finding solutions that enable compliance with environment protection and safety regulations.

This article shows that environmental inspectors negotiate their relationship with the entity they inspect, notably since the reform of the Environmental Code, which came into effect on 1 July 2013 and changed their role.

The article compares recent sociological studies of environmental inspectors, and the current state of regulations related to industrial activities in France. It gives also some examples from other countries, which are similar to the French situation. It addresses the question of whether safety imperatives can be negotiated.

The methodology consists of a bibliographic review of inspection and regulatory compliance, especially the sociological and juridical literature. It also examines the new control procedures contained in the Environmental Code (Articles L 170-1 and following). This review is complemented by a study of reports prepared by French inspection agencies (available on the internet), especially those of the agency in the *Provence-Alpes-Côte d'Azur* region. Finally, we study legal verdicts published on the official French website *Légifrance*, to identify information concerning prosecutions. This search used the keywords: inspection, compliance, violation, penalty, warning, fine and imprisonment for the period 2000–2013.

2 INSPECTIONS—IN THEORY

The objective of an inspection is that an industrial plant achieves regulatory compliance with

environmental regulations. Checks are usually carried out by the national environmental agency, whose staff are experts in their sector: for example, Control of Major Accident Hazard (COMAH) regulations are enforced by national agencies such as the Environment Agency for England and Wales and the Scottish Environment Protection Agency; the Environmental Protection Agency in the USA; and the Regional Department for Environment, Planning and Housing (*Direction Régionale de l'Environnement, de l'Aménagement et du Logement*—DREAL) in France.

DREAL comes under the authority of the local representative of the State (the *Préfet*), and is the competent authority in decisions concerning industrial plants (notably permits and administrative sanctions). The agency's inspectors are engineers, who have both a scientific and technical background and very good knowledge of the French environmental legal framework.

The procedure for inspections and the powers of inspectors are detailed in the Environmental Code, supplemented by directives from the Department of Ecology. The inspection procedure has changed: first in 2006 and then on 1 July 2013, which introduced a new mode of inspection, based more on transparency and negotiation (see below).

The inspection is led by environmental inspectors and takes place at several key moments in the industrial plant's history: before activity begins (through the assessment of the project proposal put forward by the future operator), during active operations, and when activity ends and the plant is closed down. At each of these times, the objective is to check that the plant complies with regulations and does not cause disturbance (noise, smell, etc.) or increase risk to the neighbourhood. The most interesting period is when the plant's activities may cause several types of damage; this is the most important inspection carried out by inspectors and the one we focus on in our study.

Generally, environmental legislation gives inspectors special powers to check regulatory compliance: they can enter an industrial site, grant or withdraw permits, enforce standards and if necessary, prosecute the operator of a non-compliant plant (Fineman 2000). There is a graduated scale of threats and sanctions, ranging from financial penalty notices, compliance notices and restoration notices to criminal charges, etc. In France, inspectors are sworn officers and this status gives them certain powers. To obstruct the work of an inspector is an offense, punishable by a fine (€150,000) and imprisonment (six months). To check regulatory compliance, inspectors may enter the plant at any time. The visit can be requested or unannounced. Most of the unannounced visits are due to complaints from neighbourhood residents. Inspectors can access any documents concerning the plant. They can also ask an external expert for their advice on the level of pollution or risks, which must be paid for by the plant's operator, if they consider the documentation to be insufficient or incomplete.

After an inspection, the inspector prepares a report (the *lettre de conclusion*), in which all the examples of non-compliance that have been observed are recorded. This report forms the basis for a prosecution in cases of non-compliance or failure to hold a permit. Before beginning a prosecution, the inspector can ask the *Préfet* to send a formal notice to the operator, which gives them time to rectify any deficiencies.

In principle, every case of non-compliance can be prosecuted, either once the notice's deadline has expired or, in serious cases immediately following the visit. Two types of sanctions can be applied: administrative and/or penal. Administrative sanctions are applied if the plant remains non-compliant after the notice's deadline has expired. The objective is to make the plant compliant. To that end, the *Préfet* can order that the sums needed to pay for the necessary works be deposited (the amount depends on the cost of the work to be carried out to achieve compliance); have the work done at the operator's expense; or suspend the plants activity until it is compliant.

Depending on the offenses committed, criminal sanctions can be applied to the operator. They can be fined for non-compliance with the applicable legislation or non-compliance with the formal notice (up to €100,000 and two years of imprisonment). If the reason for the non-compliance creates serious damage to the environment, or is a risk to health or safety, the sanction may be a €75,000 fine and a year of imprisonment. The operator can also be issued with a penalty (maximum €3000 per day) until the plant is compliant.

We saw earlier that in France there is a special environmental inspection agency that is dedicated to monitoring regulatory compliance. In theory, a prosecution can be launched each time an inspector notes a case of non-compliance.

However, does this theoretical scheme correspond to reality? Several sociological studies on the subject suggest that there are differences between what an inspection is supposed to be and what it really is.

3 INSPECTIONS—IN PRACTICE

First of all, it is important to note that the overall number of inspectors is not enough to monitor all industrial plants. No government has sufficient resources to check regulatory compliance in each

industrial plant and to prosecute every failure (Zaelke & Higdon 2006). The response to this situation is for environmental agencies to target their activities on those industrial plants that can cause serious pollution and damage to people and the environment, and those with the worst compliance records (Pedersen 2013).

In France, for example, there are about 500,000 Classified Installations (*Installations Classées*), but only 1, 250 full-time inspectors (as of 31 December 2012). It is clear that it is impossible to check the regulatory compliance of every industrial plant. For this reason, the plants to be checked are prioritized. The Department of Ecology provided a modernized inspection program for 2004–2007 and a Strategic Inspection Program for 2008–2012. These two programs outline the methodology to be used in the inspection, the organization of inspectors, information and training. Based on these programs, each year the Department of Ecology decides actions and inspection priorities. One of these priorities is to check the regulatory compliance of the most dangerous or polluting industrial plants.

In the United Kingdom, similar priorities are defined: the "risk based approach" reduces the administrative burden by organizing the work of national agencies, especially the Environment Agency. It focuses on major technological and emergent risks (Galland 2008). The same observation can be made in Belgium: a natural response to the shortage of resources is targeting, with inspection focused on those plants that are suspected to be non-compliant with environmental regulations and those that are the more dangerous or polluting (Rousseau 2007).

This first observation shows that, due to the lack of inspectors, checks of regulatory compliance cannot be as rigorous as they should be according to the legislation. Moreover, an indirect consequence of the lack of inspectors is to encourage a culture of "making arrangements": the inspector has no choice but to trust the operator to be compliant, as there are few ways to impose the regulations as they are prescribed in the legislation. This is a move away from command and control methods towards a self-regulatory approach (Pedersen 2013).

The approach to inspections is important as it determines how regulatory compliance is handled. French regulations concerning inspections take a "safety case" approach (Hale *et al*. 2002), which means that risk prevention is the responsibility of the operator of an industrial plant: they have to prove that they have identified and assessed the risks, and adopted appropriate prevention measures. In brief, they have to prove that the plant is safe for people and the environment. In this context, the plant, especially in large industrial groups, is a "self-regulated organization", to which officials can impose sanctions if self-regulation is insufficient (Dupré *et al*. 2009).

Furthermore, the Department of Ecology has directed inspectors to be more tolerant and promote industrial development. In 1995, a memo from the Department received by environmental inspectors confirmed this position: "It is clear that environmental inspectors must first establish a dialogue with the operators of inspected plants. It is not possible to prosecute each case of non-compliance" (Bonnaud 2002). Sometimes, inspectors have a dual role: to check regulatory compliance and also to advise the operator. This is the consequence of their specific technical knowledge, which can be used both to check regulatory compliance and to support prevention initiatives taken by operators (Strasser 1996).

This flexibility has an impact on the relationship between the "inspector" and the "inspected": inspectors are free to build a cooperative relationship with the inspected, and there is room for compromise (Ayres & Braithwaite 1991). Consequently, the regulatory compliance check is more based on negotiation. Etymologically, the Latin word "negotiation" means "trade or commerce". Specifically, it describes action to deal with an issue, the award of a contract and, by extension, various preliminary operations that are carried out in order to reach agreement. It also refers to discussions held before a contract is agreed or discussions concerning the settlement of a dispute (Cornu 2010).

In theory, there is no scope for negotiation in an administrative procedure that involves the inspection of an industrial plant, which may potentially lead to a prosecution in cases of non-compliance. However, sociological studies of regulatory compliance checks at industrial plants show that environmental inspectors negotiate their relationship with the entity they inspect. What is very interesting is that this conclusion is found not only in many French studies, but also in other countries (Hawkins 1984, Olsen 1992, Porter & Van der Linde 1995, Lowe *et al*. 1997, Smith 1997, Fineman 1998, 2000). In general, as White observes, "the mandate of most environmental agencies is not only to enforce compliance through use of criminal prosecutions, but to forge strategic alliances and working partnerships with industries, local governments and communities in support of environmental objectives" (White 2010). In the United Kingdom, maintaining a collaborative/negotiative relationship and a constructive dialogue with industries is crucial. Inspectors consider that without negotiation, the exercise becomes confrontational and while standards can be imposed, it is not sure they will be met (Fineman 2000).

In France, the sociologist Lascoumes carried out several surveys in the early 1990s of environmental

public policies and particularly environmental inspections. From his point of view, the purpose of environmental policies is not to protect nature (a sacrosanct value based on indisputable standards), as this would result in a prosecution each time there is environmental damage. Instead, his study of policies showed that they are more like strategic compromises between conflicting interests (environmental protection, the development of the industrial economy, urban planning, etc.) than real protection measures. Policies are more concerned with the modes of the relationship between different stakeholders, than the results to be achieved. In short, environmental policy is not a simple protection policy, but an organizational policy in which the purpose is to establish procedures for resolving problems. In this context, the main action principle for environmental inspectors is the regularization of non-compliant industrial plants. This regularization is not based on prosecutions, but on negotiation. Of course, the end goal is always compliance by industrial plants with the legal requirements. However, there are many ways to achieve this goal: visits to plants, emails, telephone calls, meetings, formal notices; prosecution is the ultimate action, which only taken when all other procedures have failed (Lascoumes 1994).

"Speak softly and carry a big stick" may be said to summarize the environmental inspector's position, without forgetting that the big stick can and will be used (White 2010). This shows that inspectors have an ambivalent role: "enforcer-as-helper" and "prosecutor-as-advisor" (Fineman 2000). With respect to sanctions, "prosecution ought to be an equal partner in the enforcement tool box" (White 2010): sanctions are necessary for the threat to be credible and to compel regulatory compliance (Zaelke & Higdon 2006). However, above all sanctions are an appropriate response to a particular set of circumstances (White 2010): this flexibility allows the inspector to tailor their response to the particular and distinct situation of each offender (Pedersen 2013). As Eckert (2004) notes in the case of Canadian and American inspectors, it is common for them to "respond to a detected violation by issuing a warning rather than prosecuting the violator". Eckert also noted that in cases of the inspection of petroleum storage facilities, the response to most violations has been a warning, with only a small number of prosecutions or fines. In this context, prosecution may be considered as a "poisoned chalice", which is unavoidable (Fineman 2000). However, the decision to prosecute depends on the size of the company, its previous performance and compliance record, the intent of the operator, and their degree of courtesy and respect for the inspector (Fineman 2000). Finally, prosecution remains a necessary last resort in the most serious cases (Pedersen 2013).

4 CONFIRMATION OF THE NEGOTIATION: THE FRENCH INSPECTION PROCEDURE

In French judicial procedures, the defendant's rights are based on the adversarial principle (the *principe du contradictoire)*, which means that both parties involved in a trial knows the arguments of their opponent.

In the context of the inspection of industrial plants, for many years administrative procedures did not provide any opportunity for the operator to be informed about developments and to present their own arguments. Prior to 2006, and the entry into law of the adversarial principle, the visit report was prepared by the inspector, working alone in their office. The plant's operator had no opportunity to make comments or to give their point of view. Moreover, the inspector was able to add new elements, which were not discussed during the visit. The time between the visit and the preparation of their conclusions was not clarified. This meant that in the time that elapsed between non-compliance being noted in the inspection and the formal notice sent by the *Préfet*, the operator was completely unaware of the subsequent procedures and administrative assessment of their case.

Little by little, the adversarial principle found in judicial procedures has influenced administrative procedures. In the following, we show that this principle forms the basis for a negotiation between the inspector and the operator of an industrial plant.

The French law that established citizens' rights in their dealings with the administration (12 April 2000) was the first to establish the principle of negotiation, by providing for "prior consultation" with the person who was the subject of a decision taken by an administrative authority; in this case the operator of the industrial plant.

At that time, the multiannual French environmental inspection program (2004–2007) had four main objectives. Two of them demonstrate the application of the adversarial principle: to increase the transparency of the actions of the inspector and to improve the coherency of all decisions taken on French territory. To achieve these objectives, the program provided easy access to information concerning the release of polluting materials, actions taken by the inspector to reduce industrial pollution and risks, and the results of the inspection, notably through the diffusion of information on the internet. This program has increased the visibility of inspection procedures and has allowed operators to be better informed of the procedures to be followed and how inspectors check industrial plants.

The Strategic Inspection Plan (2008–2012) confirmed the right of the general public to have access

to documents related to industrial plant regulation, especially those concerning the inspection visit. The 2006 modification to Article L 514-5 of the Environmental Code officially gives the operator the right to be informed of any follow-up subsequent to checks by the environmental inspector. The 2013 reform of environmental inspection confirmed this trend. Consequently, henceforth the adversarial principle is applied in post-visit procedures and before a formal notice is issued.

Transparency and the adversarial principle lead to the institutionalization of negotiations, both immediately following an inspection, and ex post, during prosecution procedures. Inspectors no longer prepare their visit report immediately after the inspection. First, they prepare a list of issues to be addressed or observations. This is written on-site, immediately following the visit, during a debriefing meeting. The document is signed by the inspectors and the plant's operator. The operator can add their own observations and comments concerning the list, by mail or e-mail, within three weeks of the visit. During this time they are expected to rectify any deficiencies.

This shows that the adversarial principle forms the basis for the procedure; the preparation of the list is the starting point for negotiations between inspectors and operators.

We have surveyed some of these lists, prepared by the environmental inspection agency in the *Provence-Alpes-Côte d'Azur* Region (in the south of France), which are available on the agency's website. This study shows that inspectors do not systematically demand compliance with the legislation. Most of the time, they indicate the issues that must be addressed within a certain timescale (usually three weeks). After the three-week deadline, the inspector updates the list with the following information: either the plant is compliant, or a formal notice is needed, or additional environmental measures are necessary. Next, they prepare their report (the *lettre de conclusion*), which summarizes the visit, the actions that were taken within the three weeks, or those which are planned and the time allowed to apply them. The same document also records any cases of previous non-compliance, which makes it possible to compare situations and see if the operator is making an effort to be compliant. The *lettre de conclusion* is send to the operator and can form the basis for a future formal notice.

This shows that the first part of the inspection procedure is based on negotiation; the objective is not to prosecute, but rather to find pragmatic solutions that address any deficiencies.

What happens in the case of non-compliance within the time indicated in the *lettre de conclusion*? The inspector, via the *Préfet*, can send a formal notice to the operator. In this notice, the *Préfet* reiterates the deficiencies that were found and gives a deadline for the operator to address them. According to a circular from the Department of Ecology (18 June 1998), this is a final warning and the deadline cannot exceed three months, except in special circumstances. However, in practice, this deadline is not always met. A study of court decisions shows that in some cases, a new deadline can be applied, notably when the plant is still non-compliant when the initial deadline expires. Moreover, several further deadlines can be applied, up to a period of two years (Baucomont & Gousset 1994)!

The second part of the inspection procedure is also based on negotiation, and allows the operator more time to make the plant compliant, beyond the deadline indicated in the legislation.

Since the 2013 reform to the Environmental Code, a new form of sanction has been introduced: "penal transaction". Before prosecution, and as a replacement to it, the *Préfet* can agree transaction with the operator, depending on the circumstances and the seriousness of the offense, the nature of the operator and its resources. In this case, the *Préfet* and the operator discuss the amount of the transactional fine and the operator's responsibilities; the idea is to both punish the operator and pay for any damages. The amount is limited to a third of the initial fine.

The introduction of penal transaction is final confirmation that the objectives of environmental policies are not to issue sanctions in cases of non-compliance, but to try to reconcile different interests, especially economic. With this kind of sanction available, public authorities may become less and less strict.

5 CONCLUSION

This study shows that the control of industrial plants is based on a negotiation between environmental inspectors and the operator. The negotiation demonstrates the real objective of environmental inspection: to try to reconcile conflicting interests and to protect the environment to the greatest extent possible without hindering the development of industrial activities. This leads to a compromise: the objective of control is not to prosecute but to find solutions that lead to compliance. The recent reform of the Environmental Code formalized the negotiation and the concept of the inspection.

What will be interesting in future work will be to examine the limit(s) of this concept of negotiation-based inspection. Are inspectors open to negotiation on any topics concerning the environment, including issues that relate to personal safety? How far can deadlines for compliance be extended? Are there some cases of non-compliance that do

not need to be prosecuted? What criteria should inspectors use to determine which cases of non-compliance should be prosecuted and those which should not?

In 1994, Pierre Lascoumes was doubtful about the limits of this kind of arrangement. Are repeated promises of compliance that are indefinitely postponed really tenable?

The answer has recently been given by the French administrative court, in the case of the AZF accident (*Cour Administrative d'Appel de Bordeaux*, January 24, 2013, n° 10BX02880, 10BX02881). The question revolved around whether or not environmental inspectors could be held responsible for the explosion of the industrial plant. Could it be argued that the inspection had failed and that this failure was one of the elements that contributed to the explosion? For the judges, the answer was "yes". They noted that the operator had committed numerous lapses in the management of the plant, which could be considered to be negligent; however, they pointed out that the inspection agency also made numerous mistakes. The plant was inspected eleven times between March 1995 and May 2001, without any formal notice being sent to the operator about poor management. It appears that the building where the explosion happened had never been inspected. The operator was never prosecuted, despite obvious and persistent failures. The judges noted that the negligence of the inspection agency was particularly serious, as the plant was located in an urban area, which should have justified harsh measures being taken against the operator. Consequently, the French State, because of the mistakes of the environmental inspection agency, was considered as responsible of a part of the accident.

The inspection of industrial plants may be based on negotiation, but the courts remind us that the application of environmental rules can only be negotiated up to a certain limit; and this limit is reached when safety is affected.

Risk assessment methods for improving urban security

C. Schoppe, J. Zehetner, J. Finger, D. Baumann, U. Siebold & I. Häring
Fraunhofer Ernst-Mach-Institut, Efringen-Kirchen, Germany

ABSTRACT: Risk management schemes have been applied to very diverse domains including logistics, health care, aviation, construction, defense, finance and security. Within common risk management processes the selection of dedicated risk assessment methods is crucial to fulfill the general requirements of such processes and some of the most critical risk management steps. There is a generic set of methods recommended by standards. These methods normally originate from a certain purpose but can be applied to systems and processes in general. The main goal of this article is to facilitate the selection of appropriate methods for risk assessment of issues occurring in the context of urban security and safety. Therefore we review and classify most of the risk assessment methods recommended by the generic standard ISO 31010 with respect to criteria relevant for their application in the urban security context, including estimated effort, needed data, expertise and technical support, specificity, and relevance.

1 INTRODUCTION

We understand urban security as prevention of and protection from unintentional and intentional harm resulting from crime or other deliberate human threats as well as anti-social behavior that take place in urban areas. Devising policies and deploying resources to enhance urban security is a complex task, in particular due to the high visibility of security issues to citizens and media and the many influences of urban security on everyday lives as well as economic prospects of citizens.

Considering the uncertainties that are involved in the rationales that determine devising policies and deploying resources there is a need for proper evidence bases that contain relevant information. Risk Assessment (RA) can be used to produce evidence bases for creating policies, for the prioritization of issues that need treatment and to assess situations with respect to the necessity to act. Therefore we propose to employ RA methods to create proper evidence bases to design security relevant policies.

There are many techniques that can be used to assess risks. The ISO standard (IEC/ISO 31010, 2009) alone lists over 30 RA techniques. The question that arises is: how to properly choose an appropriate RA technique that satisfies a given urban security need? Criteria for that can be the applicability with given constraints concerning personnel required, e.g., expert knowledge, timeframes and resources. To this end we review the methods presented in (IEC/ISO 31010, 2009).

The remainder of the article is structured as follows. In section 2 we anticipate urban security needs that RA methods are subject to. In section 3 we outline how needs are reflected within a defined taxonomy for indexing and selecting RA methods. In section 4, we briefly introduce the RA methods and classify them with respect to the taxonomy. In section 5 we conclude and give an outlook.

2 URBAN SECURITY NEEDS

In the following we list a few typical needs for organizations engaged in enhancing urban security. Decisions in urban environments usually take place in a very complex social system with very ambiguous and hardly quantifiable goals and values (Lewis and Hartley, 2001), (March and Olsen, 1989). Therefore we believe that sound explicit RA could support serious decisions and are expected to enhance the outcome of those decisions.

One reasonable need is prioritization of resources. Using RA can be a convenient way to plan resources in order to maintain security. In this way, the consequences of small capacities, e.g., limited monetary or personnel means, can be assessed and thus unforeseen negative consequences can be anticipated and mitigated.

As decisions tackling urban security often have high visibility and may trigger direct opposition, a credible and traceable narrative to justify also ongoing measures is often prerequisite. Here again RA can be of major impact as assessments of risks can be clearly communicated and often also have face validity, for example if bias-avoiding settings are used for generating qualitative assessments of consequences and frequencies.

Application of the presented methods is a complex task and should not be undertaken without proper training. Moreover note that it is not foreseen that solely one method should be applied but it is in many cases favorable to use several methods in a logical sequence.

To underpin the statements of this article we used the safety report of Luzern (Luzern 2013) to determine generic theoretical use cases in the domain of disturbances of the public (anti social behavior). We define case 1 as the generic topic disturbances of the public, case 2 as harassements in public areas, and case 3 as alcohol abuse in public areas. We will refer to these generic cases as Case 1, Case 2, and Case 3 throughout the method assesment.

3 CLASSIFICATION TAXONOMY

In this section we describe the developed taxonomy for classification of RA methods.

When choosing appropriate RA methods for urban security some aspects need consideration. Tight budgets are often a major issue in tackling urban insecurity, also see section 2. This holds true especially for proactive policies which nevertheless often have huge returns on investment. For example, in (Karoly et al., 2005) early childhood programs are evaluated regarding costs and benefits to society and found to have a good return on investment. For these reasons we select the criterion "resources" needed.

Another aspect to consider in regards to the assessment of risks in urban areas is the amount, type, and quality of data that is needed. Therefore we select the criteria "input" needed and the distinction between "qualitative" and "quantitative" for the input required.

A further criterion for using a method is the availability of supporting software, which we allocate to the criterion "software".

We try to estimate the effort that is needed to use a RA method in the field of urban security including the effort that is needed to adapt the method to particular urban security needs. We assume that the effort strongly depends on the focus of the method and the type of system it is usually applied in. So we selected the criterion "specificity". If a method is not focused on a certain aspect and is not intended for certain types of systems we rate the method as "generic". If a method is either focused on a certain aspect or it is intended for certain types of systems we rate it as "semi-specific". If a method is both focused on a certain aspect and is intended for certain types of systems we rate it "specific".

If a method is specific or semi-specific we qualify its specificity more in detail to support the assessment of the effort that is needed to apply the method in the field of urban security.

If a RA method can be used in the field of urban security in principle we determine the field within urban security in detail in the criterion "urban security field" and mention a possible benefit for above mentioned generic use cases (Case 1, Case 2 or Case 3) if applicable.

4 CATEGORIZATION OF RISK ASSESSMENT METHODS

In this section we categorize the RA methods. As proposed by (IEC/ISO 31010, 2009) RA methods can be distinguished in look-up methods, supporting methods, scenario analysis, function analysis, control assessment methods and statistical methods.

In sections 4.1–4.6 we briefly summarize the methods falling in these categories and their outstanding characteristics with respect to urban security. When discussing the methods, we use the taxonomy motivated and introduced in section 3. Table 1 sums up the classification of the RA methods according to the criterion "specificity" from the taxonomy. The values of the other taxonomies are given in the text along with the discussion of the applicability of the methods.

4.1 *Look-up methods*

In the following the look-up methods are described. These techniques present their output in lists in which the operator can look up the risk relevant entities.

4.1.1 *Check-lists*

A check-list is a collection of items (e.g. questions) which help to identify the current state of a system. Check-lists are usually developed by experts for a specific topic or system or reflect past experiences and can be used to identify hazards, risks or assess the effectiveness of a system or component (IEC/ISO 31010, 2009).

Check-lists are a generic method that can be applied in many fields within urban security. Particularly advantageous is that expert knowledge and knowledge from past experiences can be processed this way so that these check-lists can be used with relatively little experience and knowledge.

Check-lists can be applied, e.g., to assess levels of resistance of buildings against burglaries. A check-list for this application could contain questions like: Are there windows that can be seen by possible burglars? Accumulating answers to these kind of questions can help assessing resistance against burglaries. Also for pickpocketing risks rather short check-lists can be useful. In Case3 check-lists might be used to verify if a selected countermeasure was applied on every place where alcohol abuse was observed. The check-list then

Table 1. Specificity of risk assessment methods.

Section	Method name	Specificity
4.1.1	Check-lists	Generic
4.1.2	Preliminary Hazard Analysis (PHA)	Generic
4.2.1	Brainstorming	Generic
4.2.2	Structured or semi-structured interviews	Generic
4.2.3	Delphi technique	Generic
4.2.4	Structured "What if?" Technique (SWIFT)	Generic
4.2.5	Human Reliability Analysis (HRA)	Semi-specific
4.3.1	Root Cause Analysis (RCA)	Semi-specific
4.3.2	Business impact analysis	Generic
4.3.3	Fault Tree Analysis (FTA)	Semi-specific
4.3.4	Event tree analysis	Generic
4.3.5	Cause-Consequence Analysis (CCA)	Generic
4.3.6	Cause-and-effect analysis	Generic
4.4.1	Hazard And Operability Studies (HAZOP)	Specific
4.4.2	Hazard Analysis and Critical Control Points (HACCP)	Specific
4.4.3	Failure Modes and Effect Analysis (FMEA)	Specific
4.4.4	Reliability Centered Maintenance (RCM)	Specific
4.4.5	Sneak circuit analysis	Specific
4.5.1	Layer Of Protection Analysis (LOPA)	Semi-specific
4.5.2	Bow tie analysis	Semi-specific
4.6.1	Markov analysis	Specific
4.6.2	Monte Carlo simulation	Generic
4.6.3	Bayesian statistics and Bayes Nets	Generic
4.7.1	Decision tree analysis	Generic
4.7.2	FN curves	Semi-specific
4.7.3	Risk indices	Generic
4.7.4	Consequence/probability matrix	Generic

could contain names or geo-information of affected locations.

4.1.2 *Preliminary Hazard Analysis (PHA)*

PHA is conducted in several steps (Echterling, 2011) including hazards detection, preliminary classification into risk categories, assessing mitigation or reduction measures and checks if the applied measures comply with the expectations.

Aim is to appraise a preliminary risk category and to propose measures for mitigation using qualitative or quantitative techniques (Echterling, 2011).

Preliminary hazard analysis is a generic method that fits well to urban security issues. E.g. in Case 3 application of PHA could lead to the knowledge of probability and possible consequences of alcohol abuse to the public in the public. I.e. alcohol abuse takes place at certain places at certain times and can lead to a way of behaving that might compromise security of other people. Thus appropriate mitigation and response measures need to be planned and evaluated until the risk can be considered as mitigated.

4.2 *Supporting methods*

Supporting methods are techniques which are normally conducted with a survey manager who tries to educe knowledge or solution approaches from participants in interrogations. They can be applied during application of any of the described RA methods in the context of urban security.

4.2.1 *Brainstorming*

Brainstorming is a qualitative technique for generating ideas, clarifications and solutions (Gogus, 2013). It is a free flowing conversation amongst a group of knowledgeable people where ideas are proposed and discussed. It aims at inventions and the identification of failures and unnoticed hazards.

Brainstorming is a generic method and can be applied to almost any problem or assessment need. Note that results are qualitative in nature and that the analytical means of brainstorming are very limited. Usually no software is needed.

Brainstorming is appropriate for enhancing urban security. The fields of application are not restricted. It is a method that is well suited to be followed up by other methods, e.g. outcome of brainstorming can be further processed in a risk matrix. E.g. in Case1 Brainstorming could be applied at the very beginning to support identification of possible topics that have to be taken into account. In Case3 Brainstorming can be used as a supporting method within PHA to identify counter measures.

4.2.2 *Structured or semi-structured interviews*

This technique is a method to gain knowledge about a situation or a system and viewpoints of persons (Engle, 1998).

It is conducted by an interrogator who asks an interviewee a set of prepared open questions that can treat any themes (Cohen and Crabtree, 2006). Using this method a larger number of stakeholders can be involved because interviewees can be distributed over time and over location (Engle, 1998).

Interviews are a generic method and do not need additional software support. They are a proven methodology in the assessment of impacts and have in particular relevance when it comes to perceptions of risks. This has pitfalls as opportunistic policies should be prevented, nevertheless

interviews are of major use in urban security. E.g. in Case2 pedestrians could be interviewed to assess the impact of harassements in a certain area.

4.2.3 *Delphi technique*

Delphi technique is an iterative process to receive the most reliable consensus of opinions of a group of experts. It is used if there is a lack of appropriate information, for instance because of a lack of statistical/numerical data (Rowe and Wright, 1999).

In this technique multiple interrogations of different experts are conducted in a different way. Delphi techniques aim at untying the positive group effects while avoiding negative group effects. All participants contribute undisturbedly and during input collection implicit group dynamic effects are minimized. After several rounds, the group judgment is taken as the arithmetical mean of all rounds (Rowe and Wright, 1999).

Delphi is a generic method that fits perfect for utilization to enhance urban security. It is not bound to specific fields and is particularly useful to assess complex risks and larger scenarios. However, it needs dedicated time resources of all participants. E.g. in Case2 Delphi could be used to identify measures against harassment for people with different cultural background.

4.2.4 *Structured "What if?" Technique (SWIFT)*

SWIFT is a systematic team based study to identify risks and hazards (IEC/ISO 31010, 2009). It employs structured brainstorming and forms an alternative to hazard and operability studies technique (Card et al., 2012, IEC/ISO 31010, 2009).

SWIFT moderators use pre-developed guide words in combination with prompt words or phrases to stimulate participants to identify risks (Card et al., 2012, IEC/ISO 31010, 2009). 'What if' type phrases are used to investigate risk and how the further process differs from its normal behavior (IEC/ISO 31010, 2009). To identify hazards the facilitator typically asks 'How should' phrases.

SWIFT is a generic method that is useful in urban security and no software is needed for that technique. It is a straight forward approach to identify risks in almost all fields of urban security. E.g. in Case3 SWIFT could support the identification of effective countermeasures for alcohol abuse as the following: Raising alcohol prices in discos might lead to the phenomenon of pregaming as mentioned in (Luzern 2013).

4.2.5 *Human Reliability Analysis (HRA)*

Human reliability analysis is conducted in several steps. After the problem is defined the task is analyzed. During the next step the possible human errors are analyzed (event analysis). Factors that negatively influence human performance and error causes are immediately reduced and then quantified (frequency analysis). During screening in the next step it is estimated whether the error is significant or insignificant (consequence estimate). Significant errors and not screened errors are quantified in the next step. If the level of human reliability is achieved the process is documented. Otherwise the errors are reduced until the human reliability level is reached.

With regard to the aforementioned taxonomy human reliability analysis is a semi-specific method. This technique can be used to avoid faults and identify situations that are prone to induce inadequate actions. E.g. in Case 2 harassment might be encountered by explaining correct behavior to harassing people. HRA could then be used to analyze possible human errors in that task. One could then conclude that e.g. explanation should be performed by people with intercultural background as done in (Luzern 2013).

4.3 *Scenario analysis*

Under the term scenario analysis techniques are summarized, that try to assess a risk using scenarios. By defining a scenario, possible effects or possible causes of effects are analyzed. These techniques can be used to generate a solution which prevents the defined scenarios from taking undesirable turns.

4.3.1 *Root Cause Analysis (RCA)*

Root cause analysis is a technique to determine the root causes of failures in systems (Stapelberg, 2009). It can be used in multiple contexts like manufacturing improvements, safety projects, clinical accident, and crime reports (Reid and Smyth-Renshaw, 2012).

According to criteria given in section 3 RCA is a semi-specific method that focuses on failures in systems. RCA can therefore be used in urban security scenarios within the field of systems that can have failures, e.g. communication systems.

4.3.2 *Business impact analysis*

Business impact analysis is a technique to identify key disruption risks and how they affect operations and what resources are needed to manage them (IEC/ISO 31010, 2009).

This kind of technique involves several steps which are conducted by a team of knowledgeable members (Goldberg, 2008). Aim is to develop strategies for a quick recovery from unexpected incidents.

This generic method can be used in the field of urban security to assess processes and actions that are planned to mitigate risks, in particular after major disruptive events.

4.3.3 *Fault Tree Analysis (FTA)*

Fault Tree Analysis is a deductive process to identify casual factors which contribute to a specific undesired event (Modarres, 2006, IEC/ISO 31010, 2009). It is probably the most common assessment

technique in probabilistic RA to quantify the occurrence of failures in subsystems. To achieve this, it sub-divides a process into its basic components for which adequate data exist (Modarres, 2006).

Fault tree analysis has not to consider all possible failures, only these which lead to the top event (Modarres, 2006). The output is finally depicted in a directed tree diagram. The factors in the tree diagram can be hardware failures, software failures, human errors or pertinent events (IEC/ISO 31010, 2009).

The FTA focuses on the aspect of faults in every kind of system, so we classify it as semi-specific. If a top event is seen as an unintended event within the urban system FTA can be adapted with manageable effort. It should only be applied if combinations of events are crucial and necessary for understanding and improving urban security issues. E.g. in Case2 could be the negative impact on security for pedestrians. One possible failure that leads to the top event can be harassment. One failure that can lead to the aforementioned one could be alcohol abuse (which is in fact Case3). Harassment as consequence of alcohol abuse is also mentioned in (Luzern 2013).

4.3.4 *Event tree analysis*

Event tree analysis is a graphical technique following an inductive logic to represent events and consequences which can result from an initiating event. Additionally systems, functions and barriers can be considered (Stapelberg, 2009, IEC/ISO 31010, 2009).

This technique is a quite generic method to estimate consequences.

We rate this method as appropriate for use in the urban security domain, in particular for understanding and mitigating the spreading of security issues.

4.3.5 *Cause-Consequence Analysis (CCA)*

Cause consequence analysis was developed in Denmark to analyze risks in safety critical systems such as nuclear power stations (Stapelberg, 2009, IEC/ISO 31010, 2009). The difference to other tree analyses like "Decision tree analysis" is that cause-consequence is extended through the possibility to consider time delays.

CCA represents its output in a graphical way, starting from a critical event. Aim is to identify chains of events that can result in an unwanted event (Stapelberg, 2009). In this connection not every event has to be a failure event.

This technique regarding to the aforementioned taxonomy is a generic method that is able to estimate consequences of events. In the domain of urban security it is a valuable feature to take time delays into account. So we assume that this method is even more applicable in the urban security domain than event tree analysis. The drawback of ETA as well as CCA is that they inductively cover all chains of events rather than focusing from the very beginning on undesired security events, like FTA. E.g. in (Luzern 2013) it is mentioned that persons with mental issues or that are addicted to alcohol can be observed as problematic in the context of harassments, which refers to Case2. The application of CCA in Case2 can help to identify the linkage between harassments and people that are addicted to alcohol or have mental issues.

4.3.6 *Cause- and-effect analysis*

Cause and effect analysis is a qualitative method to identify possible causes of an unwanted event or problem.

Cause and effect analysis is a technique that can be used in the root cause analysis. Thereby this technique uses techniques like brainstorming, sometimes tree diagrams and mostly a fishbone diagram to structure a list of causes of a specific effect.

This generic method can be used in the domain of urban security to identify causes of events to counter reasons for unwanted events. This method could also be applied for Case2 with the same purpose as CCA.

4.4 *Function analysis*

These techniques deal with the functionality of a system. Aim is to develop an alternative technical solution to an existing problem.

4.4.1 *Hazard and operability studies (HAZOP)*

HAZOP is a structured and systematic examination of a planned or existing product, procedure or system (IEC/ISO 31010, 2009). The aim is to identify failure modes and their causes and consequences bearing the whole system in mind (IEC/ISO 31010, 2009, Dunjó et al., 2010).

This is achieved by exploring the effects of any deviation from its design condition. This way not only hazards can be identified but also operability problems (Dunjó et al., 2010).

HAZOP is a specific method that was developed for technical uses. Thus it cannot be easily adapted to urban security. Nevertheless the basic idea to identify failure modes and their causes and consequences could prove to be beneficial for urban security.

4.4.2 *Hazard Analysis and Critical Control Points (HACCP)*

HACCP is a method to protect a system against occurring hazards. Protection is achieved by putting controls in place at all relevant parts of the system, process or procedure (IEC/ISO 31010, 2009). It ensures that risks are minimized and possible contaminations are identified before they occur (Cusato et al., 2012).

In summary, HACCP is a technique in which critical key numbers in a system are defined to identify risks and hazards which can influence product quality (IEC/ISO 31010, 2009).

HACCP is a specific method that cannot readily be applied to assess urban security issues. HACCP is used to assess technical systems and thus the gap to urban security is not easily bridged. However, the idea of key sensitivities, observables and mitigation strategies could be a focusing starting point.

4.4.3 *Failure Modes and Effect Analysis (FMEA)*

Failure modes and effect analysis is a qualitative tabular technique to examine possible failure modes and solutions during system design which is conducted preventively to avoid errors and increase the technical dependability (Xiao et al., 2011, Ben-Daya, 2009).

FMEA is a specific technical method that is not particularly useful to assess urban security risks. This holds due to its technical specification.

4.4.4 *Reliability Centered Maintenance (RCM)*

RCM was developed for aircraft industry but quickly expanded in the last years to many other industries.

It is a technique to identify the policies that should be implemented to manage failures to achieve the required safety for a system or subsystem (IEC/ISO 31010, 2009). Thereby, this technique focuses on system functions not on hardware (Rausand, 1998). To analyze a system, RCM asks several questions e.g. concerning functions, causes of functional failures, modes of failures, and suitable proactive tasks (Siddiqui and Ben-Daya, 2009).

Aim of RCM is to reduce the occurrence of failures by focusing on the most important functions of the system and avoiding or removing maintenance actions that are dispensable (Rausand, 1998).

RCM analysis is a specific method. This method is specifically designed to maintain (and optimize) reliable processes. Therefore its key idea is suited for application in urban security: by using this technique strategies can be assessed with regard to their appropriateness.

4.4.5 *Sneak circuit analysis*

Sneak analysis is a technique for identifying latent hazards which arise from design or systematic errors but not from component caused failures (Whetton and Armstrong, 1994, IEC/ISO 31010, 2009).

Originally it was developed to verify design and to discover unintentional electronic circuit paths. Nowadays this technique is advanced to analyze failures in systems with complex workflows (Whetton and Armstrong, 1994). Usually it amends traditional methods such as HAZOP (Whetton and Armstrong, 1994). In this way failure points, unsuppressed inductive loads, unnecessary components, unnecessary software codes or inadequate redundancy provisions can be identified (NASA, 1995).

Sneak circuit analysis is a specific method that seems not to be useful for the enhancement of urban security due to its very technical specification.

4.5 *Control assessment methods*

These techniques assess risk by analyzing the layers of protection and how the risks harm them.

4.5.1 *Layer Of Protection Analysis (LOPA)*

Layer of protection analysis is a semi quantitative analytic tool developed for the chemical industry (Gowland, 2006, IEC/ISO 31010, 2009).

Aim is to develop independent layers of protection to prevent scenarios from changing in an undesirable scenario. Here it is important to ensure that all layers of protection are mutually independent. (Wei et al., 2008). Criteria for independency are given in (Gowland, 2006, Wei et al., 2008).

LOPA is a semi-specific method that can be used to assess the effectiveness of controls that have been put in place to mitigate urban security risks. LOPA offers a rather technical framework for performing such analyses. E.g. in Case3 one layer of protection could be the legal prohibition of selling alcohol in certain areas. A second layer of protection could be a number of social workers at the affected areas. LOPA can support the analysis of these protection layers.

4.5.2 *Bow tie analysis*

Bow tie analysis is a qualitative, iterative technique often conducted by a team. It unifies fault tree analysis and event tree analysis. This technique visualizes all effects leading to a top event and all consequences which result from the top event (Badreddine and Ben Amor, 2010).

Bow tie analysis is a semi-specific method. As it combines two methods which fit to the purpose of urban security enhancement, we believe it to be suitable for rather extensive analysis of specific security issues, e.g., terroristic events.

4.6 *Statistical methods*

Statistical methods use mathematical models to assess risks. These models use probabilities to predict the possible development of a process or system.

4.6.1 *Markov analysis*

Markov analysis is a technique which can be used when the assumption that the future state of a system depends only upon its present state holds (IEC/ISO 31010, 2009). Markov analysis assesses the reliability of a given system (Muthu and Petrou, 2007) by analyzing the transition probabilities, i.e. knowing the state the system is currently in, by the

means of Markov analysis the likelihood of transforming into another state is computed.

Markov analysis is a specific software-supported method. For many fields in urban security we deem it unlikely that the Markov property holds, i.e. that future events only depend on the present situation and are not influenced by past events.

4.6.2 *Monte Carlo simulation*

Monte Carlo simulation is a probabilistic technique conducted with software. It is applied where exact numerical methods cannot be reasonably used because of the complexity of the system (Pellicione and Lu, 2008). To cope with this complexity random distributions are estimated and the system is tested by using samples from the distributions as input.

Monte Carlo simulation is a generic RA method. Due to its complexity in calculation especially if many entities are involved we state that it can probably only be used to model very few and very particular aspects of urban security.

4.6.3 *Bayesian statistics and Bayes Nets*

Bayesian statistics are founded on the Bayes theorem that can be used to calculate conditional probabilities. Bayesian statistics are often represented as Bayesian Belief Networks (BBNs). BBNs are directed acyclic graphs that represent probabilistic dependency models. What distinguishes the BBNs from other casual belief networks is "the use of Bayesian calculus to determine the state probabilities of each node or variable from the predetermined conditional and prior probabilities" (Krieg, 2001), meaning that the probabilities can be based on a person's belief of the likelihood of an event.

Bayesian statistics are a generic method that is well suited for assessment of urban security related risks. In particular, with corresponding effort, BBNs can be applied to model severity of consequences for different scenarios based on expert opinion.

4.7 *Others*

All techniques that do not fit into one of the above categories are collected under this chapter.

4.7.1 *Decision tree analysis*

Decision tree analysis is a formal, structured and graphically supported technique used to simplify knowledgeable decision making. Branches in the diagram represent a classification rule and decision nodes indicate the value on target classes, (Doğanavşargil and Fattori, 2008). Big amounts of data and complex problems can be analyzed. Decision tree analysis helps to decompose unmanageable data volumes and problems into decision rules and to assess solutions (Doğanavşargil and Fattori, 2008).

Decision tree analysis is a generic method and should be applicable to urban security issues.

4.7.2 *FN curves*

FN curves are represented in diagrams that "are a graphical representation of the probability of events causing a specified level of harm to a specified population" (IEC/ISO 31010, 2009) or object class, e.g. built infrastructure. FN curves can be seen as continuous risk matrices and can be used to assess levels of risks by comparing the actual assessments of the risks with previously set thresholds.

FN curves are a semi-specific method and can be applied to urban security, e.g. for assessing explosive scenarios. FN curves can e.g. be applied to compare risks to levels of risk defined in standards (Suddle, 2003).

4.7.3 *Risk indices*

Risk index is a semi quantitative technique with the aim to rank different risks (IEC/ISO 31010, 2009).

After a detailed description of the monitored system, "scores are developed for each component in such a way that they can be combined to provide a composite index" (IEC/ISO 31010, 2009).

Risk indices are a generic method and can be applied for monitoring risks in urban environments.

4.7.4 *Consequence/probability matrix*

Consequence/probability matrices are also known as risk matrices. They present their output in a pictorial way in form of a matrix. Risk matrices are likewise used to rank different risks to determine which risks need further or more detailed analysis. They also create a common understanding for a level of risk (IEC/ISO 31010, 2009) and its communication.

With help of such matrices it is easy to assess risks in an intuitive way and arrange risks in damage classes. These damage classes can be of qualitative or quantitative nature. By coloring the different damage classes the risk matrix is even more intuitive understandable. Thereby the allocation of the damage classes is up to the user.

Risk matrices are a generic method that can be used intuitively and can be very convenient for a first assessment of risks to decide which risks should be considered in more detail. This way risk matrices are a very appropriate means for assessing risks in urban environments as can be seen, e.g. in Luzern (Luzern 2013).

5 CONCLUSION AND OUTLOOK

In this paper we briefly presented RA methods and assessed their relevance from the perspective of urban security. We proposed a categorization of the RA methods relevant for urban security.

In doing this we tried to extend present taxonomies as e.g. presented in (IEC/ISO 31010, 2009) for practical use in urban security. We demonstrated the practical relevance of the taxonomy for the selection of methods by giving application examples of the described methods where appropriate.

Future work could add more assessment methods and develop a software application that facilitates easy method selection for urban security practitioners. Moreover, we could refine the selection taxonomy or apply it to related domains, e.g. airport security.

This publication results from the BESECURE project (Best practice Enhancers for Security in Urban Environments, http://www.besecure-project.eu), funded by the European Union FP7 Security Programme under grant agreement number 285222.

Christian Michelsen Research AS, Bergen, Norway

ABSTRACT: Goodtech and Statnett SF have developed an online regularity calculator with minimal delay between acquisition of process values and presentation of regularity indices for the power grid. The simulation tool calculates the probability of failure on every component in the system and combined with a flow model, the reliability of power supply for every load branch. In order to analyze and understand all risk and reliability changes every 10 minutes for the large network a new representation method must be developed and tested.

In this paper a new methodology for representation of how changing risk level can be presented for power system operators is introduced. By manipulating the geographical representation of the 7000 branched power system based on calculated risk levels and power flows, it should be possible to, by "one look at the screen", understand the current risk level and weigh the changes occurred.

1 INTRODUCTION

The fascinating, but very complex field concerning reliability analysis of power systems was opened by J. Endrenyi in his excellent textbook (Endrenyi, 1978) and later expanded by R. Billinton and R. N. Allan in their textbooks (Billinton, 1983) and (Billinton, 1996). Both these pioneers pointed out the efficiency of Markov models. However, lack of efficient tools for building large Markov models restricted practical application of this method and several publications has argued, incorrectly, that Markov models was not applicable in practical applications.

In a master's thesis carried out by Arne Brufladt Svendsen (Svendsen, 2002), thesis advisor Tørris Digernes discovered a method suitable for building large Markov models. A central clue in the calculation was the Kronecker matrix operators, (Sasty, 1999). The method was tested by Svendsen in his thesis and found to be very efficient for reliability analysis of power systems. Since then, various R&D projects concerning offline calculations of reliability of supply in complex meshed power grids have been carried out.

Although the simulation program Promaps was designed for offline analysis, it was early recognized that the concept also was suitable for online analysis. In 2009 an agreement between Goodtech Projects & Services and Statnett SF in Norway was signed concerning development of a computer program for online calculation of reliability of supply in the Norwegian main electrical power grid. The project was put in online operation October 2013 in Statnett's operational central.

The industry standard for visualizing the power system consists of nodes being positioned relative to each other, with respect to their geographical position, with straight lines representing cables and connections. During testing and verification of the online risk simulation tool, the need for new ways to visualize large networks rapidly became obvious.

More expressive and informative overviews over the power system may be produced by lessening these established constraints regarding visual representation.

In order to analyze and understand all the risk and reliability results every 10 minutes for the large net-work, a new representation of the changing risk level has been developed and tested.

Similar experiments on graphs in general have been heavily researched in the recent years (Landesberger, 2011). This is partly due to graphs of larger sizes appearing in several domains and due to more powerful processing capabilities on computers.

This document contains a presentation of the online risk tool Promaps Online, currently running simulation of the Norwegian power system. Furthermore in this paper we introduce some of

these latest graph visualization techniques into the realm of power system network analysis. In the following sections, we will present three different techniques applied on a power grid, edge bundling, focus and context visualization and non-geographic graph layout with clustering.

Section 2 presents the needs as seen from the grid owner's point of view. Section 3 presents the principles and background behind the reliability calculations. Section 4 describes how results are presented today, and how new techniques can be used to enhance visualization. A brief description of "non-electrical" applications is presented in section 5. The conclusions are presented in section 6.

2 THE TSO POINT OF VIEW

The Transmission System Operator (TSO) is faced with increasing requirements regarding the reliability of power delivery. The cost of not delivering agreed energy can be substantial.

In Norway there is a cost (CENS) connected to energy not being delivered. If a grid company has low continuity of supply, the company will experience a reduction in the allowed network charges every consumer pays.

The most important tools for power system operators are power flow calculations, dynamic analyses etc. To analyze the reliability of supply, additional tools are needed.

2.1 *Calculation tool*

It is easy for a TSO to recognize the need for simulation tools that can calculate the risk levels for different time horizons. Such a simulation tool should be useful for a TSO in online operations, day-ahead and intraday short-term grid planning:

Online operation:

- In online operation the risk level is calculated every minute and evaluated if risk indexes are out of boundary or out of planed and accepted risk level for the coming hours.

Day-ahead and intraday-planning:

- Short time planning of operation to perform detailed simulations for the next days based on planned power system parameters and grid configuration.

2.2 *Visualization*

With the new reliability calculation tools entering the industry, TSOs are for the first time able to get detailed information about the state of the power system every 10 minutes. However, it's not enough to receive the data, the operators must also be able to understand it, analyze it, and if necessary take precautionary actions.

This cannot be achieved in a satisfactory manner using tables and graphs, and conventional visualization techniques do not offer the necessary flexibility. Illustrating the state of the power system using fixed nodes and straight lines limits the amount of data that can be presented to just a few key parameters. In general, all information must be presented using only changing colors and numbers. There are several drawbacks to this approach.

1. Only a very limited amount of information can be shown at any given moment
2. In order to show the entire grid, a large number of big screens must be used, making it hard to get an overview

It is however not enough to create a new visualization technique. It's even more important to obtain and select the most relevant and useful information.

3 ONLINE RELIABILITY CALCULATIONS

Online calculations in Promaps consist of the following steps:

– Data acquisition
– Calculate probability and frequency of branch failure in power grid
– Calculate probability and frequency of all contingencies, and select a subset of contingencies with the highest probability of occurring
– Calculate consequences of the contingencies selected in previous step.
– Calculated aggregated risk indices based on probability and consequences of all selected contingencies
– Present results for users

These steps are then repeated every ten minutes, as new data is available, thus enabling trending of risk indices. A closer description of each step follows.

Data acquisition requires that Promaps is integrated in the TSO's SCADA-system. Necessary data are: an electric model of the power grid, process values, switch positions, information about protection schemes, and information about available spinning reserves. During online calculations only process data, switch positions and spinning reserves are necessary to update at every iteration.

Probability and frequency of branch failures are calculated by compositing Markov models and aggregation of states. Promaps represents each component, related to power flow properties, with a Markov model. Each model describes

possible states of the component and frequency of transition between states. Examples of states can be "functioning normal", "temporary error" and "sustained error". Markov models representing each branch in the power grid are then created through compositing models of all relevant components, and aggregating all resulting states with similar net effect on the power system. This enables Promaps to model every individual component in the power grid, thus making use of all available failure statistics. The full explanation of this methodology was presented in (Digernes, 2004).

A contingency consists of one or more branches failing at the same time. For a large power grid, the number of possible contingencies is infinite for all practical purposes. Therefore, consequence evaluation of all possible contingencies is not possible. Instead, Promaps calculates the probability of each contingency occurring, and select a subset of contingencies based on the probability. This subset typically consists of a few thousand contingencies, but will usually cover close to 99% of the complete probability space.

Each contingency has to be evaluated for consequences for the power grid. Consequences of interest are reduced ability of delivering power to load points. Promaps uses an economical load flow model, where different costs are assigned to production and spinning reserves, and load shedding are prioritized according to cost of not delivering energy. The methodology also supports different kinds of system protections.

Risk of the system not being able to deliver required energy to each load point can be calculated based on probability, expected frequency and consequences of all consistencies. Several risk indices can be derived from these results, the main risk index calculated in Promaps being *system minutes*, SMS. System minutes are the expected energy shortage normalized on the size of the power grid.

In the end the results are presented graphically to the users. Promaps has based its graphical view on TSOs SCADA pictures, adding a layer of risk indices.

4 PRESENTATION OF RESULTS

4.1 *Risk parameters*

To be able to quickly asses a power system's risk level, few key risk parameters should be presented. In Norway there is a cost for energy not being delivered to the customer (CENS). This cost is divided into different customer groups and time of day. When a TSO experience a loss of load, the TSO will get a reduction in next year income based on outage and the corresponding CENS cost.

The Promaps simulation tool calculates the power delivery reliability as a function of demand, the probability for undelivered energy for each load branch in the system and for the system as a whole. Therefore the CENS cost factor could easily be included in the results and are currently one of the system risk indicators used. In addition not delivered energy and corresponding CENS cost, System Minutes (SMS) is used as an online risk indicator.

4.2 *Standard operational view*

Currently the SMS index is being used to set the limits for the dynamic color indication for the risk level in the system. In the test evaluation phase that is ongoing, the following level is set for the total System Minute (SMS):

– 0–10 minutes, no color
– 10–15 minutes, yellow color
– >15 minutes, red color

The color indication is shown on a regional level in Figure 1. The colors represent the expected energy shortage normalized of the size of the respective region.

The color indication is shown on the single line diagram of Figure 3 for each load branch and for the total system. If there is yellow risk indication for the system the operator should evaluate possible action to be taken if the risk level further increases. If the system experience red indication the operator shall perform a power system action to reduce the risk.

The schematics in Figure 2, is based on the schematics currently being used by the TSOs in their operational central.

The TSOs need several such images in order to cover the entire grid. In addition, if a critical component lies on the boundary between two areas, it will be hard to get an overall picture of how actions carried out by the operator will impact the system in both regions.

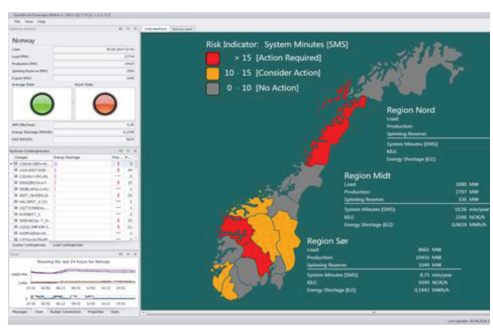

Figure 1. Overview of the risk level in each region.

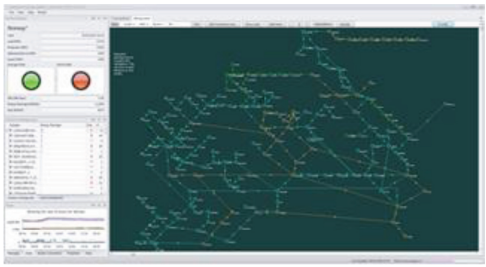

Figure 2. The standard operational view for one region.

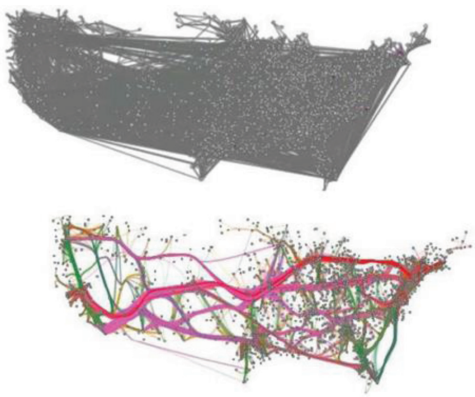

Figure 3. Edge-bundling. Naive visualization of migration between states in the US. Edge-bundling reduces clutter.

4.3 *Edge bundling*

Edge bundling is a technique where edges are attracted to each other so that edges that both move in the same direction and are next to each other bundle together into so called edge bundles. When the destination nodes are reached, the edges fan out from the bundles. The advantage of this method is most dominant in examples where the amount of edges is very high and connections are crossing each other in all directions. For such situations, normal straight edges will result in having the visual area overdrawn with edges so that none are discernible from each other. See Figure 3.

Bundle-thickness as well as color representing degree of flow adds extra information (right) (Cui, 2008).

To demonstrate this technique on the Norwegian power net, we have artificially added an extra amount of edges in the central part of the country and compared the result with original straight edge visualization (left) and edge bundling (right) in Figure 4.

The large square shows how edges are clustered into groups so it is easier to follow them. The small square shows a node with three edges going out in a similar direction and how the clustering of them before they fan out gives a more visually pleasing and easy-to-trace presentation. In general the visualization becomes more organic when using edge bundling. The technique could be particularly useful for power systems which have connectivity more similar to the one in Figure 1.

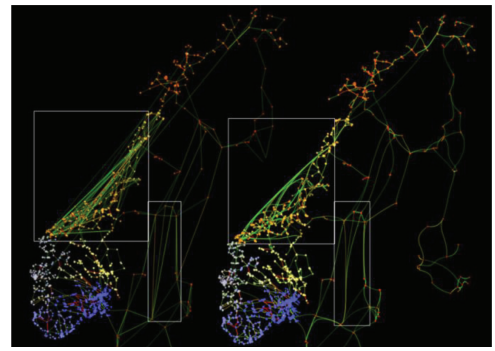

Figure 4. Demonstration of normal visualization (left) and edge bundling (right) on the power net of Norway. Extra edges have been added in the large box for demonstration purposes.

4.4 *Focus and context visualization*

Focus and context visualization is the technique of showing in the same visualization both details on the area of importance for a particular task (the focus area) and at the same time provide an overview so one can see the relations between the detail and the whole system (the context). The state of the art report (Herman, 2000) presents focus and context for the field of graph visualization.

Figure 5 shows three different views of the power system in Norway. SMS levels on nodes indicating capacity are colored from high to low with the color scale green-yellow-red. Edges are colored according to percentage of max flow with color scale blue-yellow-red where red is maximum. The smallest map to the left gives a compact overview. One can identify two areas being yellow and one being red. The center map has a higher zoom for better details while the rightmost map exhibits the focus and context property where the area which was red has been zoomed in on while displacing the nodes and edges around. One can imagine several such zoom-ins simultaneously on areas of particular importance.

Figure 5 shows such a focus and context example where the whole grid is shown as context while the area of maximum load is shown expanded in such a way that the neighboring nodes and edges

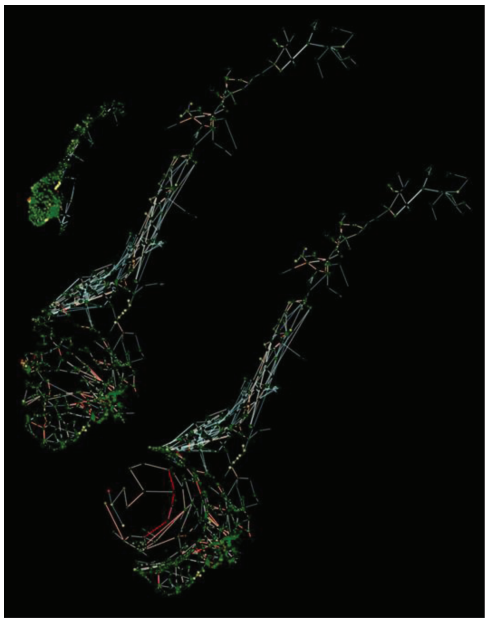

Figure 5. Three different views of the power net of Norway. SMS levels on nodes indicating capacity are colored from high to low with the color scale green-yellow-red.

are being pushed away. Such visualization can be made dynamic so that areas of importance get larger screen space while less important areas shrink, but still maintaining an overall correct geographic placement of the nodes.

4.5 *Non-geographic graph layout with clustering*

In this section we will demonstrate the effect of giving the network a new layout which is not based on geographic location, but on an abstract placement that distributes nodes and edges for reducing overlap and having a more even distance between nodes by spreading nodes that are very close to each other.

One of the main challenges of visualization of risk results is the complexity of causes and effect that comprises the results. The main contributing causes to the result might be located far from the load points affected, thus making it difficult to compress all relevant information into a single picture. For instance, a large industrial load can be greatly dependent on a few power lines supplying power to a greater topologic area. Usually the TSO are aware of these cuts, and monitor them, but new critical cuts might suddenly arise in if the total load of the system rises or maintenance work is performed on some parts of the power grid. It might thus be more appropriate to move away from the classical power grid views, and instead develop methodology for dynamic power grid view that do not focus on flow and topology, but instead highlights critical cuts and components. The idea is to make a picture of the power grid that hides away everything that is performing normal, and instead emphasizes on the few components that are critical for the reliability of the power grid. Such an approach might also lead operators to a better understanding of reliability in power grids.

Błąd! Nie można odnaleźć źródła odwołania. clearly illustrates how an abstract representation of the power grid can help emphasize the most important components.

In **Błąd! Nie można odnaleźć źródła odwołania.**, colors are added to easily differentiate the different geographic regions in the abstract network.

It can be seen that the abstract representation in Figure 7 clusters the region into parts that have weak connections in between. This can be helpful for identifying vulnerable connections and meaningful clusters.

In Figure 8 connections between clusters are shown only as single edges. The number on the

Figure 6. Figure on the left shows geographic layout while the one on the right shows abstract layout.

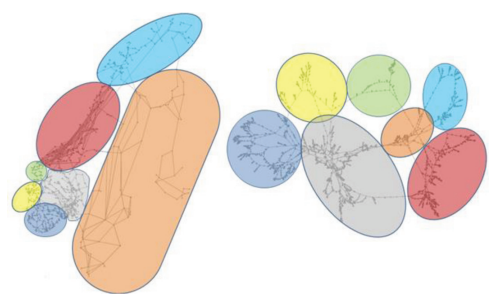

Figure 7. Figure on the left shows geographic layout while the one on the right shows abstract layout. Colors are added in order to easily identify the geograpic locations.

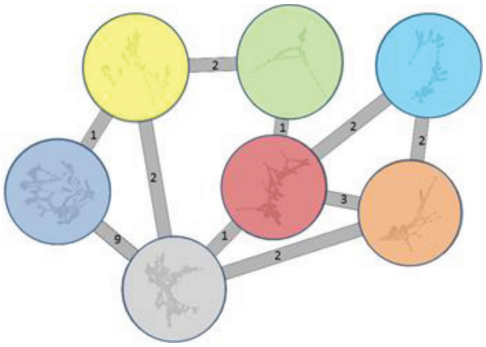

Figure 8. Regions shown as clusters, with single edges representing connections between clusters.

Figure 10. Splitting of clusters into subclusters.

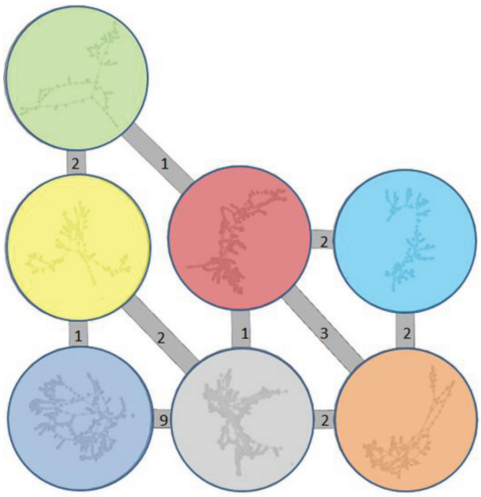

Figure 9. Regions shown as clusters, arranged in a regular grid.

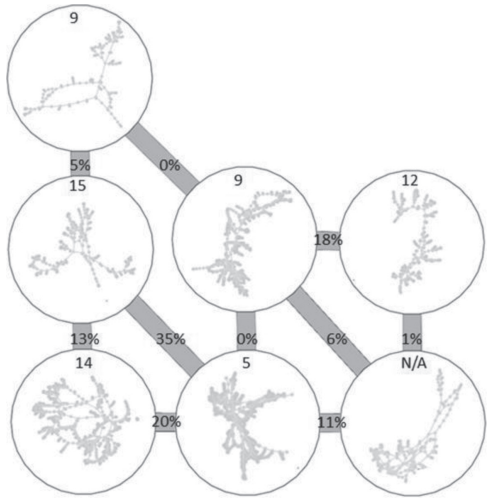

Figure 11. Values in supernodes represent SMS. Values on superedges represent percentage of maximum capacity.

edges tells how many actual branches there are between the clusters. As can be seen, few edges connect the clusters with each other. The color coding is identical to the image to the left in Figure 7.

Compared to Figure 7, the subgraphs in each cluster are represented in a more untangled way, as the connections are combined in superbranches instead of single edges. All clusters can easily be viewed in more detail by zooming in, with more information being included in the picture for each branch and node.

One of the main benefits of the clustering approach is that changes in network topology, as a result of outages or maintenance can easily be spotted, as the cuts are dynamic. If critical lines are out of operation, the entire representation will change, and new critical components will immediately be prominent.

Each of the clusters can be further split up into subclusters, that, when zoomed in on will show the most critical components within a given region, as shown in Figure 10.

Figure 11 shows how the system state can be shown in a very simple way using the clustering technique. The values in the supernodes show the SMS values, whereas the numbers on the superbranches represent the branch flows as a percentage of the maximum capacity.

Coloring of supernodes can be used to indicate information about energy surplus/deficiency in each area or the amount of spinning reserves in each area. These are important contributors to the overall risk calculation results.

5 "NON-ELECTRICAL" APPLICATIONS

Typical non-electrical applications are fluid flow systems including oil flow, and general material transport. Presumably also traffic and communication systems can be analyzed by this method. In these cases the power flow model is replaced by the actual system model. The principle based on unit models can also be used in general probability and reliability calculations to build extremely large models.

6 CONCLUSIONS

After installing the new simulation tool for reliability studies at Statnett SF, the need for a customized presentation method has become prominent.

Several approaches has been implemented and tested, some of which are included in this paper.

The most promising approach has been the graph layout with clustering. This approach gives the opportunity to, by a single look at the screen, identify the most critical cuts, and get an overview of the risk level in each area along with the state of the power system as a whole. By zooming in on a cluster, more information regarding the risk related to each individual branch and bus is shown.

The focus and context approach is particularly suitable if the operators want a complete overview of the power system, while still being able to identify individual critical components. It offers a great way of visualizing changes in a network over time, as different parts of the system will be prominent, depending on the current risk level in each area.

Edge bundling is suited to use in combination with the focus and context approach, as branches in areas of little interest can be bundled together, in order to simplify the presentation.

ABSTRACT: In the definition of safety states of water supply system the quality of drinking water plays an important role. Especially, trihalomethanes as disinfection by-products have to be taken into consideration, because they are dangerous for consumer's health and their concentration usually increase in water distribution subsystem. In this paper the method of determining the thresholds for water quality states (included in the comprehensive method of safety analysis) is presented. The states are based on chloroform because its share in total trihalomethanes is about 80%. Using the tools of mathematical statistics the relationships between chloroform and other quality and operational parameters of drinking water were analyzed and applied to an estimation of quality states. Additionally, the estimation of quality states was based on chloroform in drinking water flowing out from water treatment plant to water pipe network. The study was based on data obtained from the real water supply system.

1 THE PROBLEM OF TRIHALOMETHANES FORMATION IN WATER SUPPLY SYSTEMS

Decreasing water demand in water supply systems, that has been observed in last time, results in longer time of water delivery to consumers. This fact causes a health hazard because of water bacteriology contamination in pipe network. In order to maintain a high safety of exploitation of water supply system it is required to use monitoring system as a control process of water quality during its treatment and distribution. Testing for quality is crucial because the water's contents change constantly during its transport to the consumers. Many factors affect these changes, most importantly: chemical and biological stability of drinking water delivered into water pipe network, its temperature, water pipe's hydraulic exploitation conditions, its technical and sanitary condition, material from which the pipes are made, chemical and biological deposits and disinfectant presence.

Low concentration of disinfectant in the transported water is the cause of secondary growth of microorganisms, which leads to creation of a biofilm. Intensity of biofilm creation determines the lack of water's biological stability. Secondary growth of microorganisms is favored by high water temperature (above 15°C) and low water flow in the pipes (less then 0.1 m/s), which is the reason why water stays in the pipes even for several days (Gatel et al. 2000). The result of biofilm creation is the increase in water's color intensity, turbidity and the level of contamination with organic substances, ammonium nitrate, and corrosion products as well as bad smell and taste. Another consequence of the above phenomenon is the increase of the risk of creation in the water of heterotrophic organisms and bacteria (Okabe et al. 2002).

In order to avoid this threat the water chlorination is commonly applied in water treatment processes. This technology of water disinfection is popular in the whole world because of high efficiency and low price of chlorine. On the other hand, high chlorine concentration in water determines the formation of significant level of disinfection by-products mainly containing trihalomethanes. Trihalomethanes have toxic, carcinogenic and mutagenic character and they are dangerous for human health (WHO 2000, Krasner et al. 2006, Richardson et al. 2007, Goslan et al. 2009, Bull et al. 2009). During the water transport the chlorine react with humic substances, which are trihalomethanes precursors, and with

other organic substances of low compound mass (Rodriguez & Serodes 2001, Serodes et al. 2003, Golfinopoulos & Nokolaou 2005, Toroz & Uyak 2005, Wei et al. 2010). Also changing hydraulic conditions, caused by low demand, low flows and changing transport directions increase the trihalomethanes concentration (Francis et al. 2009, Tchórzewska-Cieślak & Rak 2010). The crucial problem is to study the kinetics of the trihalomethanes formation process. The literature review has shown many methods in which different factors are considered, however the problem has no unique solution (Baribeau et al. 2001, Lee et al. 2001, Gallard & Gunten 2002, Abdullah et al. 2003, Sadiq & Rodriguez 2004, Chowdhury et al. 2009, Shan et al. 2012, Villanueva et al. 2012).

The formation of trihalomethanes during the water transport in water pipe network is obvious considering present exploitation conditions. Disinfection by-products cause the decrease of water system safety so its monitoring is indispensable. The quality of drinking water is an important element of the comprehensive safety model (Zimoch 2011, Zimoch & Łobos 2012). They should be applicable in safety assessment which is the main matter of this paper.

2 CHARACTERISTIC OF CRACOW WATER SUPPLY SYSTEM

The current water supply system of Cracow city arise as a result of constructing the water treatment plants for over 100 years, their modernization and as well as the water-pipe network development resulting from building new housing at outskirts of the city. The system consists of two complex subsystems: water production subsystem and water distribution subsystem. The water production subsystem is built of water supply arrangements which create separated treatments lines feeding on surface water sources from Rudawa, Dłubnia, Sanka River, Dobczyce reservoir and underground water from intake in Mistrzejowice. Actual capacities of all water treatment plants cause that the Cracow water supply system is the system with excess, i.e. maximal system's reserve is about 74% of average twenty-four hours water demand.

The Raba Water Treatment Plant plays the most significant role in delivering water to the city; its average daily production is 80,760 m^3, which is approximately 48% of daily water demand. During emergency periods this water treatment production covers the full demand of citizens.

The Raba Water Treatment plant takes the raw water by tower-type water intake from reservoir Dobczyce, which has possibility of water intake from a level of the best quality parameters. The reservoir in Dobczyce is an unstable and non-homogeneous water resource. Its waters undergo typical qualitative and quantitative changes. The parameters that the most often reduce the season class of water quality are: total phosphorus, chlorophyll and oxygen sag. The eutrophication process results in domination of green algae and diatom phytoplankton that intensively develops from the spring to the late autumn. Late summer in the water depth there blue-green algae appears. These processes cause that the content of organic matter is high and its major part is precursors of trihalomethanes.

Raw water in Raba Water Treatment Plant is oxidized in the process of preliminary ozonization in contact tank with two chambers. Usually the dose of ozone is less than 4 g/m^3. Ozone is produced on the spot by system of PCI Ozone of capacity 30 kgO_3/h. Then water flows to the separation chamber where the coagulant (PAX or aluminum sulfate in dose 0–40 g/m^3), Magnaflok (in dose 0–0.5 g/m^3) and sometimes the active carbon (in dose 0–10 g/m^3) are added. In the next chamber the water jet is separated into two technological treatment lines: Raba I and Raba II.

Raba I contains a system of classic coagulation which consists of: three chambers of fast mixers, twelve flocculation chambers, and two coagulation horizontal settling tanks of capacity 8000 m^3. Then water is steered to 12 sand rapid filters of area 44 m^2 each and total capacity 1200–1300 m^3/h. The last step of technological process is disinfection using gas chlorine. Treated water is pressed by pumping station to water tanks in Gorzków, and then to water distribution subsystem.

The coagulation process in Raba II is realized in 4 accelerators of nominal capacity 2160 m^3/h. Next, water is steered to 16 fast sand filters of area 85 m^2 each and capacity 3800–4000 m^3/h. The final water treatment process is disinfection using chlorine dose 0.5–2 g/m^3. Drinking water, after disinfection, is also pressed to tanks in Gorzków.

Drinking water is transported from Raba Water Treatment Plant to the control station Piaski Wielkie (Cracow suburb) by system of transit waterpipes of diameters ∅1000 and ∅1400 and length about 17 km where water tanks in Gorzków (of capacity 22,500 m^3) and tanks complex in Siercza (4×34.000 m^3 and 3×7.500 m^3) are localized.

Drinking water in Cracow is delivered to consumers by main water-pipes (∅1200–∅350, length 282.72 km), distributing water-pipes (∅325–∅80, length 1100.21 km) and household terminals (∅100–∅25, length 466.27 km). Total length of the distribution subsystem on the city area serviced by City of Cracow Water and Sewage Utility Company is 1849.26 km. Over 100 years of functioning and continuous development of the water supply

system have resulted in great diversity of age and materials of various water-pipes. The main part of age structure is water-pipes made after 1975 (56% of total length). Majority of such water-pipes are made in 90's (26%), with application of new technologies and materials. The most significant part of water-pipes of water distribution subsystem is made of steel (32%), cast iron (26%), and PCV (23%). Inseparable elements of distribution subsystem are equalizing-reserve tanks. The Cracow water supply systems uses 11 water tanks of total capacity of over 276,200 m^3. These tanks capacities back up the level of 165% actual average twenty-four hour water demand in the city.

The complex structure of water supply system in Cracow, long distance from the main water treatment plant (Raba) and less water demand in the city result in increasing time of delivering drinking water to consumers. Additionally, the usage of chlorine in the disinfection process as well the presence of organic matter including significant part of trihalomethanes precursors in treated water cause the danger of harmful and carcinogenic disinfection by-products formation. Thus the higher concentrations of chloroform in drinking water are periodically observed.

3 RESEARCH DATA DESCRIPTION

Presented study is based on laboratory analyzes of various water quality parameters obtained by Central Water Quality Laboratory in Cracow Water Company. The analyzes were results of regular control monitoring procedures made by the company as well as additional study carried out within the framework of the project supported by Polish State Committee for Scientific Research under the contract No. 5T07E 044 25.

Data were collected from January 2007 to December 2013. Water samples were taken at Water Treatment Plant Raba and at selected 23 sampling points on water distribution network. Basic quality and operation parameters such as pH, residual chlorine, chlorine dose, chemical oxygen demand, UV absorbance in 272 nm, temperature were tested everyday at water treatment plant, but disinfection by-products parameters are analyzed once a month. Water quality parameters that characterize the process of disinfection by-products formation (such as pH, temperature, UV absorbance in 272 nm, total organic carbon, residual chlorine, chloroform, sum of trihalomethanes) in water pipes were analyzed on average once a month.

Additionally, in our research some important parameters were determined. They are: the distance from water treatment plant to sampling point, supply zone, efficiency parameter, and chlorine consumption. Each sampling point on the network was allocated to one of five supply zones dependently of its distance from water treatment plant (zones were designated every 5 km, i.e. the first zone was from 0 to 5 km, and the last zone—greater than 20 km). Efficiency parameter was defined as the ratio of zone and total production capacity. This parameter is a measure of contact time of drinking water in distribution subsystem with chlorine; it is also connected with daily water demand by consumers (the greater demand the greater production). Chlorine consumption is calculated as the difference between the total chlorine dose (the sum of chlorine doses in water treatment plant and water tank in Siercza) and the residual chlorine at sampling point.

Water samples were collected according to the Polish Standard PN-87/C-04632/01-04. The quality of water samples was specified according to the following procedures:

- pH [dimensionless]—PN-90/C-04540.01 (multifunction apparatus inoLab MultiLevel1),
- temperature [°C]—PN-77/C-04584 (mercury thermometer),
- chlorine [mg/dm^3]—PN-ISO 7393-2:1997 (photometer PC Compact Chlor),
- absorbance UV_{272} [cm^{-1}]—PN-84/C-05472 (spectrophotometer HACH DR 4000U),
- chemical oxygen demand [mgO_2/dm^3],—PB-NJL-W-15 (spectrofotometer HACH DR 4000U),
- total organic carbon [mgC/dm^3]—PN-EN-1484-1999 (analyzer TOC 5050 Shimadzu),
- chloroform and trihalomethanes [$\mu g/dm^3$]—75-PB-NJL-W-06 (gas chromatograph HP-5890GC/5970MSD).

Table 1 presents basic descriptive statistics of obtained data. Finally, the stochastic sample was consisting of 2838 cases and the total number of obtained cases of all considered variables was equal to 23,967. However, there are many missing data, so in further study the set of 333 cases was considered. This set consists of these sample points for which the chloroform concentration at network point and at water treatment plant were given (laboratory analyzes are made according to the monitoring plan which takes into account high costs of gas chromatography).

Although there was a large number of data (missing data were pairwise deleted) not all correlation coefficients between considered variables were found to be statistically significant. Statistically significant are coefficients of correlation between chloroform at network point and some variables measured at water distribution subsystem (residual chlorine, chlorine consumption) and measured at water treatment plant (total chlorine dose, chemi-

cal oxygen demand, total organic carbon, temperature, chloroform); their values are given in Table 2 and confirm known facts of disinfection by-products generation (Baribeau et al. 2001, Chowdhury et al. 2009, Villanueva et al. 2012).

One of important stage in our research on models of system safety is the selection of a valid parameter from the set of disinfection by-products. There are many papers (Lee 2001, Sadiq & Rodriguez 2004, Zimoch & Łobos 2008, Chowdhury et al. 2009) devoted to the problem of formation of trihalomethanes (THM) which are the sum of four

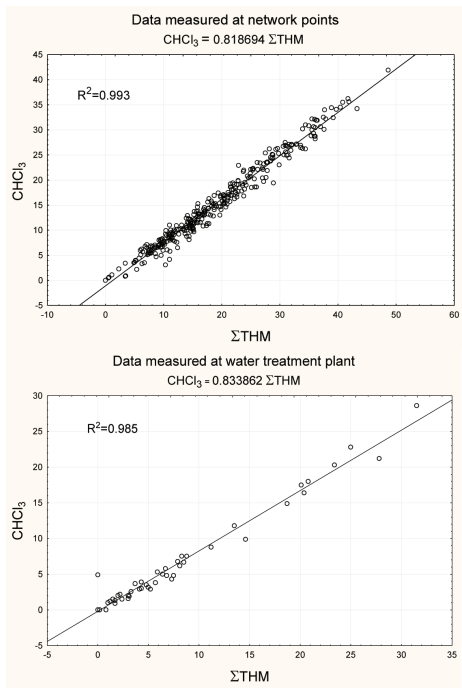

Figure 1. Relation between concentrations of total trihalomethanes and chloroform at network points (upper graph) and at water treatment plant (lower graph).

chemical compounds: chloroform ($CHCl_3$), bromodichloromethane ($CHCl_2Br$), dibromochloromethane ($CHClBr_2$), tribromomethane ($CHBr_3$). It is shown in some papers (Urbansky & Magnuson 2002, Richardson 2003) that chloroform has the largest share in total trihalomethanes. This fact was also observed in presented research in drinking water, both in water treatment plant and distribution subsystem (Fig. 1, it is worth to stress that for both obtained equations the determination coefficients are very close to 1).

Maximal allowable concentration of total trihalomethanes, established in Drinking Water Directive, is 100 μg/dm^3. The directive does not include allowable concentrations of specified compounds. Polish law imposes additionally the maximal allowable concentration of chloroform (30 μg/dm^3). Since the chloroform is about 80% of total trihalomethanes, it is possible that the total trihalomethanes satisfy the norm whereas the maximal allowable concentration of chloroform is exceeded. Therefore the concentration of chloroform is the better quality parameter to be considered in safety models of water supply systems and it is taken as the basic parameter in definitions of quality states in further study.

4 WATER QUALITY IN SAFETY STATES

4.1 *Safety states of water supply systems*

The comprehensive method of safety analysis of water supply systems described by Zimoch & Łobos (2012) takes into account drinking water quality, water production subsystem capacity and failures on water pipe network, which characterizes the operation conditions of water distribution subsystem. Depending on conditions listed above the four safety states were defined: full safety, acceptable safety menace, controlled safety menace, and safety loss.

The first of safety states is defined if delivered water is of good quality, in required quantity, under needed pressure. The second safety state includes exploitation events such that the system manager has to interfere only in one operation parameter in order to return to the full safety state. The acceptable safety menace state accepts the reduction of production capacity to 70% of full daily water demand. The third state is the consequence of essential decrement of all three parameters such that their co-occurrence influences on the secondary drinking water contamination. Thus this state forces an operator to undertake repair actions and increase the monitoring intensity of delivered water quality.

If the chloroform concentration in transported water is greater than or equal to triple maximal acceptable concentration, then the health risk is so large that the system is classified to be in the safety loss state. The complete safety loss occurs also in the situation of wrong hydraulic work of water distribution subsystem (for example if water main failure appears and water production subsystem capacity is less than 30% of water demand, the probability of water quality deterioration significantly increases and it is not acceptable by producer and consumer).

4.2 *Water quality criteria in safety model*

In the comprehensive method of safety analysis the concentration of disinfection by-products plays an important role. Therefore definitions of concrete safety states have to be strictly related to observed changes of water quality during its transport to consumers. Classes of water quality, based on chloroform concentration, were defined using its maximal allowable concentration given by Drinking Water Directive (1998) and Polish legal acts. Namely, the following three classes were presupposed:

- first quality state in which the concentration of chloroform belongs to the interval [0 μg/dm^3, 30 μg/dm^3]; such concentrations appear in the full safety and acceptable safety menace states, provided that the capacity of water production subsystem is equal to the daily water demand;
- second quality state which corresponds to water quality with chloroform concentration from interval (30 μg/dm^3, 90 μg/dm^3]; the class is mainly assigned to controlled safety menace state;
- third quality state where chloroform concentration exceeds 90 μg/dm^3, which always classifies the water supply system to be in the safety loss state.

In real water supply systems (Zimoch & Łobos 2008, Zimoch & Łobos 2011) the operation conditions usually cause the changes of water quality in the range of chloroform concentration from 0 to 60 μg/dm^3 whereas concentration greater than 90 μg/dm^3 are very rare and rather incidental random events. Mentioned facts indicate that searching more precise quality states (that characterize safety states of exploitation) are necessary.

It follows from detailed analysis of obtained data that almost all (precisely, more than 90%) items in the sample the chloroform concentration not exceeds the maximal allowable concentration, i.e. 30 μg/dm^3 (Fig. 2). From this reason the previous first quality state was divided into two new quality states, in which the concentration of chloroform belongs to the interval [0 μg/dm^3, 15 μg/dm^3] for the first quality state and to (15 μg/dm^3, 30 μg/dm^3]

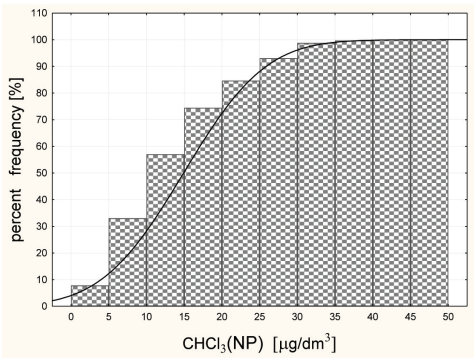

Figure 2. Empirical distribution function of chloroform concentration in drinking water at network points.

for the second quality state. Subsequently, the third quality state is determined by the interval (30 µg/dm^3, 60 µg/dm^3] and the forth one by chloroform concentrations greater than 60 µg/dm^3 which corresponds to the double maximal allowable concentration.

These newly specified thresholds for water quality states have been successfully proven in other research areas of water supply systems (in Wrocław city and several agglomerations in Silesia).

5 THE APPLICATION OF CHLOROFORM PREDICTION FUNCTIONS IN SAFETY MODELS

In these section we use the following notation for considered variables:

- $CHCl_3(NP)$ chloroform concentration at network point on the distribution subsystem,
- $CHCl_3(WTP)$ chloroform concentration at water treatment plant (in treated water),
- T temperature at water treatment plant,
- $D(Cl_2)$ total chlorine dose,
- $C(Cl_2)$ chlorine consumption,
- Z zone,
- $P(Q,Z) = 10^5 Z/Q$ efficiency parameter where Q denoted the production capacity.

Numerous predictive models obtained by multiple regression with various sets of independent variables, listed in Table 1, were tested. The dependent variable was always $CHCl_3(NP)$. The best models are following:

– model A

$$\ln\left[1+CHCl_3(NP)\right] = 1.411881 + 0.489433\ln\left[1+CHCl_3(WTP)\right] + 0.252920\ln T \quad (1)$$

– model B

$$\ln\left[1+CHCl_3(NP)\right] = 1.600953 + 0.458861\ln\left[1+CHCl_3(WTP)\right] + 0.180062\ln T + 0.314256\ln C(Cl_2) \quad (2)$$

– model C

$$\ln\left[1+CHCl_3(NP)\right] = 1.470181 + 0.459582\ln\left[1+CHCl_3(WTP)\right] + 0.170939\ln T + 0.350736\ln C(Cl_2) + 0.051175 Z \quad (3)$$

– model D

$$\ln\left[1+CHCl_3(NP)\right] = 1.451888 + 0.467855\ln\left[1+CHCl_3(WTP)\right] + 0.160356\ln T + 0.372107\ln C(Cl_2) + 0.053069\ P(Q,Z) \quad (4)$$

– model E

$$\ln\left[1+CHCl_3(NP)\right] = 1.374331 + 0.479503\ln\left[1+CHCl_3(WTP)\right] + 0.168612\ln T + 0.376004\ln D(Cl_2) + 0.053084\ P(Q,Z). \quad (5)$$

Model A is the best from the mathematical point of view. It is the result of both forward selection and backward elimination with $F_{enter} = 4$, $F_{delete} = 3$. All coefficients in this model are statistically significant. Other models have some coefficient which are not statistically significant but these models have better (i.e. greater) adjusted multiple coefficients of determination and better (i.e. less) standard estimation errors (Table 3). Basic statistical properties of discussed models are similar. The most important fact

Table 3. Comparison of statistical properties of discussed prediction models.

Model	Multiple coefficient of correlation	Adjusted multiple coefficient of determination	Standard estimation error
A	0.727	0.521	0.4284
B	0.733	0.526	0.4199
C	0.737	0.527	0.4193
D	0.738	0.529	0.4184
E	0.735	0.524	0.4208

is that all these models explain more than 52% of variability of dependent variable. One may notice that coefficients in the same variables are similar in all models. Moreover, the role of chlorine consumption (models B, C, and D) and total chlorine dose (model E) is comparable.

Prediction functions obtained by multiple regression have the following explicit forms:

– in model A

$$CHCl_3(NP) = 4.103696 \cdot \left[1 + CHCl_3(WTP)\right]^{0.489433} \cdot T^{0.252920} - 1 \quad (6)$$

– in model B

$$CHCl_3(NP) = 4.957755 \cdot \left[1 + CHCl_3(WTP)\right]^{0.458861} \cdot T^{0.180062} \cdot \left[C(Cl_2)\right]^{0.314256} - 1 \quad (7)$$

– in model C

$$CHCl_3(NP) = 4.350022 \cdot \left[1 + CHCl_3(WTP)\right]^{0.459582} \cdot T^{0.170939} \cdot \left[C(Cl_2)\right]^{0.350736} \cdot e^{0.051175\,Z} - 1 \quad (8)$$

– in model D

$$CHCl_3(NP) = 4.271171 \cdot \left[1 + CHCl_3(WTP)\right]^{0.467855} \cdot T^{0.160356} \cdot \left[C(Cl_2)\right]^{0.372107} \cdot e^{0.053069\,P(Q,Z)} - 1 \quad (9)$$

– in model E

$$CHCl_3(NP) = 3.952432 \cdot \left[1 + CHCl_3(WTP)\right]^{0.479503} \cdot T^{0.168612} \cdot \left[D(Cl_2)\right]^{0.376004} \cdot e^{0.053084\,P(Q,Z)} - 1. \quad (10)$$

For each of 333 sampling points the predicted value of variable $CHCl_3(NP)$ was calculated. Basing on this value, each point was classified to one of quality states and then the estimated quality state was compared with observed quality state.

Table 4 presents estimations of probabilities of proper and improper classifications. The use of prediction models forces an operator to make unnecessary laboratory analyzes if the estimated state is greater than the real one, which generate additional costs. The most undesirable situation is one where the estimation indicates the first or second quality state while the real chloroform concentration exceeds the maximal allowable concentration. For all models the probability of such improper classification is 0.069. Thus the best model is model B (it has the least probability of overestimation) and the worst is model E.

Table 4. Probabilities of proper and improper classifications to quality states (estimations are based on prediction functions of chloroform concentration at network points).

Model	Estimated state is equal to the real state	Estimated state is greater than the real state	Estimated state is less than the real state
A	0.679	0.171	0.150
B	0.682	0.162	0.156
C	0.676	0.165	0.159
D	0.673	0.168	0.159
E	0.661	0.174	0.165

6 RELATIONSHIP BETWEEN SAFETY STATES AND QUALITY OF TREATED WATER AT WATER TREATMENT PLANT

Since coefficients in variable $\ln[1 + CHCl_3(WTP)]$ in prediction model A-E (described in the previous section) are similar, a new question arises: is it possible to estimate quality safety states of network points using only the chloroform concentrations in treated water at water treatment plant?

In Figure 3 distributions of chloroform concentration at water treatment plant depending on quality states (defined by concentration of chloroform at network point) are shown. The analysis of data leads to the following definitions of quality safety states. In the first quality safety state the concentration of chloroform at water treatment plant belongs to interval [0 μg/dm^3, 3 μg/dm^3], in the second—to (3 μg/dm^3, 6 μg/dm^3], in the third—to (6 μg/dm^3, 12 μg/dm^3], and in the fourth—it is greater than 12 μg/dm^3.

Quality states determined at water treatment plant should correspond to appropriate quality states determined at network points. In Table 5 estimations of probabilities of proper and improper classifications (if quality states at water treatment plant are applied) are collected. On the one hand, this approach in comparison with method described in previous section is worse because it gives too much overestimations. On the over hand, there is less probability that estimated state is less

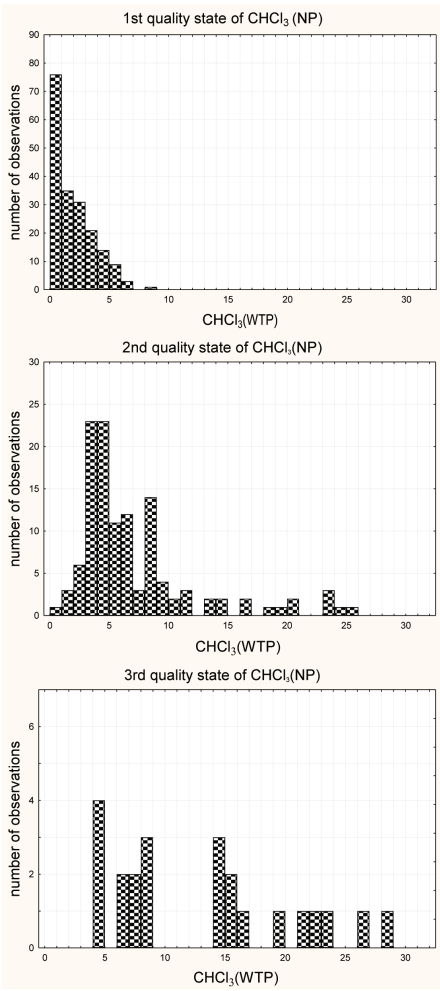

Figure 3. Distributions of chloroform concentration at water treatment plant depending on the quality states of chloroform at network points.

Table 5. Probabilities of proper and improper classifications to quality states in whole water pipe network assigned to particular zones (estimations are based on chloroform concentration at water treatment plant).

Zone	Estimated state is equal to the real state	Estimated state is greater than the real state	Estimated state is less than the real state
1	0.042	0.018	0.003
2	0.111	0.072	0.006
3	0.284	0.162	0.024
4	0.147	0.051	0.018
5	0.042	0.012	0.006
Sum	0.628	0.315	0.057

Table 6. Probabilities of proper and improper classifications to quality states in each zone (estimations are based on chloroform concentration at water treatment plant).

Zone	Estimated state is equal to the real state	Estimated state is greater than the real state	Estimated state is less than the real state
1	0.667	0.286	0.048
2	0.587	0.381	0.032
3	0.605	0.343	0.051
4	0.681	0.236	0.083
5	0.700	0.200	0.100

than the real one. Moreover, the probability that the estimation indicates the first or second quality state while the real chloroform concentration exceeds the maximal allowable concentration is very small (it is equal to 0.012 while for estimations with prediction models it is 0.069).

The level of concentration of newly formed chloroform is strictly connected with reaction time between chlorine and organic matter containing trihalomethanes precursors. The reaction time in presented models is represented by the zone. Since there are different numbers of water samples in defined five zones in water distribution subsystem, the probabilities of proper and improper classification were calculated for each separately. These probabilities are similar in all zones (Table 6) which confirms the correctness of the method.

7 CONCLUSION

Assumed in this paper new thresholds for quality safety states fit better to the range of variability of chloroform in real water supply system so they are more appropriate for consideration related to the comprehensive method of safety analysis.

Presented predictive models of chloroform concentration in drinking water delivered to consumer have not only scientific but also practical meaning. The use of them in monitoring process allows to decrease costs of laboratory analyzes. Considered models have acceptable determination coefficient about 52% because they are based on data collected in normal exploitation conditions of water supply system, during obligatory monitoring of treated and drinking water quality.

It was also shown that easier method of estimation of safety states works correctly. Namely, the quality safety state of network point may be estimated by the chloroform concentration in chlorinated water at water treatment plant. Such approach allows to optimize costs of monitoring and precisely analyze safety states of water qual-

ity in distribution subsystem. In 63% of analyzed network points (Table 5) the classification to particular safety state based on drinking water quality was the same as safety state determined by the chloroform concentration in chlorinated water in water treatment plant.

The application of described methods to the comprehensive method of safety analysis in order to develop Water Safety Plans is justified now, but study should be continued to obtain greater compatibility of quality safety states.

ABSTRACT: The SESAR research & development programme aims to drastically change Air Traffic Management (ATM) in the European airspace. The SESAR project "Develop techniques for Dynamic Risk Modelling (DRM)" aims at demonstrating the need for and potential added value of DRM in the safety assessment of new developments. The main deliverable is a DRM guideline that will help safety practitioners to decide whether DRM modelling is expected to provide added value, and how to conduct the assessment. The added value of DRM is being demonstrated by its application to a SESAR test case.

1 INTRODUCTION

1.1 *The need for dynamic risk modelling*

Today's challenge is that aviation systems are large-scale, complex and dynamic. New automated tools are developed to assist air traffic controllers and pilots to reduce separation. These technologies introduce a change in the human-machine interface and increase the complexity of Air Traffic Management (ATM) (Averty et al. 2009). New technology and new ways of interacting may have significant safety effects, which must be assessed by means of suitable methods.

Traditional methods such as fault trees and event trees have important limitations when it comes to capturing the dynamics and complexity of many sociotechnical systems and operations. Such "static" methods are often still adequate for some applications, but may be insufficient when faced with applications in which (Eurocontrol 2009):

a. There are multiple conditions affecting system response and operator behaviour.
b. There are different ways in which human operators may perform a task incorrectly, and there are multiple dynamic responses of the system and human operators to these different errors.
c. The physical status evolution has an influence on the stochastic discrete events related to failure and recovery.
d. There are multiple time-dependent interactions between the system and its environment, and between the system elements themselves.
e. There are uncertainties due to inherent randomness or unpredictable variability or due to the imperfect knowledge or incomplete information.

In the last decade, theories and methods have started to explicitly acknowledge dynamic sequencing and the need to address time-dependent interactions. In this paper, these methods are referred to as *Dynamic Risk Modelling (DRM)*. DRM is defined as the class of risk modelling techniques that explicitly represent the dynamic performance of the elements in the operation (people, equipment, procedures, environment) and their time-dependent interactions.

1.2 *SESAR and the DRM project*

SESAR (Single European Sky ATM Research) aims to eliminate the fragmented approach to European ATM, transform the ATM system and synchronize all stakeholders. ATM systems delivered in the scope of SESAR are increasingly complex and integrated. There is a need for more advanced safety assessment approaches, taking into account the dynamic nature of events preceding an incident/accident within a SESAR Safety Assessment, and for complementary models that account for technical and human, context, interactions and dynamics. This is the focus of SESAR DRM project (DRM project, Herrera et al.), which considers existing and emerging developments in the area of dynamic risk modelling. The main objective of the DRM project is to provide guidelines for ***when*** and ***how*** to apply DRM techniques in real world analysis situations. These guidelines are aimed to be included in a future edition of the SESAR Safety Reference Material (SRM) (SESAR SRM 2012).

1.3 *Organisation of the paper*

This paper is organized as follows: Section 2 explains the criteria that have been developed by the DRM project for deciding whether a given SESAR application requires the use of DRM, and it explains how the DRM project has applied these criteria to select a SESAR test case application. Section 3 explains the process that led to the selection of one particular DRM method from a list of candidate methods. Section 4 briefly explains this DRM method in steps, and presents preliminary results of its application to the test case selected in Section 2. Section 5 presents concluding remarks.

2 CRITERIA FOR APPLYING DRM

The SESAR safety assessment approach typically uses static risk modelling techniques: safety criteria and objectives are identified based on accident incident models and further safety requirements are derived using Fault Trees, Failures Modes and Effects Analysis or similar techniques. This section presents criteria to identify specific cases where DRM application is required.

Criterion 1: In SESAR an initial risk evaluation using a conventional (static) method has been conducted and the level of uncertainty in the risk results is such that it cannot be conclusively argued whether the risk is acceptable or not.

Criterion 2: The system behaviour, when considering equipment functional variability, failures, human performance variability and errors, involves occurrences which cannot be considered in isolation, as they strongly depend on system status over time.

Criterion 3: The system behaviour when considering equipment functional variability, failures, human performance variability and errors depends on process variables.

If Criterion 1 is fulfilled together with at least one of Criteria 2 or 3, it is considered that the case is eligible to risk assessment with a DRM method. The anchoring points in a preceding conventional static analysis need to be clearly identified (i.e. the Operational Hazards that will be specifically modeled with DRM, their severities and associated safety objectives together with the justifications developed during the static safety risk assessment). This will serve as the basis for developing the Dynamic Risk Modelling cycle.

The DRM project applied these criteria to SESAR concepts and as a result it selected the use case "Land vs Line up" within the Conflicting ATC clearances project P06.07.01. Conflicting ATC Clearance (CATC) detection is a system that detects early situations of conflicting clearances that, if not corrected would end up in hazardous situations. The "land vs line up" use case considers one aircraft landing and another aircraft lining up to take off on the same runway used in mixed mode. For the detection to work, the controller needs to inform the system (input) each time he provides a clearance to an aircraft. In case of a "land vs line-up" CATC alert, the controller shall resolve the hazardous situation (i.e. avoid a runway collision) by immediately cancelling the line-up instruction and/or instructing a go around, as appropriate.

The static safety assessment initially performed within the SESAR project (SAR CATC 2012) identified a major uncertainty w.r.t. the efficiency of the operational use of "land vs line-up" CATC alert, in relation to the time required for the controller to interpret the alert and communicate the resolution instruction(s) to the involved aircraft and for the pilot(s) to implement the instruction(s). Therefore this case was selected as a suitable test case for DRM.

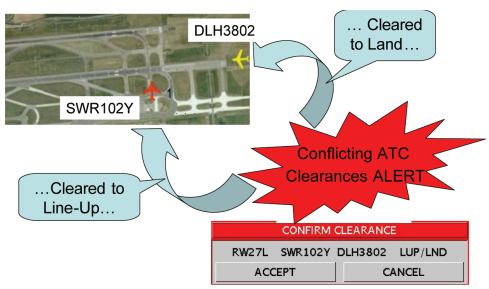

Figure 1. The land vs line-up CATC alert operation.

3 SURVEY OF POTENTIAL DRM METHODS

A variety of methods and tools for conducting DRM exist. Some methods have been in use for many years, while others are of newer date. The level of maturity of the methods varies a lot. The DRM project has identified and described a range of methods, and assessed the methods with regards to suitability for SESAR needs. In total 11 quantitative and qualitative methods have been studied. Priority has been given to methods that provide quantification of results.

The surveyed DRM methods are: Dynamic Event Trees; Dynamic Flowgraph Methodology; Discrete state-transition approaches (Markov chains, Petri Nets & extensions); Dynamic Bayesian Networks; Direct system simulation; DRM for aircraft certification; TOPAZ (Traffic Organization and Perturbation Analyzer); SoTeRia (Socio-Technical Risk Analysis); FRAM (Functional Resonance Analysis Method); STPA Hazard analysis (Systems-Theoretic Process Analysis); Collision Risk Modelling; Encounter-based model methodology. For references and brief descriptions of all these methods, refer to (DRM D04 2012).

By means of an analysis against several DRM-related criteria, the DRM project has selected TOPAZ as a suitable solution for the safety risk assessment of ATM operational scenarios. TOPAZ is an agent-based DRM method that uses Monte Carlo simulations and uncertainty evaluations to analyse the safety risk of air traffic operations up to the level of collisions. For each application, the dynamics of the agents and the time-dependent interactions within and between the agents are modelled in the syntax of Dynamically Coloured Petri Nets (DCPN) (Everdij 2010). The compositional specification by DCPNs allows for the modelling of sociotechnical systems by its broad syntax, including stochastic differential equations (e.g. describing aircraft position and velocity), discrete state transitions (e.g. describing system states or human tasks), and interactions (e.g. describing the recognition of safety-relevant conditions by humans. Detailed descriptions of TOPAZ agent-based DRM and its application to ATM operations can be accessed in Blom et al. (2001, 2006), Stroeve et al. (2009) and Eurocontrol/FAA AP15 Safety (2014).

4 APPLICATION OF DRM METHOD TO TEST CASE

The TOPAZ-based DRM method follows 10 steps which are listed below.

1. Determine the scope of operation/system for DRM
2. Get a complete/consistent description of the operation/system
3. Get a complete list of hazards
4. Develop operational hazard scenarios
5. Develop a stochastic dynamic model
6. Develop risk decomposition
7. Implement the dynamic risk model into software
8. Run Monte Carlo simulations
9. Assess bias and uncertainty
10. Develop safety risks results

The following subsections briefly describe how to apply the steps, following the initial guidance developed by the DRM project in (DRM D07 2012), and provide preliminary results on the application to the test case operation of "land vs line-up" CATC alert developed in (DRM D09 2014).

4.1 *Determine the scope of operation/system for DRM*

DRM Method: In step 1, the scope and goal of the safety assessment are identified, as well as applicable safety criteria or objectives.

Scope: The scope includes a description of the boundaries of the operation and scenarios to be modelled, the types of functions or the types of equipment/procedures/people that are included.

Goal: The goal of the risk modelling is a description of what the DRM-based safety risk assessment aims to achieve in complement to the static safety assessment results.

Safety objectives: Safety criteria or safety objectives refer to target or acceptable levels of risk that are aimed to be achieved.

Application to Test Case: The scope considers mixed mode runway operations, with aircraft landing and taking off from a single runway. The operation is considered in three cases: (1) a baseline case without CATC system, (2) a CATC-OSED case as described in Section 2, and (3) a CATC-SAR case, which is the CATC-OSED operation plus an additional requirement for the controller to enter the clearance in the CATC system before communicating it to the pilots.

The main goal of the safety study is to obtain probability estimates for three types of safety events: (a) a collision between an aircraft landing with an aircraft taxiing to the runway to line-up, (b) the taxiing aircraft entering the Instrument Landing System (ILS) sensitive area, and (c) the taxiing aircraft entering the Obstacle-Free Zone (OFZ).

4.2 *Get a complete/consistent description of the operation/system*

DRM Method: In step 2, a complete and consistent description of the operation/system under

analysis is identified. This includes the operational context of the operation, the timeframe, the traffic characteristics, the geometric aspects of operation; the roles and responsibilities of the humans involved in the operation; the operational procedures, both on the ground and on board; and the logical description of the technical systems used in the operation, how they are operated and their overall performance.

Application to Test Case: Detailed information regarding operation of the system and implementation of the CATC was gathered. A short description of the CATC land versus line-up case is in Section 2.

4.3 *Get a complete list of hazards*

DRM Method: In step 3, a complete list of hazards is identified that are associated with the operation/system to be assessed. The list should include a large number and diversity of possible hazards. In addition to the Operational Hazards (identified at the level of the ATM service provided to Airspace Users) this includes hazards and conditions that may lead to a safety relevant situation (basic causes, root hazards), hazards and conditions that may hamper the resolution of the safety relevant situation (resolution hazards), and pre-existing hazards (those aviation hazards that are not caused by the ATM system but that are aimed to be prevented or mitigated by the ATM system). All the hazards identified here will be referred to in the following as 'hazards'.

Application to Test Case: The project used the material from the preceding static safety analysis, complemented by generic hazard database material from the DRM project partners, to collect a list of 42 hazards. A selection is provided below:

- Situation in which the intended trajectory of two a/c are in conflict on the Runway Protected Area.
- Failure to detect the conflicting clearances with the conflicting ATC clearances System.
- False alert of CATC system.
- Overload of pilot.
- Pilot fails to implement timely the ATCO resolution instruction following the CATC alert.

4.4 *Develop operational hazard scenarios*

DRM Method: In step 4, Operational Hazard Scenarios are constructed. Each such scenario aims to bring into account all relevant ways in which an operational hazard may develop and evolve, under influence of the related operational conditions (such as flight phase and location, level of traffic, environmental conditions), and the related hazards (i.e. basic causes, root hazards, resolution hazards, pre-existing hazards).

Application to test case: The hazards identified in the previous step have been clustered into groups of similar hazards. Next, the relations between these clusters have been depicted in the diagram shown below (ovals are hazard clusters). The clusters in the top describe hazards that may contribute to the causation of a conflict between a landing aircraft and a taxiing aircraft. The clusters in the bottom describe hazards that may hamper the recognition and resolution of the conflict via the CATC alert, the controller, and the pilots of both aircraft.

4.5 *Develop a stochastic dynamic model*

DRM Method: In step 5, a multi-agent stochastic dynamic model is developed, which describes the stochastic dynamic evolution through time of one or more Operational Hazard Scenarios. The model uses the syntax of Dynamically Coloured Petri Net (DCPN) (Everdij 2010) and is developed in 6 steps:

- Step 5.1: Identify the relevant Agents
- Step 5.2: Identify the relevant entities per Agent
- Step 5.3: Specify a Local DCPN (LPN) per entity
- Step 5.4: Interconnect the LPNs within each Agent
- Step 5.5: Interconnect the Agent models
- Step 5.6: Check how the operation and each hazard has been modelled, and iterate.

Application to Test Case: The DCPN-based model developed for the Test Case of "land vs line-up" CATC alert is too lengthy to be included in this paper; therefore, we restrict to a list of Agents and

Figure 2. Operational hazard scenario for conflict.

Agent entities (Table 1), and the specification of one LPN plus its inter-agent interactions.

Figure 3 presents the LPN graph for 'CATC alert', which is one of the agent entities in agent ATC System. The figure follows the syntax of DCPN, which consist of Places (circles), Transitions (squares) and Arcs (arrows) that connect the places with the transitions. The places represent the discrete modes of the entity, which in this case are *No alert* and *Alert*. At any given time, only one of these modes is the current one. A current mode holds a 'token' (not drawn below), which contains continuous valued information that further models the stochastic dynamic evolution of the model. The transitions model the switches between the modes. A switch can only be made if the transition has tokens in each of its input places, and if these tokens contain specific transition-dependent continuous-valued information.

Figure 4 presents the input interactions (Arrows) between the LPN 'CATC Alert' and the LPNs for the entities 'CATC Availability' and 'FDP/EFS'. The transition from *No alert* to *Alert* now has three input places rather than just one, and it needs tokens in each of these input places before the switch can be made. The figure shows that the 'CATC Alert' can only switch from *No Alert* to *Alert* if the 'CATC Availability' is *Up*

Table 1. Description of the agents in the DCPN-based model, and their agent entities.

Agent	Agent entities, plus what they model
Airport and environment	Visibility—The visibility range
	Runway—Layout of runway
	Wind—The actual wind
ATC system	Surveillance—Status of radar surveillance on ground and final approach
	VHF Com Runway Controller—Availability of the controller's VHF Com system
	FDP/EFS—Status of clearance input for both aircraft into the Flight Data Processing/Electronic Flight Strip system as well as status of the FDP/EFS system
	CATC Availability—Availability of CATC system
	CATC Alert—Whether CATC gives an alert
Runway controller	Situation awareness—The controller's situation awareness status and updating process, incl. position and intent of both aircraft, and awareness of CATC alerts
	Conflict action—Whether the controller gives conflict warnings to the pilots
	Clearance Specification—Status of clearance specifications by the controller to the pilots, in terms of having instructed the pilots and of having entered data into the FDP/EFS
	Workload—The current level of workload
	Skill—The level of skill of the controller
	Cognitive control mode—Whether controller is working in opportunistic or in tactical mode
Landing aircraft	Characteristics—Aircraft type, and final approach, landing, missed approach and taxiing characteristics of the aircraft
	Evolution—Position and velocity during final approach, landing and taxiing on the runway, or during missed approach
Avionics of landing aircraft	VHF Com Aircraft—Availability of the VHF Com system for the landing aircraft
Pilots of landing aircraft	Situation Awareness—Situation awareness status and updating process of the pilots of the landing aircraft, incl. position of the own aircraft and of the taxiing aircraft, and the awareness of controller instructions
	Flight Control—The control of the aircraft by the pilots, which may be normal operation or initiation of a missed approach
Taxiing aircraft	Characteristics—Aircraft type, taxiing and lining-up characteristics of the aircraft
	Evolution—Position and velocity during taxiing to the take-off position. As result of a conflict recognized, the aircraft may stop
	System Boundary—Whether the taxiing aircraft is inside or outside the system boundary, i.e. the area where a conflict may occur
Avionics of taxiing aircraft	VHF Com Aircraft—The availability of the VHF Com system for the taxiing aircraft
Pilots of taxiing aircraft	Situation Awareness—Situation awareness status and updating process of the pilots of the taxiing aircraft, incl. position of the own aircraft and of the landing aircraft, and situations requiring the aircraft to stop taxiing
	Flight Control—Control of the aircraft by the pilots, which may be normal operation, or stop taxiing

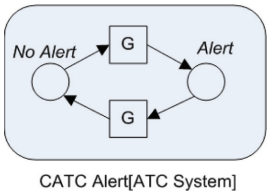

Figure 3. LPN graph for CATC alert.

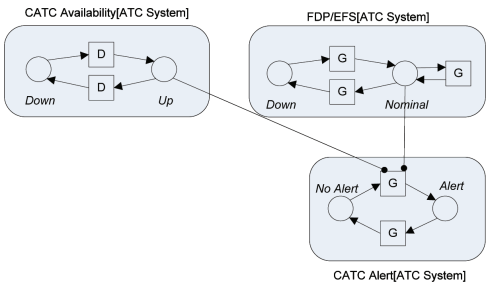

Figure 4. LPN graph for CATC alert, plus its input interactions with CATC availability and FDP/EFS.

and the 'FDP/EFS' is *Nominal*. A second condition for this switch to occur (but not visible in the figure) is that the value of the token in place *Nominal* in LPN FDP/EFS contains the information that the landing aircraft has been given the instruction to land and the taxiing aircraft has been given the instruction to line up; this should give rise to a conflicting ATC clearance alert.

The figures are further connected to other LPNs in a similar way. All figures are complemented by precise descriptions of the conditions and evolution of the LPNs and their interactions.

4.6 *Develop risk decomposition*

DRM Method: With a DCPN-based model now completed, it can next be used as basis of a Monte Carlo simulation to determine the probability of the outcome of the operational hazard, for instance an aircraft collision. To make these simulations more efficient, a risk decomposition is applied. This consists of decomposing accident risk simulations in a sequence of conditional Monte Carlo simulations and combining the results of these conditional simulations into the assessed collision risk value. The conditional runs are started from a conditional state, which is allowed due to the specific mathematic properties of DCPN-based models (Everdij 2010).

Application to Test Case: For the test case application, the probability of occurrence of a Safety Event (such as a Collision between the landing aircraft and the taxiing aircraft) is decomposed as follows:

$$P(Safety\ Event) = \sum_{k=1}^{M} P(Condition_k) \times P(Safety\ Event | Condition_k) \quad (1)$$

Here, the probabilities $P(Safety\ Event \mid Condition_k)$ are conditional probabilities of occurrence of the safety event given a certain well-defined condition *Condition_k* that occurs at a well-defined 'stopping time', and $P(Condition_k)$ is the probability of occurrence of this *Condition_k*. For the Test Case of "land vs line-up" CATC alert, the number of Conditions defined is $M = 192$, hence in the sum above, k is from 1 to 192. For example, *Condition_3* (i.e. $k = 3$) is the one where, at the stopping time: the LPN mode of the Surveillance tracking is Nominal, the LPN modes of the VHF Com for the controller and the landing aircraft are both Up, The VHF Com for the taxiing aircraft is Down, the controller intent for the taxiing aircraft is to Line-up, and the visibility condition is good.

The conditions have been chosen such that each $P(Condition_k)$ can be determined analytically as a function of one or more DCPN-based model parameter values. Hence, Monte Carlo simulations are only needed to determine the $P(Safety\ Event \mid Condition_k)$ for all k, after which all results are combined using the formula above. This significantly speeds up the Monte Carlo simulations by several orders of magnitude.

4.7 *Implement the dynamic risk model into software*

DRM method: In step 7, when the specification of the DCPN-based model and the risk decomposition are fully defined, they are implemented in software language in order to be able to run Monte Carlo simulations. Many software languages are suitable for this, as long as they accept all DCPN syntax principles. A major step in the software implementation is to test the code against all elements of the DCPN-based model and Risk decomposition.

Application to Test Case: The DCPN-based model and risk decomposition for "land vs line-up" CATC alert have been implemented in Delphi using Embarcadero RAD Studio XE3. It takes as input a list of model parameter values that can be set by the user, and that can be changed in order to determine risk values for various scenarios and parameter settings.

4.8 *Run Monte Carlo simulations*

DRM Method: In this step, the software implementation of the DCPN-based model is used to perform Monte Carlo simulations and compute safety risk results. Any Safety Event that can be observed in such simulation can be counted, and the number of counts, divided by the number of runs or the number of associated flight hours or movements, provides an estimate for the probability of occurrence of the Safety Event (e.g. a collision).

Application to Test Case: Risk results were produced by running a series of Monte Carlo simulations for three high-level CATC scenarios and for a set of parameters selected as being potentially representative for their impact on the safety event. Three parameter values were typically simulated in order to observe trends: a baseline value and a high and low value. At the time of writing of this paper, the application of this step was still ongoing. Some preliminary results are presented in the Figures 5 and 6.

In the Monte Carlo simulations the safety events defined in Step 1 were recorded: a collision between both aircraft, the taxiing aircraft entering the ILS sensitive area (150 m from the runway centerline), and the taxiing aircraft entering the OFZ (90 m from the runway centerline). The columns represent the safety event probability results for the three cases of the operation identified in Step 1: baseline without CATC, CATC-OSED, and CATC-SAR. The preliminary results indicate that the CATC system can largely reduce the collision risk, to a similar extent for the OSED and the SAR variants. The probability of entering the ILS sensitive area is hardly reduced by the CATC system. In contrast, the probability of entering the OFZ is reduced by the CATC system and notably more by the SAR variant.

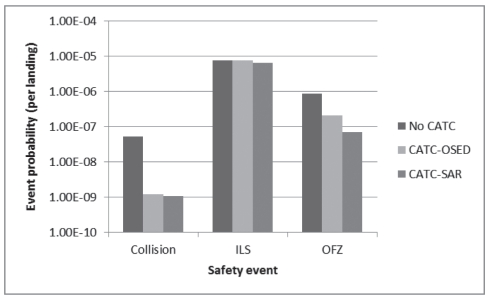

Figure 5. Event probability per landing.

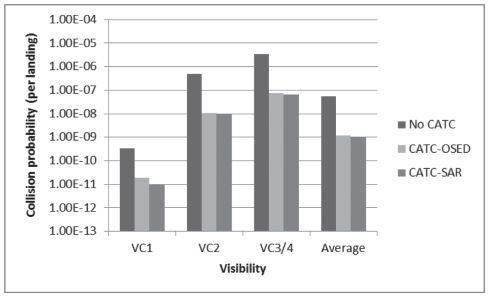

Figure 6. Collision probability per landing.

Figure 6 shows preliminary results for the conditional probability of a collision given three visibility conditions, i.e. VC1 (good visibility), VC2 (visibility range between 400 and 2450 m), and VC3/4 (visibility range between 0 and 400 m). These results show that the conditional collision risks are higher in the poorer visibility conditions, as the controller and the pilots have less opportunity to visually detect a conflict. Furthermore, the results indicate that the CATC system is effective to a similar extent in all visibility conditions.

4.9 *Assess bias and uncertainty*

DRM Method: By definition, any model is not the exact image of reality. The purpose of a bias and uncertainty assessment (Everdij et al. 2006) is to identify how the differences would impact on the evaluation of the risk level in terms of bias and uncertainty:

- Bias: the model-based accident risk is systematically higher or lower than the risk of the real operation.
- Uncertainty: the model-based accident risk lies in a range of credible values for the risk of the real operation (e.g. a 95% credibility interval).

Application to Test Case: At the time of writing of this paper, the application of this step was still ongoing. The initial results showed that:

- For all of the parameters in the DCPN-based model and risk decomposition, a credibility interval could be determined. This gives insight into which parameter values are reasonably certain, and for which more data might need to be collected.
- For most of the parameters in the DCPN-based model and risk decomposition, a sensitivity assessment could be determined. A parameter has a high sensitivity if changes to its value lead to significant changes to the collision risk result. For most parameters it appeared that they have a negligible sensitivity. For some parameters the sensitivity needs to be determined in more detail using dedicated Monte Carlo simulations.

4.10 *Develop safety risks results*

DRM Method: The results of the previous steps provide point estimates and credibility intervals for the probabilities of safety events in various conditions. Comparison of these results with safety criteria provides insight in risk acceptability and risk margins. Furthermore, these results can be used to identify safety bottlenecks (aspects of the operation that contribute to unacceptable risk levels) and they provide a basis to determine safety requirements and safety objectives.

Application to Test Case: The safety risk results achieved by the DRM approach will be compared with those of the static safety assessment initially performed for the CATC operation within the SESAR project. This comparison will be used to analyse the added value of the DRM approach.

5 DISCUSSION AND CONCLUDING REMARKS

The SESAR DRM project aims to show that consideration of dynamic aspects in the safety assessment of an operation is important when studying operational concepts in which multiple operators, technical systems, the environment, and their interactions play an important role. Within the context of SESAR, Dynamic Risk Modelling (DRM) is considered to be required if the level of uncertainty in the risk results of an initial risk evaluation using a conventional (static) method is such that it cannot be conclusively argued whether the risk is acceptable or not. In addition, at least one of the following criteria needs to hold true: a) The system behaviour, when considering equipment functional variability, failures, human performance variability and errors, involves occurrences which cannot be considered in isolation, as they strongly depend on system status over time. b) The system behaviour when consider-ing equipment functional variability, failures, human performance variability and errors depends on pro-cess variables.

By means of an analysis against several DRM-related criteria, the DRM project has selected TOPAZ from a list of candidate DRM methods as a suitable solution for the safety risk assessment of ATM operational scenarios. TOPAZ is an agent-based DRM method that uses Monte Carlo simulations and uncertainty evaluations to analyse the safety risk of air traffic operations up to the level of collisions. The project produced guidelines for the application of this method in SESAR context, and applied the method to a SESAR Test Case of "Land vs Line-up" Conflicting ATC Clearances.

The Test Case has shown that DRM is able to model the stochastic dynamic aspects of an operation with more accuracy than is possible with static methods. Examples are the position and velocity of aircraft as they evolve through time, the stochastic dynamic behaviour of human operators in response to their environment, situation awareness differences between various actors, multiple scenarios that unfold under influence of hazards occurring, environmental changes, events occurring earlier or later than average, etc.

The preliminary DRM-based risk results show interesting differences with those of the preceding static safety assessment, which will be systematically studied in the remainder of the DRM project.

ACKNOWLEDGEMENTS AND DISCLAIMER

The work presented in this paper is financed by the SESAR Joint Undertaking (SESAR JU) programme. NLR contributes to the SESAR project on behalf of DFS Deutsche Flugsicherung GmbH. The authors thank project members AIRBUS (especially Joelle Monso, Eric Hannouz, Lionel Marie-Magdeleine), DFS (especially Viktoria Weigel), ENAV (especially Tiziana Russo) and SELEX (especially Angela Errico) for their contributions. Modification of response spectra by probabilistic approach

V. Salajka, J. Kala, Z. Cada & P. Hradil
Faculty of Civil Engineering, Brno University of Technology, Brno, Czech Republic

ABSTRACT: The paper deals with the seismic linear response spectrum modification based on a probabilistic approach. The modification improves the correctness of the deterministic seismic analysis of building structures using the response spectrum method. In that case, the structure response depends strongly on computed natural frequencies. The proposed response spectrum modification accounts for uncertainties in response due to uncertainties in frequencies caused by variances of computation model parameters. The response spectrum is modified so, that with a selected probability the given spectral values should not be exceeded. The variance of natural frequency values is obtained by modal analysis of a stochastic model of the structure.

1 INTRODUCTION

The dynamic behaviour of building structures subjected to seismic action is commonly analyzed using the deterministic approach. The computation model is designed using the finite element method. The time domain response to defined non-stationary ground motion can be computed using direct integration of structure equations of motion. For many reasons, procedures based on structure vibration mode superposition are preferred. The response spectrum method is very frequently applied (ASCE 2000, Braja 1984, Kala et al. 2012). The structure response depends strongly on computed natural frequencies. Due to variances of characteristic model parameters, particularly when soil-structure interaction is considered, high values of variance of computed frequency values could be expected. Hence, possible variation of the natural frequency value in relatively wide range must be respected in the response analysis. Consequently, responses of quite different levels could be obtained (see illustration in Fig. 1).

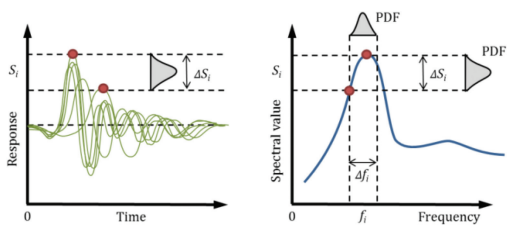

Figure 1. Variation of response spectrum values due to change of model frequency.

Uncertainties in computation of responses could be reduced by selecting appropriate configuration of parameters of the deterministic computation model. This way is lengthy and results are not guaranteed. Application of a stochastic model is limited due to pretentious computations. Another approach to account for uncertainties in response consists in modification of the given response spectrum. The modification of the response spectrum reduces e.g. the effects of random coincidences of computed frequencies with extremes of the spectrum course. Controlled broadening and lowering of the spectrum is recommended in (Cada et al. 2011, Holomek et al. 2012). The proposed response spectrum modification reduces effectively the uncertainties in response due to uncertainties in frequencies caused by variances of computation model parameters. The modification is based on the probabilistic description of natural frequencies of the analyzed structure, obtained by modal analysis of a stochastic model of the structure.

2 PROBABILISTIC DISTRIBUTION OF THE NATURAL FREQUENCY VALUE

The proposed response spectrum modification procedure will be explained using a case problem involving a thirteen-story panel building structure. The modal analysis has been performed applying an advanced finite element computation model (see Fig. 2). Solid and shell finite elements from the ANSYS program package have been used in modeling the structure. Solid massless elements have been used to model the layered subsoil. The characteristic parameters decisive for the analysis of first bending modes of vibration of the model have been selected

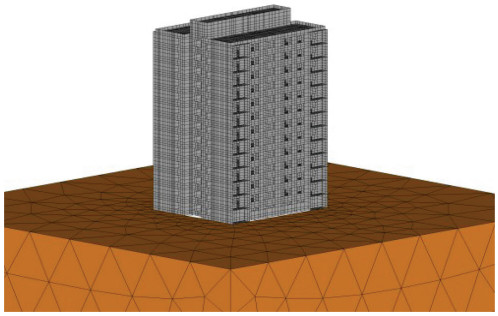

Figure 2. Finite element model of the panel building.

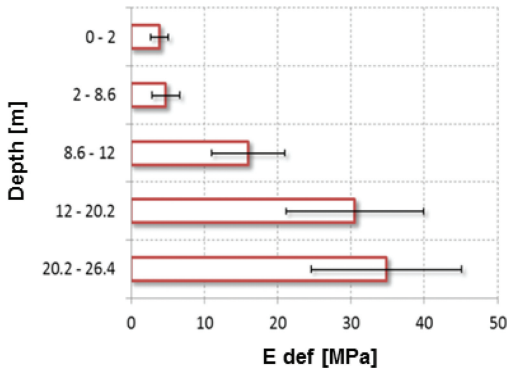

Figure 3. Modulus of elasticity of soil layers.

after performing a parametric study (Gupta 1992) of the dynamic behavior of the structure.

Moduli of elasticity of soil layers have been investigated experimentally. Effective densities of structure parts are based on the analysis of variations of masses of panels and those of floor live loads. Probability distribution types for all considered parameters have been determined (beta-type for soil, normal for panel densities, log-normal for live load). Corresponding mean values, standard deviations and coefficients of variation have been computed. Mean values of modulus of elasticity of soil layers with indicated standard deviations are shown in Figure 3 (Bajer et al. 2012).

Probability distributions of dominant horizontal bending frequencies f_x and f_y of the parametric model have been determined using the ANSYS program (ANSYS 2013) (modal analysis) in combination with the optiSlang program (Dynardo 2010) (LHS-method of generation of input parameters, analysis of output data) (Kala 2012, Kala et al. 2010, Kala et al. 2013). Results of computation are shown in Figure 4.

Stochastic analysis has been performed also at effective modal masses (m_{effx}, m_{effy}) and effective

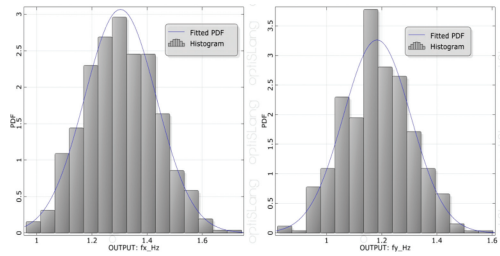

Figure 4. Probability distribution of dominant natural bending frequencies f_x and f_y of the model.

stiffnesses (k_{effx}, k_{effy}) computed from the relation in (Chopra 2001).

3 MODIFICATION OF RESPONSE SPECTRA

3.1 *The procedure description*

The procedure assumes, that the following is known:

- linear site-specific seismic response spectrum,
- probabilistic distribution of natural frequencies,
- position of the selected frequency in the probability function,
- required probability of non-exceedence of the spectral value.

3.2 *The repeated steps of the procedure*

The repeated steps of the procedure of modification are as follows (Kala et al. 2012):

1. selection of the frequency f_i,
2. construction of the probabilistic distribution function of f_i,
3. repeated steps for spectral values S_j in interval 0 to S_{max}:
   a. determination of frequency range where spectral values exceed S_j,
   b. computing area p_j under the probabilistic function of f_i,
   c. marking the point $[S_j, p_j]$ of the distribution function of exceedence of the spectral value S_i,
4. reading of the value S_i for the given probability of exceeding p from the distribution function,
5. fixing the point $[S_i, f_i]$ for the modified response spectrum,
6. return to step 1 to select next frequency.

For known probabilistic distribution of natural frequencies of the model, the modified response spectrum ensures no exceedence of spectral value at given probability p.

4 MODIFIED RESPONSE SPECTRA FEATURES

Selected cases of modified response spectra are shown in Figures 5 to 7. The parameter p is the probability of exceeding the distribution function and e is the exponent of the response change due to frequency change. Normal distribution of frequencies is assumed, with mean value corresponding to frequency f_i and with coefficient of variation v.

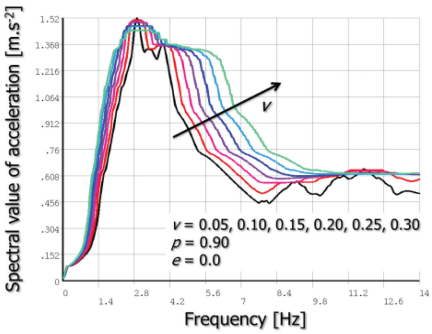

Figure 5a. Change of response due to change the frequency.

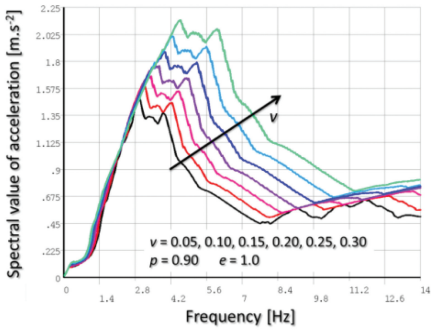

Figure 5b. Change of response due to change of model parameters.

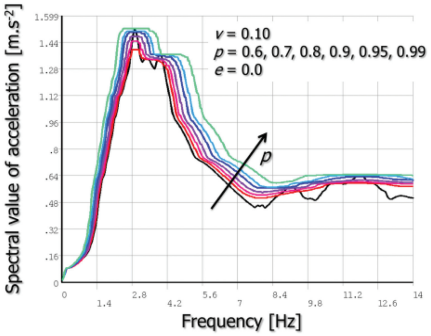

Figure 6a. Change of response due to change the frequency.

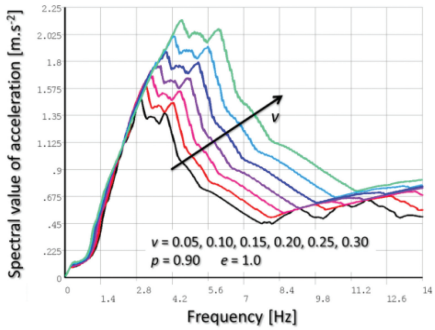

Figure 6b. Change of response due to change of model parameters.

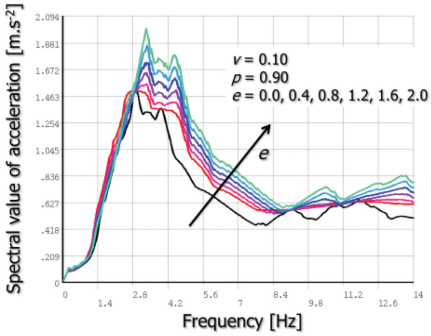

Figure 7a. Change of response due to change the frequency.

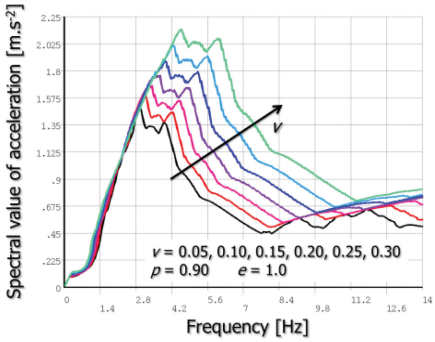

Figure 7b. Change of response due to change of model parameters.

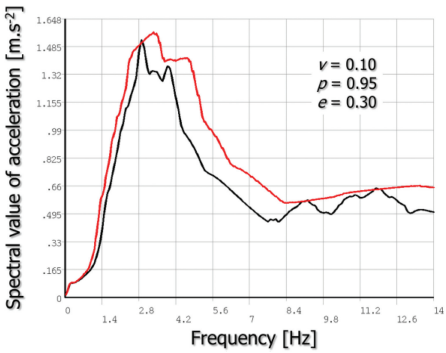

Figure 8. Response spectrum of the model as generated (black) and modified (red).

5 MODIFIED RESPONSE SPECTRUM FOR THE ANALYZED PANEL BUILDING

The modified response spectrum corresponding to parameters of the analyzed panel building is shown in Figure 8. The 95% probability of exceeding the distribution function has been selected.

6 CONCLUSION

The proposed response spectrum modification procedure ensures correctness of the deterministic seismic analysis of building structures using the response spectrum method. The modification reduces effectively the uncertainties in response due to uncertainties in frequencies causes by variances computation model parameters.

ABSTRACT: Dynamic Positioning (DP) is becoming more and more popular as the reliability of DP systems is improving and as the oil and gas industry moves into deeper and harsher environments where other station keeping methods are inefficient and very costly. The most significant risk relevant to DP operations is loss of the position control ability. The environmental condition (e.g. wind, wave, and current) is one of the main influence factors on position keeping ability of the DP system which is more important in harsh environment such as Arctic and South China Sea. In this paper the operation of a DP vessel in harsh operational conditions will be discussed. Furthermore; hazard identification, consequences of loss of position and identification of robust barriers to avoid disastrous outcomes in such harsh operational conditions will also be discussed with emphasis on safe disconnection from the ongoing activity.

1 INTRODUCTION

Vessel operations in harsh climate conditions and deep-water require a closer review of the safety of the selected station keeping methods (Chen et al., 2008). Dynamic positioning is becoming more and more popular as the reliability of DP systems is improving and as the oil and gas industry moves into deeper and harsher environments where other station keeping methods are inefficient and very costly. The DP system contains a computer program which allows the motion components surge, sway and yaw to be automatic controlled, keeping the position of the vessel or installation (Faÿ, 1990). DP systems can provide rapid response to harsh weather such as hurricanes or tropical storms, emergency disconnection of the risers and self-navigate to a safe place. A DP system does not need to use large Anchor Handling Tug Supply vessel (AHTS) for anchor handling which can reduce the risk, cost and downtime that would occur during an anchor handling operation. Moreover there is no risk for the system to damage the subsea facilities without using the mooring line and anchors. However, the need for separate engine room, expensive electronic components and constant fuel consumption can increase the operational cost of the DP system, but using new technology we can reduce the operational cost of the DP system. For example, by using special hull designs (e.g. Bulb-bow, X-bow and Axe-bow) the resistance generated by the air and water will be minimized and consequently it can reduce the operational cost.

In harsh operational conditions environmental factors can affect the performance of DP which can lead to loss of the position control ability. For a Mobile Offshore Drilling Unit (MODU), loss of position without safe disconnection could result in critical damage not only to the well, but also to the subsea equipment. For an Offshore Support Vessel (OSV), loss of position could lead to collision with the nearby installation during operation or to damage to the subsea facilities. In order to increase the safety and reliability of a DP system, it is important to identify and quantify all influence factors and the way that they can affect the DP performance. For example "bad weather condition" is an effective factor on the position reference sensor or the local position reference system. Such operational conditions can vary from place to place and may have a dynamic nature in a specific location. Moreover, it is important to investigate safe recovery back to position, safe disconnection and reconnection when the loss of position is outside the safe operational range.

In this paper we review the application of DP in harsh climate conditions; more specifically we focuses on the Arctic conditions and the conditions in the South China Sea. Moreover, the paper deals with a preliminary hazard analysis of DP systems in such operational conditions. In this paper in section 2 the DP working conditions in Arctic

and South China Sea are discussed. Section 3 provides preliminary hazard analysis of a DP system in harsh climate condition and suggests risk reducing measures. Finally, section 4 presents the conclusions.

The objective of the paper is to communicate to those planning to apply DP in harsh environmental conditions a warning that loss of DP may be expected and that planning to implement mitigating measures is needed in such situations.

2 DP IN HARSH CLIMATE CONDITIONS

Dynamic Positioning is the technique to keep a floating structure stationary by means of controlling the magnitude and the direction of thrust, based on position feedback. In DP systems the computers will get the data from the references and sensors and compare them with the pre-set data. Then the DP control system will control the propulsion system to take action eliminating the difference between the actual positions and the heading data and the pre-set data (ISO19901-7, 2005). There are different types of sensors such as motion reference units, wind sensors and draught sensors which give feedback regarding such themes as the wind velocity or roll and pitch of the vessel.

2.1 *DP in the arctic condition*

In recent years, offshore oil and gas exploration and field development are increasingly focused on the Arctic waters. The U.S. Geological Survey has estimated that as much as 28 percent of all recoverable resources (oil, natural gas and natural gas liquids) yet to be discovered are to be found north of the Arctic Circle (Kayrbekova et al., 2011, Bird, 2008). At the same time, the Arctic also has the harshest environmental condition for offshore activities, for instance, the remoteness, the extreme cold, dangerous sea ice, and a fragile environment. There have been some examples of moored offshore installations in ice. However, there is very little operational experience regarding DP operations in ice.

There are several challenges for a dynamic positioning system to be used in ice. How to accurately predict the ice force is one of the most significant challenges (Jenssen et al., 2009). Ice thickness, concentration, size distribution of ice floes and drift velocity are known to be important factors regarding ice loads (Wilkman et al., 2009). The dynamics of the ice and the vessel's dynamics interact with each other, which makes the force of the ice on the vessel difficult to predict. In DP mode, and assuming the vessel is aligned with the ice drift direction, the thrust created by the propulsion of the vessel has to resist all the forces caused by the ice drift, which include not only the mean and oscillating force in the longitudinal x-direction, but also an oscillating force in the transverse y-direction and an oscillating yaw moment (Wilkman et al., 2009). That makes the vessel easily to drift off the position.

Another challenge for DP system operation in ice is that rotating the vessel on the spot is not possible. In order to turning a vessel in ice, the vessel has to move forward and backwards in order to rotate (Hals and Jenssen, 2012, Kuehnlein, 2009). Ice under the hull of the vessel is also a big challenge for DP system operations in ice. The ice floes propelled by the thrusters with high speed could create great harm to the hull of the vessel, as well as the equipment under the hull of the vessel, such as the acoustic transducers. Thus, the design of the hull is essential.

The cold temperature and the wind could damage the wind sensor and other equipment of the DP system on deck, which may lead to the holistic system being out of work. Those challenges disqualify the DP concept for continuous operation in. Ice conditions vary from light to heavy, both the speed and direction of drifting ice may change rapidly. These, as well as the challenges mentioned above, should be taken into account for a new concept DP system design. A new conceptual design includes the following features:

- Low ice resistance of the vessel at both bow and stern. This would be achieved by optimizing the icebreaking hull shape, similar to the ones found on icebreakers.
- High ability to turn the vessel in ice in order to follow changes in ice drift. This could be achieved by implementing a strong slope at the side of the vessel. This hull shape allows the vessel to break ice over the entire ship length. Azimuth propellers could deliver the required thrust for turning the drill ship.
- The vessel should be able to operate in ice without icebreaker assistance up to very severe ice conditions (Kuehnlein, 2009). With icebreaker assistance, the operational limits of the vessel should be extended even further.

A DP vessel's station keeping capability in the Arctic can be increased through ice management. The aim of ice management operation is to decrease the severity of the ice condition to a level where the DP system is operable. In practice, before the ice is approaching the DP vessel the ice blocks should be broken into small ones, which could prevent the DP vessel from drifting off position due to collision with big blocks of ice. The role of ice management is critical, because the station keeping capability of the DP vessel is limited in ice. In order to provide sufficient ice management intensity and

effect, normally more than one ice management vessel is needed. The bigger ice management vessel will be arranged further from the DP vessel, and the smaller or equally large ice management vessel will be arranged near the DP vessel. The ice management vessels cooperate to break the ice into smaller floes, and decrease the dynamical behavior of the ice against the DP vessel.

2.2 *DP in South China Sea*

South China Sea is the deepest and widest sea offshore China, with the richest oil and gas resource down below. The petroleum geological resources are estimated to be about 20–30 billion tons; gas resources are about 16 billion cubic meters contained in the South China Sea Basin, accounting for 1/3 of China's total oil gas resources of which 70% are in deep sea areas. However, the South China Sea is very famous for its hash environment. Oil and gas exploration activity in South China Sea can be challenging due to the weather and high seas, especially for the offshore facilities equipped with DP systems. Some of the most important weather challenges in South China Sea for DP are as follows:

Monsoon and the cold front*:* The general weather pattern is represented by the monsoon. During the monsoon the directionality of the environment changes and heavier rainfall occurs (Haveman et al., 2006). Besides, there is always strong wind accompanied. The cold fronts appearing in winter frequently bring wind with force at least 7–8; the wave height is around 3 meters during the winter. All of which generate a risk for the offshore installations positioned by DP systems to drift off position.

Soliton current*:* Soliton current caused by internal waves is a special phenomenon which occurs at several locations around the world, and also in the South China Sea during the summer season. The speed of the soliton current is usually up to 3–4 knots with the tide current, which will generate ripples on the sea surface. Generally, the soliton current is hundred meters width and 50 nautical miles long. Solitons occur all year round, especially in June and July. Large energy is contained in a soliton which increases the probability of offshore installation being forced off the position. If the forces acting on the hull of the installation exceed the power of the thrusters, then it will lose the keeping position ability. It also creates a significant risk that the position keeping ability is lost due to its high speed and rapid changing direction. The rapid change of speed and direction of the soliton will lead to a certain delay for the DP system to react to the environment, causing the installation to drift off the original position, even out of the warning limits. Thus, it is very important for the DP operator to detect the soliton early and take preactions to resist it from drift off position. Tide is the original cause for the generation of soliton. Thus the occurrence of solitons can be more or less predicted. Their intensity cannot be estimated but there may be measures to provide an advance warning of their impending arrival. With advance warning the facility activities can be scheduled until soliton passage is complete (Millmaker et al., 1997). Radar could also be used to detect the solitons. Solitons will generate ripples on the sea surface, so shipboard radar could be used to detect them. The speed and the wave length of the soliton could be accurately measured by radar and Acoustic Doppler Current Profiler (ADCP). In the case of Soliton:

– All generators should be kept at good working conditions to resist the effects of the soliton especially the ones that are not detected in time.
– After a soliton warning, the DP operator should ready all the thrusters and generators, in order to cope with the coming soliton impact.
– Adjust the heading of the installation directly against the soliton before the soliton arrival as far as possible to avoid soliton side attack.
– Adjust the DP system to quickly response to the changes of the environment. The quick mode could be used in this circumstance to cope with the rapid speed and direction changes of the soliton. Thus, enough time could be obtained for the thrusts to resist the external force before the rig is being forced off.

The typhoon: Most of the oil fields in the South China Sea will be affected during the typhoon season (around July to October) and there are some disasters related to the typhoons. For example in October 23rd 1983, the rig "Java Sea" was capsized due to the attack of a typhoon. All 81 people on board died, and the total economic loss was 350 million US dollars. Root cause for this disaster was that people in charge did not pay enough attention to the local typhoon, and it was too late when the actions were taken. In September 14th 2009, rig "West Hercules" operated in South China Sea. The rig was being forced off the original well position due to an attack of a typhoon. The root causes were that the people in charge were too confident about the ability of the rig to resist the typhoon attack. Typhoons are generated from east of Luzon Island, and are then moving into the South China Sea. The most predominant characteristics of this kind of typhoons are high strength, large affection area, but with enough warning time. There is another kind of typhoons named local typhoons. These develop from the tropical low pressure. The characteristics of this kind of

typhoons are less horizontal domain, low vertical height, and relatively low intensity. They are generated fast, are difficult to prevent and are usually destructive to the offshore facilities as strong wind and heavy seas are generated.

Typhoons increase the risk for the installation being forced off position, due to the external extremely high wave forces which may be exceeding the force generated by thrusters of the installation. Loss of position may occur as drift-off. Associated well damage, equipment damage, and even personnel injury accidents may occur. Additional measures should be taken to minimize the risk generated by typhoons, and make sure that the wind speed and wave do not exceed the rig's operational standards before disconnection.

The DP system accompanied by a mooring system for station keeping is a proven concept in typhoon areas. However, for some areas the mooring system could not be accompanied with DP system, because of the water depth. Much more additional actions should be taken to cope with the coming typhoon:

- The routine report will be more frequent when there is a typhoon. Then the installation management could decide whether to keep the original position or disconnect and navigate to safe area. Make sure that there is enough time to navigate to the safe area when deciding to disconnect;
- The installation should recover all the risers and subsea facilities timely before the approach of the typhoon near. All moving equipment or materials should be lashed tightly, and all the watertight openings should be checked. Enough maneuvering space should remain for the DP system to avoid collision with other installations nearby;
- Generators and thrusters should be used reasonably, avoid continuous use at full load condition. Reasonable heading should be adjusted to avoid that the rig is being directly exposed to the heavy wind and waves.
- Suitable navigation methods should be selected when deciding to disconnect. According to the moving path of the typhoon, the manager should justify the rig's relative position from the typhoon's eye;
- The location could shield the installation from exposing to the strong wind and waves. Hainan Island could provide an ideal shielding area for offshore DP installations. However, attention should be paid to a sudden direction change of the typhoon.

Offshore DP installations for the offshore oil and gas industry in the South China Sea must be outfitted with the ability to cope with unexpected coming of solitons, typhoons, cold fronts and other severe weather conditions. Successful operational experience of other DP installations in the South China Sea could be used for reference.

3 HAZARD IDENTIFICATION OF DP SYSTEM WITH EMPHASIS ON HARSH CLIMATE CONDITIONS

As mentioned the most significant risk relevant to DP operations is loss of the position control ability (Bakken and Smedvig, 2001, Fougere, 2005). Normally, there are two basic failure modes for loss of positions; they are drive-off and drift-off. For drive off, the OSV/MODUs go off position by their own thrusters' force, because inaccurate position data are received, which lead to that the DP system drives the installation to a wrong position. For drift-off, the force generated by thrusters could not resist the external environmental force; the installation will drift off its original position by the force of the wind, waves as well as the currents. Figure 1 shows the causes of the loss of position incidents from year 1994–2003 (Tjallema et al., 2007).

As Figure 1 shows the causes of loss of position, these can be categorized in three main groups including *i) environmental factors, ii) dynamic positioning system*, and *iii) DP operation associated personal*. As mentioned the environmental factors such as wind, wave, and current, directly influence DP vessels' resistance to loss of position. The possibility of sudden changes of wind and current direction, and the possibility of certain atmospheric conditions that influence the GPS, are the factors to evaluate (Chen et al., 2008, Chen et al., 2009). The characteristics of the dynamic positioning systems components (DP computer, power generation, position references, thrusters and electrical components) play significant contributions to resistance of loss of position. Using system redundancy is an effective way in order to increase the availability and reliability of the dynamic positioning system. Redundancy can reduce the probability of the DP installation's loss of position and protect the installation from dam-

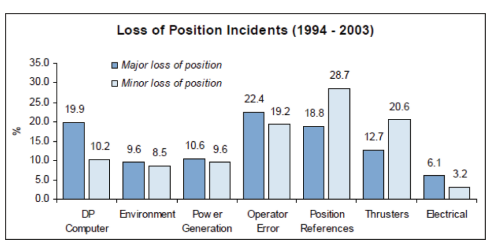

Figure 1. DP incidents causes (Tjallema et al., 2007).

Table 1. DP loss of position preliminary risk analysis.

Equipment node	Deviation	Failure causes	Consequence	Recommendation
Position reference	Total failed	1. Power supply off; 2. Satellite failure; 3. Device out of work; 4. Device damaged 5. *Positioning system inadequate (for example in the Arctic)*	1. Loss of position; 2. Environment pollution	1. More position reference; redundancy with different work principle; 2. Properly protect outer part of the device from damaging; 3. Emergency power supply 4. *Get ready for leaving location/abandon the operation*
	Position data with large error	1. Antenna signal damped; 2. Calculation part error; 3. Interrupted with each other	Moving out of limitation	1. Check the antenna regularly 2. Regularly system self-test; 3. Proper satellite or transponder position
	Do not get proper signal occasionally	1. Maintenance defect; 2. Transponder contaminated; 3. System disorders; 4. System setup error	1. Large thrusters load; 2. High fuel consumption; 3. Less position control accuracy; 4. Degradation of DP operation status	1. Regularly maintenance by specialist; 2. Check the satellite and transponder working condition; 3. Restart the system; 4. Properly system setup
Power station	No power supply	1. Fuel run out; 2. Fire alarm generate; 3. Switch-board burn out; 4. All generators out of work	1. Loss of position; 2. Collision with other installations; 3. Environment pollution	1. Enough fuel for daily consumption; 2. Establish emergency response procedure; 3. The emergency generator available at any moment
	Insufficient power supply	1. Damaged of power cable; 2. One of the generator shut down; 3. One or more power route blocked up	1. Moving out of limitation due to insufficient thrusters force; 2. Lower position keeping accuracy and reliability	1. Regularly power supply system checkup; 2. Generator maintenance regularly according to the PMS
Thruster	All thrusters shut down	1. No power supply; 2. Control station error; 3. Power switch board out of work; 4. Main power cable erosion	1. Loss of position; 2. Collision with other installations adjacent; 3. Environment damage	1. Regularly thruster system checkup; 2. Establish thruster working status monitoring system; 3. Redundancy power route setup
	One or two thruster out of work	1. Partly power route blocked up; 2. Electrical signal blocked from input to control station 3. *Repair has not been possible due to harsh environmental conditions*	1. Lower position keeping ability and reliability; 2. Loss of position may occur	1. Fulfill the check list before operation; 2. Redundancy power route setup; 3. Electrical signal checkup before input to DP control station
	Thrusters working abnormal	1. Mechanic part fail of the thruster itself 2. *Thruster power insufficient to keep up with environmental loading*	1. Out of work of the thruster; 2. Lower DP system position keeping capacity	1. Thruster maintenance according to the requirement; 2. Get ready of the spare part 3. *Ready for leaving location/abandon the operation*

		4. Wrong software operation		

age (Li Jr, 2013). The minimum redundancy requirements of the DP systems are defined by different guide line such as Lloyd rules: Rules for classification and construction. Finally, the action of DP personnel may directly lead to loss of position of the DP system, or they may interact with the technical failure both contributing to loss of position. The following elements affect the human actions: training, certification, operation experiences, knowledge about the DP system, work attitude, teamwork spirit and so on. Besides, lack of competence may also lead to wrong system operation. HAZOP is one of the most commonly used techniques in the offshore industry (Khamidi and John, 2011). Dynamic positioning system can be analyzed through HAZOPs to identify the potential risk during a normal operation. Based on our experience related to risk analysis for harsh environment and experience from working in the South China Sea, we present a DP loss of position risk analysis in Table 1.

We review here the risk for "*DP loss of position*" by evaluating potential failure modes and their consequences. Mitigating measures are suggested. It should be noted that the Table 1 also specifies generic hazards; specific aspects for the harsh environment are highlighted in italic letters.

4 CONCLUSION

There is limited experience about using the DP system in harsh condition such as arctic condition and it is not a very mature technology being used in the harsh environment, such as the Arctic area. To have a safe operational, the resistance to loss of position and the robustness of the recovery as the key parameters for safe dynamic positioning operation of a drilling rig should be evaluated considering all influence factors. Loss of position when using DP systems in harsh operational condition is a major hazard and for a Mobile Offshore Drilling Unit (MODU), loss of position without safe disconnection could result in critical damage not only to the well, but also to the subsea equipment. Hence, the reliability of the DP methods should be considered by for example training and using the appropriate level of redundancy. Moreover, a well establish plan for safe disconnection and reconnection when the loss of position is occur should be established. To achieve this goal at first stage all influence operational conditions should be identified and their effect should be quantified.

Wear time-dependent reliability analysis using Bayesian inference

J. Feng, J. Zhang, J. Si & P. Wang
Science and Technology on Reliability and Environmental Engineering Laboratory, Beihang University, Beijing, China
School of Reliability and Systems Engineering, Beihang University, Beijing, China

ABSTRACT: Wear is one of the most important reasons for failures of mechanical systems and components. This paper presents a simulation approach for reducing the uncertainty in the wear time-dependent reliability analysis for a pin of a lifting mechanical system. The wear time-dependent reliability modeling of the pin is established based on Archard theory, and the material parameters, elastic modulus and Poisson's ratio are treated as uncertain variables. Then, Bayesian inference is used to incorporate the new information to update the probability density functions of elastic modulus and Poisson's ratio, and reduce the uncertainty. Wear time-dependent reliability of the pin before and after updating are evaluated using PHI2 method which is based on the up-crossing rate approach and allows to solve time-dependent problems using classical time-invariant reliability tools such as FORM/SORM methods.

1 INTRODUCTION

It is generally known that wear is one of three major causes of failures (wear, corrosion and fatigue) of mechanical systems and components. In general, wear is a gradual process, and the consequences of wear are not disastrous. Therefore people pay little attention to the importance of wear. In fact, the economic loss caused by the wear failure of mechanical equipment is enormous. Based on relevant data (Tung & McMillan 2004): about 70% of the mechanical equipment damage is caused by various forms of wear; US's annual economic loss caused by the wear is about 4 percent of its Gross National Product (GNP). Therefore, the wear reliability analysis and evaluation for mechanical systems and components is very important in scientific research and engineering.

Due to influences of measurement error, manufacturing, assembly and other factors, there is uncertainty in mechanical components' geometry size, material properties parameters (such as elastic modulus, Poisson's ratio), and so on. The uncertainty significantly affects the reliability of the mechanical components. Therefore, it is important to choose appropriate distributions of random variables before wear reliability analysis. The traditional probability theory method is one of common methods which are used to deal with the uncertainty of variables. However, the method of probability and statistics is subject to restrictions of sample size, sampling time and sample conditions. Sometimes, because sample size is too small, it is impossible to obtain the probability density functions of random variables.

When prior information about random variables is scarce, Bayesian inference method can reduce random variables uncertainty through integrating new information with prior information effectively. Based on Bayesian inference, we can obtain accurate reliability analysis results. Although Bayesian inference method has been widely used in some engineering fields (Rusk et al. 2011, Zhang & Mohammadian 2008, Zhang et al. 2009), few studies on its applications in mechanical time-dependent reliability area have been performed. A pin, the key component of a lifting mechanical system, is researched in this paper. Firstly, the elastic modulus and Poisson's ratio of the pin are considered as random variables; secondly, the wear time-dependent reliability model of the pin is established based on Archard wear theory; thirdly, the probability density functions of elastic modulus and Poisson's ratio are updated by Bayesian inference method in order to reduce the uncertainty; finally, based on PHI2 method, three examples about wear time-dependent reliability of the pin are analyzed: (i) updating elastic modulus only; (ii) updating Poisson's ratio only; (iii) updating both elastic modulus and Poisson's ratio.

2 WEAR MODEL OF THE PIN BASED ON ARCHARD THEORY

2.1 *Archard wear model*

The Archard model is one of the wear models which are widely accepted in engineering. It is firstly proposed by R. Holm, and then is developed

by Archard et al. The Archard model is given by (Archard 1953)

$$W = K\frac{PS}{H} \tag{1}$$

where W is the wear volume, K is the coefficient of wear, P is the normal load, S is the sliding distance, and H is Brinell hardness of materials.

2.2 *Weal model of the pin*

The diagram of a lifting mechanical system is shown in Figure 1. The lifting mechanical system consists of a lifting platform, 2 connecting rods, 2 cylinders, a pedestal, several hinges and so on. The lifting mechanical system is used to lifting the antenna. The pedestal is used to support the whole system, the lifting platform is used to install the antenna, the two connecting rods are used to transmit motion and force, and the cylinders are used to provide the driving force.

By Failure Mode, Effects and Criticality Analysis (FMECA) of the lifting mechanical system, it is found that the pin is one of the key components which have significant influence on system reliability, and the failure mechanism of the pin is wear. The finite element model of the lifting mechanical system shown in Figure 2 is established in ABAQUS. The ring in Figure 2 is the position that the pin is located in. During this process of lifting the antenna repeatedly, wear volume of the pin increases with an increasement in the number of lifting. According to Archard wear theory, after the lifting mechanical system lifting the antenna n times, the actual wear volume of the pin is given by:

$$W(n) = K\frac{PS}{H}n \tag{2}$$

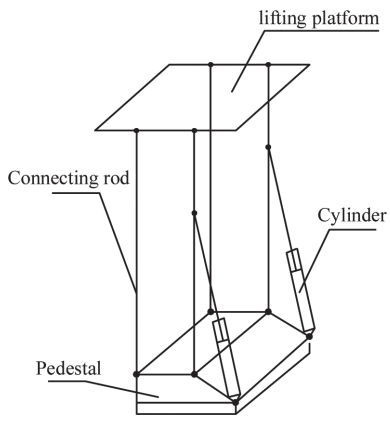

Figure 1. Diagram of the lifting mechanical system.

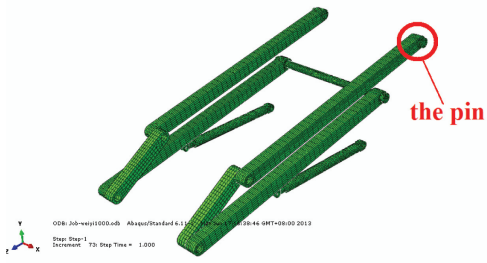

Figure 2. Finite element model of the lifting mechanical system.

where the sliding distance S is given as:

$$S = \frac{\pi}{2}r_1 \tag{3}$$

where r_1 is radius of curvature of the pin.

According to Hertz contact theory, the normal load P which the pin is subjected to, is given by:

$$P = \frac{\pi\sigma^2 r_1 r_2\left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)L}{r_2 - r_1} \tag{4}$$

where σ is contact stress, r_1 is radius of curvature of the pin, r_2 is radius of curvature of the hole in the connecting rod, ν_1 is Poisson's ratio of the pin, ν_2 is Poisson's ratio of the connecting rod, E_1 is elastic modulus of the pin, E_2 is elastic modulus of the connecting rod, and L is the length of contact line, given by:

$$L = \pi r_1 \tag{5}$$

Substitute Eq. (3), Eq. (4) and Eq. (5) into Eq. (2) to obtain the wear model of the pin based on Archard wear theory:

$$W(n) = \frac{K}{2H}\frac{\pi^3\sigma^2 r_1^3 r_2\left(\frac{1-\nu_1^2}{E_1}+\frac{1-\nu_2^2}{E_2}\right)}{r_2 - r_1}n \tag{6}$$

3 BAYESIAN INFERENCE

Accurate estimates of the Probability Density Functions (PDFs) of random variables require large amount of data. However, in most engineering cases, the number of samples that can be obtained is ex-tremely limited, sometimes even cannot obtained. So the traditional probability statistical method is no longer applicable. In such circumstances, Bayesian inference method offers a workable solution, and

by integration of prior information with new information, it can be used to estimate the PDFs of random variables accurately.

Bayesian inference forms a normative and rational method for the probability updating when new information is made available (Karandikar et al. 2012). Considering a random variable X, let the prior PDF of X be $f(x)$, which expresses the uncertainty about X before the new information is taken into account. And let the likelihood function of X be $L(\theta|x)$, when new information θ is obtained. Then, the posterior PDF $f(x|\theta)$ of the random variable X can be obtained using the Bayes theorem (Zhu & Frangopol 2013):

$$f(x|\theta) = kL(\theta|x)f(x) \tag{7}$$

where k is a normalizing constant, given as (Zhu & Frangopol 2013):

$$k = \left(\int_{-\infty}^{+\infty} L(\theta|x)f(x)dx\right)^{-1} \tag{8}$$

It is noticed from Eq. (7) that the PDF of the random variable X is updated from the prior $f(x)$ to the posterior $f(x|\theta)$ by incorporating the new information θ. The posterior $f(x|\theta)$ expresses the uncertainty about X after the new information θ is taken into account.

4 TIME-DEPENDENT RELIABILITY ANALYSIS BASED ON PHI2 METHOD

Let us assume generalized stress to be $s(t)$, and generalized strength to be r. Mechanical products failure, when generalized stress exceeds general strength. The time-dependent limit state function of mechanical products is given by:

$$g(t, X) = r - s(t, X) \tag{9}$$

where X is the basic random variables, and t is time.

Let us define the instantaneous probability of failure of the mechanical products at time t by:

$$P_{f,i}(t) = \text{Prob}(g(t, X) \le 0) \tag{10}$$

This probability does not take into account what happened before t. It is independent of the previous states, i.e. it is not a conditional probability. It is computed by considering time as a fixed parameter in Eq. (10).

Let the up-crossing rate be $v(t)$. The key to time-dependent reliability analysis using PHI2 method is $v(t)$ (Andrieu-Renauda et al. 2004). Before computing $v(t)$, let us define two events:

$$\begin{cases} A = \{\exists t \in [0, T_f] | g(t, \boldsymbol{X}) > 0\} \\ B = \{\exists t \in [0, T_f] \,|\, g(t + \Delta t, \boldsymbol{X}) \le 0\} \end{cases} \tag{11}$$

where the two events are:
A = {mechanical products are in the safe domain at t}
B = {mechanical products are in the failure domain at $t + \Delta t$}

Then, the up-crossing rate $v(t)$ is defined by a limit formula (Andrieu-Renauda et al. 2004):

$$v(t) = \lim_{\Delta t \to 0} \frac{\text{Prob}(A \cap B)}{\Delta t} \tag{12}$$

According to Eq. (12), as long as we calculate the value of Prob($A \cap B$), we can obtain the value of $v(t)$. Figure 3 illustrates the probability of $A \cap B$ in FORM approximation (First Order Reliability Method) in the space of the standard variables $U = T(X)$ where T is an isoprobabilistic transformation. In this figure, $\beta(t)$ and $\beta(t + \Delta t)$ are respective the reliability indices of the events A and B. $\mathbf{n}(t)$ and $\mathbf{n}(t + \Delta t)$ are respective the unit normal vectors of A and B. ϕ_2 represents the probability density function of the binormal law. The probability $A \cap B$ is represented by the integral of ϕ_2 over the hatched volume.

Let us denote by ρ_t the correlation between A and B. The probability of $A \cap B$ is then, in FORM approximation (Andrieu-Renauda et al. 2004):

$$P(A \cap B) = \Phi_2(\beta(t), -\beta(t + \Delta t); \rho_t) \tag{13}$$

where Φ_2 is the binormal cumulative distribution function. And ρ_t is computed by (Mejri et al. 2010):

$$\rho_t = -\mathbf{n}(t) \cdot \mathbf{n}(t + \Delta t) = -\frac{\mathbf{x}^*(t)}{\beta(t)} \cdot \frac{\mathbf{x}^*(t + \Delta t)}{\beta(t + \Delta t)} \tag{14}$$

where $\mathbf{x}^*(t)$ and $\mathbf{x}^*(t + \Delta t)$ are respective Most Probable Point (MPP) at time t and $t + \Delta t$ in the standard normal space.

The reliability indices $\beta(t)$ and $\beta(t + \Delta t)$ are computed by considering time as a fixed parameter, i.e. using a time-invariant reliability analysis. Then the up-crossing rate is approximated by (Mejri et al. 2010):

$$v(t) \approx \frac{\Phi_2(\beta(t), -\beta(t + \Delta t); \rho_t)}{\Delta t} \tag{15}$$

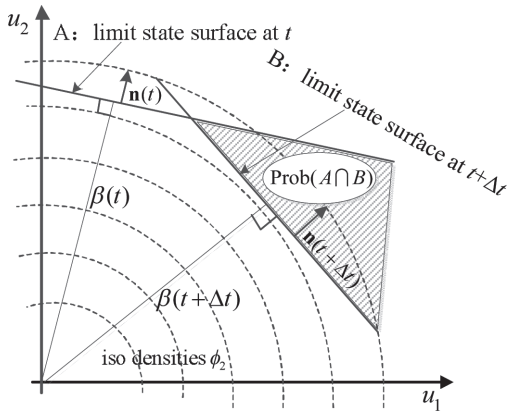

Figure 3. Computing $A \cap B$ based on FORM.

The binormal cumulative distribution function Φ_2 can be computed by using:

$$\Phi_2(\beta(t), -\beta(t+\Delta t); \rho_t) = \Phi(\beta(t))\Phi(-\beta(t+\Delta t)) + \int_0^{\rho_t} \frac{1}{2\pi\sqrt{1-z^2}} \exp\left\{-\frac{1}{2(1-z^2)}(\beta^2(t)+\beta^2(t+\Delta t) + 2z\beta(t)\beta(t+\Delta t))\right\} dz \quad (16)$$

Knowing the initial instantaneous probability of failure and the up-crossing rate $v(t)$, it is possible to compute an upper bound of the cumulative probability of failure of mechanical products within the time interval [0, T_f] by (Mejri et al. 2010):

$$P_{f,c}(0,T_f) \le P_{f,i}(0) + \int_0^{T_f} v(t)dt \quad (17)$$

5 TIME-DEPENDENT RELIABILITY ANALYSIS FOR THE PIN USING BAYESIAN INFERENCE

The lifting mechanical system discussed in this paper is made out of ASTM 1045 steel. And the values of parameters of the pin are given in Table 1.

In order to facilitate the calculation, only random variables of the pin are taken into account in this paper. The elastic modulus E_2 and Poisson's ratio ν_2 of the connecting rod are assumed to be deterministic, and the values of the two parameters are respective $E_2 = 206.000$ MPa, $\nu_2 = 0.269$.

In this paper, the finite element software ABAQUS is adopted to simulate and analyse the process of the lifting mechanical system lifting the antenna. The simulation shows that the ultimate stress of the pin during the process is $\sigma = 109.5$ MPa, and Figure 4 shows the stress nephogram of the pin.

Table 1. The values of parameters of the pin.

Parameters	Mean	Standard deviation
K	0.5×10^{-9}	–
H	286 HB	–
ρ_1	60 mm	–
E_1	200,000 MPa	11547 MPa
ν_1	0.26	0.01154

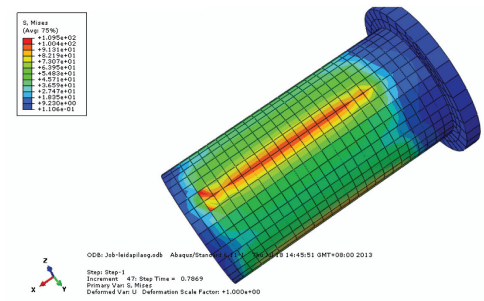

Figure 4. The stress nephogram of the pin.

Let the permitted value of the wear volume of the pin be W, and assume that W follow normal distribution with the mean of $\mu_W = 5$ mm^3 and the standard deviation $\sigma_W = 0.5$ mm^3. When the actual wear volume $W(n)$ exceeds W, the pin failures. According to Eq. (6) and Eq. (9), after the lifting mechanical system lifting the antenna n times, the time-dependent limit state function of the pin is

$$g(n,X) = W - \frac{K}{2H} \frac{\pi^3 \sigma^2 r_1^3 r_2 \left(\frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2}\right)}{r_2 - r_1} n \quad (18)$$

where X is the basic random variables of the wear model of the pin, and X is expressed as $[E_1, \nu_1]$.

5.1 *Wear time-dependent reliability analysis for the pin before Bayesian updating*

Assume that both of prior distributions of E_1 and ν_1 follow uniform distribution, and E_1 and ν_1 are independent of each other. Prior distributions for E_1 and ν_1 are selected as: $E_1 \sim U(a_1, b_1)$, $\nu_1 \sim U(a_2, b_2)$, where

$$\begin{cases} a_1 = \mu_{E_1} - \sqrt{3}\sigma_{E_1} = 180{,}000\,\text{MPa} \\ b_1 = \mu_{E_1} + \sqrt{3}\sigma_{E_1} = 220{,}000\,\text{MPa} \end{cases}$$

$$\begin{cases} a_2 = \mu_{\nu_1} - \sqrt{3}\sigma_{\nu_1} = 0.24 \\ b_2 = \mu_{\nu_1} + \sqrt{3}\sigma_{\nu_1} = 0.28 \end{cases}$$

and μ_{E_1} and σ_{E_1} are respective the mean and standard deviation of E_1; μ_{ν_1} and σ_{ν_1} are respective the mean and standard deviation of ν_1.

The prior PDFs of E_1 and ν_1 are respective:

$$f_{E_1}(x)=\begin{cases}\dfrac{1}{40000}, & 180,000\le x\le 220,000\\ 0, & otherwise\end{cases} \tag{19}$$

$$f_{\nu_1}(y)=\begin{cases}\dfrac{1}{0.04}, & 0.24\le y\le 0.28\\ 0, & otherwise\end{cases} \tag{20}$$

Before the PDFs of E_1 and ν_1 are updated, according to Eq. (18), the wear time-dependent reliability analysis results of the pin within the interval [0, n] is obtained using PHI2 method. The results are shown in Figure 5, where n is the number of the lifting mechanical system lifting the antenna, and $n = 4200$.

It is found from Figure 5 that: (i) the upper bound of cumulative probability of failure gradually increases with the increasement of n; (ii) the lower bound of the reliability of the pin gradually decreases with the increasement of n; (iii) the upper bound of cumulative probability of failure and the lower bound of the reliability are respective 0.4626 and 0.5374 within the interval [0, n].

5.2 *Wear time-dependent reliability analysis for the pin after Bayesian updating*

5.2.1 *Bayesian updating of random variables*

1. Update elastic modulus E_1

According to Bayesian inference method, the posterior distribution is proportional to the product of the prior distribution and likelihood functions. Under given the prior PDF of E_1, if we want to obtain the posterior PDF, we must firstly define the likelihood function. Based on the new information (Yu & Zhang 2011), the elastic modulus

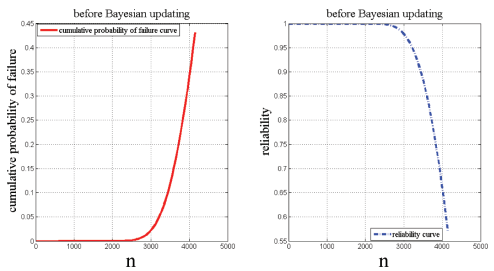

Figure 5. Reliability analysis results before Bayesian updating.

E of ASTM 1045 steel is subject to a normal distribution with the mean of 206,000 MPa and the variance of 6180^2 MPa^2. Therefore we can assume that the likelihood function of the elastic modulus E_1 is:

$$L_{E_1}(x)=\frac{1}{\sqrt{2\pi}\sigma_E}\exp\left(-\frac{(x-\mu_E)^2}{2\sigma_E^2}\right) \tag{21}$$

where, $\mu_E = 206{,}000$ MPa and $\sigma_E = 6180$ MPa.

Based on Eq. (7), the posterior PDF of E_1 is

$$f'_{E_1}(x)=\frac{1}{K_{E_1}}L_{E_1}(x)\quad 180,000\le x\le 220,000 \tag{22}$$

where K_{E_1} is a constant, given as (Christian 1995)

$$K_{E_1}=\int_{a_1}^{b_1}L_{E_1}(x)dx=\Phi\left(\frac{b_1-\mu_E}{\sigma_E}\right)-\Phi\left(\frac{a_1-\mu_E}{\sigma_E}\right) \tag{23}$$

Therefore, the posterior PDF of E_1 follows a truncated normal distribution within the interval [a_1, b_1], and the cumulative distribution function of E_1 is (Christian 1995):

$$F'_{E_1}(x)=\frac{1}{K_{E_1}}\left(\Phi\left(\frac{x-\mu_E}{\sigma_E}\right)-\Phi\left(\frac{a_1-\mu_E}{\sigma_E}\right)\right) \tag{24}$$

After Bayesian updating, the mean and variance of E_1 are respective (Christian 1995):

$$\mu'_{E_1}=\sigma_E\left(\frac{\phi\left(\frac{a_1-\mu_E}{\sigma_E}\right)-\phi\left(\frac{b_1-\mu_E}{\sigma_E}\right)}{\Phi\left(\frac{a_1-\mu_E}{\sigma_E}\right)-\Phi\left(\frac{b_1-\mu_E}{\sigma_E}\right)}\right)+\mu_E \tag{25}$$

$$\sigma'^{2}_{E_1}=\sigma_E^2\left(1+\frac{\frac{a_1-\mu_E}{\sigma_E}\phi\left(\frac{a_1-\mu_E}{\sigma_E}\right)-\frac{b_1-\mu_E}{\sigma_E}\phi\left(\frac{b_1-\mu_E}{\sigma_E}\right)}{\Phi\left(\frac{b_1-\mu_E}{\sigma_E}\right)-\Phi\left(\frac{a_1-\mu_E}{\sigma_E}\right)}\right)-\sigma_E^2\left(\frac{\phi\left(\frac{a_1-\mu_E}{\sigma_E}\right)-\phi\left(\frac{b_1-\mu_E}{\sigma_E}\right)}{\Phi\left(\frac{b_1-\mu_E}{\sigma_E}\right)-\Phi\left(\frac{a_1-\mu_E}{\sigma_E}\right)}\right)^2 \tag{26}$$

where ϕ represents the PDF of standard normal distribution.

Substituting values of a_1, b_1, μ_E, and σ_E back into Eq. (25) and Eq. (26) yields $\mu'_{E_1} = 206{,}190$ MPa and

$\sigma'_{E_1} = 5955$ MPa . After updating, the coefficient of variance of E_1 is $C.V'_{E_1} = \sigma'_{E_1}/\mu'_{E_1} = 0.0289$.

Comparing the posterior of E_1 with the prior, it is found that after Bayesian updating: (i) the distribution type of E_1 changes from the assumed uniform distribution to truncated normal distribution, as shown in Figure 6; (ii) the mean of E_1 increases, changing from 200,000 MPa to 206,190 MPa; (iii) the standard deviation of E_1 decreases significantly, changing from 11,547 MPa to 5955 MPa; (iv) the coefficient of variance also decreases significantly, changing from 0.0577 to 0.0289. We can see easily from the above point (ii) ~ point (iv): integration of the new information dramatically reduces the uncertainty of E_1.

2. Update Poisson's ratio ν_1

The updating process of ν_1 is the same as E_1. According to the new information (Yu & Zhang 2011), the Poisson's ratio of ASTM 1045 steel is subject to a normal distribution with the mean of 0.269 and the variance of 0.00807^2. So we can define the likelihood function of ν_1 of the pin as:

$$L_{\nu_1}(y) = \frac{1}{\sqrt{2\pi}\sigma_\nu}\exp\left(-\frac{(y-\mu_\nu)^2}{2\sigma_\nu^2}\right) \tag{27}$$

where, $\mu_\nu = 0.269$ and $\sigma_\nu = 0.00807$.

According to Eq. (7), the posterior PDF of ν_1 is:

$$f'_{\nu_1}(y) = \frac{1}{K_{\nu_1}} L_{\nu_1}(y) \quad 0.24 \le y \le 0.28 \tag{28}$$

where K_{ν_1} is a constant, given as (Christian 1995):

$$K_{\nu_1} = \int_{a_2}^{b_2} L_{\nu_1}(y)dy = \Phi\left(\frac{b_2-\mu_\nu}{\sigma_\nu}\right) - \Phi\left(\frac{a_2-\mu_\nu}{\sigma_\nu}\right) \tag{29}$$

Therefore the posterior PDF of ν_1 follows a truncated normal distribution within the interval $[a_2, b_2]$, and the cumulative distribution function of ν_1 is (Christian 1995):

$$F'_{\nu_1}(y) = \frac{1}{K_{\nu_1}}\left(\Phi\left(\frac{y-\mu_\nu}{\sigma_\nu}\right) - \Phi\left(\frac{a_2-\mu_\nu}{\sigma_\nu}\right)\right) \tag{30}$$

After Bayesian updating, the mean and variance of ν_1 are respective (Christian 1995):

$$\mu'_{\nu_1} = \sigma_\nu\left(\frac{\phi\left(\frac{a_2-\mu_\nu}{\sigma_\nu}\right) - \phi\left(\frac{b_2-\mu_\nu}{\sigma_\nu}\right)}{\Phi\left(\frac{a_2-\mu_\nu}{\sigma_\nu}\right) - \Phi\left(\frac{b_2-\mu_\nu}{\sigma_\nu}\right)}\right) + \mu_\nu \tag{31}$$

$$\sigma'^2_{\nu_1} = \sigma_\nu^2\left(1 + \frac{\frac{a_2-\mu_\nu}{\sigma_\nu}\phi\left(\frac{a_2-\mu_\nu}{\sigma_\nu}\right) - \frac{b_2-\mu_\nu}{\sigma_\nu}\phi\left(\frac{b_2-\mu_\nu}{\sigma_\nu}\right)}{\Phi\left(\frac{b_2-\mu_\nu}{\sigma_\nu}\right) - \Phi\left(\frac{a_2-\mu_\nu}{\sigma_\nu}\right)}\right) - \sigma_\nu^2\left(\frac{\phi\left(\frac{a_2-\mu_\nu}{\sigma_\nu}\right) - \phi\left(\frac{b_2-\mu_\nu}{\sigma_\nu}\right)}{\Phi\left(\frac{b_2-\mu_\nu}{\sigma_\nu}\right) - \Phi\left(\frac{a_2-\mu_\nu}{\sigma_\nu}\right)}\right)^2 \tag{32}$$

The coefficient of variance of ν_1 is $C.V'_{\nu_1} = \sigma'_{\nu_1}/\mu'_{\nu_1} = 0.0256$ after updating.

Comparing the posterior of ν_1 with the prior, it is found that after Bayesian updating: (i) the distribution type of ν_1 changes from the assumed uniform distribution to the truncated normal distribution, as shown in Figure 7; (ii) the mean of ν_1 increases, changing from 0.26 to 0.2704; (iii) the standard deviation of ν_1 decreases significantly, changing from 0.01154 to 0.00691; (iv) the coefficient of variance also decreases significantly, changing from 0.0444 to 0.0256. The trend in ν_1 is the same as E_1. Integration of the new information dramatically reduces the uncertainty of ν_1.

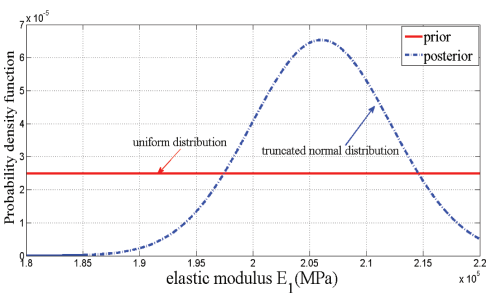

Figure 6. Prior and posterior PDFs of E_1.

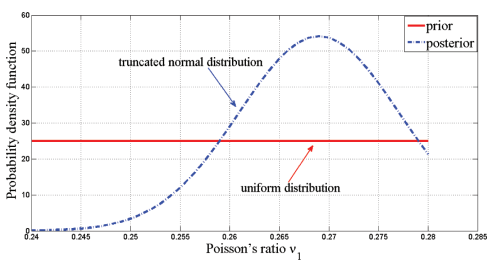

Figure 7. Prior and posterior PDFs of ν_1.

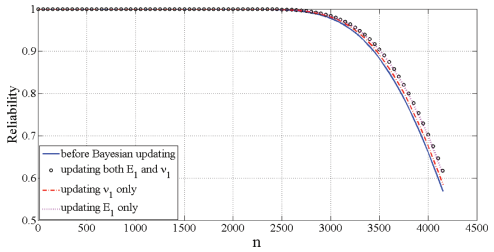

Figure 8. Reliability before and after Bayesian updating.

5.2.2 *Time-dependent reliability analysis for the pin after Bayesian updating*

After Bayesian updating, both of distribution types of E_1 and ν_1 change, which may lead to obvious changes in reliability results. Based on PHI2 method, three cases are analyzed herein: (i) ν_1 is treated as deterministic while E_1 is considered as a random variable to be updated; (ii) E_1 is treated as deterministic while ν_1 is considered as a random variable to be updated; (iii) update both E_1 and ν_1, assuming that they are statistically independent.

After Bayesian updating, the wear time-dependent reliability analysis results of the pin are shown in Figure 8.

We use the wear time-dependent reliability curve after updating both E_1 and ν_1 as the baseline, shown as the curve with circular makers in Figure 8, and we can see from Figure 8:

1. Based on prior distributions of E_1 and ν_1, the reliability result of the pin is conservative compared with the baseline;
2. Compared with ν_1, E_1 has greater influence on the reliability result. Because after updating E_1 only, the wear time-dependent reliability curve is more close to the baseline;
3. Under the condition of updating only one random variable (either updating E_1 or ν_1), the reliability result is conservative compared with the baseline. The accuracy of the reliability results depends on random variables. The more abundant the statistical information about random variables is, the higher the accuracy of the reliability result is.

6 CONCLUSION

This paper presents a simulation approach for reducing the uncertainty in the wear time-dependent reliability analysis for the pin of the lifting mechanical system. Bayesian inference is performed to update the PDFs of elastic modulus E_1 and Poisson's ratio ν_1. Then, based on PHI2 method, three examples about wear time-dependent reliability are analyzed: (i) updating E_1 only; (ii) updating ν_1 only; (iii) updating both E_1 and ν_1. The following conclusions are drawn:

1. In order to reduce uncertainty, Bayesian inference is proposed to incorporate the new information with the prior information. After Bayesian updating: (i) distributions of E_1 and ν_1 change; (ii) both the variances of E_1 and ν_1 decrease significantly; (iii) both the coefficients of variance of E_1 and ν_1 decrease significantly. So the uncertainty is reduced dramatically, and the random variables are more closer to their true statistical distributions;
2. It is not appropriate to deal with wear time-dependent reliability analysis based on prior information, and the reliability analysis result is conservative compared with the result after updating. The reason is that there is not enough information to describe the statistical nature of the random variables accurately;
3. The influences of different random variables on the reliability results are different;
4. If sufficient new information become available in the future, to ensure the accuracy of reliability results, the correlations among E_1 and ν_1 need to be taken into account.

ACKNOWLEDGEMENT

The authors express sincere appreciation to the editor and reviewers for their efforts to improve the quality of the paper. This work is supported by Space Mechanisms Reliability and its Dynamics and System Control, National Basic Research Program of China (2013CB733000).

RAVEN and dynamic probabilistic risk assessment: Software overview

Andrea Alfonsi, Cristian Rabiti, Diego Mandelli, Joshua Cogliati & Robert Kinoshita
Idaho National Laboratory, Idaho Falls, USA

Antonio Naviglio
University "La Sapienza", Rome, Italy

ABSTRACT: Risk Analysis Virtual Environment (RAVEN) is a generic software framework to perform parametric and probabilistic analysis based on the response of complex system codes. The initial development was aimed at providing dynamic risk analysis capabilities to the Reactor Excursion and Leak Analysis Program v.7 (RELAP-7) Thermo-Hydraulic code, currently under development at the Idaho National Laboratory (INL). Although the initial goal has been fully accomplished, RAVEN is now a multi-purpose probabilistic and uncertainty quantification platform, capable to agnostically communicate with any system code. This agnosticism includes providing Application Programming Interfaces (APIs). These APIs are used to allow RAVEN to interact with any code as long as all the parameters that need to be perturbed are accessible through input files or via python interfaces. RAVEN is capable of investigating the system response as well as the input space using Monte Carlo, Grid, or Latin Hyper Cube sampling schemes, but its strength is focused toward system feature discovery, such as limit surfaces, separating regions of the input space leading to system failure, using dynamic supervised learning techniques. The paper presents an overview of the software capabilities and their implementation schemes followed by some application examples.

1 INTRODUCTION

1.1 *Initial development*

The development of RAVEN (Alfonsi, Rabiti, Mandelli, Cogliati, & Kinoshita 2013) started in 2012, when, within the Nuclear Energy Advanced Modeling and Simulation (NEAMS) program, the need to provide a modern risk evaluation framework became stronger. RAVEN's principal assignment is to provide the necessary software and algorithms in order to employ the concept developed by the Risk Informed Safety Margin Characterization (RISMC) (Smith, Rabiti, et al. 2012) program. RISMC is one of the pathways defined within the Light Water Reactor Sustainability (LWRS) program. In the RISMC approach, the goal is not just specifically identifying the frequency of an event potentially leading to a system failure, but the closeness (or not) to key safety-related events. This approach may be used in identifying and increasing the safety margins related to those events. A safety margin is a numerical value quantifying the probability that a safety metric (e.g. as peak pressure in a pipe) is exceeded under certain conditions.

The initial development of RAVEN has been focused on providing dynamic risk assessment capability to RELAP-7, currently under development at the INL and, likely, future replacement of the RELAP5-3D (RELAP5-3D Team, 2009) code.

Most of the capabilities implemented having RELAP-7 as principal focus are easily deployable for other system codes. For this reason, several side activities are currently ongoing for coupling RAVEN with software such as BISON, fuel performance, (Williamson, Hales, et al. 2012), RELAP5-3D. This paper is focused on the RAVEN software infrastructure and its functionality.

2 SOFTWARE INFRASTRUCTURE

2.1 *Outlines*

RAVEN has been developed in a highly modular and pluggable way in order to enable easy integration of different programming languages (i.e., C++, Python) and, as already mentioned, coupling with any system code.

RAVEN is composed of three main software systems that can operate either in coupled or stand-alone mode:

- Control Logic System
- Graphical User Interface
- Probabilistic and Parametric framework

The control logic system and the Graphical User Interface are currently available for RELAP-7 only. For this reason, attention is focused on the probabilistic and parametric framework.

2.2 *Probabilistic and parametric framework*

The probabilistic and parametric framework represents the core of the RAVEN analysis capabilities. The main idea behind the design of the system is the creation of a multi-purpose framework characterized by high flexibility with respect to the possible performable analysis. The framework must be capable of constructing the analysis/calculation flow at run-time, interpreting the user-defined instructions and assembling the different analysis tasks following a user specified scheme.

In order to achieve such flexibility, combined with reasonably fast development, a programming language naturally suitable for this kind of approach was needed: Python.

Hence, RAVEN is coded in Python and is characterized by an object-oriented design. The core of the analysis performable through RAVEN is represented by a set of basic components (objects) the user can combine, in order to create a custom analysis flow. A list of these components and a summary of their most important functionalities are reported as follows:

- *Distribution*: In order to explore the input/output space, RAVEN requires the capability to perturb the input space (initial conditions of a system code). The initial conditions, that represent the uncertain space, are generally characterized by Probability Distribution Functions (PDFs), which need to be considered when a perturbation is applied. In this respect, a large library of PDFs is available.
- *Sampler*: A proper approach to sample the input space is fundamental for the optimization of the computational time. In RAVEN, a "sampler" employs a unique perturbation strategy that is applied to the input space of a system. The input space is defined through the connection of uncertain variables and their relative probability distributions.
- *Model*: A model is the representation of a physical system (e.g. Nuclear Power Plant); it is therefore capable of predicting the evolution of a system given a coordinate set in the input space.
- *Reduced Order Model (ROM)*: The evaluation of the system response, as a function of the coordinates in the input space, is very computationally expensive, especially when brute-force approaches (e.g. Monte Carlo methods) are chosen as the sampling strategy. ROMs are used to lower this cost, reducing the number of needed points and prioritizing the area of the input space that needs to be explored. They can be considered as an artificial representation of the link between the input and output spaces for a particular system.

The list above is not comprehensive of all the RAVEN framework components (visualization and storage infrastructure).

2.2.1 *Distribution*

As already mentioned, the perturbation of the input space, through the initial conditions (parameters) affected by uncertainties, needs to be performed by the proper distribution functions. RAVEN provides, through an interface to the BOOST library, the following univariate (truncated and not) distributions: Bernoulli, Binomial, Exponential, Logistic, Lognormal, Normal, Poisson, Triangular, Uniform, Weibull, Gamma, and Beta.

The usage of univariate distributions for sampling initial conditions is based on the assumption that the uncertain parameters are not correlated with each other. Quite often uncertain parameters are subject to correlations and thus the univariate approach is not applicable. This happens when a generic outcome is dependent on different phenomena simultaneously (i.e. the outcome dependency description can not be collapsed to a function of a single variable). RAVEN currently supports both N-Dimensional (N-D) PDFs. The user can provide the distribution values on either Cartesian or sparse grid, which determines the interpolation algorithm used in the evaluation of the imported CDF/PDF:

- N-Dimensional Spline (Habermann, & Kindermann 2007), for Cartesian grids
- Inverse weight (Gordon & Wixom 1978), for sparse grids

Internally, RAVEN provides the needed N-D differentiation and integration algorithms to compute the PDF from the CDF and vice versa.

As already mentioned, the sampling methods use the distributions in order to perform probability-weighted perturbations. For example, in the Monte Carlo approach, a random number $\in [0,1]$ is generated (probability threshold) and the CDF, corresponding to that probability, is inverted in order to retrieve the parameter value usable in the simulation. The existence of the inverse for univariate distributions is guaranteed by the monotonicity of the CDF. For N-D distributions this condition is not sufficient since the $CDF(X) \rightarrow [0,1]$, $X \in R^N$ and therefore it could not be a bijective function. From an application point of view, this means the inverse of a N-D CDF is not unique.

As an example, the Figure 1 shows a multivariate normal distribution for a pipe failure as

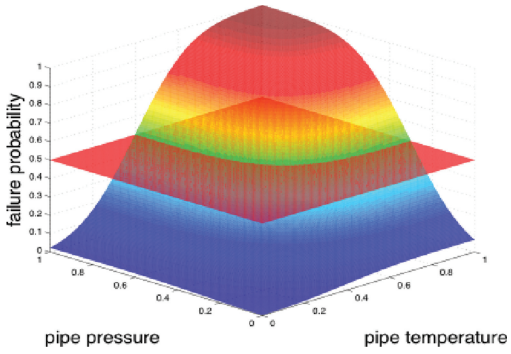

Figure 1. 2-D CDF, function of pressure and temperature.

function of the pressure and temperature. The plane identifies an iso-probability surface (in this case, a line) that represents a probability threshold of 50% in this example. Hence, the inverse of this CDF is an infinite number of points.

As easily inferable, the standard sampling approach cannot directly be employed. When multivariate distributions are used, RAVEN implements a surface search algorithm for identifying the iso-probability surface location. Once the location of the surface has been found, RAVEN chooses, randomly, one point on it.

2.2.2 *Sampler*

The sampler is probably the most important entity in the RAVEN framework. Indeed, it performs the driving of the specific sampling strategy and, hence, determines the effectiveness of the analysis, from both an accuracy and computational point of view. The samplers, that are available in RAVEN, can be categorized in three main classes:

- Once-through
- Dynamic Event Tree (DET)
- Adaptive

2.2.2.1 *Once-through samplers*

The once-through sampler category collects all the strategies that perform the sampling of the input space without exploiting, through dynamic learning approaches, the information made available from the outcomes of calculation previously performed (adaptive sampling) and the common system evolution (patterns) that different sampled calculations can generate in the phase space (dynamic event tree).

In the RAVEN framework, three different and well-known "once-through" samplers are available:

- Monte Carlo (MC)
- Latin Hyper Cube (LHS)
- Grid Based

As already mentioned, all these sampling strategies are well known, as well as their properties. Therefore, a detailed investigation of their application is not provided.

2.2.2.2 *Dynamic event tree sampler*

In order to clarify the idea behind the DET Sampler currently available in RAVEN, a small overview is needed.

In technological complex systems, as nuclear power plants, an accident scenario begins with an initiating event and then evolves over time through the interaction of dynamics and stochastic events. This mutual action leads to the production of infinitely many different scenarios, which define a continuous dynamic event tree with infinite branches. At each time point, the stochastic variability of the accident outcomes is determined by a multivariate probability distribution. The PRA analysis needs an approximation to this distribution for selected consequence variables. A way to achieve this goal is an Event Tree approach. In dynamic PRA analysis, conventional Event Tree (Alfonsi, Rabiti, Mandelli, Cogliati, Kinoshita, & Naviglio 2013) sequences are run simultaneously starting from a single initiating event. The branches occur at user specified times and/or when an action is required by the operator and/or the system, creating a deterministic sequence of events based on the time of their occurrence. One of the disadvantages of this method is that the timing/sequencing of events and system dynamics is not explicitly accounted for in the analysis. In order to overcome these limitations a "dynamic" approach is needed. The DET (Alfonsi, Rabiti, Mandelli, Cogliati, Kinoshita, & Naviglio 2013) technique brings several advantages, among which is the fact that it simulates probabilistic system evolution in a way that is consistent with the severe accident model. This leads to a more realistic and mechanistically consistent analysis of the system taken into consideration. The dynamic PRA, in general, and the DET methodologies in particular, are designed to take the timing of events explicitly into account, which can become very important especially when uncertainties in complex phenomena are considered. Hence, the main idea of this methodology is to let a system code determine the pathway of an accident scenario within a probabilistic "environment".

From an application point of view, a N-D grid is built on the CDF space. A single simulation is spawned and a set of triggers is added to the system code control logic. Every time a trigger gets activated (one of the CDF thresholds in the grid is overpassed), a new set of simulations (branches) is spawned. Each branch carries its own conditional probability.

As expected, a continuous monitoring of the system evolution in the phase space is needed.

Figure 2 shows a practical example. In this particular case, it is assumed that the probability failure of a pipe depends on the fluid pressure magnitude. Three probability thresholds are defined on the cumulative distribution function. One simulation is spawned (0). As soon as the pressure of the fluid reaches a value corresponding to a 33% probability (CDF), a stop signal is sent and the framework starts two new simulations (branches). The branch in which the system evolved to the newer condition (pipe failed, red line) carries 33% of the probability, while the other the complementary amount. The same procedure is repeated at point 2.

Generally, not all the input space can be explored using a DET approach. For instance, usually the parameters affected by aleatory uncertainty are sampled using a dynamic event tree approach, while the ones characterized by epistemic uncertainty are sampled through "once-through" sampling strategies. At the moment a hybrid approach ("once-through" sampling of initial conditions followed by a dynamic event tree strategy) is currently under development.

As already mentioned, this strategy requires a tight interaction between the system code and the sampling driver (i.e., RAVEN framework). In addition, the system code must have a control logic capability (i.e. trigger system). For these reasons, the application of this sampling approach to a generic code needs a bigger effort when compared to the other Samplers available in RAVEN. Currently, the DET is fully available for the thermal-hydraulic codes RELAP-7 and RELAP5-3D.

2.2.2.3 *Adaptive samplers*

A recent feature available within RAVEN is the possibility to perform smart sampling (also known as adaptive sampling) as an alternative to classical "once-through" techniques.

The motivation is that nuclear simulations are often computationally expensive, time-consuming, and high dimensional with respect to the number of input parameters. Thus, exploring the space of all possible simulation outcomes is infeasible using finite computing resources. During simulation-based probabilistic risk analysis, it is important to discover the relationship between a potentially large number of input parameters and the output of a simulation using as few simulation trials as possible.

This is a typical context for performing adaptive sampling where a few observations are obtained from the simulation, a Reduced Order Model (ROM) is built to represent the simulation space, and new samples are selected based on the model constructed. The ROM, discussed in section 2.2.4, is then updated based on the simulation results of the sampled points (see Fig. 3). In this way, it is attempted to gain the most information possible with a small number of carefully selected sampled points, limiting the number of expensive trials needed to understand features of the system space.

In the following, the specific use case of identifying the limit surface, i.e. the boundaries in the simulation space between system failure and system success (see Fig. 4) is analyzed.

For this scope two classes of algorithms are considered:

- Model-based algorithms
- Data-based algorithms

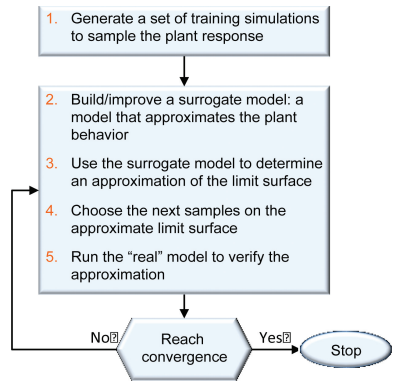

Figure 3. Adaptive sampling algorithm.

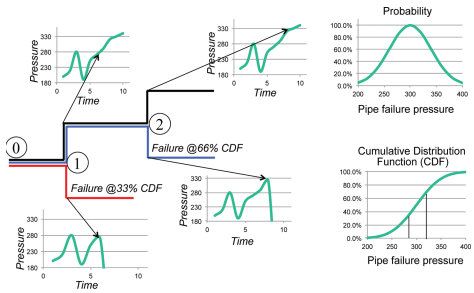

Figure 2. Dynamic event tree simulation pattern.

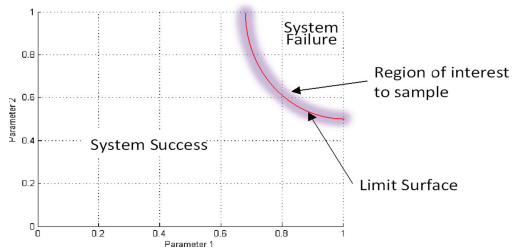

Figure 4. Graphical representation of the limit surface.

In the first class, the created ROM aims at approximating the real response function of the system as function of the input parameters. Once it is built, it is used to search for the points that are in the proximity of the limit surface using contour reconstruction based algorithms. Response function can be built using Support Vector Machines (SVM) (Mandelli & Smith 2012) or Kriging based interpolators (Mandelli, Smith, Rabiti, Alfonsi, et al. 2013).

On the other side, data-based algorithms do not build a response function based ROM but determine the location of the limit surface directly from the neighborhood graph constructed from the training data, without any dependencies on a particular prediction model.

These algorithms begin the search of the limit surface by directly building a neighborhood structure as the ROM (e.g. a relaxed Gabriel graph) (Mandelli, Smith, Rabiti, Alfonsi, et al. 2013) on the initial training data. It then creates a candidate set by first obtaining linearly interpolated points along spanning edges (i.e. edge of the graph that connect points having different outcomes) of the graph, and introducing a random perturbation along all dimensions to these points.

2.2.3 *Models*

The Model entity, in the RAVEN environment, represents a "connection pipeline" between the input and the output space. The RAVEN framework does not own any physical model (i.e. it does not posses the equations needed to simulate a generic system), but implements APIs by which any generic model can be integrated and interrogated. The RAVEN framework provides APIs for three different model categories: Codes, Externals and ROMs.

The Code model represents the communication pipe between the RAVEN and any system code. Currently, RAVEN has APIs for RELAP5-3D, RELAP-7 and any MOOSE (Gaston, Hansen, et al. 2009) based application.

The External model allows the user to create, in a Python file (imported, at run-time, in the RAVEN framework), its own model (e.g. set of equations representing a physical model, connection to another code, control logic, etc.). This model will be interpreted/used by the framework and, at run-time, will become part of RAVEN itself.

The data exchange between RAVEN and the system code can be performed either by direct software interface or by files. If the system code is parallelized, the data exchanging by files is generally the way to follow since it can be much more optimized in large clusters.

Figure 5 shows a schematic representation of the whole framework, highlighting the communication pipes among the different modules and engines. As can be seen, in the figure all the components discussed so far are reported. In addition the data management, mining and processing modules are shown.

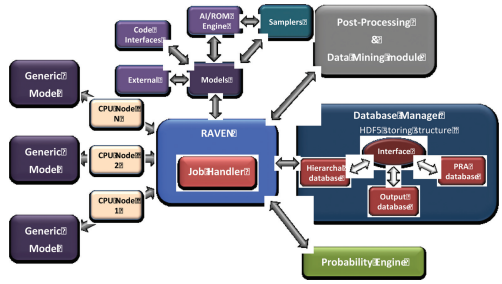

Figure 5. RAVEN probabilistic and parametric framework.

2.2.4 *Reduced order models*

As briefly mentioned, a ROM is a mathematical representation of a system, used to predict a selected output space of a physical system.

The "training" is a process that uses sampling of the physical model to improve the prediction capability (capability to predict the status of the system given a realization of the input space) of the ROM. More specifically, in RAVEN the reduced order model is trained to emulate a high fidelity numerical representation (system codes) of the physical system. Two general characteristics of these models can be generally assumed (even if exceptions are possible):

1. The higher the number of realizations in the training sets, the higher is the accuracy of the prediction performed by the reduced order model. This statement is true for most of the cases although some ROMs might be subject to the over-fitting issues. The over-fitting phenomenon is not discussed here, since its occurrence is highly dependent on the algorithm type, (and there is large number of ROM options available in RAVEN). Every time the user chooses a particular reduced order model algorithm to use, he should consult the relative literature.
2. The smaller the size of the input domain with respect to the variability of the system response, the more likely the surrogate model will be able to represent the system output space.

In most of the cases of interest, the information that is sought is related to defining the failure boundaries of a system with respect to perturbations in the input space. For this reason, in the development of RAVEN, it has been given priority to the introduction of a class of supervised learning algorithms, which are usually referred to as classifiers. A classifier is a reduced order model that is capable of representing the system behavior through a binary response (failure/success).

The first class of classifier introduced has been the SVM (Mandelli & Smith 2012) with several different kernels (polynomial of arbitrary integer order, radial basis function kernel, sigmoid) followed by a nearest-neighbor based classification using a K-D tree search algorithm. All these supervised learning algorithms have been imported via an API from the scikit-learn (Pedregosa et al. 2011) library. In addition, the N-D spline and the inverse weight methods, that are currently available for the interpolation of N-D PDF/CDF, can also be used as ROMs.

2.2.5 *Simulation environment*

RAVEN is perceived by the user as a pool of tools and data. Any action in which the tools are applied to the data is considered a 'step' in the RAVEN environment. For the scope of this paper, "multiRun" type of step will be described, since all others are either closely related (single run and adaptive run) or just used to perform data management and visualization. Firstly, the RAVEN input file associates the variable definition syntax to a set of PDFs and to a sampling strategy. The "multiRun" step is used to perform several runs (sampling) in a block of a model (e.g. in a MC sampling).

At the beginning of each sub sequential run, the sampler provides the new values of the variables to be modified. The code API places those values properly in the input file. At this point the code API generates the run command and asks to be queued by the job handler. The job handler manages the parallel execution of as many runs as possible within a user prescribed range and communicates with the step controller when a new set of output files are ready to be processed. The code API receives the new input files and collects the data in the RAVEN internal format. The sampler is queried to assess if the sequence of runs is ended, if not, the step controller asks for a new set of values from the sampler and the sequence is restarted as described in Figure 6.

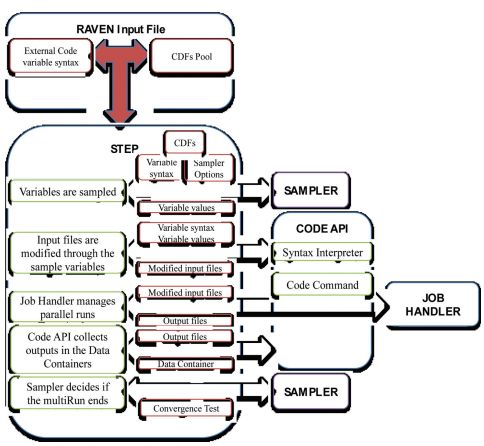

Figure 6. Calculation flow for a multi-run sampling.

The job handler is currently capable to run different run instances of the code in parallel and can also handle codes that are multi threaded or using any form of MPI parallel implementation.

RAVEN also has the capability to plot the simulation outcomes while the set of sampling is performed and to store the data for later recovery.

3 EXAMPLES

This section shows examples of analyses performed using RAVEN with three different codes: RELAP-7 (Section 3.1), RELAP5-3D (Section 3.2) and an external model (Section 3.3).

3.1 *RELAP-7 analysis*

As already mentioned, the first system code that has been driven by RAVEN is RELAP-7. This section shows a station blackout analysis on a simplified Pressurized Water Reactor using RELAP-7 as system code. The plant response has been analyzed using the Monte Carlo and DET approach.

3.1.1 *Monte Carlo analysis*

Once the plant is in Station Black-Out (SBO) condition, the probability of recovering the emergency cooling system is set dependent from the recovery of any of the following systems:

- Diesel Generators (DGs): the power is restored when two of the three DG trains are recovered. The recovery time t_{DG1} of the first train is characterized by a normal distribution (σ = 200 s, μ = 800 s). The recovery time of the second train t_{DG2} is characterized by a uniform distribution (min = 0.5, max = 1.0) and driven by the relation: pdf (t_{DG2}) = pdf (t_{DG1}) · U (x).
- The Reserve Station Service Transformer and the main AC line recovery times t_{RSST} and t_{138} are described by normal distributions ($\sigma_{RSST/138}$ = 500 s, μ_{RSST} = 1400 s, μ_{138} = 2000 s).

The simulation scope is to assess the failure/success ratio of the plant. The goal function associated is: $\theta_f(T_{c\,MAX}, t) = \delta(T - T_{fC})$.

Where $T_{c\,MAX}$ and T_{fC} are the maximum and the failure clad temperatures, respectively. The failure temperature of the clad is also a stochastic variable characterized by a triangular distribution (min = 1255 K, max = 1700 K, peak = 1477 K).

Note that the time at which both diesel generators are available needs to be treated as a multidimensional distribution function unless the recovery of the second train is computed inside the system control logic once the recovery time of the first

train is already known. For this analysis, 4000 MC samples were performed.

3.1.2 *Dynamic event tree analysis*

The situation considered is exactly the one presented in the MC analysis (see Section 3.1.1) and the details of the analysis can be found in (Alfonsi, Rabiti, Mandelli, Cogliati, Kinoshita, & Naviglio 2013). Figure 7 shows the time evolution of the clad temperature and a projection of the sampling grid pattern generated by the dynamic event trees approach. The green lines are the simulation continuing while the red dots signal a point where a simulation was stopped when reaching the maximum clad temperature. It could be noticed that there are simulations being stopped at a level of temperature that is exceeded in other simulations. The reason is of course the random value of the clad failure temperature. On the bottom, the plot shows a projection of the threshold triggered by the DET simulation of the transient. The projection is performed by defining the recovery time of the auxiliary system $\mathbf{t_{AC} = min(t_{DG2}, t_{138}, t_{RSST})}$. It is clear how the competing variable (max clad temperature and AC recovery time) are alternatively moved towards higher values of their CDF until a transition point between success and failure is reached. This pattern is generated by contemporaneously sampling two antagonist variables (or in a terminology more familiar in the RISMC framework, contemporaneously sampling capacity and load).

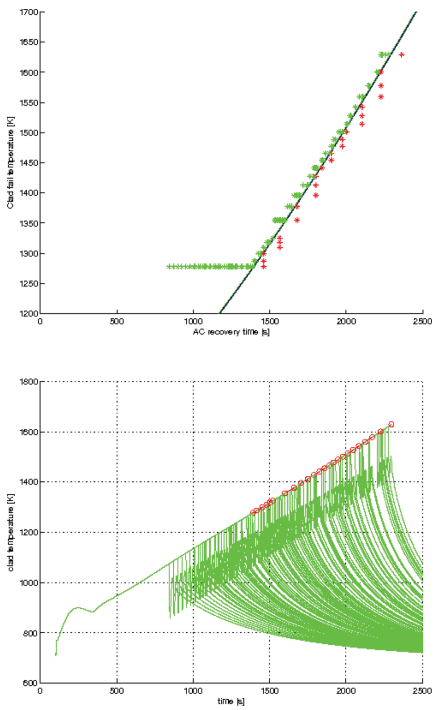

Figure 7. Top: DET a-posteriori limit surface. Bottom: clad temperature evolution.

3.2 *RELAP5-3D BWR SBO analysis*

For the RISMC project, we employed RAVEN and RELAP5-3D to analyze a Station Black-Out (SBO) accident scenario for a Boiling Water Reactor (Mandelli, Smith, Alfonsi, Rabiti, et al. 2014). In particular, we employed both classical statistical tools, i.e. MC, and more advanced machine learning based algorithms to perform uncertainty quantification in order to quantify changes in system performance and limitations as a consequence of power uprate.

In one of these analyses we focused on considering a 2-dimensional state space: Firewater (FW) availability time (measured after ADS activation) and battery life. By randomly changing these two parameters we observed the outcome of each simulation (failure or success) and, by using a SVM based classifier, we were able to determine the limit surface.

Results are shown in Figure 8 for two different values of power: 100%, and 120%. As expected, a longer battery life and a shorter firewater injection alignment time lead to success, while a short battery life and long firewater alignment time failed.

3.3 *Space propulsion system*

For the PSAM conference, a benchmark problem, a space propulsion system, was issued in

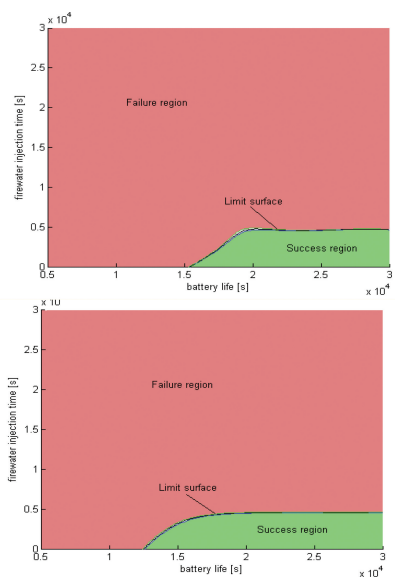

Figure 8. FW availability time vs. battery life: limit surface for 100% (top) and 120% (bottom) power.

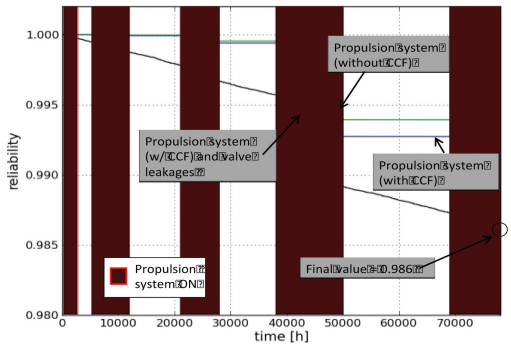

Figure 9. Temporal profile of the PSAM 2014 space propulsion system reliability.

order to compare Dynamic PRA methods. In this respect, the RAVEN team proposed a solution to this benchmark problem using RAVEN coupled with an external model that mimics both the dynamic (deterministic) and stochastic (e.g., failure on demands, damage accumulation, common cause failures) behavior of the propulsion system (Mandelli, Smith, Alfonsi & Rabiti 2014). The goal was to measure the temporal profile of the system reliability over the design life (78,000 hours, approximately 9 years). Results are shown in Figure 9 for two different cases: propulsion system only (with and without common cause failures) and propulsion system coupled with valve leakages.

4 CONCLUSIONS

RAVEN is reaching a level of maturity that merits its release of the code for testing outside of Idaho National Laboratory. The statistical analysis framework based on grids and Monte Carlo relies on very well assessed methodologies, and has been performing well during internal testing. The integration of those methodologies with the data handling flexibility, the visualization capabilities and the ease of coupling with different physical model simulators show how RAVEN can be a powerful tool for PRA analysis. The DET implementation allows also a rapid turnaround time for the coupling with other codes as long as access to the simulator's control logic is provided. DETs have been identified as one of the most promising approaches for PRA. Thus, the development is currently focused on making the DET an adaptive approach.

Moreover, the coming release will let the PRA community familiarize itself with these enhanced techniques like limit surface or ROM construction for identifying the leading mechanisms of system failure.

Integrated Deterministic Probabilistic Safety Analysis (IDPSA) of a fire scenario

M. Kloos & J. Peschke
GRS mbH, Garching, Germany

B. Forell
GRS mbH, Cologne, Germany

ABSTRACT: A research project at GRS aimed at demonstrating how a combination of the MCDET tool and the FDS code can be used to perform an IDPSA in the frame of a probabilistic fire safety analysis. The mixture of MCDET and FDS provided a sample of dynamic event trees comprising many different time series of quantities of the fire evolution associated with corresponding conditional occurrence probabilities. These results were used to derive exemplary probabilistic fire safety assessments from criteria such as the temperatures of targets or the time periods with target temperatures exceeding critical values. The paper gives an overview on the fire scenario investigated, outlines the steps of the analysis and presents a selection of results including a quantification of the influence of epistemic uncertainties. Lessons learned from the analysis are discussed.

1 INTRODUCTION

IDPSA—frequently also called Dynamic PSA—can be regarded as a complementary analysis to the classical Deterministic (DSA) and Probabilistic (PSA) Safety Analyses (Adolfsson et al. 2011, Adolfsson et al. 2012). It makes extensive use of a deterministic dynamics code and applies advanced methods for an improved modeling and probabilistic assessment of complex systems with significant process/hardware/software/firmware/human interaction (Aldemir 2013). An IDPSA is particularly suitable in the frame of a fire PSA, since it can more realistically model and assess the interaction of the fire dynamics with the performance of technical systems and human actions.

A useful software tool for performing an IDPSA is the MCDET tool which applies a combination of Monte Carlo (MC) simulation and the Dynamic Event Tree (DET) approach (Kloos & Peschke 2006, Kloos et al. 2013b). The first tool proposed in literature which applied the DET approach is DYLAM (Dynamical Logical Methodology; Amendola and Reina 1984; Cojazzi 1996). Other software tools using the DET approach are, for instance, ADS-IDAC (Hsueh & Mosleh 1996, Chang & Mosleh 1998), SCAIS-TSD (Izquierdo J.M. et al. 1994, Munoz et al. 1999) or ADAPT (Catalyurek et al. 2010).

Since the MCDET tool can in principal be coupled with any deterministic dynamics code, the FDS (Fire Dynamics Simulator) code from NIST (McGrattan K. et al. 2013) was selected to be applied for fire simulation. What makes the MCDET tool particularly useful for a fire safety analysis is its Crew Module which allows for considering the human actions performed for fire fighting as a dynamic process (Kloos & Peschke 2008).

The fire scenario selected to be analyzed deals with the fire fighting means designated to be applied in a reference NPP once a fire occurs for any reason. One major assumption is the failure of the automatic actuation of the fixed fire extinguishing system in the compartment where the fire is supposed to start. This implies that fire fighting mainly depends on the operability of the fire detection and alarm system, the performance of human actions as well as on the operability of active fire barrier elements (e.g. fire dampers and fire doors) and of the fire extinguishing systems which can be manually actuated.

The first steps of the analysis which were already presented in Kloos et al. (2013a) mainly focused on the performance of the human actions to be applied for fire fighting without running the FDS code. In those situations where human actions had to be considered as dependent on the fire evolution, case-by-case analyses were performed on conditions defined by decisive states of the fire evolution (e.g. smoke in front of the door visible or not, when fire fighters reach the fire compartment). The computational effort of those case-by-case analyses was negligible, since the MCDET tool making use just of the Crew Module without applying a

dynamics code (such as FDS, for instance) runs very fast. Results of the analyses were conditional distributions referring to the timing of human actions. These distributions were used as input to the analysis presented in this paper.

Main subject of the analysis presented here was the fire dynamics as simulated by the FDS code in interaction with stochastic factors affecting the fire over time. The mixture of MCDET and FDS was used to simulate many different time series of quantities of the fire dynamics associated with corresponding conditional occurrence probabilities. From these results, distributions referring to the temporal evolution of target temperatures and quantifications of the influence of epistemic uncertainties could be derived.

Chapter 2 of this paper gives a short overview on the MCDET method. Information on the fire scenario including the scenario-specific fire model and the fire fighting procedures investigated can be found in chapter 3. The steps of the analysis and a selection of results are described in chapter 4. Conclusions and lessons learned from the analysis are presented in chapter 5.

2 MCDET METHOD

Coupled with a deterministic dynamics code such as FDS, the MCDET tool performs a combination of Monte Carlo (MC) simulation and the Dynamic Event Tree (DET) approach (Kloos & Peschke 2006, Kloos et al. 2013b). This combination is able to treat any kind of uncertainty. Aleatory uncertainties due to stochastic influences referring to discrete quantities (e.g. success/failure of the fire detection and alarm system to operate; success/error of human actions) are handled by the DET approach, whereas aleatory uncertainties referring to continuous quantities (e.g. time periods for carrying out human actions) are handled by MC simulation. MC simulation is also applied to consider epistemic uncertainties (due to lack of knowledge). The sampling of values for continuous aleatory variables is not performed a priori, i.e. before the calculation of a DET is launched. It is performed when needed in the course of the calculation. In this way, it is possible to treat the influence of the dynamic process on aleatory uncertainties and to consider, for instance, a higher failure rate of a component, if a high temperature seriously aggravates the condition of the component.

Output of the simulations with the MCDET tool coupled to a dynamics code is a large spectrum of different sequences, for instance, of the evolution of the fire. It can be considered as a sample of individual DETs, each constructed from a set of values sampled for the continuous aleatory variables. From the time series of output quantities of the dynamics code (e.g. the temperature inside the jacket of cable targets provided by FDS) and the corresponding likelihoods available for each sequence, conditional DET-specific and, by the application of statistical methods, unconditional scenario-specific likelihoods of damage states can be calculated.

3 FIRE SCENARIO

Main subject of the analysis presented here are the fire fighting means designated to be applied in a German reference Nuclear Power Plant (NPP) in case of a fire. The fire was assumed to initially occur in a compartment with cooling and filtering equipment for pump lubrication oil. Besides this process equipment, the compartment is equipped with electrical cables routed below the ceiling. These cables partly carry out safety related functions.

It was assumed that malfunction of the oil-heating system designated to heat up the pump lubrication oil in the start-up phase of the NPP causes an ignition of the oil. The evolution of the fire was considered to depend on the leakage rate of the oil. The heat release rate may be limited by the oxygen available in the compartment.

The dimensions of the compartment are about $w \times l \times h = 8\ m \times 6.2\ m \times 6\ m$. Compartment walls are from concrete. The compartment is divided into a lower and an upper level by a steel platform at 2.4 m height. The steel platform can be reached by steel stairs. The three compartment doors lead to the lower level of the compartment. It was assumed that one of these doors was left in open position with a reference probability of 0.005 (see Table 1). The mechanical air exchange by an air intake and an exhaust vent was assumed to be 800 m^3/h. The fire damper at the exhaust vent was supposed to close after melting of a fusible link at 72 °C. This mechanism was supposed to fail with a reference probability of 0.01 (see Table 1). If the outlet damper is closed, the mechanical air supply into the room was assumed to be reduced to 400 m^3/h. This value was chosen to account for increased pressure losses, if the inlet air leaves the room via other leakages.

The fire was supposed to start on the steel platform at the electrical oil heater. The evolution of the fire was considered as being linear over time. The characteristic time to reach 1 MW heat release rate was varied from 250 s to 700 s (see Table 1). In the upper layer cable tray, the cable targets were exposed to hot smoke and radiation.

3.1 *Scenario specific model*

The fire simulation was performed with the Fire Dynamics Simulator (FDS) 6.0 (McGrattan K.

Table 1. Epistemic uncertainties.

Epistemic variables	Refer. value	Distrib. type	Distribution parameters
Value of optical density at which emerging smoke is visible under door [1/m]	0.3	Uniform	Min = 0.2, Max = 0.4
Response time index for activation temperature of fire dampers [$\sqrt{m \cdot s}$]	125	Uniform	Min = 50, Max = 200
Threshold of optical density D below which fire compartment can be entered [1/m]	0.4	Uniform	Min = 0.3, Max = 0.5
Fraction of fuel mass (oil) converted into smoke	0.097	Uniform	Min = 0.095, Max = 0.099
Time to reach 1 MW heat release rate [s]	425	Uniform	Min = 250, Max = 700
Cable Conductivity [W/m*K]	0.275	Uniform	Min = 0.15, Max = 0.4
Specific heat of cable [kJ/kg*K]	1.225	Uniform	Min = 0.95, Max = 1.5
Depth of cable isolation [m]	0.0016	Uniform	Min = 0.0012, Max = 0.002
Cable density [kg/m^3]	1131	Uniform	Min = 833, Max = 1430
Specific heat of concrete [kJ/kg*K]	0.65	Uniform	Min = 0.5, Max = 0.8
Conductivity of concrete [W/m*K]	1.75	Uniform	Min = 1.4, Max = 2.1
Thickness of concrete walls in the compartment [m]	0.37	Uniform	Min = 0.32, Max = 0.42
Probability that fire door falsely stays open	0.005	Beta	$\alpha = 1.5$, $\beta = 236.5$
Probability that fire damper fails to close	0.01	Beta	$\alpha = 1.5$, $\beta = 117.5$
Failure temperature of I&C cables [°C]	170	Uniform	Min = 145, Max = 195
Critical time periods [s] with I&C cable temperatures:			
≥145 °C	420	Uniform	Min = 360, Max = 480
≥150 °C	300	Uniform	Min = 240, Max = 360
≥160 °C	215	Uniform	Min = 180, Max = 250
≥170 °C	160	Uniform	Min = 120, Max = 200
≥180 °C	80	Uniform	Min = 40, Max = 120

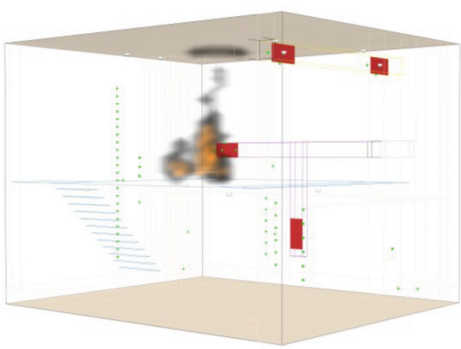

Figure 1. Snapshot of the compartment layout by FDS.

et al. 2013). The compartment was discretized in one mesh with a grid solution of 0.2 m in all three directions (see Fig. 1).

The air inlet duct (violet in Fig. 1) has one diffusor above the fire and one to the lower level. The outlet duct (yellow) sucks air from the upper layer by two diffusors which can be closed by the fire damper. The mechanical air supply was assumed to allow for a heat release rate of about 800 kW inside the compartment that is reduced to 400 kW after closing the damper. The inlet air damper was supposed not to close, because the fusible link is kept cold.

The thermal penetration of the cable material was described by the model for Thermally Induced Electrical Failure (THIEF) implemented in FDS. The THIEF model predicts the temperature of the inner cable jacket under the assumption that the cable is a homogeneous cylinder with one-dimensional heat transfer. The thermal properties—conductivity, specific heat, and density—of the assumed cable are independent of the temperature. In reality, both the thermal conductivity and the specific heat of polymers are temperature-dependent. In the analysis, conductivity, specific heat, density, and the depth of the cable insolation were considered as uncertain parameters with relevant influence (see Table 1).

The local optical density D of the smoke at 3.20 m height of the fire compartment was assumed to be an important factor affecting the time needed to suppress the fire. For optical densities below D = 0.1 m^{-1}, it was assumed that the personnel in charge of fire fighting can detect the fire and start to suppress it by means of a portable fire extinguisher after a delay of 10 s. For 0.1 m^{-1} < D < 0.4 m^{-1}, it is assumed that the delay time until

the fire source is detected and the suppression can be started increases, when the optical density rises. The delay time was assumed to be D times 100 seconds. For $D \geq 0.4\ m^{-1}$, fire suppression with a portable fire extinguisher and without any personal protective equipment was supposed to be impossible. More details are given in section 3.2. The threshold value of $0.4\ m^{-1}$ for the optical density was considered as a relevant parameter subjected to epistemic uncertainty (Table 1).

Once the fire suppression had started in a sequence, the simulation of the fire dynamics was stopped as soon as the temperature inside the cable jacket fell below 120 °C. Otherwise, a sequence was calculated up to 1800s after ignition.

3.2 *Fire fighting means*

If equipment and procedures work as intended, fire fighting is a rather short process, because the compartment where the fire is assumed to occur is equipped with a fixed fire extinguishing system which suppresses the fire with a sufficiently large amount of water after actuation by the fire detection and alarm system. However, one major assumption of the analysis presented here was the failure of the automatic actuation of the fixed fire extinguishing system. This implies that the fire has to be extinguished by manual fire fighting means performed by the plant personnel in charge.

Three states of the fire detection and alarm system can be assumed as decisive for the human actions to be performed for fire fighting, namely at least two detectors, only one detector or none of the detectors indicating an alarm signal to the control room. If at least two fire detectors send an alarm signal, the control room operator (shift leader) immediately instructs the shift fire patrol and the on-site fire brigade to inspect the compartment and to perform the necessary steps for fire suppression. If there is a signal by only one detector, the signal might be a faulty or spurious one (e.g. due to dust, steam, etc.). This is why the fire patrol trained for fighting incipient fires is instructed to inspect the fire compartment and to verify the fire. Suppose the fire patrol verifies the fire, the shift leader, who is immediately informed, calls the on-site fire brigade. In the meantime, the fire patrol tries to suppress the fire either by a portable fire extinguisher or by manually actuating the fixed fire extinguishing system from outside the fire compartment. If none of the fire detectors sends an alarm, the detection of the fire depends on the shift patrol inspecting the compartment at a random time once during a shift.

The fire patrol usually is the first person who arrives at the fire compartment. His/her success of suppressing the fire with a portable fire extinguisher was assumed to be depending on the local optical density D of the smoke at 3.20 m height (0.80 m above the level of the platform). If the optical density is too high (see section 3.1), fire suppression by the fire patrol inside the compartment is assumed to be impossible due to reduced visibility and irritant smoke effects on eyes and breathing organs. The fire patrol does not wear personal protective equipment. In this case, his/her only chance of successfully fighting the fire is to manually actuate the fixed fire extinguishing system. If the fire extinguishing system does not operate as intended, the fire brigade has to extinguish the fire with their equipment.

Besides the reliability of the fire detection and alarm system and the performance of human actions, the success of fire fighting mainly depends on the reliability of active fire barrier elements such as fire dampers or doors and of the fire extinguishing systems which can be manually actuated.

4 EXEMPLARY ANALYSIS

4.1 *Analysis steps*

In the first analysis steps, the human actions applied during the fire scenario were investigated in detail (Kloos et al. 2013a). The dynamic model of these actions was constructed on the basis of documents from the reference NPP and walk-talk-throughs at locations relevant for fire fighting. After the model was encoded in corresponding datasets of the Crew Module, the parameters of the Crew Module subjected to epistemic or aleatory uncertainty and considered as relevant for the analysis results were identified and the probabilistic information used to express the uncertainty (distributions and branching information) was specified. The corresponding data were entered as input to the Probabilistic Module of the MCDET tool.

The simulation runs of the first analysis steps were performed without running the FDS code. They were performed just by the combination of Crew Module, Probabilistic Module and the Scheduler of MCDET. That combination ran very fast and provided more than 100 Dynamic Event Trees (DETs) for each of several conditions. Those conditions identified as being decisive to the human actions of the fire fighting process were given by the relevant states of the fire detection and alarm system (none, only one or at least two of the detectors operate as required) as well as by the fire progression (e. g. visibility of smoke in front of the door when shift personnel reaches the fire compartment or production of smoke in the fire compartment).

From the DETs resulting from the simulations of the MCDET modules, various conditional distributions could be derived by using the

corresponding post-processing module of the MCDET tool. The distributions refer to the timing of human actions such as the time period between fire alarm and the arrival of fire fighters at the fire compartment door or the time period between the arrival at the fire compartment door and the beginning of fire extinguishing. They express stochastic variability and were used as input to the simulations performed in the subsequent analysis steps. Those analysis steps dealt with the modelling, simulation and evaluation of the interaction of the fire dynamics with relevant stochastic factors affecting the fire dynamics.

The stochastic factors taken into account refer to the timing and outcome (success/error) of tasks of human actions affecting the fire evolution, the operability of the fire detection and alarm system as well as to the functioning of active fire barrier elements (i.e. fire dampers and fire doors) and of the fire extinguishing systems which could be manually activated. Modelling information on the dynamics-stochastics interaction was specified as input to the FDS code as well as to the Probabilistic Module of the MCDET tool. The input file of the Probabilistic Module included a listing of the parameters subjected to stochastic variability (aleatory uncertainty) as well as the corresponding distributions and branching information expressing the stochastic variability. It also comprised information on the relevant parameters subjected to epistemic uncertainty. Corresponding information is given in Table 1.

The simulations of the FDS code and those of the Probabilistic Module were supervised by the old version of the MCDET Scheduler which allowed for calculating each DET in one process. The simulation approach made extensive use of the restart capabilities of the FDS code. The fire scenario was calculated up to 1800s (0.5 hours) after ignition.

The output of the simulations comprised data of about 2400 different fire sequences from a sample of 120 individual DETs. These data were evaluated by using corresponding post-processing modules of the MCDET tool.

4.2 *Consideration of epistemic uncertainties*

Like with continuous aleatory uncertainties, the influence of epistemic uncertainties is considered by Monte Carlo (MC) simulation (see chapter 2). The approach applied to account for both types of uncertainties is a double loop nested MC simulation: Sets of values of the parameters subjected to epistemic uncertainty (epistemic variables) are sampled in the outer loop. For each of these sets, different sets of values for the continuous aleatory variables are sampled and contribute to the generation of different Dynamic Event Trees (DETs) in the inner loop. That means a sample of DETs is constructed per set of epistemic variable values.

The approach applied to quantify the influence of epistemic uncertainties at least needs two distinct DETs per set of epistemic variable values. The results from all DETs generated for all sets of epistemic variable values can be used to estimate the mean $E(P_{Ep})$ and variance $Var(P_{Ep})$ of output quantity P_{Ep} subjected to epistemic uncertainty only:

$$P_{Ep} = E(P|Ep) \tag{1}$$

$$E(P_{Ep}) = E(E(P|Ep)) = E(P) \tag{2}$$

$$Var(P_{Ep}) = Var(E(P|Ep)) = Var(P) - E(Var(P|Ep)) \tag{3}$$

where P_{Ep} is, for instance, the (mean) likelihood of a damage state as a function of epistemic parameters. P_{Ep} can be estimated from the corresponding damage state likelihoods P derived from each DET per set of epistemic variable values.

An expression of the epistemic uncertainty of P_{Ep} can be obtained by applying the estimators for the mean $E(P_{Ep})$ and variance $Var(P_{Ep})$, for instance, to derive the parameters of a distribution supposed to be appropriate for P_{Ep} (e.g. Log. Normal or Beta distribution). The estimators for the mean $E(P_{Ep})$ and variance $Var(P_{Ep})$ can also be applied in the unequation of Cantelli to get a conservative estimator of the 95%-quantile of P_{Ep}:

$$P(P_{Ep} \geq E(P_{Ep}) + t) \leq \frac{Var(P_{Ep})}{Var(P_{Ep}) + t^2}, t \geq 0 \tag{4}$$

Another alternative to express the epistemic uncertainty of P_{Ep} is the calculation of the one-sided upper (95%; 95%) tolerance limit of P_{Ep} (Wilks 1942). The only requirement of this alternative is that at least 59 values of P_{Ep} are available (Wilks 1941). In the analysis presented here, 60 different sets of values were sampled for the epistemic variables. Information on the parameters subjected to epistemic uncertainty and with relevant influence on the output quantities (e.g. temperatures of cable targets) to be investigated is given in Table 1.

4.3 *Analysis results*

The safety related targets which could be damaged and, therefore, were selected to be considered in this analysis, are I&C cables routed below the ceiling of the fire compartment. The fire was regarded as successfully suppressed as soon as the temperature inside the cable jacket fell below 120 °C after the fire fighters started to extinguish the fire.

The temporal evolution of the temperature inside the cable jacket was already presented in Kloos et al.

(2014). For comparison, Figure 2 shows the evolution of the gas temperature at a height of 5.4 m of the compartment where the fire occurred. Differences between the sequences are due to the combined influence of aleatory and epistemic uncertainties. Distinct colors used in Figure 2 make clear which sequences lead to successful fire suppression (green, red and blue curves) and which not (black curves). The fire can be successfully suppressed either by the fire patrol (green curves) or by the fire brigade (red curves).

The value estimated for the mean conditional probability that the fire patrol is able to suppress the fire within 1800s after ignition is 0.994. If the fire patrol fails to suppress the fire (this is usually the case if he/she is not able to manually activate the fixed fire extinguishing system), the mean conditional probability that the fire brigade is able to extinguish the fire is estimated to be 0.999. The fire brigade arrives at the fire compartment about 3 to 16 minutes later than the fire patrol with a probability of 0.95. The mean conditional probability that neither the fire patrol nor the fire brigade is able to suppress the fire within 1800s was calculated to be 5.97 E-06.

Figure 3 compares distributions of the maximum temperatures of the gas layer at a height of 5.4 m and of the inner jacket of the I&C cables routed below the ceiling of the compartment where the fire occurred. The two dotted curves are the conditional distributions of the maximum temperatures of the gas layer and of the inner cable jacket, if the fire is not successfully extinguished within 1800s after ignition. The distributions under the condition of successful fire suppression are shown by the solid curves. The overall unconditional distributions are not shown separately. They are nearly identical with the corresponding conditional distributions, if the fire is successfully suppressed. This is due to the very high conditional probability for

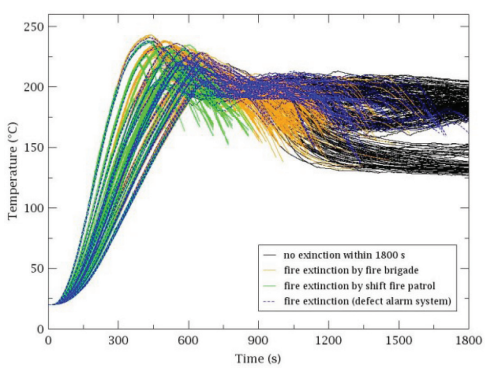

Figure 2. Temporal evolution of the gas temperature at a height of 5.4 m of the fire compartment.

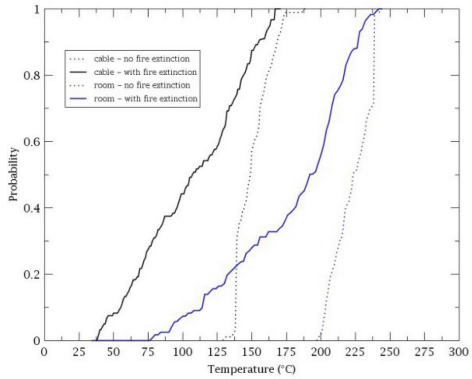

Figure 3. Conditional distributions of the maximum temperatures of the gas layer at a height of 5.4 m and of the inner jacket of I&C cables routed below the ceiling of the fire compartment.

successful fire suppression within 1800s. The mean value that fire suppression within 1800s is not successful was estimated to be 5.97 E-06.

From Figure 3, it can be concluded that the maximum gas temperature at a compartment height of 5.4 m does not exceed 230 °C, and the maximum temperature inside the cable jacket does not exceed 163 °C with a mean probability of 0.95. What is interesting and what cannot be concluded from Figure 2 is the mean probability of approx. 0.3 that the maximum gas temperature is between 75 °C and 155 °C. The corresponding range of the maximum temperature inside the cable jacket is between 30 °C and 75 °C. Reason for the low maximum temperatures is early successful fire extinguishing by the fire patrol. The mean probability that the fire patrol successfully suppresses the fire within 450 s after ignition is approx. 0.5.

Distributions referring to the time period with the temperature exceeding 160 °C inside the cable jacket are shown in Figure 4. They indicate, for instance, that this time period is not longer than approx. 113 s with a mean probability of 0.95, if the fire can be successfully suppressed. This result is also applicable to the overall unconditional distribution because of the very high conditional probability for successful fire suppression. If the fire cannot be suppressed within 1800s, the 95%-quantile of the time period with the temperature exceeding 160 °C inside the cable jacket is 192 s. The differences between the two conditional time distributions in Figure 4 seem to be not very large. Nevertheless, these differences might be relevant, if the time period with a high temperature inside the cable jacket is a relevant criterion for cable failure.

Estimates of the probability of I&C cables to be damaged by the fire were derived on the basis of

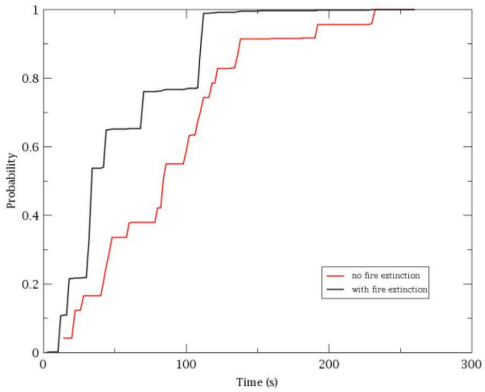

Figure 4. Conditional distributions of the time period with the temperature exceeding 160 °C inside the cable jacket.

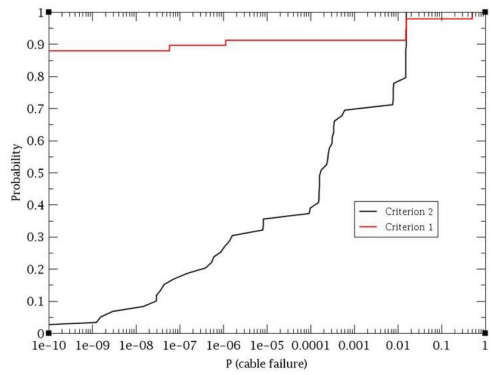

Figure 5. Epistemic uncertainty of the conditional probability of damaged I&C cables.

two different failure criteria. According to failure criterion 1, the cables were assumed to be damaged, if the temperature inside the cable jacket exceeds a critical value. With criterion 2, the failure of a cable was supposed to be determined by both a high level of the temperature inside the cable jacket and a critical time period with the inner cable temperature on a high level (see Fig. 4). Reference values and uncertainty quantifications referring to the failure temperature (criterion 1) and the critical time periods (criterion 2) are specified in Table 1. It is emphasized that the specifications are used only for demonstration purposes. They were derived from available experimental data on failure temperatures of I&C cables (Babst et al. 2011) and should be checked for real applications, in particular, with respect to the critical time periods for given temperature levels.

The mean conditional probability that an I&C cable in the fire compartment is damaged during the fire scenario was estimated to be 1.76 E-02 based on failure criterion 1 and 4.10 E-03 based on criterion 2. Figure 5 shows the epistemic uncertainty of the cable damage probability for each criterion. It can be seen that the epistemic probability distributions due to both criteria differ significantly. Since just a sample of 60 values is available from the simulations of MCDET and FDS, the one-sided upper (95%, 95%) tolerance limit was calculated to quantify the epistemic uncertainty of the cable damage probability (see section 3.2). With failure criterion 1, the (95%, 95%) tolerance limit is 0.5. The (95%, 95%) tolerance limit based on criterion 2 is 1.53 E-02.

The results clearly show the effect of different failure criteria on the calculated cable damage probability. They underline what intuitively seems to be more realistic, namely to consider both high temperature and the exposure time to high temperature as a criterion for assessing targets as deteriorated or damaged. To this purpose, corresponding data should be made available. As demonstrated, the MCDET method can use these data in order to provide corresponding risk assessments.

5 CONCLUSIONS

An exemplary IDPSA of a fire scenario was performed to demonstrate its modelling capacity and evaluation options in the frame of a probabilistic fire safety analysis. The simulations were carried out by a combination of the MCDET tool and the FDS code. This combination allowed for a quite realistic simulation of the interaction between the fire dynamics and relevant stochastic influencing factors over time.

What made the MCDET tool particularly useful for the analysis was its extra Crew Module which permitted to consider the human actions designated to be performed for fire fighting as a dynamic process. MCDET simulations performed just with the Crew Module without running FDS provided a huge amount of data for generating conditional distributions of the timings of human actions. Those distributions were used as input to the IDPSA performed with the combination of FDS and MCDET.

Besides the timings of human actions, the individual performances of all systems and components designated to be applied for fire detection, alarm, confinement and suppression were considered as subjected to aleatory uncertainty. Epistemic uncertainties were taken into account as well. Those ones which were considered as potentially important refer to parameters of the FDS code and failure criteria specified for cable targets.

From the huge amount of output data provided by the FDS-MCDET simulations, distributions referring to the temporal evolution of target temperatures could be calculated. Based on these distributions, quantifications useful for fire safety assessment were derived.

The main lesson learned from the analysis was the importance of having a well validated dynamics model when performing an IDPSA. Since a scenario-specific model was not available as input to FDS, it had to be created just in the course of the IDPSA project. The amount of work necessary to make that model applicable in combination with the MCDET tool was higher than initially expected. A lot of activities had to be spent to find a way of how to handle the limited restart capabilities of FDS in order to make the code running in combination with MCDET while simultaneously avoiding extensive calculation time and data storage.

ABSTRACT: This paper presents a holistic treatment to multiple dependent competing degradation processes, by employing the Piecewise-Deterministic Markov Process (PDMP) modeling framework. The proposed method can handle the dependencies between physics-based models, between multi-state models and between these two types of models. A Monte Carlo simulation algorithm is developed to compute the components/systems reliability. A case study on one subsystem of the Residual Heat Removal System (RHRS) of a nuclear power plant is illustrated.

1 INTRODUCTION

Physics-based models and multi-state models are widely used to model the degradation processes of components/systems. A physics-based model aims at developing an integrated mechanistic description of the component/system life consistent with the underlying real degradation mechanisms (e.g. wear, stress corrosion, shocks, cracking, fatigue, etc.) by using physics knowledge and equations (Chookah et al. 2011), whereas a multi-state model describes the degradation process in a discrete way, supported by material science knowledge (Li et al. 2012), degradation and/or failure data (Giorgio et al. 2011) from historical field collection or degradation tests.

Components/systems are often subject to multiple competing degradation processes and any of them may cause failure (Wang & Pham 2012). The dependences among these processes need to be considered under certain circumstances, e.g. when the degradation state of some components/systems can influence the degradation state dynamics or lifetime distribution of other components/systems (Rasmekomen & Parlikad 2013), or/and the various degradation processes within one component/system are physically not independent (Wang & Pham 2012). This makes the analysis and prediction of the components/systems reliability a challenging problem (Peng et al. 2010). Wang and Pham (Wang & Pham 2012) applied time-varying copulas for describing the dependencies between the degradation processes modeled by statistical distributions. Straub (Straub 2009) used a dynamic Bayesian network to represent the dependencies between degradation processes modeled by multi-state models. For some highly reliable components (e.g. pumps and valves in nuclear power plants, light-emitting diodes, etc.), degradation and/or failure data are often limited and do not allow building their lifetime distributions. Physics-based models are an alternative for characterizing the degradation processes (Fan et al. 2011).

In this work, we extend the existing modeling approaches to a more general setting, whereby the components degradations are modeled by physics-based models or multi-state models and dependencies exist among the components and the degradation processes within one component. To treat various dependencies, we employ the Piecewise-Deterministic Markov Process (PDMP) (Davis 1984, Cocozza-Thivent 2011) for components and system modeling.

The remainder of this article is organized as follows. Section 2 presents the proposed degradation model for systems with degradation dependency. Monte Carlo simulation procedures to solve the model are presented in Section 3. Section 4 presents one case study on one subsystem of a residual heat removal system (Coudray & Mattei 1984) from Électricité de France (EDF). Numerical results and analysis are presented in Section 5. Section 6 concludes the work.

2 DEGRADATION MODELING WITH DEGRADATION DEPENDENCY

Based on the available information/data about components degradations and failures, two main types of models are used to represent the degradation processes of components: physics-based model and multi-state model.

2.1 *Physics-based model*

The time-dependent evolution of continuous variables is often used to describe the degradation processes of components. The continuous variables

$$\vec{X}(t) = \begin{pmatrix} \vec{x}(t) \\ \vec{y}(t) \end{pmatrix} \tag{1}$$

may represent: 1. degradation variables $\vec{x}(t)$ such as crack length (Keedy & Feng 2012), which describe the components degradation condition; 2. physical variables $\vec{y}(t)$ such as operation time, velocity and force (Daigle & Goebel 2011a), which influence the evolution of degradation variables. Physics equations, mathematically written as differential equations (which are often a set of first-order ordinary differential equations), are then used to describe the variation of $\vec{x}(t)$ in time, considering external influencing factors $\vec{\theta}_L$, such as temperature and pressure (Jacobsen 2006), whose behaviors are not modeled by the physics equations.

We assume that there are M components in the system, $\vec{L} = (L_1, L_2, \ldots, L_M)$, whose degradation processes are modeled by physics-based models. Let

$$\overrightarrow{X_{L_m}}(t) = \left(\overrightarrow{x_{L_m}}(t), \overrightarrow{y_{L_m}}(t)\right) \in \mathbb{R}^{d_{Lm}}, m = 1, 2, \ldots, M \tag{2}$$

denote the vector containing all d_{Lm} time-dependent variables for component L_m; their evolutions are described by the following first-order ordinary differential equations:

$$\overrightarrow{\dot{X}_{L_m}}(t) = \overrightarrow{f_{L_m}}\left(\overrightarrow{X_{L_m}}(t), t \mid \overrightarrow{a_{L_m}}\right) \tag{3}$$

where $\overrightarrow{a_{L_m}}$ represents the parameters in the physics equations, including external influencing factors $\overrightarrow{\theta_{L_m}}$.

To consider the dependences between the components, let

$$\vec{X}(t) = \left(\overrightarrow{X_{L_1}}(t), \overrightarrow{X_{L_2}}(t), \ldots, \overrightarrow{X_{L_m}}(t)\right) \in \mathbb{R}^{d_L} = \mathbb{R}^{d_{L1} + d_{L2} + \cdots + d_{LM}} \tag{4}$$

denote the overall degradation condition of all the M components. We extend the set of differential equations in (3) by including the variables of the other $M - 1$ components:

$$\overrightarrow{\dot{X}_{L_m}}(t) = \overrightarrow{f_{L_m}}\left(\vec{X}(t), t \mid \overrightarrow{a_{L_m}}, \overrightarrow{b_{L_m}}\right) \tag{5}$$

where $\overrightarrow{b_{L_m}}$ is the vector of parameters characterizing the influence of the other components on the degradation processes of component L_m.

For any component L_m, the degradation variables

$$\overrightarrow{x_{L_m}}(t) = \left(x^1_{L_m}(t), x^2_{L_m}(t), \ldots, x^{d^1_{L_m}}_{L_m}(t)\right) \tag{6}$$

have the critical values (thresholds):

$$\overrightarrow{x_{L_m}}^*(t) = \left(x^{1\,*}_{L_m}, x^{2\,*}_{L_m}, \ldots, x^{d^1_{L_m}\,*}_{L_m}\right) \tag{7}$$

Component L_m fails when one of the degradation variables exceeds the corresponding critical value. The failure time t_f of component L_m is defined as follows:

$$t_f = Min_{\arg t} \left[x^1_{L_m}(t) = x^{1\,*}_{L_m}, \ldots, x^{d^1_{L_m}}_{L_m}(t) = x^{d^1_{L_m}\,*}_{L_m}\right] \tag{8}$$

2.2 *Multi-state model*

Under the situation that there is not any available physics-based model for the degradation processes of the components, a multi-state model (Lisnianski & Levitin 2003) can be built using historical degradation and/or failure data of components. Markov processes (Giorgio et al. 2011) and semi-Markov processes (Chryssaphinou et al. 2011) are widely used in practice as multi-state models, where the degradation conditions of the components are represented by a limited number of states describing the degradation severity. The transition rates (estimated from historical data) between two different degradation states are used to describe the speed of reaching another degradation state.

We assume that there are N components in the system, $\vec{K} = (K_1, K_2, \ldots, K_N)$, whose degradation processes are modeled by multi-state models. The component K_n has $d_{Kn} + 1$ states, $S_{Kn} = \{0, 1, \ldots, d_{Kn}\}$, ranging from perfect functioning state 'd_{kn}' to complete failure state '0'. The component is partially functioning in all generic intermediate states.

To consider the dependences between the components and the influencing factors, let

$$\vec{Y}(t) = (Y_{K_1}(t), Y_{K_2}(t), \ldots, Y_{K_N}(t)) \in S = S_{K_1} \times S_{K_2} \ldots \times S_{K_N} \tag{9}$$

denote the overall degradation condition of all the N components, where $Y_{Kn}(t)$, $n = 1, 2, \ldots, N$, indicates the degradation state of component K_n at time t. Let $\{\vec{Y}_k, T_k\} \in S \times \mathbb{R}^+$, $k \in \mathbb{N}$ denote the degradation processes of the N components, where $\vec{Y}_k$ denotes the state of the N components after k transitions (a transition occurs as long as any one of the N components changes its state) and T_k denotes the time of arrival at state $\vec{Y}_k$. Then, the state of the N components at time t can be defined as follows:

$$\vec{Y}(t) = \vec{Y}_k, \forall t \in [T_k, T_{k+1}[\tag{10}$$

We assume that $\{\vec{Y}_k, T_k\}$, $k \geq 0$ follows a Markov renewal process which generalizes the notion of Markov jump process. Then, the probability that the N components will step to state $\vec{J}$ from state $\vec{i}$ in the time interval $[T_n, T_n + \Delta t]$, given $\{\vec{Y}_k, T_k\}$, $k \leq n$, is defined as follows:

$$\begin{aligned} &P[\vec{Y}_{n+1} = \vec{J}, T_{n+1} \in [T_n, T_n + \Delta t] \,|\, \{\vec{Y}_k, T_k\}_{k \leq n}, \vec{\theta}_K] \\ &= P[\vec{Y}_{n+1} = \vec{J}, T_{n+1} \in [T_n, T_n + \Delta t] \,|\, \vec{Y}_n = \vec{i}, \vec{\theta}_K] \\ &\forall n \geq 0, \Delta t \geq 0, \vec{i}, \vec{J} \in S, \vec{i} \neq \vec{J} \end{aligned} \tag{11}$$

where $\vec{\theta}_K$ represents the external influencing factors. The process $\vec{Y}(t)$ is a continuous time Markov process if the holding time at any state $\vec{i} \in S$ is exponentially distributed according to state $\vec{i}$ and the system total running time t, denoting by the transition rate $\lambda_{\vec{i}}(t, \vec{\theta}_K)$. Otherwise, it is a semi-Markov process. The system fails if one of the N components reaches its complete failure state. The reliability of such system at time t can be calculated as follows:

$$\begin{aligned} R(t) = P[&Y_{K_1}(s) \neq d_{K_1}, Y_{K_2}(s) \neq d_{K_2}, \ldots, Y_{K_N}(s) \\ &\neq d_{K_N} \forall s \leq t] \end{aligned} \tag{12}$$

2.3 *PDMP for systems with degradation dependency*

In this section, we consider that the system contains M components described by physics-based models and N components described by multi-state models. The interdependencies between the two groups of components are taken into account. We assume that the degradation levels of the components in the first group may influence the transition times and transition directions of the degradation processes of the second group, and the degradation states of the second group may influence the evolution trajectories of the continuous variables in the first group. We employ PDMP to model this type of interdependence. Let

$$\vec{Z}(t) = \begin{pmatrix} \vec{X}_{L_1}(t) \\ \vec{X}_{L_2}(t) \\ \vdots \\ \vec{X}_{L_M}(t) \\ \vec{Y}(t) \end{pmatrix} = \begin{pmatrix} \vec{X}(t) \\ \vec{Y}(t) \end{pmatrix} \in E = \mathbb{R}^{d_L} \times S \tag{13}$$

represent the degradation condition of the whole system defined on E, a hybrid space of $\mathbb{R}^{d_L}$ and S. $(\vec{Z}_t = \vec{Z}(t))$ $t \geq 0$ is a stochastic process with values in the probability space (E, ε) where ε is a σ-algebra of E (Cocozza-Thivent 2011). Let

$$\vec{Z}_k = \vec{Z}(T_k) = \begin{pmatrix} \vec{X}(T_k) \\ \vec{Y}_k \end{pmatrix} \in E, k \in \mathbb{N} \tag{14}$$

denote the degradation state of the whole system at the transition time T_k of the process $\vec{Y}(t)$. $\{\vec{Z}_k, T_k\}$, $k \geq 0$ is then a Markov renewal process defined on the space $E \times \mathbb{R}^+$, since the probability that the whole system will step to state $\vec{J}'$ from state $\vec{i}'$ in the time interval $[T_n, T_n + \Delta t]$, given $\{\vec{Z}_k, T_k\}$, $k \leq n$ is as follows:

$$\begin{aligned} &P\left[\vec{Z}_{n+1} = \vec{J}', T_{n+1} \in [T_n, T_n + \Delta t] \,\middle|\, \left\{\vec{Z}_k, T_k\right\}_{k \leq n}, \vec{\theta}_K\right] \\ &= P\left[\vec{Z}_{n+1} = \vec{J}', T_{n+1} \in [T_n, T_n + \Delta t] \,\middle|\, \vec{Z}_n = \vec{i}', \vec{\theta}_K\right] \\ &\forall n \geq 0, \vec{i}', \vec{J}' \in E, \vec{i}' \neq \vec{J}' \end{aligned} \tag{15}$$

where the transition probability depends also on the variables of the M components from the first group. The evolution of the whole system between two consequent jumps of process $\vec{Z}(t)$, when $t \in [T_k, T_{k+1}[$, $k \in \mathbb{N}$ is defined as follows:

$$\dot{\vec{Z}}(t) = \begin{pmatrix} \dot{\vec{X}}_{L_1}(t) \\ \dot{\vec{X}}_{L_2}(t) \\ \vdots \\ \dot{\vec{X}}_{L_M}(t) \\ \vec{0} \end{pmatrix} = \begin{pmatrix} \vec{f}_{L_1}^{\vec{Y}_k}\left(\vec{X}(t), t \,|\, a_{L_1}, b_{L_1},\right) \\ \vec{f}_{L_2}^{\vec{Y}_k}\left(\vec{X}(t), t \,|\, a_{L_2}, b_{L_2},\right) \\ \vdots \\ \vec{f}_{L_M}^{\vec{Y}_k}\left(\vec{X}(t), t \,|\, a_{L_M}, b_{L_M},\right) \\ \vec{0} \end{pmatrix} \tag{16}$$

where $\vec{f}_{L_M}^{\vec{Y}_k}$, $n = 1, 2, \ldots, M$ are the physics equations, given the influence of the degradation state $\vec{Y}_k$ of the N components from the second group. The process $\vec{Z}(t)$ that takes values in E is a Piecewise-Deterministic Process (PDP) since it can be written as follows [Lorton et al. 2013]:

$$\vec{Z}(t) = \varphi(\vec{Z}_k, t - T_k), \quad for \quad t \in [T_k, T_{k+1}], \forall k \in \mathbb{N} \tag{17}$$

and $\overline{Z}(t)$ is a PDMP on the condition that φ satisfies the following [Cocozza-Thivent. 2011]:

$$\varphi(\vec{y},t+s)=\varphi(\varphi(\vec{y},t),s),\forall t,s\geq 0,\vec{y}\in E \tag{18}$$

This is especially true in our case, as φ is the solution of a first-order ordinary differential equations system [Lorton et al. 2013].

Let $\mathcal{F}=\mathcal{F}_{\overline{X}}\times\mathcal{F}_{\overline{Y}}\subsetneq E$ denote the space of the failure states of $\vec{Z}(t)$, where $\mathcal{F}_{\overline{X}}$ denotes the sub-space of the failure states for $\vec{X}(t)$ and $\mathcal{F}_{\overline{Y}}$ denote the sub-space of the failure states for $\vec{Y}(t)$; then, the reliability of the system at time t can be calculated as follows:

$$R(t)=P[\vec{Z}(s)\notin\mathcal{F},\forall s\leq t] \tag{19}$$

3 RELIABILITY ESTIMATION

Analytically solving the PDMP is a difficult task due to the complex behavior of the system (Marseguerra & Zio 1996), which contains the stochasticities in the components modeled by multi-state models and the time-dependent evolutions of the components modeled by physics-based models. On the other hand, Monte Carlo simulation methods are suited for the reliability estimation of the system.

3.1 *The simulation procedure*

The procedure of the MC simulation is represented as follows:

Set N_{max} (the maximum number of replications) and $k=0$ (index of replication)
Set $k'=0$ (number of trials that end in the failure state)
While $k<N_{max}$
  Initialize the system by setting $\overrightarrow{Z'}$ (initial state), and the time $T=0$ (initial system time)
  Set $t'=0$ (state holding time)
  While $T<T_{miss}$
    Sample a t' through the probability density function
    Sample an arrival state $\overrightarrow{Y'}$ for stochastic process $\vec{Y}(t)$ from all the possible states through the conditional probability function
    Set $T=T+t'$
    Calculate $\vec{X}(T)$ by using the physics equations (16)
    Set

$$\overrightarrow{Z'}=\begin{pmatrix}\overrightarrow{X}(T)\\ \overrightarrow{Y'}\end{pmatrix}$$

    If $T\leq T_{miss}$
      Calculate all the extreme values $(\overline{X}_n^0, n\in\mathbb{N})$ of $\overline{X}(t)$ in the interval $[T-t', T]$ by using the physics equation (16)
      If $(\exists m\in\mathbb{N}, \overline{X}_m^o\in\mathcal{F}_X)\vee(\overrightarrow{Z'}\in\mathcal{F})$
        Set $k'=k'+1$
        Break
      End if
    Else (when $T>T_{miss}$)
      Calculate all the extreme values $(\overline{X}_n^o, n\in\mathbb{N})$ of $\overline{X}(t)$ in the interval $[T-t', T_{miss}]$ by using the physics equations (16)
      If $\exists m\in\mathbb{N}, \overline{X}_m^o\in\mathcal{F}_X$
        Set $k'=k'+1$
        Break
      End if
    End if
  End While
  Set $k=k+1$
End While

Since the first derivative of $\overline{X}(t)$ on the interval $[T_k, T_{k+1}]$, $k\in\mathbb{N}$ exists, $\overline{X}(t)$ is continuous on such interval. If $\overline{X}(t)$ is monotonous in the interval $[T_k, T_{k+1}]$, the extreme values of $\overline{X}(t)$ are reached at the boundary points of the interval. Otherwise, the extreme values of $\overline{X}(t)$ can be obtained by comparing all the local extreme values found by Fermat theorem (Bronshtein et al. 1985). To calculate the value of $\overline{X}(t)$, Runge-Kutta methods can be applied for the numerical solution of the ordinary differential equations (Hairer et al. 1993, Hairer et al. 1996).

The estimated component reliability at time T_{miss} can be obtained by

$$\hat{R}(T_{miss})=1-k'/N_{max} \tag{20}$$

where k' represents the number of trials that end in the failure state of the system, and the sample variance is (Lewis & Böhm 1984):

$$var_{\hat{R}(T_{miss})}=\hat{R}(T_{miss})(1-\hat{R}(T_{miss}))/(N_{max}-1) \tag{21}$$

4 ILLUSTRATIVE CASE

In this section, one important subsystem of a residual heat removal system (Coudray & Mattei 1984) has been considered to illustrate the proposed method. This subsystem consists of a pneumatic valve and a centrifugal pump, which are used in conjunction in a variety of domains for fluid delivery. The degradation model of the pump is modified from the one originally supplied by EDF, while that of the valve is an existent physics-based model presented in (Daigle & Goebel 2010, Lorton

et al. 2013). Two types of dependence have been considered, as follows:

1. Common degradation cause: the abrasive particles in the fluid which can aggravate the degradation processes of both components (Wierman et al. 2007).
2. Degradation dependency: the degradation of the pump can lead it to vibrate (Zhang et al. 2006), which will, in turn, cause the vibration of the valve and therefore aggravate the degradation process of the latter (Moussou et al. 2001).

The common degradation cause and degradation dependency leads us to resort to our proposed method to assess the reliability of this two-component series system.

4.1 *Pneumatic valve*

The pneumatic valve refers to a normally-closed and gas-actuated valve with a linear cylinder actuator which has been studied by Daigle and Goebel (Daigle & Goebel 2010) and Lorton et al. (Lorton et al. 2013) by using physics-based modeling. A simplified scheme of the valve is shown in Figure 1.

The valve contains a top chamber (above the piston) and a bottom chamber (below the piston), which are respectively connected to a top pneumatic port and a bottom pneumatic port. The position of the piston (between fully closed position '0' and fully open position 'L_s') is controlled by filling or evacuating the chambers by regulating the pressure of the pneumatic ports. A return spring is linked with the piston to ensure the closure of the valve when pressure is lost due to the spring force.

One of the most common degradation mechanisms of the valve is the internal leak at the seal surrounding the piston (Lorton et al. 2013). Owing to the internal leak of the piston, the pneumatic gas can flow between the two chambers therefore influencing the response time and the behavior of the valve. The degradation variable of the valve is then the equivalent orifice area of the internal leak of the piston, denoted by $L(t)$. At the initial stage, the valve is set to the fully closed position.

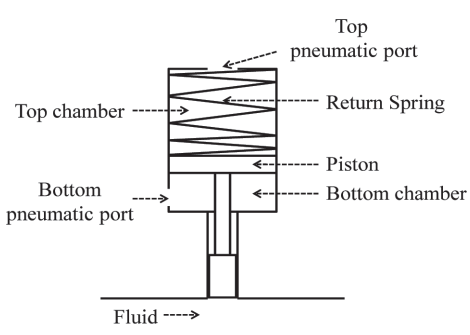

Figure 1. Simplified scheme of the pneumatic valve (Daigle & Goebel 2010).

The degradation process of the valve at time t is described by the following vector:

$$\overrightarrow{X_v}(t) = \begin{pmatrix} L(t) \\ x(t) \\ v(t) \\ m_t(t) \\ m_b(t) \\ t \end{pmatrix} \tag{22}$$

where $x(t)$ is the position of the valve, $v(t)$ is the velocity of the valve, $m_t(t)$ is the mass of the gas in the top chamber, $m_b(t)$ is the mass of the gas in the bottom chamber and t is the running time of the valve. The derivatives of these variables are represented by:

$$\overrightarrow{\dot{X}_v}(t) = \begin{pmatrix} \dot{L}(t) \\ v(t) \\ a(t) \\ f_t(t) \\ f_b(t) \\ 1 \end{pmatrix} \tag{23}$$

where $a(t)$ is the valve acceleration, $f_t(t)$ and $f_b(t)$ are the mass flows going into the top and bottom chambers, respectively. The development of the internal leak is defined as follows:

$$\dot{L}(t) = w(1+\alpha_v)rv(t)^2 \tag{24}$$

where $v(t)$ is the velocity of the valve, w is the wear coefficient without the consideration of abrasive particles in the fluid, and α_v is a constant to characterize the relative increment of the developing rate of the internal leak influenced by the abrasive particles in the fluid. All the other physics equations of the valve and the parameter definitions and values can be founded in (Daigle & Goebel 2010).

The critical value L^* for the internal leak of the piston $L(t)$ is defined as the value above which ($L(0) > L^*$) the valve cannot reach the fully open position within the 15 s time limit after an opening command is executed at time $t = 0$s. The size of the internal leak is assumed to be constant during the opening procedure ($\dot{L}(t) = 0$, $0 \le t \le 15$) (Lorton et al. 2013) to obtain a conservative critical value

that $L^* = 3.20e-6$ m^2 in this case. The behavior of the valve within 15 s with different values of $L(0)$ is shown in Figure 2.

4.2 *Centrifugal pump*

We assume that the degradation process of the centrifugal pump is modeled by a continuous-time homogeneous Markov chain with constant transition rates as shown in Figure 3.

The perfect functioning state is denoted with the label '3' and '0' is the label of the complete failure state. At the initial stage, the valve is set to the perfect functioning state. The vibration of the pump caused by degradation is classified into two levels: 'smooth' and 'rough' (Vlok et al. 2002) corresponding to the degradation states '2' and '1', respectively. Let $Y_p(t)$ denote the degradation state of the pump at time t and $S_p = \{0, 1, 2, 3\}$ denote the degradation states set. The formulations of transition rates are assumed as follows:

$$\begin{cases} \lambda_{32} = \lambda'_{32}(1+\alpha_{p32}) \\ \lambda_{21} = \lambda'_{21}(1+\alpha_{p21}) \\ \lambda_{10} = \lambda'_{10}(1+\alpha_{p10}) \end{cases} \tag{25}$$

where λ'_{32}, λ'_{21} and λ'_{10} are the original transition rates without the consideration of abrasive particles in the fluid. The constants α_{p32}, α_{p21} and αp_{10} represent the relative increments of transition rates caused by the abrasive particles in the fluid.

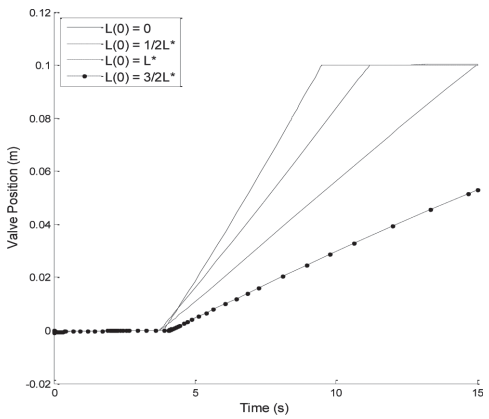

Figure 2. Valve behavior with different sizes of the internal leak.

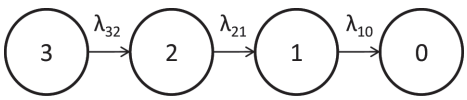

Figure 3. Degradation process of the pump.

4.3 *PDMP for the degradation processes of the system*

The degradation processes of the whole system are modeled by PDMP as follows:

$$\vec{Z}(t) = \begin{pmatrix} \overrightarrow{X_v}(t) \\ Y_p(t) \end{pmatrix} = \begin{pmatrix} L(t) \\ x(t) \\ v(t) \\ m_t(t) \\ m_b(t) \\ t \\ Y_p(t) \end{pmatrix} \in R^6 \times S_p \tag{26}$$

and

$$\dot{\vec{Z}}(t) = \begin{pmatrix} \overrightarrow{\dot{X}_v}(t) \\ 0 \end{pmatrix} = \begin{pmatrix} \dot{L}'(t, Y_p(t)) \\ v(t) \\ a(t) \\ f_t(t) \\ f_b(t) \\ 1 \\ 0 \end{pmatrix} \tag{27}$$

where $\dot{L}'(t, Y_p(t))$ is the derivative of the internal leak of the valve with the consideration of the degradation dependency between the valve and the pump while the development of the internal leak of the valve is dependent on the degradation state of the pump, we have

$$\dot{L}'(t, Y_p(t)) = w(1+\alpha_v)(1+\beta_{Y_p(t)})rv(t)^2 \tag{28}$$

where $\beta_{Yp}(t)$ is the relative increment of the developing rate of the internal leak caused by the vibration of the pump (if we ignore the degradation dependency, then $\beta_{Yp}(t) = 0$). The times between two consequent jumps of PDMP follow the exponential distribution with constant transition rates determined by equation (25). The space of the failure states of $\vec{Z}(t)$ is $\mathcal{F} = \mathcal{F}_{\overrightarrow{Xv}} \times \mathcal{F}_{Yp} = [L^*, +\infty] \times \{0\}$.

5 RESULTS AND ANALYSIS

Due to the high reliability of the components, it is typically computationally expensive to simulate the failures or certain degradations. The values of the parameters of the pump and of the parameters

characterizing the degradation dependency are shown in Table 1. We set them in a way to simulate the system functioning under an accelerated aging condition.

At the initial stage, the two components are both in perfect state and the valve is in the fully closed position. The command of the valve is a 30 s-periodic-signal and the valve is commanded to open in the first half-period and to close in the second half. The pump is functioning until it reaches the failure state '0'.

A Monte Carlo simulation over a time horizon of $T_{miss} = 700$ s is run $N_{max} = 10^5$ times. In Figure 4, we compare the reliability of the whole system

Table 1. The values of the parameters of the pump and of the parameters characterizing the degradation dependency.

Parameter	Value
w	5e-9 m/N
α_v	20%
λ'_{32}	5.00e-3/s
λ'_{21}	5.00e-3/s
λ'_{10}	5.00e-3/s
α_{p32}	20%
α_{p21}	20%
α_{p10}	20%
β_3	0
β_2	10%
β_1	20%
β_0	0

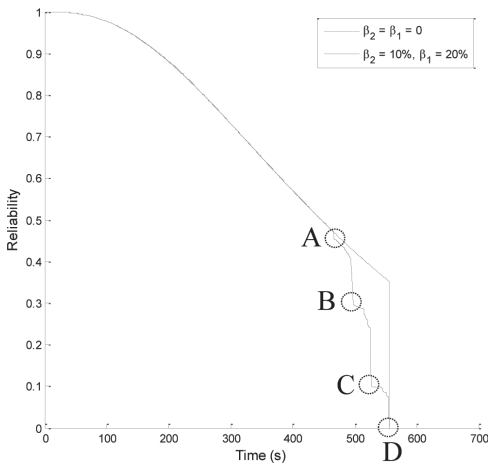

Figure 4. System reliability with common degradation cause and w/o degradation dependency.

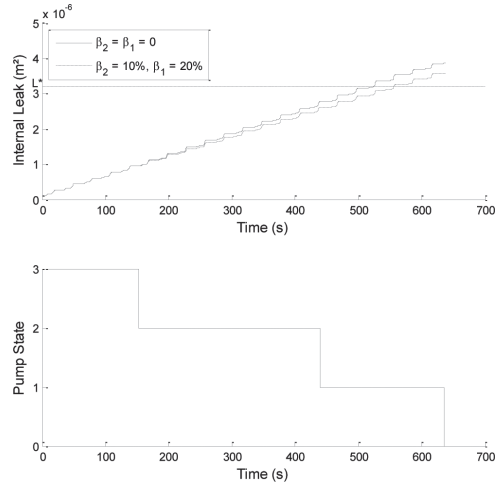

Figure 5. Development of the internal leak of the valve in one simulation trial with common degradation cause and w/o degradation dependency.

with common degradation cause and degradation dependency to that with only common degradation cause. From the Figure, we can see that before 465.67 s (point A) the two curves coincide and the system reliability is equal to the reliability of the pump. After that time, the valve begins to fail in some simulation trials, which corresponds to the situation when the pump jumps to state '1' very quickly and stays there until the valve fails. The system reliability, then, experiences three sharp decreases at around 497.39 s (point B), 526.77 s (point C) and 556.45 s (point D) respectively, and the system is definitely failed afterwards. The longest failure time of the valve is at point D, corresponding to the situation when the pump stays in the initial state '1' from the beginning until the failure of the valve.

The development of the internal leak of the valve during one simulation trial is presented in Figure 5, where the pump is seen to reach state '2' at 152.83 s, state '1' at 439.92 s and failure state '0' at 635.78 s. The valve fails at 525.03 s which is 31.28 s earlier than the failure time without degradation dependency.

6 CONCLUSION

We employ the PDMP approach to develop a new method for modeling multiple dependent competing degradation processes. The significance of the proposed method lies in its capability to describe the degradation dependency between physics-based models, between multi-state models and between

the two types of models. A Monte Carlo simulation algorithm is designed to compute the components/systems reliability. The results of a illustrative case study have shown the effectiveness and capabilities of our modeling and simulation framework.

Development of a new algorithm for optimal multi-level redundancy allocation

M.A. Farsi
Astronautic Research Institute, Iranian Space Research Center, Tehran, Iran

ABSTRACT: Nowadays, the Redundancy Allocation Problem (RAP) is increasingly becoming an important tool in the initial stages of or prior to planning, designing, and control of systems. The Multi-Level Redundancy Allocation Problem (MLRAP) is an extension of the traditional RAP such that all available items for redundancy (system, module and component) can be simultaneously chosen. Although, RAP has been considered by several researchers, attention to MLRAP is little. In this paper, we focus on this subject and develop a new method to solve MLRAP. In this paper, the total cost is assumed as the most important constraint. A new meta-heuristic optimization algorithm, called Hybrid Bat Algorithm (HBA), to solve constrained optimization problem (MLRAP) is developed. This method based on bat behavior to detect a prey. To demonstrate this method capability, a multi level system redundancy allocation is described. This method results are comprised with HGA, MA and Two Dimensional Arrays encoding and Hybrid Genetic Algorithm (TDA-HGA). For this system, optimal results are same as TDA-HGA and better than HGA and MA in all cases. Thus, proposed method is a simple and powerful tool to determine the optimal multi-level redundancy allocation.

1 INTRODUCTION

One of the most important steps to design a new system is reliability modeling and prediction. In this step, usually reliability allocation is done to achieve a desired reliability value. The typical reliability allocation problem may be stated as maximization of system reliability subject to some budget constraint, or minimization of system cost subject to the attainment of some specified level of system reliability. Nowadays, the Redundancy Allocation Problem (RAP) is increasingly becoming an important tool in the initial stages of or prior to achieve a desired reliability value and predefined performance. The industrial systems include several modules and subsystems. Each subsystem is divided to several units and finally several components (parts) are used to build a unit. The RAP is one of the most important reliability optimization problems with regards to improving the reliability of real-world systems in the design phase. The most optimal redundancy allocation methods try to solve a problem in system level and other items are ignored. In real-world systems (for example, communication systems, computing systems, control systems, and critical power systems), the influence of subsystems and components on system reliability cannot be ignored, therefore all available items for redundancy (system, module and component) should be considered. The Multi-Level Redundancy Allocation Problem (MLRAP) is an extension of the traditional RAP such that all available items for redundancy can be simultaneously chosen. Although, RAP has been considered by several researchers [1–4], attention to MLRAP is little.

The RAP has been proved to be an NP-hard problem. Thus, how to find effective approaches to it is a hot topic. There are many approaches proposed to cope with RAPs, including exact methods, max-min approaches, dynamic programming, heuristic methods, and meta-heuristic algorithms. Among them, meta-heuristic methods, especially Genetic Algorithms (GAs), are widely, successfully utilized due to their robustness, and strong ability of global search, even though sometimes they are time-consuming. From these reviews, it can be observed that, in spite of its importance in the real world, the MLRAP has rarely been investigated.

G. Levitin (2003) proposed an algorithm based on a GA framework with a universal generating function technique for the system survivability evaluation. This method aims to solve multi-level protection cost minimization problems subject to survivability constraints. Later, Yun and Kim (2004) proposed a restricted multi-level redundancy allocation model, and addressed a tri-level RAP using a customized GA. However, the customized GA employs a fixed-length vector to represent the solution to the MLRAP, and thus redundancy is

required to be allocated to only one unit in a direct line, which is defined as a set of units from the system-level unit down to one component unit. Though, both introduced methods were designed to cope with MLRAPs, they were based on strong assumptions or rigid rules that do not accord with reality. Recently, Kumar et al. (2008 and 2009) reformulated MLRAPs so that redundancy allocation can be carried out at any level of a multi-level system. In this work, a solution to an MLRAP was represented by a hierarchical structure, and a simple GA was adopted to tackle the MLRAP involved. He et al. (2013) proposed Two Dimensional Arrays encoding and Hybrid Genetic Algorithm (TDA-HGA). Their method is very useful to determine the best structure of system. Although these researches have been shown to be effective via empirical studies, its effectiveness on the MLRAP can still be improved significantly.

In this paper, we proposed a new heuristic method (hybrid Bat Algorithm) to solve MLRAP. This method use bat movement principle to find prey. This method is simple and very fast to find the best result. This method described in the next section.

2 BAT ALGORITHM

Bats are fascinating animals. Microbats are a type of bats that they use a type of sonar, called echolocation, to detect prey, avoid obstacles, and locate their roosting crevices in the dark. If we idealize some of the echolocation characteristics of microbats, we can develop various bat inspired algorithms or Bat Algorithms (BA). In echolocation, each pulse only lasts a few thousandths of a second (up to about 8–10 ms). However, it has a constant frequency which is usually in the region of 25–150 kHz corresponding to the wavelengths of 2–14 mm. In BA, the echolocation characteristics of microbats can be idealized as the following rules (Yang, Xin-She et al. 2011 and 2012):

1. All bats use echolocation to sense distance, and they also "know" the difference between food/prey and background barriers in some magical way;
2. Bats randomly fly with velocity v_i at position x_i with a fixed frequency f_{min}, varying wavelength and loudness A_0 to search for prey. They can automatically adjust the frequency (or wavelength) of their emitted pulses and adjust the rate of pulse emission r ϵ [0,1], depending on the proximity of their target;
3. Although the loudness can vary in many ways, it is assumed that the loudness varies from a large (positive) A_0 to a minimum constant value A_{min}. A_0 in this research (optimal reliability allocation) is 1 and A_{min} is zero. The basic steps of BA can be summarized as the pseudo code shown in Figure 1.

For each bat (i), its position x_i and velocity v_i in a N-dimensional search space should be specified. x_i and v_i should be subsequently updated during the iterations, since bat should be moved to target (prey). The new solutions x_i^t and velocities v_i^t at time step t are determined by:

$$f_i = f_{\min} + \left(f_{\max-} - f_{\min} \right) \beta \tag{1}$$

$$v_i^t = v_i^{t-1} + \left(x_i^{t-1} - x^* \right) f_i \tag{2}$$

$$x_i^t = x_i^{t-1} + v_i^t \tag{3}$$

where β in the range of [0,1] is a random vector drawn from a uniform distribution. Here, x^* is the current global best location (solution), which is located after comparing all the solutions among all the n bats. As the product $\left(x_i^{t-1} - x^* \right) f_i$ is the velocity increment. For implementation, $f_{min} = 0$ and $f_{max} = 1.0$ are used in this research. Initially, each bat is randomly assigned a frequency that is drawn uniformly from [0, 1].

For the local search part, once a solution is selected among the current best solutions, a new solution for each bat is generated locally using a local random walk:

Bat Algorithm

Objective function f(x), x=(x_1,x_2,…,x_n)
Initialize the bat population x_i and v_i
Define plus frequency f_i at x_i
Initialize pulse rates r_i and the loudness A_i
While (t<max number of iterations)
Generate new solution by adjusting frequency,
And updating velocities and locations/solutions (eq. 2 to 4)
If rand > r_i
Select a solution among the best solutions randomly
Generate a local solution around the selected best solution by a local random walk
End if
If (rand<A_i and f(x_i)<f(x*))
Accept the new solutions
Increase r_i and decrease A_i
End if
Rank the bats at each iteration and find their current best x*
End while
Post process results and visualization

Figure 1. Pseudo code of BA.

$$x_{new} = x_{old} + \varepsilon A^t \quad (4)$$

where, the random number ε is drawn from [–1, 1], while A^t is the average loudness of all the bats at this time step.

The update of the velocities and positions of bats has some similarities to the procedure in the standard particle swarm optimization (Kennedy et al. 1995) as f_i essentially controls the pace and range of the movement of the swarming particles. To a degree, BA can be considered as a balanced combination of the standard particle swarm optimization and the intensive local search controlled by the loudness and pulse rate.

Furthermore, the loudness A_i and the rate r_i of pulse emission have to be updated accordingly as the iterations proceed. Once a bat has found its prey, the loudness usually decreases and the rate of pulse emission increases. The loudness can be chosen as any value of convenience. In this paper, $A_0 = 1$ and $A_{min} = 0$ is used. Assuming $A_{min} = 0$ means that a bat has just found the prey and temporarily stop emitting any sound, we have:

$$A_i^{t+1} = \delta A_i^t, \quad r_i^{t+1} = r_i^0 \left[1 - \exp(-\gamma t) \right] \quad (5)$$

where δ and γ are constants. In fact, δ is similar to the cooling factor of a cooling schedule in the simulated annealing (kirkatrick et al., 1983). For any $\delta > 0$ and $\gamma < 1$:

$$A_i^t \to 0, \quad r_i^t \to r_i^0, \quad as \quad t \to \infty \quad (6)$$

According to our study and simulation results, $\delta = \gamma =$ 06–0.9 can be used for reliability allocation problem modeling.

2.1 *Modified bat algorithm*

Original bat algorithm has been proposed for continues variable. In this paper we develop this algorithm for discrete variable. Therefore, this algorithm should be modified. In proposed algorithm, the random walking and random fly are used and the next location (solution) is determined according to predefined data (or available values). In this condition, the closest state is selected as the next location for each bat. For example, a bat is characterized with A, B and C parameters, in random fly; all these parameters are calculated using equations 3 and 4. Then, distances between this new value and predefined values are compared. The closest value to determined value is selected as the next value. After this step, this new location is checked by problem constraint such as cost. If this location can satisfy constraint, this value is accepted. Some bats are motivated to better search and increase convergence speed to find the best solution. In each iteration, some of bat position and location is changed randomly. We call it motivation. In this process, some bats (5% of bats) are selected according to their position (out of the best zone particle). Then, their positions are changed randomly. Thus, modified and proposed method in this paper, it is called Hybrid Bat Algorithm (HBA). This algorithm is applied via a developed Visual Basic.Net Program.

Problem modeling and handling of constraints to MLRAP is explained in the following sections.

3 PROBLEM DESCRIPTIONS

In this section, we will first present the background description of MLRAP and then provide the formulation of this problem. To avoid confusion, the differences between the three most commonly used words in this paper are first presented below:

– Component: the elementary part of a system, at the lowest level.
– Unit: any part of a system either refers to the system, subsystems, or the components.

Also, the MLRAP investigated in this paper is formulated based on multi-level serial systems with the following assumptions.

- *Assumption 1*: The redundancy can be allocated to the units on any level.
- *Assumption 2*: The quality (reliability, cost) of each component is predefined. If one unit is not a component, its reliability, and cost are calculated based on its child units.

3.1 *Multi level serial system*

A multilevel serial system is defined as a hierarchical system with the entire system at the topmost level, the subsystems at lower levels, and the components at the lowest level. The system, subsystems, and components are all referred to as units. Child units of one unit refer to a fixed number of serial units at its immediately lower level while parent unit refer to the unit at the immediately higher level. Figure 2 shows an example of multilevel serial systems. As Figure 2 shows, U1 is a system unit with three serial child units U11; U12 and U13. U11 is the parent unit of three units: U111; U112 and U113. This structure applies to all of the units except for the component units, which have no child units.

3.2 *Multilevel series redundancy allocation model*

Redundancy could be configured to any unit from system level to component level. Once the

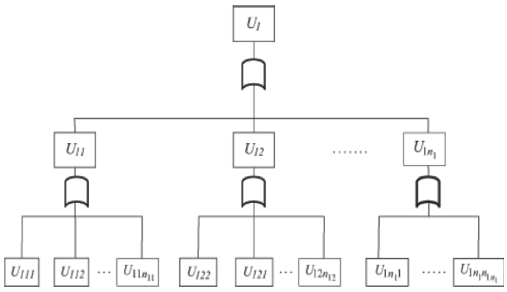

Figure 2. A general multi level series system.

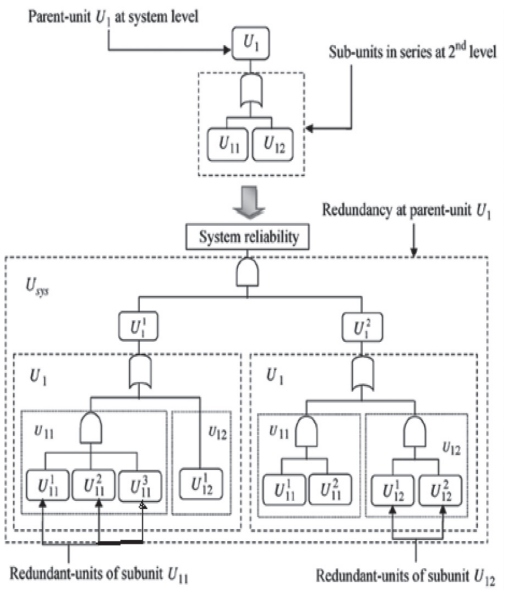

Figure 3. An example of redundancy allocation in bi-level series configuration.

redundancy is allocated to units at parent level, there will be multiple child units at lower levels. Figure 3 illustrates an example of multilevel redundancy allocation model to a bi-level serial system. Figure 3 consists of one system unit and two component units. The redundancy of unit U_1 is 2, so there are two groups of child units under U_1^1 and U_1^2 respectively. Under parent unit U_1^1 and U_1^2, the redundancy for unit U_{11} and U_{12} is (3,1) and (2,2) respectively. Example in Figure 3 indicates that it might be difficult to represent the redundancy information in one multilevel system, because the overall number of the replica of one unit in the child level is determined by the redundancy of its parent unit and the redundancy of itself. For example, the redundancy of unit U_1 is 2, so there are two groups of child units U_{11}. The redundancy of child units U_{11} belonging to different parent unit U_1^1 and U_1^2 is 3 and 2 respectively. So the overall number of replica of U_{11} is 3 + 2 = 5.

3.3 *Redundancy allocation optimization problem*

In a multilevel serial system after redundancy allocation, the reliability of the higher level units could be obtained from the reliability of all its child units including all replicas. In general, a given unit U_i in the multilevel system has n_i subunits, U_{i1}; U_{i2}; . . .; U_{in_i}, which must be connected either in series or in parallel. When x_i is the number of U_i redundant units, there are $n_i x_i$ sub-units in the level below U_i. A unit in the jth redundant unit of the mth sub-unit of U_i is denoted $U_{i,m}^j$. Thus, the reliability R_i of unit U_i for multilevel series and parallel configurations can be calculated using the following equations:

$$R_i = \prod_{m}^{n_i}\left[1 - \prod_{j}^{x_i}\left(1 - R_{i,m}^{j}\right)\right] \tag{7}$$

$$R_i = 1 - \prod_{m}^{n_i}\left[\prod_{j}^{x_i}\left(1 - R_{i,m}^{j}\right)\right] \tag{8}$$

where $R_{i,m}^j$ are reliability values of the sub-unit $U_{i,m}^j$. Each $R_{i,m}^j$ value is calculated using the above equation at the level immediately below the unit, and these calculations are recursively iterated to the level just above the very lowest hierarchical level.

Using Eq. (7, 8), the reliability of the system could be calculated. For example, the reliability of the system shown in Figure 2 is calculated as Eq. (9).

$$R = 1 - \left(1 - \left[\left(1 - \prod_{j=1}^{3}\left(1 - R_{11}^{j}\right)\right)\left(R_{12}^{1}\right)\right]\right) \times \left(1 - \left[\left(1 - \prod_{j=1}^{2}\left(1 - R_{11}^{j}\right)\right)\left(1 - \prod_{j=1}^{2}\left(1 - R_{12}^{j}\right)\right)\right]\right) \tag{9}$$

In a multi lenvel system, the cost can be calculated as the sum of its child units and some additional cost. Wang et al. (2010) sugessted following Eq. for the system cost calculation. This equation has been used by the most of research to cost modeling, we also use this equation.

$$C_i = \sum_{m=1}^{n_1}\left(\prod_{j=1}^{x_{1m}} C_{im}^{j} + \left(\lambda_{im}\right)^{x_{im}}\right) \tag{10}$$

As shown by Eq. (10), the cost C_i of unit U_i may be calculated from $C_{i,m}^j$, the cost of jth replica of mth child unit and λ_{im}, the additional cost of mth child unit when configuring redundancy. x_{im} also denotes the number of redundant units in the mth

serial child unit and n_i denotes the number of child units under U_i. Wang et al. (2010) specified that to reflect the hierarchical structure, additional cost is only introduced in the component level. In our model, we do not specify it but allow different value of kim for each unit. We only need to set $\lambda_{im} = 0$ for all the units except for the component units to meet the assumptions made by Wang et al. (2010).

For the system illustrated in Figure 2, using this equation, the system cost is calculated as Eq. 11.

$$C_{sys} = \left[\left(\sum_{j=1}^{3} C_{11}^{j} + (\lambda_{11})^3\right) + (C_{12} + \lambda_{12})\right] + \left[\left(\sum_{j=1}^{2} C_{11}^{j} + (\lambda_{11})^2\right) + \left(\sum_{j=1}^{2} C_{12}^{j} + (\lambda_{12})^2\right)\right] + (\lambda_1)^2 \tag{11}$$

MLRAP is an NP-hard problem. To find optimal state, we use a hybrid BA. In real-world problems, the several constraints such as cost, volume, mass, and etc impress the optimal solution. Cost is an important constraint and often, its influence is more than other constraints. Thus, the typical MLRAP may be stated as maximization of system reliability subject to some cost constraint. In this paper, MLRP is formulated as shown by Eq. 6.

4 EXPERIMENTAL STUDY

In this section, the performance of our TDA-HGA is evaluated on two MLRAP examples. The results are compared with MA (Wang et al., 2010) and IMA (He et al., 2012), which are the most recent algorithms in the literature and outperform other algorithms such as HGA (Kumar et al., 2008). The structures of the multilevel serial systems are illustrated in Figure 4 This system comprises three levels.

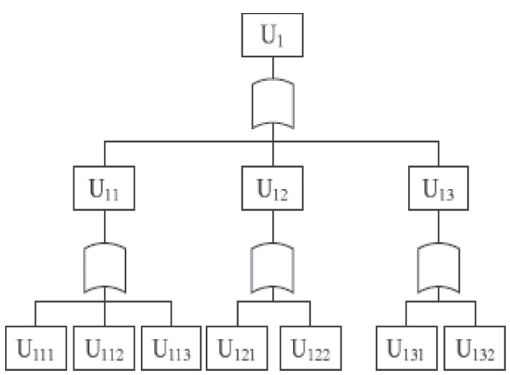

Figure 4. Experimental study.

The MLRAP for this system has been used by He et al. (2013), Wang et al. (2010), and Kumar et al. (2008) to evaluate the performance of TDA-HGA, HGA, MA. To make a fair comparison between other algorithms and HBA, the control parameters set for MA by Wang et al. (2010) were also used in experiments for HBA.

Specifically, the population size was set to 100, the maximum generation was 500, the crossover rate was set to 0.8, and the mutation rate was set to 0.1. In our algorithm, the local search rate was set to 0.2. For this system, the redundancy that can be allocated to a single unit was set between 1 and 5. The input parameters for the units in the two systems are shown in Table 1.

In this experiment, we aim to evaluate the convergence behavior of our HBA on a case study. The same group of input parameters used by Wang et al. (2010) was also used here. The cost constraint value was set to 300, and the parameters of the components of the system were given in Table 1. The best solution obtained in each generation was recorded, and the reliability of the corresponding system was calculated. The convergence curves of HBA shows that this method is very fast to find the best result. The detailed comparison of HBA and TDA-HGA, MA and HGA will be given in next sub-sections.

4.1 *Performance over different constraint values*

The previous experiment only provides a case study on which the HBA outperformed, and further comparisons between the four methods subject to different cost constraint values were carried out in this experiment. Seven cost constraint values were sampled between the intervals 150–340. All the system parameters were kept the same as the previous sub-section.

For each cost constraint value, HBA, TDA-HGA, HGA and MA were carried for 10 times. Table 2 summarizes the results of this experiment including the best reliability and cost obtained. For each cost constraint value, the reliability that is significantly better than the others is highlighted in boldface. From Table 2, we can observe that the proposed

Table 1. Input parameters.

Table 2. MLRAP results.

Cost con.	Best solutions							
	MA		HGA		TDA-HGA		HBA	
	Reli	Cost	Reli	Cost	Reli	Cost	Reli	Cost
150	0.8005	141	0.764	148	0.8057	140	0.8057	140
180	0.8781	179	0.8617	173	0.8826	179	0.8826	179
200	0.9032	198	0.8899	198	0.9220	200	0.9220	200
250	0.9628	249	0.947	250	0.9689	249	0.9689	249
280	0.9729	278	0.9647	279	0.9853	280	0.9853	280
300	0.9849	299	0.9730	292	0.9884	299	0.9884	299
340	0.993	338	0.9835	337	0.9943	340	0.9943	340

HBA outperformed original MA and HGA on all the cases, in terms of both the quality of the best solutions, and overall performance. In particular, the best solutions found by our HBA are always better than those found by MA and HGA. HBA performed similar to TDA-HGA on best reliability in all of the test cases. TDA-HGA is a method that it is improved in several version, but our algorithm is a first version of HBA, therefore, we hope, the capability of this method is improved by developing of the proposed algorithm in next, specially, we focus on local search method in the next work.

5 CONCLUSION

In this paper, the RAP on multi-level systems is investigated. A novel Hybrid Bat algorithm (HBA) is proposed to solve this problem. This algorithm is based on micro bat fly to find prey. This method is improved and modified in this paper to determine the best result in a MLRAP. Fundamental of this method is described and capability of this method id demonstrated using a practical problem. This problem has been solved using Genetic Algorithm and Memetic Algorithm, our study shows that the proposed method is very fast and powerful to solve MLRAP. The best solutions found by our HBA are always better than those found by MA and HGA. HBA performed similar to TDA-HGA on best reliability in all of the test cases. Therefore, we hope the capability of this method is improved by developing of the proposed algorithm in next, especially; we focus on local search method in the next work.

Aircraft crew escape system assistant

N. Grzesik & R. Czapla
Aviation Faculty, Polish Air Force Academy, Dęblin, Poland

ABSTRACT: In this publication the authors presented a proposal to use fuzzy expert systems in crew escape onboard pilot decision making systems. The subject of research is to ensure the ability of those systems to adapt to changing environmental conditions and, in consequence, their reliable operation (support and ensure pilots' safety. The authors use fuzzy logic to present advanced work in this field. The development of fuzzy expert aircraft onboard pilot decision making system assistant projects used by a pilot in emergency situations is referred to in the study. One of the projects was presented in the publication. It has been developed on the basis of Matlab Fuzzy Logic Toolbox and Simulink software. Complexity of the problem cause imposed restrictions. This publication is an integral part of the author's scientific researches.

1 INTRODUCTION

In this publication the authors presented a proposal to use fuzzy expert pilot decision making system assistant for determining the ejection seats mode in emergency situation during air task.

The subject of research is to ensure their ability to adapt the crew escape system to changing environmental and aircraft conditions, reliable operation and pilots' safety improvements. Advanced work in this area the authors present using of fuzzy logic.

Described the occurrences and imprecise defined terms, using classical mathematical apparatus, based on the methods required to be strictly limits or decisions such as binary logic, in which the elements belong to the set or not, Grzesik (2012); Piegat (1999); Yager & Filev (1995). Natural language operates inaccurate and quality concepts, such as "flight speed is low" or "flight altitude is high". Those concepts are very difficult to translate into machine language without losing of their nature. The values of quality, like a description of the world through words, are more natural to man. For example, determine the aircraft altitude with the words: too small, quite low, medium or too high is more natural and simpler than the estimation in meters or feet. Qualitative description is less precise and depends on the person describing it. Hence the proposal to use fuzzy expert system, where experts determine the criteria and principles of operation of these systems (base of inference rules). Proper selection of the experts is one of the most important procedures in the design process of such systems, Żurek & Grzesik (2014). The experts could be not only pilots (very experienced—a lot of flight hours on under consideration type of aircraft) but also engineers (specialized in under consideration type of aircraft ejection seats and crew escape systems), Smykla & Adamski & Burek & Walczak (2006).

Conducting extensive analysis and preliminary studies and very wide range of applications of fuzzy logic (also in safety and reliability systems), Grzesik (2006); Kacprzyk & Yager (1985); Mulawka (1996); Piegat (1999); Yager (2004); Zio (2009); Żurek & Grzesik (2014), the authors found that its properties can also be used in aircraft onboard safety systems like crew escape. For example in military aircraft equipped with ejection seats. Most of used ejection seats work in several modes. In emergency situation pilot must choose proper work mode for safe escape. All modes depend on aircraft flight parameters like flight altitude and velocity (sometimes position of an aircraft in the air is also crucial). Flight parameters data have ranges for emergency systems work. The ranges of work are divided into sets of data which determine the mode of emergency systems work. Example is presented on Figure 1.

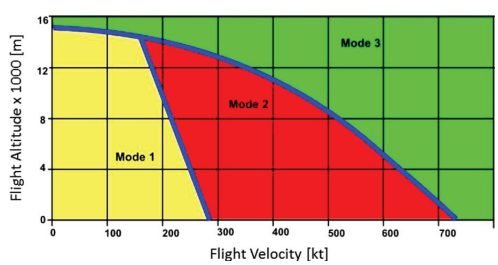

Figure 1. Ejection seat work modes, Lockheed Martin (2006).

Those sets and ranges are characteristic for fuzzy logic and provide opportunity to use the data in fuzzy inference systems. According to those facts authors made an effort to develop of fuzzy expert aircraft crew escape onboard pilot decision making system assistant projects which can be used by pilot (or work autonomously—in case of emergency situations concerns pilots unconsciousness) during the air task. One of the projects was presented in the publication. It has been developed based on Matlab Fuzzy Logic Toolbox and Simulink software, Mrozek & Mrozek (1998, 2001).

Complexity of the problem cause imposed restrictions. This publication is an integral part of the author's scientific researches.

2 PROJECT OF FUZZY EXPERT AIRCRAFT ONBOARD PILOT DECISION MAKING SYSTEM

Project is Mamdani type non-adaptive fuzzy inference system with two inputs and one output (MISO—many inputs—single output), Wrona (2013). The project is shown on Figure 2.

Speed in knots („SPEED (kt)") and pressure height in feet („ALTITUDE (ft)") are input variables. Output variable is required ejection mode („MODE").

Ejection mode selection analysis provided information about number of fuzzy sets in specific variables. „SPEED (kt)" input should consist of three fuzzy sets (membership functions—small, moderate and high). „ALTITUDE (ft)" input should consist of two fuzzy sets (membership functions—small and high). "MODE" output variable should consist of three fuzzy sets assigned to specific ejection modes (Mode 1, Mode 2 and Mode 3). However, the system work precision was unsatisfactory. To improve it more fuzzy sets in inputs should be added. Changes are presented on Figures 3–4.

Rules base consist of sixteen „If-Then" rules (Fig. 6). Premises (speed and altitude) are connected with „and" operator. Conclusions describe specific ejection modes.

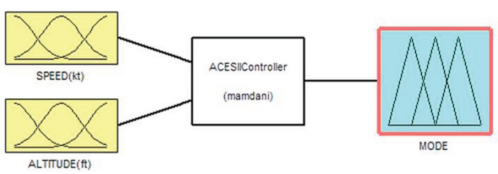

Figure 2. Fuzzy expert aircraft onboard pilot decision making system for ACES II ejection seats mode selection.

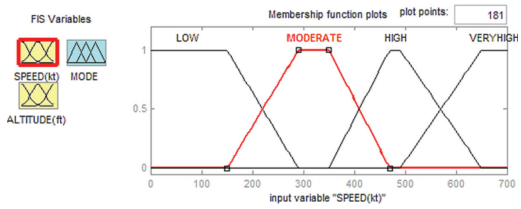

Figure 3. Fuzzy sets, shapes and ranges of membership function for SPEED input variable.

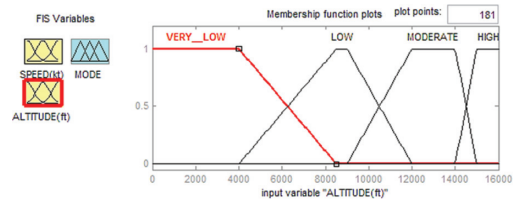

Figure 4. Fuzzy sets and shapes and ranges of membership function for ALTITUDE input variable.

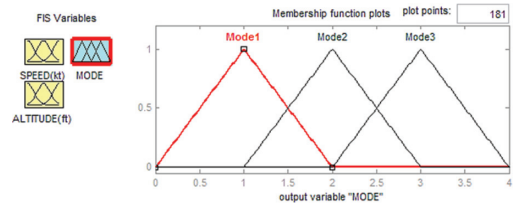

Figure 5. Fuzzy sets and shapes and ranges of membership function for MODE output variable.

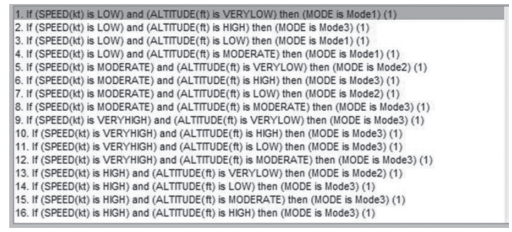

Figure 6. „If-Then" rules base.

Implication was made with „PROD" operator and aggregation with „MAX" operator.

Center of gravity method (*„Centroid"* name is used in Matlab software) was used in output variables defuzzification process (because all active rules are used in defuzzification process). It improved model sensitivity on input parameters change. Disadvantage of center of gravity method is large amount of calculation (because irregular shaped

surface, like Gausses' functions, surface integration difficulty). This disadvantage was eliminated by using polygonal membership functions.

Examples of membership functions and output variables defuzzification for specific speed and altitude data were presented on Figure 7.

For aircraft speed 100 kt, flight altitude 3000 ft, aircraft crew escape system assistant calculated that optimal ejection mode is 1. For aircraft speed 350 kt, flight altitude 8000 ft, aircraft crew escape system assistant calculated that optimal ejection mode is 2. And finally, for aircraft speed 600 kt, flight altitude 12000 ft, aircraft crew escape system assistant calculated that optimal ejection mode is 3.

Examples of control surface for specific speed and altitude data were presented on Figure 8.

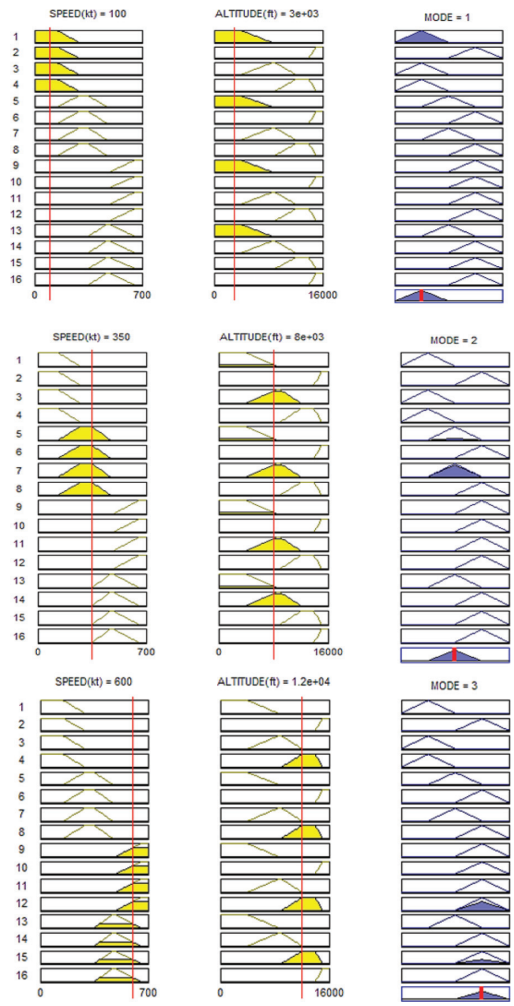

Figure 7. Rules base and defuzzification for specific speed and altitude data.

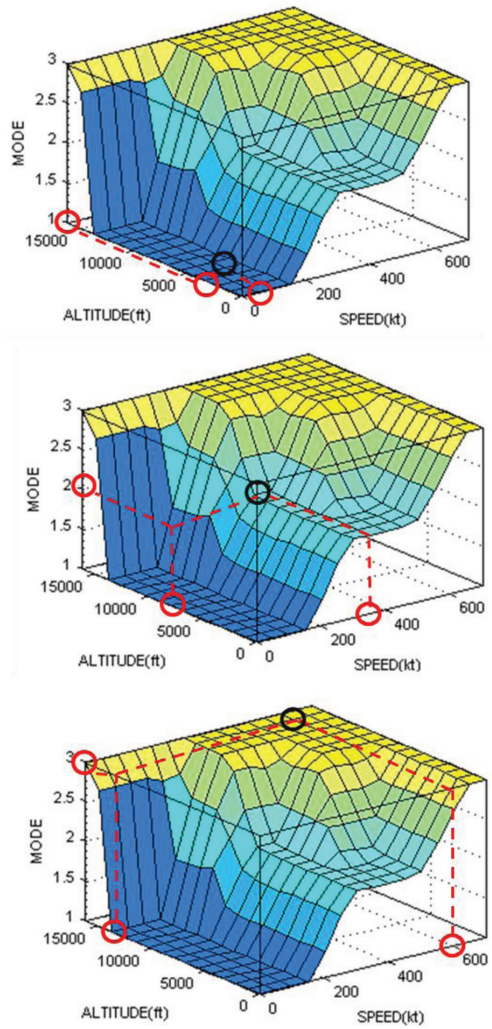

Figure 8. Control surface for specific speed and altitude data.

3 FUZZY EXPERT AIRCRAFT ONBOARD PILOT DECISION MAKING SYSTEM EXPERIMENTAL WORK VERIFICATION

Experimental system work verification is presented in Table 1. Table includes aircraft speed, altitude and ejection modes calculated by fuzzy expert inference system, Wrona (2013).

For fuzzy expert inference system and aircraft onboard crew escape data comparison, selected samples points were placed on ejection modes diagram (Fig. 9). The samples for ejection mode number 1 are yellow, for mode 2—red and finally

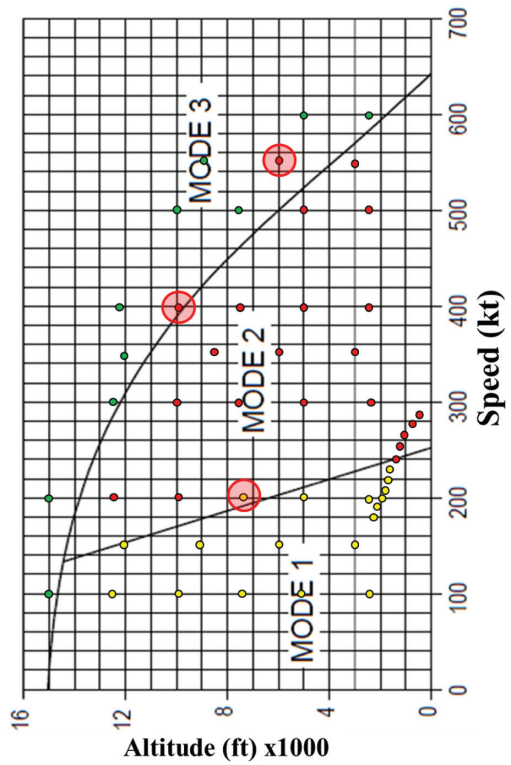

Figure 9. Experimental research results.

mode 3—green. Additionally, wrong ejection modes selected by the fuzzy expert system were marked as red circles (3 of 50 samples had wrong ejection modes selected). Due to real work of crew escape system, the mistakes of data values are insignificant. Small aircraft speed increasing solves the problem and fuzzy expert inference system work properly.

That is why further research and analysis of the system are indispensable (like: changing shapes of membership functions could eliminate the mistakes).

4 FUZZY EXPERT AIRCRAFT ONBOARD PILOT DECISION MAKING SYSTEM SIMULATION WORK VERIFICATION

Simulink software was used to verify of fuzzy expert aircraft onboard pilot decision making system work. Simulation data came from F-16 training manuals and emergency situation conducted by F-16 pilot on aircraft simulator. Designed in Simulink software ACES II fuzzy controller consists of two kinds of blocks: Signal Builder and Fuzzy Logic

Controller, Mrozek & Mrozek (1998, 2001). Signal builders (one for aircraft speed and one for aircraft altitude) present a full range of speed and altitude changes during selected air task. Data from fuzzy expert aircraft onboard pilot decision making system designed in Matlab Fuzzy Logic Toolbox are transferred to Simulink Fuzzy Logic Controller. In addition, to observe a calculation in the real time, Scope was connected to each block (to inputs and to the output).

To verify of proper system work one of emergency situation was considered. It was aircraft engine malfunction (shortly after takeoff). For that kind of F-16 malfunction pilot emergency procedure is as follows:

– pull up the aircraft to increase altitude (speed is decreased);
– drop all stores (inventory);
– eject from the aircraft.

According to simulation assumptions engine malfunctions occurs at 68 feet of altitude with 285 kt of speed (aircraft landing gear retracted). Pilot needs to confirm the malfunction. Then aircraft altitude required to be increased (to 2300 feet) speed is decreased (to 180 kt), stores dropped and at the end pilot ejects. All procedure lasts approximately 10 seconds. During that time 11 samples were received.

Emergency situation simulation input data for the samples are presented in Table 2. Inputs and output diagrams are presented on Figures 11–13.

If the emergency ejection procedure started before 6-th second after malfunction occurs,

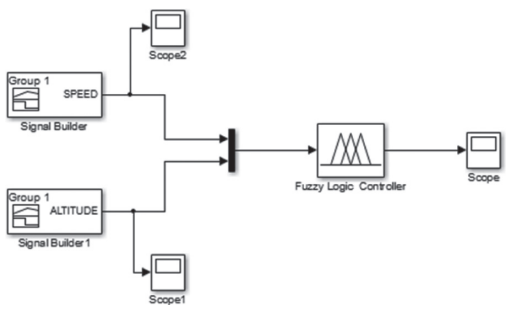

Figure 10. Project of fuzzy expert aircraft onboard pilot decision making system in Simulink software.

Table 2. Emergency situation simulation input data for the samples.

Number of samples	Speed [kt]	Altitude [ft]
1	285	680
2	275	850
3	265	1025
4	255	1200
5	245	1370
6	232	1550
7	220	1730
8	210	1870
9	200	2015
10	190	2160
11	180	2300

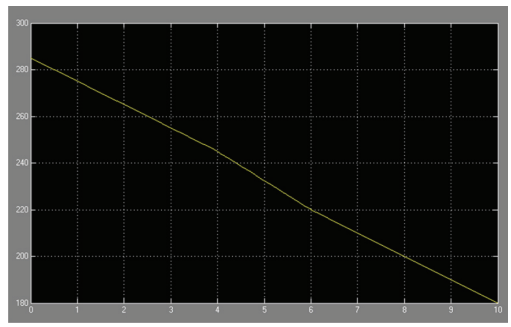

Figure 11. Speed diagram.

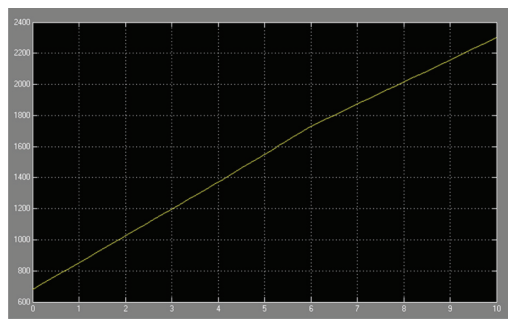

Figure 12. Altitude diagram.

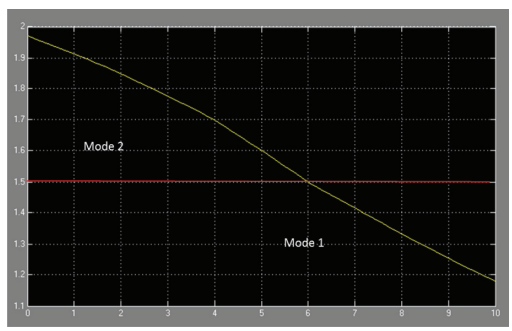

Figure 13. Mode diagram.

the fuzzy expert system would select ejection mode 2. While if the emergency ejection procedure started after 6-th second when malfunction occurs, the fuzzy expert system would select ejection mode 1.

Comparing simulation results with F-16 crew escape system, authors concluded that wrong ejection mode was selected by fuzzy expert system only once, but error value was negligible. That is why authors recognize fuzzy expert system work accurately and correctly at the system design level.

5 CONCLUSIONS

According to research results authors concluded that make full use of non-adaptive Fuzzy expert systems in emergency situations concerning use of ejection seats is possible. It is advisable to continue the research because fuzzy system work error range was minor. What is a more, dynamic change of flight parameters and measurement systems inaccuracies can be liable for errors occurrence. Nevertheless fuzzy expert aircraft onboard pilot decision making system work correctly and use it in emergency situation is possible and reasonable.

It is real time working system with high level of accuracy of ejection mode selection. However, increase a number of fuzzy sets was necessary to reach the required precision system work level. Increasing the number of fuzzy sets can lead to designing difficulties (mathematical calculations enlargement).

What is more, because of the heuristic nature of the fuzzy logic methodology there is no guarantee that the project will operationally well perform. One of the most important aspects therefore is testing and validation of the system performance. Full testing is crucial factor for those kinds of safety systems.

As a result authors propose take under consideration to use in future projects Takagi-Sugeno models or neutral network.

Use of fuzzy expert systems in aircraft emergency situation (ejection) is pioneering and never found before in the world literature.

A fuzzy system for evaluation of baggage screening devices at an airport

J. Skorupski
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

P. Uchroński
Upper Silesian Aviation Group, Poland

ABSTRACT: An airport is a complex engineering system; it is composed of many elements interconnected with numerous internal relations with a strongly pronounced role of the human factor. One of the specific tasks carried out by the Airport Managing Entity (AME) is to configure the Airport Security System (ApSS) so that to attain the expected level of confidence in the airport safety and security. This task consists in selection of infrastructure, technical equipment, allocation of personnel and financial means that are necessary to perform all functions of the ApSS. One of the aspects of the configuration of the ApSS is the allocation of available x-ray baggage screening devices searching for items prohibited for transportation. To make this allocation, we need to know how effective these devices are (in terms of detecting prohibited items). This assessment is dependent on several factors which are treated as linguistic variables and are input to fuzzy inference system: the ability to detect explosives (linguistic variable *Detectability*), the number of detection lines (linguistic variable *Number of detection lines*), the effectiveness of the TIP (Threat Image Projection) system (linguistic variable *TIP evaluation*) and the age of the machine (linguistic variable *Device age*). Some of these elements are difficult to objective assessment, as they are heavily dependent on the human factor or the information is uncertain and incomplete. So fuzzy ApSS analysis is proposed. The output from the fuzzy inference system is linguistic variable *Device evaluation*. The meaning of this variable is the ability to protect the aircraft against prohibited items. The proposed new method of assessing the airport baggage screening system involves the construction of a hierarchical fuzzy inference system. Such a system has been built with the use of the compositional fuzzy inference rule. The usefulness of the method is exemplified for Katowice-Pyrzowice international airport, for which an assessment of devices has been performed. The results show that not only allocation of specific devices for specific control points is important for the security of passengers. Also important are the locally accepted principles of their work, which so far are not specified by international regulations. This applies for instance to the selection of the number (frequency) of TIP images. Preliminary analyzes show that the proposed approach can be effective as part of an expert system for supporting the airport operator in configuring ApSS.

1 INTRODUCTION

An airport consists of numerous elements which are linked with various internal relations with a strong impact of the human factor. It is therefore a complicated socio-technical system. The correct operation of an airport requires providing the appropriate level of security by the Airport Managing Entity (AME). One of the aspects involved in providing security is protection against the acts of unlawful interference (ICAO 2010). The research related to providing the continuity of operation of an airport conducted so far focused mainly on the problem of operational availability i.e. the reliability of various technical components of the airport system considered together with their structural reliability as well as the external factors e.g. weather conditions (Kozłowski 2004). Among papers that are strictly related to the problems of airport security it is worth to note the work of (Gkritza et al. 2006), which indicates the need to provide the proper security level at an airport but at the same time minimize the nuisance caused by the security control process to the passengers. The new way of meeting the requirements for security control were suggested in (de Lange et al. 2013), where considerable savings were found by using the "virtual queues".

Airport Managing Entity (AME) is responsible for keeping the airport in operation availability. One of the specific tasks performed by the AME is configuring the Airport Security System (ApSS) so that the required level of trustworthiness regarding its safety is reached (Kirschenbaum et al. 2012). This

task requires the selection of infrastructure, technical equipment and personnel allocation (Soukour et al. 2013) and assigning the financial means required for the implementation of all ApSS functions. Configuring the ApSS in a rational manner requires the knowledge on how the different elements of the complicated structure affect the final security level of an airport (Gerstenfeld & Berger 2011).

Review of literature indicates that there are no effective methods for the evaluation of airport security. With this in mind, we suggest a mathematical model based on the theory of fuzzy reasoning whose output would be an evaluation of the airport security system as a factor for providing the continuity of operation of an airport. This evaluation will be expressed as linguistic variable value and the method used to obtain it will involve all the required factors related to airport security: screening baggage, control of passengers, perimeter security and security culture. It will also include the impact of the environment in the form of the organisational and operational characteristics.

In this work we present the idea of evaluation the entire ApSS, however, we will concentrate on more detailed description of the local model for evaluating of the x-ray equipment used for scanning of the checked and hand luggage. The developed model, together with its computerised implementation in the SciLab environment may be treated as an expert system supporting the decision making process for persons who are in practice responsible for selecting infrastructure components, technical equipment and personnel required by the airport security system.

2 AIRPORT SECURITY SYSTEM

An Airport Security System (ApSS) is used to prevent acts of unlawful interference. This notion is defined in (ICAO 2010) as an unlawful and purposeful act involving e.g.:

- destruction of an aircraft or causing damage to it,
- placing objects, devices or substances on-board an aircraft which may cause the destruction of the aircraft,
- hijacking an aircraft,
- destruction of ground or on board equipment or causing interference in their operation,
- providing false information which causes hazard for people and their belongings in aviation communication,
- destruction or severely damaging devices at an airport.

A practical method of achieving the goals of the ApSS is to perform a security control of the persons and their baggage before they are boarded on an aircraft. On the other hand it also involves the so called perimeter security i.e. the prevention of unlawful access to the airport area.

There are numerous structures related to security control which are discussed in detail in (Uchroński 2011). The security control is performed at the Security Control Points (SCP) and is a complex process that involves numerous devices whose effectiveness and pace of operation has a big impact on the ability of the ApSS to perform its functions (Hainen et al. 2013). The following devices are used:

- metal detector gates,
- manual metal detectors,
- x-ray baggage screening equipment used for detecting explosives and other prohibited items (Wetter 2013),
- radioactive material detectors.

This paper analyses the effectiveness of equipment (x-ray devices) used to detect prohibited items in registered and hand baggage.

3 MODEL OF THE AIRPORT SECURITY SYSTEM

Four basic factors which influence the airport security level may be defined. These are: the baggage screening system, the passenger control system, external security and security culture. A general schematic of relations between these factors is presented in Figure 1.

Each of the elements (rectangles) presented in Figure 1 is a complex structure. The internal relations are highly dependent on the human factor and other factors which are not subject to precise description. As a result, they will be treated as representations of fuzzy hierarchical local models with numerous inputs. Establishing the values of linguistic variables *Baggage Screening*, *Person Control*, *External Security* and *Security Culture* requires a further development of the diagram. Due to the limited volume of the paper it is impossible to present the entire diagram structure. In order to illustrate the essence of the method, Section 5 discusses a local model used for the evaluation of devices used for registered and hand baggage screening.

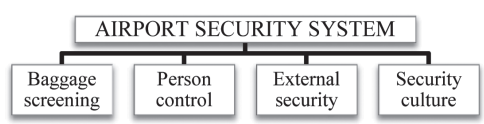

Figure 1. Diagram of a fuzzy model of main factors influencing the security level at an airport.

4 CONCEPT FOR THE EVALUATION OF AN AIRPORT SECURITY SYSTEM

This paper suggests an evaluation of an airport security system based on a hierarchical model of fuzzy reasoning. This approach results from the fact that the tested system is heavily influenced by the human factor and other elements, which are not subject to unequivocal and precise description. It is impossible to detect the functional relationships between the various factors which influence the effectiveness of the security system and an evaluation of the security level. In such cases it is required to use expert opinions. As we have to deal with expert opinions, it is a known fact that very often they are formulated in a descriptive and an imprecise way. We must therefore view the decision making problem in context of uncertainty related to decision making (Dubois & Prade 1992). All this locates the decision making problem in an area described by e.g. the theory of fuzzy sets or rough sets (Greco et al. 2001).

This paper focuses on fuzzy reasoning. A similar approach, although related to the evaluation of an aircrew status, was presented in the work by (Skorupski & Wiktorowski 2013). This paper is a follow up to the work by (Skorupski & Uchroński 2014), where the general structure of interaction model in the airport security model is discussed in detail.

A fuzzy set A will denote a set of

$$A = \left\{ \left(x, \mu_A(x)\right) : x \in X, \mu_A(x) \in [0,1] \right\} \tag{1}$$

where μ_A is the membership function of this set and X is a set of considerations.

A linguistic variable is a variable whose values are words or sentences in a natural or artificial language. These words or sentences will be called the linguistic values of a linguistic variable.

Our models will most often assume that the membership functions of linguistic variable values have a trapezoidal shape and that a typical membership function with the parameters (a,b,c,d) is as follows:

$$\mu_i(x;a,b,c,d) = \begin{cases} 0, & x \le a \\ \dfrac{x-a}{b-a}, & a < x \le b \\ 1, & b < x \le c \\ \dfrac{d-x}{d-c}, & c < x \le d \\ 0, & x > d \end{cases} \tag{2}$$

Within the scope of the reasoning process we will use the input value fuzzification block, reasoning block using a number of rules and the defuzzification block. The rule sets will be created using experts' opinions, in particular those presented by persons responsible for organising a Security Management Systems (SeMS) at airports. Such set may contain classic non-fuzzy implications as well as fuzzy implications. In the second case we will use the so called compositional method of reasoning introduced by Zadeh (1973) which uses a generalised "modus ponens" fuzzy reasoning rule. This results in the following reasoning scheme (Kacprzyk 1986), where P, P', Q, Q', S are fuzzy relations.

$$\begin{aligned} &I : P \Rightarrow Q \\ &P : P' \\ &C : P' \circ (P \Rightarrow Q) \end{aligned} \tag{3}$$

where I denotes implication, P—premise, C—conclusion, while "$\circ$" is a max-min composition, defined on the sets X, Y, Z, whose result for fuzzy relations $A \subset X \times Y$ and $B \subset Y \times Z$ is a fuzzy relation $A \circ B \subset X \times Z$ with a membership function:

$$\mu_{A \circ B}(x,z) = \vee_{y \in Y} (\mu_A(x,y) \wedge \mu_B(y,z)), \quad \forall x \in X, \forall z \in Z \tag{4}$$

Relations P and P' are often constructed on the basis of the AND operator, as in Tables 1 and 2. We will use implications in the form of fuzzy conditional sentences (rules) i.e.

$$IF\ P\ THEN\ Q\ ELSE\ S \tag{5}$$

The conditional sentence is equal to a certain fuzzy relation $R \subset X \times Y$; we will use the max-min rule that was selected from the numerous definitions of such fuzzy relations found in the literature

$$R = (P \times Q) + (\sim P \times S) \tag{6}$$

which is expressed in the form of the following membership function

$$\mu_R(x,z) = \left(\mu_P(x) \wedge \mu_Q(y)\right) \vee \left(\left(1 - \mu_P(x)\right) \wedge \mu_S(y)\right), \quad \forall x \in X, \forall y \in Y \tag{7}$$

If we write down the reasoning scheme (3) in the form of a fuzzy reasoning system we will reach the following form

$$\begin{aligned} &I : IF\ P\ THEN\ Q \\ &P : x\ IS\ P' \\ &C : y\ IS\ Q' \end{aligned} \tag{8}$$

where $P, P' \subset X$, $Q, Q' \subset Y$

R292	TIP_Evaluation IS very_high AND Number_of_detection_lines IS medium AND Device_age IS very_low	Device_evaluation IS high

The result of reasoning Q' is specified according to the compositional rule of inference as

$$\mu_{Q'}(y) = \bigvee_{x \in X} \left(\mu_{P'}(x) \wedge \mu_R(x,y)\right), \forall y \in Y \tag{9}$$

where $R \subset X \times Y$ is a fuzzy relation specified by the formulas (6–7). In such cases the membership function of the result has the final form of

$$\mu_{Q'}(y) = \bigvee_{x \in X} \left(\mu_{P'}(x) \wedge \left(\left(\mu_P(x) \wedge \mu_Q(y)\right) \vee \left(1 - \mu_P(x)\right)\right)\right), \quad \forall y \in Y \tag{10}$$

A fuzzy reasoning system implemented in the SciLab package and applied in Section 5 uses the above inference reasoning method specified in formulas (8–10).

5 A FUZZY MODEL FOR THE EVALUATION OF X-RAY BAGGAGE SCREENING DEVICES AT AN AIRPORT

5.1 *General structure of the fuzzy model "Device evaluation"*

Figure 1 presents a general diagram of interactions in the *Airport Security System* model. As mentioned before it is a complex hierarchical structure. One of its elements is the *Screening baggage* local model. It consists of two local sub-models: *Hand baggage* and *Registered baggage*. Each of these is further composed of three sub-models: *Device evaluation*, *Personnel evaluation* and *Control procedure*.

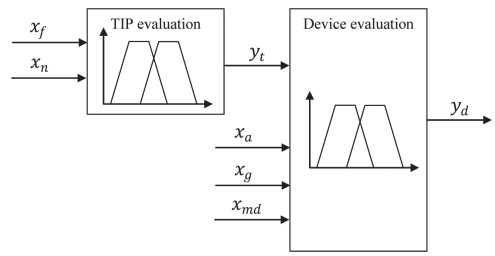

Figure 2. Diagram of the *Device evaluation* fuzzy model.

The subject of analysis in this section is the *Device evaluation* fuzzy model. Its diagram is presented in Figure 2. The output of the fuzzy reasoning system (y_d) associated with this fuzzy model is dependent on four input variables: *Detectability*(x_{md}), *TIP evaluation* (y_t), *Number of detection lines* (x_g), *Device age* (x_a).

5.1.1 *"Detectability" input variable*

The *Detectability* linguistic variable characterises the technical parameters of the x-ray devices which determine the effectiveness of the entire security control process. This category encompasses the conventional RTG devices and EDS (Explosive Detection System) devices. The latter are more

advanced as they are able to detect explosives on their own. In case of conventional RTG devices the effectiveness of security control rests in the most part on the abilities of the Security Screener (SS). EDS devices, apart from the parameters of conventional equipment, also allow:

– detecting explosive materials located in the baggage or other parcels irrespective of their shape, location and position and signalling their presence using an alarm,
– sending an alarm signal in case of: detecting an object that is used to prevent the detection of explosive materials, contents of the baggage or parcel are too dense to perform an control.

The values assumed by the *Detectability* linguistic variable are: *very small*, *small*, *medium*, *big* and *very big*. It is assumed that the membership functions of given fuzzy sets will have a trapezoidal shape. To establish them we will use a standard procedure for the evaluation of the device that is performed during every start-up. This calls for using a standard test sample that help verify if the device meets the minimum values related to set requirements (European Commission 2010):

1. resolution of a single wire,
2. useable penetration,
3. spatial resolution,
4. singular penetration (thin material),
5. singular penetration (dense material),
6. differentiating materials,
7. detection of explosive material and signalling,
8. signalling the detection of an item preventing the detection of explosive materials,
9. signalling if the contents of the baggage or parcel are too dense to perform an control,
10. indicating the location of the item that triggered the alarm.

The end result of the test is a filled record form which specifies the number of requirements being met. For a standard, fully functional RTG device this number is 6 (requirements 1–6) and for an EDS class device—10 (additional requirements 7–10). Other values are possible for devices which are partially damaged during operation which is not noticed by the technical personnel. The representation of the *Detectability* linguistic variable is shown in Figure 3.

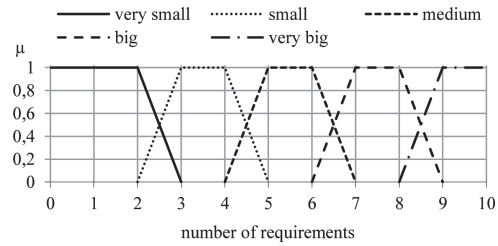

Figure 3. Membership functions of the *Detectability* linguistic variable values.

5.1.2 *"TIP Evaluation" local model*

The second input variable in the device evaluation model is the variable specifying the TIP (Threat Image Projection) system effectiveness. In reality this variable is an output of another local model with *TIP number* (x_n) and *TIP frequency* (x_f) being the fuzzy input variables. The TIP system used for projection of virtual threat images is one of the tools which allow for constant improvement of the operator's skill. Its idea is to project a virtual prohibited item on the image of the piece of baggage being screened. The task of the operator is to detect the virtual object in the image and confirm this fact by pressing the button on the RTG device. This increases the awareness of screening personnel who are forced to search for prohibited items in the baggage image more often than is the case when the TIP system is not used. The effectiveness of the TIP system depends on two parameters:

– number of dedicated TIP images (number of TIPs), which must be numerous enough to prevent memorising their configuration, shape, type etc.; the greater the number of virtual images available in the device the more effective it is at screening baggage,
– frequency at which the TIP images are projected on the real screen image (TIP frequency); in this case, too high frequency of the TIP images in relation to the number of baggage items being screened may cause automatic indications of suspect baggage without an in-depth analysis of the reviewed baggage image.

TIP frequency is established based on individual practice at every airport and this value is kept secret. The *TIP number* and *TIP frequency* input variables assumed for this model are shown in Figures 4–5.

The output variable of the local fuzzy reasoning model for TIP evaluation is presented in Figure 6. This variable is at the same time the input variable for the device evaluation model. The example assumed fuzzy reasoning rules are shown in Table 1.

5.1.3 *"Number of detection lines" input variable*

The x-ray devices differ with the number of generators creating the image. Each generator creates one detection line which allows for creating an image seen from one set direction (angle). In a multiple generator variant, the screened baggage (as it passes through the device's tunnel) is inspected

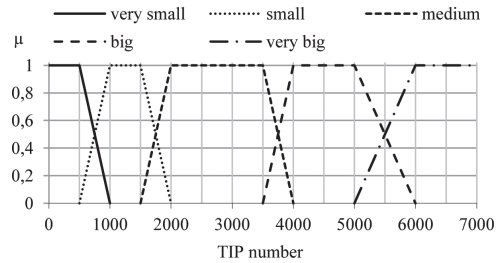

Figure 4. Membership functions of the *TIP Number* linguistic variable.

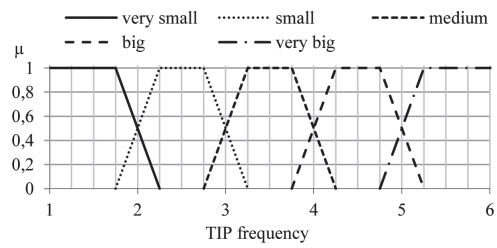

Figure 5. Membership functions of the *TIP Frequency* linguistic variable.

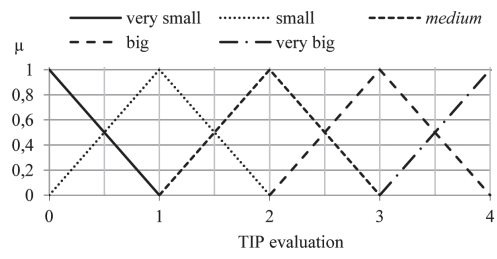

Figure 6. Membership functions of the *TIP Evaluation* linguistic variable.

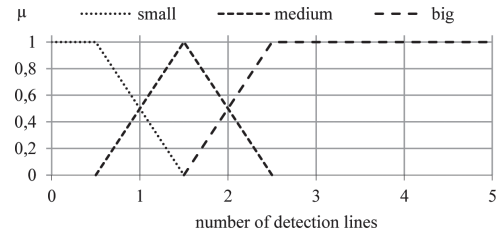

Figure 7. Membership functions for the *Number of detection lines* linguistic variable.

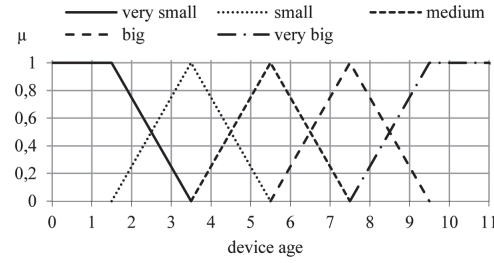

Figure 8. Membership functions of the *Device age* linguistic variable.

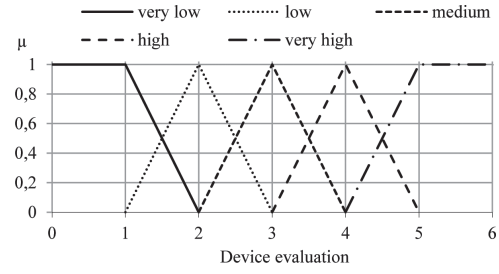

Figure 9. Membership functions of the *Device evaluation* output variable.

by several beams of Roentgen radiation which generates signals in multiple detectors installed in the device at various angles. This allows to obtain images as seen from different directions. Therefore, the probability of detecting a prohibited item hidden in the baggage is much greater if a device with several radiation generators is used during security control. The membership functions for the *Number of detection lines* linguistic variable are shown in Figure 7.

5.1.4 *"Device age" linguistic variable*

The fourth factor taken into account in the analysis is the device age. It influences the probability of failure of the device during operation. Due to frequent reliability checks of the device (at every start-up) the possible time of operation at less the full operational capability is relatively limited. Thus, the age of the device will also be considered a minor factor in the evaluation. The assumed membership functions for different values of the *Device age* linguistic variable are shown in Figure 8.

5.1.5 *Output variable of the "Device evaluation" local model*

The *Device evaluation* local model assumes a five-level scale of linguistic variable values. This is shown in Figure 9.

The fuzzy reasoning system is completed by 301 fuzzy rules defined by expert practitioners; some examples are shown in Table 2.

Table 3. List of baggage x-ray devices at the Katowice-Pyrzowice International Airport.

No.	Manufacturer/model	x_n	x_f [%]	x_{md}	x_g	x_a	y_d
1	Heimann 6040 aTiX	6000	2.8	10	4	6	5.2

7	Smiths 100100 V-2is	0	0	6	2	3	2.7

5.2 *Example of device evaluation for Katowice-Pyrzowice International Airport*

The Katowice-Pyrzowice International Airport has almost 2.5 million passengers per year with 1.7 million passenger in scheduled traffic and about 0.8 million in charter. In the years 2011–2013 about 30 thousand air operations per year were performed (GTL, 2014a). The Upper Silesian Aviation Group, the entity managing the airport has developed and implemented its own security policy. One of its elements is to perform effective and proactive corrective actions in order to minimise the risk (GTL, 2014b). One of the elements of such actions is the evaluation of x-ray devices presented below.

At the Katowice-Pyrzowice International Airport baggage screening is performed using standard commercially available equipment listed in Table 3. Using the hierarchical fuzzy model described above and a calculation tool created using the SciLab package utilising the max-min compositional inference rule based on relations (8–10) the following results were achieved which are specified in the last column of Table 3. It contains defuzzified values of the *Device evaluation* linguistic variable (see Fig. 9).

Analysis of the results shows that the devices operating in the EDS standard ($x_{md} = 10$) are evaluated as *very high* or *high* (see Fig. 9). The evaluation of the device without the EDS function ($x_{md} = 6$) depends mostly on the number of detection lines. In case of devices with two lines the evaluation results are close to *medium* even though these devices have very few TIP images or do not have such function at all (no 6–7). Devices with a single detection line are rated in the scope from *very low* for a x-ray without TIP image function (no 4), through *low* for older device (no 3), to *medium* for newer devices of this class (no 2).

6 METHOD FOR SELECTING EQUIPMENT AND WORK TECHNOLOGY FOR A X-RAY DEVICES AT AN AIRPORT

It is obvious that the most beneficial solution would involve using only new, modern EDS devices with numerous detection lines and equipped with many TIPs. However, this is a very costly solution, which is often hardly justified by the volume of air traffic.

The presented method for the evaluation of a x-ray devices allows us to present an interesting solution in the field of work technology. This solution is a result of analysis of impact of increasing the frequency of TIPs. A model of relation between the *Device Evaluation* output variable and *TIP Frequency* input variable has been analysed by changing the x_f value in the scope between 0 and 6%. Figure 10 shows the results for an EDS standard device but with a small number of TIPs using the Smiths Detection 10080 EDX-2is as an example.

As we can see the x-ray devices's evaluation result depends on the frequency of TIP images. The borderline values which guarantee the highest evaluation values for the device reaching 4.4, which is the intermediate zone between the *high* and *very high* result, are values 1% and 2.8%. Exceeding those values would result in lowering the effectiveness of the baggage screen system to as low as level 3.1 i.e. *medium* value. The decrease of the result is explained by the low number of TIPs available in the x-ray machine. High frequency of images not only lowers the alertness of the SIO but also allows him to memorise the TIPs, thus decreasing the effectiveness of the control.

In case of a standard RTG device, the selection of the correct TIP frequency may also result in increased work effectiveness (Fig. 11).

As we can see the evaluation result for this device is not affected very much by the TIP display frequency. This is understandable as they are very numerous and the SIO is unable to memorise them. Yet, the remark made in the chapter describing input variables still applies—too high TIP frequency lowers the alertness of the operator. Assuming a work technology which displays more than 3% of TIPs results in an evaluation result of about 3.0, which is equal to the *medium* value. Lowering the TIP frequency to about 1.6–1.8% allows slightly improve the effectiveness of the system (to 3.3).

Taking into consideration the borderline frequencies for device with a low number of TIPs and

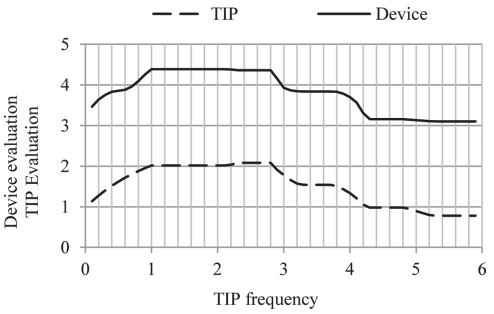

Figure 10. Relation between the *TIP Evaluation* and *Device Evaluation* variables and the *TIP Frequency* variable for the Smiths Detection 10080 EDX-2is.

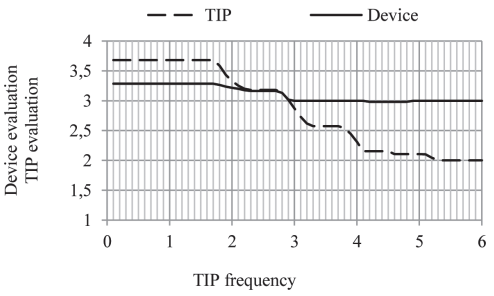

Figure 11. Relation between the *TIP Evaluation* and *Device Evaluation* variables and the *TIP Frequency* variable for the Heimann Smiths 6046 si device.

for devices with a high number of TIP we suggest assuming the *TIP Frequency* parameter value at about 1.8% as a simple and cost-free method of improving the effectiveness of baggage screening system at the airport.

7 SUMMARY AND CONCLUSIONS

The method for the evaluation of effectiveness of x-ray devices at an airport suggested in this paper allows for simple evaluation of individual devices. The developed *Device Evaluation* fuzzy model is part of a bigger model constructed in order to improve the effectiveness of the airport's entire security system.

The evaluation of effectiveness, although important, needs not to be a goal by itself. The suggested approach allows for researching the possible changes in equipment and work technology in order to find solutions that are better than those currently in use. The presented practical example of the Katowice-Pyrzowice International Airport shows that this is not only possible but also does not necessarily require any expenditure.

Quantification and modelling of epistemic uncertainties for availability risk of future offshore wind farms using expert judgment

A. Zitrou, T. Bedford & L. Walls
Department of Management Science, University of Strathclyde, Glasgow, Scotland

ABSTRACT: We develop a model to capture state-of-knowledge, as well as aleatory, uncertainties associated with off-shore wind farm technologies, processes and environments. Our goal is to better understand systemic technology risks and support investment decisions for effective, efficient risk management. Typical epistemic uncertainties present in the offshore wind context are articulated. A protocol for eliciting expert judgment to quantify variables representing epistemic uncertainties and other relevant model parameters is presented. We discuss the elicitation of judgments from an expert panel of energy company technical specialists and show an application of our model to a generic new design offshore wind farm.

1 INTRODUCTION

The UK government has set ambitious renewable energy targets to address the issue of increased carbon emissions (Department of Energy & Climate Change, 2013). To meet these targets, capacity is being increased by, for example, building offshore wind farms which use novel large-scale, complex technology and are sited further from shore. However, deploying innovative technology in partially understood environments introduces the potential for systemic weaknesses associated with the design, manufacturing and operation of wind farm systems. Since weaknesses increase the perceived levels of risk related to offshore wind projects they inhibit capacity growth and act as a barrier to investment.

Understanding of the level of control one has over risk is important in the context of financial decision-making associated with new offshore wind farm projects. Effective risk management requires a new model to adequately address systemic risk, which is important for two reasons. First, if systemic risk, which impacts across all turbines, is ignored then overall farm performance will be over-estimated. Second, the epistemic uncertainty associated with systemic risk can be reduced by as we learn from relevant data and information gathered from, for example, relevant testing.

We have developed a novel availability growth model that takes into account the sources of systemic risk to provide a more accurate estimation of farm performance over early life (Zitrou & al, to appear). Our model focuses on early operating life, which usually covers the first five years of operation, because the impact of systemic risk is more prevalent when teething problems arise and are resolved through remedial actions at the price of additional investment. Our model can be used to understand the scale of uncertainties involved in wind farm development and, thus, inform decisions to grow availability and buy-down risk. In particular, the farm performance estimates obtained through modelling can be used to support assessment of the risk-return profile of offshore wind projects at a pre-construction phase. Our model has a general structure that can be adjusted to reflect a particular application and requires to be populated using an appropriate mix of expert judgment and empirical data.

In this paper we explain how we have designed and implemented a structured expert judgment elicitation process to identify the key uncertainties for a particular offshore wind farm context and to quantify selected model parameters associated with epistemic uncertainties. In Section 2 we overview our contextual model to set the scene before describing the mathematical approach to modelling the epistemic uncertainties. In Section 3 we explain our general protocol of expert judgment elicitation, while in Section 4 we discuss how we gathered judgmental data from a panel of experts with experience in wind farm engineering, technology and operations for a UK Round III wind farm application. In Section 5 we show how the subjective assessments of epistemic uncertainties made by our expert panel can be used to instantiate the model and present selected outputs of modelling. We conclude in Section 6 by discussing the methodological and practical implications of our results.

2 MODELLING FARM PERFORMANCE

2.1 *Conceptual framework*

Our model is designed to represent the key sources of epistemic uncertainties from a risk-management perspective. The model captures the specific effect of epistemic issues on the wind farm subassemblies, as well as their aggregated effect on overall farm performance. Compared to the standard uncertainty analysis, where epistemic uncertainty is represented by varying the model parameters over intervals, the output from our model has a practical interpretation and, therefore, can be used meaningfully to inform decision-making.

Figure 1 provides a diagrammatic representation of our model framework. Farm performance is measured in terms of its availability-informed capability. We introduce this measure to merge farm energy capacity with the technical availability because we believe that this better supports uncertainty analysis. Availability informed capability is a function of the uptime, whether full or partially operating states, and downtime performance. Oval nodes represent the uncertainties affecting performance, with shaded nodes being specifically the epistemic uncertainties affecting reliability and hence uptime performance. That is, design inadequacy, operation error and manufacturing fault, which we collectively refer to as "triggers" because they act as initiators of failure events that will reduce reliability and they represent factors about which we shall gain knowledge through experience. Other uncertainties, such as waiting and repair times, are treated as aleatory. The boxes represent interventions taken to grow performance and reduce uncertainty, and include major innovations such as design changes as well as minor adaptations such as refinements of operational procedures.

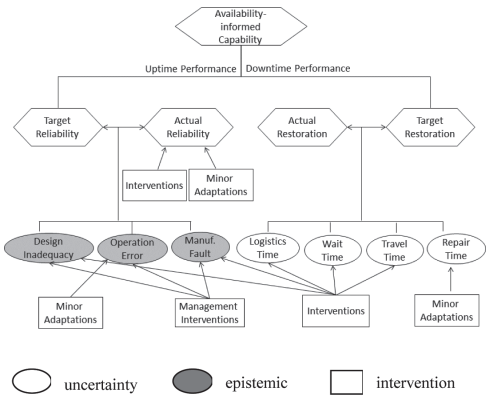

Figure 1. Conceptual model framework of model.

2.2 *Mathematical foundations*

We represent uncertainties in our model at the level of the farm subassemblies, such as gearboxes, generators, blades. The combined effects of uncertainties at the subassembly level are then aggregated to the wind farm level through the model structure.

2.2.1 *Failure intensity function*

The failure intensity $\lambda(t)$ is a function of the inherent reliability properties of the subassembly at start of life, $t = 0$, denoted by the hazard rate, $h(t)$, and the modification of these properties through maintenance and other interventions prior to some time, t, which can be represented by the virtual age, v_t. Therefore by combining the hazard rate with the virtual age, the failure intensity of the subassembly at time t is given by:

$$\lambda(t) = h(v_t), \quad t > 0 \tag{1}$$

2.2.2 *Parametric model for hazard rate*

We assume two classes of subassembly failure mechanism, shock and wearout, which occur in sequential phases. During the first phase shock failures occur at a constant rate, ρ. The second phase relates to wearout which, for the purposes of this paper, we assume to have a Weibull rate, with scale parameter a and shape parameter b. We assume that the transition between the first and second phases occurs at time w. Thus the parametric form of the hazard rate at time s is given by:

$$\begin{aligned} &\rho \text{ if } s \le w \\ &\rho + ab(s-w)^{b-1} \text{ if } s > w. \end{aligned} \tag{2}$$

Extending our reasoning to capture the additional risk due to triggers, we write the hazard rate as:

$$h(v_t) = \tilde{h}(v_t \mid \underline{\theta}) + \sum_{j=1}^{3} X_j(t) h_j(v_t \mid \underline{\theta}_j) \tag{3}$$

where components $h_j(\cdot)$ for $j = 1, 2, 3$ represent the risk added to the subassembly due to their exposure to triggers and the parameters are represented by θ. We assume that triggers cause affected subassemblies to fail more frequently due to shocks and/or age prematurely. We also assume that hazards $\tilde{h}(\cdot)$ and $h_j(\cdot)$ ($j = 1, 2, 3$) have the same parametric model as in Equation (2). To represent epistemic uncertainty, variables $X_j(t)$ in Equation (3), and also the parameters, are assumed to be uncertain. This allows hazard $h(\cdot)$ to be take alternative formulations, allowing for the possibility of different (epistemic) scenarios.

Triggers can have different properties in terms of the way they impact on subassembly reliability.

For example, design inadequacies and manufacturing faults might affect subassemblies from the moment turbines start operating, implying:

$$X_1(t) = X_1, \forall t \text{ and } X_2(t) = X_2, \forall t \quad (4)$$

Bernoulli distributions with parameters p_1 and p_2 can be used to model the variables $X_1(t)$ and $X_2(t)$ respectively. In contrast, an operational error may manifest itself after a maintenance operation at any time during operational life implying that $X_3(t)$ has again a Bernoulli distribution, but is "switched on" with a given probability after a maintenance action. In the model, design triggers simultaneously impact all turbines, manufacturing triggers impact independently on individual turbines subassemblies, and (maintenance) operational triggers occur independently at each subassembly maintenance event.

2.2.3 *Trigger probabilities*

We discuss a functional relationship that allows us to assess what trigger probabilities we should adopt for a given subassembly class. We assume that the susceptibility of subassemblies to a trigger depends on a number of factors relating to design, operational and environmental characteristics. We call these attributes, denoted by A_i for $i = 1, \ldots, n$, and assign to each one a scale. For example, the chance of a manufacturing fault developing may depend quality control processes applied during manufacturing (i.e. Quality Control), the degree to which novel process principles are used in the manufacturing process (i.e. Process Novelty) and the track record of the manufacturer (i.e. Manufacturer Status) as depicted in Figure 2. Each of these attributes has a number of levels which have been defined in conjunction with domain experts. For example, Manufacturer status has five levels, ranging from a new manufacturer with lack of relevant track record through to an established manufacture with a long positive track record producing a given subassembly.

To assess a trigger probability, the analyst chooses the appropriate level for each attribute that influences the particular trigger. The probability

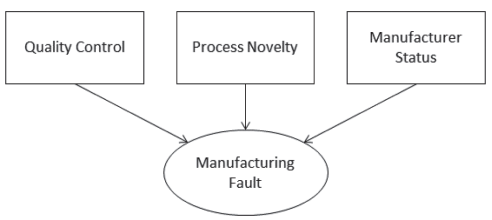

Figure 2. Attributes influencing manufacturing fault trigger.

can then be determined by using a log-linear model, viz:

$$p_j(x_1, \ldots, x_n) = q_j r_1^{x_1 - 1} \ldots r_n^{x_n - 1} \quad (5)$$

where x_i is the level of attribute A_j, q_j is the trigger probability for the worst case scenario (i.e. attribute levels are at the minimum) and r_i is the proportion by which the trigger probability changes when A_j moves by one level whilst the levels of A_k for $k \neq j$ remain fixed.

2.3 *Quantification and model implementation*

Expert judgment is a key source of data especially in relation to the failure process and the quantification of epistemic uncertainties. For example, we need to specify and to determine the values of target variables, such as the baseline probability and risk reduction proportions, which we assume are fixed. The shock rate, wear-out parameters and onset of premature wear-out also require to be assessed. For the epistemically uncertain parameters, such as the onset of aging, we use the whole uncertainty distribution as assessed by experts.

To run our model we also need to specify farm features, such as the number of turbines, rated power, farm layout, time horizon, entry into service times. The details of the maintenance strategy, such as the restoration rates under different degrees of repair, the impact on virtual age, the times and durations of anticipated overhauls, the effect of de-rating on turbine energy output and the characteristics of the logistics operations such as waiting times. Historical experience data can be used, where appropriate, to provide estimates of repair rates and waiting times, conditional on weather. Sources of experience data include Reliawind.

The model has been coded in MATLAB and is implemented as a two-loop Monte Carlo simulation (Bier & Lin, 2013; Wu & Tsang, 2004). The outer loop determines realizations of the epistemically uncertain parameters, whereas the inner loop is a nested loop that performs iterations given the parameters determined in the outer-loop. This code configuration allows us to distinguish between the epistemic and aleatory uncertainty: variation within the inner loop is linked to aleatory uncertainty whereas variation across the outer loop is a representation of epistemic uncertainty.

3 PROTOCOL FOR EXPERT JUDGEMENT

A formal expert judgment elicitation comprises of the stages of motivating (i.e. establishing rapport between the experts and the analyst), structuring (i.e. clarify the objects and events

that are the subjects of the elicitation process), conditioning (i.e. explaining to the experts how to coherently assess their degree of belief), encoding (i.e. obtaining expert assessments) and verifying (i.e. ensuring that the assessments made by the experts reflect their true belief) (Morgan and Henrion, 1990; Merkhofer, 1987; Spetzler and von Holsteins, 1975).

In our protocol, motivating, structuring and conditioning are undertaken during a qualitative stage involving a workshop with the selected experts to identify key uncertainties and to prepare experts for encoding. Encoding of subjective probability assessments are conducted during a follow-up quantitative stage when experts are asked individually to complete questionnaires with questions associated with the parameters associated with epistemic uncertainties. Figure 3 summarizes our protocol.

3.1 *Qualitative stage*

The aims of the qualitative stage are two-fold: to agree the structure the general model for the specific application; and to identify the key uncertainties relevant to the application. A facilitated, semi-structured workshop provides a suitable mechanism for achieving these aims because it allows experts to share their knowledge and reasons for articulating uncertainties and to be made aware of the issues to consider when expressing their later judgments probabilistically. For example, the potential for biases such as representativeness and anchoring (Tversky, 1974) can be explained to improve the quality of expert assessments. The qualitative stage is extremely important because the insights gained can be used to simplify the model complexity and reduce the requirements from the quantitative stage.

A key workshop activity will be the identification of key subassemblies whose reliability estimates are subject to large or moderate epistemic uncertainty for the farm under consideration. In other words, these are subassemblies that are exposed to triggers and can potentially have a worse than expected reliability. Thus we first identify the key subassemblies and secondly we identify for each key subassembly the relevant failure mechanisms in a typical situation, as expected, or when a trigger is present.

The selection of key subassemblies potentially subject to epistemic uncertainties is done both to reduce the quantitative elicitation burden on experts and to ensure that the computations will run faster. The cost of this is some loss of variance in the overall computed epistemic uncertainty in the model, but it is judged that this is relatively small. Furthermore, the kind of decisions that we wish to consider will be around the subassemblies with larger epistemic uncertainties.

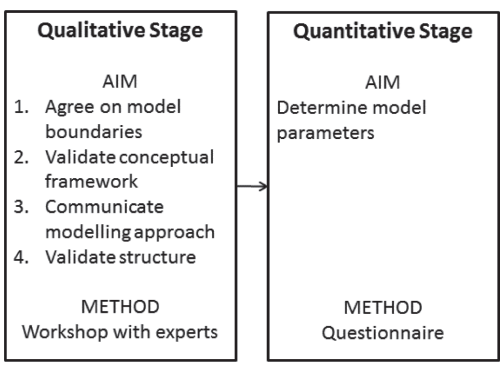

Figure 3. Two-stage expert judgment elicitation protocol.

3.2 *Quantitative stage*

Prior to quantification, the analyst determines the model parameters on the basis of expert judgment gained at the qualitative stage. Typically we might expect to want to elicit probabilities related to the trigger probabilities and the reliability of subassemblies under different scenarios. We choose a questionnaire as the data collection method because it gives experts the time and freedom to consult other sources of information (e.g. past data, event reports, etc), in order to form a probability assessment with which they feel comfortable.

A number of techniques are reported that allow the analyst to associate expert assessments to target variables (Merkhofer, 1987; Meyer & Booker, 1991; Kadane & Wolfson, 1998). We use the quantile method, according to which experts assess, for example, the 5%, 50% and the 95% quantiles of their uncertainty distribution on the target variable. We subsequently use the classical method with equal weights (Cooke, 1991) to aggregate the expert responses. For epistemically uncertain parameters the output of the elicitation exercise is an uncertainty distribution. For the remaining parameters, the output is a median value. Let us consider two examples in relation to the elicitation of the trigger probabilities and their reliability profiles.

3.2.1 *Eliciting trigger reliability profiles*

The trigger reliability profiles questionnaire supports elicitation of the uncertainty distributions on the parameters of the trigger-induced hazard functions h_j for each key subassembly. The hazard parameters are not directly observable quantities and so it is hard for experts to assess their values. To facilitate elicitation, experts are asked to assess the times by which a certain number of

Table 1. Example question on quantile assessment of wear-out onset from trigger reliability profiles questionnaire.

Consider a turbine that operates under normal conditions. Assume that the turbine is affected by a design inadequacy in the gearbox but by no other triggers. The design inadequacy causes the gearbox to age prematurely (over early life).			
After how many months of operation (since installation) will initial signs of degradation be observed?	Lower value (5%-ile)	Upper value (95%-ile)	Central value (50%-ile)

Table 2. Example question from the trigger probabilities questionnaire. *Central value corresponds to the 50% quantile of the expert's uncertainty distribution.*

Suppose that the subassembly has the worst possible configuration across Quality Control, Process Novelty and Manufacturer Status i.e. vector of attribute levels (1, 1, 1), which means no existing process standards, new manufacturer, no quality control. This configuration results in the highest probability of a manufacturing fault.	
Please provide your assessments of this probability.	Central value

subassemblies in a group behave in a certain way (e.g. fail or exhibit premature wear-out). Responses are subsequently linked to the parameters based on the distributional assumptions made within the model framework (i.e. shocks occur according to an exponential distribution). Table 1 shows an example question relating to the assessment of the times of wear-out onset. Since these are epistemic uncertainties, we elicit three quantiles to determine an uncertainty distribution.

3.2.2 *Eliciting trigger probabilities*

The trigger probabilities questionnaire supports elicitation of the information necessary to determine the parameters of the model given in Equation (5). In effect we are assessing the relative weights of the influencing factors. To determine the parameters, experts are asked to state the median of their individual, internal uncertainty distribution on relative risk reductions. Table 2 provides an example of such a question. Assuming the validity of Equation (5), we can then restrict the number of questions we have to ask of experts, because the impact of a specific factor can be determined by holding the other factors constant. Hence the experts are asked to answer a set of questions in which one factor at a time is changed.

4 ELICITATION WITH ENERGY EXPERTS

We have worked with a panel of eight experts with experience in wind farm engineering, technology and operations to conduct a formal elicitation following the protocol explained in Section 3. All experts were employed by the same renewable energy company and had many years of experience in the sector or in the relevant technologies. Experts were selected in collaboration with a lead technical specialist to ensure all were suitably qualified to provide probability assessments. The purpose of our study was primarily to trial our elicitation process and to challenge our modelling approach. Hence the wind farm under consideration was a typical UK Round III Offshore Wind Farm.

4.1 *Workshop insights*

We found that it was very important to carefully explain the difference between state-of-knowledge uncertainty and the aleatory uncertainties associated to lifetimes of the subassemblies: our experience was that after some initial confusion the experts quickly understood. It was the explanations of epistemic uncertainties as arising through triggers that helped to create this understanding.

Figure 4 shows the set of key subassemblies and the triggers to which they are believed to be susceptible as elicited during the workshop. This diagram is particularly important because it illustrates where the experts believe there is no significant epistemic uncertainty arising from the triggers. This qualitative step therefore justifies a simplification in modelling.

4.2 *Quantitative expert subjective assessments*

Quantitative elicitation used the two questionnaires on reliability profiles and trigger probabilities. The former was used to determine the form of the hazard when the trigger is present, and the latter was used to assess the weights in the trigger model.

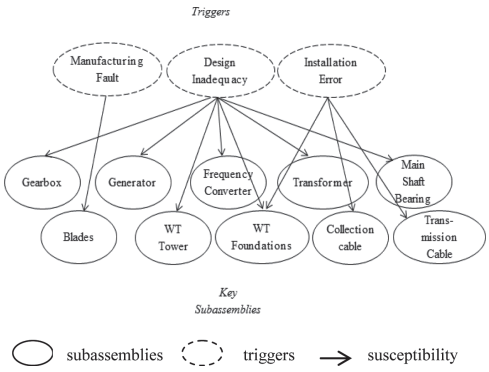

Figure 4. Illustrative output of qualitative elicitation stage.

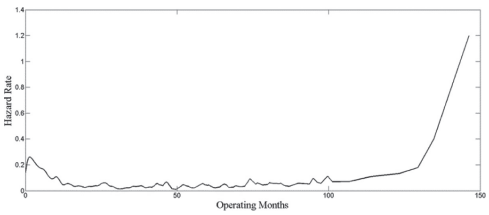

Figure 5. Hazard rate of gearboxes affected by a design inadequacy consistent with the elicited judgments of expert panel.

For example, each expert in our panel provided their own subjective probability assessment of the number of months of operation, since installation, will initial signs of degradation be observed for a type of turbine affected by a design inadequacy in the gearbox but by no other triggers; the example question shown in Table 1. On analysis of the elicited judgmental data we found that a lognormal distribution gave the best fit on the distributions aggregated across experts.

Figure 5 shows the hazard rate, $h(v_t)$ computed from Equation (3), for the population of gearboxes affected by a design inadequacy, consistent with the questionnaire data collected. During the first months of operation, the hazard rate decreases due to infant mortality failures but then the hazard rate levels out. Since design inadequacy issues cause gearboxes to age prematurely, the first signs of ageing start as early as after 100 operating months.

Our expert panel also provided individual probability judgments about the chance of each of the trigger probabilities such as a manufacturing fault for a subassembly produced by a new manufacturer who had not employed process standards and not used any form of quality control. That is, a worst case scenario as shown in Table 2.

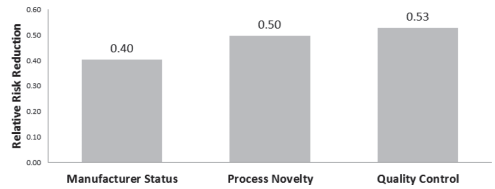

Figure 6. Relative risk reduction achieved by moving each attribute affecting the Manufacturing Fault trigger from the best to the worst level configuration, whilst the other attributes remain fixed to a mid-level.

By using the aggregated probability assessments of the expert panel for each trigger scenario within the model given in Equation (5), we can obtain the relative risk reduction of each attribute as illustrated in the bar chart in Figure 6. Interpreting the relative risks we find that improving the configuration of a subassembly across Manufacturer Status from new manufacturer (i.e. worst level) to established manufacturer (i.e. best level) will be reduced to 40% of its original value. The bar chart shows that Manufacturer Status is the most important attribute in terms of exposing the subassembly to the trigger and, in the context of our data for this application, Quality Control of the least important attribute.

5 EXAMPLE MODELLING OF EPISTEMIC UNCERTAINTY ON FARM AVAILABILITY

To illustrate how the expert judgment elicited from our panel of experts for a typical UK Round III wind farm might be used within our availability informed capability model depicted in Figure 1 and explained in Section 2, let us consider the following example situation.

Our interest lies in assessing the early-life technical performance of the large-scale offshore wind farm at a pre-construction stage. The farm comprises 100 5 MW turbines of a new design and its target performance is 97% availability. The turbines will be subject to both corrective and preventive maintenance, and the effect of maintenance is expected to vary from perfect to imperfect, depending on the type of failure and maintenance action. The maintenance strategy setting is similar to the one considered in (Zitrou et al, 2013).

Each turbine has the key subassemblies shown in Figure 4 and these represent the subassemblies likely to have large or moderate epistemic uncertainties in their reliability estimates. We also create a further generic subassembly category that collectively represents the other non-key subassemblies for which it is anticipated to have small epistemic

uncertainties in their reliability estimates. We assume that this generic subassembly will be subject to shock failures only over early life and will achieve target reliability.

Using Equation (5) we can determine the exposure of key subassemblies to triggers. Specifically, we assume that gearboxes are the main source of epistemic risk, with a design inadequacy probability as high as 0.8. The generator follows with a 0.5 probability of a design inadequacy, whereas blades have a 50% chance of having manufacturing faults.

As well as populating our availability model using the elicited expert judgment from our panel, we also used sources such as Reliawind (REF) to provide generic data for this example. We make additional assumptions about the timing of major interventions to address the realization of weaknesses that trigger a drop in reliability to illustrate their effect on availability estimates and their uncertainties. We have run the Matlab model as a simulation with 50 outer-loop (i.e. epistemic uncertainties) and 50 inner-loop iterations (i.e. aleatory uncertainties).

5.1 *Selected results*

Figure 7 shows weekly farm availability-informed capability during early life when the simulation results across all 2500 iterations are combined. The output is summarized in terms of the median weekly capability, together with the 5% and 95% quantiles. These uncertainty bounds represent a mix of epistemic and aleatory uncertainties. Farm performance appears to deteriorate over the first two years dropping to near 85% in the worst case around year 2. Major innovations to replace the original gearboxes which possess a design inadequacy being in year 2 allow farm performance to gradually reach the target levels, close to 97%.

We can focus on the effect of epistemic uncertainty only by calculating the mean farm availability averaged over the whole early life from the inner-loop iterations of the model. Figure 8 shows the empirical probability distribution of this mean.

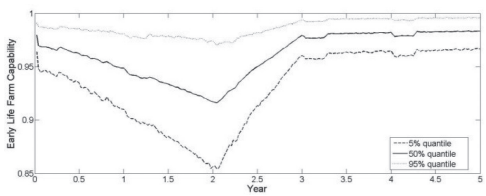

Figure 7. Estimated weekly farm availability-informed capability with 95% combined epistemic and aleatory uncertainties from simulation model of example scenario.

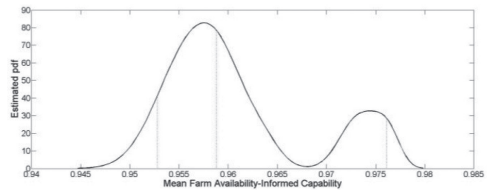

Figure 8. Epistemic probability distribution function on the mean farm availability-informed capability averaged over first 5 years of operation.

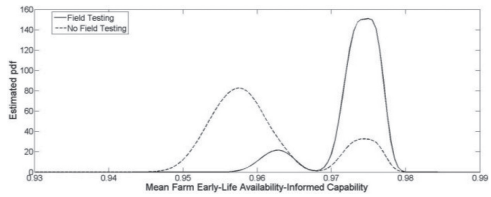

Figure 9. Epistemic probability distribution function on the mean farm capability averaged over first 5 years of operation under the two decision scenarios with and without field testing.

The variance of this distribution is a representation of the effect of epistemic uncertainty.

Now, suppose that extensive testing can reduce the chance of design inadequacy in gearboxes to 15%. This value has been obtained by modulating the Field Testing attribute from the worst to the best level and is, thus, consistent with Equation (5). Our model can then provide insight into the impact of this decision on farm performance and, at the same time, on our ability to assess this at a pre-construction stage. Figure 9 compares the distributions of the mean early-life farm availability-informed capability under the two decision scenarios: with and without field testing. Our outputs suggest that, in the worst case scenario, the mean farm capability might drop to 95% if no field testing is undertaken. However, if field testing is undertaken, this capability will increase to 96%.

6 CONCLUSIONS

New offshore wind farms deploy novel large-scale and complex technology. Such high degree of innovation brings the potential for systemic weaknesses in, for example, design, manufacturing and operational processes. As farms accumulate experience such weaknesses should be resolved, although most likely at the cost of additional investment. Our goal is to support pre-construction stage modelling to capture our

state-of-knowledge uncertainties so that we might better understand systemic technology risks and make good decisions to buy down these uncertainties in a timely manner.

Throughout our research we have worked with engineering experts with experience with the offshore wind technology, environment and business to ground our model in the real decision-making context. In this article we focus on the role played by a panel of experts from a particular company to provide judgments about their epistemic uncertainties on selected variables and parameters. Through their engagement our experts also played a role in validating our model structure and allowing us to test our expert judgment elicitation protocol.

In this paper we have presented elements of our mathematical model relevant to the representation of epistemic uncertainty and show how the model can be used with the expert judgment elicited from the panel of engineers from the company. We have sought to explain the rationale for our elicitation protocol and provide insight into elements of the judgmental data collected and its analysis.

Our model requires further validation study to mature our framework for practical implementation. Equally there are technical improvements required for the simulation model to speed computation, for which either parallelization of the code, or use of statistical code emulators, may provide useful approaches. Also, we have designed the modelling software in a modular manner so that the richness of the set of, for example, degradation models and so on, can be increased beyond those already reported.

Expert method and real time simulation in navigational safety analysis

T. Abramowicz-Gerigk
Gdynia Maritime University, Poland

ABSTRACT: The navigational analysis is the important part of the design process of new port facilities as well as development and reconstruction of existed ports. A significant amount of effort is devoted to predicting and reducing the navigational risk. Recently due to the growing number of big container vessels many ports conduct the accessibility studies to determine the possibility of operation of the vessels bigger than the design ship for the particular port. The methods traditionally used to determine the navigational risk in restricted areas are based on fast time and real time simulations. The comparison of the navigational safety analyses based on the real time simulation and expert judgement using the interview questionnaires gives a new insight into the problem of safety margin. The accessibility study of the container vessel bigger than the design ship for the particular port has been presented as an example.

1 INTRODUCTION

1.1 *Background*

Navigational safety analysis is a usual task in the design process of a navigational area. In the tasks related to the new design of a manoeuvring area all the factors affecting safety of ship navigation in restricted waters should be investigated (Abramowicz-Gerigk, 2008; Abramowicz-Gerigk & Burciu, 2012). The accessibility study carried out for a particular vessel allows the reduction of the number of examined parameters. In the simplest cases the required towing force and manoeuvring procedures are assumed in the range close to the maximum permissible weather conditions for the port operation.

The current situation and prognosis of shipping market development is the reason of widely performed accessibility studies in many ports, with the assumed smaller safety margins than those used before.

East Asia is the area of the fastest development in the global container shipping services. Since 2012 the main Far-East container shipping lines: AE10 (Maersk), Loop 3 (G6), FAL1 (CMA CGM) have introduced in their services the biggest ships in the world and they have the further plans to increase their ULCS (Ultra Large Container Ship) fleets in near future.

There are several reasons for shipping companies to operate ultra large container ships. Operational costs for modern ultra-large eco-ships, characterized with 50% reduction of CO2 emissions per unit of transported cargo (TEU), are now 25% to 35% less than the ships built before 2010.

Widening reconstruction works of Panama Canal allow the vessels up to 12,000 TEU to use this waterway. The new Panamax vessel—maximum vessel to pass the Panama Canal, has the main particulars almost equal to the largest ships in the world: 385.7 m length, 54.9 m beam and 15.2 m draft.

For the planned Post Malacca-Max vessels, with the main particulars: 400 m length, 60 m beam and 21 m draft only two accessible ports Singapore and Rotterdam are now available.

Harbour efficiency and safety is defined by its nautical accessibility, capacity and economic viability. The increase in size of container ships will cause marginalization or even elimination of the ports which are unable to handle the largest ships over 8,000 TEU. Service of ultra large vessels requires infrastructure changes in the ports.

Due to the changes in the fleet structure, and elimination of the smaller feeder containerships, many of the competitive ports have already adopted their infrastructure to fulfil the requirements of ultra-large container ships services. The others are still in front of these challenges planning a navigational safety analysis which allow determining the possible solutions of the accessibility problems.

1.2 *Accessibility studies*

The knowledge and the possibility of prediction of the manoeuvrings performance of large vessels in shallow and confined waters are the basis to perform the navigational safety analysis.

The important aspects in the accessibility studies of ships larger than the design vessel for the particular port are depth, length, width and curvature

of approach channels and port internal channels, depth, length and width of docks and berthing areas, diameters of turning basins. The other aspects are the possibilities and cost of dredging and making changes in the port lay-out. The stakeholders involved in decision making process are port authorities and ship-owners.

In cases of already operated vessels moved to the new shipping routes, the first opinion about port accessibility is given by the experienced ship master of a particular vessel. In case of a new vessel different methods should be applied. In all cases the opinion of local maritime pilots based on their experience and real time simulation trials performed by pilots is very important.

2 METHODS

2.1 *Preliminary expert assessment of ship accessibility*

The usual preliminary assessment of ship accessibility starts during the meeting of the port authority, shipowner and ship operator representatives, experienced ship masters, experienced local pilots and naval architects, specialists in ship hydrodynamics, maritime engineers and port engineers.

The method based on a desk study comparing the control forces of the ship with the forces required to compensate for disturbing forces or to perform a given trajectory is used.

The example of this kind of analysis is presented in Figure 1, where the control forces are compared

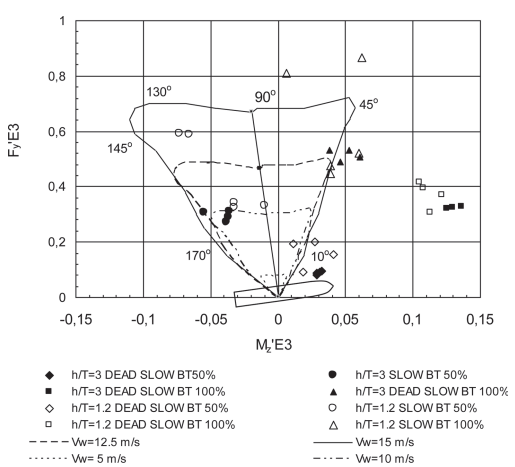

Figure 1. Control forces—non-dimensional lateral force F_y' and yawing moment M_z' compared with the envelope of disturbing wind forces for ship crabbing during berthing, distance from the berth equal to 0.75 ship beam, v_w—wind speed.

with the envelope of disturbing wind forces during ship berthing.

The presented crabbing manoeuvre can be examined for the different combinations of main engines (Dead Slow, Slow) and bow thrusters (50% or 100% of maximum available power) settings at shallow water (water depth to ship draft ratio h/T = 1.2) and deep water conditions (h/T = 3) and at different distances from the berth. In Figure 1 the assumed distance to the berth is equal to 0.75 ship beam.

Prediction of ship performance in real conditions allows estimating the influence of the propeller jets on the seabed (Gucma & Jankowski, 2007; PIANC, 2012).

For propeller driven ships, there are limits of applied main propulsion power usually assumed as 25% of full power in dependence on the type of seabed protection (Abramowicz-Gerigk. & Burciu, 2011).

The empirical methods, rules and best practice can be used to predict safe ship manoeuvring areas during the sequence of ship manoeuvres in port (Abramowicz-Gerigk & Burciu, 2013).

The local bylaws and national rules are different in different ports and countries. For example the diameter of turning basin according to Polish rules should be not less than 1.6 to 2.5 ship length, in dependence on type of the vessel and new design or conversion of the port layout case.

USACE U.S. Army Corps of Engineers rules are less restrictive. For the 180° turn the diameter of turning basin should be not less than 1.2 times overall ship length. If the assumed wind speed during manoeuvres is greater than 12.9 m/s and current is greater than 0.8 m/s safety analysis based on computer simulation of turning manoeuvres is required.

The requirements of PIANC (World Association for Waterborne Transport Infrastructure) are formulated with respect to ship steering-propulsion equipment. The diameter of turning area should be not less than 1.5 overall ship length when main propulsion and bow thrusters can be used. In other cases the diameter should be not less than 1.6 ship length.

In many ports the restrictive rules cannot be obeyed if the large vessels are going to be operated. In these cases the exemptions given by maritime administration are based on the detailed navigational analyses mainly using simulation studies.

The estimation of vessel draft includes the ship squat defined as the overall decrease in the static under keel clearance due to ship motion in shallow water. Ship squat of ultra large container vessels can be predicted using the empirical methods recommended by PIANC (Briggs, 2011).

The squat values calculated using different methods for the ship velocities in the range of

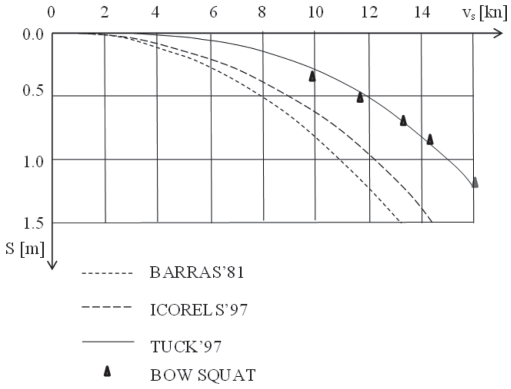

Figure 2. Maximum ship squat of ULCS with the main particulars: 400 m length, 50 m beam and 17 m draft block coefficient c_B = 0.837, with the static under keel clearance UKC = 2 m, calculated by different methods (Barras'81, Icorels'97, TUCK'97) and bow squat calculated on the basis of the physical model tests results (www.baw.de, 2005).

6–10 knots (3–5 m/s), usually assumed in approach and port areas, can be even three times greater than the real values (Briggs M.J. 2011, www.baw.de, 2005).

The comparison of squat assessment calculated using the selected empirical methods for ULCS with main particulars: 400 m length, 50 m beam, 17 m draft and block coefficient c_B = 0.837, with the static under keel clearance UKC = 2 m (www.baw.de, 2005) is presented in Figure 2.

The strategic dimensioning lay-out and operational entrance windows depended on weather, tide or current can be optimized by fast-time simulation, physical model tests and real time simulations.

2.2 *Fast time simulation*

Fast Time Simulation (FTS) technique uses algorithms simulating the decision-making logic of the master or pilot. By using this technique, it is possible to carry out simulations by off-line fast-time mode, which enables simulations for a number of scenarios The number of the examined cases can be about a few hundred runs (Gong et al., 2006).

Similar to the Real Time Simulation (RTS) technique the manoeuvring indices: rudder angle, engine revolutions, drift indices, proximity to fixed points and towing force can be analysed in dependence on environmental conditions.

The statistically evaluated data from independent runs can be used to determine the probability of accident. The dimensions of the area should meet the safe area at the confidence level related to the value of probability of the accident (Alfredini et al., 2011).

The accepted confidence level for the safe navigation should be not less than 95% or not less than the level related to the acceptable risk level. FTS method is a very useful tool however not all practical cases, including instant variable settings of propulsion and manoeuvring devices or special escort towing techniques can be studied using FTS (Gong et al., 2006; Abramowicz-Gerigk & Burciu, 2012).

FTS allows for the synthetic analysis but in most cases it is combined with RTS technique to compare the results with experts—pilots and ship masters opinions.

2.3 *Open water physical model tests*

The physical model tests are usually performed in towing tank to develop simulation model of ship motion (Eloot et al., 2010) or accessibility and siltation study (Willems et al., 2013).

The analyses based on the open water physical model tests can be compared to the RTS techniques. They are less time consuming as the model time is equal:

$$t_m = \frac{t}{\sqrt{\lambda}} \tag{1}$$

where t_m = time in model scale; 1:λ = geometrical scale of the physical model; and t = time in real scale.

Physical model tests are more expensive than the computer simulation (Burciu & Grabski, 2011), the large geometrical scale of man manned models allows testing real procedures, however it is difficult or even not possible to model the shallow water effect and environmental forces. Wind, current and wave parameters can be measured on-line during the experiment.

The example results of physical model tests carried out in the Research and Training Centre of the Foundation for Safety of Navigation and Environment Protection are presented in Figures 3 and 4.

The ship model and escort tug boat models are in the same geometrical scale 1:24.

The models used in the experiments are equipped with instruments simulating ship's systems and the basic navigational aids. motion parameters of the model are measured by a precise GPS RTK system.

The big advantage of open water model tests is a possibility to observe manoeuvres performed by experienced ship masters and local pilots. The influence of human factor is more close to reality in this case than during simulation studies performed using the full mission simulator.

The main dimensions of the example containership and her physical model are presented in Table 1.

Figure 3. Physical model tests carried out in the training facilities of Research and Training Centre of Foundation for Safety of Navigation and Environment Protection, photo. P. Michalowski (Abramowicz-Gerigk et al., 2012).

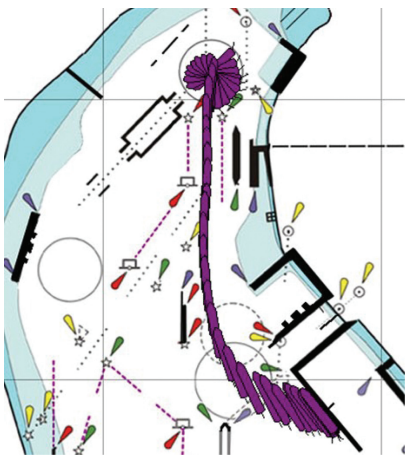

Figure 4. Ship manoeuvring area obtained using physical model tests: unberthing, towing ahead to the turning basin and turning carried out in the training facilities of Research and Training Centre of Foundation for Safety of Navigation and Environment Protection (Abramowicz-Gerigk et al., 2012).

Table 1. Main dimensions of the ship and physical model used in tests.

Parameter	Symbol	Ship	Model
Length	L [m]	372.00	15.50
Beam	B [m]	43.00	1.79
Draft	T [m]	14.50	0.60
Model scale	λ [–]	–	1:24

There are only a few facilities in the world where the open water tests, using large scale models can be carried out they are mainly used for training purposes. Therefore the basic tool used for navigational safety analysis is the real time simulation, integrating close to real conditions and experts knowledge.

2.4 *Real time simulation*

The process of manoeuvring safety analysis based on real time simulation studies starts with modelling of the examined vessel, harbour and environment. In most cases the commercial full mission simulators are used to carry out the real time simulations in collaboration with local pilots and ship masters.

The wide range of about 50 variables for the running ship models can be recorded along with the parameters to be assessed during the analysis.

The most important in the accessibility studies of large containerships is the determination of safe manoeuvring procedures, distances to the fixed points of port infrastructure, contact energy, minimum towing force and boundary hydro-meteorological conditions. The boundary values for dangerous situations can be also defined (Abramowicz-Gerigk & Burciu, 2012).

The repetitious simulations of the particular manoeuvre performed by the ship masters and pilots are the reason of the learning effect. It could be observed for the trials performed in the same weather conditions (Gong et al., 2006). Very often the second trial carried out by the same pilot even in strong wind conditions is more successful than the first trial in calm weather (Abramowicz-Gerigk et al., 2012).

3 REAL TIME SIMULATION AND EXPERT METHOD

Pilotage is an essential part of every Port Safety Management System. The essential part of navigational safety analysis based on RTS method is the contribution of local pilots. Their skills decide of the proper performance of manoeuvres and they can express their opinion about their difficulty and safety.

Their opinion before and after the trials can be different, but the observed results of several projects done with collaboration with the experienced pilots from three major Polish ports show well prediction of manoeuvres feasibility.

Human factor is the main factor in safety analyses performed in maritime transportation (Burciu, 2011; Gerigk, 2004; Gerigk, 2005; Gerigk, 2006; Gerigk, 2008; Gerigk 2012). Different combinations of the attitudes to the risk, safety assessment and performance of the manoeuvres have been observed. For example in the group of 10 pilots only one assumed a particular manoeuvre as not practical and decided not to try to perform it. The other wanted to try manoeuvres even if they assumed they are very difficult and unsafe.

The results of the navigational safety analysis performed in collaboration with 10 pilots, who performed 65 RTS accessibility trials of large container vessel, show the relationship between the pilot opinion and the results of the RTS analysis.

The trials were performed on full mission ship handling simulator SimFlex Navigator 4.0 at Gdynia Maritime University.

The assessment of safety and difficulty of particular manoeuvres was evaluated using semi quantitative approach. The proposed measures are presented in Table 2.

The pilots employed in the project were asked to fill questionnaires, evaluating the manoeuvres they had performed.

They assessed difficulty and safety of manoeuvres according to the scale presented in Table 2, taking into account weather conditions, towing force (tug boats currently available in the harbour and greater—up to 75 Tons), bow thrusters and stern thruster forces available for the tested vessels.

The calm weather conditions, 10 m/s, 15 m/s and 20 m/s wind speeds were simulated during the trials and taken into account in the questionnaires. The maximum available thruster forces and towing forces of bow and aft tug boats up to 75 Tons were allowed to use.

The example performances of the turning manoeuvres in the turning basin with diameter equal 1.3 ship length, using RTS are presented in Figure 5.

Lateral distances measured from the central point of the turning basin to the left side and right side berths, determined for the manoeuvring area occupied by the turning ship using RTS, during 20 trials (No.—number of a trial), wind sped 0 m/s, 10 m/s and 15 m/s are presented in Figure 6.

The trials performed at wind speed 15 m/s are marked with circles. It can be noticed that the ship manoeuvring area was not always tighter in calmer weather.

However as it is presented in Figures 7 and 8 the probability of safe performance of the manoeuvres and manoeuvres difficulty in pilots questionnaires were always assessed with respect to the wind speed.

All the manoeuvres carried out at the wind speed equal to 15 m/s—the boundary weather conditions for the port, were assessed as difficult (one

Table 2. Difficulty (D) and probability of safe manoeuvre performance (P).

%	Difficulty	Safety
100	Very easy to perform	Very safe
99–70	Easy to perform	Safe
69–30	Standard	Standard
29–10	Difficult	Unsafe
10–0	Not practical	Not acceptable

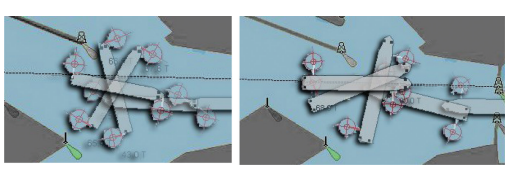

Figure 5. Ship manoeuvring area in the turning basin obtained using RTS (Abramowicz-Gerigk et al., 2012).

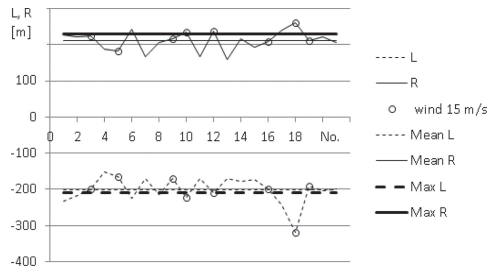

Figure 6. Lateral distances measured from the central point of turning basin to the Left side (L) and Right side (R) berths, determined for the manoeuvring area occupied by the turning ship using RTS. Mean L, Mean R—mean distances of the 20 trials, Max L, Max R—maximum safe distances.

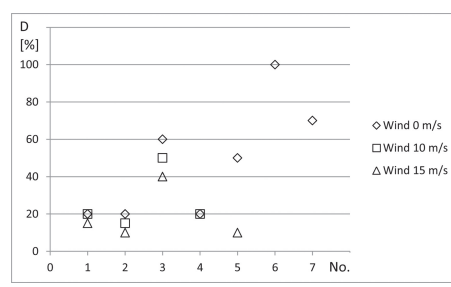

Figure 8. Difficulty of performance of the turning manoeuvre in the turning basin at wind speed 0 m/s, 10 m/s and 15 m/s (No.—number of a pilot performing the manoeuvre).

pilot placed the manoeuvre in the standard difficulty zone) and unsafe.

4 CONCLUSIONS

There are the following conclusions coming from the study presented in the paper: fast time simulation should be followed by real time simulation or open water trials on physical man manned models to include human factor in navigational safety analysis. Real time simulation is the most powerful tool as it allows examining all influencing factors at reasonable cost. It is also practical to use full mission simulator for the assessment of emergency manoeuvres.

The local pilots must be involved in navigational safety analysis as experts, because even if the mean result of the trials shows that the manoeuvre is feasible and safe with respect to its geometrical boundaries it can be assessed by the experts as feasible but unsafe and additional risk prevention measures should be undertaken.

Causal modeling in industrial Reliability and Maintenance Management

Y. Pang & G. Lodewijks
Section Transport Engineering and Logistics, Delft University of Technology, The Netherlands

ABSTRACT: To ensure the healthy performance of complex industrial system and production process, Reliability and Maintenance Management (R&MM) requires accurate assessment of the degradation at both system level and component level, as well as the discovery of the interdependency among individual system components. This paper presents a novel intelligent R&MM system based on Bayesian belief network. The R&MM system models the causal relationship and assesses the reliability of complex industry systems in a generic way to optimize maintenance decision-making when degradation occurs. The study of two application cases proves that the developed generic R&MM system can be applied in various industrial areas.

1 INTRODUCTION

In industrial practice, a complex system is composed of a number of assembled components or subsystems. The reliability of the system relies on the combined reliability of the components. The malfunction of one of the components may lead to expensive process downtime if it causes a total shutdown of the system. Since an industrial system and relative production process cannot be designed to be 100% reliable and the reliability of system components decreases with aging and when degradation occurs, proper maintenance strategies and decision-making are required to maintain the reliability of the various components and the overall system. Therefore, reliability and maintenance management (R&MM) plays an important role to ensure the proper functioning and to achieve optimized performance of industrial systems.

To ensure the reliability of industry systems, preventive maintenance strategies are traditionally applied by means of Condition Monitoring (CM). CM is the continuous or periodic measurement and interpretation of the data and information to indicate the technical healthy condition of individual components to determine the needs for maintenance (Leaney & Sharpe 1999). CM deals with the acquisition of data and information from both human operators and sensor systems and further with taking corrective or preventive maintenance actions on the components that are to fail (Niu et al. 2010). It means that traditional CM aims to R&MM at either a parameter level or an individual components level (Leung & Romagnoli 2002). Due to the interdependency among the parameters and the components within complex industry systems, advance R&MM development, which is able to integrate the CM of individual components and subsystems, are desired to achieve:

- the overview of the operation condition at a system level instead of only taking monitored individual parameters and components into account;
- the exploration of the interrelationship among parameter and components instead of only taking separated monitoring outputs into account;
- the discovery of cause-effect relationship to provide optimal R&MM strategies and activities by means of data and information integration;
- the optimization of reliability assessment and maintenance decision-making for both the overall system and its components.

This paper presents the development and the application of a novel intelligent R&MM system by means of causal modeling. Such a R&MM system models the causal relationship of complex industrial systems in an generic way and assesses the reliability on a system level. Bayesian method is applied to model and integrate the data and information derived from individual parameters and components within complex systems. The intuitive modeling principle of Bayesian Belief Network (BBN), the mechanism of Bayesian inference and the intelligent reasoning ability enable the system to achieve the advanced R&MM. In the R&MM system, a generic Bayesian causal model and its reasoning framework are developed, which can deal with the R&MM for various complex industrial environments. Especially, the causal model takes the integration and reasoning on four R&MM levels, namely, the parameter level, the component level, the function level and the system level. The original concept of the integrated

R&MM system has been introduced and tested by the maintenance decision-making for large-scale material transport systems (Pang 2006). As the extended development of previous application, two case studies showed the opportunities to apply the developed generic R&MM system in wider industrial areas.

In this paper, Section 2 introduces the principles of Bayesian method and the inference of BBN. Section 3 describes the structure of the Bayesian causal modeling in the R&MM system and the approaches of reliability assessment and maintenance decision-making. In Section 4, both the main functions and the implementation of the generic R&MM system are provided to show the wide application scopes. Finally, Section 6 gives some conclusions.

2 BAYESIAN BELIEF NETWORK

Nowadays, with respect to reliability and maintenance decision-making, the management of complex industrial systems tends to complicated reliability analysis and optimized maintenance performance. The challenges of advanced industrial R&MM include the modeling of the overall systems, the representation of the reliability of both the system and its components, and the quantification of the uncertainty of system behaviors. In addition, the transition of system reliability, the integration of both quantitative and qualitative information at different levels, and the representation of the status of system events as well as the interdependency among events are also the issues to be taken into account for R&MM. Over the last decades, causal modeling approaches have been used to overcome the challenges of R&MM (Weber et al. 2012). Bayesian inference, as a proven sound causal modeling method, has been widely applied in various industrial areas, with respect to reliability assessment (Freitas, et al. 2010, Langseth & Portinale 2007), maintenance (Iung et al. 2005) and risk analysis (Trucco et al. 2008). However, there is still the lack of the applications of integrated intelligent system which takes the most issues of R&MM into account. Especially for complex industrial systems, these issues need to be considered simultaneously to achieve advanced R&MM.

2.1 *Bayesian method*

Bayesian method is a formalism for reasoning under uncertainty and causality (Pearl 2000). The foundation of Bayesian method is the Bayes theorem to use the prior knowledge $P(B)$, the probability that an event B occurs, to calculate the posterior probability $P(B|A)$ when the causal event A of B occurs:

$$P(B|A) = \frac{P(A|B)P(B)}{P(A)} \tag{1}$$

where $P(A|B)$ is the conditional probability that A occurs with given event B, and $P(A)$ is the marginal probability that event A occurs.

Bayesian method can be applied to discover the cause-effect relationship between events, or in other words, to discover the occurrence of one event when other events occur. Considering multiple events in complicated industry systems, the Bayes theorem can be expressed as

$$P(e_i \mid H) = \frac{P(H \mid e_i) \cdot P(e_i)}{\sum_i P(H \mid e_i) \cdot P(e_i)} \tag{2}$$

which uses the prior knowledge $P(e_i)$ of a set of events e_i ($i = 1, 2, \ldots, n$) to discover the posterior knowledge $P(e_i|H)$ of the set of events with given hypothesis H.

Bayesian method has the advantages of handling both certain and ambiguous information and knowledge, representing both discrete and continuous events, and reasoning with partial or limited information. Most importantly Bayes theorem is used to confirm the belief that one event is approaching the truth based on the causal events that have been observed. Such advantages of Bayesian method enable the causal modeling and information integration by means of BBN.

2.2 *Inference of Bayesian Belief Network*

A BBN is an acyclic directed graph that represents a factorization of the joint probability over a set of events or random variables. The graphical structure of the network is the qualitative part of a BBN and embodies a set of nodes representing the random variables and a set or arrows representing direct dependencies between connected variables. Absence of an arrow between variables indicates that these variables are conditionally independent. The parents of a variable are the variables connected with an arrow with its direction going into this variable. The joint probability is the quantitative part of a BBN and embodies the conditional probability defined with each variable. This probability characterizes the influence of the valuated parents on the probabilistic values of the variable itself. A probability is the prior probability when a variable has no parents. The uncertainties in the parent nodes, represented by marginal probability, produce uncertainties in the child nodes that are based on conditional probabilities and physical cause-and-effect relationship. The directed

graphs of BBN provides a representation of the set of variables that are related to each other in providing knowledge about the state of the system (Pearl 2000).

Based on the principle of Bayes theorem, a BBN provides its inference mechanism in two directions: forward Bayesian inference and backward Bayesian inference (Kilner 2007). With respect to the events happened in industrial systems, forward inference is the inference from causes to effects, which gives the prediction of the occurrence of effect event(s). In forward inference, Bayesian method discovers the probability of a hypothesis (the effect) with known information of observed events (the causes). For instance, the probability of a poor braking operation of a material conveying system, with the key performance indication of long braking time, can be derived from known information of worn brake pads and degraded braking hydraulic system. Backward inference is the inference from effects to possible causes, which provides the diagnosis or explanation of the occurrence of cause event(s). In backward inference, Bayesian method concludes the conditional probability of observed events (the causes) with occurred hypothesis (the effect). For instance, the main cause between the observed worn brake pads and degraded braking hydraulic system can be identified, when a longer braking time is being known (Pang 2006).

3 CASUAL MODELING

3.1 *Modeling principle*

By applying the principle of Bayesian inference and the graphical intuitive structure of BBN, an generic R&MM system has been developed to integrate the data and information derived from industrial systems. Further, the R&MM system represents the interrelationship within the systems. In applications the a generic BBN model consists of four layers for inference and intelligent reasoning (Fig. 1).

Parameter layer monitors the parameters required for R&MM. It checks whether the values of individual parameters fall into the range of expectation. If not, it may indicate the degradation or potential failure of relative components. Then the uncertainty of the occurrence failure will be assessed by component layer. Based on the set points and pattern recognition algorithms of the parameter layer, the evaluation of the normality of the operational condition related to each parameters can be derived.

Component layer assesses the degradation and technical healthy condition of individual components based on the causal events monitored and

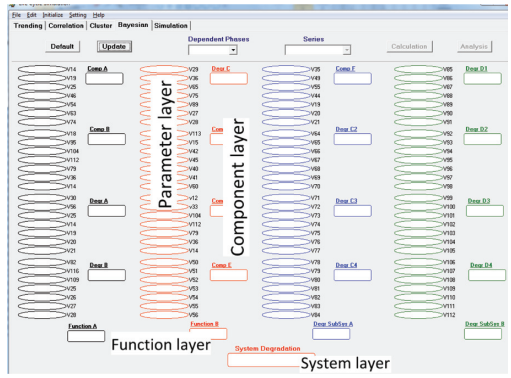

Figure 1. Structure of Bayesian causal modelling.

evaluated in the parameter layer. By obtaining the prior knowledge of the occurrence of individual causal events at the parameter level, the posterior probability derived from Bayesian inference provides the assessment of the effects of the monitored parameters. Then the technical healthy condition and the reliability of relative components can be represented.

Function layer integrates the assessment of the healthy conditions of individual components. By means of the integration, the overall performance of the system can be assessed with respect to specified system functions. The posterior probability derived in the function layer indicates whether the system is able to function in a proper and expected way when any abnormality or degradation is observed at component level.

System layer provides an overall reliability assessment at a system level by integrating all the assessments of system components and specified functions.

3.2 *Reliability assessment*

Based on the forward cause-effect inference of BBN, the R&MM system implements the reliability analysis and degradation assessment from a parameter level to an individual component level. Further, the reliability assessment arrives to a function and/or subsystem level until an overall system level by mean of information integration and causal analysis.

3.3 *Maintenance decision-making*

System layer has two functions. The first function is to assess the reliability of the entire system based on the forward inference from the monitoring of parameters to the assessment of individual components, and further to the evaluation of system

functions. If the assessment of the entire system shows undesired situation, maintenance decision-making will be needed. In this case, the second function of the system layer is to fulfill the backward inference of the BBN model to trace the main cause(s) of low system reliability with respect to degraded components, predictable system malfunctioning or system downtime. By doing so, the developed R&MM system enables advanced predictive maintenance to replace traditional preventive maintenance.

4 IMPLEMENTATION AND CASE STUDY

In the generic structure of the BBN model as shown in Figure 1, the currently developed intelligent R&MM system allows intuitive causal modeling to build up a large-scale BBN containing 120 parameters. For the application of the R&MM system with respect to various industrial systems and processes, in total the reliability of 16 individual components and 4 main system functions can be assessed based on the causal relationship from parameters to components and further to system functions. The reliability assessment at a system level can be provided by the R&MM system in term of the indication of system degradation.

4.1 *Main functions*

The R&MM system has following main functions (Fig. 2):

Modeling functions include trending analysis for monitored parameters, correlation and cluster analysis for causal relationship, Bayesian inference mechanism and simulation based analysis.

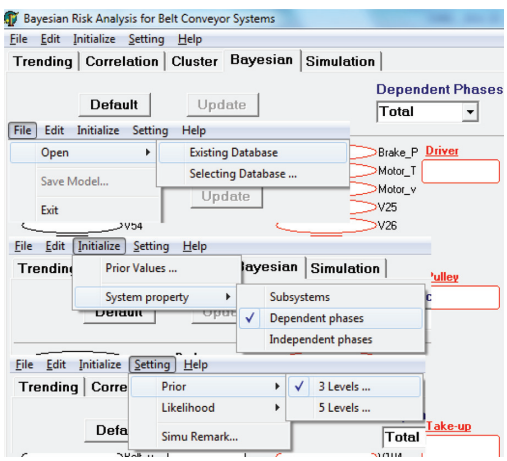

Figure 2. Main functions of the R&MM system.

Data acquisition functions enable the system to deal with both online R&MM and offline analysis by means of either selecting dynamic monitoring outputs or choosing existing historical database, respectively.

Initialization functions allow the system to initialize the configurations and properties of the R&MM system to match the requirements of different industry systems so that the generic causal model can be applied in various industry fields.

Setting functions allow the domain specialists of the industry systems to set and change the prior knowledge and the likelihood of events which are required for Bayesian inference and the intelligent reasoning of the R&MM system.

Model update functions provide users the possibility to change, update and reconfigure the BBN model intuitively. The original generic BBN model can be adjusted based on the specific requirements of the R&MM for a certain industrial system or process. After the update, the new model can be saved and utilized for future application.

Analysis functions can be mainly considered to be the backward Bayesian inference process. When the system reliability is assessed as lower than a threshold, in other words, when system degradation happens, analysis functions generate the analytic results based on Bayesian reasoning to indicate current healthy condition and reliability assessment at system level, function level and component level. The most important is that, based on the backward Bayesian inference, the analysis functions indicate the main cause(s) of low system reliability or system degradation and further provide optimized maintenance decisions.

As a generic modeling approach, the developed R&MM system needs to satisfy the requirements in different industrial areas. As well, the reliability assessment and relative maintenance decision-making need to be interpretable and accurate sufficiently. The ability and success of the developed R&MM system can be proved by the study of two application cases.

4.2 *Case I: R&MM for material conveying system*

In material conveying system, such as a belt conveyor system to transport large volume dry bulk material over a distance of kilometers in mining industry, dry bulk material terminal and power plants, diverse equipment and system components involve into the transportation process. Due to the large-scale of the system, the system components and information sources during CM are highly distributed which hinder the realization of accurate reliability assessment and optimal integrated maintenance decision-making.

The developed intelligent R&MM system has been applied on such a large-scale belt conveying system. Figure 3 shows the Bayesian model updated from the original generic model shown in Figure 1. This application integrate the data and information from the parameters that relate to the degradation of four system components (brake, take-up, belt and motor drive). It also integrates the assessment of the reliability and the technical healthy condition based on three main system operational functions (start, stop and loading situation). By means of the integration and uncertainty inference of the BBN model, the reliability of the overall system in term of system degradation can be gained for further maintenance decision-making.

The analytic output of the R&MM system is shown in Figure 4. Combined with the reliability assessment derived by the forward inference of BBN shown in Figure 3, the maintenance-decision results derived by the backward inference of BBN indicate the high degradation of the conveyor brake, which reduces the reliability of the entire system with a potential worse stop procedure. Further, after analyzing the interrelationship between the brake and the monitoring results regarding causally related parameters, optimized maintenance decision-making can be obtained to maintain the reliability of the overall belt conveyor system.

4.3 *Case II: R&MM for chemical production*

The second case study shows the implementation of the R&MM system for a polymerization chemical production process.

Figure 5 describes the overall polymerization production process and the basic components of the chemical system. The main aim of the R&MM system is to ensure the high quality of final polymerization products. Therefore, the overall system assessment, as the system degradation in the original system model, is represented by the key performance indication of product quality.

Figure 6 presents the basic structure of the BBN model updated and applied for the chemical production process. The results of forward Bayesian inference indicate the potential decrease of the quality of the production when any abnormalities are monitoring within the production process.

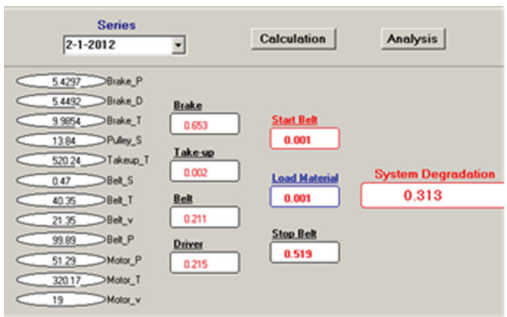

Figure 3. Bayesian causal model for belt conveying system.

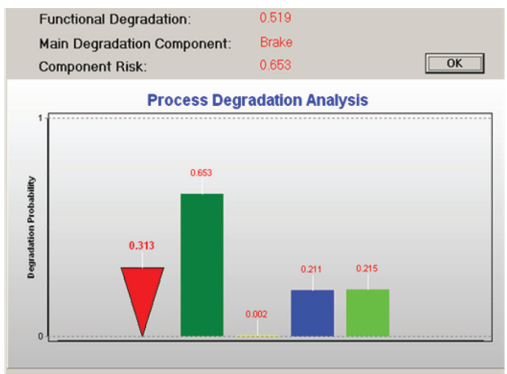

Figure 4. Analysis for system reliability.

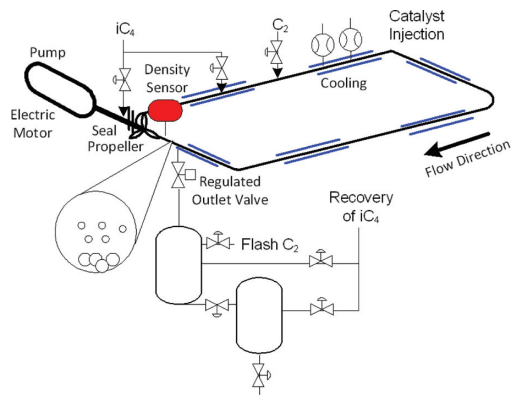

Figure 5. The process description of chemical production.

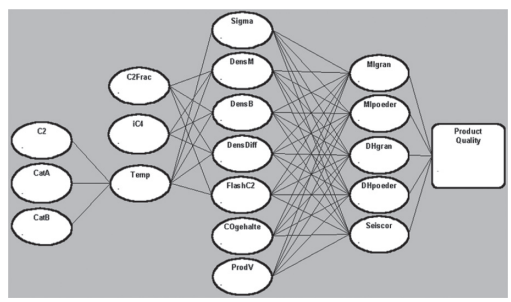

Figure 6. Model structure for polymerization process.

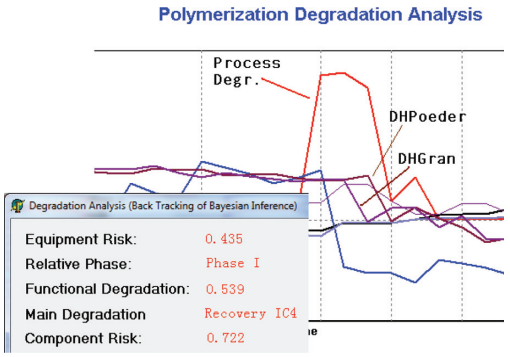

Figure 7. Results of Bayesian inference and analysis.

On the other hand, when poor product quality is observed after each production life cycle, the backward Bayesian inference provides the causal reasoning to discover the main causes to improve the performance of the chemical production.

In Figure 7, the intelligent reasoning outputs of the R&MM system are demonstrated, including the assessment of system degradation and the healthy condition regarding the individual components and functions within the production process. In addition, the main causes of system degradation and the optimized operational decision are provided by the analytic functions of the BBN model so that the performance of the production process with respect to the quality of final chemical products can be improved.

The study of both cases above has shown that BBN causal modeling and the developed R&MM system are able to provide accurate reliability assessment and maintenance optimization for industrial systems and production processes. In fact, past experiments and industrial applications have validated that the generic R&MM methodology can be applied in various industry areas.

5 CONCLUSIONS

Advanced industrial R&MM requires intelligent integrated reasoning towards accurate reliability assessment and optimal maintenance decision-making. By means of Bayesian inference and the causal modeling of Bayesian belief network, this paper presents the development and the implementation of a generic R&MM system. Such a system aims to provide the reliability assessment on both a system level and an individual component and function level. As a generic model and intelligent application, two case studies showed the opportunities to widen the applications of the developed R&MM system to various industrial areas. In fact, besides the case studies presented in this paper, the generic BBN model and the developed intelligent system have been successfully applied in diverse R&MM fields including electronic production line, steel manufacturing system, gasification process, and so on.

The application of risk and reliability techniques to acquire knowledge in the development of expert system for fault diagnosis

E.M.P. Hidalgo & G.F.M. de Souza
University of São Paulo, Brazil

ABSTRACT: The process of knowledge acquisition is a major step in developing an expert system and is considered as one of the most difficult stages. This difficulty is due to the lack of an efficient methodology, reliable and standard for extraction and organization of knowledge from various sources. One of the great difficulties in the development and construction of an expert system is attributed to the extraction of expert knowledge. The contribution of this paper is to present a methodology to assist the knowledge engineer and expert in acquiring knowledge of a logical and orderly manner to develop the expert systems. The paper aims to propose a methodology to integrate the techniques of risk and reliability analysis in the acquisition of knowledge for the development of expert systems. The process of knowledge acquisition is proposed in two stages. The first step is to acquire knowledge of system operation through the study of engineering documents and operational description of the equipment. The second step is the process of knowledge acquisition for fault diagnosis applying HAZOP, FMEA and FTA techniques.

1 INTRODUCTION

Expert systems are a branch of applied artificial intelligence, and were developed by the artificial intelligence community in the mid-1960s. The basic idea behind expert systems is simply that expertise, which is the vast body of task-specific knowledge, is transferred from a human to a computer. (GRAHAM-JONES and MELLOR, 1995). This knowledge (heuristic nature) is the stored in the computer and users call upon the computer for specific advice as needed. The computer can make inferences and arrive at a specific conclusion. The expert systems powerful and flexible means for obtaining solutions to a variety of problems that often cannot be dealt with by other, more traditional and orthodox methods (ASHARAFI et al., 1995).

An expert system structure is made up of the following components (O'KEEFE and PREECE, 1996): a) the knowledge acquisition can be defined as the process of understanding and organizing the skilled knowledge through extraction, structuring, organization and representation of the same. It will be encoded and stored in a knowledge base for later redemption of an expert system; b) the knowledge base contains the expert's knowledge in the form of facts and rules. Rules are conditional statements that give the action that occurs of a specific condition is satisfied, and they are generally based on the problem-solving expertise developed by human experts; c) the inference engine is a computer program which simulates the user's deductive thinking. It applies a reasoning strategy, and generates solutions based on the rules in the knowledge base and the data collected by the expert system and d) the user interface links the expert system with the user and makes possible the data input about the special subject under discussion.

This paper will be focused on the knowledge acquisition for the development of an expert system. The process of knowledge acquisition is a major step in developing an expert system and is considered as one of the most difficult stages, Asharafi et al. (1995) and Maher et al. (1984). This difficulty is due to the lack of an efficient, reliable and standard methodology for extraction and organization of knowledge from various sources.

The potential sources of knowledge used in the knowledge acquisition process can be documented or not. Sources documented are: books, charts, diagrams, manuals, among others. The undocumented sources reside in the minds of people who work in the field of application of the system (experts who have the knowledge that must store on the expert system).

One of the great difficulties in the development and construction of an expert system is attributed to the extraction of expert knowledge. An initial problem is the communication between the expert and the knowledge engineer. The engineer can perform a series of interviews without have good grasp of the subject matter.

Thus, the expert to be understood must use trivial terms, but these are not terms that express their natural way of working, so there is a considerable loss of information in its transmission (SONG, 2008). Ideally, both the knowledge engineer and the expert, learn a little about each other's work so that the conversation more naturally. However, until that happens, a lot of time is consumed. For this reason, the quality, accuracy and completeness of acquired knowledge has a great effect on the quality of the expert system (SONG, 2008; O'KEEFE and PREECE, 1996).

In the area of knowledge acquisition efforts have been made to systematize and automate this process. The existing techniques used for the extraction of knowledge can be classified into manual and semi-automatic techniques.

Manual techniques are the traditional and conventional ways in which the knowledge engineer centralizes the incorporation of the same to build the program, gathered based on direct interaction with the domain expert. For this technique interviews experts with are carried out. Two types of interviews are used: unstructured and structured. Unstructured interviews are free and provide a good relationship between the knowledge engineer and the expert, but are not recommended beyond the early stages of identifying the knowledge and ambiance of the engineer with the domain. Structured interviews are more formal and questions are prepared with care and tend to take the conversation to the acquisition of specific knowledge about the domain. One problem encountered in this type of structured interview is that it can produce results influenced by the interviewer, so it must be planned and reviewed before being applied. The semi-automatic techniques consist in the use computational tools that provide a structured interface that help the experts and knowledge engineers to encode the knowledge base within a predetermined architecture.

Li and Liu (2010) had performed a comprehensive review of intelligence fault diagnosis. They pointed out that there are some problems in the existing intelligent fault diagnosis expert system theory, such as the difficulty in acquiring and managing knowledge extraction of expert, low online usage of fault diagnosis, high error rate, poor efficiency of inference process, and so on. This article proposes a structured method to improve efficiencies in the extraction of expert knowledge, allowing that interaction between the specialist and knowledge engineer be more didactics.

The goal of this paper is to present a methodology to assist the knowledge engineer and expert in acquiring knowledge in a logical and orderly manner to develop the expert system. The method integrates risk and reliability analysis techniques aiming at the acquisition of knowledge for the development of expert system.

This paper is organized in five sections. The first one presents the introduction and objective. In section 2 is presented the proposed method for knowledge acquisition. Section 3 presents the comparison between the methods presented by different authors cited in the bibliography and the proposed method. The application of method is carried out in the speed governing system of a Francis turbine, as shown in the section 4. Finally, section 5 presents the conclusions and recommendations for future work.

2 METHOD

According to O'Keefe and Preece (1996), the process of knowledge acquisition is the most difficult challenge for the development of an expert system. The quality of knowledge acquired supports on the quality of the analysis results obtained of expert system.

The process of knowledge acquisition proposed is divided in two steps. The first step is the knowledge acquisition of system operation through study and operational description of the equipment. The second is the process of knowledge acquisition for fault diagnosis.

2.1 *Study and operational system description*

This first step is characterized by a sequence of activities aimed to carry out an operating description of the equipment to be analyzed. To accomplish with the goals it is important to follow the steps specified in Figure 1.

As shown in Figure 1 it can be observed that the study and operational system description starts by defining the system to be analyzed, and then is carry out the survey of main subsystems and components. To carry out operational description

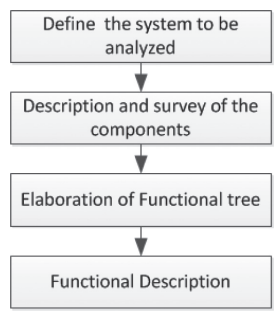

Figure 1. Procedure of study and functional description of the system.

is necessary to survey the technical characteristics of the components through the study of plans, catalogs, manufacturer manuals, etc. This step may present some difficulties in the industry since this information may not be available. Its correct execution influences the success of the analysis; in addition, allow the identification of the components and their functions performed in the system within a specific operational context. The authors propose the use of functional tree to support that analysis.

The functional tree allows the definition of the functional links between the equipment subsystems. To develop the functional tree it is necessary to clearly define the functions performed by the system components' aiming at attending a given system operational performance (CASAL, 2008).

The functional tree can be applied to various types of systems. The detail of the analysis depends on the amount of components and the level of functions to be analyzed. Functional analysis is represented by a graph called functional tree having a hierarchical structure, formed by branches as shown in Figure 2. The system breakdown structure used in the functional tree is the top-down division of a system into subsystems and components (KRISHNASAMY et al., 2005).

Finally, the functional description goal is to establish the interconnection between the components that compose the system and further to identify the functions performed by each of the identified components in the different functional levels of the tree. The development of this tool it is important since it allows understanding the complex functional relationships of the system components (RAUSAND and ARNOLJOT, 2004).

2.2 *Knowledge acquisition for fault diagnosis*

As for knowledge acquisition to support fault diagnosis the method proposes the use of reliability and risk analysis tools, such as HAZOP, FTA and FMEA. In Figure 3 is presented the sequence of use of those tools.

As suggested by Figure 3, the first step is the application of HAZOP technique. The HAZOP is

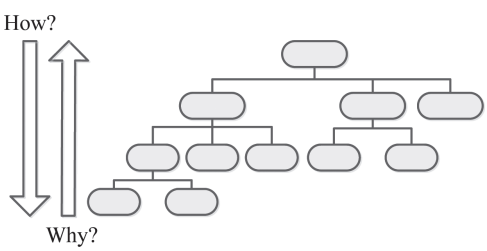

Figure 2. Functional tree.

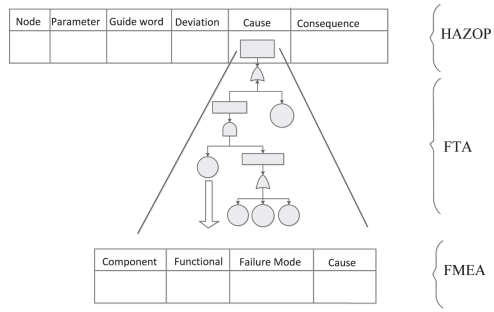

Figure 3. Application of risk and reliability techniques for knowledge acquisition for fault diagnosis.

Table 1. Guide word to analysis (ERICSON, 2005).

Parameter	Guide word	Deviation
Flow	No	No flow
	Low	Low flow
	High	High flow
	Reverse	Reverse flow
Pressure	Low	Low pressure
	High	High pressure
Temperature	Low	Low temperature
	High	High temperature
Level	Low	Low level
	High	High level
Viscosity	Low	Low viscosity
	High	High viscosity
Vibration	Low	Low vibration
	High	High vibration

used to identify deviations of operation parameters in the system and to identify its consequences. The procedure for performing this technique for fault diagnosis can be synthesized in the following steps (CUI et al., 2010; BRITISH STANDARD, 2001):

- Choose the node (are the points of the process) where deviations should be analyzed;
- Identify which operating parameters can be measured at each node to be analyzed: temperature, flow, vibration, pressure, among others;
- Application of "word-guides", determining the possible deviations that are occurring at that node. For each shift, investigate the possible causes of teasing him. To search for possible causes the Fault Tree method is applied.

Table 1 provides a list of parameters and guides words, along with the types commonly used in HAZOP analysis.

To carry out HAZOP a table composed of five columns is used, as shown in Table 2. The node

Table 2. Spreadsheet used in HAZOP analysis.

System					
Component					
Node location	Parameter	Guide word	Deviation	Causes	Consequences

location (points in the process are located through the flowcharts of the plant, which are examined in cases where deviations occur), the parameter (which are the physical process variables), the guide word (are applied to the process parameters that remain within the standards established by the intention of operation), deviation (intentions are operating clearances which are evidenced by the systematic application of the words study guides), causes (are the reasons why deviations occur, this step will be taken of fault trees) and consequence (the consequences are the outcome of a deviation from the intended operating on a given node-of-study).

Once identified the deviation the Fault Tree technique is used to search for causes that led to the occurrence of that deviation. The deviation is recognized as the top event for the tree construction. The reason for applying the Fault Tree is the capacity of dealing with simultaneous failures, which usually happens in electro-mechanical systems. The development of the Fault Tree enables the identification of the basic events which lead to the occurrence of the top event or deviation.

Once the Fault Tree for each identified deviation is elaborated, the qualitative evaluation of combinations of basic events that cause the occurrence of the top event can be executed. In other words, the cut set of tree that cause the top event are identified. To identify the minimum cut is necessary to apply the main rules of Boolean algebra.

The minimal cut of a Fault Tree is the set of basic events that cause the occurrence of the top, in other words, the deviation of a given operating condition. Thus a cut is the combination of basic events that modify the operating condition of the system. A cut is defined as the minimum cut when it is constituted by the smallest possible number of basic events whose occurrence is necessary and sufficient to cause the occurrence of the top event cannot be reduced without losing its cutting condition (O'CONNOR, 1985).

Once identified these basic events that lead to the occurrence of the deviation of the operating condition the Failure Modes and Effects Analysis is applied, because the basic events listed in the FTA

Table 3. Margin settings for A4 size paper and letter.

Failure mode and effects analysis			
Component	Functional	Failure mode	Cause

are the failure modes of the system components. The analysis will help to identify the causes of failures and propose recommendations for maintenance to repair the machine.

For the application of Failure Modes and Effects Analysis was used the Table 3 that consists of four columns: component (identifying each component belonging to the system), function (summary description and precise task that must carry out by the component), potential failure mode (description of how the loss of function is observed by operating staff) and cause of failure (simple and concise description of the causes that generate the occurrence of the failure mode) (BRITISH STANDARD, 2007).

Finally, the most appropriate maintenance policies to each component can be selected through the application of decision diagrams for selection of maintenance practices proposed by the RCM philosophy.

3 COMPARATIVE ANALYSIS BETWEEN THE METHODS LISTED IN THE REFERENCES AND THE PROPOSED METHOD

A literature review was executed to search for articles that present methods based on reliability and risk analysis techniques to support the development of fault diagnosis expert systems. Those articles, published from 1995 to 2014, are used to define the main contributions of the present methodology.

Batanov et al. (1993) presented an approach to the design and development of knowledge-based systems in general and their application in the field of maintenance management. The case study was a

rotary screw type air compressor. The knowledge-acquisition process has been organized and realized using a decision tree diagram and functional tree. The knowledge base contains 154 rules for the fault diagnosis and 54 rules for the maintenance model selection.

Wang et al. (2012) carried out a fault diagnosis expert system based on neural network and fault tree to study control box faults of a certain digital control system. Duan and Zhou (2012) presented a method for diagnosing faults using fault tree analysis and Bayesian networks to optimize system diagnosis in oil pressure warning instructions system. Zhou et al. (2009) presented a fault diagnosis expert system for the EAST cryoplant based on fault tree analysis. The EAST cryoplant consists of a 2 kW/4 K helium refrigerator and a helium distribution system. Zhi-Ling et al. (2012) carried out an Expert System of Fault Diagnosis for Gear Box in Wind Turbine based on fault tree.

Leone (1996) presented one of the main aspects of SERO, a knowledge representation structure, which has been developed to encode the different kinds of knowledge used in a HAZOP study. Venkatasubramanian et al. (2000) presented an intelligent system which allows identifying and suggesting hazard mitigation measures in a chemical process facility based on Process Hazards Analysis (PHA) and HAZOP analysis. Chan (2005) presented the development process of an expert decision support system for monitoring, control and diagnosis of a petroleum production and separation plant. The system can monitor operations at the plant based on input data, detect abnormalities in the data and suggest diagnostic actions to the operator. Rahman et al. (2009) developed ExpHAZOP+ which is the fault propagation algorithm, an aspect of the inference engine, which defines the propagation of deviations to all downstream equipment. The dynamic knowledge-base of ExpHAZOP+ allows a user to update knowledge while performing the HAZOP analysis.

The main innovations and contributions of the proposed method are:

– After doing the literature review it can be concluded that the articles only applied one of the risk or reliability analysis technique. It can be observed also that the FMEA analysis was not applied in the knowledge acquisition for expert systems. The contribution of this paper is to integrate the HAZOP, FMEA and FTA techniques to develop the proposed method for knowledge acquisition in expert systems
– The proposed method is different from others presented in the literature by the fact that it integrates and apply the reliability and risk analysis techniques for acquiring knowledge in the elaboration of the expert system.

The proposed method is suitable for acquiring knowledge for the development of an expert system applied in the diagnosis of deviations in the process including operational failures in order to search for the components which fail can cause these deviations. It is emphasized the importance of following the proposed flow chart that shows the sequence of activities that allows to make detailed and reliable analysis, because they are used and organized in a logical order, so that the method is applied correctly.

– The method proposed in knowledge acquisition step is divided into two phases. In the first phase techniques of functional tree and functional description are applied as a starting point for knowledge acquisition. The functional tree technique allows to create a functional structure of the system, which maps the relationships between the various components within a system. The functional description is used to establish the interconnection between components that comprise the system. Additionally it identifies the functions performed by each of the components in the different functional levels of the tree. The second phase applies risk and reliability techniques. The integration and application of these techniques will help the knowledge engineer and the expert to represent knowledge in an organized way based on logical rules. The HAZOP analysis is used to select the nodes where the analysis will be held, covering all possible deviations in the operating system. In order to identify the causes of deviations, FTA is applied, enabling modeling the occurrence of simultaneous events, which usually happens in electro-mechanical systems. Given the FTA, it is possible to identify those basic events which led to the occurrence of the deviation. The Failure Modes and Effects Analysis is applied to identify the causes of the occurrence of the basic events identified in the Fault Tree. Moreover, FMEA will assist in the proposition of recommendations for preventive or predictive maintenance.

4 METHOD APPLICATION

The system to be analyzed is the speed governing system of Francis turbine (schematically presented in Fig. 4) installed in a hydroelectric power plant localized in São Paulo state in Brazil. The hydroelectric power plant has a generation capacity of 120 MW.

The first step is to obtain knowledge of system operation through the study and description of the

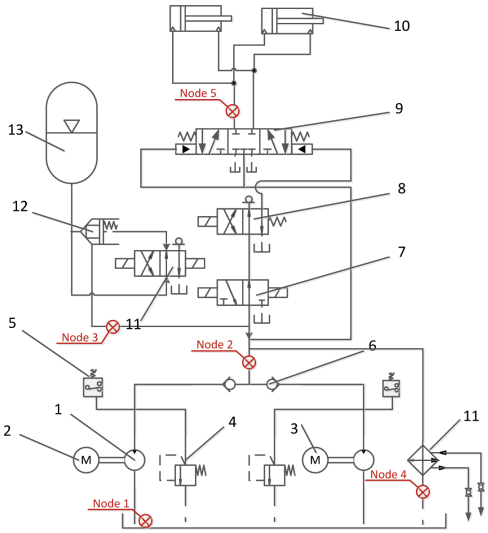

Figure 4. Speed governing system of Francis turbine. Legend: 1) Pump 2) Motor A.C. 3) Motor D.C. 4) Relief Valve 5) Pressostat 6) Check Valve 7) Proport Ional Valve 8) Emergency Valve 9) Distribution Valve 10) Cylinders Hydraulics 11) Insulation Valve 12) Command Valve 13) Accumulator 11) heat exchanger.

operating equipment. The second is the process of knowledge acquisition for fault diagnosis.

4.1 *Study and operational system description*

The speed governing system has the primary function of increasing or decreasing the power generated by the turbine when speed or frequency deviate from a reference value. According to the system demand, the speed governing system acts on the position of the blades of the distributor controlling the distributor opening and therefore the flow that reaches the rotor, generating only the required power for consumption. Figure 4 shows the speed governing system components of the Francis turbine.

The speed governor is an electro-mechanical device that detects any variation of speed in the turbine shaft and the correct it according to a reference value. In the case of Francis turbines a hydraulic actuator is used to move the ring distributor and consequently, to adjust the water flow. The distributor is a ring of adjustable blades involving the turbine rotor. To change the rotation speed of the turbine it is necessary to modify the volume of water flowing through the rotor.

Once defined the system to be studied, the functional tree of the speed governing system is presented in Figure 5. The functional tree is developed

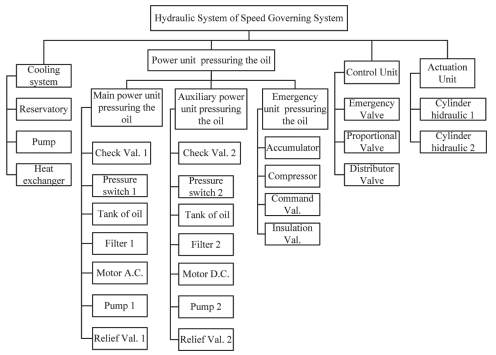

Figure 5. Functional tree of speed governing system.

based on information presented in the flow sheet presented in Figure 4 and in the plant operational guide.

The equipment is divided into main subsystems: Cooling system, oil power pressuring unit, control unit and actuation unit. Those subsystems are divided in components, each one performing a specific function linked with the subsystem main function. A failure in a component at the bottom of the tree affects all subsystems above it, causing a possible degradation in the system, represented by any change in regulation capacity or even environmental degradation.

4.2 *Knowledge acquisition for fault diagnosis*

The main purpose of a Hazard and Operability Study is to investigate thoroughly and methodically each thread of a process (focusing on specific aspects of the project—node—one at a time), in order to discover all possible deviations from normal conditions operation, identifying the causes responsible for such deviations and their consequences.

It was consulted manuals, articles, book and maintenance personnel of the plant, who regularly participate in the maintenance of equipment and possess the necessary experience about the system operation.

As a result of this systematic process four points or reference nodes were identified and considered relevant, shown in Figure 4, and the parameters and deviations associated with the guide words are described in Table 4. For each deviation identified, in each node, the causes for the events were investigated using the technique of tree failures that allows us to identify faults in simultaneously. Through the FMEA technique allowed us to identify the medium to detect these causes and present the possible maintenance policies.

In the Figure 6 the application of HAZOP and FTA analysis to node 2 can be observed as a

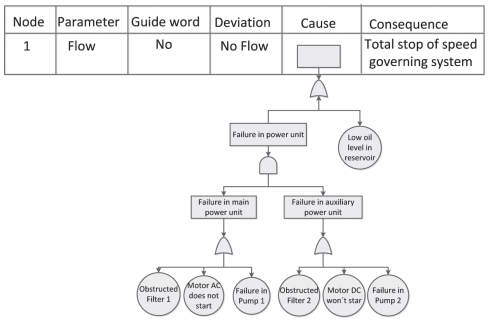

Figure 6. Application of HAZOP and FTA to node 1.

deviation when it does not have flow. As can be noted in the column of causes two causes are basic source of speed governing system stop: failure in power unit and low oil level in the reservoir. For the event failure in power unit to happen is necessary the simultaneous failure of main and auxiliary power unit. As a result of this deviation the speed is governing system inoperable causing the turbine emergency stop. The system failure can bring economic and material consequences and consecutively affecting the generation of electric power. The same way was used to prepare for each node identified in Table 4 their respective HAZOP, FTA and FMEA analysis.

Once identified the basic events analyzed for the occurrence of deviation (as an example no flow), it can observe that the basic events correspond to the failure mode of a component for that reason the FMEA technique is applied in order to identify the causes of failure that lead to the occurrence failure mode and consecutively select maintenance policies. As an example, the failure modes and effects analysis for the Electric Motor A.C. considering the failure "Motor A.C. won't start" is shown in Table 5. Those systems are submitted, according to manufacturer's recommendation, to a detailed maintenance policy based on predictive or preventive techniques.

To select an appropriate maintenance policy for the identified failure mode the maintenance team has to apply a decision process, which allows selecting the most recommended maintenance practices for each component, in accordance with the characteristics of their failure modes.

To apply the decision diagram proposed by RCM philosophy (MOUBRAY, 2000) it is necessary to carry out the classification of failures of components, as a function of the consequences of their failure on the operational performance. On the point of view of decision making in maintenance, failures can be functional or potential. Functional failures are non-fulfillment of desired component functions. The potential failure is represented by the presence of physical evidences that a process of deterioration of a component is going on, which will culminate in a functional failure.

The application of maintenance decision diagram for hydraulic systems components is shown in Table 6 taking as an example of application the analysis of the Electric Motor A.C.

According to Jingyi (2006) about 50% of the problems encountered in hydraulic systems are related to the hydraulic fluid. In this way, maintaining, controlling or eliminating the failure modes of the hydraulic fluid, can prevent a greater number of undesirable effects on the system.

The authors recommend carrying out periodical oil analysis. The tests can be performed to determine the viscosity, particle contamination and the presence of water in the fluid. The results of those tests will allow the maintenance team to identify the quality and state of the hydraulic fluid. The presence of metallic particles in the fluid can be used as indicators of bearing material degradation allowing maintenance actions planning before the bearing failure.

In case of electric motor failure can be associated to both mechanical and electrical faults. The main mechanical failures are: bearing failures and rotor and stator winding failure. Their maintenance can be based on scheduled replacement or inspection. The thermography analysis can be applied to monitor the wear of the insulation. Also for the electric motor, the shaft vibration analysis pattern can be used as an indication of potential bearing failure. Regarding the electrical devices preventive inspection, the use of thermography inspection technique is recommended aiming at checking the component temperature at periodical scan.

The pump failure can be associated with wear that can cause unbalancing and consequently mains shaft vibration. The use of accelerometers as vibration transducers allows the use of condition-based monitoring of the pump. Also, ultrasound analysis can be applied for detection of cavitation at the pump.

The use of thermography inspection technique is recommended aiming at checking the component temperature to identify internal leaks in valves and in hydraulic actuators. The seal wear can be associated particle contamination of hydraulic oil causing internal or external leaks in the valves and actuators.

The failure of the check and relief valve can be associated to both wear and fatigue degradation of spring. The use of preventive maintenance inspection and replacement can reduce the failure frequency of occurrence.

In case of accumulator failure can be associated to failed valve access oil or air, bladder rupture,

Table 4. Reference node, parameter, words guide and deviations from HAZOP analysis.

Node	Parameter	Guide word	Deviation	Consequences
1	Level	No/low	No level	SGS total stop
			Low level	High oil temperature
				Possible stop of SGS
2	Flow	No/low	No flow	Total stop of SGS
			Low flow	Total stop or possible of SGS

Table 5. Failure mode and effects analysis: example electric motor.

Component	Functional	Failure mode	Failure causes
Electric motor A.C.	Transforma electrical energy in mechanical energy to drive the pump	Motor A.C. does not start	Failure in motor terminal or broken connections
			Overload
			Low voltage to allow motor start
			Loss of insulation of the coils
			Bearings damage causing excessive friction

presence of cracks in the structure and seal wear. Their maintenance can be based on scheduled replacement or inspection. As inspection can be carry out ultrasound analysis for detection presence of cracks.

Other very important elements in the hydraulic system are the filters. The state of the filters is shown by the pressure difference observed between the input and output, which indicates possible obstruction of the component. The filters must be changed before the blockage or rupture of the filter element. The temporal evolution of this pressure differential is indicative of the occurrence of deposits on the filter and can be used as a parameter for applying the practice of predictive maintenance.

Table 6. Maintenance policies for the electric motor.

5 CONCLUSIONS

The implementation of this research has provided method to integrate reliability, risk and expert system concepts for diagnosing of operating conditions and to proposed maintenance policies in mechanical systems.

The proposed method proved to be feasible for knowledge acquisition for the development of expert system. It is important to follow the proposed flow chart, showing the sequence of activities that allow you to make detailed and reliable analysis of the system, because they are used in a logical order and organized, so that the method is applied correctly.

The process of knowledge acquisition is a major step in developing an expert system and is considered as one of the most difficult and important stages. The proposed steps for the acquisition of knowledge allows the knowledge engineer and experts to acquire the knowledge in an organized and clean manner, ensuring the quality of this acquisition.

The method developed in this paper presents the use of Functional tree and Functional Description techniques as a starting point for the knowledge acquisition. Functional tree enables to create a functional structure that maps the relationships between the various components within the system. Functional description enables to establish the interconnection between the components of the system. Moreover, identifies each component function, supporting the implementation of FMEA.

The HAZOP analysis is used to select the nodes where the analysis will be held, covering all possible deviations in the operating system by associating guide words to each of these nodes. These guide words are applied to the variables of the process and then the deviations of the processes corresponding to these variables are obtained. In order to identify the causes of deviations, FTA is applied, enabling modeling the occurrence of simultaneous events, which usually happens in mechanical systems. Given the FTA, it is possible to identify those basic events which led to the occurrence of the deviation. The Analysis of Failure Modes and Effects is applied to identify the causes of the occurrence of the basic events identified in the Fault Tree. Moreover, FMEA will assist in the proposition of recommendations for preventive or predictive maintenance, in order to minimize the possibility of the occurrence of operational deviations considered critical to the system under analysis.

As future work the fault diagnosis expert systems of Francis turbine speed governing will be developed. The expert system will be divided into four steps. In this article, the knowledge acquisition modulus is presented. Once acquired the knowledge, it will be presented in form of rules IF/THEN to build the knowledge base. Also, it will be developed the inference engine and user interface. The expert system will be developed using two programming language: Clips (C Language Integrated Production System) and Java.

ABSTRACT: The tuner is a kind of microwave electronical assembly with long-life and highly-reliable characteristics. In order to evaluate the life and reliability of tuner, the Constant-Stress Accelerated Degradation Testing (CSADT) is applied by varying temperature. The principal component analysis method is utilized to analyse the tuner degradation data of multiple performance parameters. Then, the drift Brownian motion is used in describing the degradation process of the principal component. After fitting the model by maximum likelihood estimation, the life and reliability of the tuner under operational temperature is obtained.

1 INTRODUCTION

The tuner is a kind of microwave electronical assembly, which is used to simulative process the useful signal received. It is the key part which affects the reliability of the system and has long-life and highly-reliable characteristics. For this kind of long-life and highly-reliable products, it is not an easy task to assess the lifetime and reliability by using the traditional life-testing procedures which record only time to failure data.

The Accelerated Degradation Testing (ADT) technology is the effective way to solve this problem. The ADT is not need to observe the occurrence of failure and just need to monitor the changes of specified products performance parameters. Recently, ADT has been successfully applied in many kinds of products, such as direct methanol fuel cells (Bae Suk-Joo et al. 2010), aerospace electrical connector (Chen Wenhua et al. 2011), light bars (Wang Fu-Kwun & Chu Tao-Peng 2012), satellite assemblies (Li Xiao-yang & Jiang Tong-min 2007), and so on. However, most of previous researches have been focusing on the ADT method based on single performance parameter. In practice, a product may have multiple performance parameters, but the related research is still little presently (Wang Peng & Coit David W 2004, Yang Kai & Yang Guangbin 1997, S. Lu et al. 2001). These works assume either independence of the performance parameters, or dependent with a multivariate normal distribution, which may be unrealistic in practice.

A life and reliability evaluation method of tuner by Constant-Stress Accelerated Degradation Testing (CSADT) based on multiple performance parameters is proposed in this paper. Firstly, in order to evaluate the lifetime and reliability of the tuner rapidly, the CSADT is applied by varying temperature, and the power gain and noise figure are measured. Then, the Principal Component Analysis (PCA) method is introduced to simultaneously analyse the accelerated degradation data of multiple performance parameters. Finally, the drift Brownian motion model is used in describing the degradation process of the principal component. After fitting the model by maximum likelihood estimation, the life and reliability of tuner can be obtained.

2 THE CSADT OF TUNER

The failure mechanism analysis shows that temperature is the major factor that causes tuner output degradation. So, in order to evaluate the lifetime and reliability of the tuner rapidly, a temperature CSADT with 4 stress levels has been conducted, and the power gain and noise figure of tuner are measured by a computerized measuring system. The sample size of each accelerated stress level is 3 and the parameters of testing are shown in Table 1. Where, S_1, S_2, S_3, and S_4 are indicated the accelerated stress level, and the operational stress level is $S_0 = 25°C$.

During the testing, every tuner has four performance parameters need to be measured,

Table 1. Testing parameters of tuners' CSADT.

Stress level	Temperature/°C	Censoring/hours
S_1	55	494
S_2	70	348
S_3	80	310
S_4	85	228

3 EVALUATION METHOD OF MULTIPLE PARAMETERS CSADT

3.1 *Life and reliability evaluation procedure*

The PCA and the drift Brownian motion is utilized to analyse the tuner multiple performance parameters degradation data obtained by CSADT. The research program is show in Figure 6.

In order to reduce the dimension of the tuner's performance parameters, PCA is performed on the testing data firstly. Since the obtained princi-

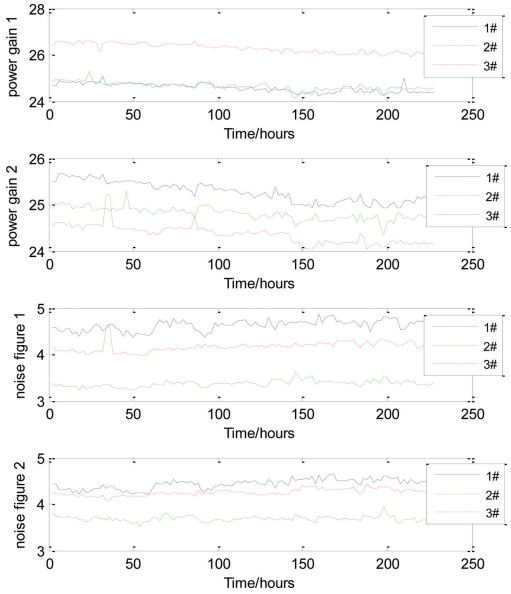

Figure 5. The testing data of all tuners on S_4.

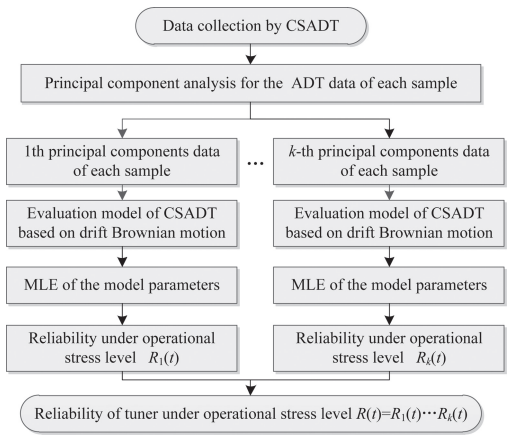

Figure 6. Life and reliability evaluation procedure of tuner.

pal components are independent to each other, the below analysis process is similar with the reliability series model. Then, the drift Brownian motion is adopted to evaluate the accelerated degradation data of the principal components. The parameters of the model are obtained through regression analysis and maximum likelihood estimating.

3.2 *Principal component analysis of ADT data*

Principal Component Analysis (PCA) is a kind of multivariate statistical analysis method, which is able to transform multiple variables into a few principal components through dimension reduction techniques.

Suppose that the number of the product performance parameters is p, and the total number of the parameters monitored in ADT is M. The matrix of the parameters observation is noted as:

$$\boldsymbol{X} = \begin{bmatrix} \boldsymbol{x}_1 \\ \boldsymbol{x}_2 \\ \vdots \\ \boldsymbol{x}_M \end{bmatrix} = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & & \vdots \\ x_{M1} & x_{M2} & \cdots & x_{Mp} \end{bmatrix} \tag{1}$$

where, each column of $\boldsymbol{X}$ corresponds to a product performance parameter, and each line corresponds to the observed values of the parameters at one monitoring. Then, the covariance matrix and correlation coefficient matrix of the sample are

$$\boldsymbol{S} = \frac{1}{M-1}\sum_{i=1}^{M}\left(\boldsymbol{x}_i - \bar{\boldsymbol{x}}\right)'\left(x_i - \bar{\boldsymbol{x}}\right) = (s_{ij})_{p\times p}$$
$$\hat{\boldsymbol{R}} = (r_{ij})_{p\times p}, \quad r_{ij} = \frac{s_{ij}}{\sqrt{s_{ii}}\sqrt{s_{jj}}} \tag{2}$$

where, $\bar{\boldsymbol{x}} = \frac{1}{M}\sum_{i=1}^{M}\boldsymbol{x}_i$ is the sample mean.

Then, the PCA can be performed by solving the eigenvalues and related eigenvectors of $\hat{\boldsymbol{R}}$. Let $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_p \geq 0$ be the eigenvalues of $\hat{\boldsymbol{R}}$, and $\mathbf{a}_1$, $\mathbf{a}_2$, …, $\mathbf{a}_p$ be the related orthogonal identity eigenvectors. The principal components are

$$\boldsymbol{y}_i = \boldsymbol{X}\boldsymbol{a}_i, \quad i = 1,2,\ldots,p \tag{3}$$

The accumulative contribution rate can reflect how much information that the principal components have extracted from the initial variable. It is usually to choose the k ($k < p$) principal components to make the accumulative contribution reach a required threshold (such as 85%).

3.3 *Accelerated model*

Accelerated model quantifies the manner in which the "life" changes with different stress levels. On the basis of the failure mechanism analysis, the key sensitive stress of tuner is temperature. Therefore, the Arrhenius model is adopted to describe the relationship between the degradation rate and the temperature.

$$L = A\cdot\exp(-E_a/kT) \tag{4}$$

where, T is the absolute temperature; k is the Boltzmann constant, 8.6171×10^{-5} eV/°C;

E_a is the activation energy with unit eV; A is a constant.

3.4 *Reliability modeling*

The drift Brownian motion (Wiener process) is commonly used stochastic processes degradation model for the degradation process.

In this research, the tuner performance degradation process $Y(t)$ can be described by the following drift Brownian motion model:

$$Y(t) = Y_0 + \sigma B(t) + \mu \cdot (t - t_0) \tag{5}$$

where, $Y(t)$ is the tuner performance parameter, and $B(t)$ is a standard Brownian motion on [0, ∞), $B(t)$~$N(0, t)$. Y_0 is the initial degradation level at time zero, and μ is the drift. σ is the dispersion and describes unit-to-unit variability due to operating and environmental conditions.

In the equation (5), the drift coefficient μ is the concerned degradation rate of the product. It characterizes the function relation between the environmental stress and the performance variables. Therefore, the relation of the drift coefficient and the temperature is the accelerated model, noted as $d(T)$, where T is the temperature. Then,

$$d(T) = A \cdot \exp(-E_a / kT) \tag{6}$$

Bhattacharyya & Fries (1982) pointed out that the product's failure time is the first passage time of the drift Brownian motion to a critical value (threshold), and it follows inverse Gaussian distribution. The corresponding reliability function is

$$R(t) = \Phi\left[\frac{a - y_0 - d(T)t}{\sigma\sqrt{t}}\right] - \exp\left(\frac{2d(T)(a - y_0)}{\sigma^2}\right) \Phi\left[-\frac{a - y_0 + d(T)t}{\sigma\sqrt{t}}\right] \tag{7}$$

where, a is the threshold, Φ is the standard normal cumulative distribution function.

For a drift Brownian motion, the differences of two consecutive performance measurements are independently, normally distributed with mean and variance proportional to the time lag between two measurements. Utilizing this property, Doksum & Normand (1995) discussed the maximum likelihood estimation of the parameters in degradation mean function and variance. Therefore, the solution to model parameter estimation is obtained by maximizing the marginal likelihood function, which in turn is obtained by integrating out the random coefficient from the joint conditional probability of individual observations (Rong Pan & Taeho Crispin 2011).

4 DATA ANALYSIS OF THE TUNER CSADT

The proposed evaluation method is used to analyse the tuner CSADT data. At the start, PCA is performed on the performance degradation data of each tuner. And the accumulative contribution rates of first principal component of all tuners are larger than 85%. Therefore, only the first principal component of each product is adopted. The first principal components of all tuners are shown in Figure 7.

Then, the drift Brownian motion is utilized to establish the reliability model for the first principal component data. The parameter estimation results

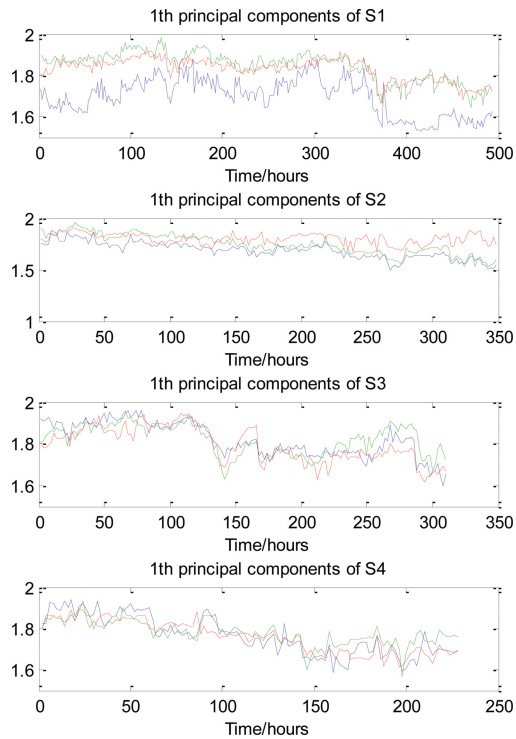

Figure 7. The first principal components of all tuners.

Parameters	A	E_a	σ
Estimates	2404.0368	0.4503	0.0156

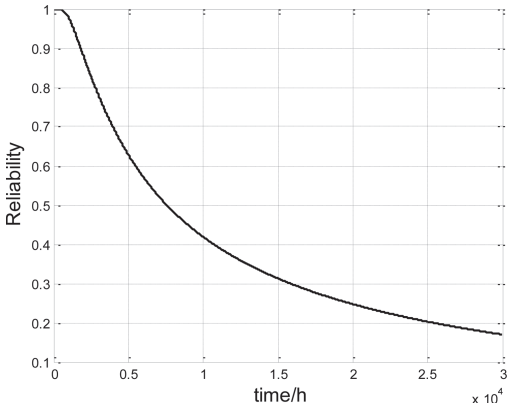

Figure 8. The reliability curve of tuner under 25°C.

are obtained through MLE, as shown in Table 2. If the failure criterion is 50% of the performance parameter initial value, the reliability curve of tuner under operational stress level (S_0 = 25°C) is shown in Figure 8.

5 CONCLUSION

Life and reliability evaluation of high reliability and long life products is hotspot and difficulty in the field of reliability research. This paper introduced a statistical analysis approach for a multiple performance parameters CSADT based on principal component analysis and drift Brownian motion. And, the life and reliability of tuner is evaluated using the proposed method. The proposed method can evaluate product life and reliability in the case of zero-failure data, which has certain reference significance to the long-life and highly-reliable products.

Estimation of lifetimes of components that operate under ageing-attributable wearing conditions

H. Tomaszek & M. Zieja
Air Force Institute of Technology, Warsaw, Poland

M. Ważny
Military University of Technology, Warsaw, Poland

ABSTRACT: The paper presents a probabilistic method to assess lifetimes of devices/components that operate under conditions typical of ageing processes. It has been assumed that the random rate of the component's wear is of the form taken by the failure rate function for the Weibull distribution, or approximately follows the linear pattern. From the point of view of mathematics, it has been based on the difference equation that, after some rearrangements, results in a partial differential equation of the Fokker-Planck type. From the particular solution to this equation one gets density function of the wear-and-tear in the form of normal distribution. Having found the density function of the wear-and-tear, one can formulate a relationship for reliability for the assumed permissible value of the wear-and-tear. With the normal distribution normalized and the required level of reliability reached, one can then compute the lifetime of a device or component under consideration.

1 INTRODUCTION

The paper presents a probabilistic method to assess lifetimes of components and (sub)assemblies that operate under conditions typical of ageing processes (induced by corrosion and/or other phenomena) within aircraft devices. Health of at least some of aircraft devices can be assessed by means of diagnostic parameters. The assessment in question needs that known are boundary values of parameters, for which the device or component is acknowledged to be serviceable (fit for use).

The diagnostic parameters can be used to describe the general condition of both the device under analysis and particular components thereof. An aircraft sight system with one of its primary functions being generation of sight information in the form of a sight marker is a pretty good example of such a device. The data found determines both the sighting angle and the angle of allowance, which reflects position of the point at which the warfare agent launched from the aircraft meets (hits) the target. Such being the case, it is necessary to determine the zero position of the optical line of sight to make the sighting system operate correctly and the aiming process proceed properly. Due to ageing processes the zero position of the line of sight given consideration gets out of the adjustment. Therefore, to improve the aiming accuracy, there is a chance and possibility to adjust the zero position of the line of sight. Such a chance appears in the course of the periodic maintenance. Corrections that allow for destructive factors are fed to the sighting system. Then, the line of sight is given its nominal parameters. What is of importance through this process is determination of time points, at which the system should be subjected to adjustment. With the system used as an example, one has to determine the system's life, i.e. to find the time up to the moment the current position of the line of sight reaches the permissible boundary value (Ważny 2008).

2 ASSUMPTIONS

The following assumptions have been made in the proposed life-assessment model (Tomaszek et al. 2011):

– the device's/system's health is determined with one diagnostic parameter „z" in the form of deviation from the initial (zero) value:

$$z = |X - X^{nom}| \tag{1}$$

where: X = current value of the diagnostic parameter, X^{nom} = nominal value of the diagnostic parameter;

– value of the diagnostic parameter's deviation keeps changing throughout the system's

operational phase (i.e. operations and maintenance, or operational use and down time);
- the 'z' parameter is non-decreasing;
- if random changes follow the linear pattern, the rate of changes in the diagnostic parameter can be described with the following relationship:

$$\frac{dz}{dt} = c \tag{2}$$

where: c = a random variable which describes the system's/component's susceptibility to changes that depend on their features and operating conditions; t = the calendar-based time;
- in the case the increment in the diagnostic parameter is non-linear it is assumed that the intensity of deviation increments takes the following form:

$$\lambda(t) = \frac{\alpha}{\theta} t^{\alpha-1} \tag{3}$$

where: α and θ = constants in the Weibull distribution.

3 HOW TO FIND THE DENSITY FUNCTION WITH ACCOUNT TAKEN OF THE RELATIONSHIP (2)

With stochastic approach applied, the dynamics of changes in value of the deviation „z" is described with the following difference equation (Casciati & Roberts 1996):

$$U_{z,t+\Delta t} = (1 - P)\, U_{z,t} + P U_{z-\Delta z,t} \tag{4}$$

where: $U_{z,t}$ = probability that at time instance t the diagnostic parameter will take value z; P = probability that in the course of time interval Δt the deviation will increase by value Δz; Δz—*i*ncrement in deviation.

For the case $P = 1$, equation (4) written down in functional notation takes the following form:

$$U(z,\ t + \Delta t) = U(z - \Delta z, t) \tag{5}$$

Equation (5) illustrates the following point: probability that at time instance t value of the deviation was $z - \Delta z$ and has increased in the course of time interval Δt by value Δz. Equation (5) is now to be rearranged in the partial differential equation. Therefore, the following approximations are assumed (Żurek et al. 2012):

$$U(z,t + \Delta t) = U(z,t) + \frac{\partial U(z,t)}{\partial t}\Delta t \tag{6}$$

$$U(z - \Delta z,t) = U(z,t) - \frac{\partial U(z,t)}{\partial z}\Delta z + \frac{1}{2}\frac{\partial^2 U(z,t)}{\partial z^2}(\Delta z) \tag{7}$$

With equations (6) and (7) applied, equation (5) takes the following form:

$$\frac{\partial U(z,t)}{\partial t} = -b\frac{\partial U(z,t)}{\partial z} + \frac{1}{2}a\frac{\partial^2 U(z,t)}{\partial z^2} \tag{8}$$

where:
$b = E[c]$ = a mean increment in value of the diagnostic parameter's deviation per time unit;
$a = E[c^2]$ = a mean square of increment in the diagnostic parameter's deviation per time unit.

Now, a particular solution to equation (8) is looked for, such that at $t \to 0$ is convergent to the so-called Dirac delta function, i.e. $u(z,\ t) \to 0$ for $z \neq 0$ and $u(0,\ t) \to +\infty$, in such a way, however, that the function integral u equals „1" for all and every $t>0$. Equation (8) takes the following form for the above defined condition (Risken 1984):

$$u(z,t) = \frac{1}{\sqrt{2\pi A(t)}} e^{-\frac{(z-B(t))^2}{2A(t)}} \tag{9}$$

where:

$$B(t) = \int_0^t b\,dt = bt = \overline{c}t, \tag{10}$$

$$A(t) = \int_0^t a\,dt = at = \overline{c}^2 \tag{11}$$

The density function of the increase in the diagnostic parameter's deviation can be used to assess reliability of the device's/system's assembly/component.

4 HOW TO FIND THE DENSITY FUNCTION WITH ACCOUNT TAKEN OF THE RELATIONSHIP (3)

With stochastic approach applied, the dynamics of changes in value of the diagnostic parameter, including the deviation, will be described with the difference equation. Let $U_{z,t}$ denotes probability that at time instance t the diagnostic parameter's deviation takes value 'z'.

A difference equation takes the following form for the assumed conditions and relationship (3):

$$U_{z,t+\Delta t} = \left(1 - \frac{\alpha}{\theta} t^{\alpha-1}\Delta t\right) U_{z,t} + \frac{\alpha}{\theta} t^{\alpha-1}\Delta t\, U_{z-\Delta z,t} \tag{12}$$

where: Δz—increment in the diagnostic parameter's deviation in time interval Δt.

Equation (12) written down in functional notation takes the following form:

$$u(z,t+\Delta t)=\left(1-\frac{\alpha}{\theta}t^{\alpha-1}\Delta t\right)u(z,t)+\frac{\alpha}{\theta}t^{\alpha-1}\Delta t\,u(z-\Delta z,t) \quad (13)$$

where:
$u(z,\ t)$ = density function of the diagnostic parameter's deviation;
$(1-\alpha/\theta(t^{\alpha-1}\Delta t))$ = probability that in time interval Δt there will be no increment in the diagnostic parameter's deviation;
$\alpha/\theta(t^{\alpha-1}\Delta t)$ = probability that in time interval Δt the increment in the diagnostic parameter's deviation will be Δz.

Rearrangement of equation (13) in a partial differential equation results in the following approximation:

$$u(z,t+\Delta t)=u(z,t)+\frac{\partial u(z,t)}{\partial t}\Delta t \quad (14)$$

$$u(z-\Delta z,t)=u(z,t)-\frac{\partial u(z,t)}{\partial z}\Delta z+\frac{1}{2}\frac{\partial^2 u(z,t)}{\partial z^2}(\Delta z)^2. \quad (15)$$

Having substituted relationships (14) and (15) in equation (13) and with some rearrangements done, the following is arrived at:

$$\frac{\partial u(z,t)}{\partial z}=-\frac{\alpha}{\theta}t^{\alpha-1}\Delta z\frac{\partial u(z,t)}{\partial z}+\frac{1}{2}\frac{\alpha}{\theta}t^{\alpha-1}(\Delta z)^2\frac{\partial^2 u(z,t)}{\partial z^2}. \quad (16)$$

Consideration is given to the increment in the diagnostic parameter's deviation per time unit (when $\Delta t=1$), hence

$$\frac{\Delta z}{\Delta t}=c,\Rightarrow \Delta z=c\Delta t,\ \underset{\Delta t=1}{\Rightarrow}\ \overline{c} \quad (17)$$

where $\overline{c}$ denotes increment in the diagnostic parameter's deviation per one time unit.

With account taken of what has been deduced above, equation (16) takes the form:

$$\frac{\partial u(z,t)}{\partial z}=-\underbrace{\frac{\alpha\overline{c}}{\theta}t^{\alpha-1}}_{\gamma(t)}\frac{\partial u(z,t)}{\partial z}+\frac{1}{2}\underbrace{\frac{\alpha\overline{c}^2}{\theta}t^{\alpha-1}}_{\beta(t)}\frac{\partial^2 u(z,t)}{\partial z^2} \quad (18)$$

As one can see, the forms of coefficients in equation (18) depend on values of parameters α. For $\alpha=1$ the coefficients take the forms:

$$\gamma(t)=\frac{\overline{c}}{\theta};\ \beta=\frac{\overline{c}^2}{\theta} \quad (19)$$

For $\theta=1$, the case in question resolves itself into the description of linear wear of stochastic form. Solution to equation (18) (for conditions described in p. 3) takes the following form:

$$u(z,t)=\frac{1}{\sqrt{2\pi A(t)}}e^{-\frac{(z-B(t))^2}{2A(t)}} \quad (20)$$

where:
$B(t)$ = an average value of the diagnostic parameter's deviation for the operating time t,

$$B(t)=\int_0^t\gamma(t)dt \quad (21)$$

$A(t)$ = a variance of the diagnostic parameter's deviation for the operating time t,

$$A(t)=\int_0^t\beta(t)dt \quad (22)$$

With integrals (21) and (22) calculated, the following expressions are arrived at:

$$B(t)=\int_0^t\frac{\alpha\overline{c}}{\theta}t^{\alpha-1}dt=\frac{\alpha\overline{c}}{\theta}\int_0^t t^{\alpha-1}dt=\frac{\alpha\overline{c}}{\theta}\frac{1}{\alpha}t^{\alpha}\Big|_0^t=\frac{\overline{c}}{\theta}t^{\alpha}-0=\frac{\overline{c}}{\theta}t^{\alpha} \quad (23)$$

$$A(t)=\int_0^t\frac{\alpha\overline{c}^2}{\theta}t^{\alpha-1}=\frac{\alpha\overline{c}^2}{\theta}\frac{1}{\alpha}t^{\alpha}\Big|_0^t=\frac{\overline{c}^2}{\theta}t^{\alpha} \quad (24)$$

5 DETERMINATION OF RELIABILITY AND LIFETIME OF THE DEVICE'S COMPONENT

With the density function found, one can write down the relationship for reliability and life with respect to time of the diagnostic parameter's deviation increasing up to the boundary value. The formula takes the form:

$$R(t)\cong\int_{-\infty}^{z_d}u(z,t)dz\cong\int_0^{z_d}u(z,t)dz \quad (25)$$

where: $u(z,t)$ = density function determined with equation (9) or equation (20); z_d = a permissible value of the diagnostic parameter's deviation with respect to safety; t = the calendar-based time of operating the device/system.

Figure 1 schematically shows how the density function proceeds and how reliability and life are determined.

If the relationship

$$\omega(t) = \frac{B(t)}{\sqrt{A(t)}} \tag{26}$$

exceeds the value of 3.5 in a short time, then the lower limit of the integral in equation (25) can be assumed $-\infty$ (Pham 2006).

The random variable z is standardized:

$$l_t = \frac{z - B(t)}{\sqrt{A(t)}} \tag{27}$$

After standardization equation (25) takes the form

$$R(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\frac{z_d - B(t)}{\sqrt{A(t)}}} e^{-\frac{l_t^2}{2}} dl \tag{28}$$

Assuming that the required value of reliability is $R(t)=R^*$, the value of the upper limit of the integral, such that the integral (28) equals R*, is to be found in the Standard Normal Distribution Table. Let w be this value. Hence,

$$w = \frac{z_d - B(t)}{\sqrt{A(t)}} \tag{29}$$

Having solved equation (29) with respect to t one receives such value of t^*, for which the level of reliability, for $t \le t^*$, is $R(t) \ge R^*$. Therefore, t^* can be assumed either the component's life or time of the deviation's increasing up to the value that does not exceed the level assumed the permissible value.

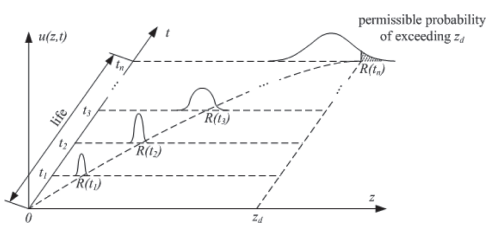

Figure 1. Schematically shown density function.

Two models have been given consideration. One linear, of stochastic nature, and the other one non-linear. The relationship (29) takes, therefore, two forms:

– for a linear model:

$$w = \frac{z_d - \bar{c}t}{\sqrt{\bar{c}^2 t}} = \frac{z_d - bt}{\sqrt{at}} \tag{30}$$

– for a non-linear model:

$$w = \frac{z_d - \frac{\bar{c}}{\theta} t^\alpha}{\sqrt{\frac{\bar{c}^2}{\theta} t^\alpha}} = \frac{z_d - \bar{b} t^\alpha}{\sqrt{\bar{a}} t^\alpha} \tag{31}$$

Now, t is found from the relationship (30).

$w\sqrt{at} = z_d - bt,$
$w^2\, at = (z_d - bt)^2,$
$w^2\, at = z_d^2 - 2z_d\, bt + b^2\, t^2,$
$b^2t^2 - 2z_d\, bt + z_d^2 - w^2\, at = 0,$
$b^2t^2 - (2z_d\, \mathrm{b} + w^2 a)t + z_d^2 = 0.$

Hence,

$$t_{1,2} = \frac{-\left(-\left(2bz_d + w^2 a\right)\right) \pm \sqrt{\left(2bz_g + w^2 a\right)^2 - 4b^2 z_d^2}}{2b^2},$$

$$t^* = \frac{\left(2bz_d + w^2 a\right) \pm \sqrt{\left(2bz_g + w^2 a\right)^2 - 4b^2 z_d^2}}{2b^2} \tag{32}$$

From relationship (31) t is found. We assume $\theta = 1$ and find $t^\alpha = s$. Hence,

$$w = \frac{z_d - bs}{\sqrt{as}} \tag{33}$$

Equation (33) is in its notation exactly the same as equation (30); after rearrangement the following is, therefore, arrived at:

$$s^* = \frac{\left(2bz_d + w^2 a\right) \pm \sqrt{\left(2bz_g + w^2 a\right)^2 - 4b^2 z_d^2}}{2b^2} \tag{34}$$

Hence,

$$t^* = \frac{\log s}{\alpha} \tag{35}$$

To make use of the above written relationships, one should find values of (assess) constants in these equations. Therefore, it is assumed that data on values

of deviation of the diagnostic parameter come from monitoring the device under examination throughout its operational phase (Kececioglu 2002):

$$[(z_0, t_0), (z_1, t_1), (z_2, t_2), \ldots, (z_n, t_n)]. \quad (36)$$

The best method to find values of b and a is one that uses the likelihood function. The form of it in the general case can be presented as the following relationship (37) (Dhillon 1999):

$$L = \prod_{k=0}^{n=1} g(t_k, z_k, \theta_1, \theta_2, \ldots, \theta_m) \quad (37)$$

where: $g(t_k, z_k, \theta_1, \theta_2, \ldots, \theta_m)$ = the density function of the total probability of the variable z; $(\theta_1, \theta_2, \ldots, \theta_m)$ = parameters of the density function; z_k = the measured values of the wear-and-tear parameter z with suitably at time instances $(t_1, t_2, \ldots, t_k)$. Finding estimates $\theta_1^*, \theta_2^*, \ldots, \theta_m^*$ of unknown parameters $(\theta_1, \theta_2, \ldots, \theta_m)$ with the maximum likelihood method resolves itself in solving equations of the following form (Tomaszek et al. 2008):

$$\frac{\partial \ln L}{\partial \theta_j} = 0 \quad (38)$$

where: $j = 1,2, \ldots, m$; m = the number of parameters that best describe the engineered object in question.

Such being the case, estimation of b^* and a^* of unknown parameters b and a with the maximum likelihood method resolves itself into solving a system of equations:

$$\begin{cases} \dfrac{\partial \ln L}{\partial b} = 0 \\ \dfrac{\partial \ln L}{\partial a} = 0 \end{cases} \quad (39)$$

Solving the system of equations (39) one finds b^* and a^*:

$$b^* = \frac{z_n}{t_n} \quad (40)$$

$$a^* = \frac{1}{n} \sum_{k=0}^{n-1} \frac{\left[(z_{k+1} - z_k) - b^*(t_{k+1} - t_k)\right]^2}{(t_{k+1} - t_k)} \quad (41)$$

6 A NUMERICAL EXAMPLE

One of the components of a sighting system is a surveillance-and-sighting head, by means of which the aiming information is displayed. Its health is determined with diagnostic parameters that describe coordinates of the sighting marker's position. Having analyzed results of checks of some specific population of sighting heads it has been found that as the operating time elapses, due to destructive factors affecting the system, values of these parameters suffer changes. A sample course of changes in value of one of the diagnostic parameters recorded in the course of the operational process has been presented in Figure 2. From the plot one can deduce that in this case a linear model of changes in diagnostic parameters is used (Ważny 2008 & 2009).

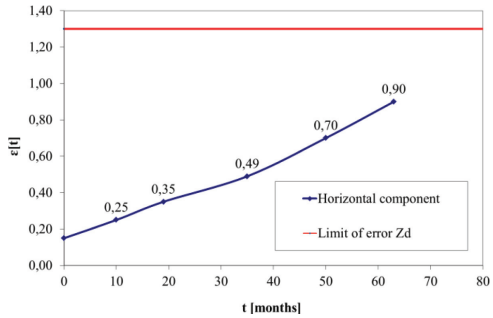

Figure 2. Changes in value of the diagnostic parameter throughout the sighting head's operation.

Therefore, having got data that describe values of diagnostic parameter's deviation in the following form:

$$[(z_0, t_0), (z_1, t_1), (z_2, t_2), \ldots, (z_n, t_n)]$$

and on the basis of equations (40) and (41), values of coefficients of the density function could be found:

$$b_\varepsilon^* = 0{,}034 \qquad a_\varepsilon^* = 0{,}001 \quad (42)$$

Assuming the level of maintaining the zero state, value of the parameter $\gamma^* = 2{,}35$ could be found from the Standard Normal Distribution Table. The z_d parameter could be found in the system's technical documentation (Maintenance Manual), where values of permissible deviations of diagnostic parameters are given.

Thus, values of parameters $b_\varepsilon^*, a_\varepsilon^*, \gamma^*, z_d$ have been substituted in equation (32); time, after which values of deviations of the diagnostic parameters reach and exceed the boundary state has been calculated. For the case under analysis this time is:

$$t_\varepsilon = 17 \text{ [months]} \quad (43)$$

Results gained (43) can be used in maintenance procedures, depending on the maintenance

strategy accepted. On the basis of the above-presented methodology, one can find subsequent time intervals (periods of time), when the device's/system's diagnostic parameter(s) should be checked and adjustments made to bring values of measured quantities to the zero (nominal) position.

7 FINAL REMARKS

To recapitulate, one can state that the above-presented method seems to be correct and right, and allows of analyses of the device's/system's health with reference to the nature of changes in values of diagnostic parameters. The presented numerical example has made verification of the formulated model possible and emphasizes application-oriented qualities of the developed method. The method may prove suitable for further works on improving both the operational/maintenance processes and the way of using the aircraft with its on-board systems, all this owing to the capability of determining time the device/system remains serviceable (fit for use).

Furthermore, owing to its versatility, the method can be successfully used to determine residual life of any engineered object, the health of which is determined on the basis of analyses of values of diagnostic parameters.

A Physics-of-Failure-based approach for failure behavior modeling: With a focus on failure collaborations

Z. Zeng, R. Kang & Y. Chen
School of Reliability and Systems Engineering, Beihang University, Beijing, China

ABSTRACT: Traditional Physics-of-Failure (PoF) methods assume independence among failure mechanisms. In this paper, a failure behavior modeling approach is proposed to allow for considering interdependence in PoF modeling. The interdependence is characterized by modeling failure mechanisms and relations among them. Three basic relations among failure mechanisms, i.e., competition, superposition and coupling are discussed in the first place. Models for the three relations are also established. Based on the developed relation models, the failure behavior modeling approach is presented. Finally, a case study of a spool valve is conducted to show that the proposed method can provide a more accurate description of failure behaviors than traditional PoF methods.

1 INTRODUCTION

Failure behaviors of a system refer to the observable changes of system states which take place during the system's failure process. Characterization of failure behaviors plays a central role in reliability engineering (Zeng et al. 2013). Traditionally, failure behaviors of a system are characterized by recording time-to-failure of the system and fitting a probability distribution to them (Meeker & Escobar 1998). However, fitting TTF distributions requires collecting large amount of failure data, which severely limits the applicability of TTF-based characterization of system failure behaviors. To cope with this problem, more and more researchers are trying to use Physics-of-Failure (PoF) as a new way to characterize system failure behaviors.

PoF models establish relationships among failure inducing factors, their corresponding failure times and failure phenomena by understanding physical processes leading to the failure (failure mechanisms). The concept of PoF was formally established in 1962 in the first of a series of symposia (which now becomes the International Reliability Physics Symposium, IRPS) organized by the Rome Air Development Center (RADC) of the US Air Force (Chatterjee et al. 2012). From then on, researches have been conducted to develop PoF models for various failure mechanisms and products. Till today, most of the commonly encountered failure mechanisms have been well understood and modeled. For example, McPherson (2010) and Liu et al. (2011) discuss commonly encountered failure mechanisms for electronic products and interconnects and summarize PoF models. For discussions on mechanical failure mechanisms and corresponding PoF models, readers can refer to Tinga (2013) and Collins et al. (2009).

The well-established PoF models lay down a solid foundation of PoF-based system failure behavior modeling. Generally, there are three PoF-based system failure behavior modeling approaches. Pecht & Dasgupta (1995) propose a TTF-oriented method to characterize a system's failure behavior based on components' PoF models. They assume that the shortest TTF among all failure mechanism will determine the TTF of the whole system (failure competition) and thus, by calculating TTF of each failure mechanism, TTF of the system can be decided.

The second PoF-based failure behavior modeling method is the Failure-Rate-oriented (FR-oriented) method. The method uses failure rates as a measure of system failure behaviors. A typical example of the method is the RAMP method developed by IBM cooperation (Srinivasan et al. 2003). Under the assumptions of constant failure rate and failure competition, the method firstly calculates the Mean Time To Failure (MTTF) of each component from corresponding PoF models. Then, failure rates of the system are established by summing up all components' failure rates.

Apart from the aforementioned two methods, another PoF-based failure behavior modeling method tries to model the variation of systems' performance measures over time and uses the performance measures as an indicator of failure behaviors. For example, Savage & Son (2011) proposes a framework to obtain the variations of systems' performance measures over time from

PoF-based degradation models. Cao et al. (2014) uses PoF-based degradation model of electronic devices to determine the performance degradation in circuit levels.

The three PoF-based failure behavior modeling methods have been applied widely in both academia and industries. However, they share a defect, i.e., all of them are grounded on the assumption of failure competition. The assumption suggests that all the failure mechanisms evolve independently from each other and the mechanism with the shortest TTF will determine the TTF of the system. However, in actual cases, failure mechanisms often interact with each other and thus exhibit some collaboration behaviors (by collaboration we mean the mechanisms "work together" to cause failures). For example, it is widely observed that collaborations exist among failure mechanisms to accelerate the failure processes, e.g., the interaction between fatigue and corrosion (Dong et al. 2012), fatigue and creep (Zhu et al. 2012), erosion and corrosion (Malka et al. 2007), etc. The assumption of failure competition ignores these collaboration effects and thus will lead to inaccurate results when predicting failure behaviors.

In fact, some progress has been achieved in modeling the collaboration effects among failure mechanisms, e.g. Burgazzi (2009) used coefficient of variances to model the interdependence among failure mechanisms. Peng et al. (2010) developed a model for interdependency among a generic degradation process and a shock process. Keedy & Feng (2013) proposed a similar model and applied it to analysis a stent with dependent competing failure processes. However, all these researches provide methods to model the collaboration effects in a statistical way. Few methods have provided the physical insights of failure collaborations. In this paper, we will present a physics-based method to analysis and model the failure collaborations.

2 A TWO-TIER STRUCTURE FOR MODELING FAILURE COLLABORATIONS

Since the principle of failure competition obtains the TTF of the system as the shortest TTF among all the failure mechanism models, it does not take the interaction among the failure mechanisms into account. The interaction, referred to as failure collaboration in this paper, has a hierarchical structure of two tiers, as shown in Figure 1. In the component-tier, failure collaboration refers to the interactions among failure mechanisms. When a component is subjected to multiple failure mechanisms, the mechanisms might exert influences on each other, as shown in Figure 1. For example,

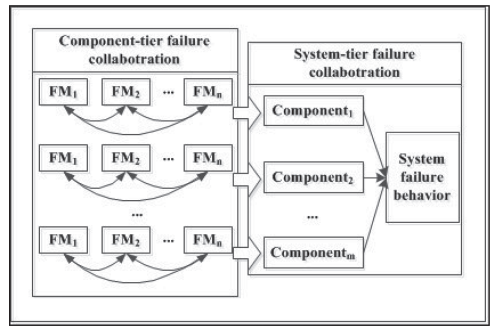

Figure 1. The two-tier structure of failure collaboration. FM: Failure Mechanism.

it is observed from experiment data that the two mechanisms, erosion and corrosion are mutually enhanced, resulting in a more significant degradation effect (Malka et al. 2007). Also, failure collaboration exists in test specimens exposed to high temperature and heavy load, where the two failure mechanism of fatigue and creep interact with each other and severely reduce the TTF of the test specimens (Zhu et al. 2012). In microelectronic devices, similar but more sophisticated phenomena can also be observed between the two mechanisms Hot Carrier Injection (HCI) and Negative Bias Temperature Instability (NBTI) (Kufluoglu 2007). The interactions among the failure mechanisms are regarded as component-tier failure collaboration.

Even for components subjected to only one failure mechanism, which means there is no failure collaboration in the component-tier, we still have to consider the effect of the system-tier failure collaboration. In the system-tier, failure collaboration refers to the joint effects of the components on the failure behavior of the system, as shown in Figure 1. According to Figure 1, the failure behavior of components is determined from their corresponding failure mechanisms. Failure behaviors of the system are in turn decided by the failure behaviors of the components. In the process, different components might contribute to the same failure behavior of the system and thus result in the system-tier failure collaboration.

In order to accurately model the system's failure behavior, both the component-tier and system-tier failure collaboration should be addressed properly. However, in this paper, we mainly focus on the modeling of component-tier failure collaboration (the treatment of system-tier collaborations will be addressed in a separated paper) and model the component-tier failure collaboration from two perspectives, i.e., failure mechanisms and interactions among them.

3 COMPONENT-TIER FAILURE BEHAVIOR MODEL DEVELOPMENT

3.1 *Performance parameter and failure behavior model*

In this section, a PoF-based component failure behavior modeling approach will be presented to characterize failure behaviors under the influences of component-tier failure collaborations. Failures are the event or state that a system no longer fulfills its intended function. In most cases, a system's function can be represented by several performance parameters. A failure state is reached when the performance parameter exceeded its associated failure threshold.

Definition 1. Suppose a given function of a system (or a component) will not be fulfilled if and only if the following inequality holds,

$p \geq p_{th}$.

Then parameter p is defined as a performance parameter of the system, while p_{th} is defined as the associated failure threshold.

Example 1. A beam is designed with a function of withstanding a given load. Thus, its performance parameter is the stress σ calculated from the load, and associated failure threshold is the strength of the beam $[\sigma]$. When $\sigma \geq [\sigma]$, failures of the beam will take place.

Example 2. A spool valve is designed with a function of controlling the flow of hydraulic oils. The enlargement of the spool's clearance due to wear will lead to oil leakage and thus affects the desired function. Therefore, a performance parameter of the spool is its clearance x, and its corresponding failure threshold x_{th} will be determined from its functional requirements, so that when $x \geq x_{th}$, failures of the spool will take place.

Thus, failure behaviors can be characterized by developing a model for the performance parameter and its variation over time, as shown in equation (1). In equation (1), $\mathbf{x}$ denotes a vector of failure inducing factors. By substituting p_{th} into equation (1), TTF of the system (or component) can be determined, as shown in equation (2).

$$p = f_{be}(\mathbf{x};t). \tag{1}$$

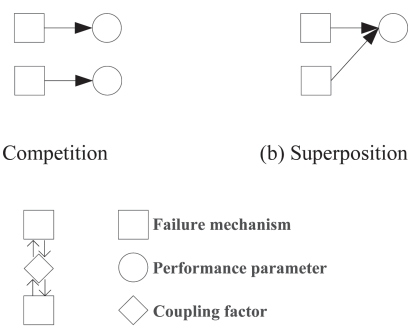
$$\mathrm{TTF} = \arg_t \left(f_{be}(\mathbf{x};t) = p_{th} \right). \tag{2}$$

3.2 *Models for mechanism interaction relations*

Performance parameters in equation (1) can be obtained from PoF models. However, as shown in Figure 1, failure collaboration effects exist in component tier and should be accounted for in the development of component failure behavior model. The collaboration effects can be modeled as a combination of three basic interaction relations among failure mechanisms, i.e., competition, superposition and coupling.

3.2.1 *Models for mechanism competition*

Competition is an interaction relation among two or more failure mechanisms where each mechanism contribute to a specific performance parameter and the presence of one mechanism has little or no influence on the others, as shown in Figure 2(a). Thus, the interactions among failure mechanisms can be modeled by the weakest-link model, where the failure mechanism first evolves to failure will determine the failure behavior of the component. If the failure mechanism models takes the form of equation (1) (which means, the performance parameters will vary over time), the weakest-link model can be expressed as equation (3).



$$TF = \min_{i=1}^{n} TF_n. \tag{3}$$

Example 3. An example of mechanism competition is the failure of composite plies (Whiteside et al. 2012). There are three failure mechanisms for the composite ply and each of them results in a specific failure mode. The mechanisms include fiber tensile (f_{ft}), matrix failure (f_{mat}) and fiber kinking/splitting ($f_{kink/split}$) and models describing them are presented in Eq. (4) to (6).

1. Fiber tensile

$$f_{ft} = \left(\frac{\sigma_1}{\sigma_L^+} \right)^2 \geq 1, \tag{4}$$

where σ_1 is the main stress and σ_L^+ is the tensile strength in the longitudinal direction parallel to the fibers.

(a) Competition (b) Superposition

(c) Coupling

Figure 2. Illustrations of the three basic interaction relations.

2. Matrix failure

$$f_{mat} = \left(\frac{\tau_{23}^{\phi_0}}{\tau_T - \mu_T \sigma_n^{\phi_0}} + \frac{\tau_{12}^{\phi_0}}{\tau_L - \mu_L \sigma_n^{\phi_0}} + \frac{\sigma_{n+}^{\phi_0}}{\sigma_T^+} \right) \geq 1, \tag{5}$$

where $\tau_{23}^{\phi_0}, \tau_{12}^{\phi_0}, \sigma_n^{\phi_0}$ is the components of stresses in the specific directions, $\tau_T, \tau_L, \sigma_T^+$ are the corresponding strengths and μ_L, μ_T are coefficient of frictions in the specific directions.

3. Fiber kinking/splitting

$$f_{kink} = f_{split} = \left(\frac{\tau_{23}^{m_0}}{\tau_T - \mu_T \sigma_2^{m_0}} \right)^2 + \left(\frac{\tau_{12}^{m_0}}{\tau_T - \mu_T \sigma_2^{m_0}} \right)^2 + \left(\frac{\sigma_{2+}^{m_0}}{\sigma_T^+} \right). \tag{6}$$

The meaning of each parameter is consistent with those in equation (4) and (5). In an actual composite ply, the three mechanisms are independent from each other and the weakest link model can be used to model the interactions among them, as shown in equation (7).

$$f_{PB} = \max\left(f_{ft}, f_{max}, f_{kink}, f_{split} \right) \geq 1. \tag{7}$$

3.2.2 *Models for mechanism superposition*

Superposition is an interaction relation among two or more failure mechanisms where all the mechanisms contribute to one performance parameter, as shown in Figure 2(b). Superposition of failure mechanisms can be modeled by summing up all the variation rates individually determined by each failure mechanism, as shown in equation (8),

$$\frac{dp}{dt} = \sum_{i=1}^{n} \frac{dp_i}{dt}, \tag{8}$$

where dp/dt is the variation rate resulting from all mechanisms and $dp_i/dt, i = 1,2,\ldots,n$ are the variation rates resulting from each individual failure mechanism. From the performance variation rate determined from equation (8), the failure behavior model in equation (1) can be obtained easily given the initial conditions.

Example 4. An example of mechanism superposition is the relation between two failure mechanism models contributing to Time-Dependent Dielectric Breakdown (TDDB) (McPherson 2010). TDDB can be modeled by two mechanism models, the E-model (equation (9)) and the 1/E-model (equation (10)).

$$TF = A_0 \exp\{-\gamma E_{ox}\} \exp\left\{ \frac{Q}{K_B T} \right\}. \tag{9}$$

$$TF = \tau_0(T) \exp\left\{ \frac{G(T)}{E_{ox}} \right\}. \tag{10}$$

Since the two mechanisms exist simultaneously, the velocity summation principle is employed to model the time to failure of TDDB, as shown in Eq (11),

$$k = k_E + k_{1/E}, \tag{11}$$

where k, k_E, $k_{1/E}$ are the rate constant of the whole process, the E-model and the 1/E-model, respectively. If the rate of each model is a constant, equation (11) leads to

$$TF = \frac{TF_E \cdot TF_{1/E}}{TF_E + TF_{1/E}}. \tag{12}$$

3.2.3 *Models for mechanism coupling*

Coupling is an interaction relation among two or more failure mechanisms where the presence of one mechanism will exert influence on the other mechanisms, as shown in Figure 2(c). In order to accurately model failure behaviors under coupled failure mechanisms, one has to start with an investigation of the way in which the mechanisms are coupled. Often the couplings are caused by the change of driving conditions of one mechanism due to the affections from other mechanisms. For example, the wear of materials will deteriorate their strengths and in turn affect the fatigue life under cyclic loads. The coupling effect can be modeled by introducing the concept of coupling factor.

Definition 2. Coupling factors are parameters in one of the coupled failure mechanisms which are influenced by the other failure mechanisms.

Equation (13) shows how to use coupling factors to model the coupling effects of two failure mechanisms. In equation (13), p denotes the performance parameter, $f_{FM_1}(\cdot), f_{FM_2}(\cdot)$ are the two PoF models, respectively, x_{couple} is the coupling factor and $\mathbf{x}_{rest}, \mathbf{x}_2$ are other parameters in the PoF models.

From an analysis of the coupling process, we can identify the coupling factors, i.e., the x_{couple} in equation (13). Then, coupling relations are modeled by the $g(\cdot)$ in equation (13). To determine the form of $g(\cdot)$, a deeper analysis should be conducted into the coupling mechanisms. Finally, equation (13) is solved to obtain the performance parameter p. Sometimes the $\mathbf{x}_2$ in $g(\cdot)$ might be a function of p, making equation (13) hard to be solved. Thus,

approximations are often needed when trying to solve equation (13).

$$\begin{cases} p = f_{FM_1}\left(\mathbf{x}_{rest}, x_{couple}; t\right), \\ x_{couple} = g\left(f_{FM_2}\left(\mathbf{x}_2; t\right)\right). \end{cases} \tag{13}$$

Example 5. An example of modeling coupled failure mechanisms is the failure behavior model for components subjected to the coupling of fatigue and creep (Collins et al. 2009). For components subjected to only low-cycle fatigue, a Coffin-Manson model will approximate the failure behaviors quite well (Equation (14)). In equation (14), N_f is the TTF in cycles, $\Delta\gamma_p$ is the plastic strain range and both m and C are constants associated with material properties.

$$\left[N_f\right]^m \Delta\gamma_p = C. \tag{14}$$

The coupling effects of creep and fatigue result that frequency of applied loads also influences the failure behavior. Thus, a coupling factor k is introduced in equation (14) to model the coupling effect, as shown in equation (15). In equation (15), υ is the frequency of applied loads and k is the coupling factor. The coupling factor k is determined from the coupling mechanism of creep and fatigue. Since it is much too complicated to be modeled, the value of k in equation (15) is often determined via experiments (Collins et al. 2009).

$$\left[N_f \upsilon^{k-1}\right]^m \Delta\gamma_p = C. \tag{15}$$

In actual cases, interaction relations among failure mechanisms might be a combination of the three basic relations discussed above. The failure behavior models can be built by the same combination of the three relation models. An example will be given in Sect. 4 to illustrate how to use combinations of basic relations to model failure mechanisms.

4 CASE STUDIES

4.1 *Failure mechanisms and PoF models*

A spool valve in an aviation hydraulic actuator is chosen as a case study to demonstrate the proposed PoF-based component failure behavior modeling approach. As discussed in Example 1, the performance parameter of the spool is its clearance. According to the result of failure mode, mechanism, effect analysis (Liao, 2013), the spool is subjected to two failure mechanisms, i.e., adhesive wear and abrasive wear.

Adhesive wear can be modeled by Archard model (Archard 1953), as shown in equation (16). In equation (16),

x_{adh} is wear depth cause by adhesive wear,

K_{adh} is a constant associated with surface conditions and lubrication,

W_a is the normal load in the wear surfaces and

H_m is the hardness of the wear surface.

$$\frac{dx_{adh}}{dt} = K_{adh}\frac{W_a}{H_m} = k_1. \tag{16}$$

Abrasive wear can be modeled by equation (17). In equation (17), K_{abr} is a constant associated with the wear properties of the wear surfaces while other parameters in equation (17) share the same meaning as those in equation (16).

$$\frac{dx_{abr}}{dt} = K_{abr}\frac{W_a}{H_m} = k_2. \tag{17}$$

The constants k_1 and k_2 are often estimated from wear experiments. Both equation (16) and (17) suggest that the wear depth is a linear function of time. Thus, if we do not take into the collaboration effects into account, the PoF models will suggest constant rate wear process.

4.2 *Failure collaboration effects*

However, collaboration effects exist between the two failure mechanisms, as shown in Figure 3. Both the wear depth from adhesive wear and abrasive wear contribute to the total wear depth x_{total}. Thus, superposition relation exists between the two mechanisms.

Besides, the K_{adh} in Archard model is influenced by the surface roughness σ_S. The result of the two wear mechanism will in turn change the surface roughness. Thus, the two failure mechanisms are coupling together.

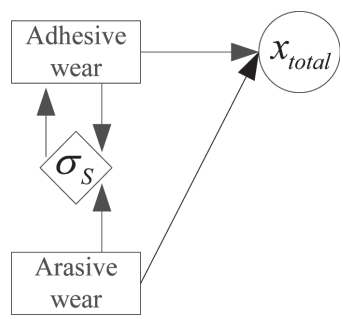


Figure 3. Failure collaborations of the two mechanisms.

4.3 *Failure behavior model development*

In order to develop failure behavior model for the spool, the model for mechanism superposition and coupling should be combined. From superposition model (equation (8)), we have

$$\frac{dx_{total}}{dt} = \frac{dx_{adh}}{dt} + \frac{dx_{abr}}{dt} = k_1 + k_2. \tag{18}$$

In equation (18), k_1,k_2 denote the wear velocity decided from adhesive and abrasive wear, respectively. Traditionally, the coupling effects between the two failure mechanisms are omitted in the development of failure mechanism model. Thus, a linear model shown in equation (18) is used as the traditional PoF model for components subjected to wear mechanisms.

In this case study, we use the proposed method to model the coupling of the two failure mechanisms. Since K_{adh} is a function of σ_S and σ_S is a function of x_{total}, it is assumed that

$$k_1 = g\left(x_{total}\right). \tag{19}$$

By using its first order Tylor expansion as an approximation of equation (19) and assuming that $g(0) = 0$, we have,

$$k_1 = -k'_1 x_{total}. \tag{20}$$

Substitute equation (20) into equation (18) and solve for x_{total}, we have,

$$x(t) = \frac{k_2 - \exp\left\{-k'_1 t + \ln k_2\right\}}{k'_1} \tag{21}$$

Equation (21) is the failure behavior model after considering the collaboration effects.

4.4 *Experimental results and discussions*

In order to compare the built failure behavior model built from the proposed method with that from traditional method, a wear test is conducted. Wear depths are monitored at equal intervals, as shown in Figure 4 (The wear depth data are scaled for confidential reasons). Failure behavior model in equation (21) and a linear model (traditional method) are both fitted to experimental data. The results are also shown in Figure 4.

It can be seen from Figure 4 that the failure behavior model from the proposed method provides a better fit to experimental data than the linear one from traditional method. This conclusion can be justified from the Mean Square Error (MSE) of both models. The MSE of proposed model is 0.5298, which is far less than the 5.7981 of the traditional model.

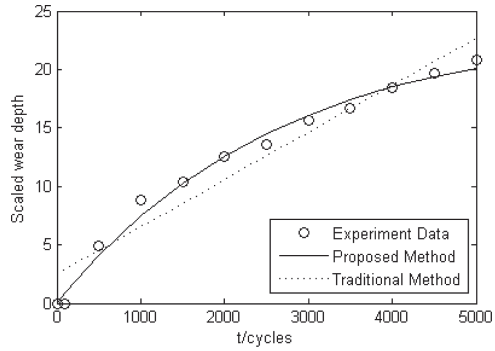

Figure 4. Experimental results and model fitting.

The result can be explained by the trends of experimental data. From Figure 4, we can see that the wear rate of the spool is decreasing over time, which suggests that the spool is in running-wear period. In this period, the interaction between the two wear mechanisms tends to slow down the wear process. However, the traditional method ignores this interaction effects and thus leads to inaccurate results. Since the proposed method has taken the interaction between the two failure mechanisms into account, it outperforms the traditional model in this case study.

5 CONCLUSIONS

In this paper, three basic interaction relations among failure mechanisms are discussed and the models for these relations are developed. A PoF-based component-tier failure behavior modeling approach is then proposed. Based on the developed interaction relation models, the proposed method provides a tool to model the interdependencies among failure mechanisms in a physical way.

ACKNOWLEDGEMENT

The work in this paper is supported by the Innovation Foundation of Beihang University (BUAA) for PhD Graduates.

The authors would also like to express special appreciations to Mr. Liao Xun for his help in the analysis of wear mechanisms and the design and implementation of wear tests.

Fault diagnosis method for circuit board based on BP neural networks

Y. Peng & J. Shi
School of Reliability and System Engineering (Science and Technology on Reliability and Environmental Engineering Laboratory), Beihang University, Beijing, China

ABSTRACT: This paper presents a new fault diagnosis method for circuit boards based on BP neural networks. First, a description of traditional fault diagnosis methods is given and the shortcomings are demonstrated. To improve the accuracy of fault diagnosis, a new method based on BP neural networks is proposed, which takes the temperature data of chips as well as voltage data as the basis of diagnosis. Finally, an example is provided, which shows that the proposed method performs better in fault diagnosis of the circuit board.

1 INTRODUCTION

In modern times, electronic equipment has become more and more complex, which usually leads to a higher failure rate of the system. Once a crucial fault happens, the function of the equipment may be heavily affected. To guarantee the efficiency of maintenance, the system capability of accurate fault identification is of great significance (Shi et al. 2012).

In recent years, some intelligent fault diagnosis methods, such as fault trees, expert systems and fuzzy comprehensive evaluation, are commonly used in electric devices (Yu et al. 2012). Besides, with its strong ability of parallel information processing and adaptive learning, ANN (Artificial Neural Network) has also become an ideal tool for fault diagnosis. Among the ANNs, BP neural network, which is a typical feedforward neural network owning strong capabilities to execute function approximation, classification and non-linear mapping, has been widely used in fault diagnosis of circuits (Li et al. 2011).

However, there are some shortcomings in the traditional method of circuit fault diagnosis with BP neural network. Firstly, because of the limit of test points, not all the failure modes can cause obvious voltage changes of the specific points monitored by the voltage acquisition system, which lowers the system fault identification rate. Next, when a fault happens in the feedback circuit, change in voltage data is sometimes too slow for neural networks to diagnose the fault correctly. Moreover, BP neural network may make specific mistake in fault diagnosis due to the data characteristics in practical application. Last but not the least, there are always some failure types causing the same voltage change that the network cannot distinguish.

To solve the problems above, we propose a multi-BP neural network, which takes both voltage and chip temperature data of a circuit as diagnosis information. In this paper, the principle of BP neural network is given. Then the new fault diagnosis method based on BP neural network is proposed. Finally, the new method is applied to an experiment, which shows its efficiency in fault identification.

2 PRINCIPLE OF BP NEURAL NETWORK

2.1 *Structure and algorithm*

As is shown in Figure 1, BP neural network is a multi-layer feedforward network with error back-propagation learning, which consists of an input layer, an output layer and several hidden layers. Each layer includes a set of neurons interconnected by weight (Han et al. 2009).

A Common BP ANN has two basic steps of execution. The first step is forward computation, which means the output value is calculated layer

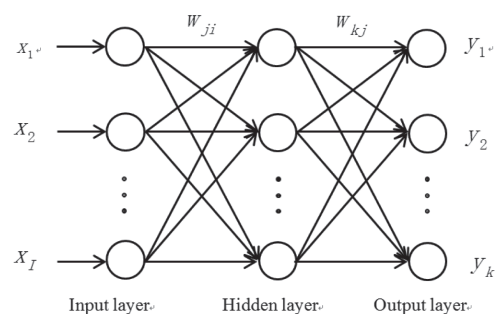

Figure 1. Three layer BP neural network.

by layer due to the weights and biases. The second step is backward computation, at which step the weights and biases are updated by reducing the error between the output value and the expected one. The process of training a network is the repetition of forward and backward computations (Dong & Watanabe 2008).

Taking a three-layer BP network model for example, the BP algorithm is described as follows. Appoint the input vector $X = \{x_1, x_2, x_3, \ldots, x_I\}$, the output vector $Y = \{y_1, y_2, y_3, \ldots, y_K\}$, and the hidden layer neuron number J.

For the input layer nodes i, its output is equal to $x_i (i = 1, 2, 3, \ldots, I)$. So the input and the output of the hidden layer nodes j are as follows:

$$s_j = \sum_{i=1}^{I} w_{ji} \cdot x_i - \theta_j \tag{1}$$

$$o_j = f(s_j) \tag{2}$$

where $j = 1, 2, \ldots, J$; s_j stands for the input of the hidden layer nodes j; o_j stands for the output of the hidden layer nodes j; w_{ji} stands for connection weight from the hidden layer to the input layer; θ_j stands for the threshold.

The input and output of the output layer nodes k are as follows:

$$h_k = \sum_{k=1}^{K} w_{kj} \cdot o_j - \theta_k \tag{3}$$

$$y_k = f(o_k) \tag{4}$$

where $k = 1, 2, \ldots, K$; h_k stands for the input of the output layer nodes k; y_k stands for the output of the output layer nodes k; w_{kj} stands for connection weight from the output layer to the hidden layer; θ_k stands for the threshold (Sun & An 2009).

2.2 *Application in fault diagnosis*

In the traditional fault diagnosis of circuits based on BP neural network, voltage data of key points which can be obviously affected by faults is usually taken as input information of the network. Generally, the output of the net is the codes of failure modes. After the data samples obtained from the simulation or fault injection experiments, training and testing can be carried out (Ma et al. 2013).

3 FAULT DIAGNOSIS METHOD

3.1 *Structure*

Considering the problems of traditional diagnosis method based on BP neural network put forward in INRODUCTION, this paper propose a new method of fault identification.

According to the experiment results, the occurrence of faults in circuits usually causes obvious temperature variation of the main chips. Though the variation speed is lower than that of voltage, it can be used for supplementary information to make results more accurate in fault diagnosis.

In this arithmetic, two BP neural networks are established, named net α and net β.

The input information of net α is the key voltage data of the circuit. Sometimes, for a better effect of classification the data ought to be processed in advance such as filtered or uniformized when necessary. As usual, the output of net α is the codes of failure modes, which indicate where the faults locate. Generally a code usually represents several failure modes, for the reason that there are always some failure types causing the same voltage change.

The temperature data of main chips can be obtained from temperature sensors. In spite of the influence of environment, the difference value of temperature between chips remains stable in rated working condition. Thus the difference between the temperature and the average value of chips in the circuits can be taken as a feature of working state. So the input of node i of net β is described as follows:

$$x_i = temp_i - \frac{\sum_{q=1}^{I} temp_q}{I} \tag{5}$$

where *temp* stands for the temperature value of the chip.

If the variation ranges differ greatly, the temperature values can be classified into groups according to the variation. At this time, the input data of net β is the difference between the temperature and the average of the group. Same with net α, the output of net β is the codes of fault modes.

Data samples obtained from the simulation or fault injection experiments ought to be divided into training and testing data set. After separate training and testing, make record of all the wrong identification results of net α. Then the final diagnosis result can be gained from the integration of net α and net β outputs, the arithmetic of which is proposed in the Section 3.2.

3.2 *Arithmetic of output integration*

Appoint the failure mode set represented by net α output codes is S_1, the set represented by net β output codes is S_2, and the set of the final diagnosis result is S. When a set is empty, it

means the circuit works normally with no faults happening.

As usual, the shortcomings that neural networks may present in fault diagnosis are described as follows:

– There are several failure types causing the same voltage change that the network cannot distinguish.
– The failure mode set C in fact is identified as set D.
– The normal working state is identified as failure mode set E by mistake.
– Failure mode set F cannot be identified when happening.

All the C, D, E, F sets can be recorded in the testing process. Appoint the C, D, E, F sets of net α are C_1, D_1, E_1, F_1 and those of net β are C_2, D_2, E_2, F_2. Then arithmetic of output integration is proposed as follows based on the logic:

– When S_1 is empty, if $S_2 = S_1$ or $S_2 \subseteq E_2$, then $S = S_1$, meaning that the circuit works normally. If $S_2 \subseteq F_1$, then $S = S_2$.
– When $S_1 \subseteq D_1$, if $S_2 = S_1$, then $S = S_1 = S_2$. If $S_2 \subseteq C_1$, then $S = C_1$.
– When $S_1 \subseteq E_1$, if $S_2 = S_1$, then $S = S_1 = S_2$. If S_2 is empty, then $S = S_2$.

Table 1. Output integration rule.

$S_1 = \phi$	$S_2 = \phi$	$S = \phi$
	$S_2 \subseteq E_2$	$S = \phi$
	$S_2 \subseteq F_1$	$S = S_2$
$S_1 \subseteq D_1$	$S_2 = S_1$	$S = S_1 = S_2$
	$S_2 \subseteq C_1$	$S = C_1$
$S_1 \subseteq E_1$	$S_2 = S_1$	$S = S_1 = S_2$
	$S_2 = \phi$	$S = S_2$
$S_1 \neq \phi$	$S_2 \neq \phi$	$S = S_1 \cap S_2$
$S_1 \not\subset (D_1 \cup E_1)$	$S_2 \not\subset (D_2 \cup E_2)$	

– When S_1, S_2 is not empty, $S_1 \not\subset (D_1 \cup E_1)$, and $S_2 \not\subset (D_2 \cup E_2)$, then $S = S_1 \cap S_2$.

As is shown is Table 1, the description above can be summarized.

4 APPLICATION

4.1 *Transformer circuit*

The fault diagnosis method is applied to a transformer circuit which is designed to alternate current of 28 V to 12 V, 5 V, and 0.9 V. Shown in Figure 2, the circuit consists of three main parts, the 12 V transforming and voltage-stabilizing circuits, the 5 V transforming and voltage-stabilizing circuits, and the 0.9 V transforming and voltage-stabilizing circuits, each of which also contains a temperature sensor circuit.

4.2 *Neural network establishing*

As is shown in Table 2, there are 9 main failure modes in this circuit. Due to the influence on the voltage, the faults are classified into 4 groups, in each of which net α cannot distinguish a failure mode from another. For convenience, these groups are coded from 001 to 100, which is the output of net α. In the same way, the modes are also grouped according to the influence on temperature in experiments.

Then construct net α. The data of three output voltage is taken as the input. For net β, the input is the difference value between the chip temperature and the average. The nodes of each network input layer, hidden layer and output layer are set as 3, 5 and 3. Overall system error is E = 0.001.

With the data acquisition system, 300 sets of samples are obtained. Then execute the training and testing. Record the results as Table 3.

F8	0.1952	0.3648	0.2193	F
F9	0.2450	0.7467	0.1921	F

Table 5. Results of net β.

Failure	Output 1	Output 2	Output 3
F1	0.1652	0.2644	0.8739
F2	0.2261	0.1732	0.7994
F3	0.1054	0.9376	0.2268
F4	0.0943	0.8792	0.2655
F5	0.1375	0.9121	0.8747
F6	0.8649	0.2032	0.1295
F7	0.1053	0.2476	0.2341
F8	0.8264	0.8753	0.1429
F9	0.9023	0.8937	0.1362

Carry out the experiments separately and make record of the neural network outputs when a fault happens, shown as Table 4 and Table 5. Then make a judgment of the correctness of net α results.

Table 6. Final diagnosis results.

	Results of net α	Results of new method
F1	F1, F2, F3	F1, F2
F2	F1, F2, F3	F1, F2
F3	F1, F2, F3	F3
F4	F4, F5	F4
F5	F4, F5	F5
F6	–	F6
F7	–	–
F8	–	F8, F9
F9	F5	F8, F9

After the calculation of output integration, we can get the final fault diagnosis results and make a comparison with the traditional diagnosis results, shown as Table 6.

From the comparison of the fault diagnosis results, it can be seen that the new method increases the fault identification rate from 44.4% to 88.9%, and makes the diagnosis result more accurate.

5 CONCLUSIONS

Based on BP neural network, a new method of fault diagnosis of circuits is proposed. According to the results of experiments, the problems which traditional diagnosis methods are faced with are solved with this method. With the increase of fault identification rate, this method enhances the efficiency of circuit fault diagnosis.

Physics of Failures (POF) version B for MTBF prediction

Y. Bot & J.B. Bernstein
BQR Reliability Engineering Ltd., Israel

ABSTRACT: In this article we will presents a method for predicting the failure rate, MTBF, and thus the reliability of an electronic system by summing the failure rates of each known failure mechanism, as specified in the JEDEC standard JEP-122G. We use a competing acceleration factor methodology by combining the physics of failure for each mechanism with their effects as observed by High/Low temperature and High/Low voltage stresses. Our new method assumes that lifetime of each of its failure mechanisms follows constant rate distribution and each mechanism is independently accelerated by the stress factors, which include also frequency, current, and other factors that can be entered into a reliability model. The overall failure rate also follows an exponential distribution and is described in the standard FIT (Failure unIT or Failure in Time). The method combines mathematical models for the known failure mechanism and solves them simultaneously at a multiplicity of accelerated life tests to find a consistent set of weighting factors for each mechanism. The result of solving the system of equations is a more accurate and a unique combination for each system model by proportional summation of each of the contributing failure mechanisms. This method is applied to board design using our established parameters based on the chip technology and to chip manufacturers by matching HTOL Data with the foundry's reliability models.

1 THE CHALLENGE

Modern chips are composed of tens or hundreds of millions and even billions of transistors. Hence, chip level reliability prediction methods are mostly statistical allowing a constant-rate assumption to be applied. Chip level reliability prediction tools, today, model the failure probability of the chips at the end of life, when the known wear-out mechanisms are expected to dominate. However, modern reliability tools do not predict the random, post burn-in, constant failure rate that would be seen in the field. All the current physics of failure solutions try to determine an average effect that can be represented by a single relation that gives an average value for the Mean Time Between Failures (MTBF), however this single relation can never reflect the true physics of multiple mechanisms.

Chip and packaged system reliability is measured by a FIT. The FIT is a rate, defined as the number of expected device failures per billion part hours. A FIT is assigned for each component multiplied by the number of devices in a system for an approximation of the expected system reliability, MTBF. The semiconductor industry provides an expected FIT for every product that is sold based on operation within the specified conditions of voltage, frequency, heat dissipation and etc. Hence, a system reliability model is a prediction of the expected for an entire system as the sum of the FIT rates for every component.

A FIT is defined in terms of an acceleration factor, A_F, as:

$$\mathrm{FIT} = \frac{\#\mathrm{failures}}{\#\mathrm{tested} \cdot \mathrm{hours} \cdot \mathrm{AF}} \cdot 10^9 \tag{1}$$

where #failures and #tested are the number of actual failures that occurred as a fraction of the total number of units subjected to an accelerated test. The acceleration factor, A_F, must be supplied by the manufacturer since only they know the failure mechanisms that are being accelerated in the High Temperature Operating Life (HTOL) and it is generally based on a company proprietary variant of the MIL-HDBK-217 approach for accelerated life testing. The true task of reliability modeling, therefore, is to choose an appropriate value for A_F based on the physics of the dominant failure mechanisms that would occur in the field for the device.

The acceleration of a single failure mechanism is a highly non-linear function of temperature and/or voltage. The temperature Acceleration Factor (AF_T) and voltage Acceleration Factor (AF_V) can be calculated separately and is the subject of most studies of reliability physics. The total acceleration factor of the different stress combinations will be the product of the acceleration factors of temperature and voltage,

$$AF = \lambda(T_2,V_2)/\lambda(T_1,V_1) = [\![AF]\!]_t * [\![AF]\!]_v = \exp[E_a/k(1/T_1 - 1/T_2)]\exp(\gamma_1(V_2 - V_1)) \tag{2}$$

This acceleration factor model is widely used as the industry standard for device qualification. However, it only approximates a single dielectric breakdown type of failure mechanism and does not correctly predict the acceleration of other mechanisms. The challenge to accurate reliability prediction is to incorporate multiple mechanisms into the calculation of MTBF.

1.1 *Multiple mechanism solution*

Our unique system makes the assumption of multiple failure mechanisms whereby each will be accelerated differently depending on the physics that is responsible for each mechanism. If an HTOL test is performed at an arbitrary voltage and temperature for acceleration based only on a single failure mechanism, then only that mechanism will be accelerated. In that instance, which is generally true for most devices, the reported FIT (especially one based on zero failures) will be meaningless with respect to other failure mechanisms. Thus, In order to make an accurate approximation to a true field failure rate, electronic devices should be considered to have several failure modes degrading simultaneously. Each mechanism 'competes' with the others to cause an eventual failure. When more than one mechanism exists in a system, then the relative acceleration of each one must be defined and averaged at the applied condition. Every potential failure mechanism should be identified and its unique AF should then be calculated for each mechanism at a given temperature and voltage so the FIT rate can be approximated for each mechanism separately. Then the final FIT will be the sum of the failure rates per mechanism, as is described by:

$$FIT_{total} = FIT_1 + FIT_2 + \ldots + FIT_i \quad (3)$$

whereby each mechanism leads to an expected failure unit per mechanism, FIT_i. Unfortunately again, individual failure mechanisms are not uniformly accelerated by a standard HTOL test, and the manufacturer is forced to model a single acceleration factor that cannot be combined with the known physics of failure models.

In order to address this fundamental limitation of qualifying the reliability with only a single mechanism model, we developed a special multiple-mechanism qualification approach that allows companies to tailor specifications to a variety of customer's needs.

Chip manufacturers can use our software to design a custom Multiple HTOL *(M-HTOL)* test that matches their results with the foundry's reliability models or with JEDEC models to make accurate MTBF calculations based on specific customer's environments including voltage, temperature and speed. The board manufacturers can use the data from our models based on multiple failure mechanisms to calculate the system MTBF based on the device technology.

1.2 *Benefits*

This approach fits the highly developed and sophisticated models of the foundry based on years of knowledge and testing of the physical failure mechanisms. These mechanisms are known inherently to lead to degradation and ultimately to a chip failure. Our approach puts this knowledge in the hands of the chip designers allowing for qualification at any expected operating conditions. This way, the same product may accommodate additional potential markets by selling the same design for higher reliability applications with broader operating margins or higher performance applications where long life is not as critical.

The traditional single-model HTOL gives an unrealistically low value for the expected FIT and customers invariably find that their application shows a much higher reported failure rate than what was provided by the supplier using the traditional approach. Our M-HTOL matrix methodology will give a more accurate prediction for the expected field failure rate that is based on actual test data and on the reliability models provided by the foundry to the chip designer. This way, the designer has a much more dependable picture for device reliability and the customer will be satisfied that his design will match their customer's expectations for performance life.

1.3 *Features the matrix method*

As part of processing the results, experimental results are collected into a database. Determine acceleration factors for the various failure mechanisms, a matrix is constructed based on the JEDEC standard and experimental results. The matrix is a forecasting tool that allows the supplier to determine the dominance of each failure mechanism and its relative contribution to the chance occurrence of a system failure. By solving a system of equations whose information can be obtained from the matrix, one can assess and even predict the acceleration time for the multiple causes of a component failure and thus can calculate the duration of the warranty and the exact lifetime of the component.

The basic method for solving the system of equations is based on the suggestion of a Sum-of-failure-rate method as described in JEDEC Standard JEP122G. It is clear that the manufacturers of

electronic components recognize the importance of combining failure mechanisms in a sum-of-failure-rates method. Also, the formula for each mechanism is well studied and published.

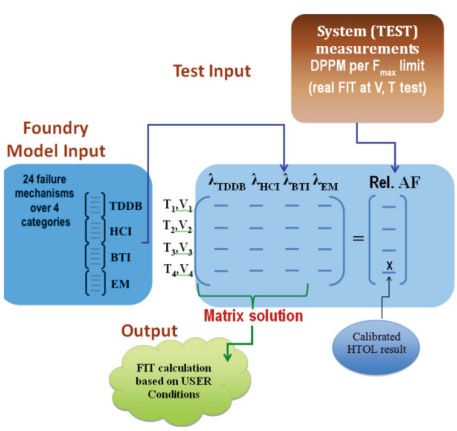
Hence, the standard system reliability FIT can be modeled using traditional MIL-handbook-217 type of algorithms and adapted to known system reliability tools, however, instead of treating each component as individuals, we propose treating each complex component as a series system of sub-components, each with its own reliability matrix.

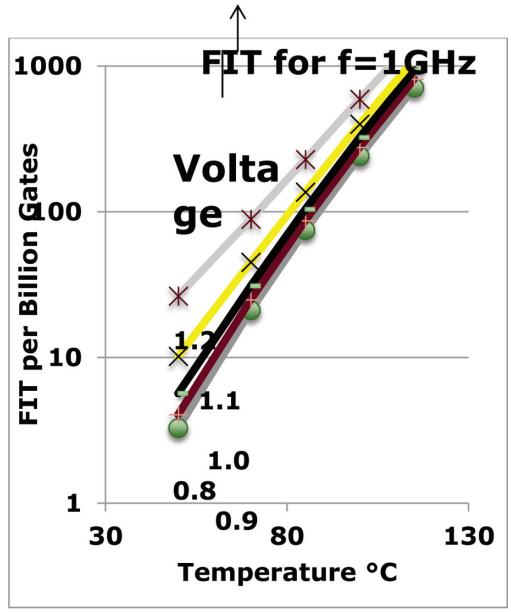
1.4 *Workflow*

The workflow for solving MTBF using our Sum-Of-Failure-Rate Matrix is shown:

A failure mechanism matrix can be solved at any given set of conditions, i.e. voltage, temperature and frequency, as a percentage at each stressed operating condition, there is a unique proportion of each mechanism for a given set of stressed conditions that will result in the given time to fail.

In order to find a relative failure rate for each mechanism, we take the accelerated life test at various voltages and temperatures and extrapolate to an end-of-life time at each temperature and voltage condition. For each condition, a consistent failure criterion must be chosen and the times to reach that condition yield "Mean Time To Fail" (MTTF) for the given conditions of voltage and temperature. Since the formula for percentage degradation is given as $y = \ldots$ Thus, solving each formula for the time to fail gives the results for the extrapolated failure rate. The Acceleration Factors (AF) are the ratio of the longest time to fail divided by the extrapolated time to fail for the other conditions. Also, an absolute FIT value





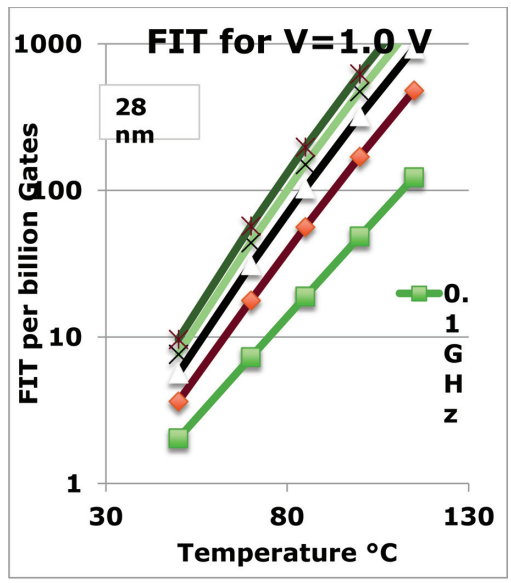


Figure 1. Workflow.

a) Voltage

b) Frequency

Figure 2. Extrapolated failure rate (FIT) versus temperature for different a) Voltage and b) Frequency.

is determined in the next row based on the Mean time to fail. This allows calibration of the final results in operation. The solution of this matrix gives us a relative importance for each mechanism and allows for failure rate prediction at any given voltage, frequency and temperature as seen below.

2 SUMMARY

We present here for the first time a simple and accurate way to combine the physics of failure equations for reliability prediction from accelerated life testing. We show that a matrix approach allows the reliability physics equations to be fit proportionally to the results of monitored accelerated life testing in order to extrapolate failure rate one would expect given actual operating parameters. This methodology can be extended to include radiation effects, frequency and even packaging and solder joint effects to give a complete system reliability evaluation framework.

This approach fits the highly developed and sophisticated models of the foundry based on years of knowledge and testing of the physical failure mechanisms. These mechanisms are known inherently to lead to degradation and ultimately to a chip failure. Our approach puts this knowledge in the hands of the chip designers allowing for qualification at any expected operating conditions. This way, the same product may accommodate additional potential markets by selling the same design for higher reliability applications with broader operating margins or higher performance applications where long life is not as critical.

An adaptive fault detection threshold hardware circuit design to reduce False Alarms

Y. Cui, J. Shi, L. Chen, K. Liu & W. An
School of Reliability and System Engineering, Beihang University, Beijing, China

ABSTRACT: Built-In Tests (BITs), responsible for detecting and isolating faults, are widely used in mechanical and electronic products to improve reliability and testability. However, the False Alarm (FA) phenomenon greatly reduces the BIT accuracy and credibility, which becomes one of the most troublesome problem in BIT applications. Compared with the single-threshold fault detection method, an adaptive and automatically adjustable threshold for determining the current state would better to reduce false alarms. In this paper, an adaptive fault detection threshold hardware circuit is designed and tested. The concept of the adaptive fault detection threshold strategy is introduced at the beginning. The outlines and details of circuit design implementations are also discussed, including the function requirements, input/output specifications, and implementation tools. Finally, a hardware BIT circuit board monitoring a typical fault mode is made out, and a performance analysis of the hardware design is carried out.

1 INTRODUCTION

Built-In Tests (BITs) are widely used in mechanical and electronic systems to find whether system faults occur (Malcolm 1982, Jager 1984), aiming at reducing the time of fault detection, raising system availability and reliability (Steininger 2000). However, the false alarms phenomenon is always a troublesome problem in BIT applications: a BIT can make a noise when a fault does not occur, resulting in extra detachments and inspections (Anderson & Laskey 1988, Westervelt 2004, Khan et al. 2014). The operators may lose heart towards the unreliable indications, or feel disturbed and annoyed towards the nuisance alarms (Adnan et al. 2011).

One of the major causes of false alarms is the operating condition factors or environment changes (Allen 2003, Byington 2010). A BIT using a single fixed threshold is more apt to be entangled with false alarms (Qi et al. 2008). For an open fault, the basic detection and judgment rules are: when the monitoring voltage is higher or equal to the fixed threshold, the BIT will remain silent. When the monitoring voltage declines and cross below the fixed threshold, the BIT will give an alarm.

However, the operating condition of a product is uncertain and unsteady. A voltage deviation is common for a product in the normal operating stage, but the voltage at some time points may be lower than the threshold and causes the BIT actions (Westervelt 2002). In this case, there is actually no faults, and a fixed BIT threshold would not be so satisfactory. Some researchers proposed the concept of adaptive threshold to reduce false alarms (Balaban & Simpson 1983, Simpson & Agre 1983). However, only the concept of adaptive threshold are discussed in these papers. It remains to be seen how to determine the value of the threshold, as well as the adaptive BIT can solve what kinds of problems. At the same time, the current researches focused much less on the hardware implementations of the adaptive threshold BITs than the BIT design concept.

The major contribution of this paper is to propose a designing method of an adaptive threshold BIT that can accommodate to operation condition changes, which is seldom considered in pervious works. The adaptive BIT aims at identifying real hard faults from environmental changes, and thus reduce false alarm rate. To achieve this, the hardware designing approach of capturing signal changing speed is presented to distinguish an environmental change from a hard fault. The BIT can automatically adjust its threshold following the direction of the signals under test.

The remainder of this paper mainly focuses on the fault detection model of the electronic products containing instant faults (i.e. hard faults), and take the environmental changes and external stresses into consideration. The fault and false alarm model is introduced and a type of BIT circuit adopting an adaptive threshold is developed. The hardware implementations are discussed in this paper according to the designing requirements, and a printed circuit board is also made for test and verification.

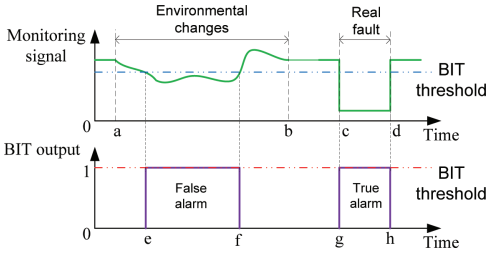

Figure 1. False alarm profile.

2 FALSE ALARM PROFILE

This part we mainly consider the faults and false alarm phenomenon of electronic product experiencing environmental changes or sustaining external stresses. For electronic products, the typical hard faults like open faults or short faults are all instant faults, i.e. hard faults (Fenton et al. 2001, Weglarz & Saluja 2004). The fault occurs suddenly, and the duration of fault development can be regarded as zero.

The operating environment of the electronic product may have an effect on the output signal monitored by a BIT. For one thing, the parameter drifts caused by temperature or humidity changes are very common for electronic products. For another, some external stresses (e.g. vibration) can indirectly reflected on the monitoring signal. These variations of the monitoring signal do not necessarily mean a fault occurs, yet the BIT would not recognize it and declares a fault. Compared with a hard fault, the effect of the environmental changes or the external stress is relatively slow.

A false alarm profile records the monitoring signal and false alarm conditions during a period of time. Figure 1 gives an example of a BIT using a single fixed threshold for fault detection. In Figure 1(a), the operating environment begin to change before at t = a, leading down the voltage of the monitoring signal. At t = e when the voltage begin to be lower than the threshold, the BIT misunderstands this and false alarm happens. With the revocation of the environmental changes, the voltage climes up and the BIT stops alarming at t = f. At t = c, a hard fault (e.g. open fault) really happened, and the BIT gives a correct indication. The false alarm coverage rate is dependent on the false alarm profile.

3 SYSTEM-LEVEL DESIGN

3.1 *Designing principles*

From Figure 1, we can see that the BIT using a single fixed threshold is not a good choice when the operating condition of the electronic product is not very optimistic. To solve the problem, we proposed the approaches of adopting adaptive detection threshold.

The designing principles are as follows. If an environmental change or external stress is identified, the BIT threshold will change following the direction of the original monitoring signal. This means when the monitoring signal climbs up, the BIT threshold will also rise; when the monitoring signal goes down, the BIT threshold will correspondingly decline. The reaction volume of the BIT threshold follows a direct proportion relationship. In our research, the direct ratio is set to be 0.5. However, when a hard fault (open or short) is identified, the threshold will remain the same, and the BIT should detect the fault.

3.2 *System structure*

The system structure of the BIT circuit is shown in Figure 2. The names and functions of the modules are listed below.

- Signal Variation Detection Module (SVDM), which detects the changing speed of the monitoring signal.
- Comparison Module (CM), which compares the changing speed. If the speed is lower than the predetermined value, then an environmental change or external stress is identified and CM outputs "1". On the contrary, if the speed is higher than the predetermined value, then a hard fault is identified and CM outputs "0".
- Gating Module (GM), which controls signals to pass through. When CM outputs "1", the SVDM output will be selected and pass through. Otherwise, the SVDM output is blocked.
- Threshold Difference Construction Module (TDCM), which makes compensations for the monitoring signal variations. In other words, TDCM is responsible for generating a reaction volume of the BIT threshold following a direct proportion relationship.

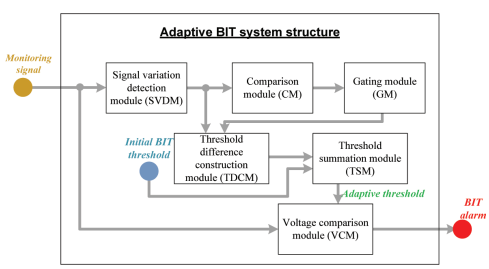

Figure 2. System structure of adaptive BIT circuit design.

– Threshold Summation Module (TSM), which adds the threshold difference on the original threshold to construct new adaptive threshold.
– Voltage Comparison Module (VCM), which executes the BIT voltage comparison function to give an alarm that indicates a fault.

4 HARDWARE IMPLEMENTATIONS

4.1 *Signal Variation Detection Module (SVDM)*

In order to capture the speed change of the monitoring signal, we use the differentiation circuit carried out with the aid of LM324 op amps. A capacitor is used at the input connection. A typical integration circuit using an op amp is placed as the feedback loop of the main op amp. For this application, a positive differentiation of the monitoring signal can be obtained. A low pass filter composed of a capacitor and a resistance is attached at the end of this module to avoid undesired peaks. The schematic diagram of Signal Variation Detection Module (SVDM) is shown in Figure 3.

4.2 *Comparison Module (CM)*

We compare the output of SVDM with a preset determination value. If the absolute value of the former is below the latter, then the comparison module outputs a digital high level "1"; otherwise a digital low level "0". The function of the module is achieved by using two voltage comparators in a LM339 chip. The first one is responsible for restricting the upper bound, and the second is responsible for restricting the lower bound. With the pull-up resistors linked to a +5V voltage, the outputs of the LM339 chip can either be about 5V or 0V, which can be recognized as the digital high level "1" or the digital low level "0". The schematic diagram of Comparison Module (CM) is shown in Figure 4.

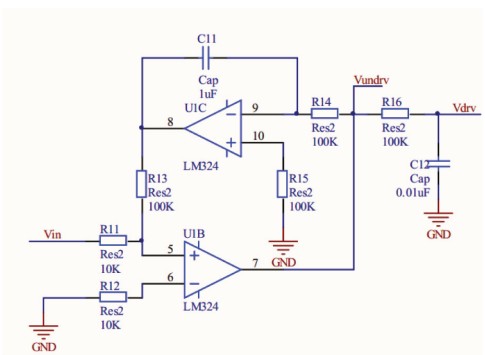

Figure 3. Schematic diagram of Signal Variation Detection Module (SVDM).

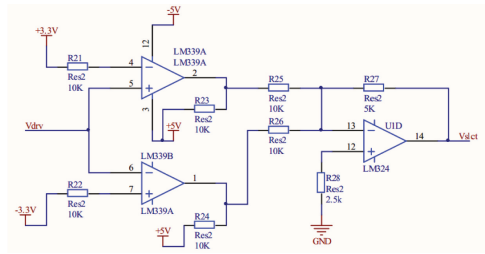

Figure 4. Schematic diagram of Comparison Module (CM).

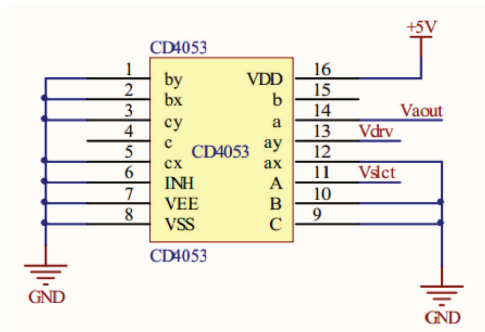

Figure 5. Schematic diagram of Gating Module (GM).

4.3 *Gating Module (GM)*

In this BIT circuit, we use a CD4053 Triple 2-channel analog multiplexer to serve as the gating module. The analog multiplexers in the chip are digitally controlled analog switches. CD4053 has three separate digital inputs A, B and C. We only use switch a and ax, ay for convenience. The analog ground and the digital ground are all set to be 0V. The connections of the chip are determined according to the truth table. The schematic diagram of Gating Module (GM) is shown in Figure 5. Together with CM, the theoretical comparison and gating model is illustrated in Figure 6.

4.4 *Threshold Difference Construction Module (TDCM)*

This module is responsible for constructing a threshold difference that follows the variation direction/volume of the monitoring signal. This is actually the complementary function to differentiation, and can be carried out by an integration circuit with the aid of an op amp. The current in the feedback loop charges the capacitor, which provides a negative integration value of the input signal. It is noted that a switch is added in parallel with the capacitor.

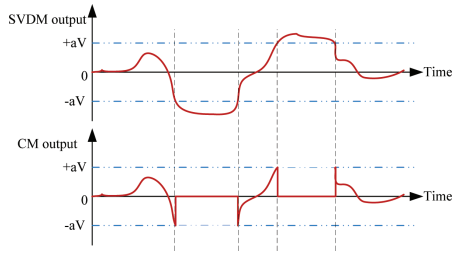

Figure 6. Theoretical comparison model.

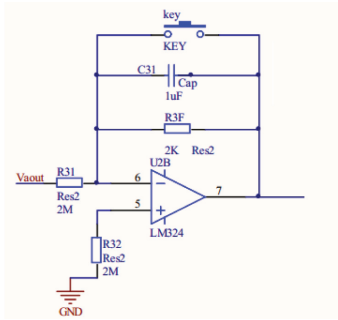

Figure 7. Schematic diagram of Threshold Difference Construction Module (TDCM).

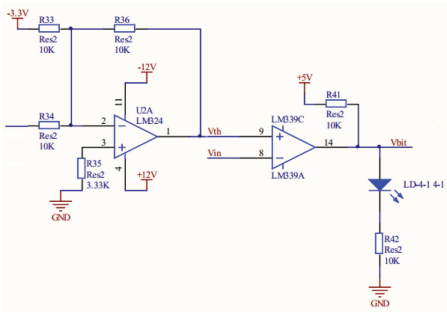

Figure 8. Schematic diagram of Threshold Difference Construction Module (TDCM) and Voltage Comparison Module (VCM).

Before the BIT works, it is required to press the switch button and discharges the capacitor to make sure that the integral initial value is 0. The schematic diagram of Threshold Difference Construction Module (TDCM) is shown in Figure 7.

4.5 *Threshold Summation Module (TSM) & Voltage Comparison Module (VCM)*

The adaptive threshold of the current BIT circuit is gained by the summation of a preset fixed threshold and the threshold difference generated by TDCM. The function is achieved by a simple oppositional op amp summation circuit. The new threshold is then brought to the BIT Voltage Comparison Module (VCM). The original monitoring signal is compared against the adaptive threshold, as an accomplishment of the BIT fault detection process. The schematic diagram of Threshold Difference Construction Module (TDCM) and Voltage Comparison Module (VCM) is shown in Figure 8.

5 EXPERIMENTAL RESULTS

In order to verify the effectiveness of the circuit design, we draw the circuit diagrams in Altium Designer software and make out the physical PCB hardware circuit, as is shown in Figure 9. The circuit has two input choices. The first one is CON1 Input, which is directly linked to the real monitoring signal. The second choice is a simulative fault injection part, in which a 5KΩ variable resistance serves as the external stress controlling unit, and a detachable connection pin serves as the hard fault injector. Critical test signals of the circuit are collected and recorded by the data acquisition computer.

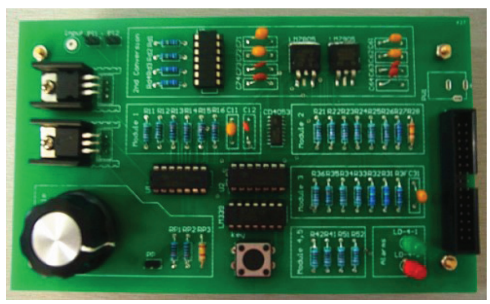

Figure 9. Physical circuit board.

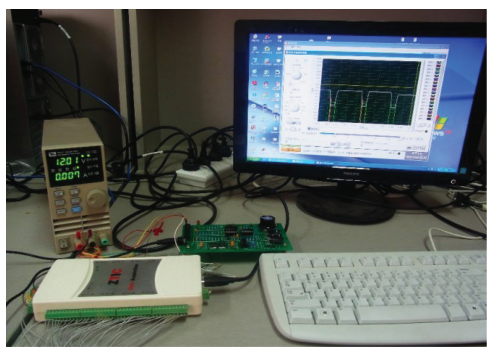

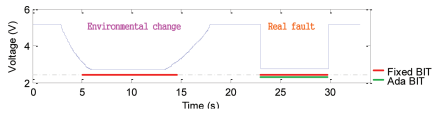

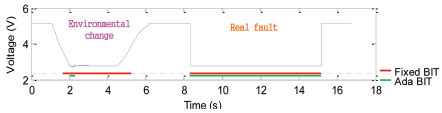

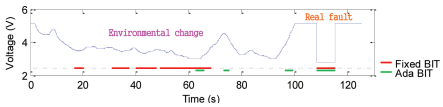

Figure 10. Data acquisition experiment environment.

Table 1. BIT performances under different false alarm profiles.

No.	False alarm profile	FACR of Ada BIT	FACR of fixed BIT	Reduction rate
1		0.00%	56.03%	100%
2		5.01%	33.20%	84.93%
3		47.70%	88.77%	49.64%

The traditional BIT using a single and fixed threshold is also installed for performance comparisons.

Several experiments are conducted with the BIT PCB and the results are analyzed. The data acquisition experiment environment is shown in Figure 10. The fixed BIT threshold is determined to be 3.3V, and an open fault is to be injected in the circuit. Table 1 lists several false alarm profiles, and the False Alarm Coverage Rates (FACR) of the BIT using the adaptive threshold and that using the single threshold are also given in Table 1, respectively.

It can be seen from Table 1 that the average false alarm coverage rates of BITs using the adaptive threshold are obviously lower than BITs using the single threshold. When the environmental changes are mild, the false alarm phenomenon can be fully eliminated, as is the case in Profile 1. When the environmental changes are relatively rapid and dramatic, the adaptive BIT has some false alarms, yet the FACR is much less than traditional fixed BIT, as is the case in Profile 2 and 3. The false alarm coverage rate for the former is about 1/6 and 1/2 of the latter in Profile 2, Profile 3, respectively. The results reveal that the adaptive threshold BIT really has an advantage over the fixed BIT concerning the false alarm phenomenon.

6 CONCLUSIONS

This paper introduces a designing concept of adaptive detection threshold for a Built-In Test (BIT).

The background knowledge and working principles are discussed. The circuit design implementations are also presented in this paper. A hardware BIT circuit board monitoring a typical fault mode is manufactured. Finally, the experimental analysis show that the BIT using adaptive detection threshold has a much lower false alarm coverage rate than the tradition BIT adopting a single fixed threshold. A major contribution is that the concept of adaptive BIT threshold is implemented in a hardware design corresponding to the fault model. Although a hardware design is feasible, the adaptive threshold concept can sufficiently be realized by a software BIT design, which will not add additional weight on the whole product to reduce weight and raise robustness.

ACKNOWLEDGEMENT

The authors express sincere appreciation to the editor and reviewers for their efforts to improve this paper. ABSTRACT: This paper illustrates the main features of the MUlti-STAte DEgradation Process analysis Tool (MUSTADEPT), a new software tool which allows quantitatively describing the evolution of the degradation process of an industrial equipment, modeled as a discrete-state transport process. Two different, complementary approaches are offered. One is based on statistics, specifically the Maximum Likelihood Estimation (MLE) technique to estimate the parameters of the degradation process model and the Fisher Information Matrix for evaluating the uncertainty associated to the estimates. The other approach relies on information elicited from experts and describes and propagates the associated uncertainty within the DSTE framework. In both cases, the probabilities that the component occupies the different degradation states over time are estimated with the associated uncertainties.

1 INTRODUCTION

The degradation mechanisms affecting industrial systems, structures and components (SSCs) can be modeled as discrete-state transport processes (e.g., Baraldi et al., 2013 a and b; Moghaddas & Zuo, 2011). The stochastic transitions between the states obey known models (e.g., Weibull distribution, exponential distribution, etc.), whose parameters (e.g., the scale and shape factors for the Weibull distribution, the failure rate for the exponential distribution, etc.) need to be estimated. Degradation models are used in support to maintenance decision making, for example to optimize the inspection period in a preventive maintenance approach or to estimate the remaining useful life of a SSC in a predictive maintenance approach (Zio & Compare, 2013).

In this context, MUSTADEPT has been developed to characterize and describe the evolution of the degradation processes affecting industrial SSCs, modeled as discrete-state transport processes. In particular, the following assumptions are made:

- There are 4 degradation states, which are identified by the maintenance operators on the basis of the associated symptoms;
- Transitions can occur from one degradation state to the next degraded state, only;
- The stochastic transition models are supposed to be known, for example on the basis of mathematical/physical considerations.
- At least one out of the following two sources of information is available:
  1. A dataset containing, for every SSC, the degradation state in which it has been found at inspection and the corresponding inspection time. This means that the available data must be interpreted as left censored test data (i.e., interval censored data, with the initial time set to 0, Zio, 2007).
  2. A number of experts with different skills and competences, who can provide the intervals in which they suppose the true values of the uncertain parameters are contained.

In these conditions, MUSTADEPT allows exploiting the available information to evaluate the probabilities that the SSC will occupy the different degradation states over time.

Two different, complementary approaches are offered:

1. 'Statistical', which exploits the available dataset containing left censored data to estimate the parameters of the stochastic transitions between the degradation states, and the associated uncertainties.
2. 'DSTE'. This approach allows integrating field data and expert knowledge for estimating the parameters of the stochastic laws of degradation, and propagating the associated uncertainty. The methodology used in MUSTADEPT is based on the DSTE (Baraldi et al., 2013 a; Baraldi et al., 2012; Dempster, 1967; Helton et al., 2004).

The rest of the paper is organized as follows. Sections 2 illustrates an example of industrial case study where the application of MUSTA-DEPT is shown to bring an added value. Section 3 focuses on the statistical approach: some theoretical bases are given, the main features of the approach described, and the results provided are discussed. Section 4, illustrates the features of the DSTE-based approach, and its outputs. The theoretical background of this latter approach has been already presented by the authors (Baraldi et al., 2013 a and b), and, thus, is not reported in this work. Section 5 concludes the paper.

2 CASE STUDY

The illustrative case study concerns the crack growth degradation mechanism of a mechanical component subject to cyclic load, which is typically modeled as a four-state degradation process (Fig. 1, Grall et al., 2007):

- Good state: crack incubation; it is the short initial phase of the phenomenon, which is connected with plastic strains locally occurring in the most stressed parts of the mechanical component subject to cyclic loads. At this stage, coalescence of dislocations and vacancies, as well as ruptures due to local stresses lead to the formation of sub-micro-cracks in the slip bands at the boundaries of blocks, grains and twins.
- Light State: crack initiation; it is characterized by the growth and coalescence of the sub-micro-cracks, which transform into micro-cracks; these start increasing under the cyclic loads, and form macro-cracks, which are typically detectable by measurement instrumentation.
- Medium State: crack rapid-propagation; the crack grows under cyclic loads, up to a critical threshold.
- Heavy State: the failure state; the crack length is above the acceptable threshold.

The presence of four steps requires characterizing the statistical behavior of three stochastic processes:

- Degradation from Good state to Light degradation state;
- Degradation from Light state to Medium degradation state;
- Degradation from Medium state to Heavy degradation state;

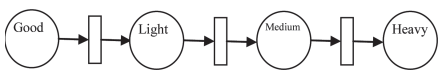

Figure 1. Scheme of the degradation mechanism.

For brevity, the degradation states will be indicated by S_k, $k = 1, \ldots, 4$, whereas the transition times from state S_k to state S_{k+1} by T_k, $k = 1, 2, 3$.

A further assumption is that the transition from any degradation state towards its next more degraded state obeys a Weibull or Log-normal distribution. In this respect, the Weibull distribution is often considered to describe the evolution of ageing processes (e.g., Moghaddas & Zuo, 2011) and in particular of fatigue processes (Baraldi et al., 2013). The Cumulative Distribution Function (CDF) of the transition time T_k, $k = 1, 2, 3$, reads:

$$F_{T_k}(t \mid \alpha_k, \beta_k) = 1 - e^{-\left(\frac{t}{\beta_k}\right)^{\alpha_k}} \quad (1)$$

where α_k and β_k are the shape and scale factors, respectively.

Also the Log-normal distribution is often considered to model the stochastic behavior of the transitions of the fatigue degradation process (e.g., Ray et al., 1998). The CDF of Log-normally distributed transition times T_k, $k = 1, 2, 3$ is:

$$F_{T_k}(t \mid \mu_k, \sigma_k) = \Phi\left(\frac{ln(t) - \mu_k}{\sigma_k}\right) \quad (2)$$

where μ_k and σ_k are the mean and the standard deviation, respectively, of the standard normal distribution, whose CDF Φ is defined as:

$$\Phi(t) = \left(\frac{1}{\sqrt{2\pi}}\right)\int_{-\infty}^{t} e^{-z^2/2dz} \quad (3)$$

3 STATISTICAL APPROACH

3.1 *Main concept*

The statistical approach analyzes the degradation mechanisms affecting industrial SSCs by exploiting the information contained in a database of outcomes of maintenance inspections. In details, the available dataset consists of $N \geq 1$ records containing:

- The ID;
- The inspection time;
- The degradation state of the component;
- The time at which the observation started, to give due account to the left censored data;
- In some cases, a number n of SSCs may be installed on the same system (i.e., the SSCs have the same ID). For example, every turbine (system) has a given number of nozzles (SSC), affected by the crack growth degradation process; then, a record in the dataset may also refer to a system with n SSCs: in this case, the record

contains the numbers n_k of SSCs found in state S_k, $k = 1, \ldots, 4$, where $n = \sum_{k=1}^{4} n_k$.

The procedure implemented in MUSTADEPT to exploit the maintenance inspection records uses the MLE technique to estimate the stochastic transition parameters, and a bootstrap-based technique to estimate the Fisher Information Matrix, which allows evaluating the uncertainty in the MLE values.

3.2 *Theoretical issues*

The parameter estimation problem tackled by MUSTADEPT consists in inferring the values $(\theta_{k1}, \theta_{k2})$ of the transition time T_k from state S_k to state S_{k+1}, for $k = 1, 2, 3$. The model parameters are arranged in the vector $\theta = (\theta_{11}, \theta_{12}, \theta_{21}, \theta_{22}, \theta_{31}, \theta_{32})$. In particular, we have $\theta_{k1} = \alpha_k$, and $\theta_{k2} = \beta_k$ in the Weibull case, whereas $\theta_{k1} = \mu_k$, and $\theta_{k2} = \sigma_k$ in the Log-normal case.

To find the MLE of θ, we need determining the analytical expression of the Likelihood function $L(T; \theta)$, where T is the vector containing the three stochastic transition times T_k, $k = 1, 2, 3$, we are interested in.

To this aim, we first compute the probabilities P_k^i of finding the component in state S_k at inspection time t_i, $k = 1, \ldots, 4$ (number of states), $i = 1, \ldots, N$ (number of records in the dataset). Namely, P_1^i is the probability of finding the component in state S_1 at inspection time t_i, which reads:

$$P_1^i = R_{T_1}(t_i; \theta_{11}, \theta_{12}) \tag{4}$$

where $R_{T_1}(t; \theta_{11}, \theta_{12})$ is the Complementary Cumulative Distribution Function (CCDF) of the transition time T_1 from state Good to state Light.

The probability P_2^i is given by:

$$P_2^i = \int_0^{t_i} f_{T_1}(\tau; \theta_{11}, \theta_{12}) R_{T_2}(t_i - \tau; \theta_{21}, \theta_{22}) d\tau \tag{5}$$

where $f_{T_1}(t; \theta_{11}, \theta_{12})$ is the probability distribution function (pdf) of T_1, whereas $R_{T_2}(t; \theta_{21}, \theta_{22})$ is the CCDF of the transition time T_2 from state Light to state Medium.

The probability P_3^i reads:

$$P_3^i = \int_0^{t_i} f_{T_1}(\tau_1; \theta_{11}, \theta_{12}) \int_{\tau_1}^{t_i} f_{T_2}(\tau_2 - \tau_1; \theta_{21}, \theta_{22}) R_{T_3}(t_i - \tau_2; \theta_{31}, \theta_{32}) d\tau_2 d\tau_1 \tag{6}$$

where $f_{T_2}(t; \theta_{21}, \theta_{22})$ represents the pdf of T_2, whereas $R_{T_3}(t; \theta_{31}, \theta_{32})$ is the CCDF of the transition time T_3 from state Medium to state Heavy.

Finally, the probability P_4^i of finding the component in state Heavy at inspection at time t_i is computed as:

$$P_4^i = 1 - P_1^i - P_2^i - P_3^i \tag{7}$$

The Likelihood function is a multinomial distribution, which reads:

$$L(T; \theta) = \prod_{i=1}^{N} \frac{n!}{n_1^i! n_2^i! n_3^i! (1 - n_1^i - n_2^i - n_3^i)!} \cdot P_1^{i\,n_1^i} P_2^{i\,n_2^i} P_3^{i\,n_3^i} (1 - P_1^i - P_2^i - P_3^i)^{n - n_1^i - n_2^i - n_3^i} \tag{8}$$

where

- n_k^i represents the number of SSCs in state k at time t_i, $k = 1, 2, 3$
- n is the total number of SSCs for every system.

MUSTADEPT utilizes optimization algorithms available in Matlab to find the maximum of the Log-likelihood function log $(L(T; \theta))$, as detailed in Section 3.3.3.

To estimate the uncertainty in the ML estimate, MUSTADEPT exploits the asymptotic properties of the ML estimator (Papoulis & Pillai, 2002). That is, if $\hat{\theta} = (\hat{\theta}_1, \ldots, \hat{\theta}_M)$ is a unique solution to the maximization problem of $L(T; \theta)$, then:

i. $E(\hat{\theta}) \to \theta$
ii. $\hat{\sigma}_{\hat{\theta}} = (\hat{\sigma}_{\hat{\theta}_1}, \ldots, \hat{\sigma}_{\hat{\theta}_M}) \to (\hat{\sigma}_{\hat{\theta}_1}, \ldots, \hat{\sigma}_{\hat{\theta}_M})_{CR}$ where $(\hat{\sigma}_{\hat{\theta}_1}, \ldots, \hat{\sigma}_{\hat{\theta}_M})_{CR}$ is the Cramer-Rao lower bound (Papoulis & Pillai, 2002) of the standard deviations of any unbiased estimator of θ. That is, any choice of an unbiased estimator of θ brings a variability in $\hat{\theta}_m$ necessarily larger than $\hat{\sigma}_{\hat{\theta}_{m\,CR}}$, $\forall m = 1, \ldots, M$.
iii. $\hat{\theta}$ is asymptotically normal.

Approximated values of the variances $\hat{\sigma}_{\hat{\theta}} = (\hat{\sigma}_{\hat{\theta}_1}, \ldots, \hat{\sigma}_{\hat{\theta}_M})$ of the parameters $\hat{\theta}_m$ of $\hat{\theta}$, are provided by the main diagonal of the estimated covariance matrix. This is defined the inverse $F(\theta)^{-1}$ of the expected Fisher information matrix $F(\theta)$, whose generic (r, j) entry, for any (r, j) and $j = 1, \ldots, M$ is:

$$F_{rj} = E\left[\frac{\partial log L(T; \theta)}{\partial \vartheta_r} \cdot \frac{\partial log L(T; \theta)}{\partial \vartheta_j} \right] \tag{9}$$

Under mild regularity conditions, the covariance matrix we are interested in is equal to:

$$\begin{pmatrix} -E\left[\frac{\partial^2 log L(T;\theta)}{\partial \vartheta_1^2}\right] & \cdots & -E\left[\frac{\partial^2 log L(T;\theta)}{\partial \vartheta_1 \partial \vartheta_M}\right] \\ \vdots & \ddots & \vdots \\ -E\left[\frac{\partial^2 log L(T;\theta)}{\partial \vartheta_M \partial \vartheta_1}\right] & \cdots & -E\left[\frac{\partial^2 log L(T;\theta)}{\partial \vartheta_M^2}\right] \end{pmatrix}^{-1} \tag{10}$$

In particular, these second derivatives can be interpreted as measures of how quickly the pdfs change when we change the parameters in the closeness of the MLE estimation. The expectations of the square of these values give us a more robust version of the measure. In turn, if Fisher information is large, then the distributions change quickly when we move far from the MLE value of the parameters. This entails that we should be able to properly estimate $\hat{\theta}$ based on the data. On the other hand, if Fisher information is small, this means that the distributions corresponding to $\theta = \hat{\theta}$ are 'very similar' to those with parameter values not so close to $\hat{\theta}$ and, thus, more difficult to distinguish: then, our estimation would be worse.

To estimate $F(\theta)$, MUSTADEPT resorts to a bootstrap-based approach proposed in (Spall 2009), which is useful when analytical methods for computing $F(\theta)$ are infeasible.

The essence of the method is to produce a large number of Simultaneous Perturbation (SP) estimates of the hessian matrix (i.e., the matrix of the second derivatives) of $logL(T; \theta)$, and, then, average the negative of these estimates to obtain an approximation to $F(\theta)$.

In details, the algorithm consists of the following steps:

Step 0. (Initialization). Set the number S of pseudo-data vectors that will be generated, and inizialize $s = 1$.

Step 1. (Generating pseudo-data). Based on the ML Estimate $\hat{\theta}$, generate the s-th pseudo-dataset Z_{pseudo} (s) of N records. That is, to produce the SP hessian estimates, we implement the following procedure to generate a dataset similar to the original:

1. Set $i = 1$.
2. Consider the inspection time of the i-th record in the available dataset.
3. Simulate the histories of the n SSCs in the i-th record, assuming that the parameters of the stochastic process take their ML estimates θ.
4. Store the outcomes.
5. $i = i+1$.
6. Repeat steps 2–4 until $i > N$.

Step 2. (Hessian estimation): With the s-th pseudo-data vector in Step 1, compute the Γ Hessian estimates H_γ, $\gamma = 1, \ldots, \Gamma$.

To do this, we first build the perturbation vector $h = (h_1, \ldots, h_M)$, whose elements are uniformly distributed mean-zero random variables with bounds satisfying the condition $E[|1/h_m|] < \infty$, $m = 1, \ldots, M$.

Then, we use the finite difference method (Quarteroni, 2013) for estimating the second derivates. In particular, the r-th element on the diagonal of H_γ is:

$$\frac{\partial^2 logL(\theta|Z_{pseudo})}{\partial \vartheta_r^{\,2}} \cong \frac{logL\left(\theta_{\vartheta_r=\widehat{\vartheta}_r+h_r}\middle|Z_{pseudo}\right) - 2logL(\theta|Z_{pseudo}) + logL\left(\theta_{\vartheta_r=\widehat{\vartheta}_r+h_r}\middle|Z_{pseudo}\right)}{h_r^2} \tag{11}$$

whereas the (r, j) elements, $r, j = 1, \ldots, M$ and $r \neq j$, outside the diagonal, are:

$$\frac{\partial^2 logL(\theta|Z_{pseudo})}{\partial \vartheta_r \partial \vartheta_j} \cong \frac{logL\left(\theta_{\vartheta_r=\widehat{\vartheta}_r+h_r,\vartheta_j=\widehat{\vartheta}_j+h_j}\middle|Z_{pseudo}\right) + logL\left(\theta_{\vartheta_r=\widehat{\vartheta}_r-h_r,\vartheta_j=\widehat{\vartheta}_j-h_j}\middle|Z_{pseudo}\right)}{4h_rh_j} - \frac{logL\left(\theta_{\vartheta_r=\widehat{\vartheta}_r+h_r,\vartheta_j=\widehat{\vartheta}_j-h_j}\middle|Z_{pseudo}\right) + logL\left(\theta_{\vartheta_r=\widehat{\vartheta}_r-h_r,\vartheta_j=\widehat{\vartheta}_j+h_j}\middle|Z_{pseudo}\right)}{4h_rh_j} \tag{12}$$

where $\theta_{\vartheta_r=\vartheta_r^*,\vartheta_j=\vartheta_j^*}$ represents vector $\hat{\theta}$, with its r-th and j-th elements taking values ϑ_r^* and ϑ_j^*, respectively.

Finally, the sample mean $H^{(s)} = H^{(s)}(\theta|Z_{pseudo})$ of the Γ estimates is computed.

Step 3. (Averaging Hessian estimates). Repeat Steps 1 and 2 until $s = S$. Then, the negative of the average of the S Hessian estimates $H(s)$ produced in Step 2 give the estimate of $F(\theta)$.

The approach is computationally efficient because it requires a low number of Log-likelihood values to produce each estimate.

3.3 *Input setting*

In order to perform the statistical analysis MUSTADEPT requires the user to specify four different pieces of information concerning: the data set, the stochastic model representing the transition from a state to another, the MLE algorithms and the level of confidence for the visualization of the results.

3.3.1 *Dataset*

The dataset is stored in a text file; then, to start the analysis, the user just specifies the name and the path of this file.

3.3.2 *Stochastic model*

The user is required to select between Weibull and Log-normal, the probability distribution used

to model the transitions among the degradation states.

3.3.3 *Algorithm in support to MLE*

The software asks the user to select and set the algorithm to find the maximum of the Log-Likelihood Function (i.e., the ML estimates of the parameters of the probability distributions). In particular, the user can:

- Select the preferred Matlab optimization algorithm among two alternatives: constrained and unconstrained algorithms. In the former case, MUSTADEPT calls the 'fmincon' Matlab function, whereas in the latter case the 'fminsearch' algorithm.
- Suggest the starting point for the search of the maximum of the Log-likelihood function. In this respect, notice that the closer is the starting point to the MLE point, the smaller is the computational time.
- Define the number of optimization runs and the number of iterations in each run. In this respect, notice that setting the number of optimization runs larger than 1 allows cross-validating the result of the search.
- Choose the number of parallel jobs, to optimally exploit the computing capabilities of the CPU when running MUSTADEPT.

3.3.4 *Level of confidence*

The user needs to specify the level of confidence conf ∈ [1, 100[for the visualization of the results (Zio, 2007).

3.4 *Results*

MUSTADEPT provides in output the probability with which the SCC occupies the different degradation states over time, and the uncertainty associated to this evaluation. In particular, such uncertainty encodes both aleatory (i.e., inherent to the SSC stochastic behaviors) and epistemic (i.e., due to the lack of precise knowledge of the model parameters and the Monte Carlo estimation) contributions.

Two different outputs are provided, which are discussed in the following Sub-Sections:

Specific solutions, referred to specific time instants.

Overall solutions, representing the probabilities that the analyzed SSC resides in the different states over the considered time horizon.

3.4.1 *Specific solutions*

The specific solutions are computed for all the time instants of the discretized time horizon, and give the CDFs of the probabilities of finding the SSC in the 4 degradation states (i.e., a plot for each degradation state).

For example, Figure 1 shows the results relevant to state S_1 at time instant $t = 14$ Units of Time (UoT). The interpretations of the Figure may be: the probability of the SSC being in state S_1 at $t = 14$ cannot be smaller than 0.25; it is smaller than 0.3 with probability 0.5; certainly, it is smaller than 0.4. Another example is reported in Figure 2. The probability that the SSC is in the fourth state at time $t = 14$ UoT is smaller or equal to 0.1 with probability almost 1. Similar plots are produced for S_2 and S_3.

The information contained in the plots of the specific solutions is also summarized by MUSTADEPT, on the basis of the confidence level entered by the user: specifically, MUSTADEPT estimates the values of the 0.5(100-*conf*)th and the [100–0.5(1-*conf*)]th percentiles of the CDF of the specific solutions.

With reference again to $t = 14$ UoT (Figs. 2–3), considering $conf = 90$, MUSTADEPT estimates the 5th and 95th percentiles of the CDFs relevant to t.

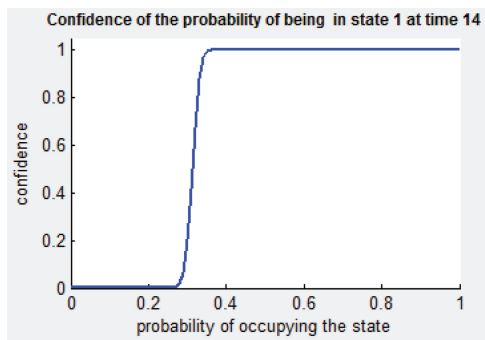

Figure 2. Specific solution, referred to state S1 and t = 14 UoT (statistical approach).

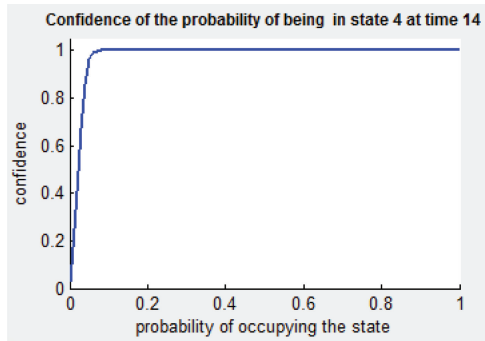

Figure 3. Specific solution, referred to state S4 and t = 14 UoT (statistical approach).

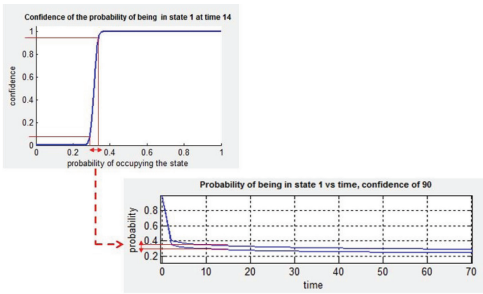
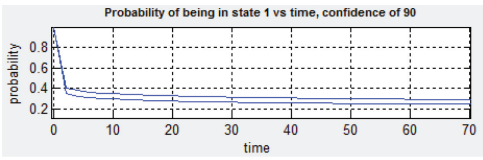
This information is also summarized in the following statements:

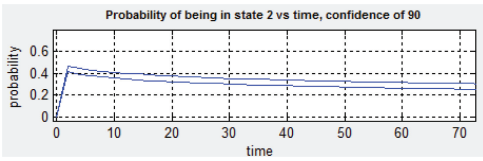
- the probability of being in state 1 is between 0.28% and 0.34%;
- the probability of being in state 2 is between 0.34% and 0.39%;
- the probability of being in state 3 is between 0.26% and 0.33%;
- the probability of being in state 4 is almost 0% (between 0% and 0.04%).

3.4.2 *Overall solutions*

The overall solutions lump together the specific solutions to provide a representation of the evolution of the probability of having the SSCs in the different states over time. In particular, for every time instant the overall solutions give the percentiles computed as explained above. For clarity, Figure 4 shows the link between the specific and the overall solutions. In general, the higher the confidence required by the user, the wider the bands in Figures 5–8.







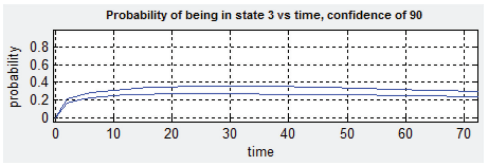


Figure 4. Example of passage from specific to overall solution.

Figures 5. Overall solution referred to state S_1 (statistical approach).

Figures 6. Overall solution referred to state S_2 (statistical approach).

Figures 7. Overall solution referred to state S_3 (statistical approach).

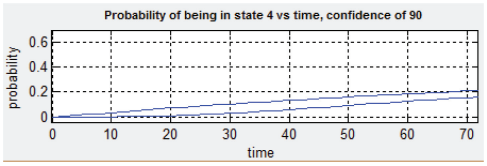

Figure 8. Overall solution referred to state S_4 (statistical approach).

The comparison of the probability values of the SSC being in the four degradation states over time provides the analyst with a useful information to make decisions. For example, from Figures 5–8 it emerges that:

- At the beginning of the simulation all the items are healthy, being the probability of finding the SSC in state 1 at time 0 equal to 1.
- In successive time instants, the SSC starts to leave state 1 and pass into state S_2.
- As the time goes on, all the probability that SSC undergoes a transition from state S_2 to state S_3 increases.
- Finally, as the time evolves, the SSC reaches the failure state.

4 DSTE APPROACH

4.1 *Main concept*

The DSTE procedure implemented in MUSTADEPT allows investigating the same degradation model analyzed by the statistical approach, within the framework of DSTE. This allows exploiting the rough and imprecise estimations of the model parameters retrievable from experts. A detailed description of such procedure is provided in (Baraldi et al., 2013, Helton et al., 2004, Baraldi et al., 2012) whereas its theoretical bases are given in (Dempster 1967, Shafer 1976, Baudrit et al., 2006).

4.2 *Input data*

To carry out the analysis based on the DSTE approach, MUSTADEPT requires three different

input types concerning: the stochastic model for the representation of the transition between different states, the Monte Carlo-DSTE algorithm, and the level of confidence for the visualization of the results.

4.2.1 *Stochastic model*

Similarly to the statistical approach, the user can select the probability distributions governing the transitions among two alternatives: the Weibull distribution or the Log-normal distribution.

Once the model is selected, the software requires information about the 6 model parameters $\theta(\theta_{11}, \theta_{12}, \theta_{21}, \theta_{22}, \theta_{31}, \theta_{32})$. In details, for every parameter, the user enters the information elicited from the experts, who have estimated the bounds of the intervals they believe to contain the true values of the parameters. In this respect, notice that the output of the statistical approach may be considered as given by a 'virtual' expert, and thus accounted for in the DSTE analysis.

Figure 9 shows the MUSTADEPT graphical user interface to enter the bounds of the intervals provided by the experts and the other parameters.

4.2.2 *Monte Carlo-DSTE algorithm*

The software allows the user to customize the Monte Carlo-DSTE method implemented in MUSTADEPT for the representation and propagation of the uncertainty associated to the imprecise information provided by the experts. In particular, the user has to set two parameters: the length of the time steps partitioning the time horizon of interest and the number of Monte Carlo simulations. These variables determine the level of precision of the final results and the computational efforts required to carry out the analysis: the larger the desired precision, the more expensive the computational cost. A good compromise solution between reasonable computational efforts and precision needs to be found by the user, depending on the application and the intended use of its results.

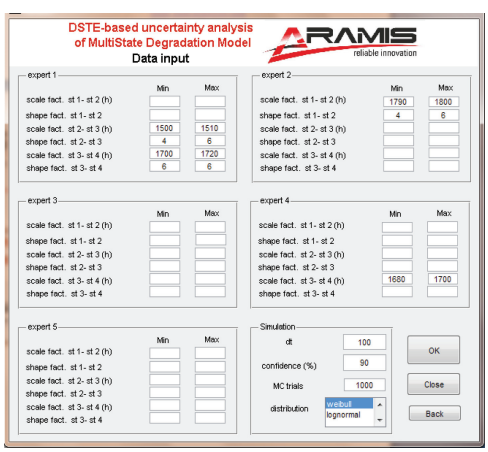

Figure 9. User interface to enter the algorithm settings.

4.2.3 *Level of confidence*

The user has to specify the level of confidence for the visualization of the results.

4.3 *Results*

The results provided by the DSTE approach are similar to those in output from the statistical approach; also in this case the results are divided into:

- Specific solutions, referred to given time instants;
- Overall solutions, representing the probabilities of the SSC being in the different states over the considered time.

In general, the considerations reported for the statistical approach in sub-Section 3.3 hold also in this case. However, attention must be paid to the fact that the statistical approach considers probability distributions, whereas the DSTE approach refers to Plausibility and Belief functions, and Pignistic probability, as discussed in the following Sections.

4.3.1 *Specific solutions*

For each time instant, the specific solutions of the DSTE approach give the bounds of the probabilities of finding the SSC in the 4 degradation states, and the associated uncertainties, described in terms of Belief and Plausibility functions. These encompass both epistemic and aleatory uncertainties and, roughly speaking, can be regarded as the lower and upper bounds, respectively, of all the possible CDFs encoded by the imprecise estimations provided by the experts on the model parameters.

Therefore, for every degradation state S_k, the output distributions provided by MUSTADEPT as specific solutions at time t, bracket the unknown probability of occupying S_k at time t corresponding to the true value of θ. Generally speaking, the closer the Plausibility and Belief functions, the smaller the uncertainty in the solution, which however, heavily depends on the width of the intervals provided by the experts.

For example, Figure 10 shows the specific results at time instant t = 14 UoT. A possible interpretation is that the probability of the SSC being in state 1 at the considered time instant is smaller than 0.3 (on abscissa) with a probability value between 0 and 0.7 (on ordinate).

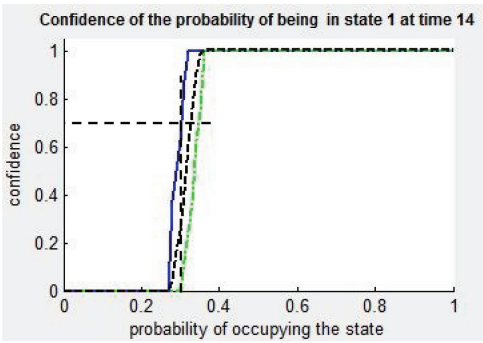

Figure 10. Specific solution, referred to state 1 and 14 UoT (DSTE approach). Continuous blu line = Plausibility; Dashed black line = Pignistic; Dashed-Dotted green line = Belief.

Finally, the specific solutions also give for every degradation state the Pignistic distribution associated to the uncertainty setting defined by the user. Roughly speaking, this distribution allows 'translating' the representation of the uncertainty from the DSTE framework to the probability theory framework, with the minimum commitment of information (Smets & Kennes, 2008).

4.3.2 *Overall solutions*

The overall solutions represent the evolution of the probability of having the SSCs in the different states over time. In the DSTE approach, such solutions are computed similarly to what explained in sub-section 3.3.2, but with reference to Belief, Plausibility and Pignistic functions. Namely, given the level of confidence conf set by the user, MUSTADEPT computes for every time bin partitioning the time horizon, the following values:

a. the 0.5(100-*conf*)th percentile on the Plausibility function and the [100–0.5(1-*conf*)]th on the Belief function (Fig. 9) of the corresponding specific solutions. For example, if the user sets *conf* = 90, then MUSTADEPT takes the 5th percentile of the Plausibility measure and the 95th percentile of the Belief curve.
b. The 0.5(100-*conf*)th and the [100-0.5(1-*conf*)]th percentile of the Pignistic distribution function, of the corresponding specific solutions.

These values are the upper and the lower bounds of the probability of occupying the degradation states provided by the overall solutions.

The user can select from the alternatives a) and b) above the preferred method to obtain the overall solutions from the specific ones. Generally speaking, method a) yields a wider range of probability values (i.e., a wider band), which gives due account to the uncertainty deriving from the propagation of the imprecision in the input collected information.

In addition, the larger the confidence required by the user, the wider the band of the results.

5 CONCLUSION

In this paper, a new software tool has been presented, which allows to exploit the information available in terms of statistical data and expert judgments to build and simulate a multistate degradation model. A typical industrial case study has been shown. The sound theoretical bases which the tool is based on have been summarized, the information required to the user detailed, and the output results described.

Additional research work will be dedicated on developing computational methods that can easily guide the user in making maintenance decisions on the basis of the four-states degradation model.

Provision of the reliable video surveillance services in heterogeneous networks

P. Lubkowski & D. Łaskowski
Military University of Technology, Warsaw, Poland

E. Pawlak
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

ABSTRACT: Process of ensuring the security of citizens requires access to the information from sensors located in different points of monitoring and data acquisition systems. The IP video surveillance networks are nowadays the main part of such a systems. Transmission of data from multiple video sensors may lead to the degradation of video quality and even to lack of transmission abilities especially in heterogeneous networks. The paper presents a study of selected QoS supporting mechanisms and components elaborated for video monitoring service that were implemented in the prepared testbed which consists of QoS-aware application, QoS Streaming Server and Resource Broker modules. Suitable testing scenarios were selected in order to present an effect of functioning of these components in the QoS-supporting video monitoring network.

1 INTRODUCTION

Video surveillance systems for many years are used to enhance the safety of citizens and the protected objects. With video surveillance we meet both in public and national utility facilities, in places publicly available and in the areas with limited access. Monitoring systems are a combination of video recording (sensors), transmitting, storing and reproducing devices in one integral unit. They enable the observation of people or objects in real time as well as the event recording for later analysis.

The possibility of cooperation between video surveillance and security forces (police, municipal police and private companies) provides a rapid intervention and the precise identification of the perpetrators of the offense or offenses. Another application is to identify, in near real-time, persons performing essential roles in numerous and various systems of transportation for people and goods.

As it can be seen the detection and identification of persons and events is one of the main advantages offered in today's surveillance systems. A characteristic feature of the video monitoring systems is also their performance on an ongoing basis. A relatively brief interruption of the surveillance system may determine the overall effectiveness of the solution. Requirements for video surveillance systems are defined in the area of functional and quality constraints. Quality assurance at the network level (QoS—Quality of Service) is extremely important because it allows prediction of the size of the available bandwidth and the level of losses at the application layer. However, this information will only allow a fair distribution of bandwidth between the cameras and does not reflect the user's requirements on service severability. Thus in the case of video surveillance systems it is important to consider also the quality at the application layer. The QoS at the application layer is defined in ITU-T Recommendation G.1010 and includes parameters related to the establishing, disconnecting and call-blocking of connection (ITU-T G.1010 Recommendation 2001). Within this group of parameters, service accessibility and service retainability are particularly relevant. They determine the possibility of obtaining on demand services in the specified range and under certain conditions, and to continue it for the required period. Provision of QoS with respect to network layer and the application layer for such systems is a great challenge and requires an appropriate QoS platform with traffic control mechanisms to handle video traffic transferred through such systems.

Many QoS-enabled architectures and protocols have been proposed to solve the problem of end-to-end quality of real-time video services (Engel T. 2003, Callejo-Rodriguez MA 2008, Awduche D. 2001). However the mentioned solutions are not well suited to the large variation of maximum available data rate of video monitoring systems. In our proposal we decided to use our own cross-layer

mechanism discussed in (Lubkowski P. et al 2006, Lubkowski P. et al 2013). It uses a Cross-Layer Data Base (CLDB) and Cross-Layer Signaling (CLS) to share information's between LINK and APP layers.

In this paper, the QoS platform is presented which is composed of QoS Streaming Server and Resource Broker modules and QoS-aware Client module. They are part of modified End-to-end RatE Adaptation (EREA (Lubkowski P., Laskowski D., 2013)) application with ability to negotiate of traffic contract parameters for preserving service accessibility and retainability.

2 THE CONCEPT OF QoS PLATFORM

The QoS platform should be based on the layer independent from the techniques as well as network mechanisms applied in the administrative domains of video monitoring network. It should also deliver unified interfaces to individual network devices and applications. In order to fulfill these requirements, the QoS platform consist of QoS Streaming Server and Resource Broker modules and QoS-aware Client module with signaling and link capacity estimation functionalities, as it was already mentioned. Such platform is shown in Figure 1.

The QoS-aware application is based on cross-layer signaling between layers and implements a series of procedures that result in the adaptation of video bit rate to the available throughput of the transmission channel. It is also equipped with the dedicated signaling module that is able to acquire QoS requests to QoS Streaming Server (Qo3S). Each Qo3S is responsible for informing the Resource Broker (RB) about the QoS requirements coming from applications. The RB manages and estimates its known resources and decides about resources allocation for video stream transferred from IP camera in access device.

All the mechanisms located in adequate QoS-supporting components and responsible for QoS

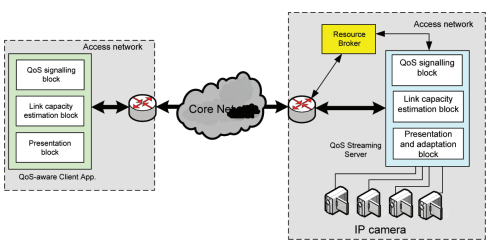

Figure 1. Functional diagram of QoS platform.

support were elaborated within the framework of the ongoing project. The QoS-aware client application was initially described and verified in (Lubkowski P., Laskowski D., 2013) and (Lubkowski P., Laskowski D., 2014). This paper is focused on the practical verification of these mechanisms implemented in prepared testbed configuration. Next section describes the functionalities of Qo3S and RB. The testbed structure and the testing plan are also presented.

3 QoS SUPPORTING IMPLEMENTATIONS

In this paragraph, the focus is set on functional description of QoS supporting implementations developed for provisioning of reliable video surveillance service. These include, as already mentioned, the QoS-aware client application and the QoS Streaming Server with the functionality of Resource Broker modules. The modules, named respectively "user" and "admin", were implemented in the form of executable programs written in C++ and configured to operate under Windows. Running the application requires the installation of additional C/C++ libraries included in the "libjpeg-turbo-1.2.0-vc" application. This application accelerates the video encoding and decoding as well as floating point operations, so it is possible to use the full power of x86 computing.

Qo3S and RB module ("admin") retrieves images from surveillance cameras and provides it on demand to the Client application ("user"). Streaming server (Qo3S) cooperates simultaneously with eight cameras of monitoring system. For each video stream Qo3S performs the procedure of video rate adaptation according to the throughput estimated by RB. Throughput estimation and video rate adaptation procedures have been described in detail in (Lubkowski P., Laskowski D., 2013). Additionally, RB executes also resource reservation for the selected video stream according to the QoS requirements coming from "user" application. The RB manages and estimates its known resources and decides about resources allocation for each selected video stream. Functional characteristics of "admin" application are given in Table 1 while the application window is shown in Figure 2.

The "user" application provides a possibility of communication with "admin" module and reception of video sequences from cameras supported by the server Qo3S. As it was already mentioned the customer of "user" application has the ability to manually select the best image quality and the priority of video stream in each of maintained class of services.

Table 1. Functional characteristics of "admin" application.

Functionality	Description
Number of supported surveillance cameras	More than 1, max. 8
Measurement of bandwidth	Yes
Transmission protocol	TCP/IP
Video rate adaptation according to the variable bandwidth	Yes
Visualization of link occupancy	Yes
Support for Diff Serv class of service Code Points	Yes
The ability to prioritize video stream	Yes, for each of supported cameras

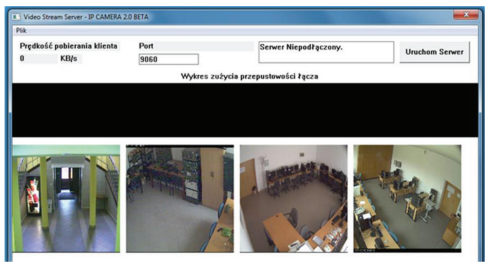

Figure 2. The "admin" application window.

4 QoS RISK ASSESSMENT

The provision of end-to-end QoS while maintaining the required level of service accessibility and retainability is an important issue as far as heterogeneous video surveillance networks are taken into account. It should be noted, that in order to provide the video surveillance services with required QoS some threats and consequences have to be taken into account. This so called risk analysis is a part of validation process of proposed QoS solution.

The heterogeneous video surveillance networks are often characterized by such properties as topology changes, mobility of users and service providers, common use of wireless links and limited processing and power capacity of network nodes. In turn the video transmission requires sufficient bandwidth and small delays but tolerates partial packet losses. Taking this into account the following threats can be identified: lack of bandwidth, large packet delivery delay (round trip time), large jitter, considerable percentage of packet loss and high level of packet duplication. The mentioned threats can lead to

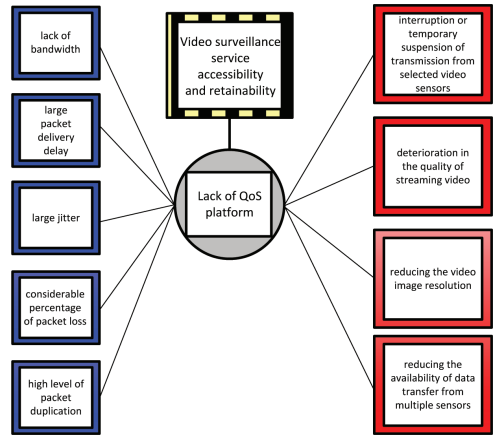

Figure 3. The Bow-tie risk assessment for proposed QoS platform.

the following consequences: the interruption or temporary suspension of transmission from selected video sensors, deterioration in the quality of streaming video, reducing the video image resolution and reducing the availability of data transfer from multiple sensors (Fig. 3). The proposed QoS platform ensures the minimization of the presented risks and reduces identified consequences in the provision of video surveillance services.

5 VALIDATION AND VERIFICATION OF QoS PLATFORM

All components of the QoS platform were implemented in the demonstration network established in the MUT (Military University of Technology) laboratory within the INSIGMA project. The main goal of the project is the development and implementation of a complex information system for comprehensive detection and identification of risks and the monitoring and identification of moving objects. The demonstration network consists of three access domains, which are connected by a backbone network. Two domains are a source of information from video monitoring and one of them represents a monitoring centre. The domains are connected over backbone network where tunnels of predefined bandwidth are established. Only under this condition we can use our mechanism for available bandwidth evaluation. The overall architecture of demonstration network is presented in Figure 4.

The set of tests and scenarios were proposed for verification and validation of the developed QoS supporting implementations. For this paper only

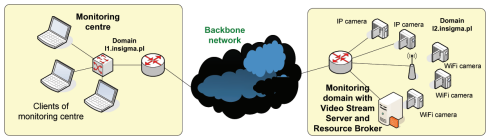

Figure 4. The overall architecture of demonstration network.

Table 2. Practical experiment scenarios.

#	Experiment	Description
1	Functional tests	Evaluation of QoS supporting mechanism in terms of bandwidth changes
2	Qualitative tests	Evaluation of image quality in case of class of service change Assessment of image quality with PSNR (Peak Signal-to-Noise Ratio)

Table 3. The characteristics of cameras (Axis).

The camera model	Resolution of video stream
Axis M1031-W	640×480
Axis Q1755	1280×720
Axis 207MW	640×480
Axis 207MW	640×480
Axis 215 PTZ	702×576

some of them were selected and discussed. The tests were divided onto following groups:

1) Functional tests.
2) Qualitative tests.

The goal of the functional tests was to verify the QoS-support implementations. The goal of qualitative tests was to validate the implementations and its usefulness in surveillance network.

Detailed description of each group of tests is given in Table 2.

The image was derived from IP Axis cameras whose main characteristics are given in Table 3. The server performs additional video compression using bilinear interpolation based on the designated bandwidth. Throughput restriction is performed by the client application. It reduces the bandwidth of the client interface to the value declared in the application window. The measurement results are related to quality indicators defined in the following recommendations (ITU-T G.1010 Recommendation, 2001), (ITU-T P.800 Recommendation, 1996).

The first experiment selected for discussion in this paper is based on a video streams transmitted to client application with different quality and priority. It represents the behaviour of QoS supporting mechanism caused by changes of throughput given in the transmission channel. The "admin" application handled five video cameras. Five video streams were sent to the "user", of which the last three are assigned the highest class of service and different priorities (high, medium and lowest). During the experiment a reduction of the available bandwidth was carried out from the maximum value (approximately 10 Mbps) to 100 kbps.

Figure 5 show a picture of the main application window once all cameras are plugged. With respect to the supported cameras (marked with colour squares) information concerning percentage occupancy of the available bandwidth is presented. The figures show also the colour indicator which represents actual link occupancy by each of the handled cameras. Cameras marked with red, magenta and dark blue are serviced with highest class of service. The others (green, blue) are not supported with developed QoS mechanisms. In the first part of the experiment, all cameras share the bandwidth according to the approved resolution of video stream (Table 3). The overall bandwidth occupancy is equal to 4.08% of available link capacity.

Next, the available bandwidth was restricted. As a result the quality of the video streams of the first two cameras was also restricted (reduction of available bandwidth) while the throughput for other cameras were maintained according to the values declared for the supported class of service (Fig. 6).

We can also observe only three color bars presented in the link occupancy indicator due to the fact that with respect to the other two streams (without QoS support) a significant reduction of the resources was made.

Further reduction of the available bandwidth should lead to a situation in which the STR server

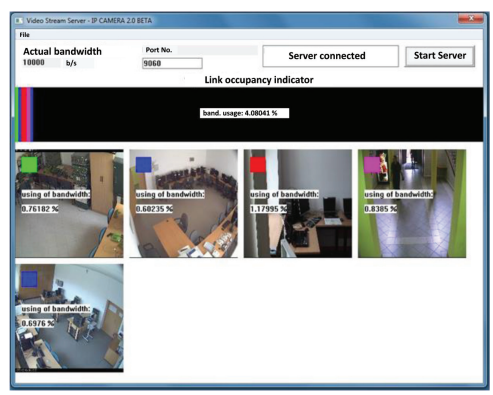

Figure 5. The "admin" application window during the experiment.

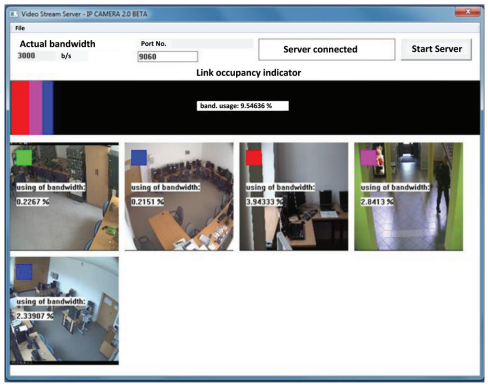

Figure 6. The effect of available bandwidth reduction—only throughput for cameras supporting QoS mechanisms is maintained (red, magenta, dark blue squares).

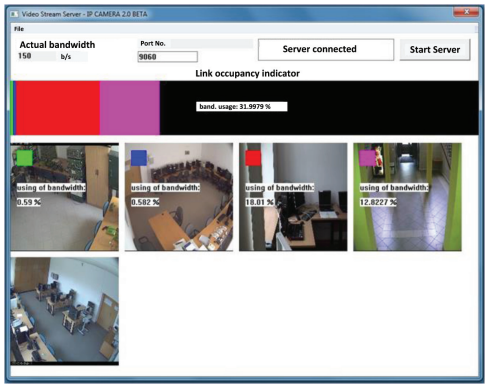

Figure 7. Suspension of video from the camera with the lowest priority due to lack of resources.

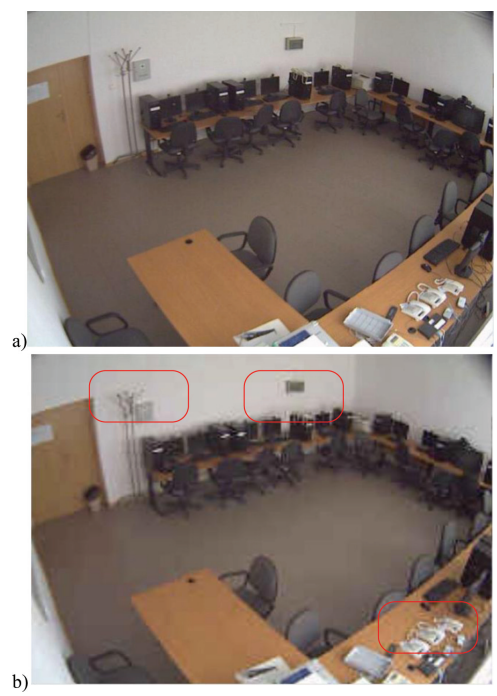
will stop streaming of a video data from the camera with the lowest priority. This is due to the fact that the server task is to maintain the guaranteed quality of video transmission according to given class of service and priority. The lack of resources results in termination of data transmission from the camera, which is assigned the lowest permissions.

We can observe this in Figure 7 which show that the streaming of video data from the fifth camera (marked previously with dark blue square) was stopped. The link occupancy indicator show red and magenta bars which occupy more than 30% of available link capacity. Also first two streams are still serviced according to the fact that remaining resources can be used for video data transmission from cameras without any QoS requirements.

The results obtained confirm the effective functioning of the proposed QoS mechanisms in the presence of changes in the available bandwidth.

Further part of the paper presents the results of qualitative tests. The results showing the impact of the applied-class services on achieved video stream quality are discussed first. During the tests the video from the camera Axis 207MW operating at a resolution of 640×480 was used. Figure 8 presents the video shown by the client application serviced in highest (DSCP = EF) and lowest class of service (DSCP = BE), respectively. It can be seen that in the case of highest quality there is no significant degradation of image quality. A deterioration of the image is invisible; we can observe a high focus and good contrast. However, for BE class of services, visible artifacts can be observed with respect to the previous image (the fields marked with a red border).

Qualitative tests of QoS platform incorporate also the assessment of image quality with PSNR. This parameter is used to determine the level of similarity between the reference image and the compressed one, and is expressed in decibels (dB). In practice, the smaller value of coefficient-t means lower similarity. For the measurements of PSNR, a MSU Video Quality Measurement Tool 3.0 application was used (MSU). Figure 9 show the value of PSNR when video serviced with EF and AF class



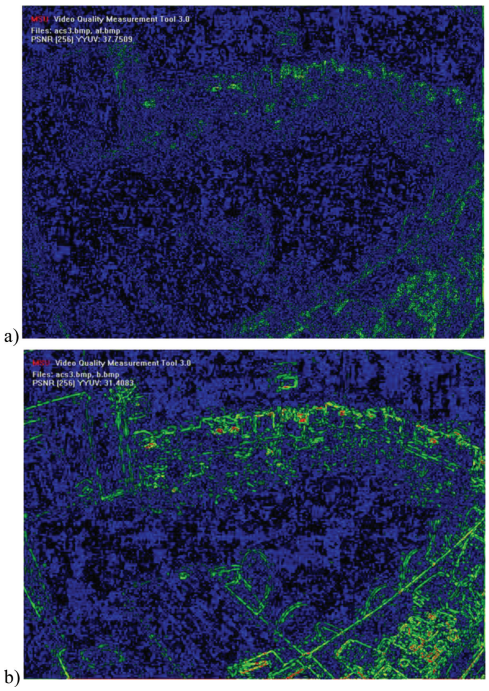


Figure 8. Image quality shown in client application window (a—EF class of services selected for video stream, b—BE class of services selected for video stream).

a)

b)

Figure 9. Result of the comparison of the images with MSU application (a—PSNR = 37.75, b—PSNR = 31.408).

of services is compared. Increasingly bright colors can be noticed in image quality, which means a greater difference of images. An even greater lack of fit can be seen when comparing video quality of video streams serviced in EF and BE class of services, respectively. However, the value of PSNR is still high, indicating a high probability of correct identification of the information contained within the image.

6 CONCLUSIONS

Testing results presented here confirm that the elaborated QoS mechanisms work correctly in conditions of changing the throughput of the transmission channel. From these results we can see that video monitoring can be ensured using proposed QoS platform.

The results obtained show also that the provision of video stream classification preserves the continuity of service without significant deterioration of image quality. This enables the support of end-to-end QoS in terms of service accessibility and retainability. The proposed QoS platform supports the INSIGMA monitoring network in maintaining the transmission of video stream with a specified level of quality.

ACKNOWLEDGEMENT

The work has been supported by the European Regional Development Fund within INSIGMA project no. POIG.01.01.02,00,062/09.

Identification of degradation processes of seabed protection in ports

T. Abramowicz-Gerigk
Gdynia Maritime University, Gdynia, Poland

ABSTRACT: Monitoring and maintenance of seabed protection is vital for the safe operation of vessels in shallow waters. The growing number of self-manoeuvring high powered vessels is the reason of the growth of the protected seabed areas of in ports. The variety of bottom protection systems is related to the variety of the degradation processes to be controlled. Traditionally the identification of degradation processes is based on empirical methods and periodical inspections. It is followed by maintenance works. The cost of maintenance is related to the state of degradation. The method of the permanent identification of degradation is proposed in the paper. The monitoring method based on the measurement of the ship propeller jets velocities is presented in the paper.

1 INTRODUCTION

Degradation processes of seabed in the areas exposed to the direct action of ship propellers and thrusters or strong sea currents have a significant influence on the port operational costs. The maintenance costs are dependent on the type of soil, type of seabed protection and proper schedule of the maintenance works.

In modern ports due to economic reasons port manoeuvres of large vessels are commonly performed in the conditions very closed to the limiting values related to ship dimensions, under keel clearance, used power of thrusters and main propulsion, weather conditions and towing assistance.

This is mainly caused by the introduction of Ultra Large, high powered Container Ships (ULCS) over 8,000 TEU (Twenty feet Equal Unit), of 300–400 m length, equipped with 2000–3500 kW thrusters and 60–80 MW propulsion systems (Hermans & Degens, 2011). They can perform manoeuvres in very tight areas and strong weather conditions, up to port operational limits, using their thrusters and propellers to increase efficiency of manoeuvres assisted by tug boats.

The large power of vessel main engines is the reason of high propeller jets velocities. To protect the seabed from scouring and seabed protections from damage the maximum used power of main propellers is reduced to 40%–25% of maximum power.

In the cases the port operations intensity is on nearly equal level, the identification of seabed degradation can be assessed on the basis of prediction methods developed on the basis of real observations, physical model tests and CFD (Computational Fluid Dynamics) calculations (Kraskowski, 2009). If the port operations are carried out near the limiting values of operational characteristics for seabed or seabed protections more often inspections are included in the maintenance plan and they are carried out after each crossing of the limits.

2 DEGRADATION PROCESS OF SEABED PROTECTION

2.1 *Types of seabed protection*

To allow more powered manoeuvres in the areas exposed to strong influence of propeller jets the dredging works are followed by seabed protection works.

In ports with bigger water depth to draft ratios assumed for the design (maximum for the port) vessel the three layered granular filter of rip rap, a block mat on geotextile or a stone asphalt mat with riprap can be applied (Gijt & Broeken, 2005).

In ports with smaller depths where the soft bottom (similar to sand) effect is required the mattress of geotextile bags filled with sand on geotextile sheet are used. The reason is the required under keel clearance. It should be 0.45 m for sand and 0.6 for rocks and stone riprap.

When the berth is in operation it is possible to apply seabed protection that allows increasing size of ships manoeuvring in this area. In the available limited space the expensive and fragile 0.15–0.25 m thick stone asphalt mat can be used.

For example riprap bottom protection made of the 10–60 kg quarries limestone is necessary for a current 1.5–2.5 m/s, for the greater velocities 1.8–3.3 m/s the required weight is 60–300 kg.

Several layers built up a good filter structure depending of soil filter characteristics.

The flirter layer is usually the sand–tight geotextile. For the highly turbulent propeller jets over 3.5 m/s the required weight of block is 1–3 t. The alternative protection is asphalt mattress, quarry stone pattern grouted with asphalt bitumen or colloidal concrete.

2.2 *Prediction of degradation process of seabed protection*

This phenomenon depends on the type of protection, frequency and capacity of loading. Design and operation of seabed protection including the frequency of inspections of its technical condition undergoes the rules of civil engineering codes. Up to this rules the inspection should be carried out once a year.

The technical state between inspections is not known. It can be predicted using models of system degradation. If the seabed protection systems undergo the gradual degradation the limiting state of a system is assumed as the state when the preventive maintenance is required.

Time to the maintenance is a random variable. To avoid the discrete time and states of the system the model based on gamma process can be used (Zhou et al., 2009). Degradation process of a system

$$(\tilde{X}_t)_{t\geq 0}$$

is a gamma process, which can be described using system degradation characteristics, for every s:

$$0 \leq s < t, \tilde{X}_t - \tilde{X}_s$$

it has gamma distribution with parameters

$$\alpha(t-s), \beta$$

$$f_{\alpha\cdot(t-s),\beta}(x) = \frac{1}{\Gamma(\alpha\cdot(t-s))}\cdot\frac{1}{\beta^{\alpha(t-s)}}\cdot x^{\alpha(t-s)-1}\exp\left(-\frac{x}{\beta}\right)I_{\{x\geq 0\}} \quad (1)$$

where: $\alpha\cdot\beta$ = mean index of process degradation rate, $\alpha\cdot\beta^2$ = variance.

The characteristics of this monotonically increasing process are related to irreversible degradation processes of concrete structures, dykes, hydro-technical constructions during one service cycle. The inspection dates and the limit state of the system are the decision variables.

If the gradual degradation of the seabed protection system cannot be assumed different methods based on prediction of the propeller and thruster jet velocities are applied in the models degradation processes.

They are used to predict the maximum design loads and distribution of the loads in time and space domains to determine reliability or safety functions of seabed protection (Abramowicz-Gerigk & Burciu 2013; Roubos, 2006, Verheij, 1983; Verheij et al., 2010; Wilson et al., 2006; Zhou, 2009.). The methods of jet velocities assessment are based on different empirical formulae for open water propellers modified to real conditions (Hamill et al., 1999; PIANC, 2012; Gucma & Jankowski 2007; Whitehouse, 1998.) or numerical methods (Lam et al., 2006; Muscari et al., 2011.).

The effect of water depth to draft ratio and influence of rudder angle examined on big physical model with geometrical scale 1:16 was presented in (Abramowicz-Gerigk, 2010; Abramowicz-Gerigk, 2011). The mean axial velocities v of propeller jet behind the rudder in deep water (water depth to ship draft ratio h/T = 3) and shallow water (h/T = 1.2) conditions related to v_o—jet velocity in deep water with rudder angle 0 are presented in Table 1.

The observed velocities in shallow water are 20% higher than in deep water. The effect of 35° helm to port is propeller jet deflection to the port side and smaller area of higher velocities observed within the asymmetrical measuring plane.

In 2011 Ryan and Hamill (Ryan & Hamill, 2011) presented the findings from the experiment of a ship berthing alongside a quay wall and the effect of rudder angle on the magnitude of the scouring.

Van den Brink and Nielsen (van den Brink, 2014; Nielsen, 2005) performed physical model research in order to investigate the diffusion or spreading of velocity field due to bow thrusters of vessels moored near a vertical quay. More complex investigations on ship accessibility and port presented Willems (Willems et al., 2012).

In maritime transportation the results of model experiments are used in all aspects to o bserve the physical phenomena and predict the performance of real object (Burciu & Grabski, Gerigk 2005, Gerigk 2012; Kee et al., 2006). The modern trend is the development of complex methods including operational limits and human factor (Abramowicz-Gerigk & Burciu, 2011; Gerigk, 2004; Gerigk, 2008; Gerigk, 2012) to determine system safety.

Table 1. Mean axial velocities of propeller jet behind the rudder for Half Ahead.

h/T	Rudder angle [°]	v/v_o [m/s]
3	0	1.000
	35	0.970
1.2	0	1.251
	35	1.119

In 2013 the full scale measurements of scour holes formed due to bow thrusters and main propellers action in front of the quay wall were performed in Port of Rotterdam. After each departure the bathymetry near the quay was measured using a multi-beam echo sounder.

Along the full scale measurements in Port of Rotterdam Van den Brink (van den Brink, 2014) presented CFD study of bow thruster induced score holes formation at the quay wall in number of departures domain. However the results of prediction were very sensitive to the type of the seabed soil (sand and clay layers) and did not give the satisfactory results.

CFD methods can be used to determine the characteristics of the flow around berthing or unberthing vessel: stream lines, flow velocity and pressure fields (Kraskowski, 2009). Flow field generated by bow thruster during ship unberthing is presented in Figure 1.

This method of prediction can be used for the flat layer of unmovable protection material, like geotextile mattresses. A good conformity of CFD calculation with real performance of seabed protection was observed in Port of Gdynia in ferry terminal (Abramowicz-Gerigk & Burciu, 2011).

The presented methods are used in ports to predict the degradation processes however due to the operation of large vessels in divergent operational conditions and relatively cheap monitoring methods the inspections using a multi-beam echo sounder in many ports are carried out in month periods.

2.3 *Monitoring of loads determining the degradation process*

Data collection allows following the behaviour of the structure over time and determination of its remaining lifetime. The monitoring is essential to give well found information if the design loads are exceeded.

The best method of monitoring is a multi-beam echo sounding (Hermans & Degens, 2011). The program of inspections includes periodical, usually every month inspection and additional inspections after hazardous operations. The multi-beam echo sounders can map the seafloor by a fan of narrow acoustic beams, providing 100% coverage of the bottom. The three dimensional seabed maps are enough detailed to observe score holes or local damages of seabed protection.

Comparing the measurements with the results of CFD flow field calculations (Abramowicz-Gerigk & Burciu, 2011; Kraskowski, 2010) the velocities near the seabed can be predicted. Every crossing of limits can be noted and immediate inspection and repair works can be ordered. The example of CFD prediction of streamlines in the aft and fore parts of the car-passenger ferry during unberthing is presented in Figure 2.

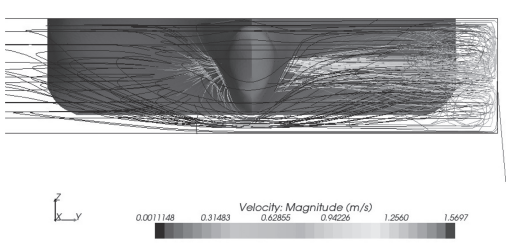

Figure 1. Bow thruster influence on the quay wall and seabed, CFD calculations.

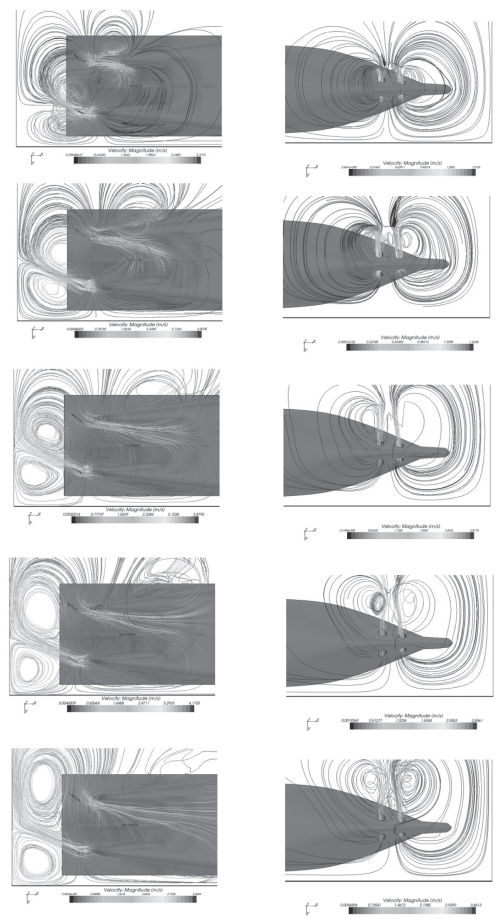

Figure 2. CFD streamlines prediction in the aft and fore parts of the car-passenger ferry during unberthing. Distance from the berth is equal to 0.1 ship breadth, water depth to draft ratio h/T = 1.2 (Abramowicz-Gerigk & Burciu, 2011).

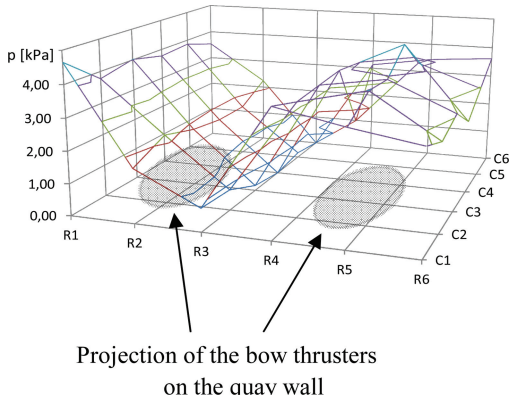

Figure 3. Pressure distribution measured on the quay wall during unberthing of m/f Stena Baltica, generated by bow thrusters. Positions of pressure meters CiRj: j = 1, ..., 6, i = 1, ..., 6 (Abramowicz-Gerigk, 2014).

The experimental solution for monitoring loads on the quay wall, introduced by Gdynia Maritime University in Port of Gdynia was a system for measurements of propeller or thruster jet induced pressure field. The system was installed in ferry terminal at berth Helskie II.

The pressure distribution measured on the quay wall is presented in Figure 3.

3 INFLUENCE OF LOADS MONITORING ON MAINTENANCE COSTS OF SEABED PROTECTION

The costs of inspections and repairs of seabed protection in berthing areas depend on berth construction and type of seabed protection.

Examples of expenses bear for the inspections and repair of mattress of geotextile bags filled with sand and pinned together, placed along the steel Larsen type tight wall are presented in Table 2 (Abramowicz-Gerigk, 2014).

This type of seabed protection is used in Port of Gdynia. The protected areas cover the zone along the whole length of the berth but have different width. In the area of propeller influence the protected area is about ship's beam.

The cost of hydrographical survey due to the technological development of echo sounding survey systems is still getting cheaper. Since last 10 years the cost dropped down about six times.

Comparing the costs of inspections giving 3D analysis of seabed protection with the costs of a system for monitoring loads from propeller jets, based on pressure meters it can be assumed that the pay of time of this system is 5 years. The calculations are based on the prototype system designed for research purposes. The main part of the cost is due to the expensive pressure meters.

Table 2. Examples of a unit price for expenses bear for the inspections and repair.

No	Type of costs	Cost
1	Soundings officially approved by the state marine hydrographical services in 50 m wide zone along the berth	11.00 EUR/1000 m^2
2	Inspections of protected seabed with siltation and damage measurements with divers attest	0.25 EUR/m^2
3	Inspections of protected seabed with siltation and damage measurements with divers attest, graphical cataloguing and digital recordings	0.35 EUR/m^2
4	Replacement of a damaged element of seabed protection	350 EUR/apiece

Loads monitoring has another economic aspect. The seabed protection in the form of mattress, made of single elements, pinned and tight together with ropes, should be repaired immediately after the damage of a few elements because the next excess of loads can result in extensive damage. The cost of not detected repair can include replacement of several dozen elements and delays in berth operation.

4 CONCLUSIONS

To limit scour of the seabed several pro-active measures can be undertaken. The higher water depths, limits of used power of propulsion units, seabed protection and frequent monitoring are the most popular solutions.

The latest investigations with respect to the prediction methods of score holes formation still need more research.

It can be observed that the differences between modelled and real soil—grain, cohesion, layers formation have the significant influence on the accuracy of prediction (van den Brink, 2014). The more departures the larger is the deviation between measured and calculated scour depth, therefore the complex methods including all influencing parameters should be introduced (Abramowicz-Gerigk & Burciu, 2013; Gerigk 2006).

The monitoring of loads induced by propeller jets on the seabed near the quay wall is especially important in shallow water, defined in the non-dimensional sense, with respect to the ship draft.

The loads monitoring system presented in the paper operated on line allows for the detection of all emergency situations, when ship master uses the power of propellers and thrusters over the permissible limits. This is the most important factor in the prediction of the condition of seabed protection made as geotextile sand filled bags mattresses. It can save maintenance costs related to the replacement of wide area of damaged elements and are the most important for a modern port as allows avoiding the delay in the berth operation.

The use of Self-Organizing Maps for diagnosing faults in motor bearings

S. Al-Dahidi
Energy Department, Politecnico di Milano, Milan, Italy

ABSTRACT: In this paper, the use of Self-Organizing Maps (SOM) for fault diagnostics is proposed. The method is tested with an artificial case study representing three start-up faulty behaviors of equipment and then, applied for diagnosing faults in motor bearings: the data have been collected from Case Western Reserve University Bearing Data Center with three failure modes. The method has been tested and compared to the K-Nearest Neighbor (KNN) method. The obtained results show that the SOM algorithm is a powerful visualization tool able to recognize the fault classes with a low misclassification rate. Furthermore, the quality of the SOM has been assessed using two measures: average quantization error and topographic error and their sensitivity with respect to the map size is investigated.

1 INTRODUCTION

In industries such as nuclear, oil and gas, and chemical, equipment may have different types of faults, for example, motor bearings may degrade due to cracking, valves may leak or sensors may provide wrong readings (Gonçalves et al. 2011, Huang 2012, McDonnell et al. 2014).

In modern society, motor systems are used in industrial applications in a wide range of operating areas. Thus, the reliability of motor systems is of paramount importance in several industrial applications (Isermann & Balle 1997, Kowalski & Orlowska-Kowalska 2003, Önel et al. 2006, Huang 2012). Various studies show that more than 40% of all machine failures occur because of bearing failures (Schoen et al. 1995, Ng et al. 2014). Therefore, a prompt diagnosis of these faults can greatly increase equipment reliability and safety and reduce corrective maintenance costs (Tamilselvan et al. 2013a).

For these reasons, several fault diagnosis techniques have been developed in the last few decades. Some examples of fault diagnosis techniques applied in diagnosing faults of motor bearings are: Artificial Neural Networks (ANNs) (Alguindigue et al. 1993, Li et al. 2000, Gao & Ovaska 2001, Yang et al. 2002, Samanta & Al-Balushi 2003), Support Vector Machines (SVMs) (Abbasion et al. 2007, Sugumaran et al. 2007, Yu et al. 2007), Deep Belief Networks (DBNs) (Tamilselvan & Wang 2013b), Fuzzy Logic (FL) (Klir & Yuan 1995, Gao et al. 2001, Wang & Hu 2006, Zio & Gola 2006b, Wang & Chen 2007), Genetic Algorithms (GA) (Gao & Ovaska 2001), and Self-Organizing Maps (SOM) (Kalyan et al. 2010, Gonçalves et al. 2011). Recently, SOM have got much interest because of their performance in fault detection and diagnosis in numerous industrial systems (Gonçalves et al. 2011).

These methods can be broadly classified into supervised and unsupervised learning methods. The supervised learning methods learn the relationship between the input values and the desired target values, i.e. labels, by feeding the method with a set of inputs and the desired target outputs, whereas the unsupervised learning methods learn a hidden relationship in the input values without the target outputs (Baraldi et al. 2013, Tamilselvan et al. 2013a).

In this work, the SOM technique has been adopted for fault diagnosis purposes for both, supervised and unsupervised learning. The method has been applied firstly to an artificial case study representing three start-up faulty behaviors of equipment and then applied to a real case study concerning three failure modes of motor bearings (inner race, outer race and ball faults): the data have been collected from the Case Western Reserve University Bearing Data Center (CWRU). The method has been tested using 144 test patterns and the misclassification rate has been calculated and compared to the misclassification rate obtained by using the K-Nearest Neighbor (KNN) method for the same dataset.

The final results show that the SOM algorithm is a powerful visualization tool able to recognize the fault classes with a lower misclassification rate than those of other empirical classifiers such as KNN. Furthermore, the quality of the SOM has been assessed using two measures: average quantization error and topographic error and their sensitivity with respect to the map size is investigated.

The remaining of this paper is organized as follows; in Section 2, the problem is stated, in Section 3, the Self-Organizing Maps (SOM) are briefly introduced, Section 4 presents the application of SOM to the artificial case study, whereas Section 5 presents the application of SOM to motor bearings datasets. In Section 6, a sensitivity analysis of the SOM quality measures for different map sizes is introduced. Finally, some conclusions are reported.

2 PROBLEM STATEMENT

In this work we assume that we have available the vibration measurements of a motor corresponding to different types of bearing faults. These vibration values have been used to extract several features which are used to train a fault diagnostic model whose objective is the classification of the fault type. Each fault is assumed to be represented by a cluster, *C* (Baraldi et al. 2013). In the following sections, we discuss the use of Self-Organizing Maps (SOM) for diagnosing the motor bearing faults.

3 THE SELF-ORGANIZING MAPS (SOM)

Self-Organizing Maps (SOMs) or Kohonen maps are types of Artificial Neural Networks (ANNs) that are trained using supervised/unsupervised learning to produce a low-dimensional discretized representation (typically 2-dimensional) of an arbitrary dimension of input space of the training samples (Zhong et al. 2005).

Figure 1 shows the basic SOM in which the continuous *n*-dimensional input $\vec{x} = [x_1, ..., x_n]$ is mapped into a discrete output of ℓ neurons (map units) organized in 2-dimensional lattice matrix with a height *h* and a width *w*, $\ell = h \times w$.

The number of neurons may vary from a few dozen up to several thousand depending upon the application. Each neuron *j* is represented by an *n*-dimensional weight vector $\vec{w}_j = [w_{j1}, ..., w_{jn}]$ and is connected to its adjacent neurons by a neighborhood relation, which dictates the topology or structure of the map. Furthermore, it is fully connected to all inputs (Vesanto et al. 2000, Zhong et al. 2005).

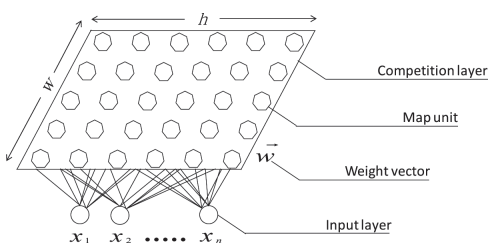

Figure 1. Basic SOM structure.

For each input vector, the best matching weight vector is selected and its topological neighbours on the map are updated. The final results are that the neighbouring neurons have similar weight vectors (Zhong et al. 2005). In more detail, the internal process of SOM can be divided into the following steps (Zhong et al. 2005, Zio & Popescu 2006a, Gonçalves et al. 2011):

1. Initialization: in which random values are chosen for the initial weight vector $\vec{w}_j(0)$ of each neuron *j*, $j = 1, \ldots, \ell$ in the output layer, and
2. Training the map: that is based on three principles repeated for *NI* iterations (Kohonen 1997, Araujo & Barreto 2002):
   - Competition: in which a competition between all the ℓ neurons for each input vector *x* is done, with the winning neuron being called the Best Matching Unit (BMU) for which the Euclidean distance $\|\vec{x} - \vec{w}_j\|$ is minimized. The BMU index for the corresponding input vector *x* is denoted by $i(x)$.
   - Cooperation: in this process, the neighbors of the BMU of the corresponding input sample *x* are selected. This is done according to the topological neighborhood function $h_{j,i}(x)$. A typical choice of this function is the Gaussian function $h_{j,i}(x) = exp(-d^2_{j,i}/2\sigma^2)$, where $d_{j,i}$ is a lateral distance between the winning neuron *i* and neuron *j*, and σ is the neighborhood radius. The neighborhood shrinks gradually with time, i.e. number of iterations, according to a time constant τ_1.
   - Adaption: in which the weights of the BMU neighbors are updated according to the formula $w_j(t+1) = w_j(t) + \alpha(t) \times h_{j,i(x)}(t)[\vec{x} - \vec{w}_j(t)]$, where $\alpha(t)$ is the learning rate. The learning rate decreases gradually with time, i.e. number of iterations, according to a time constant τ_2.

     Since the SOM algorithm is based on Euclidian distances; the scale of the input features is very important in determining the map, so the features in the dataset are usually normalized. For example, each feature to have a unit variance (Vesanto et al. 2000).
3. Visualization and analysis: in which the trained SOM map is shown as a regular lattice of cells, the properties of which show the associated values. For this purpose, several ways can be used such as (Vesanto et al. 2000, Ultsch 2003):
   - Unified distance matrix (U-matrix) that visualizes distances between neighboring map units using indexed colour coding and helps to recognize the clusters of the map:

high values of the U-matrix indicate a cluster boarder, whereas uniform areas of the low values indicate clusters themselves.

Labelling that is typically an empty grid that shows the edges of the map units and helps to categorize the units by giving them names, i.e. labels.

- Hit histogram that shows for a given dataset the distribution of their hits on the U-matrix.

Several indicators can be calculated to measure the quality of the trained SOM. In this work, the following indicators have been considered (Vesanto et al. 2000, Pölzlbauer 2004):

1. Average quantization error (q_e) between training vectors and their BMUs on the map: it is used to measure the data representation accuracy.
2. Topographic error measure (t_e) which is the percentage of data vectors for which the first and second BMUs are not adjacent units: it is used to measure the dataset topology representation accuracy.

In this work, training and testing of the SOM have been performed using the SOMVIS software package, an adds-on for the Matlab SOM toolbox (Vienna University of Technology). The learning has been done under the default settings: the learning algorithm is the batch algorithm with linear initialization (Vesanto et al. 2000).

4 ARTIFICIAL CASE STUDY

In this Section, the results of the application of SOM to an artificial case study are presented and the performance of the method is examined. The artificial case study is designed by simulating $N = 750$ transients representing the start-up behaviors (Baraldi et al. 2013, Al-Dahidi et al. 2014) of $C = 3$ faulty classes (250 transients for each class); exponential, parabolic, and linear. The length of each transient T is 101 time steps. All transients of the same class differ only for different values of the parameters governing the functional behavior e.g. the slope value in the linear behavior, whereas two transients of different classes are in a different functional behavior (Baraldi et al. 2012a, Baraldi et al. 2013).

Figure 2 shows the simulated 750 transients of the three faulty classes. Among these transients, 450 transients have been used to train the SOM, i.e. 150 transients for each class, whereas the remaining transients have been used to verify the performance of the method.

However, the total number of classes, C, and the target outputs i.e. labels are not expected to be known and hence, they will not be used to derive the fault classification but only to verify the performance of the method i.e. unsupervised learning (Zhong et al. 2005).

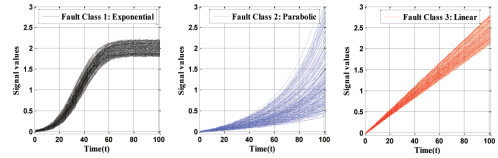

Figure 2. Simulated 750 transients of the three fault classes: exponential, parabolic, and linear.

The definition of the similarity between the transients is performed by considering the functional characteristics of the signal transients, e.g. slope, form, curvature.

In this regard, a statistical indicator feature extraction technique has been used to describe the functional characteristics of the i-th transient by considering its mean μ^i, standard deviation σ^i and skewness s^i, $i = 1, \ldots N$, according to the Equations 1, 2, and 3, respectively (Joentgen et al. 1999):

$$\mu^i = \frac{1}{T}\sum_{\ell=0}^{T-1} x_\ell^i \tag{1}$$

$$\sigma^i = \sqrt{\frac{1}{T}\sum_{\ell=0}^{T-1}\left(x_\ell^i - \mu^i\right)^2} \tag{2}$$

$$s^i = \frac{\frac{1}{T}\sum_{\ell=0}^{T-1}\left(x_\ell^i - \mu^i\right)^3}{\left(\sigma^i\right)^3} \tag{3}$$

In this way, each transient i is transformed into a vector of length 3 and hence, a matrix of size 750×3 is produced when considering the 750 transients. The matrix data has been normalized so that each feature has a unit variance and the SOM map has been trained using the Matlab SOM toolbox under the default settings. The topology of the map was fixed manually to contain 240 neurons, i.e. map size $(h \times w) = 20 \times 12$.

The results of the training phase are shown in Figure 3. The U-matrix (Fig. 3 (left)) shows the distances between the neighbouring map units and thus visualizes the cluster structure of the map. Each value is indicated with a colour, and the colour bar on the right shows what the colours represent: high values on the U-matrix mean large distances between the neighbouring map units, and thus indicate cluster borders, whereas uniform areas of the low values indicate clusters themselves (Vesanto et al. 2000).

From the visual assessment of the U-matrix, it is clear that there are three clusters ($C = 3$) denoted

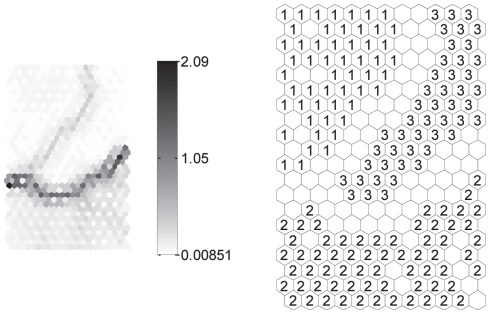

Figure 3. Unsupervised training phase (U-matrix (left) and labelling (right)).

by 1, 2, and 3 as shown in Figure 3 (right): the labelling plot that shows the label of each training transient added to the map to verify the performance of the method.

It is clear that each cluster contains only the transients which have the same functional behaviour represented by the three statistical indicators, μ^i, σ^i, and s^i. It is worth noticing that the distance between fault class 1, i.e. the exponential behaviour, and fault class 3, i.e. the linear behaviour, is small as indicated by the whiter map units compared to the distance between fault class 2 and fault class 3 (blacker map units).

Several measures have been developed to quantify the quality of the trained SOM maps, among these:

- The average quantization error (q_e), in which the average distances of the sample data to their correspondence BMUs is calculated. The actual average quantization error (q_e) of the trained SOM map is 0.06.
- The topological error measure (t_e), in which the respective first and second BMUs of all the data samples, are determined: If these are not adjacent on the map, then, this is considered an error. The total error is then normalized to a range from 0 to 1, where 0 means perfect topology preservation (Pölzlbauer, 2004). The actual topological error (t_e) of the trained SOM map is 0.05.

Finally, 300 test samples, i.e. 100 transients for each fault class, have been used to verify the performance of the trained SOM map: for each test sample, the BMU is located in the map, a counter in the map unit is increased each time it is the BMU and hence its size is increased, i.e. hit histogram (Vesanto et al. 2000). Figure 4 shows the hit histogram of the 300 testing data. It is worth noticing that each of the 100 test samples belonging to one fault class have been grouped inside its corresponding cluster. Hence, the actual misclassification rate is 0%.

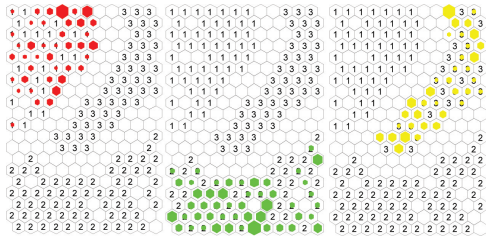

Figure 4. Hit histogram of 300 test samples.

5 MOTOR BEARING CASE STUDY

In this Section, the results of the application of the SOM algorithm to motor bearing datasets are presented and the performance of the method is examined. The bearing data have been collected from the Case Western Reserve University Bearing Data Center (CWRU). Three failure modes have been considered, $C = 3$: inner race, outer race, and ball faults that have been denoted in this work by 2, 3, and 4, respectively.

It is worth mentioning that the experiments were conducted using a 2 hp Reliance Electric motor, and acceleration data was measured at locations both near to and remote from the motor bearings. Faults ranging from 0.007 inches in diameter to 0.021 inches in diameter have been considered and 720 vibration data were recorded for four different operational conditions represented by motor loads from 0 to 3 horsepower (motor speeds of 1797 to 1720 RPM). More details can be found in (CWRU).

Then, five features extracted using Haar basis (Baraldi et al. 2012b) and Symlet6 basis (Chebil 2009) have been used: minimum & maximum Haar wavelet coefficients, Norm Node 5 Symlet6 wavelet, Norm Node 7 Symlet6 wavelet, and Norm Node 12 Symlet6 wavelet. 80% of the total collected data set has been used as the training set, i.e. 576 vectors, whereas the remaining data, i.e. 144 vectors, has been used as the testing set. In this way, the size of the training data is 576×5, whereas the size of the testing data is 144×5. Then, according to the differences in the ranges of the features values, the data has been normalized by applying the natural logarithm and the SOM map has been trained using the Matlab SOM toolbox under the default settings. The topology of the map was fixed manually to contain 375 neurons, i.e. map size $(h \times w) = 25 \times 15$.

The total number of classes, C, and the target outputs i.e. labels will not be used to derive the fault classification but only to verify the performance of the method, i.e. unsupervised learning (Zhong et al. 2005). The results of the training phase are shown

in Figure 5. Again, the U-matrix (Fig. 5 (left)) shows the distances between the neighbouring map units and thus visualizes the cluster structure of the map, whereas the labels plot (Fig. 5 (right)) shows the label of each training transient added to the map to verify the performance of the method (Vesanto et al. 2000). From the visual assessment of the U-matrix, it is clear that there are more than 10 clusters ($C > 10$). This means that each of the original fault classes has been split into three/four sub classes. This can be explained by the fact that the vibration data was recorded for different load levels, i.e. 0 to 3 horsepower (motor speeds of 1797 to 1720 RPM) (CWRU).

For this reason, each main cluster has been divided into several sub clusters each containing the same fault behavior but for different load levels, i.e. 0 to 3 horsepower. Another way to see the classification of the fault data is shown in Figure 6 in which the distance measure has been used to indicate the differences between the map units.

The actual average quantization error (q_e) and the topological error (t_e) of the trained map are calculated and equal to 0.09 and 0.02, respectively.

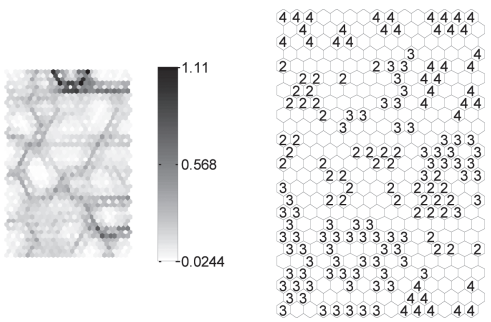

Figure 5. Unsupervised training phase (U-matrix (left) and labelling (right)).

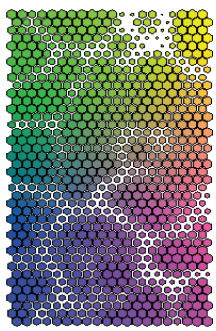

Figure 6. Unsupervised training phase using another visualization tool.

One has to remember that the class information has not been used to derive the fault classification and thus, the obtained results could be suboptimal. However, within the SOM toolbox, it is possible to train the network taking the class information into account, i.e. supervised learning (Vesanto et al. 2000), so the map has been trained, in addition to the 576 training patterns and the five features with the class information, i.e. the labels.

Figure 7 shows the results of the supervised 25×15 trained SOM. Again, from the visual assessment of the U-matrix, it is clear that there are more than 10 clusters, whereas the labelling plot shows the three main fault classes. For each main class, one can determine the sub clusters of each from the U-matrix.

It is worth mentioning that the class of each map unit shown in Figure 7 has been determined by taking the label of the maximum similarly added patterns to that map unit (Vesanto et al. 2000). In this way, the misclassification rate of the 576 patterns has been calculated to be 0.87% (5 out of 576 patterns are misclassified).

Figure 8 shows the hit histogram of the 144 testing data classified into their corresponding clusters. It is worth mentioning that two test patterns belonging to cluster 3 have been classified wrongly as belonging to cluster 4 as indicated in the Figure.

To verify the power of the SOM method compared to other classification methods: the K-Nearest Neighbour (KNN) method has been adopted to classify the same bearing dataset and the misclassification rate has been compared to the misclassification rate obtained by using the SOM method. Both methods, KNN and SOM, have been trained and tested with the same 576 and 144 patterns, respectively. It is worth mentioning that in the KNN method the number of neighbors has been fixed to 24 (i.e. square root of the number of patterns in the training set). Again, using the

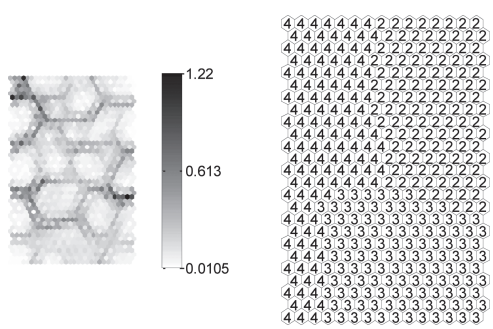

Figure 7. Supervised training phase (U-matrix (left) and labelling (right)).

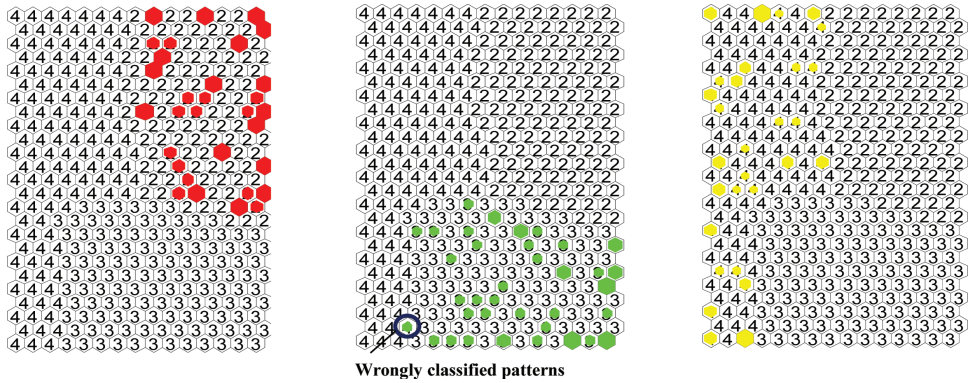

Figure 8. Hit histogram of 144 test samples.

Table 1. SOM quality measures with respect to the different map sizes of the two case studies.

Parameters	Artificial case study			Bearing case study		
Map sizes	5×3	10×6	20×12	10×5	20×10	40×20
q_e	0.34	0.12	0.05	0.34	0.13	0.05
t_e	0.01	0.03	0.06	0.017	0.018	0.019

KNN method, three fault classes have been identified, whereas the misclassification rate has been calculated that as 4.17% (i.e. 6 patterns have been classified wrongly). However, the misclassification rate obtained by using the supervised trained SOM has been calculated as 1.39% (i.e. 2 patterns have been classified wrongly). For more details of the KNN method, refer to (Moosavian et al. 2013).

6 SENSITIVITY ANALYSIS OF SOM QUALITY MEASURES FOR DIFFERENT MAP SIZES

In this Section, the sensitivity of the SOM quality measures with respect to the map size is discussed for the two case studies of Section 4 and 5. According to the size of the dataset in each case; three map sizes have been examined. Table 1 reports the three map sizes and the corresponding SOM quality measures, q_e and t_e, for each case study.

It is worth noticing that as the map units are increased, the average quantization error (q_e) decrease s since the data samples are distributed more sparsely on the map, whereas the values of the topographic error (t_e) increase because an unnecessary fold (train) occurs (Pölzlbauer 2004).

7 CONCLUSIONS

In this work, a diagnostic method based on Self-Organizing Maps (SOM) has been presented. The method has been tested on an artificial case study representing the behavior of equipment during start-up in the presence of different faults. The model has then been applied to a real industrial case study concerning motor bearing degradation data.

The method shows its ability in identifying correct fault classes and classifying the subsequent test data with a low misclassification rate compared to other fault diagnosis methods such as the K-Nearest Neighbour (KNN) method.

In addition, two quality indicators have been calculated for each trained map: the average quantization error, q_e and the topographic error measure, t_e. In addition, their sensitivity to the map size has been investigated. Their sensitivity to other SOM parameters could be an object of future research work.

Selected safety aspects of polymer composites with natural fibres

A. Krzyżak & D. Vališ
University of Economy and Innovation, Lublin, Poland

ABSTRACT: The paper deals with selected aspects of safety features of polymer composites with natural fibres. These kinds of composites have been starting to be used quite widely in the technical industry like automotive and aerospace, etc. Our paper will present approaches for selection of those properties and features of polymer composites which are to be used for an event cause description. In this paper we will present selected mechanical properties and qualities which usually create the fundamental point of view in terms of decision about the applicability of polymer composites. The materials measures like strength, hardness and elasticity play vital role in terms of physical in-situ applicability. Such properties are firstly observed and assessed in terms of system and object safety parameters.

1 INTRODUCTION

Failure is a term widely used in technical practice especially concerning dependability theory. It is inevitable to realize that a failure is of key importance for operation and function of technical items. Theory and practice in particular shows that failures occur under different situations, various circumstances, ranging conditions, etc. For safety and reliability practitioners failure is a basic term in theory, and it is key and essential for observing stochastic relations of item behaviour. It is an event which is used in probability theories on a general level; the term probability event is used. In dependability theory it is necessary to realize the fact of failure as a stochastic term, to understand its meaning, and to understand other links. What we need to catch up here is the meaning and relation to safety. The requirements on polymer composites are to be failure safe or to prevent further failure propagations—once failures occur. For more details see e.g. Elsayed 1996, Meeker & Luis 1998, Stodola et al. 2013, Werbinska-Wojciechowska 2013, Werbińska 2007.

It is inevitable at some point failure (of equipment, a device, an item or a system) will occur. The reasons for this occurrence can vary. Usually the main factor is that the applied load exceeds the dimension/robustness of the product. The load can be purely mechanical (i.e. force, tension), purely electrical (i.e. power, electromagnetic field), purely chemical (such as the effect of chemical substances), general physical (i.e. warmth, radiation), a combination of these or of a totally different nature. Whenever the applied load exceeds the assumed dimension of the item, unwanted (usually irreversible) processes start, and sooner or later a failure occurs. The load can be one time load or it can be applied a number of times. Concerning the first instance, overload failure will occur and in the second case fatigue failure will occur. As time passes, the product could become weaker for any one of many reasons (unless a failure occurs immediately). Our concern is focused on polymer composites characteristics which—influenced by operational environment—may lead to failures without expecting them.

In describing failures there are many factors and characteristics to consider. One of which is the failure profile—for general principles see Figure 1. This profile depends on the failure causes; the failure manifestations (namely the ways and mechanisms of failure) and the failure consequence. These failure causes can be design failures, manufacturing failures, overstress failures, misuse failures or degradation failures. The failure manifestations may be random, gradual, sudden, common cause, primary, secondary, intrinsic or extrinsic. The consequences could be insignificant, marginal, minor, major, critical, catastrophic or also scaled differently. For more

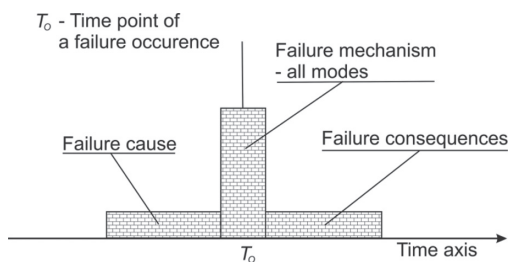

Figure 1. Failure profile—essential approach.

details see e.g. Blishke 2000, Modares et al. 1999, Woch & Leski 2014, Woch 2013.

While observing a technical item—the polymer composites in our case, the main concern is on the possible causes of failures and their development over time which might result from a failure occurrence. Theoretically dealing with failures, it is possible to describe their causes, nature of occurrence, process of development, and modelling of these failures is possible at the same time.

A range of importance and numerical values associated with the failures can be determined. However, the fundamental desire is to eliminate failure occurrence, reduce its frequency, limit the number of its occurrences over a specified time period or in relation to another observed dependent quantity (e.g., cycles, etc.). The ultimate intention is to be able to determine failure occurrence exactly, simply, the aim is to get a better profile of an observed item from the view of its dependability and related properties.

Furthermore, there is a necessity to be able to describe the possible classes of failures, their profiles, development, consequences, and other relations which might be important for dependability theory and especially for this paper itself.

Due to lack of knowledge in the area of composite materials our main concern is to determine principles for failure occurrence. We focus on assessment in the area of polymer composites with natural fibres where both failure causes and mechanisms will be investigated. As the composite materials are intended for using like safety measures e.g. covers, cases, shields, walls, etc. we try to investigate possible failures caused by hard impact onto the material structure. This impact is simulated in lab by concentrated mechanical load of defined features and characteristics. The composite covers are used in order to protect the surroundings of technical system both against failure propagation and impact from outside. Therefore the failure occurrence in the polymer composites with natural fibres will be our main concern from the safety aspects point of view.

1.1 *Current situation in terminology*

Due to the ISO/IEC representatives, industrial experts and national bodies there is a set of terminology related to the issue of failure. Failure according to the present version of the IEC 60050 (191) is defined as: "termination of the ability of an item to perform a required function". There are three things to note: (1) After failure the item has a fault; (2) Failure is an event, as distinguished from fault, which is a state; and (3) This concept as defined does not apply to items consisting of software only. Failure according to the newly upgraded version IEC 60050 (191) is defined as: "loss of ability to perform as required". It is noted that: (1) When the loss of ability is caused by a pre-existing condition, the failure occurs when a particular set of circumstances is encountered; (2) A failure of an item is an event, as distinct from a fault of an item, which is a state; and (3) Qualifiers may be used to classify failures according to the severity of consequences, such as catastrophic, critical, major, minor, marginal and insignificant, the definitions depending upon the field of application. We fully respect this concept regarding the polymer composites with natural fibres.

It results from these definitions and further analysis that the term "failure" will be in terms of polymer composites understood as an event which leads straight to either a partial or complete loss of ability of an item to fulfil a required function. There is currently in process the modification and updating of terminology related to this topic, and hence the existing view of the understanding of these concepts (failure and related facts) has been changing.

While working with the term failure, as well as with relating states, it is necessary to take the current terminology mismatch into account and to adapt possible decisions to it. The possibility of a realized change has to be accepted along with all the resulting consequences. Unfortunately, this change will violate the understanding of all existing terms/disciplines introduced so far that deal with failure and dependability.

Nevertheless our concept of understanding failures of polymer composites with natural fibres will be oriented on the identification of failure causes. The investigation shall open the area where safety aspects of failures of polymer composites with natural fibres will be clearer.

1.2 *Influence of the failure*

When considering a failure of polymer composites with natural fibres it is necessary to draw attention to some related events. As the term failure relates to the prevention of an item's ability in performing a required function it is clear that this inability of a system or a product to operate in a required way is a key term determining a failure.

Based on many studies and approaches a factual scale of individual functions description was formed for a system. On the basis of these assumptions it is also essential to distinguish the influence of a failure on a function performed by an item. A failure occurrence might affect the range of the function especially when main observed system serves as safety element. An outline of item functions is provided to make the understanding much easier, though it should be remembered that failure

occurrence is not strictly limited to the type of item function.

A required function specifies an item task. A correct, exact and unequivocal definition is a primary starting point for all dependability definitions as well as for a right failure definition. Operation conditions affect significantly both dependability and especially possible failure occurrence, hence the reason why they have to be determined very thoroughly. We concentrate on the main and support functions (Valis & Bartlett 2010) in terms of failure occurrence and function loss of polymer composites with natural fibres.

The required function and/or operation conditions might be time and operation environment dependent. In this case a mission profile has to be determined and all safety and dependability viewpoints have to be related to it. A representative mission profile and corresponding dependability targets have to be stated in the item's specification. The mission duration is often/usually considered as a parameter *t,* that is time. The dependability function—especially the reliability function is designated as R(t). R(t) is the probability that no failure at item level will occur in the interval (0;t⟩, often with the assumption R(0) = 1, meaning that at time $t = 0$ the item was in the state of operation. For clearer statement we will also work here with pdf $f(t)$. In order to avoid confusion a distinction between predicted and estimated (assessed) dependability should be made on the basis of a real evaluation during operation or tests. The predicted reliability—failure free interval or failure occurrence load point is calculated on the basis of the item's structure. The estimated reliability is specified on the basis of a statistical evaluation of reliability tests. Our experimental data and procedure for gaining them will be described further. The field data will be collected thank to the mechanical experiments with polymer composites with natural fibres while operating and environmental conditions will be changed. The change of environmental conditions is to serve the acceleration of system deterioration and technical life shortening. This will be possible thank to the climatic chamber used for experiments. We apply specific climate environment in the chamber for degradation and deterioration of the polymer composites with natural fibres. The climate will be represented by increased or decreased temperature with humidity influence in positive temperatures range.

1.3 *Failure occurrence cause*

According to the IEC 60050 (191) the circumstances occurring during design, manufacture or use which have resulted in a failure are the cause of a failure. To decide how to prevent a failure or its reoccurrence it is necessary to know the cause of a failure. This is the main concern of our assessment of polymer composites with natural fibres. Failure causes can be classified in relation to the life cycle of the system. The cause of a failure can be intrinsic, due to weaknesses in the item and/or wear out, or extrinsic, due to errors, misuse or mishandling during the design, production and especially the use itself. Extrinsic causes often lead to systematic failures which are deterministic and might be considered like defects (dynamic defects in software quality). Defects are present at $t = 0$, even if they cannot be discovered at $t = 0$. Failures always seem to appear in time, even if the time to failure is very short as it can be with systematic or early failures.

The main causes according to Valis & Bartlett 2010 can be further explained. However we will concentrate only on:

– design failure,
– weakness failure,
– manufacturing failure,
– ageing failure.

These causes are shown diagrammatically in Figure 2. Design failure occurs due to inadequate design. It is basically any failure directly related to the item design. It means that due to the item design a part of the whole degraded or got damaged and this resulted in a failure of the whole. Weakness failure occurs due to weakness (internal) inherent or induced in the system so that the system cannot stand the stress it encounters in its normal environment. Manufacturing failure is caused by nonconformity during manufacturing and processing. It is basically any failure caused by faulty processing, or inadequate manufacturing, or an error made while controlling the process during manufacturing, tests and repairs. An ageing failure is caused by the effects of usage and/or age.

In further steps principles of failure occurrence investigation in the area of polymer composites with natural fibres will be presented.

The investigation will cover laboratory mechanical tests which will be performed on composited materials after accelerated environmental influence.

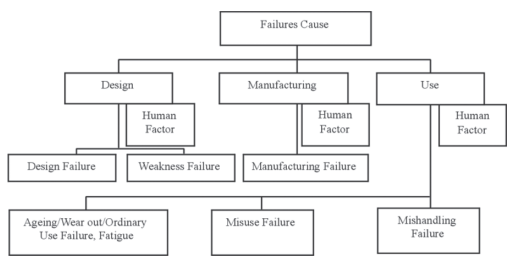

Figure 2. Typical failure causes.

At the moment of this paper submission several climatic tests on composite materials have been completed (see details in the proposed methodology bellow) and mechanical tests launched. Since this paper is describing a possible methodology for composite materials investigation the results describing composite materials properties in terms of safety features will be presented at the conference presentation.

1.4 *Context with risk assessment*

Since we are aware of co-relation of the obtained outcomes with risk area we propose following principles. We expect the risk here is again the combination of probability of undesired event occurrence and consequences measure of the composite material. We do not take into account the sometimes used discover/detection ability neither the countermeasures. Therefore for further calculation the probability of composite material fracture at certain level of load will be taken into account.

Our point of view on risk therefore looks following way:

$$\text{Risk} = \text{Probability} \times \text{Consequences} \tag{1}$$

We respect that the probability will be delivered in the numerical form. Therefore also the consequences will be described in the quantitative form in order to perform further description of the risk. For more details please refer e.g. to Vališ et al. 2011.

2 PROPOSAL OF ESSENTIAL STEPS IN METHODOLOGY FOR ASSESSMENT OF A POLYMER COMPOSITES FAILURE OCCURRENCE

2.1 *Properties of laminate*

Composite materials consist of at least two components constituting the reinforcement and the matrix. Laminates are specific group of composites with reinforcement layer. They are used for structural components such as a plate, which are loaded on the surface in points. The properties, characteristics, structure and texture of the laminates-composites was given and guaranteed during the manufacturing process. For more details see e.g. Błażejewski et al. 2010, Krzyżak 2013.

The active forces acting on the laminate are generally orthogonal to surface of the laminate. Plates are loaded with static and dynamic forces. Therefore there is a need for research on the flexural strength and impact resistance. Currently there are used significant quantities of composite reinforcements with plant origin such as for example, kenaf, jute, flax. The increase in the volume fraction of the strengthening increases flexural strength. In some cases, it is important the way how to prepare the production of composites, and increase the adhesion in combination two materials: fibre—resin. Yousif and others (Yousif et al. 2012) showed that reinforcement of epoxy with treated kenaf fibres increased the flexural strength of the composite by about 36%, while, untreated fibres introduced only 20% improvement. Often natural fibres of plant origin are used as reinforcement in a hybrid combination with, for example, glass fibre (Ramesh et al. 2013), carbon fiber (Noorunnisa Khanam et al. 2010) or others natural fibers (Jawaida et al. 2010). This increases the mechanical strength of the laminates, which is advantageous in view of the potential use of natural composites.

With respect to the laminates as a structural material, regardless of the type of reinforcement, there are known some behaviour characteristics during the mechanical loading of laminates. Composites with woven reinforcement demonstrate (Dauda et al. 2009) a linear relationship between stress and deformation. Whereas the reinforcement of laminates in the form braided reinforcement show a non-linear dependence is determined by an angle of orientation of the fibre bundles with respect to the axis of symmetry. The increase in flexural strength and modulus values affects the volume fraction of fibres in the composite volume, and the surface density of the strengthening.

The volume fraction of fibres in the composite greatly affects a method of producing composites. Composites produced by hand lay-up method have the most resin. Therefore, their strength is relatively small because of the small percentage of fibres. In addition, a significant share of the resin also contributes to their rapid destruction. The resin in a larger volume is fragile and easily undergoes cracking under stress. The lack of continuity of the resin matrix leads to the direct and uniformly distributed impact of the load on the reinforcing fibres of the composite, causing their premature failure. Hand lay-up method is fraught with a total lack of the possibility of eliminating the defects of the composite structure in the form of air bubbles, which significantly decrease the mechanical properties of composites. Other methods such as pressing, vacuum bagging method, and the infusion method with other more technologically and machine advanced—like winding methods or the autoclave. Such methods allow greater or lower extent to the elimination formation of defects in the structure. They also contribute to an increase in the volume fraction of the strengthening and greater repeatability in production. The principles in listed methods reduce the large measurement

errors that are typical for measurements by most physical and mechanical properties of all polymer composites. Measurement error may become large while it does not show any statistically significant changes in the properties despite considerable differences in the average value of the flexural strength (de Deus et al. 2005).

Natural fibres unfortunately have a high water absorption and susceptibility to deformation under the influence increased temperature. Composites reinforced natural fibres demonstrate significant decrease in the mechanical strength even at 75°C (Kaundal et al. 2012).

Laminates are subject to mechanical damages as a result of the creation of dynamic, cyclic loads. The sudden point impact of quite a considerable force over a large area of the laminate causes a surface and internal damages to the composite structure at the impact's place. Surface damage consists in break of the continuity of the matrix and its possible chipping. Cracks of resin at the impact point are in general a network of densely arranged features. In contrast, outside the place of impact cracks usually move more or less radially from the point of impact and direction collapses in places of occurring defects in the structure. Furthermore by local action of sudden forces there are also ruptures of brittle fibres, for example, glass fibres (Xu et al. 2012). As a result of impact is also created delamination between each inner reinforcement layers (Sevkat et al. 2009). At each successive dynamic load there has been increasing internal delamination, increasing damage of surface and brittle failure of the fibre, until complete destruction of the laminate which occurs at the moment of puncture (Evci & Gülgeç 2012). In the case of stroke during impact testing according to standards such as standard Charpy method, occur usually to fracture of laminate samples.

2.2 *Methodology*

Polymer composite materials which we investigated on failure occurrence are made on the basis of natural fibres, such as linen, cotton and jute. As the matrix material used epoxy resin R70 with hardener H71 often used for laminating contact while the texture is determined in advance. Jute fabric has a surface density in level 340 $g \cdot m^{-2}$, linen fabric 320 $g \cdot m^{-2}$ and cotton fabric 130 $g \cdot m^{-2}$. For each reinforcement three components types have been prepared. Laminates structures with two, four and six layers have been prepared.

The resin has a relatively low viscosity to improve its adhesion to the non-homogeneous natural fibres. The process of manufacture of polymer composites containing fibres of natural origin has been based on the method of contact lamination process in combination with pressing process.

High compression pressure during the press process guarantees achievement of repeatable product type. We want to prepare pieces of composites which fit dimensionally and will also fulfil the required quality. The air bubbles remaining in the structure of laminates during the manufacture of laminates, especially those with fibres of non-homogeneous geometry, are important factor that influence the quality and formation damage during their use. Each empty space is a defect, from which a crack may develop leading to lower mechanical properties and the bulk destruction of the composite. Each empty space is a defect, from which it can develop a crack leading to the total destruction of the composite.Therefore the proper manufacturing procedure helps to limit the number of these defects to a minimum. High compression pressure will push the resin voids and reduce their number, but their complete elimination by using natural fibres is not possible.

Polymer composites based on natural fibres were produced with an equal number of material layers 2, 4 and 6. A small number of layers allow keeping possibility of modelling the shape of the laminates easily in the application to cover curves into bows. For this reason it is very important appointment flexural strength of laminates, as well as the maximum angle of deflection and angle deflection from the destruction of the sample. Research will be carried out by using standard EN ISO 14125 Fibre-reinforced plastic composites—determination of flexural properties. Brittle fracture of the resin takes place during flexion and bending of the laminates based on glass fibres, carbon or jute fibres with small elongation (Sgriccia, Hawley & Misra 2008).

Brittle fractures of fibres in the lower layers of the laminate structure can be also observed as the results of further flexure and bending. This is the same principle to breaching the strength of the whole laminate. Breaking the continuity fibres is unacceptable from the point of view of the further exploitation of the laminate, as a construction material.

Natural fibres are characterized by high water absorption. It is therefore necessary check the flexural strength of laminates during their using in terms of exposure to the effects of water in the air with a relative humidity of 75%. Moreover, in the case of polymeric materials important factor in determining functional characteristics is temperature of they use. Simultaneous interaction of high humidity at variable air temperature from –25°C to +95°C during a month period of time, will allow the estimation of the probability of a failure in a simulated operational environment of use of the laminate.

Our tests of composite materials were set up to simulate accelerated life usage. The equipment used for the climatic testing is Vötsch chamber VC^3 7034. Therefore we organised two climatic tests so far. First one was performed on the three types of composites samples (for exact composition see above) at the temperature –25°C for a month. The second test has been performed at the temperature 95°C and relative humidity 75%. In both instances significant influence of the climatic condition on the mechanical properties of the materials are expected. Flexural test will go by using testing machine for static tests Zwick Z100. Speed of traverse will be constant at 5 mm/min. Flexural stresses σ_f can calculate based on formula:

$$\sigma_f = \frac{3FL}{2bh^2} \tag{2}$$

where: F—force [N], L—length of sample between the supports [mm], b—width [mm], h—thickness of sample [mm].

Deformation ε on the outside surface of the sample is given by:

$$\varepsilon = \frac{6sh}{L^2} \tag{3}$$

where s is band deflection [mm].

After the mechanical test we expect having set of results presenting initially level of mechanical stress corresponding to fracture of the composite material. Secondary we will create probability distribution, where the stress will be continuous variable representing fracture occurrence. This will be our initial information to the equation (1) for determining the risk level in case if mechanical impact into the composite shield occurs. Investigation the possible consequences in the equation (1) is not the goal of this paper. Both graphical and numerical results will be presented during the conference.

2.3 *Conclusions*

The "green" composites are very important new engineering materials. Natural laminates are a good possibility for laminates reinforcement with glass fibres. Laminates with glass fibres have higher mechanical properties, but natural composites are more friendly to ecology. Composites with natural fibres as for example jute, kenaf, flax or cotton, have an application in means of transport. The significant properties of laminates in their application are flexural and impact strength. This properties of samples will be measurement when the will be ageing one month by different value of air temperature and by constant value of relative humidity.

The safety aspect of these kind of materials are based on the area of their utilisation and application. In this instance we investigate and focus on their resistance against mechanical load—dynamic impact. Their strength, stability and flexibility are important in order to guarantee no-propagation of failure occurred. So the composites might be indirectly responsible for propagation of initial failures which may cause secondary failures or domino effects. However if the initial failure is severe the composites used as a shield for example are supposed to stop it. Our proposed methodology shall present approach how failure occurrence once emerging may influence the safety features of the whole system. It will extend the principles published e.g. in (Babiarz 2006, Babiarz 2014, Rak & Pietrucha 2008, Stodola & Mazal 2012, Studzinski & Pietrucha-Urbanik 2012).

Application of selected diffusion processes on system state assessment

D. Vališ
University of Defence, Brno, Czech Republic

O. Pokora
Masaryk University, Brno, Czech Republic

ABSTRACT: The aim of the article is to apply selected diffusion processes in order to estimate system technical life. As we possess reasonably big set of field data the system residual technical life might be well estimated statistically. It includes the information about particles contained in oil which testify to oil condition as well as system condition. We focus on the particles which we consider to be interesting—both from the point of view towards the oil itself and also towards the system state and condition. This kind of information has good technical and analytical potential which has not been explored well yet. The way of modelling in this article is based on the specific characteristics of diffusion processes, namely the Wiener processes. Following the modelling results we could in fact set the principles of "CBM—Condition Based Maintenance", mission planning, life cycle costing, etc.

1 INTRODUCTION

Reliability, safety and availability of complex and time dynamic systems—like mechatronic, communication, space and smart systems—has attracted more and more attention in recent years—see, e.g. (Labeau 2000). The systems we would like to present work in various and mostly adverse operating conditions due to their applications. Therefore it is hardly possible to analyse the reliability of individual system using prior complex reliability tests, the historical pieces of information of other similar systems, or using expert judgement. Dependability characteristics are of our interest as we are concerned of a system reliability and availability level. However, the reliability and availability level of systems under our observation is the area of high interest for designers and engineers so that they could monitor condition and make decisions about maintenance. Based on the practical development in this area, it emerges that condition-based maintenance has become an attractive research area over the last decades—see, e.g. (Park 1993, Maillart & Pollock 2002, Yang 2003, Li & Pham 2005).

At present there is a tendency to change the format of technical maintenance. Preventive Maintenance (PM) at fixed intervals has been abandoned and condition based maintenance has been introduced instead. This trend might be followed only on condition that high-quality data on system condition is available. In technical literature, e.g. (Ghasemi et al. 2010a,b, Medjaher et al. 2012, Gebrael & Pan 2008, Ghasemi et al. 2010), there are different ways of using direct and indirect diagnostic data. There are introduced the possibilities of vibrodiagnostics, thermal radiation, and also tribo-diagnostics there. As for the vibro-diagnostics and the thermal radiation, they frequently appear in existing publications and scientific papers. Regarding the tribodiagnostic data, it has been assessed mainly empirically, restrictedly and by specialists.

Since specific types of technical equipment have been observed extensively, a big amount of data is available for the analysis. This special technical equipment is used in very harsh conditions. To have the observed technical equipment operating, it is important not only to have an adequate maintenance system, but also to operate under specific conditions, to plan and complete the mission.

1.1 *Motivation*

There were a few reasons for starting this research. The main reason was obviously to save costs during the phase of operation and maintenance of the observed technical equipment. It is rather clear that both the operation and the maintenance have the potential to save costs. The question is how the potential might be identified. The technical literature currently available shows us that the condition based maintenance is a right alternative. However, to introduce this type of maintenance, a certain amount of high-quality data as inputs should be available.

During the operation of the observed technical equipment in previous years, a lot of tribodiagnostic data were obtained. And the truth is that these data have not been used efficiently. The authors of this article identified the potential of these data and applied it in further analysis.

Another reason for assessing and searching for RUL (Residual Useful Life) was to find a lot more adequate model than the ones introduced earlier. Previous models are based on a regression analysis and fuzzy logic which has the potential to support regression models. What we are trying to do in the paper, is to present a new view on the same issue which is supposed to either support the conclusions or disprove them. Therefore we assume that First Hitting Time driven by Wiener process with drift is suitable tool for Residual Useful Life. Usage of Wiener process was motivation by generalisation of random walk suitable for this technical system.

2 OBJECTS OF DIAGNOSTICS AND OIL DIAGNOSTIC METHODS

The assumed objects of diagnostics are in our case engines from heavy tracked vehicles. These engines have not been designed and constructed to use an ON-LINE diagnostic system. However, there are other applications which might be used in practice, e.g. Gesellschaft et al. (2002), Czichos & Habig (2003), Quigley & Walls (2007), Revie et al. (2011) a,b, Rak & Pietrucha 2008, Cornak & Skolil (2009), Studzinski & Pietrucha (2012), Ghasemi & Hodkiewicz (2012). We still apply the OFF-LINE engine diagnostics system when sampling lubrication fluid at certain intervals, and use known and optimised special tribodiagnostic methods. We use the results and information from Atomic Emission Spectrometry (AES). Following this analysis we can obtain the information about the presence of specific individual elements and their amount. The amount is usually the weight of a respective element in one standardised unit of lubricant—e.g. milligrams of iron (ferrum) in one kilogram of oil [ppm]. However, we cannot identify the real origin of the respective elements because of fatigue, cutting or sliding. We also try to identify where these elements might come from. We will work with the idea to increase the potential for maintenance optimisation inputs and cost benefit analysis inputs (Stodola & Mazal 2012, Stodola et al. 2013). During the analysis we will focus on Fe particles, because we suppose that they originate from kinematic parts of a motor. We know the critical value of Fe particles amount.

3 OIL FIELD DATA, ASSESSMENT, MODELLING AND RESULTS

– As it has been mentioned before, the data are available in a big amount—it is a statistically important set. The data is collected at intervals and under conditions determined by a methodology. This includes:
– homogenous time intervals given by technical equipment mileage,
– oil temperature and right oil mixing,
– the same place of sample collection,
– the same way of performing the tribo analysis after the sampling.

Based on the data amount, the results are believed to be valuable and statistically reliable. We concentrate in this paper on Fe particles contents only. The example of the data form is in Table 1.

3.1 *Utilization of regression model*

A linear regression model is applied as a basic input characteristic. It helps to determine a linear course of Fe particles generation. The course is completed by dependability intervals for a mean (group) value and for an individual value. These courses are used for setting the point estimations of standard deviations of an individual and mean value for every instant of time—as stated in Table 1. These values are later used for Wiener process modelling. In the paragraph below there is an example of this procedure. In view of their random character, a random vector $\boldsymbol{X} = (\boldsymbol{X}_1, \ldots, \boldsymbol{X}_k)$ represents independent variables and a dependent variable is represented by a random variable Y. When describing and examining the dependence of Y on X, we use a regression analysis, and this dependence is expressed by the following regression function:

$$y = \varphi(x, \boldsymbol{\beta}) = E(Y \,|\mathbf{X} = \mathbf{x}), \tag{1}$$

Table 1. Input data of fe particles form engine oil—example.

Sample time [Mh]	Fe particles [ppm]	Standard deviation mean values	Standard deviation individual value
1/0.15	13.71158	0	4.753368
2/0.30	13.72016	0.001014	4.753368
3/0.45	13.73055	0.002029	4.753368
4/0.60	13.74004	0.003043	4.753369
5/0.75	13.74953	0.004058	4.753370
6/0.90	13.75902	0.005073	4.753371

where $\mathbf{x} = (x_1, \ldots, x_k)$ is a vector of numerical variables, y is a dependent variable, $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_m)$ is a vector of regression coefficients β_j.

For our data we will look for a regression function in a linear form and we will apply a linear regression model:

$$y = \sum_{j=1}^{m} \beta_j f_j(\mathbf{x}), \tag{2}$$

where $f_j(\mathbf{x})$ are well-known functions where $\beta_1, \ldots, \beta_m$ are not involved.

For the data we used the following regression functions:

- $m = 2$, $f_1(x) = 1$, $f_2(x) = x$, regression function: $y = \beta_1 + \beta_2 x$
- $m=2$, $f_1(x) = 1$, $f_2(x) = x$, regression function: $y = k + \beta_1 x$

The graphical outcomes from the regression analysis for an individual vehicle and a group of vehicles of the same type are presented below in Figure 1 and Figure 2. Numerical values have been also recorded and used later for the Wiener process.

3.2 *Utilisation of Wiener process*

We assume that the case we observe is a stochastic process with time dependence. Examples of applications might be found e.g. in Si et al. (2012), Linden (2000), Smith & Lánský (1994), Doksum & Hóyland (1992) or Sherif & Smith (1980), The generation of Fe particles is operation time dependant. Therefore the application of a diffusion process seems to be perfectly adequate. Due to normal distribution of random variable and its application capabilities, the Brownian motion might be used universally. The application of the Brownian motion can be found in many areas. Standard use is related to modelling with the use of differential

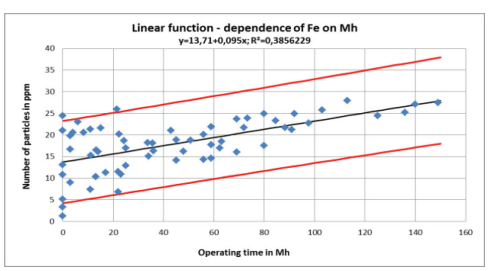

Figure 1. Dependence of Fe particles course on operating time in Mh: mean and 95% confidence interval for individual vehicle observation.

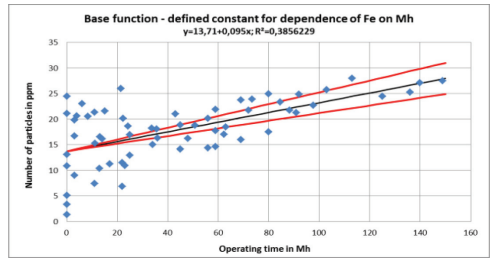

Figure 2. Dependence of Fe particles course on operating time in Mh: mean and its 95% confidence interval.

equations. We select one specific example of diffusion processes which is the Wiener process. Rules of the general Wiener process might be specified as follows. A real stochastic process $\{W(t)\ t \in \langle 0; +\infty)\}$ in a probability space (Ω, A, P) is called *the Brownian motion* or *the Wiener process*, if the following applies:

1. $W(0) = 0$,
2. $W(t) - W(s)$ has $N(0, t - s)$ distribution for $t > s \geq 0$,
3. For arbitrary $0 < t_1 < t_2 < \cdots < t_n$ increments $W(t_1), W(t_2) - W(t_1), W(t_3) - W(t_2), \ldots, W(t_n) - W(t_{n-1})$, $W(t)$ trajectories are mutually independent random variables and continuous almost everywhere.

Next, it applies that:

1. $E[W(t)] = 0$ for $t \geq 0$
2. Var $[W\text{^}2(t)] = t$ for $t \geq 0$

The Wiener process represents one possible form of diffusion processes. It is actually the integral of what in practical applications is called a white noise. The Wiener process with drift will be used in our application. The initial mean value (drift) is β_1 and standard deviations for each time increment have been previously calculated—see Table 1. For our model we apply Wiener process with drift given by stochastic differential equation.

$$dY(t) = \mu \cdot dt + \frac{\sigma \cdot dW(t)}{\sqrt{(t)}} \tag{3}$$

where dW(t) is increment of Wiener process and dt is increment of time, σ is a standard deviation (either of an individual or a mean value), μ is a mean value, t is an instant of time, process initial value $Y(0) = \beta_1$. Time increment for modelling was 0.15 Mh. When modelling—simulating, an example of the process course for individual course is shown in Figure 3, and for a mean value it is in Figure 4. The critical value of particles amount is 50.

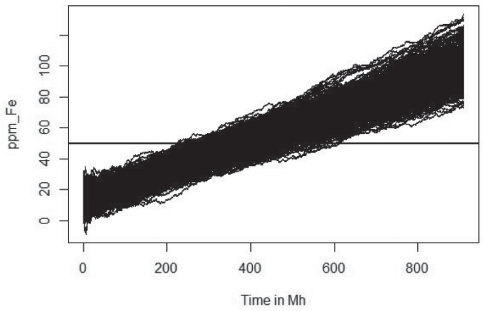

Figure 3. Course of Wiener process simulation for individual value.

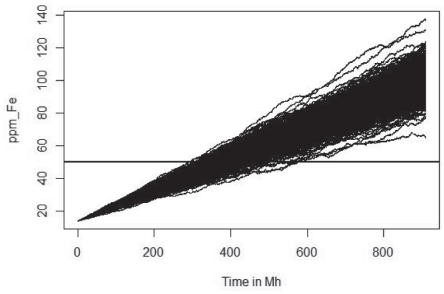

Figure 4. Course of Wiener process simulation for mean value.

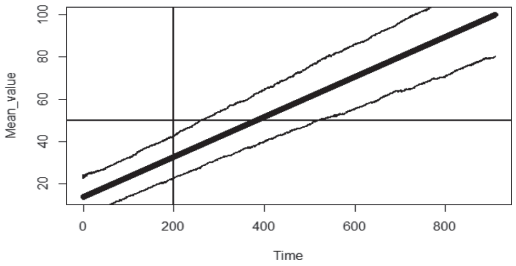

Figure 5. Confidence interval thresholds—95% for individual value.

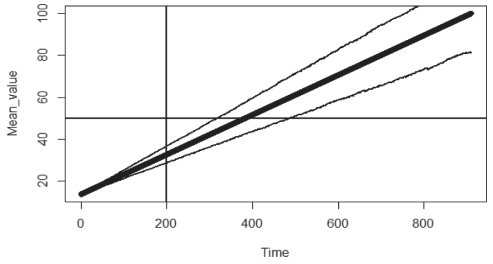

Figure 6. Confidence interval thresholds—95% for mean value.

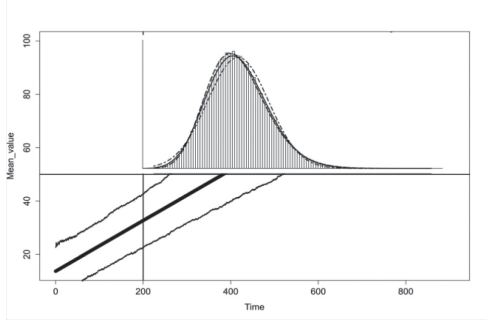

Figure 7. Course of FHT pdf for individual value.

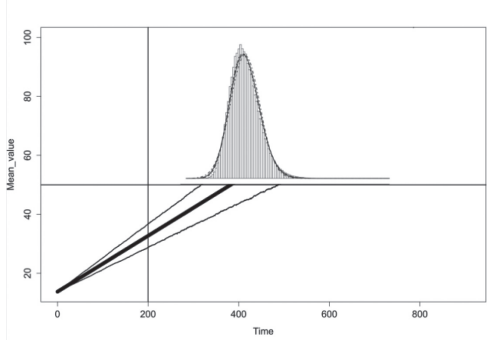

Figure 8. Course of FHT pdf for mean value.

We take into account 95% interval of trajectories which achieve a critical value 50. The vertical line 200 shows a determined interval of PM. These intervals are for the individual and mean value put in Figure 5 and Figure 6.

In order to determine the First Hitting Time (FHT) distribution of the individual and mean value, we set histograms and performed tests for a presumed type of distribution. The expected types of probability density distribution such as Gamma (full/firm line), LogNorm (dashed line—overcovered by IGD), Inverse Gaussian (IGD)—dotted line), Normal (dash and dotted line) or Weibull´s were not proved. The courses of these tested distributions are shown in Figure 7 and Figure 8. We expect then to obtain FHT distribution only in the form of empiric distribution function.

3.3 *Discussion*

The tested values reached for the individual value the following limits: minimum value = 134 Mh,

lower confidence interval 2.5% = 265 Mh, upper confidence interval 97.5% = 524 Mh, mean value = 382 Mh, median = 378 Mh, maximum = 887 Mh.

As to the mean value, the following limits were achieved: minimum value = 258 Mh, lower confidence interval 2.5% = 315 Mh, upper confidence interval 97.5% = 480 Mh, mean value = 385 Mh, Median = 381 Mh, Maximum = 746 Mh.

It follows from the results stated above that the mean value is more or less the same, but the lower threshold of confidence intervals are not. However, the lower confidence intervals are interesting for us in order to determine the possible beginning of PM interval. But if we used the mean value, it would be sufficiently far from the original/fixed PM interval. On the basis of the results we could work with a conservative version and set a new PM interval using the lowest value of lower threshold of confidence interval. This would be 265 Mh (individual value). If we were for a benevolent alternative, we could rely on the mean value and set the PM interval at 380 Mh (more or less the same for both the individual and for the mean value).

When planning a mission, we could work with versions that if common operating conditions were observed, a vehicle could be operated with one oil filling theoretically up to the upper confidence limit 97,5%. Considering conservative or benevolent versions, it would be 480 Mh, or 520 Mh.

4 CONCLUSION

In the article we have introduced possible approaches to modelling indirect diagnostic measures. We were looking for first hitting time distribution which represents a critical limit of Fe particles amount. The modelling is based on the diffusion Wiener process with drift. The observation and the analysis focused on the individual and mean value of Fe particles amount in oil.

The achieved results complement the set of approaches to the indirect observation of a technical condition. The approaches using purely a regression analysis and fuzzy logic, see e.g. Koucky & Valis (2011), Vališ et al. (2012), have been applied so far. Following the conclusions of modelling with the Wiener process, the results of previous approaches might be completed when searching for:

– optimum interval PM,
– recommended/allowed time for mission completion,
– optimizing dependencies of life cycle cost analyzing.

The approach introduced above opens the possibilities of analysing other important diagnostic indicators. It is important so that setting the time derived from the histogram and pdf course could be as accurate as possible and undistorted. Some inspirational examples for further development might be found e.g. in Babiarz 2006; Babiarz 2014a,b; Kierzkowski et al. 2012a,b; Kierzkowski 2010; Klimaszewski & Woch 2012, Kowalski et al. 2011, Nowakowski & Werbińska-Wojciechowska 2009, Wierbińska-Wojciechowska 2013, Wierbińska 2007, Woch 2013, Woch, M. 2014; Zajac et al. 2012.

In our further analysis we are going to develop this approach even more and complement it with other approaches like ARIMA or ARMA methods.

ABSTRACT: The application of the Auto Associative Kernel Regression (AAKR) method to the reconstruction of correlated plant signals is not satisfactory from the point of view of the robustness, i.e. the capability of reconstructing abnormal signals to the values expected in normal conditions. To overtake this limitation, we propose to modify the traditional AAKR method by defining a novel measure of the similarity between the current measurement and the historical patterns. An application of the proposed modified AAKR method to the condition monitoring of a pressurizer of a Pressurized Water Reactor (PWR) Nuclear Power Plant (NPP) shows benefits with respect to the traditional AAKR method, in terms of earlier detection of abnormal conditions and correct identification of the signals responsible for triggering the detection.

1 INTRODUCTION

The objective of condition monitoring is to assess the health state of industrial components and to identify possible incipient faults (Venkatasubramanian et al. 2003a, 2003b, 2003c, Hines et al. 2007). To this aim, a model is usually built to reconstruct the values of the monitored signals expected in normal conditions (Hameed et al. 2009). During operation, observed signal measurements are compared with the reconstructions provided by the model: abnormal conditions are detected when the reconstructions are remarkably different from the measurements.

Several empirical reconstruction modeling technique have been applied for condition monitoring of industrial components (Guglielmi et al. 1995, Nabeshima et al. 1998, Jack et al. 2002, Harkat et al. 2007, Chevalier et al. 2009, Baraldi et al. 2013a). These methods provide accurate reconstructions of the measured signals under normal operations, but they often tend to be not robust, i.e. in case of abnormal conditions the reconstructions of the signals are not properly estimating the values of the signals expected in normal conditions (Baraldi et al. 2012). In particular, it has been shown that the reconstruction provided by the Auto Associative Kernel Regression (AAKR) method (Baraldi et al. 2011a, Di Maio et al. 2013) of an anomalous transient characterized by a drift of one signal can be not satisfactory for two reasons: 1) the reconstruction of the signal affected by the drift tends to assume values in the middle between the drifted values and the expected values of the signal in normal conditions; 2) the reconstructions of other signals not affected by the drift tend, erroneously, to be different from the signal measurements. The consequence of 1) is a delay in the detection of abnormal conditions, whereas the consequence of 2) is that the condition monitoring system, although it correctly triggers an abnormal condition alarm, is not able to correctly identify the signal that triggers the alarm.

The objective of the present work is to propose a robust signal reconstruction method capable of early detecting abnormal conditions and providing accurate reconstructions of the values of the signals subject to the abnormal conditions.

The proposed method is based on the modification of the measure of similarity used by the AAKR method: instead of using the Euclidean distance, the proposed method introduces a penalty vector which reduces the contribution provided by those signals which are expected to be subject to the abnormal conditions. The rationale behind this modification is the attempt to privilege those abnormal conditions caused by the most frequently expected malfunctions and failures.

The performance of the proposed method has been tested on simulated data describing the behaviors of a pressurizer of a Pressurized Water Reactor (PWR) Nuclear Power Plant (NPP) (Baraldi et al. 2010, Baraldi et al. 2013b). The remainder of the paper is organized as follows. In Section 2, the fault detection problem is introduced. In Section 3, the AAKR method is briefly recalled. Section 4 shows the limitation of the traditional AAKR approach to condition monitoring and states the objectives of the present work. In Section 5, the proposed modification of the traditional AAKR is described and discussed. In Section 6, the application of the proposed method to a case study concerning the monitoring of 6 signals in the pressurizer of a Nuclear Power Plant is presented. Finally, in Section 7 some conclusions are drawn.

2 FAULT DETECTION

The condition monitoring adopted in this work is based on an empirical model reproducing the plant behavior in normal conditions. The model receives in input the vector, $\boldsymbol{x}^{obs}(t)$, containing the actual observations of the J signals monitored at the present time, t, and produces in output the reconstructions, $\hat{\boldsymbol{x}}_{nc}(t)$, i.e. the values that the signals are expected to have in normal conditions (Baraldi et al. 2012) (Fig. 1). If the actual conditions at time t are abnormal instead, the residuals $\Delta\boldsymbol{x} = \boldsymbol{x}^{obs}(t) - \hat{\boldsymbol{x}}_{nc}(t)$, i.e. the variations between the observations and the reconstructions, are large and can be detected by observing the exceedance of a prefixed thresholds by at least one signal.

3 AUTO ASSOCIATIVE KERNEL REGRESSION (AAKR)

The basic idea behind AAKR is to reconstruct at time t the values of the signals expected in normal conditions, $\hat{\boldsymbol{x}}_{nc}(t)$, on the basis of a comparison of the currently observed signals measurements (also referred to as test pattern), $\boldsymbol{x}^{obs}(t) = [x^{obs}(t, 1), \ldots, x^{obs}(t, J)]$, and of a set of historical signals measurements collected during normal condition of operation. In practice, AAKR performs a mapping from the space of the measurements of the signals $\boldsymbol{x}^{obs}(t)$ to the space of the values of the signals expected in normal conditions, $\hat{\boldsymbol{x}}_{nc}(t)$:

$$\hat{\boldsymbol{x}}_{nc}(t) = \varphi\left(\boldsymbol{x}^{obs}(t) \mid \overset{=obs-nc}{X}\right) : \mathrm{R}^J \rightarrow \mathrm{R}^J \tag{1}$$

where $\overset{=obs-nc}{X}$ indicates a $N \times J$ matrix containing N historical observations of the J signals performed in normal conditions. Since the mapping is independent from the present time, t, at which the signals observations are performed, the present time t will be omitted from the notations. Thus, $x^{obs}(j)$, $j = 1, \ldots, J$, indicates the value of signal j at the present time. The reconstruction of the expected values of the signals in normal conditions, $\hat{\boldsymbol{x}}_{nc} = [\hat{\boldsymbol{x}}_{nc}(1), \ldots, \hat{\boldsymbol{x}}_{nc}(J)]$, is performed as a weighted sum of the available historical observations; for the generic j-th element of $\hat{\boldsymbol{x}}_{nc}$:

$$\hat{\boldsymbol{x}}_{nc}(j) = \frac{\sum_{k=1}^{N} w(k) \cdot x^{obs-nc}(k, j)}{\sum_{k=1}^{N} w(k)} \tag{2}$$

The weights, $w(k)$, measure the similarity between the test pattern, $\boldsymbol{x}^{obs}$, and the k-th historical observation vector, $\boldsymbol{x}^{obs-nc}(k)$. They are evaluated through a kernel, *Ker*, i.e. a scalar function which can be written as a dot product (Burges, 1998, Müller et al. 2001, Widodo et al. 2007).

Traditional AAKR adopts as *Ker* function the Gaussian Radial Basis Function (RBF) with bandwidth parameter h, i.e.:

$$w(k) = \frac{1}{\sqrt{2\pi h^2}} e^{-\frac{\|\boldsymbol{x}^{obs} - \boldsymbol{x}^{obs-nc}(k)\|^2}{2h^2}} \tag{3}$$

In fault detection applications, Euclidean and Mahalanobis distances are typically used to compute the distance in the Gaussian RBF (Baraldi et al. 2011b). In this work, in order to account for differences in the scale and variability of the different signals, a Mahalanobis distance is used, defined by the covariance matrix, S, such that:

$$\| \boldsymbol{x}^{obs} - \boldsymbol{x}^{obs-nc}(k) \|^2_{mahal} = \left(\boldsymbol{x}^{obs} - \boldsymbol{x}^{obs-nc}(k)\right) S^{-1} \left(\boldsymbol{x}^{obs} - \boldsymbol{x}^{obs-nc}(k)\right) \tag{4}$$

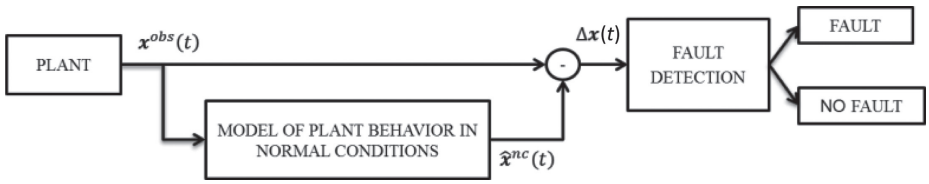

Figure 1. Scheme of condition monitoring for fault detection.

Assuming independence between the signals, S is given by:

$$S = \begin{bmatrix} \sigma_1^2 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & \sigma_j^2 \end{bmatrix} \quad (5)$$

where σ_j^2 indicates the estimated variance of signal j in the historical observations.

4 LIMITATIONS IN THE USE OF AAKR FOR SIGNAL RECONSTRUCTION

The low robustness of the traditional AAKR method is well illustrated by the following case study concerning the monitoring of the pressurizer of a Pressurized Water Reactor (PWR) Nuclear Power Plant (NPP) (Baraldi et al. 2010, Baraldi et al. 2013b). The dataset is composed of 37 simulated transients in normal conditions. Each transient is monitored for 100 time steps by 6 sensors measuring pressure, liquid temperature, steam temperature, spray flow, heaters power and liquid level. Table 1 reports the high degree of correlation between the signals.

Table 1. Degree of correlation between monitored signals. S1: pressure, S2: liquid temperature, S3: steam temperature, S4: spray flows, S5: heaters power, S6: liquid level.

	S1	S2	S3	S4	S5	S6
S1	1.00	–0.07	0.98	–0.46	–0.23	0.98
S2	–0.07	1.00	–0.08	0.01	0.18	–0.22
S3	0.98	–0.08	1.00	–0.46	–0.23	0.97
S4	–0.46	0.01	–0.46	1.00	–0.14	–0.45
S5	–0.23	0.18	–0.23	–0.14	1.00	–0.26
S6	0.98	–0.22	0.97	–0.45	–0.26	1.00

A traditional AAKR reconstruction model has been developed using the 37 transients. Then, an abnormal condition transient has been simulated by assuming sensor failures leading to a jump of the liquid temperature from time 10 to 20, a linear drift on the steam temperature signal from time 30 followed by a step at time 80 and an additive noise impacting the spray flow sensor from time 70 till the end of the observation period. Figure 2 shows the measured (dashed-light) and the real value (dotted-dark) of the 6 signals in the test transient, whereas Figure 3 shows the reconstructions of the signals provided by the AAKR method (dashed-light) and the signals expected in normal condition (dotted-dark). Notice that the reconstructions are not robust: 1) pressure, steam temperature and level reconstruction do not reflect the expected normal conditions after time step 30; 2) sprayers flow and heaters power reconstruction are far from the correct reconstruction during the time window 10–20.

A low robustness in the reconstruction leads to two practical problems: 1) delay in the detection of abnormal conditions; 2) identification of abnormal conditions on signals different from those which are actually affected by the abnormal behaviors.

5 MODIFIED AAKR

In order to enhance the AAKR robustness, we propose to modify the computation of the weights w performed by the traditional AAKR (Eq. 2). The basic ideas underling the proposed modification are (a) to identify the signals affected by abnormal behaviors and (b) to reduce their importance in the computation of the similarity between the test pattern and the historical observations.

With respect to (a), we assume that the probability of occurrence of a fault causing variations on a large number of signals is lower than that of

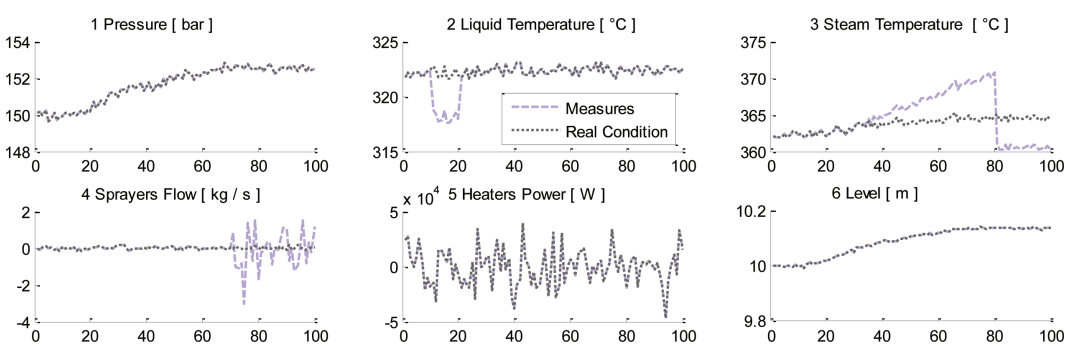

Figure 2. Measured abnormal value (light-dashed line) and corresponding normal condition value (dark-dotted line) of a test transient.

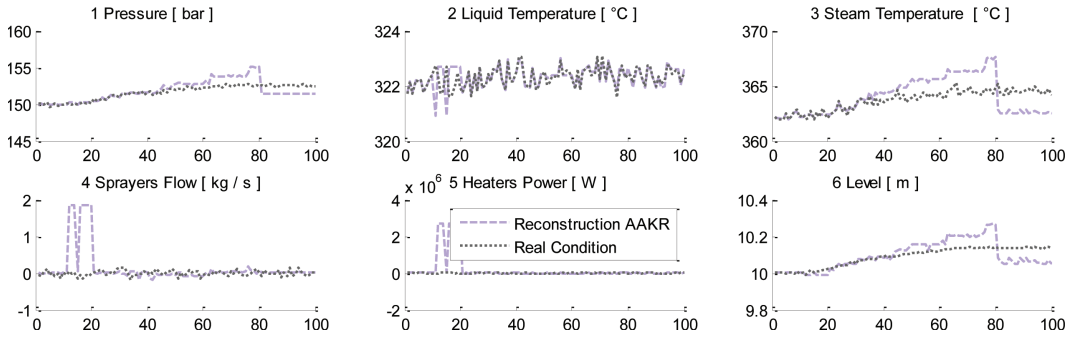

Figure 3. Reconstruction (light-dashed line) of the expected normal values (dark-dotted line) of a transient affected by abnormal conditions.

a fault causing variations on a small number of signals:

$$P(S_{fault\,1}) \leq P(S_{fault\,2}) \text{ if } |S_{fault\,2}| \leq |S_{fault\,1}| \quad (6)$$

where $S_{fault\,1}$ and $S_{fault\,2}$ indicate the sets of signals affected by variations due to the abnormal (faulty) conditions, and $|S_{fault\,1}|$ and $|S_{fault\,2}|$ their cardinality. If we consider, for example, the problem of sensor failures, it is reasonable to assume that the probability of having N_1 faulty sensors at the same time is lower than that of having a lower number of faulty sensors, $N_2 \leq N_1$, at the same time.

The proposed procedure computes the similarity measure between the observation, $\boldsymbol{x}^{obs}$, and the generic *k-th* historical observation, $\boldsymbol{x}^{obs-nc}(k)$, in two steps: (a) a pre-processing step consisting in the projection of $\boldsymbol{x}^{obs}$ and $\boldsymbol{x}^{obs-nc}(k)$ in a new space defined by a penalty vector, $\boldsymbol{p} = [p(1), \ldots, p(J)]$, with increasing entries, i.e. $p(1) \leq \ldots \leq p(J)$ and (b) the application of the Gaussian RBF kernel in the new space.

Step (a) is based on:

– computing the vector of the absolute values of the normalized differences between $\boldsymbol{x}^{obs}$ and $\boldsymbol{x}^{obs-nc}(k)$:

$$|x^{obs} - x^{obs-nc}(k)|_{\sigma} = \left(\left| \frac{x^{obs}(1) - x^{obs-nc}(k,1)}{\sigma_1} \right| \ldots \left| \frac{x^{obs}(J) - x^{obs-nc}(k,J)}{\sigma_J} \right| \right) \quad (7)$$

– defining a permutation matrix, P_{perm}, i.e. a matrix which, when multiplied to a vector, only modifies the order of the vector components; in our procedure, we define a matrix, P_{perm}, such that when it is applied to the vector $|\boldsymbol{x}^{obs} - \boldsymbol{x}^{obs-nc}(k)|_{\sigma}$, the components of the obtained vector are the same of that of $|\boldsymbol{x}^{obs} - \boldsymbol{x}^{obs-nc}(k)|_{\sigma}$, but they appear in a decreasing order, i.e. the first component is the one with the largest difference in $|\boldsymbol{x}^{obs} - \boldsymbol{x}^{obs-nc}(k)|_{\sigma}$;

– defining a diagonal matrix with decreasing entries on its diagonal:

$$D_p = \begin{bmatrix} \sqrt{p(1)} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \sqrt{p(J)} \end{bmatrix} \quad (8)$$

where the vector $\boldsymbol{p} = [p(1), \ldots, p(J)] = tr(D_p)$ will be referred to as penalty vector;

– projecting $\boldsymbol{x}^{obs}$ and $\boldsymbol{x}^{obs-nc}(k)$ in a new space defined by the transformation:

$$\begin{aligned} &\psi : \mathbb{R}^J \rightarrow \mathbb{R}^J \\ &\psi(\boldsymbol{x}^{obs}) = D_{\boldsymbol{p}}\ P_{perm}\ \boldsymbol{x}^{obs} \\ &\psi(\boldsymbol{x}^{obs-nc}) = D_{\boldsymbol{p}}\ P_{perm}\ \boldsymbol{x}^{obs-nc} \end{aligned} \quad (9)$$

In step (b), we apply to $\psi(\boldsymbol{x}^{obs})$ and $\psi(\boldsymbol{x}^{obs-nc})$ the Gaussian kernel with Euclidean distance:

$$w(k) = \frac{1}{\sqrt{2\pi h^2}} e^{-\frac{\left\| \psi(\boldsymbol{x}^{obs}) - \psi(\boldsymbol{x}^{obs-nc}) \right\|^2}{2h^2}} \quad (10)$$

6 APPLICATION OF THE METHOD TO THE CASE STUDY

The data previously introduced in Section 4 are used to develop the modified AAKR reconstruction

Table 2. Alarm thresholds for traditional and modified AAKR.

AAKR	S1	S2	S3	S4	S5	S6
Traditional	0.37	0.10	0.32	0.23	5.74E+04	0.02
Modified	0.40	0.53	0.68	0.15	3.96E+04	0.02

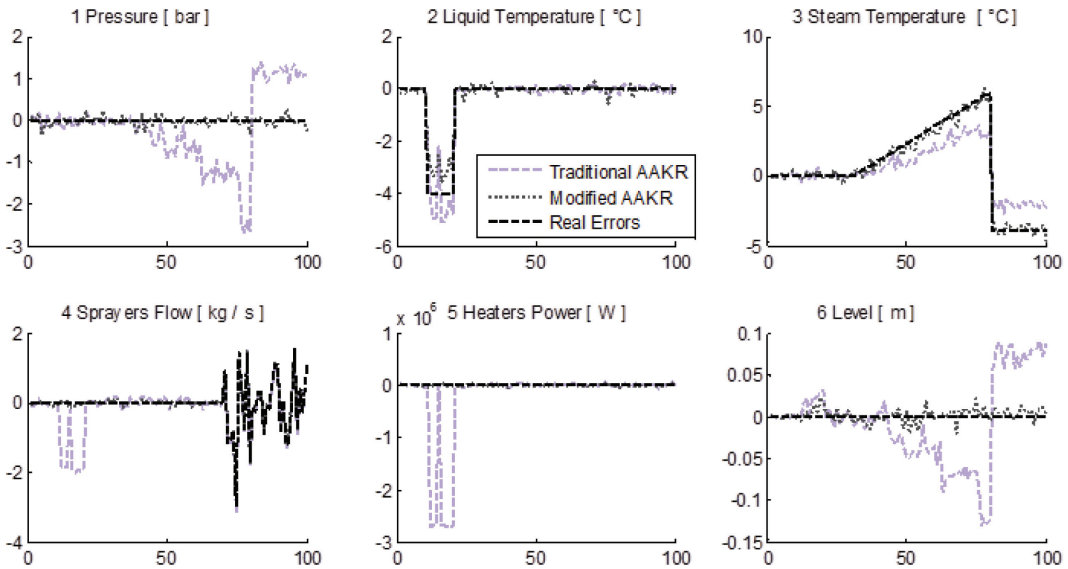

Figure 4. Residuals obtain by the traditional AAKR (light-dashed line) and by the modified AAKR (dark-dotted line); the synthetic error added to the signal is also reported (black-dashed line).

method. In particular, the 37 transients have been divided into 3 subsets:

- Training set $\overline{\overline{X}}_{train}^{obs-nc} \in \mathbb{R}^{2700\times 6}$, which is used as historical dataset to train the model;
- Validation set $\overline{\overline{X}}_{val}^{obs-nc} \in \mathbb{R}^{1000\times 6}$, which is used to set the optimal parameter values;
- Test set, $\overline{\overline{X}}_{test}^{obs-nc} \in \mathbb{R}^{400\times 6}$, which is used to test the performance of the method.

For both the traditional and modified AAKR methods, the optimal bandwidth parameter, h, has been identified by minimizing the Mean Square Error (MSE) of the reconstructions on the validation set, $\overline{\overline{X}}_{val}^{obs-nc}$:

$$MSE_h = \frac{\sum_{k=1}^{N_{val}} \sum_{s=1}^{J} (\hat{\boldsymbol{x}}_{val}(k,s) - \boldsymbol{x}_{val}^{obs-nc}(k,s))^2}{N_{val}} \quad (11)$$

The transients in the test set are used to set the alarm thresholds (see Table 2), which have been taken equal to 3 times the standard deviation of the obtained residuals. Notice that for signals 2 and 3 the traditional AAKR provides lower thresholds; on the contrary, the modified AAKR provides lower thresholds for signals 4 and 5. This is due to the fact that the traditional AAKR provides more accurate reconstructions of signals 2 and 3, whereas the modified AAKR of signals 4 and 5.

We have then tested the performance of the modified AAKR on the same abnormal condition transient introduced in Section 4. Figure 4 shows that the modified AAKR provides residuals that tend to reflect the simulated abnormal condition. For example, considering the time window 10–20, the modified AAKR identifies the wrong calibration of the liquid temperature sensor, whereas the traditional AAKR identifies, erroneously, an abnormal condition also on sprayer flow and heaters power sensors. Furthermore, the modified AAKR provides a more robust reconstruction of the steam temperature when the corresponding sensor is subject to a linear drift followed by a step change.

7 CONCLUSIONS

In this work, we have considered condition monitoring via Auto Associative Kernel Regression (AAKR) for fault detection in a pressurizer of a Pressurized Water Reactor (PWR) Nuclear Power Plant (NPP). A modification of the traditional AAKR has been proposed to achieved a more robust reconstruction of the signal expected in normal condition. By projecting the data in a new signal space according to a penalty vector, the modification aims at reducing the contribution of the signals affected by malfunctioning to the evaluation of the similarity.

The application of the modified AAKR to the monitoring of 6 signals in a pressurizer of a Nuclear Power Plant has shown that it provides a more robust reconstructions of the signals than the traditional AAKR method.

ABSTRACT: This paper aims to analyze the Critical Heat Flux (CHF) experimental design for a small-scaled pressurized nuclear reactor. The CHF or Departure from Nucleate Boiling (DNB) is one of the most important thermal-hydraulic safety criteria for pressurized reactors since its occurrence can lead to fuel damage. A 3×3 test section is simulated through COBRAIIIc/MIT-1 code for thirty operational conditions. The results are presented through response surfaces and used to evaluate the DNBR (DNBR ratio) at the hotspot. The lowest DNBR value was 1.587 for the maximum pressure, mass flux and inlet temperature.

1 INTRODUCTION

The Brazilian Navy is building the first nuclear reactor for propulsion in Brazil, the LABGENE (Nuclear Energy Generation Laboratory) ((Natacci and Corrêa 2005, Nascimento et al. 2005, Maragni et al. 1995, Giovedi et al. 2011)), a prototype small-scale pressurized nuclear reactor. One of the most important thermal-hydraulic safety aspects in reactor design is the Critical Heat Flux (CHF), which is under evaluation for this project. CHF occurs when heat transfer mechanisms change and a vapor film is formed on the fuel rods leading to a high temperature increase in a very short period of time (Groeneveld 2011). Therefore, CHF can damage the fuel rods leading to the fission products release into the primary coolant and even to a severe accident by fuel melting.

Although many CHF correlations exist, it is important to perform experiments specifically for each reactor core, once the phenomenon depends on a lot of factors such as: geometry, subcooling, pressure, mass flux, materials, etc. Besides, currently theoretical models cannot predict CHF because of its complexity. Thus, other CHF correlations for small modular reactors have been also researched (Greenwood et al. 2013).

This work evaluated the CHF for LABGENE through experimental design and by simulating the test section under reactor operational conditions through COBRAIIIc/MIT-1 code (Jackson & Todreas 1981). COBRA is a thermal-hydraulic code widely used to evaluate the core of PWRs by means of subchannel analysis. An EPRI (Electric Power Research Institute) correlation (EPRI 1983) is also used to predict CHF, based on the parameter range and previous analysis (Carajilescov & Valente 2011). The geometry of a test section previously designed for CHF experiments consists in 3×3 electrically heated one meter high cylindrical fuel rods. The inlet temperature, mass flow and pressure were the independent variables of the simulated experiments.

The results are presented through response surfaces (Box, Hunter, & Hunter 2005). Aiming at future experimental analysis and licensing, two additional situations were simulated: a 30 cm high shorter test section and one with real power profile.

Section 2 describes the test section as well as some reactor parameters. Section 3 shows the model used through COBRAIIIc and finally, sections 4 and 5 display the results and conclusions, respectively.

2 TEST SECTION

The test section which will be used in the critical heat flux experiments can be seen in Figure 1. Its 3×3 geometry is a fair initial option used for CHF experiments once it can represent the reactor conditions. Rod diameter, rod height, and pitch are the same as in the reactor core. However, the first rod bundle will have a uniform axial heat flux profile. From a uniform power profile, it is still possible to

Table 1. Core reactor parameters.

Parameter	Value
Nominal pressure (MPa)	13.1
Mass flux (kg/s)	454.4
Inlet temperature (°C)	264.15
Average heat flux (MW/m^2)	0.3
Maximum heat flux (MW/m^2)	0.9
Hotspot factor	3.0
Rod diameter, r_f (mm)	10
Pitch (mm)	13
MDNBR[1]	1.5
L (mm)	43.4

[1]Minimum DNB ratio.

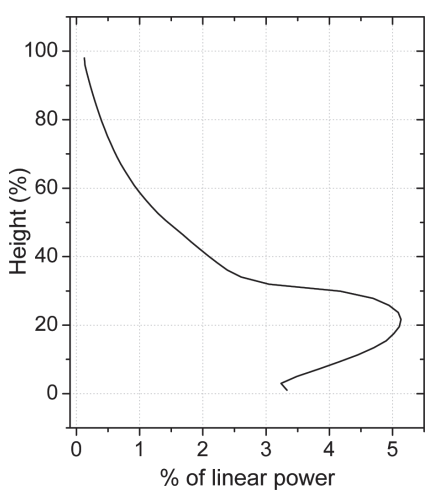

Figure 2. Linear power in the Beginning Of Life (BOL).

calculate a correction factor to predict the CHF in a non-uniform one (Todreas & Kazimi 2012). Core reactor parameters are shown in Table 1.

The rods will be indirectly heated by electrical resistors and rod number 5 will have 10 percent power more than the other ones to induce the DNB (departure from nucleate boiling) at this point.

Once the axial power profile has an uncommon shape (Fig. 2) as compared to commercial PWRs (pressurized water reactors), a shorter test section will be constructed.

3 MODEL

COBRAIIIc is a widely used code for the thermal-hydraulic analysis of nuclear reactor cores. Its approach is based on subchannel analyses where conservation equations are axially solved and coupled through mixing coefficients (Todreas & Kazimi 2001).

The single phase friction model available in COBRAIII is based on the friction factor f and the Reynolds number according to Eq. 1.

$$f = aRe^b + c \tag{1}$$

where a, b and c are specified constants that depend upon the subchannel roughness.

The Armand model was chosen to calculate the two-phase friction multiplier, φ, through Eq.2.

$$\varphi = \begin{cases} 1.0 & \alpha \le 0.0 \\ \dfrac{1-X}{(1-\alpha)^{1.42}} & 0.39 < (1-\alpha) \le 1.0 \\ 0.478\dfrac{(1-X)^2}{(1-\alpha)^{2.2}} & 0.1 < (1-\alpha) \le 0.39 \\ 1.730\dfrac{(1-X)^2}{(a-\alpha)^{1.64}} & 0.0 < (1-\alpha) \le 0.1 \end{cases} \tag{2}$$

where X is the quality and α is the void fraction.

The subcooled void model used is the Levy's one (Jackson & Todreas 1981), which calculates the true quality in terms of the equilibrium quality and the quality started by bubble departure. It is also necessary to choose a turbulent crossflow model. The model used is shown in Eq. 3. The slip ratio between liquid and vapor was considered equal to 1.0.

$$W = aS_kG_k \tag{3}$$

where a is equal to 0.002;

S_k is the gap width;
G_k is the axial mass flux around the gap.

Finally, three parameters were fixed: cross flow resistance equal to 0.5; turbulent momentum factor equal to 0.0; and transverse momentum factor equal to 0.5. These values are typically used for a PWR, once there are no specific values available for the LABGENE.

A sensitivity analysis is needed for the models. However, as we do not yet have experimental data, we have chosen the models we judge more appropriate for the problem among those available in COBRAI-IIc. In particular, the two-phase friction model was compared to the Baroczy model and no significant difference between both models was observed.

3.1 *Critical heat flux*

Two other correlations have been considered earlier for the simulation (Carajilescov & Valente 2011). However, EPRI correlation for CHF (Eq. 4) has shown to be more adequate due to its parameter range for the application to LABGENE. It is worth noting this correlation was chosen for simulation before the experiments. The main goal of the CHF experiments for LABGENE is to formulate a correlation its own.

$$q''_{crit} = \frac{A - x_{in}}{C + \left(\frac{x_e - x_{in}}{q''_L} \right)} \tag{4}$$

where

$$A = P_1 P_r^{P_2} G^{P_5 + P_7 P_r}$$

$$C = P_3 P_r^{P_4} G^{P_6 + P_8 P_r}$$

and
q''_L is the local heat flux in $MBtu/hr - ft^2$;
x_{in} and x_e are the inlet and local qualities;
P_r is the ratio between the pressure and the critical pressure;
G is the mass flux in $M.lbs/hr - ft^2$.

4 RESULTS

Based on the operation conditions, and transient parameters where the non occurrence of DNB is required, an experimental table was proposed. From these values, the CHF was predicted using COBRA. Brent iterative method (Press et al. 2007), was implemented to find the heat flux where the DNBR was equal to 1.0. The results for the two test sections and one with the real power profile (ST1PP) are also presented in Figure 3.

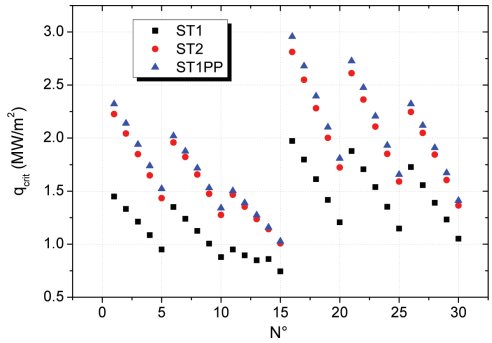

Figure 3. Critical heat flux for thirty simulated points.

Figure 3 shows the CHF behavior for the thirty simulated points. One can note that the two mass flux levels can be easily discriminated as well as the three pressure levels and the five different inlet temperatures.

CHF is approximately linear with the temperature except in the experiments from 10 to 15 for the ST1. This happens because for these operational conditions the simulations indicate CHF occurrence at rod 5(6), 1(1), 1(1), 9(16), 5(7) and 5(7), where the number between parentheses indicates the channel according to Figure 1. All other simulations indicate the DNB occurrence at rod 5 and channel 7. These results are important to foresee specific instrumentation at these rods.

Other germane points are the maximum and minimum CHF values. The maximum value indicates the power needed to perform the experiments and the minimum one indicates critical operation conditions, which are nearer to a boiling crisis.

4.1 *CHF response*

The analysis in this section was performed in order to better visualize the CHF behavior in the established conditions. Through a multi-linear regression one can evaluate the CHF as a function of temperature, pressure and mass flux. The variables were codified for values between –1.0 and 1.0 so that –1.0 represents the minimum value and +1.0 represents the maximum one. The coefficients and their standard errors are shown in Table 2, where quadratic terms proved to be non significant based on p-values greater than 0.10. The regression was performed through STATISTICA™ version 12 (Hill & Lewicki 2006).

The verification that there is no distortion (bias) in the regression was analyzed by the Pearson cor-

relation test for the assumed independent factors. The correlation matrix displays the correlation coefficients between factors taken two by two followed by the p-value representing the significance probability of the correlation judged at a specified level of significance α (Box, Hunter, & Hunter 2005).

Table 3 shows the correlation values and p-values for the regression. It can be seen that the variables are practically orthogonal to each other. The three highest correlations had a p-value greater than 0.1 (α) and therefore we cannot say that there is correlation.

Response surfaces for ST1 are presented in Figures 4–9. Each figure shows the unfolded equations for fixed conditions in its caption. These six surfaces show the critical heat flux dependence on two variables while the third one is fixed at the lower or higher value. The orange color indicates the greatest CHF and the dark green indicates the lowest one. For all cases a low temperature suggests we need more heat flux to reach the DNB point. An interesting information to get from response surfaces are CHF contour lines.

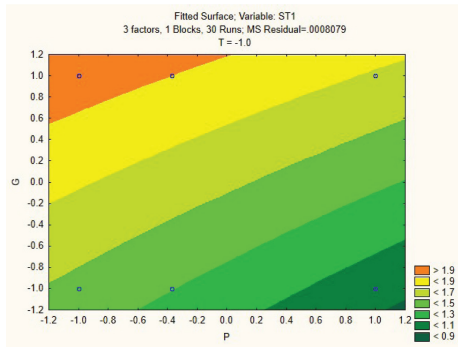

Figure 4. Critical heat flux in MW/m^2 for T = –1.0. $q''_{crit} = 1.55 - 0.19P + 0.31G + 0.04P \cdot G$.

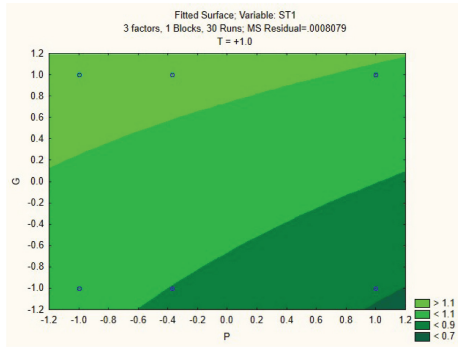

Figure 5. Critical heat flux in MW/m^2 for T = 1.0. $q''_{crit} = 1.01 - 0.09P + 0.14G + 0.04P \cdot G$.

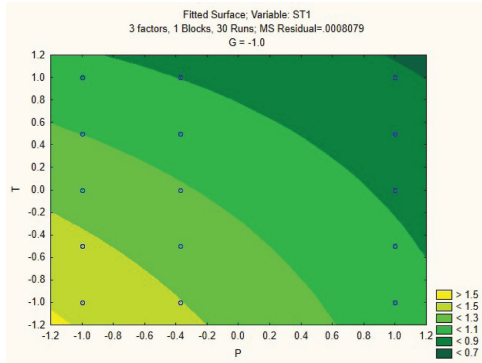

Figure 6. Critical heat flux in MW/m^2 for G = –1.0. $q''_{crit} = 1.05 - 0.18P - 0.18T + 0.05P \cdot T$.

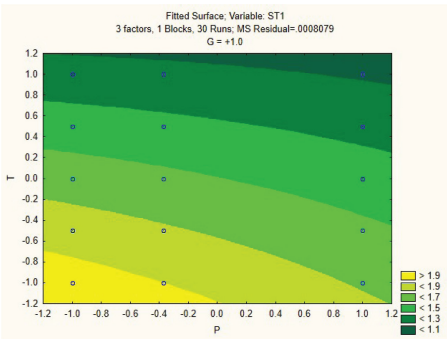

Figure 7. Critical heat flux in MW/m^2 for G = 1.0. $q''_{crit} = 1.51 - 0.10P - 0.35T + 0.05P \cdot T$.

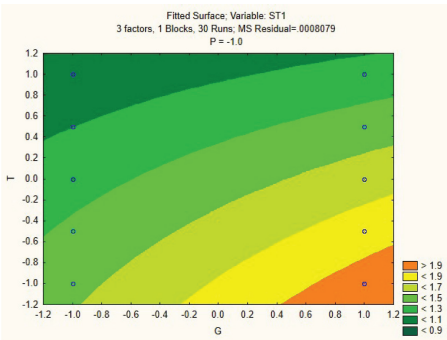

Figure 8. Critical heat flux in MW/m^2 for P = –1.0. $q''_{crit} = 1.42 + 0.19G - 0.32T - 0.08G \cdot T$.

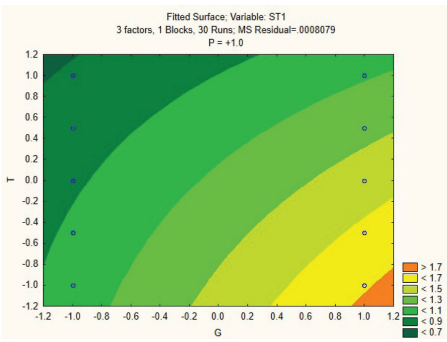

Figure 9. Critical heat flux in MW/m^2 for P = 1.0. $q''_{crit} = 1.14 + 0.26G - 0.22T - 0.08G \cdot T$.

Once we have the critical heat flux simulated for the hotspot, we can evaluate the DNBR given by Eq. 5.

$$DNBR = \frac{q''_{crit}}{q''_{real}} \quad (5)$$

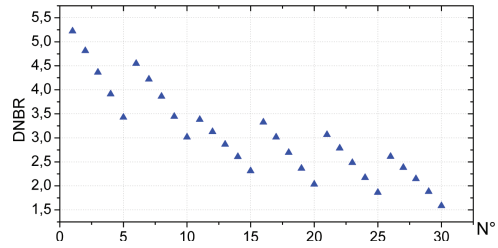

Figure 10. Departure from nucleate boiling for thirty simulated points.

where q''_{real} is given by Table 1 and Figure 2. However, the conditions of the lower mass flux are possible just with 50% power.

The calculated DNBR is shown in Figure 10. The simulations predict a boiling crisis at a height close to 25 cm. All values are above the MDNBR (Table 1), indicating a safe reactor operation. The lowest DNBR value occurs when all the parameters (pressure, mass flux and temperature) reach their maximum values, as expected.

5 CONCLUSION

Critical Heat Flux (CHF) experiments will be performed for the LABGENE with the purpose of creating a specific CHF correlation for it. In this sense, this work presents an initial analysis of the design of experiments which considered 30 operational points that take into account anticipated situations where no boiling crisis occurred. These operational points were simulated by the COBRAIIIc computer code for three cases. The results for the first case are shown by means of response surfaces in order to better visualize the CHF behavior for each condition. Once the CHF was estimated, the DNBR (Departure from Nucleate Boiling Ratio) was also estimated. The lowest DNBR found occurred for the maximum pressure, mass flux, and inlet temperature.

The stochastic approach in road network vulnerability analysis

Michal Bíl

Palacký University, Olomouc, Czech Republic

ABSTRACT: This paper draws attention to the vulnerability of road networks, when larger numbers of links are interrupted. These situations can arise as a consequence of natural disasters, terrorist attacks or additional random events. The primary aim of the vulnerability analysis is to identify those links whose interruptions have the highest impact on the given network. In order to identify the respective links, a large number of combinations of the links need to be analyzed which is beyond the scope of any computer. In this paper we provide a means of dealing with the problem using methods based on simulated annealing which do not produce the worst-case scenario in general but which enable us to produce scenarios with a sufficiently high impact.

1 INTRODUCTION

Despite the fact that miscellaneous networks can be found practically everywhere, the first papers published by Erdős & Rényi (1959, 1960) appeared in the first half of the 20th century. The boom in networks dates back to the beginning of the 21st century and is connected with a paper by Barabási & Réka (1999). This fact has two causes. The first one involved a limitation due to the slow computational speed of computers. The second limitation was caused by numerous successes in continuum mechanics in physics which assumed that the real world can be viewed as continuous. It began to be clear at the beginning of the 21st century that this approach cannot be applied universally and is completely inappropriate in various areas of physics.

Road networks represent one of the areas. Road networks have a number of features in common with additional networks (telecommunication networks, power grid). Some features are completely different, however. The first one is that road networks are of vital importance for all of society. It is almost impossible to supply people with food and medication without roads. The second one is the relative sparsity of networks when compared, for instance, with the World Wide Web. The number of road links outgoing from a node is rarely higher than 5. This means that the interruption of a small number of links can have a major impact on the functioning of human society.

The robustness and vulnerability of the road networks thus needs to be studied due to the above-mentioned reasons. The robustness enables us to study the resistance of a network to random events such as floods, landslides, etc. The analysis of the vulnerability of a road network provides us with information about those links whose interruptions have the highest impact on the entire network. This impact can consist not only of a prolongation of the shortest paths among several nodes but also the disintegration of the complete network into several parts. The respective events can be caused consciously (terrorist attacks) or unconsciously during repairs to road surfaces.

Numerous papers involve an analysis of the vulnerability of the road networks which only cover the case of one interrupted link or node (Erath et al., 2010; Jenelius et al., 2006; Latora & Marchiori 2004; Sohn 2006; Taylor et al., 2006 Van Knoop et al., 2008). The situation is actually much more complicated and the number of interrupted links is much larger. The primary aim of the administrator of the road network is to avoid the worst-case scenarios caused by interrupted links. This is the reason why there is a need to identify those links whose interruption can lead to these scenarios. The respective combination of the links must be found among the large number of combinations, however. There are, for example, 166,000,000 combinations of three interrupted links in a network with 1000 links. Despite progress in computer science, it is still impossible to analyze all the combinations and process the entire state space. Therefore, certain algorithms based upon random searching in the state space have been developed. The algorithms based upon simulated annealing are presented in this paper.

The paper consists of several parts. A basic algorithm of the simulated annealing is introduced in section 2 along with its modifications and setup. The obtained results are presented in section 3 and discussed in section 4.

2 SIMULATED ANNEALING

The algorithm was developed in connection with issues involving a large state space and with the existence of several local minima of some loss function. The algorithm does not require further assumptions on the loss function as continuity, differentiability and convexity and can also be used in the case of a discrete state space. The state space is obviously discrete and consequently the identification of the minimum of any loss function is extremely difficult as even a small change in the current combination of interrupted links can have a dramatic impact on the value of the loss function.

2.1 *The basic algorithm*

Let us assume that $\theta = (\theta_1, \ldots, \theta_n)$ represents a combination of n-interrupted links and $L(\theta)$ is a loss function which measures the impact of damage on the network. The value of the function is lower while the impact on the network is higher. Let us further denote "temperature" with T. The meaning of the variable will be clarified in the description of the algorithm. The algorithm for simulated annealing has the following form (for more details about the simulated annealing we refer to (Spall, 2003)):

1. Set an initial temperature T, a combination of interrupted links θ_0 and a loss function $L(\theta_0)$.
2. Find a new combination of interrupted links θ and determine $L(\theta)$.
3. If $L(\theta) < L(\theta_0)$, put $\theta_0 = \theta$. If $L(\theta) >= L(\theta_0)$, put $\theta_0 = \theta$ with a probability depending on T.
4. If you are unable to improve the value of L after the given number of iterations, decrease the value of T. If the new value of T is lower than the given limit, it is completed. If this is not the case, return to 2.

There are two key parts in the algorithm. The first one is part 2 where a new combination of interrupted links needs to be found. Since there is a nonzero probability of accepting a worse combination of interrupted links, there is a need to save such a combination of interrupted links which represents the smallest found value of L. The treatment of the second part is presented in the next subsection. The second one is part 3 which makes possible an escape with a certain probability from a local minimum of the loss function L. The probability depends on T and is a decreasing function.

2.2 *The basic setup*

The generation of interrupted links is based upon probabilities which are assigned to all links. There are three approaches to assigning the probabilities to links used in the paper.

1. All links have the same probability.
2. The probability is directly proportional to the length of the link.
3. The probability is directly proportional to the betweeness index of the link (Newman 2010).

The above-mentioned probabilities are used to replace the given number of interrupted links with other links which need to be interrupted. The chosen interrupted links are then assumed not to be interrupted. To obtain the number of interrupted links the following three strategies are used:

a. The maximum number of interrupted links is replaced. This number is equal to the minimum of the number of interrupted and uninterrupted links.
b. The number of replaced interrupted links is random but its value cannot exceed the minimum of the number of interrupted and uninterrupted links.
c. The number of replaced interrupted links depends on temperature T. 4 links are replaced for the range 30–40, 3 links are replaced for the range 20–30, etc.

The loss function can finally be defined. The function should be able to measure the disintegration of the network into several parts which seem to be the most important aspect in the case when greater numbers of links are interrupted. The loss function has the form:

$$L(\theta) = \sqrt{\frac{1}{m}\sum_{i=1}^{m+1}(l_i - \bar{l})^2} \tag{1}$$

where

$$\bar{l} = \frac{1}{m+1}\sum_{i=1}^{m+1} l_i \tag{2}$$

and m are the number of interrupted links and l_i is the number of people living in i-th component. The maximum number of components is $m+1$. If the network disintegrates into a smaller number of components, the further components are assumed up to the number $m+1$ but with zero people living within them. The worst-case scenario is thus the case when m interrupted links can cause the disintegration of

3c	180405.694892	168104.220931	8

the network into *m+1* components with the same number of people living within them. In this case the loss function is equal to zero. It is positive otherwise. This means the lower value of the loss function the higher damage of the network.

3 RESULTS

We first pay attention to input data. The initial temperature has the value 40 and after 100 iterations without an improvement of the best obtained value of the loss function L it decreases by a value 0.9 until it reaches the value 1. The number of interrupted links is 5 in the case of the Olomouc region and 10 in the case of the Zlín region. The computation was repeated 5 times.

The obtained results are presented in the tables below (see Tables 1 and 2). The used method is denoted by a combination of a digit and a letter which corresponds to the strategies introduced in the previous section. The next two columns indicate the worst initial value of the loss function, which corresponds to the case when the network remains intact, and the best total value of the loss function after 5 computations. In the last column the number of components is mentioned.

In the Table 1 we can see the result for the Olomouc region. In this case the network was adjusted in such a way that there is no dead-end link. It is apparent that there are no major differences among the results apart from the strategy a) which can be caused by the stochastic background of the algorithm. It can be seen that the disintegration of the network into a higher number of components need not represent the worst-case scenario. Moreover, in certain cases the best value of the loss function corresponds to several combinations of interrupted links.

In the second case (Table 2) we can see the results for the Zlín region. In this case dead-end links were not removed. An interesting aspect is that for all distribution of probabilities of the links strategy 3 produced the best results, because it enables the algorithm to refine the obtained results.

4 CONCLUSION

In this paper, several strategies including the method of the simulated annealing were applied to two regions with a different number of interrupted links. The primary difference between the networks was the presence of dead-end links.

Despite the fact that it is impossible to determine such a combination of interrupted links which would lead to a minimum value of the loss function, it is apparent that the used methods were able to improve the value of the loss function and in certain cases find several results corresponding to the obtained value of the loss function. The time of computation does not usually exceed 15 minutes. Improving the obtained results by prolonging the computational time would seem to be plausible. It was also observed that the strategy 3 is suitable if the dead-end links are present. The strategy is unable, however, to produce better results if all the dead-end links are removed.

The situation is interesting in the case of the use of the betweenness index. In the case the links with a larger betweenness index have the higher probability to be interrupted which corresponds more to the real world scenarios where the links with higher transit are more prone to an interruption than other links. This approach leads close to the border between the vulnerability and robustness of networks. Unfortunately, this additional information does not lead to improved results. It was also observed that the number of components of the disintegrated network need not represent the worst-case scenario which is determined by the used loss function.

It would seem apparent that the presented approach contains an unspent potential, because only a minimum of information concerning the structure of the network and about the people living within it was made use of.

ACKNOWLEDGMENTS

This paper was prepared with the help of a project undertaken by the Transport Research Centre (OP R&D for Innovation No. CZ.1.05/2.1.00/03.0064). Analysis of brake testing methods in vehicle safety

A. Bojko, A.I. Fedotov & W.P. Khalezov
Irkutsk State Technical University, Irkutsk, Russia

M. Młyńczak
Wroclaw University of Technology, Wrocław, Poland

ABSTRACT: Safety in automotive engineering depends very much on brake system and its availability for use. That ability is usually tested on stands having cylindrical drums or on stands in form of flat plates. Functionality of brake system means not only slowing down a vehicle, but requires achieving desired result as stopping a vehicle from a given speed on desired distance (Haisler 2007). There are some reports stating discrepancy of brake force measurement using two above mentioned testing methods. Paper presents methodology and results of comparative measurements of braking force on drum and flat stands. The system for experimental testing of phenomena between elastic tire and solid counter surface of diagnostic drum and flat road is shown. Results of experimental tests and analysis of normal and longitudinal stresses in contact point in the two above cases are shown. It has been noticed that distribution and values of normal and longitudinal stresses in the contact area of the tire against flat surface are meaningfully different from that obtained against cylindrical diagnostic brake drum. It is planned to propose assessment index of measurement discrepancy corresponding to hazard of brake testing.

1 INTRODUCTION

Currently, the control of brake systems of motor vehicles is performed under operational conditions as well as in the road and in the test bed conditions (testing stand). Under the conditions of the Russian climate the most effective method of brake system control is said to be stand methods. According to the magazine "*Motor Transport Company*": "*Suggested by various firms stands for assessing the technical condition of the brake system in a government inspection, for example, models LTK and stationary models STS stands Novgorod plant SIPA and foreign company Cartec, can not provide objective indicators of behavior in traffic*" (Kulko 2005, Li et al. 2011).

Studies at the Chair "Road transport" in Irkutsk State Technical University have confirmed the poor quality of assessment of technical condition of vehicles braking system in the diagnosis on a drum dynamometer. Repeatability study showed that the measured values of 40 consecutive braking forces of the same car TOYOTA-COROLLA, on the same bench STM 3500 ranges of 27,9%. The specific braking force varies of ±20% (Fedotov & Boiko 2009).

2 ANALYSIS OF DIFFERENCES IN VEHICLE BRAKE SYSTEM

There are couples of reasons for the large variability of the results of the brake system control on a drum dynamometer few. One of the most important reasons is the difference in tire contact shape on the cylindrical surface of drum stand compared to a flat road surface. The length of the tire contact patch with the cylindrical surface of the drum of 320 mm diameter is 50% less compared to the flat road surface. If the drum diameter decreases from 320 to 202 mm, this difference increases from 50% to 52%.

Width of tire contact against the surface of the drum stand of 320 mm in diameter is 5,5% larger than that against the road surface. With decreasing diameter of the drum from 320 to 202 mm, this difference increases from 5,5% to 13,4% (Fedotov et al. 2009).

3 DESCRIPTION OF LABORATORY BRAKE STAND

Based on the above results, laboratory studies have been conducted on longitudinal and normal reactions at the contact patch of the tire against rolling drum surfaces and flat, road surface. Their ultimate goal is to get a technique that allows transferring stand tests results on road conditions, i.e. predicting the magnitude of the longitudinal reactions of the wheels on the road. Scientific group of Irkutsk State Technical University (ISTU) designed and made measurement unit (Fig. 1), which allows measuring the normal and longitudinal stresses at

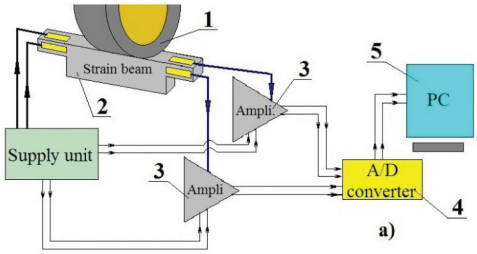

Figure 1. Block diagram of electrical circuit of measurement unit. 1—car wheel, 2—strain gauge bar, 3—electronic signal amplifier unit for longitudinal and normal stresses in the con tact wheel, 4—analog—digital converter, 5—PC.

the contact patch of the tire as on the road (flat surface) and on drum stand (Fedotov et al. 2012). Designed units consist of: strain gauge beams, electronic signal amplifier, Analog/Digital Converter (ADC) and a computer.

3.1 *Measurement of longitudinal and normal stresses on flat surface*

A system for measuring the longitudinal and normal stresses in the flat contact area is shown in Figures 2 and 3.

Flat Surface Testing System (FSTS) consists of an elastic plate 1, on the side surfaces of which the strain gauges 7 are pasted. Strain gauges of the sensor are included in the measuring circuit in a bridge circuit. Plate 1 is attached with two screws 4 to the intermediate support 3, which is attached to the support basement 2. One of the side surfaces of the plate 1 enters into the slot of the support platform of the base 2.

To prevent rotation of the plate 1 in the center of the screws 4 it has a reaction arm 5 connected to the elastic spring 8. This spring is mounted with screws on the plate 6.

The basement of the unit creates a rigid structure 2 (Fig. 4) having installed inside a transducer that while rolling the wheel allows to record two values: normal and longitudinal stresses along the contact patch of the tire.

3.2 *Measurement of longitudinal and normal stresses on drum stand*

Similar structure has Drum Testing System (DTS) recording normal and longitudinal stresses of the tire against the surface of the cylindrical surface of drum stand (Figs. 5 and 6). Running drum 10 has a cylindrical surface and for this purpose special sensor was designed, manufactured and installed in the drum stand. Especially profiled plate 2 fits

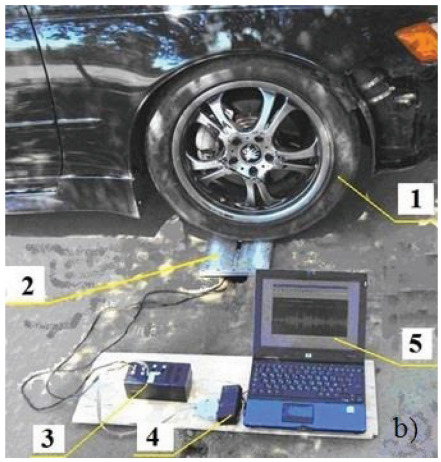

Figure 2. Stress measurement unit in flat contact area.

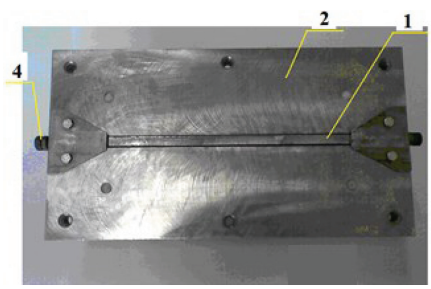

Figure 4. General view of the sensor for measuring stress in the flat contact area (road surface like).

to cylindrical surface of the drum 10 and is bolted to it. Universal elastic strain gauge plate 1 is attached to the plate 2. When the drum rotates the wheel with elastic tire runs cyclically into the built in sensor. The sensor detects the distribution of

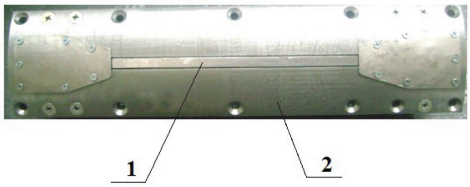

Figure 6. General view of the sensor measuring the stress in the contact of the wheel with the counter surface of the drum: 1—strain gauge plate, 2—base plate.

normal and longitudinal stresses along the length of the contact patch of the tire.

3.3 *Laboratory testing stand*

For laboratory research a stand was designed and manufactured. It is schematically shown in Figure 7. Stand allows defining the voltage at the contact patch of tire supported by the surface of the rolling drum. Wheel with test tire 5 is mounted on pivoted by ball bearing lever 6. Tire presses against the drum 9 with the support of spring 7. Drum 9 is driven by an electric motor 8 through the gearbox 10. Profile of the drum surface corresponds to usual profile of the commercial drum brake testers. Setting a weight on loading arm 4 it is possible to load tire with required value of the normal load. The beam 1 is pivotally mounted on the arm 2 and transmits the normal load to the spring 7 and the tire 5. Along the beam 1 extends an arm 6 which supports the wheel with tested tire 5. Strand 3 is connected to the sensor 11 measuring longitudinal reaction. The sensor 11 can be moved in the vertical direction in case if tested tire is of other size. Disc brake 12 provides brake torque to the wheel. Prior to testing, varying the length of the beam 3, wheel 5 is mounted on a chassis dynamometer 9 so, that the resultant braking force vector is parallel to the axis of the beam 3.

To enhance the range of research it is provided in the design of the stand an apparatus 2 to allow

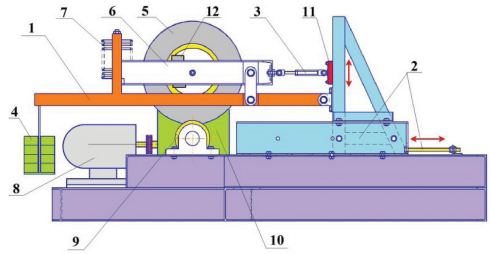

Figure 7. Scheme of the stand to determine the stresses in the tire contact area with cylindrical drum surface.

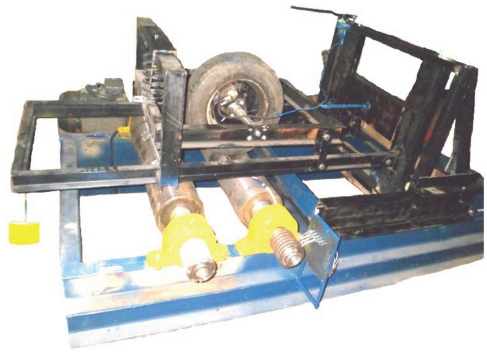

Figure 8. General view of the stand to determine the stresses in the tire contact area with cylindrical drum surface.

longitudinal displacement relative to the center of brake drum. Designed testing system (Fig. 8) allows studying processes occurring in the contact area of tire and drum surface and get diagrams of normal and longitudinal stresses.

It was tested radial tire manufactured by Amtel Planet T-301 of a size 185/65 R14, 86 N. Tread height was measured as 5 mm, which corresponds to the wear level of the wheel of about 30%. Normal wheel load was 3400 N, which corresponds to the weight of the wheel running at front axle on Toyota Fielder. Experiments were carried out at different inflation pressure. The range of pressure was: 0.231, 0,21, 0.19, 0.17, 0.15, 0,13 and 0,105 MPa. The purpose of the research with different pressure was to study on brake properties of the tire.

4 RESEARCH OF STRESSES RESULTS

Experiments were performed both on road and in the test bed conditions in braking mode (full blocked wheel while moved over the sensor surface).

Laboratory experiments were performed on a drum dynamometer (Fig. 8) in the laboratory of "Road Transport Chair" of Irkutsk State Technical University.

The experimental road results were compared with results obtained on laboratory drum stand. Diagrams of distribution of normal and longitudinal stresses along the length of the tire contact area of the flat testing surface were compared with that on cylindrical drum surface.

Comparison of the results of research carried out in a braking wheel (Fig. 9) shows that the shape of diagrams of normal stresses in the road and stand conditions is significantly different. In the road conditions, the length of the tire contact is two times larger than on a braking drum. Inflation pressure varies length of the contact from 110 mm at highest pressure to 160 mm at lowest one at "road conditions" (flat tester) and respectively from 48 mm to 92 mm. The contact length is doubled for flat contact surface.

The numerical values of the normal stresses at the contact area of the tire in the road and stand conditions differ significantly. The maximum value of the normal stresses at the contact patch on a flat tire braking road surface is $\Delta Rz = 0{,}55$ kN and on the cylindrical surface of the brake drum is $\Delta Rz = 1{,}25$ kN, by tire pressure 0,23 MPa. For braking wheel on cylindrical surface having a diameter 0,24 m, normal stress in the contact area ΔRz exceeds the normal stress on a flat road surface about 2,2 times.

The results of studies of the longitudinal stresses in the wheel braking mode (Fig. 10) show that the shape of the distribution diagram of the longitudinal stresses in the road and stand conditions also differ considerably. On a flat road surface diagram of the longitudinal stresses distribution is sinusoidal. In the laboratory, on the cylindrical surface of a drum dynamometer, diagram of normal stress has a shape close to a triangle, and with decreasing of tire pressure it becomes trapezoidal.

The maximum value of the longitudinal stresses in the contact patch on a flat tire braking road surface is $\Delta Rx = 0{,}15$ kN and on the cylindrical surface of the drum stand is $\Delta Rx = 1{,}45$ kN, at tire pressure of 0,23 MPa. When braking wheels with elastic tire on the cylindrical surface of the drum having a diameter of 0,24 m longitudinal stress ΔRx exceeds the longitudinal stresses in the wheel braking on a flat road surface of 9,5 times.

Comparing brake tests performed on flat and drum testers one may notice large difference in contact length between tire and counter surface. Stand with flat counter surface makes double contact length at comparative inflation.

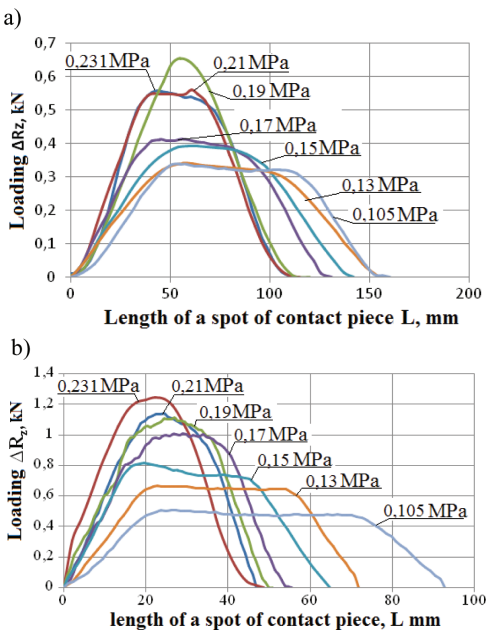

Figure 9. Graph of normal stresses in the tire contact patch while braking a wheel with respect to inflation pressure: a) on a flat road surface, b) on the cylindrical surface of the drum of 0,24 m in diameter.

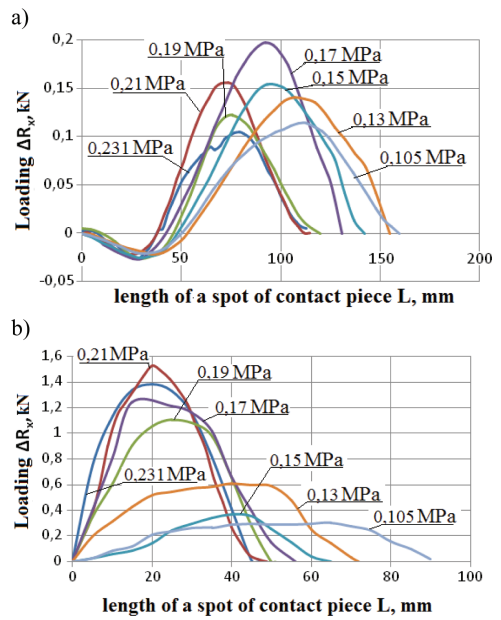

Figure 10. Graph of longitudinal stresses in the tire contact patch while braking a wheel: a) on a flat road surface, b) on the cylindrical surface of the drum of 0,24 m in diameter.

5 CONCLUSIONS

The results of the pilot study suggest the following conclusions:

- shape of distributions of longitudinal and normal reactions at the contact patch of elastic tires against flat and cylindrical surface (in the road and stand conditions) significantly differ both qualitatively and quantitatively,
- braking wheels with elastic tire (tire company Amtel Planet T-301 size 185/65 R14 86 N, normal wheel load was 3400 N) on the cylindrical surface of the drum having a diameter of 0,24 m to the normal stress in the contact exceeds ΔRz normal stress on the flat road surface 2,2 times,
- while braking, the numerical values of the longitudinal stresses ΔRx of tire contact patch with the cylindrical surface of the drum are different from the numerical values of the longitudinal stresses at similar ΔRx wheel braking on a flat supporting surface by 9,5 times,
- with decreasing of pressure in the tire contact patch length increases by more than two times,
- ΔRx of longitudinal stress in the tire contact patch with the cylindrical surface of the drum having diameter of 0,24 m exceeds the longitudinal stresses in the tire contact patch with a flat supporting surface by 35%.

Hilbert-Huang Transforms for fault detection and degradation assessment in electrical motors

M. Rigamonti
Energy Department, Politecnico di Milano, Milan, Italy

S. Rantala
VTT Technical Research Centre of Finland, Tampere, Finland

ABSTRACT: The present work develops a methodology for the analysis of transient signals for fault detection and diagnosis in electrical motors. The objective of this work is the initial development of a Prognostic and Health Monitoring System (PHMS) for the demagnetization of the magnetic field source of a Permanent Magnet Synchronous Motor (PMSM) used in electrical vehicles. The developed methodology is based on the Hilbert-Huang Transform (HHT), a technique which is particularly suitable for processing oscillating transient signals, such as the stator currents typical of automotive electric traction machines. The HHT represents a time-dependent series in a two-dimensional time-frequency domain by extracting instantaneous frequency components within the signal through an Empirical Mode Decomposition (EMD) process. The developed framework has been applied to four transients simulating different levels of demagnetization of the permanent magnet of the PMSM; the obtained results show that HHT enables us to detect and assess the degradation level for a demagnetized core of a PMSM.

1 INTRODUCTION

Permanent Magnet Synchronous Motor (PMSM) machines are attractive for a variety of applications, such as automotive and aerospace drives, because of their excellent efficiency and high power density. This work has been performed within the European project "*Electrical powertrain Health Monitoring for Increased Safety of FEVs*" (HEMIS) which aims at developing a Prognostic and Health Monitoring System (PHMS) for increasing safety and reliability and reducing the maintenance costs of FEVs (Sedano et al. 2013, Baraldi et al. 2013a).

The most significant signatures for fault detection and fault diagnosis of PMSM are the stator currents, which are heavily influenced by several degradation mechanisms typical of these electrical machines, such as permanent magnet demagnetization, stator windings short and open circuits, bearings degradation and rotor shaft eccentricities. Several techniques, such as Fast Fourier Transform (FFT) and advanced Wavelet Analysis, have already been used in order to analyze the motor currents for the identification of incipient failures (Rosero et al. 2006a, b, Gritli et al. 2012). These techniques generally allow performing fault detection and diagnosis, but they are suitable for treating oscillatory signals only in stationary conditions.

Although these represent a common situation in most industrial applications, in this work the focus is on the development of a PHMS for a PMSM used in automotive drives, which typically works under non-stationary conditions. In order to be able to treat those non-stationary signals and to properly extract the meaningful informations, we will apply the Hilbert-Huang Transform (HHT) (Huang et al. 1998, Kizhner et al. 2004) to the stator currents of the PMSM. The HHT represents a time-dependent series, i.e. in this case the stator current, in a two-dimensional time-frequency domain by extracting instantaneous frequency components within the signal through an Empirical Mode Decomposition (EMD) process (Huang et al. 1998, Kizhner et al. 2004, Espinosa et al. 2010, Yan & Gao 2007, Ruiz et al. 2010). The HHT analysis of the stator current signals enables us to identify and compare the instantaneous frequency and the instantaneous amplitude of the Intrinsic Mode Function (IMF) obtained by the EMD process.

As previously noted, there are several typical degradation mechanisms which can affect the PMSM: this work, in particular, will focus on the detection of demagnetization of the permanent magnet of the PMSM, aiming at identifying and assessing the level of demagnetization, i.e. quantifying the degradation (Baraldi et al. 2013b). The developed framework has been finally applied to four transients simulating different levels of demagnetization, showing that the HHT analysis allows the degradation level for a demagnetized

core of a PMSM to be detected and assessed. The remaining part of the paper is organized as follows: Section 2 states the problem; Section 3 describes the methodology; Section 4 shows the obtained results; finally, in Section 5, some conclusions and remarks are provided.

2 PROBLEM STATEMENT

The PMSM can be considered as a combination of a Brushless DC motor (BLDC) and an AC induction motor. They have similar rotor than BLDC, but they are commonly called as brushless AC machine. The permanent magnets, which contain usually rare earth magnetic materials, are located either in the surface of the stator or buried inside to the stator. Since magnetic properties of rare earth materials are highly temperature dependent, too high temperatures inside the motor can cause partial demagnetization of magnets. In order to identify the demagnetization of a PMSM, the most significant signature to be considered is the stator current (Rosero et al. 2006a, b, Gritli et al. 2012). In this study the simulation model of PMSM and inverter has been created in MathWork's Simulink environment with Simscape and SimPowerSystems. There are ready-made models of PMSMs in the library of SimPowerSystems. The model of the 3 phase PMSM was modified so that it was possible to modify its flux linkage. The motor is driven by the PWM inverter with was added to the system. Also some measurements were appended. The model is shown in the Figure 1. Inputs to the model is torque and speed demand. Outputs are different measurements. From the measurements we have considered only the phase α of the stator current.

2.1 *Dataset description*

The dataset consists of four simulated stator current transients (phase α) of a PMSM: one transient represents the normal operating condition, i.e. the permanent magnet is not degraded, while the other three represent the behavior of the stator current under different levels of demagnetization. In these

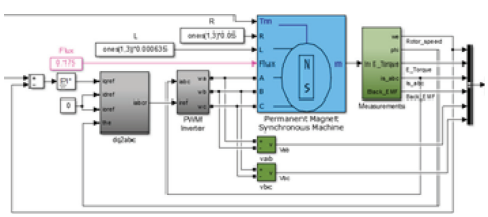

Figure 1. Simulation system of PMSM and inverter.

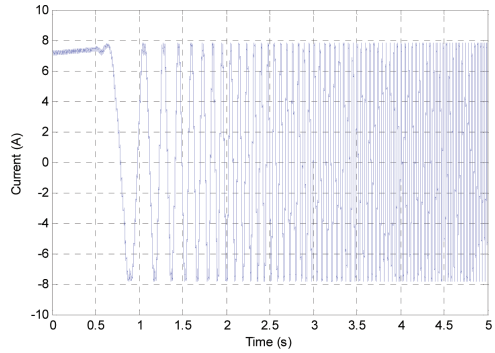

Figure 2. Stator current phase α—20% flux linkage.

simulations the motor speed was increased linearly from 0 rpm to 1800 rpm over 4.5 seconds starting from 0.5 s, in order to represent typical operating conditions of an automotive drive, which are continuously varying. In order to represent the degradation of the permanent magnet, the simulations were performed with different values of the flux linkage, a motor parameter which represents the demagnetization level of the permanent magnet. The three transients representing different levels of demagnetization are characterized respectively by 20%, 50% and 80% of the nominal flux linkage: the lower the flux linkage, the larger the degradation level. Figure 2 shows the phase α of the stator current for the transients representing the most degraded condition, which is characterized by the 20% of the nominal flux linkage value.

3 METHODOLOGY

The proposed approach comprises three steps: pretreatment of the transient to reduce the size of the datasets, EMD to extract the IMFs, and HHT to analyze the IMFs.

3.1 *Data pre-treatment*

To limit the computational requirements, we reduced the size of the original datasets, which were in the order of 2.5 million values in 5 seconds, equal to a sampling frequency of 0.5 MHz. We achieved this by resampling one point in every 25 from the original signal. In doing this, we have tried to lose the least possible information carried by the signal whilst trying to preserve the main functional behavior which characterizes the stator currents. Moreover, in order to further reduce the computational requirements, for each transient we have considered only the time interval in which the rotational speed of the motor increases from 800 rpm to 1600 rpm.

Our dataset is finally composed by four transients of the stator current signal, each one including about 40000 measurements for a time length of 2 seconds. Figure 3 graphically shows the impact of this procedure; the original signal is represented in the bottom-left figure, while the resampled signal is represented in the bottom-right figure. In the upper part of Figure 3 an enlargement of the original stator current signal shows the presence of high-frequency (40 kHz) low-amplitude (0.2 A) internal oscillations that have been lost through the resampling procedure. Although these oscillations may provide some useful information about the degradation of the PMSM, excessive computational requirements prevent their treatment with the techniques described below. However, the results have shown that the majority of the information about the behavior of the degraded PMSM is contained in the principal functional behavior of the stator current signal, which, as shown in Figure 2 bottom-right, has been preserved by our data pre-treatment procedure.

The sampling frequency of the final dataset is then around 20 kHz, which closer to the sampling frequency of a real current sensor than that of the raw simulation data (0.5 MHz).

3.2 *Empirical-Mode Decomposition (EMD)*

An IMF is a function that satisfies two conditions: i) in the whole dataset, the number of extrema and the number of zero crossings must either be equal or differ at most by one; ii) at any point, the mean value of the envelope defined by the local maxima and the envelope defined by the local minima is zero. The EMD extracts the first IMF by the following sifting process (Liu et al. 2006):

1. Find the upper envelope of $x(t)$ as the cubic spline interpolated of its local maxima, and the lower envelope, as the cubic spline interpolated of its local minima.

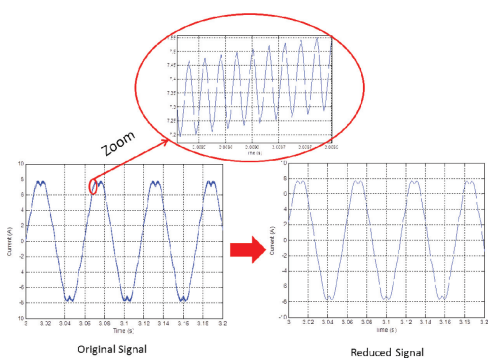

Figure 3. Illustration of the sampling and smoothing procedure used for signal pre-treatment.

2. Compute the envelope mean $m(t)$ as the average of the upper and lower envelopes.
3. Compute

$$h(t) = x(t) - m(t) \tag{1}$$

4. If the sifting result $h(t)$ satisfies the criteria for an IMF, stop. Otherwise, treat $h(t)$ as the signal and iterate on $h(t)$ through steps 1–4.

The EMD extracts the next IMF by applying the aforementioned procedure to the residue

$$r_1(t) = x(t) - c_1(t) \tag{2}$$

where $c_1(t)$ denotes the first IMF. This process is repeated until the last residue $r_n(t)$ has at most one local extreme. The first IMF component from the data contains the highest oscillation frequencies found in the original data $x(t)$.

3.3 *Hilbert-Huang Transform (HHT)*

Once the IMFs have been obtained by means of the EMD method, the Hilbert transform is performed to each IMF component as follows:

$$H\left[c_i(t)\right] = \frac{1}{\pi}\int_{-\infty}^{+\infty}\frac{c_i(\tau)}{t-\tau}d\tau \tag{3}$$

which means that $c_i(t)$ and $H[c_i(t)]$ form a complex conjugate pair, so that an analytic signal z_i is defined as:

$$z_i(t) = a_i(t)e^{j\omega_i(t)} \tag{4}$$

where $a_i(t)$ and $\omega_i(t)$ represent the instantaneous amplitude and frequency, respectively. To transform this temporal-space data to time-frequency space, the Hilbert transform is performed on each IMF component obtained by means of the EMD method as:

$$a_i(t) = \sqrt{c_i^2(t) + H^2\left[c_i(t)\right]} \tag{5}$$

$$\theta_i(t) = \arctan\left(\frac{H^2\left[c_i(t)\right]}{c_i(t)}\right) \tag{6}$$

In this way, the instantaneous frequency $\omega_i(t)$ is given by:

$$\omega_i(t) = \frac{d\theta_i(t)}{dt} \tag{7}$$

After performing the Hilbert transform on each IMF component, we can finally express the original data in the following form:

$$x(t) = \mathrm{Re}\sum_{i=1}^{n} a_i(t)\exp\left(j\int_{-\infty}^{t}\omega_i(t)dt\right) \tag{8}$$

where $Re\{\cdot\}$ denotes the real part of a complex quantity.

Following this procedure, the amplitude and instantaneous frequency for every IMF at every time step are computed. This result can be projected on the time-frequency-energy space, with energy defined as the amplitude squared, enabling us to compare the Hilbert spectra of the simulated currents waveforms.

4 APPLICATION OF THE METHOD AND RESULTS

As described in Section 3.1, our final dataset is composed by $k = 4$ transients of the stator current signal, each one comprising about 40000 measurements. For each transient signal we have performed the EMD obtaining $i = 5$ IMFs $c_{i,k}(t)$, i=1, .., 5, k = 1, .., 4: it has to be remarked that the first IMF is characterized by the highest frequency, while the fifth IMF is characterized by the lowest frequency. For each identified IMF $c_{i,k}(t)$, we have computed the Hilbert Transform by means of Eq. 3. Then, using Eq. 5 we have computed the instantaneous amplitude $a_{i,k}(t)$; finally, applying first Eq.6 and then Eq. 7 to each $c_{i,k}(t)$ we have computed the instantaneous frequency $\omega_{i,k}(t)$ for each IMF of each transient, i=1, .., 5, k = 1, .., 4. Figure 4 shows the Hilbert spectrum of the four considered transients, which are characterized by an increasing value of flux linkage, i.e. decreasing degradation level. The 3D space of the Hilbert spectrum is represented on a 2D figure, using a color scale in order to represent the amplitude of the obtained IMF. Notice that the color scale is the same for all the subfigures of Figure 4.

In order to highlight the most energetic IMFs, i.e. the IMFs characterized by the largest amplitude, we have decided to assign the black color to amplitude values close to zero and to use a black background with the intent of hiding the low energy IMFs. The effects of this choice are clearly noticeable: in the upper-left subfigure of Figure 4, the instantaneous frequency of the first IMF is a large band whose average increases from 100 Hz to 150 Hz, and is characterized by a dark red color, which represents a low amplitude. In the other three subfigures of Figure 4, the functional behaviors of the instantaneous frequencies of the first IMFs are almost the same, but it is not possible to notice them because they are characterized by a very dark color which makes them indistinguishable from the black background color. It is possible to notice the presence of these IMF frequencies only because they cover

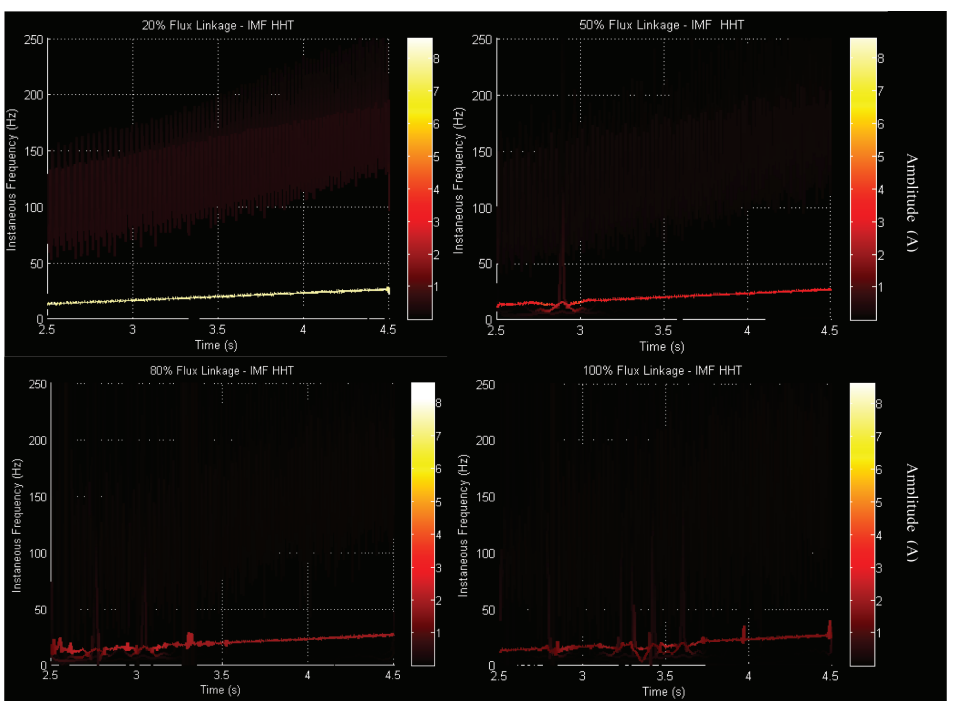

Figure 4. Hilbert spectrum for 20%, 50%, 80%, 100% flux linkage.

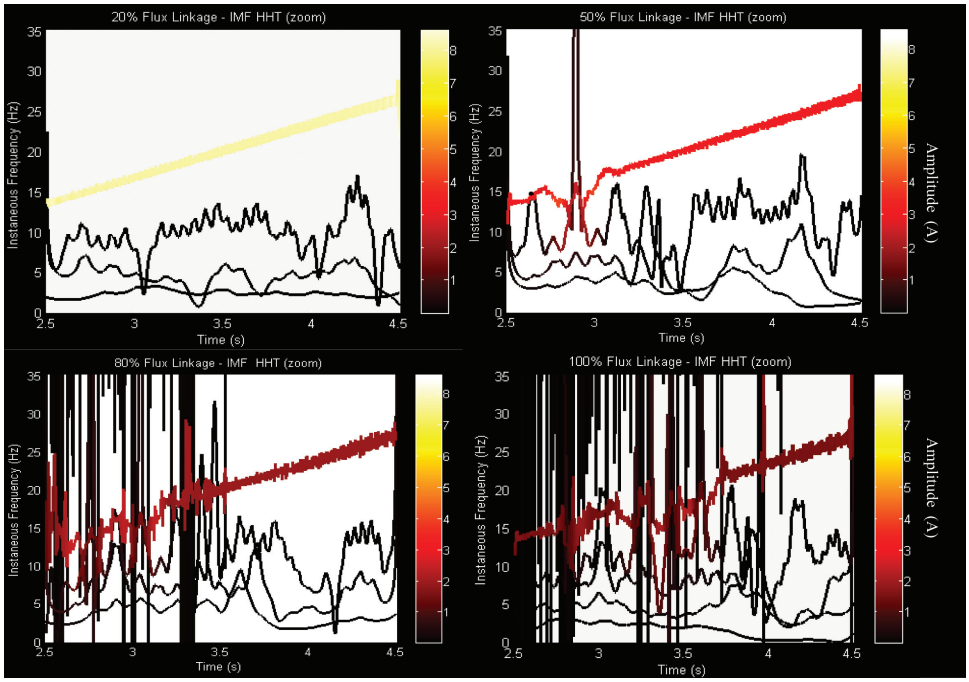

Figure 5. Enlargement of the Hilbert spectrum for 20%, 50%, 80%, 100% flux linkage.

the white grid of the figure: this means that the energy levels of these IMFs are very low. However, the main difference highlighted by Figure 4 is the amplitude of the instantaneous frequencies of the second IMFs, which are all represented by a line continuously increasing from 15 Hz to 28 Hz. Although their functional behaviors are almost the same, they are characterized by different constant amplitude values, increasing from the 1.5 A of the nominal condition (dark red, bottom-right), to the 7.8 A of the most degraded condition (yellow, upper-left). Thus, using the Hilbert spectrum of the second IMFs it is possible to clearly distinguish between healthy and degraded conditions of the permanent magnet of the PMSM; furthermore, based on amplitude of these spectra it is also possible to distinguish and classify the different degradation levels. From a physical point of view, these results can be considered as expected: in fact, if the permanent magnet of a PMSM is demagnetized (i.e. the internal magnetic field is lower than in the nominal case), a larger stator current will be needed in order to produce the same acceleration. Figure 5 shows an enlargement of Figure 4; in addition to the second IMF spectrum, it is also possible to observe the spectra of the third, fourth and fifth IMFs. Their functional behaviors can be considered comparable, even if their shapes are not exactly the same as found for the second IMF.

Their amplitudes are very close to zero, resulting in a very dark coloration which represents their low energetic significance. It is important to point out that the oscillating effects appearing in the two bottom subfigures of Figure 5 are mainly due to computational and numerical errors of the MATLAB code used for the HHT computation and do not provide any information about the demagnetization of the PMSM permanent magnet. Notice that also in this case the color scale is the same for all the subfigures of Figure 5.

5 CONCLUSION AND FUTURE WORK

In this work we analyzed four simulated stator current transients representing different levels of permanent magnet demagnetization in a PMSM, at 20%, 50%, 80% and 100% of the nominal value Since these transients represent an automotive drive linearly accelerating from 0 rpm to 1800 rpm during 5 seconds, we decided to analyze the Hilbert spectra of these signals resorting to the HHT analysis described in Section 3, which has been developed for treating non-linear and non-stationary oscillating signals (Kizhner et al. 2004). This technique can be divided in two steps: i) EMD and ii) HHT. In addition, a preliminary data reduction step was required in order to limit the computational

requirements for the analysis. The resulting Hilbert spectra have been compared in order to detect and assess the degradation level of the PMSM permanent magnet. It has been shown that, in this case, the most significant components are the Hilbert spectra of the first and second IMFs. Although the functional behavior of the signals is similar, it is possible to distinguish between the different levels of degradation by focusing on the amplitudes of the IMFs; in particular, the larger the demagnetization of the motor, the larger the amplitude of the corresponding IMFs of the stator currents. The results obtained suggest significant opportunities for the improvement of the methodology. In particular, a possible next step for this work is the development of a classification tool based on the "brightness" difference between the Hilbert spectra of the signals: the rationale behind this consideration is that the brightness difference, which is due both to the amplitude and the frequency differences, is representative of the energy difference between two signals. Thus, if we represent the Hilbert spectrum as in Figure 4, we can develop an automatic tool for the PHMS which, based on the HHT analysis, will be able to distinguish and automatically classify the PMSM degradation due to the field source demagnetization.

ACKNOWLEDGEMENTS

The research leading to these results has received funding from the European Community's Framework Programme (FP7/2007-2013) under grant agreement n° 314609. The authors are grateful for the support and contributions from other members of the HEMIS project consortium, from CEIT (Spain), IDIADA (Spain), Jema (Spain), MIRA (UK), Politecnico di Milano (Italy), VTT (Finland), and York EMC Services (UK). Volatility regime switching and jump-diffusion process for prognosis: Case of equity price modeling

H. Ghamlouch, M. Fouladirad & A. Grall
CNRS UMR 6279, Institut Charles Delaunay, Université de Technologie de Troyes, Troyes, France

ABSTRACT: Data modeling is a critical step in working with real dataset in order to characterize the collected data and their dynamics. Accurate data modeling is needed in many domains for prognosis, forecasting, passage-time prediction, and other data based analysis. In this document we give an application of financial data modeling within the framework of asset price forecasting and risk prediction. Having the price evolution of different equity indexes from different countries for almost 20 years, the aim of our project is to suggest a suitable model describing the dynamics of these indexes. Several types of asset price modeling were considered and improved over years. The work in this paper is focused on stochastic processes. Comparing the volatility behavior of different indexes, the external environment is divided into three states. The transition between these three states is controlled by an external covariate following a Markov chain. At each state the price of the index is considered to follow a jump-diffusion process with Log-Uniform Jump Amplitude. Combining the Markov chain and the jump-diffusion process the resulting model will represent the price variation behavior and can be used for price forecasting and risk prediction.

1 INTRODUCTION

In engineering, as in many domains, system design and surveillance requires the collection and analysis of different types of information. Data analysis forms the fundamental work in system understanding and performance evaluation (working conditions, reliability evaluation, risk-based decision-making ...). However, working with real data may introduce signals that cannot be modeled exactly by an analytic expression or in a deterministic way (noise waveforms, biological signals, temperature histories, communication signals, stock prices ...). Considering the random evolution of collected data over time, a good representation of their dynamic would be a stochastic process (Wiener, Gamma, stochastic differential equations ...). In general, stochastic processes are suitable tools to model the system behavior by taking into account its dynamic evolution and the influencing random phenomenon. Stochastic calculus and control play a significant role in various disciplines of engineering (Lin, de Weck, & MacGowan 2008), physics, biology (Giraudo & Sacerdote 1997) and finance (Bhar, Colwell, & Xiao 2013, Zhao, Rong, & Zhao 2013) ...

Besides their probabilistic behavior and non-deterministic general dynamics, an additional factor that may appear in real data variation is "jumps". Jumps are formed by the relatively large fluctuation (positive or negative variation) with respect to the mean and variance of the actual variation distribution. One important type of stochastic process that has the ability to describe the general behavior of data evolution as well as the particular large fluctuations is the jump-diffusion process. Taking into consideration the changes in the influencing environment, this type of stochastic model is proposed in this paper with a financial application.

Using real data, we are trying to find the suitable stochastic model. The collected dataset consists of the daily closing prices for 13 equity indexes from different countries. Starting from 1th January 1993 until 11th January 2013, the corresponding data series for each index forms 5000 daily points. In a preliminary study we found that the probability distribution of the log-returns follows a combined density function of Normal and Laplace distribution, which is consistent with the previously mentioned proprieties of real data. In section 2, the model that we propose to use for the description of the dynamic of equity indexes is presented. First the data evolution is represented and briefly descried in order to clarify the chosen model motivation. Afterwards the two essential parts of the proposed model are represented: the economic environmental is divided into three states (calm, normal and agitated) controlled by an external covariate that follows a Markov Chain, and the price evolution of different index at each state is considered to follow a log-normal diffusion, log-uniform jump

amplitude stochastic process. The jump-diffusion process description and estimation method of the process parameters are given. In the section 3 case studies are represented, giving the technical consideration of the calibration method. Real data evolution and simulated data from the chosen model are compared.

2 STOCHASTIC MODEL AND DATA EVOLUTION

In Figure 1 we show the values of daily evolution (called log-returns) of four different collected data series (SPX Index, CAC Index, DAX Index and SMI Index). In order to decide which model is the best to describe the data dynamic, we have toexamine the variation of the growth rate and the volatility of the collected data with respect to time. Visually, the return variance is not constant over the time. In addition the variance behavior is found to be similar for different indexes. Taking the period of 20 years (from Jan. 1993 to Jan. 2013), we found that the log-return variance ups and downs are almost simultaneous for a large number of indexes (9 different indexes). Another important factor appears in this figure which called "jumps". Jumps are formed by the relatively large value of return (positive or negative return) with respect to the mean and variance of the actual return distribution. These jumps appear in several instants of the overall period. Figure 1 shows that jumps (or shock) arrive randomly in time and are distributed over the whole period.

The model that we propose will take into consideration both of these observations. This model consists of an external factor controlling and relating the volatility behavior of different indexes and a jump-diffusion stochastic process that reflect the jump phenomena in addition of the normal diffusion variation of each index.

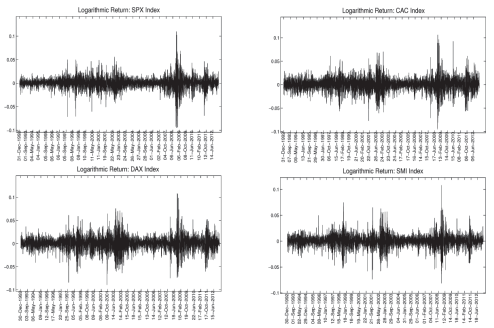

Figure 1. Daily log-returns of four different indexes from different countries.

2.1 *Environment state and Markov chain*

We study first the correlation between volatility behaviors of the 14 equity indexes. The study is based on the relative periodic standard deviation STD (with 1 period = 3 months) of different equities with respect to the STD of their log-return distribution for the 20 years period. For 9 over 14 indexes we found a strongly correlated STD behavior i.e. the relative STD increases (and decreases) appear simultaneously for this 9 indexes, which shows that the volatility of daily returns distribution may be related to an external factor that will be called the "*environment state factor or ES factor*". We suggest that a sub-period ES can be represented by a simple Markov Chain of three states. The states that represent the three different states of the ES factor are defined by the following:

- Calm: Relative STD of return less than 1.
- Normal: Relative STD of return between 1 and 2.
- Agitated: Relative STD of return greater than 2.

Transitions between the three states and the average duration in each state are defined by the Markov chain transition matrix and duration vector and are given in section 3.

2.2 *Log-normal diffusion log-uniform jump amplitude model*

Taking the data of only one specific index, the overall period is divided into smaller sub-period of 3 months. According to the relative STD of log-return distribution during one sub-period, this latter is associated to one of the three different ES. For each ES an appropriate stochastic model is associated to describe data evolution in this state.

Let $S(t)$ be the variable representing our concerned data at time t. $S(t)$ is supposed to satisfy a Markov, continuous-time, geometric Stochastic Differential Equation (SDE). A classical model of stochastic process is the BS (Black & Scholes) log-normal diffusion process. The BS model follows a basic stochastic differential equation given by:

$$dS(t) = \mu S(t)dt + \sigma S(t)dW(t) \quad (1)$$

where μ and σ are two constant parameters that represent respectively the growth rate and the volatility of the process and $W(t)$ is a standard wiener process.

BS model is widely used in finance where the log-return of asset price is considered to be normally distributed (Platen & Health 2006). However, equity returns distribution presents several realistic properties not found in the ideal BS model: (1) the presence of jumps represented by large random fluctuations such as crashes or sudden upsurges, (2) the log-return distribution are skewed,

and (3) the distribution of log-returns has a positive excess kurtosis with respect to the normal distribution i.e. the shape of the distribution has a more acute peak around the mean and fatter tails.

To model these phenomena, different modification of the Black & Scholes model have been proposed. The most two common models are the stochastic volatility model (see Hull White process (Hull & White 1987)), CIR process (see (Cox & Ross 1976)) and Ornstein-Uhmenbeck process (see (Heston 1993, Stein & Stein 1991)) and the jump diffusion model.

In Jump-Diffusion models a space-time Poisson process is added to the usual geometric Brownian motion in order to give the possibility of large fluctuations called jumps. Using a Poisson process for the jump timing and a log-normal distribution for the jump-amplitudes (Merton 1976) introduced the jump-diffusion model in financial modeling in order to describe the market crashes and rallies. Later on, (Kou 2002) proposed a jump-diffusion model with a log-double-exponential process for the jump-amplitudes. One important application of jump diffusion models is given by (Chernov, A.Ronald Gallant, & Tauchen 2003) where the jump process is added to a stochastic volatility model.

In this work, the chosen model to describe the dynamic of the data during one state will be the log-normal diffusion log-uniform jump amplitude model introduced by Hanson and al. (Hanson, Westman, & Zhu 2002) and described by the following SDE:

$$dS(t) = S(t)[\mu_D dt + \sigma_D dW(t) + (e^J - 1)dP(t)] \quad (2)$$

starting at $S(0) = S_0$, $S_0 > 0$, and where μ_D is the drift coefficient associated with the diffusion, σ_D is the diffusive volatility, $W(t)$ is the one-dimensional stochastic Weiner process, $(e^J - 1)$ is the Poisson jump amplitude and $P(t)$ is the standard Poisson process with joint mean and variance $E[P(t)] = Var[P(t)] = \lambda t$ which marks the arrival times of shocks.

The index log-return $d\ln(S(t))$ can be transformed to a simpler jump-diffusion Stochastic Differential Equation (SDE) upon use of the stochastic chain rule (Platen & Health 2006),

$$d[\ln(S(t))] = \mu_{lnD} dt + \sigma_D dW(t) + JdP(t), \quad (3)$$

where $\mu_{lnD} = \mu_D - 0.5\sigma_D^2$ can be called the log-diffusive (ld) drift and J is the log-return jump-amplitude. Note that the finite log-return jump-amplitude is supposed to respect $(e^J - 1) > -1$ in order to avoid complete investment loss (Hanson, Westman, & Zhu 2002).

Considering Hanson and al. studies (Hanson & Westman 2002a) (Hanson & Westman 2002b) and the comparison in (Hanson & Zhu 2004) between the use of normal, double exponential and uniform distribution, the jump-amplitudes in the log-return modelare assumed to be uniformly distributed on $[Q_a, Q_b]$, with $Q_a < 0 < Q_b$ which yields a mean $\mu_J = (Q_a + Q_q)/2$ and variance $\sigma_J^2 = (Q_b - Q_a)^2/12$.

$$J \sim U(Q_a, Q_b) \quad (4)$$

We assume also that the model parameters $\mu_{lnD}, \sigma_D^2, \mu_J, \sigma_J^2$ and λ are constant (time independent).

Numerical discretization of this model is needed. Taking $dt \to \Delta t$ we define the discrete stock log-return increment of the jump-diffusion process 2 as:

$$\Delta \ln S(t) = \ln S(t + \Delta t) - \ln S(t) \quad (5)$$

The basic moments of the stock log-return increment in (5) are given in Appendix 1. The increment probability distribution of the model is detailed in Appendix 2.

2.2.1 *Parameter estimation*

The object of this step is to find a Jump-Diffusion model that describe fairly the dynamic of the index log-returns. Considering a log-normal diffusion, log-uniform jump amplitude log-return model, the five parameters $\{\mu_J, \sigma_J^2, \mu_{lnD}, \sigma_D^2, \lambda\}$ have to be estimated. Let $M_1^{(sp)}$ and $M_2^{(sp)}$ be the empirical moments (mean and variance) of real log-return dataset $\Delta[\ln(S^{(sp)})]$ defined by:

$$\Delta[\ln(S_i^{(sp)})] = \ln(S_{i+1}^{(sp)}) - \ln(S_i^{(sp)}), \quad (6)$$

Two constraints are used to reduce the number of free parameters, which are the following mean and variance constraints:

$$M_1^{(sp)} = E[\Delta[\ln(S(t))]] \quad (7)$$

$$\text{and } M_2^{(sp)} = Var[\Delta[\ln(S(t))]] \quad (8)$$

where $E[\Delta[\ln(S(t))]]$ and $Var[\Delta[\ln(S(t))]]$ are the theoretical moments (mean and variance) given by equations (15) and (16) in Appendix 1.

Therefore if only the three jump parameters $\{Q_a, Q_b, \lambda\}$ are estimated,the parameters $\mu_J, \sigma_J^2, \mu_{lnD}$, and σ_D^2 can be deduced from equations (7) and (8) as follows

$$\mu_J = (Qa + Qq)/2 \quad (9)$$

$$\sigma_J^2 = (Qb - Qa)^2/12 \quad (10)$$

$$\mu_{lnD} = (M_1^{(sp)} - (\lambda \Delta t \mu_J))/\Delta t \quad (11)$$

$$\sigma_D^2 = [M_2^{(sp)} - (\lambda \Delta t)(\mu_J^2 + \sigma_J^2)]/\Delta t \quad (12)$$

Thus we have a three dimensional global minimization problem for a complex density function (19). In literature two optimization functions has been proposed and used for this problem (Hanson, Westman, & Zhu 2002, Hanson & Westman 2002a). Both of these objective functions are based on the division of the log-return domain into $N^{(bin)}$ bins and the calculation of theoretical and empirical bin frequencies. The weighted least squares function (χ^2 fit) is given by (Hanson, Westman, & Zhu 2002) as follows:

$$\chi^2 = \sum_{i=1}^{N^{(bin)}} \omega_i \cdot (f_i^{(jd)} - f_i^{(sp)})^2 \quad (13)$$

where ω_i is the weight of the ith bin, $f_i^{(sp)}$ is the ith empirical bin frequency and $f_i^{(jd)}$ is the ith theoretical jump-diffusion bin frequency corresponding to the same sample size $N^{(sp)}$ of the real data set (see Appendix 3).

Note that an unweighted least square function was also used in parameter estimation of jump-diffusion process (Hanson & Westman 2002a, Hanson & Westman 2002b).

The second used objective function is the Multinomial Maximum Log-Likelihood function (MML). This function is derived in (Hanson, Westman, & Zhu 2002) based on the assumption that the simulation distribution of a bin frequency is a multinomial distribution. The optimization function can be written as the following minimization objective:

$$-\sum_{i=1}^{N^{(bin)}} \left[f_i^{(sp)}(x_p) \ln(f_i^{(jd)}(x_p)) \right] \quad (14)$$

where x_p is the unknown parameter vector.

3 CASE STUDY

As we mentioned in section 2.1 the period of 20 years is divided into sup-periods according to the environment state "*ES*". The transition between different states is controlled by an external covariate which follow a Markov Chain model. The Markov Chain is constructed by three states (N1, N2 and N3) that represent respectively the Calm, Normal and Agitated ES. Considering the nine indexes influenced by this factor, the transition matrix between these states and the average duration in a state are defined by the following matrix and vector:

$$T = \begin{pmatrix} 0.846 & 0.141 & 0.013 \\ 0.51 & 0.432 & 0.058 \\ 0 & 0.8 & 0.2 \end{pmatrix}$$

$$D = \begin{pmatrix} 6.49 & 1.76 & 1.25 \end{pmatrix}$$

The objective of the next step is to find, for one equity, the jump-diffusion model suitable to each state. Considering the *ES classification* we can separate the data of one equity into three sets that correspond to the three ES (*Calm*, *Normal* or *Agitated*). Parameter estimation is done using the dataset formed of equity log-return belonging to the same *ES*.

Model calibration is done using the numerical Nelder-Mead optimization which serves to find the minimum of one of the objective functions cited in section 2.2. The three objective functions, weighted least square function (13), unweighted least square function and multinomial log-likelihood function (14), have been tested.

3.1 *Estimation constraint*

As seen in section 6 the three free parameters to be estimated for the jump-diffusion model are Q_a, Q_b and λ. However some constraint are needed in order to define the variation domain of each parameter and therefore to guarantee reasonable and realistic solutions for the wanted model. The first constraint derives from the fact that the number of jumps in one year cannot exceed the number of trading days. Other constraints are chosen to prevent the jump amplitude at a time t to exceed the rang of [–65%,+100%] of the price at this time. Finlay, one nonlinear constraint is needed. Considering equations (9) to (12) that permit to reduce the number of free parameters from 5 to 3, the nonlinear constraint is needed to keep positive the value of σ_D^2. No constraint is needed for σ_J^2 since $(Q_a - Q_b)^2$ is always positive.

To allow necessary boundary and nonlinear constraint to be respected a constrained Nelder-Mead optimization is used.

3.2 *First guess*

For a good global optimization method the results must be independent of the choice of parameter starting values (first guess). However a reasonable choice of starting values is needed to reduce the calculation time. Six different combinations of starting values are chosen to ensure that the optimization algorithm is converging to the same minimum. The chosen sets take into consideration the coverage percentage of the majorities of sample values. In the following, the convergence of the optimization method has been tested starting from six different *first guess* combination.

3.3 *Results*

For each equity price evolution, the log-return dataset is calculated using equation (6). Data classification is done by separating the time interval into sub-periods of 3 months. A sub-period *SubP* is considered to be in one of the three Markov chain states ($N1$, $N2$ and $N3$) as follows:

- If $V[\Delta \ln(S_i^{(sp)}))]_{SubP} < V[\Delta \ln(S_i^{(sp)}))]_{1993-2013}$, the log-return values of the sub-period *SubP* are added to the equity *Calm ES dataset* represented by $N1$.
- If $V[\Delta \ln(S_i^{(sp)}))]_{1993-2012} \leq V[\Delta \ln(S_i^{(sp)}))]_{SubP} < 2 * V[\Delta \ln(S_i^{(sp)}))]_{1993-2013}$, the log-return values of the sub-period *SubP* are added to the equity *Normal ES dataset* represented by $N3$.
- If $V[\Delta \ln(S_i^{(sp)}))]_{SubP} \geq 2 * V[\Delta \ln(S_i^{(sp)}))]_{1993-2013}$, the log-return values of the sub-period *SubP* are added to the equity *Agitated ES dataset* represented by $N3$.

Using the six different *First Guess* for the parameter set $\{Q_a, Q_b, \lambda\}$ we optimize the three different objective functions (weighted mean square, unweighted mean square and multinomial maximum likelihood). We found that the unweighted mean square objective function gives the best results in terms of convergence. Kolmogorov-Smirnov test and Q-Q plot are used to test the statistical resemblance between the real log-return distribution and simulated-data distribution resulting from the estimated model. Statistical tests show that the use of unweighted least square objective function leads to the best estimated parameters in terms of statistical comparison between real and simulated data.

Table 1 shows the estimation results for the Calm ES period of the SPX Index equity price,

Table 1. Summary of estimated parameters of log-normal diffusion, log-uniform jump amplitude process for SPX Index in the *CalmES* period using three objective functions and three different starting values. The Kolmogorov-Smirnov distance *k2stat* is also represented.

using the three proposed objective functions and starting from different chosen parameters set. This result shows that the unweighted least square function is more stable in terms of convergence. For both the weighted least square and MML functions the convergence may change with the change of *first guess* and tends to reach the limits of the field of variation of some parameters. In Table 2 the estimated parameters for the three ES periods of three different equities (*SPX Index*, *CAC Index* and *DAX Index*) are represented.

Table 3. Statistical comparison between the simulated data from the estimated model and real log-return data set for three equities (*SPX Index*, *CAC Index* and *DAX Index*) for the *Calm*, *Normal* and *Agitated ES* periods.

Equity	State	*k2stat*	*%skewness*	*%kurtosis*
SPX Index	*Calm*	0,0262	–68,66	–11,18
SPX Index	*Normal*	0,0258	24,514	–18,68
SPX Index	*Agitated*	0,04792	–296,85	–25,05
CAC Index	*Calm*	0,01090	18,55	–2,88
CAC Index	*Normal*	0,0343	–620,92	–7,49
CAC Index	*Agitated*	0,07633	–98,79	6,90
DAX Index	*Calm*	0,0215	–7,56	–7,13
DAX Index	*Normal*	0,0359	16,14	–12,89
DAX Index	*Agitated*	0,0322	–76,61	1,26

Table 3 shows the results of Kolmogorov-Smirnov distances for different equities and states, and the difference in statistical proprieties (Skewness and Kurtosis) of simulated data from the estimated model with respect to those of the real dataset. Note that the Kolmogorov-Smirnov test always leads to the null hypothesis H0 which means that the distribution of the simulated data is

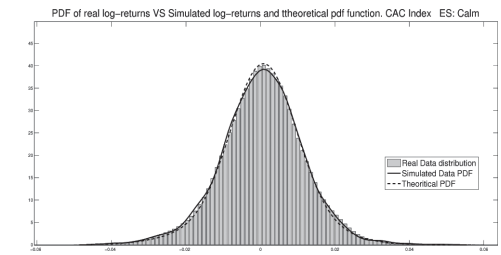

Figure 2. PDF comparison between real log-return and simulated log-return for *CAC Index* in *Calm* State.

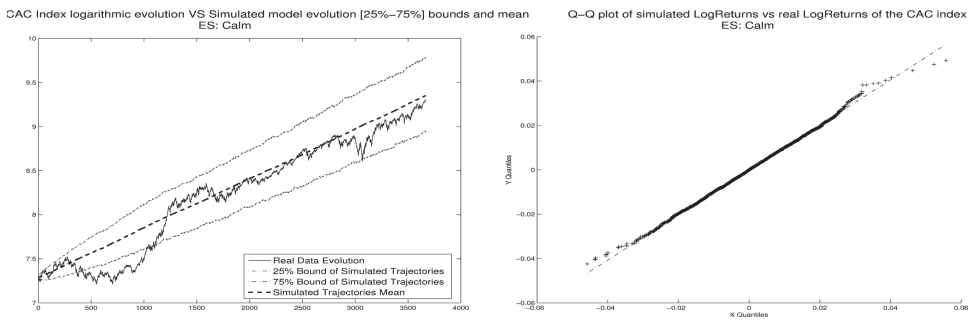

Figure 3. Data evolution comparison between real *CAC Index* log-price and simulated jump-diffusion process for *Calm* State (on left) and the Q-Q plot of these two data set (on right).

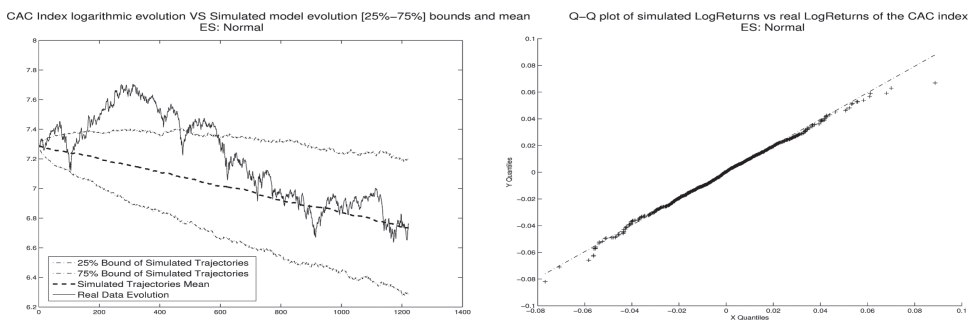

Figure 4. Data evolution comparison between real *CAC Index* log-price and simulated jump-diffusion process for *Normal* State (on left) and the Q-Q plot of these two data set (on right).

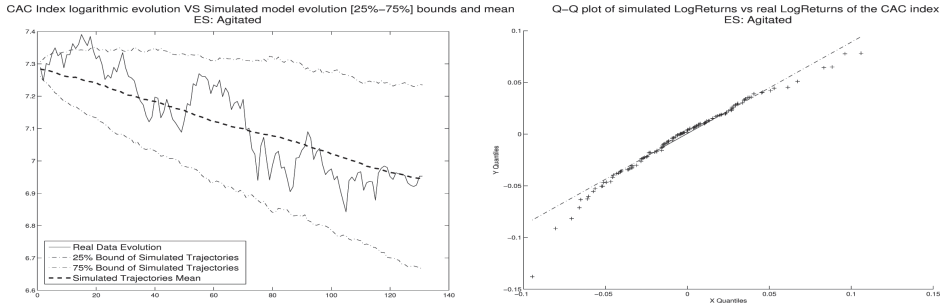

Figure 5. Data evolution comparison between real *CAC Index* log-price and simulated jump-diffusion process for *Agitated* State (on left) and the Q-Q plot of these two data set (on right).

quit similar to the distribution of real log-returns. We also notice a small difference in the kurtosis coefficient between real and simulated data while in some cases the skewness coefficient of the simulated data shows an important deviation from the skewness coefficient of the real dataset. In Figure 2 the Probability Density Function (PDF) is given for both real dataset *CalmCACIndex* and simulated data from the estimated model as well as the theoretical PDF of the calibrated model. Figure 3 shows on the left the evolution of the equity price considering only the *Calm ES CAC Index* data and a the [25% 75%] bounds of 500 random simulated data evolution using the estimated jump-diffusion model. On the right a Q-Q plot for the real dataset (*CalmCACIndex*) and the estimated dataset is represented. Similarly, Figure 4 (Fig. 5) shows the comparison between the evolution of real *NormalCACIndex* (*AgitatedCACIndex*) dataset and simulated data from the estimated model, as well as the Q-Q plot between this two dataset.

4 CONCLUSION

The *log-normal diffusion, log-uniform jump amplitude process* has been used in many paper to solve optimal consumption and portfolio optimization and control (Hanson & Westman 2002a) (Hanson & Westman 2002b). Hanson and Westman (Hanson & Westman 2002b) use a yearly decomposition of log-returns in order to estimate the appropriate parameters for their jump-diffusion model. The difference of model parameters between different years is noticeable. A reasonable division of the time domain is proposed according to the volatility behavior of log-return values. The estimation of the model parameters for the three predefined environment states is done using a numerical minimization method (constrained Nelder-Mead) for a least square objective function. The results show that the estimated model is suitable for modeling the real dataset in terms of the probability distribution. Estimated models show statistical resemblance to real data distribution which is more important in terms of the kurtosiscoefficient than the skewness coefficient. A future work is needed to test the goodness of fit between the estimated model and the log-price evolution, to find and adjust the weak points where the model does not adequately reflect the log-price dynamics. Thus, we can benefit from the estimated model in order to propose new solutions for financial control, risk-based decision-making and prognostics.

APPENDIX 1

The basic moments of the stock log-return increment in (5) are given by the following:

$$M_1^{(jd)} = E[\Delta[\ln(S(t))]] = (\mu_{lnD} + \lambda\mu_J)\Delta t, \quad (15)$$

$$M_2^{(jd)} = Var[\Delta[\ln(S(t))]] \simeq [\sigma_D^2 + \lambda(\sigma_J^2 + \mu_J^2)]\Delta t. \quad (16)$$

APPENDIX 2

Increment distribution for jump-diffusion models is studied is (Synowiec 2012) for different type of jumps. In (Hanson & Westman 2003) the probability density for the log-normal diffusion, log-uniform jump amplitude increment $[\ln(S(t))]$ is derived for the case of time dependent parameters. This probability density is used in (Hanson, Westman, & Zhu 2002) with the modified form as follows:

$$\begin{aligned}\mathbb{P}[d\ln(S(t)=x] &= \mathbb{P}[dP(t)=0]\cdot\phi^{(n)}(x;\mu_{lnD}dt,\sigma_D^2) \\ &+ \sum_{k=1}^{\infty}\mathbb{P}[dP(t)=k] \\ &\cdot\frac{\Phi^{(n)}(x-k\cdot Qb, x-k\cdot Qa;\mu_{lnD}dt,\sigma_D^2 dt)}{k(Qb-Qa)}\end{aligned} \quad (17)$$

for $-\infty < x < +\infty$, where the Poisson distribution $p_k(\lambda dt)$ is specified by (18) and $\Phi^{(n)}(x, y; \mu_{lnD} dt, \sigma_D^2 dt)$ is the integral of the normal density function $\phi^{(n)}(x; \mu_{lnD} dt, \sigma_D^2)$ between x and y.

$$\mathbb{P}[dP(t) = k] = exp(-\lambda dt)(\lambda dt)^k / k! \tag{18}$$

The derivation of this probability is based on the triad random variable $\xi + \eta \cdot \zeta$ which forms the $d \ln S(t)$ model, with diffusion $\xi = \mu_{lnD} dt + \sigma_D dW(t)$, jump amplitude $\eta = J$ and jump-time index $\zeta = dP(t)$ process.

For $\Delta t \to 0^+$ the probability density defined in (17) can be asymptotically approximated for the discrete case as

$$\begin{aligned} &\mathbb{P}[\Delta \ln(S(t))] \sim \phi^{(jd)}(x) \\ &\quad \equiv (1 - \lambda \Delta t)\phi^{(n)}(x; \mu_{lnD} \Delta t, \sigma_D^2 \Delta t) \\ &\qquad + (\lambda \Delta t) \frac{\Phi^{(n)}(x - Q_b, x - Q_a; \mu_{lnD} \Delta t, \sigma_D^2 \Delta t)}{(Qb - Qa)}. \end{aligned} \tag{19}$$

APPENDIX 3

In 13 $f_i^{(jd)}$ represent the ith expected bin frequency after $N^{(sp)}$ simulation of the theoretical jump-diffusion process is:

$$f_i^{(jd)} = N^{(sp)} \cdot \int_{x_i}^{x_{i+1}} \varphi_i^{(jd)}(x) dx. \tag{20}$$

The bin weights in 13 are chosen as the normalized theoretical values:

$$\omega_i = (1/\sigma^2_{f_i^{(jd)}}) / \sum_{j=1}^{N^{(bin)}} (1/\sigma^2_{f_i^{(jd)}}), \tag{21}$$

where

$$\sigma^2_{f_i^{(jd)}} = N^{(sp)} \cdot [1 - f_i^{(jd)} / N^{(sp)}]^2 \cdot f_i^{(jd)}. \tag{22}$$

ABSTRACT: Emergency Response Plans in case of natural or industrial disaster have to be assessed before being triggered. But it appears that there is no much works on how to assess these plans. Some tried to assess robustness but only considering two states: complete functioning or total failure. In this paper, we propose to assess Emergency Response Plan by looking its performance. It is used Multi-State System approach, for two reasons. The first is that Multi-State System approach allows to study more than the two binary states of functioning or failure, the second is that it includes probability to be in each state. Using a model-based approach to analyze Local Emergency Response Plan will systemize the analysis and allow to deal with a high variety of engaged resources. It has been chosen to work with Function-Interaction-Structure modeling method.

1 INTRODUCTION

Events threatening our societies happen in more and more complex contexts (Lewis & Mioch, 2005) and have highest frequency and intensity (United Nations 2011). United Nations ask its members to build organization to face these events. However, there is no consensus on how to assess such organization. Models have been used (Flaus 2010, Kolen et al. 2012, Robert et al. 2008, Robert, unpubl.) to capture complexity of organization where threatening events occur in order to understand crisis management mechanisms.

Consequences modeling model (Robert et al. unpubl.) and critical infrastructures model (Robert et al. 2008) have been developed to show interactions between critical infrastructures and the domino effects of consequences. Consequences and critical infrastructure models are part of work on organizational resilience (Hémond & Robert 2013) that identify needs in assessing Emergency Plan but do not treat this aspect.

Several levels of Emergency Response Plan can be considered: national, regional and individual scale (Calixto & Larouvere 2010). In this study, we will consider Local Emergency Response Plan (LERP) which is the third level in the Emergency Response Plan: Individual. It is the most important, because it is the first organizational response set up in case of emergency due to its proximity to happening event.

Plans are collection of procedures to describe organizational management in case of a threatening event and identify resources to set up to face such an event. Resources of LERP can be categorized as human resources (i.e. head quarter and field staff), technical resources (i.e. transportation means, alert means), organizational resources (procedure) and informational resources (i.e. message, order) as resources in Industrial Emergency Response Plan (IERP) (Karagiannis et al. 2010).

Also LERP contains a risk analysis part to describe threatening events which can occur in local territory. They are design to ensure warning alert, information protection and support to local population. Plans are not designed to anticipate all possible scenarios but have to be as flexible as possible to adapt to the occurring event (Perry & Lindell 2003).

Currently, potential problems are identified a posteriori thanks to feedback analysis (Karagiannis et al. 2010). A key issue is to identify potential problems of these plans before their deployment. It is necessary to know if the designed plan will

be efficient in case of emergency. Indeed, knowing ERP efficiency in its design phase gives visibility to decision makers on the possible disruptions. It allows setting preventive actions to enhance the plan before it is triggered.

However, an a priori ERP assessment is not easy due to its complexity (Flaus 2010) and it seems that local authorities do not see emergency planning as a priority (de Souza 2000, Henstra 2010). The complexity of ERP comes from resources variability in terms of type, geographical position and organizational owners. To understand all links between resources and missions it is needed to model Emergency Response Plan (that describes crisis management) at a good level of description. Works in this field are increasing (Jain & McLean 2003). Modeling an Emergency Response Plan allows a better first-aid response, knowledge of consequences before they happen, activities continuity where the event is not happening, traffic management and victims allocation to hospitals.

In previous work (Karagiannis et al. 2010) develop a method laying on models to assess robustness of Emergency Response Plan in industrial context. This method is based on questionnaires to assess probability of resource failure modes, organize and combine them in a Fault-Tree (FT) specific to each category (human, technical, organizational and informational). In this way plan failure scenarios can be built. Authors developed also a resource taxonomy for Emergency Response Plan to build patterns of Fault-Tree. A limit of this work is that it considered for model elements (both resource and function) only two binary states and so does not take into account partial failures of these elements, specifically function element. As it can be noticed in real world many elements of a system may have more than two possible states of failure. Moreover, these states may be qualified by a real value (not only 0 and 1).

For example, during an evacuation phase, 150 individuals have to be evacuated by ERP elements with 200 individuals capacity. With Boolean approach function failure is considered as a binary event. It is so complicated to get partial failure for modeled function evacuation: x% of individuals evacuated, because only two binary states (0: 0 individual evacuated or 1: 150 individuals evacuated) are considered. Another example can be given by an uncompleted coverage of the alert zone. Alert may not be spread in the entire zone which is described in ERP, because of several causes.

To solve these problems, it is proposed in this paper to use Multi-State System (MSS) approach in order to be able to deal with partial degradation of model element. Multi-State System approach has been summarized by Lisnianski & Levitin (2003) and Natvig (2010).

Next section, described the proposed approach to assess Emergency Response Plan by taking into account function partial failures.

2 METHODOLOGY FOR EMERGENCY PLAN ASSESSMENT

What is expected by decision maker is information about mission accomplishment. While previous works were able to only give information of complete functioning or failure, this work propose to give a view for decision maker for a mission to be in more than the two usual binary states $\{0,1\}$.

In this section, it is exposed methodology employed to assess Local Emergency Response Plan leading to give for each planned mission couples of mission states and probability to be at these mission states. First step of the proposed method is to handle complexity of the real world problems using model. Knowing interactions between model elements (resource and function), second step is to characterize resources to take into account in a different way the expression of functioning state. This will allow in a third step to better characterize function states, for example to have more than the two usual functioning or failure state $\{0,1\}$.

2.1 *First step: Handle complexity by using model*

2.1.1 *Concepts*

The first step of the proposed methodology is to handle the complexity of interactions between the elements of the organization in crisis time (Flaus 2010). Each element of the organization can be seen as a resource in the model and missions are expressed as functions.

Modeling method FIS (for Function Interaction Structure) (Flaus 2011) have been used to assess robustness of Industrial Emergency Response Plan using Fault Tree (Karagiannis et al. 2010). This modeling method links systems that realize functions by using resources.

By describing element of the model, it is possible to follow disruption propagation in all systems.

Work has been done on the description of Local-ERP thanks to the FIS modeling method (Girard et al. 2013). A meta-model of LERP has been designed by studying building guide (DDSC 2009) and LERPs from different towns of various size, and exposal risks. Thanks to this meta-model, generic system, functions and resources have been identified to describe a LERP.

This method is used to model LERP but with the current characteristics, it is not enough to assess Emergency Response Plan, because it does not take into account partial failure.

2.1.2 *Example*

Instance of the model is given following the generic model described in Girard et al. (2013) and laid on Function-Interaction-Structure modeling method. It has been chosen to illustrate example on a specific function of model: Evacuate.

Evacuate, is defined to move 150 individuals from A to B. Resources to set up the function are defined as follow:

- R01: 1 evacuation procedure, without any evacuation procedure the function is less performed. A lack of procedure will not lead to the function to be not fully performed. In fact it will be less efficient performed. We consider that an expert reasoning shows that if there is a lack of procedure, function will be complete at 20% whereas 100% if the procedure exists.
- R02: Population informed for evacuation
- R03: Population evacuated
- R04: Staff member
- R05.01: Bus with capacity of 75 individuals
- R05.02: Bus with capacity of 75 individuals
- R05.03: Bus with capacity of 50 individuals
- R06: Gathering point, without any gathering point function is not performed. In fact individuals do not know where buses will pick them up
- R07: Itinerary

Instance can be described by scheme at Figure 1.

This model instance is described with the FIS modeling method. Reader can notice a resource pool (evacuation vehicle: buses), that shows resources having the same goal in the Evacuate function. The buses pool is made up of 3 buses with different characteristic values (capacity). In the following paragraphs P_1 will be also used to describe this resource pool.

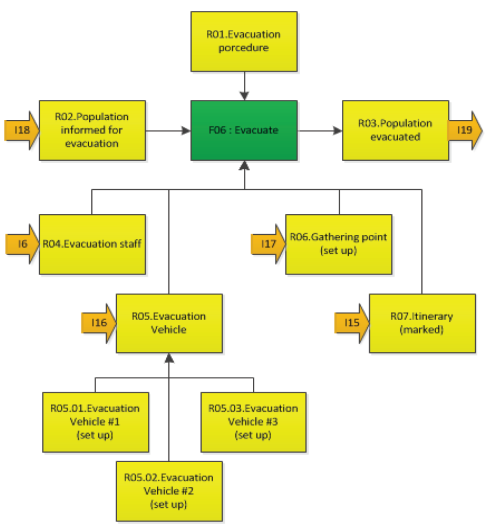

Figure 1. Instance of FIS modeled function evacuation.

Complexity of real world resource interactions can be modeled to handle it. Next step is so to enhance resource characterization to take into account in a different way expression of functioning and failure state to better characterize function states.

2.2 *Second step: Resource characterization*

2.2.1 *Concepts*

Each resource is characterized with two states complete functioning or total failure, but we introduce a different way from previous works to define functioning states. In fact, in this work we are taking into account the function demand.

We propose to give a different value regarding function demand for resource. A resource is so characterized by two state values: total failure performance (l) and complete functioning performance (m) defined regarding a function demand written W. "m" denotes the maximum service the resource can accomplish regarding function demand and "l" the minimum service.

Definition 1:

For all resource j, it exists two states corresponding to the state $g_{j,i}$ where i is state number $i \in \{1,2\}$ (Lisnianski & Levitin 2003, Natvig 2010).

$$g_i = \{g_{j,1}, g_{j,2}\} \tag{1}$$

with $g_{j,1} = l$ and $g_{j,2} = m$.

Then using previous works (Karagiannis et al. 2010), it is possible through resource taxonomy to generate failure modes and Fault-Tree structure as degradation assessment approach developed for industrial Emergency Response Plan. Fault-Tree is used to obtain probability of total failure state. Probability to be at this failure state is obtained via questionnaires developed in these previous works giving elementary events probabilities and via probabilities computation through the tree structure. By opposition since it is possible to access to total failure probability, it is possible to have an access to functioning probability.

Generic failure modes that composed Fault-Tree have been identified for LERP in Girard et al. (2013).

Definition 2:

Probability to be at state $g_{j,i}$ at instant t is given by the set (Lisnianski & Levitin 2003, Natvig 2010).

$$p_j(t) = \{p_{j,1}(t), p_{j,1}(t)\}$$

where

$$p_{j,i} = \Pr\{G_j(t) = g_{j,i}\} \tag{2}$$

At this step for each resource and each of their participation to function, it is defined values "*l*" and "*m*" of complete dysfunctioning and functioning states and the probability to be in these states.

2.2.2 *Example*
State values for each states are:

– *l* if element is in total failure
– *m* if element is fully working

An example for resource in buses pool can be illustrated as follow:

$$m = \frac{Capa_i}{W} \tag{3}$$

with
$Capa_i$ Capacity of element i and W the function demand

$Capa_1 = Capa_2 = 75$ and $Capa_3 = 50$
W = 200

Results for example are given in Table 1. Because of the chosen instance, R02, R03 R06 and R07 are defined in $\{0,1\}$ whereas R05 resources in resource pool P_1 are in $\{0,m\}$. R01 (the evacuation procedure) is coded in $\{l,1\}=\{0.2,1\}$ since experts judge that 20% of the mission is realized if R01 is missing.

In the following example, it will be used the next probability:

$p_{R01,1} = 0.3$, $p_{R01,2} = 0.7$

$p_{R05.01,1} = 0.2$, $p_{R05.01,2} = 0.8$

$p_{R05.02,1} = 0.2$, $p_{R05.02,2} = 0.8$

$p_{R05.03,1} = 0.3$, $p_{R05.03,2} = 0.7$

$p_{R04,1} = 0.05$, $p_{R04,2} = 0.95$

$p_{R06,1} = 0.2$, $p_{R06,2} = 0.8$

$p_{R07,1} = 0.15$, $p_{R07,2} = 0.85$

Table 1. List of state values by resource ID.

Resource ID	State values
R01	{0.2,1}
R02	{0,1}
R03	{0,1}
R04	{0,1}
R05.01	{0,0.50}
R05.02	{0,0.50}
R05.03	{0,0.33}
R06	{0,1}
R07	{0,1}

In this subsection it has been described characterization changes of resources from states defined in $\{0,1\}$ to state defined in $\{l,m\}$. Probability to be at each state can be obtained from Fault-Tree for state value "*l*" and "*m*". The third step is to deduce function states from the resource analysis, with more than the two usual binary states.

2.3 *Third step: Function characterization*

2.3.1 *Concepts*
For each function, participating resources' states $\{l,m\}$ are combined to give possible function states.

For the modeled function, it exists a mathematical function to compute the states and probability to be at each state, this is relative to Multi-State System theory (Lisnianski & Levitin 2003). A node characterized by its mathematical function models resource assembly to complete modeled function. As in Fault-Tree, nodes like AND, OR and K/N can be expressed, as well as more specific nodes, directly related to a function.

Definition 3:

$$G(t)=\phi(G_1(t),G_2(t),\ldots,G_n(t)) \tag{4}$$

The output $G(t)$ characterizes the state of the function in time t. In this paper we considered G functions as constant in time. ϕ characterizes the computation function for a given node.

2.3.2 *Example*
With the instance described in the previous section, we propose for the "Evacuate" function an initial event graph of Multi-State propagation in Figure 2.

Behavior at node 1 and 2 for the function "Evacuate" will be described in paragraphs below.

Mathematical computation functions for each node (1 and 2) are respectively described in Table 2 and Table 3.

At node 1, states of all resources used in resource pool P_1 are assessed. Evacuation vehicle #1, #2 and #3 are indexed respectively by *b1,b2,b3*. States are so given by the function ϕ_1. Node 1 models that each evacuation vehicles (buses) of pool P_1 participates to the evacuation function as evacuation means.

$$\begin{aligned} G_{p1}(t) &= \phi_1(G_{b1}(t),G_{b2}(t),G_{b3}(t)) \\ &= G_{b1}(t) + G_{b2}(t) + G_{b3}(t) \end{aligned} \tag{5}$$

states for P_1 are defined as:

$$G_{p1}(t) = \{0.00,0.33,0.50,0.83,1.00,1.33\} \tag{6}$$

At node 2, all resources used in the function Evacuate are assessed. All resources previously

…	…	…	…	…	…
1.00	1.00	1.00	1.00	0.00	0.00
1.00	1.00	1.00	1.00	0.33	0.33
1.00	1.00	1.00	1.00	0.50	0.50
1.00	1.00	1.00	1.00	0.83	0.83
1.00	1.00	1.00	1.00	1.00	1.00
1.00	1.00	1.00	1.00	1.33	1.33

un-described by node 1 (evacuation staff, gathering point, itinerary) except evacuation procedure, are characterized by binary sates $G_i(t) = \{0.00,1.00\}$, for $i = 1,3,4$. From the modeled instance $G_2(t) = \{0.20,1.00\}$. Evacuation staff, evacuation procedure, gathering point, itinerary are indexed respectively by *1,2,3,4*. Node 2 models the entire interaction for evacuation resources to the evacuation function.

This mean that all elements are necessary for function success, ϕ_2 is defined as follows:

$$G(t) = \phi_2(G_1(t), G_2(t), G_3(t), G_4(t), G_{P1}(t)) = G_1(t) \times G_2(t) \times G_3(t) \times G_4(t) \times G_{P1}(t) \quad (7)$$

This node is characterized by a product mathematical function. Indeed as all resources are necessary for the modeled function to be realized, it is represented as AND-gate. Concretely, if we take the evacuation procedure, it gives a kind of completion percentage in terms of number of evacuees. Buses combine this with an evacuation capacity. Other resources are viewed as switches. If the gathering point, or itinerary, or evacuation staff are unavailable, the function can not be realized.

Table 3 shows all possible performance states for the presented function. Intermediate values give the result $G(t)=0.00$.

Thus, with all combinations of performance states it is possible to access to all functional performance state in which the modeled function (in this case "Evacuation") could be.

Even if resource are defined by binary states, it is considered not only $\{0,1\}$ as state values but $\{l,m\}$. In this way function can be characterized by multi-state. In this case, if we refer to the Multi-State System theory, LERP are now considering as non-homogenous MSS with binary elements. It

allows having more information at function state for decision makers. They will better know with the developed approach the functions of their Emergency Response Plan.

As it has been written before, it is possible through model and thanks to Fault-Tree pattern to access to the probability of total failure state of a resource and in opposition to get the probability of its complete functioning state. Because goal of this paper is to present assessment method, it is used arbitrary probability values for each resource state, instead of probability coming from Fault-Tree Assessment and questionnaire. The computation rules are extracted again from Multi-State System theory.

By using the table of states for pool P_1 combined with probability in section 2.2.2, Table 4 can be filled.

Probability of each element in a row is multiplied. This is corresponding in a Fault-Tree to an And-gate. For each identical output state coming from different associations of element performance states, probability is summed. This is corresponding in a Fault-Tree to an Or-gate.

For each state of P_1, probabilities are:

$$G_{P1,1} = 0.00,\ p_{P1,1} = 0.01$$
$$G_{P1,2} = 0.33,\ p_{P1,2} = 0.05$$
$$G_{P1,3} = 0.50,\ p_{P1,3} = 0.08$$
$$G_{P1,4} = 0.83,\ p_{P1,4} = 0.30$$
$$G_{P1,5} = 1.00,\ p_{P1,5} = 0.11$$
$$G_{P1,6} = 1.33,\ p_{P1,6} = 0.45$$

A bar chart of probabilities repartition for each state is given by Figure 3.

With the probabilities given in section 2.2.2 and the previous probability computation result, probabilities at node 2 are the following:

$$G(t) = 0.00,\ p_{G(t)=0.00} = 0.36$$
$$G(t) = 0.07,\ p_{G(t)=0.07} = 0.01$$

Table 4. States crossing probabilities at node 1.

$G_1(t)\,(p_{1,i})$	$G_2(t)\ (p_{2,i})$	$G_3(t)\ (p_{3,i})$	$G_{P1}(t)\ (p_{P1,i})$
0.00 (0.2)	0.00 (0.2)	0.00 (0.3)	0.00 (0.01)
0.00 (0.2)	0.00 (0.2)	0.33 (0.7)	0.33 (0.05)
0.00 (0.2)	0.50 (0.8)	0.00 (0.3)	0.50 (0.03)
0.00 (0.2)	0.50 (0.8)	0.33 (0.7)	0.83 (0.11)
0.50 (0.8)	0.00 (0.2)	0.00 (0.3)	0.50 (0.05)
0.50 (0.8)	0.00 (0.2)	0.33 (0.7)	0.83 (0.19)
0.50 (0.8)	0.50 (0.8)	0.00 (0.3)	1.00 (0.11)
0.50 (0.8)	0.50 (0.8)	0.33 (0.7)	1.33 (0.45)

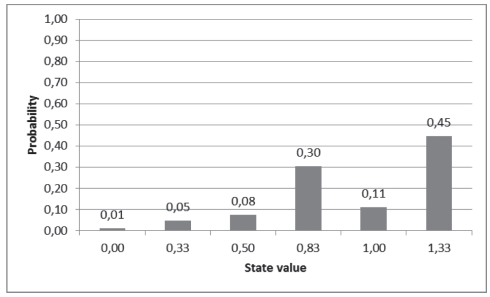

Figure 3. Probabilities of performance rates at node 1.

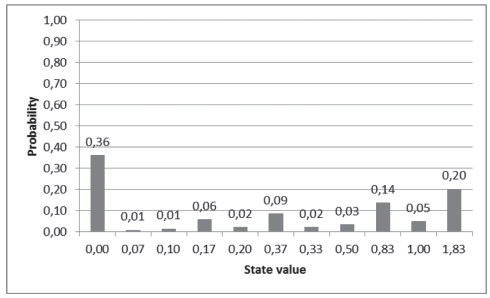

Figure 4. Probabilities of performance rates at node 2.

$$G(t) = 0.10,\ p_{G(t)=0.10} = 0.01$$
$$G(t) = 0.17,\ p_{G(t)=0.17} = 0.06$$
$$G(t) = 0.20,\ p_{G(t)=0.20} = 0.02$$
$$G(t) = 0.33,\ p_{G(t)=0.33} = 0.02$$
$$G(t) = 0.37,\ p_{G(t)=0.37} = 0.09$$
$$G(t) = 0.50,\ p_{G(t)=0.50} = 0.03$$
$$G(t) = 0.83,\ p_{G(t)=0.83} = 0.14$$
$$G(t) = 1.00,\ p_{G(t)=1.00} = 0.05$$
$$G(t) = 1.33,\ p_{G(t)=1.33} = 0.20$$

A bar chart of probabilities repartition for each state is given in Figure 4.

In the end we can better described function with a range of state it can take and a probability to be at each state described. For example, it can be considered state where more than 80% of population can be evacuated. In the instance described in this paper the probability to obtain this performance is 39%.

3 CONCLUSION

In this paper it has been presented how to use Multi-State System (MSS) with Function-

Interaction-Structure (FIS) modeling Method to assess Local Emergency Response Plan (LERP).

Because commonly failure modes are seen as binary events, it is not enough to assess LERP. Multi-State System approach has been chosen to deal with partial failures of LERP.

Thanks to previous work, we laid on a generic model of LERP to assess and propose propagation mechanisms of Multi-State through a model. Laying on a generic model will allow having a quick access to homogenous resource information.

Performance assessment (via MSS approach) makes possible to determine performance (G) of a function regarding demand (W). With probability assessment (and Fault-Tree patterns obtained with generic model), the probability to be at total failure state can be given and so the probability to be in the opposite state for a resource. But instead of considering state in $\{0,1\}$, we consider in $\{l,m\}$, enabling more relevant analysis of resource participation. As for example being capable of analyzing partial function realization even with a complete dysfunctioning resource, analyzing over performance in case of redundant resources and partial execution evaluation.

This is a new result because even if we considered binary state for resources, at modeled function level we are now considering Multi-State.

By using the model-based proposed performance propagation event graph, it is easy to follow performance propagation in a LERP model.

Further work can be done by implementing the proposed approach in a software which already implement FIS formalism for risk assessment. The proposed approach could be implemented to help building and computing all state relations at node. Another perspective can be to consider more than only two binary states for being more precise in modeling and considering a homogenous (or non) MSS with multi-state elements. This model integrating Multi-State system could also be used to simulate LERP performance behaviors.

ACKNOWLEDGMENT

This works received a founding from the Région Rhône-Alpes (FRANCE).

The model of a pilot competency as a factor influencing the safety of air traffic

J. Skorupski
Faculty of Transport, Warsaw University of Technology, Warsaw, Poland

M. Wiktorowski
33rd Polish Air Force Base, Poland

ABSTRACT: The level of safety in air transport is affected by many factors: the widely understood human factor, technical factor and environmental factor. The aim of the research is to develop indicators for quantitative assessment of the flight crew status in the context of its impact on the safety of air traffic. The paper presents a new definition of a flight crew status of a formal nature. The proposed approach takes into account functional dependencies between the various factors influencing the air crew status. These dependencies are hardly definable and partly subjective, so the research concerning them belongs to the area of uncertain information analysis. We propose to use fuzzy inference methods using expert knowledge for this analysis. The paper gives a detailed description of the new fuzzy local model of a pilot competence, which is expressed by the linguistic variable values. They are influenced by the pilot's experience, training process and the Crew Resource Management (CRM). A fuzzy inference system corresponding with the model was built. Some examples of membership functions of linguistic variables and sample fuzzy inference rules are presented in the paper. This system was used for the model experiments, which led to the interesting results. These include finding the relationships between the experience of the pilot, the various elements of the pilot training process and the flight crew status. The obtained results allow, among others, to optimize the process of flight crew selection to specific tasks, and to optimize the process of a pilot training.

1 HUMAN FACTOR IN THE AIR TRAFFIC MANAGEMENT SYSTEM

The very important problem in the Air Traffic Management (ATM) is to maintain the control subsystem's ability to interact with the controlled objects in order to achieve the intended objectives. The efficiency of this interaction is affected by many factors like suitable communication or surveillance systems reliability. As well the control subsystem as the controlled objects (aircraft) are strongly human-related and in this paper particular attention will be given to a flight crew as the human component of the air traffic. The crew's ability to proceed with basic tasks of managing flight as aircraft control and positive two-way communication process with air traffic controllers is one of crucial factors determining the main goal—maintaining the flight safety at assumed level. This ability is to a great extent dependent on a crew selection or, saying more widely, on a crew resource management at the air carrier's level. This paper presents the method of flight crew status assessment, particularly the crew competency as one of the most important elements.

Problems concerning human factor's role in the air traffic safety are the point of interest of scientists of different domains. The paper (Afrazeh & Bartsch 2007) presents human reliability as the human ability to perform the task in given frames, covering all the physical and psychological skills, experience and personal characteristics. The other one (Dekker 2006) states that the whole human performance of people taking part in aviation transportation process is located in a specific context that consists of the aircraft and its equipment type, weather, air traffic and other Performance Shaping Factors—PSF. They were incorporated in (Swain & Guttman 1983) as the set of factors affecting human capabilities. They are divided to internal ones—like stress, fatigue, knowledge, personality, experience, and external ones—such as ergonomics, educational programs, organizational structure, motivation and procedures (Pei-Hui 2011).

According to system approach to air traffic safety problem, the human factor is placed in the center of interest. However, the other important factors that influence the operational risk in

direct or indirect manner are not omitted. There are two most popular system models of human factor in the air traffic safety. One of them is the SHELL model (Edwards 1972; Hawkins 1993) and the second one—the Reason's model (1990). The first model describes the threats connected with interface between human and environment, software, hardware and other human. The second one presents dependencies among different areas of operations which can include different safety gaps.

The attempt to analyze flight crews and air traffic controllers using fuzzy sets theory was introduced in (Lower et al. 2013). The likelihood of an incident to accident transformation was analyzed assuming adverse human operation.

The literature analysis shows the most common way to divide human factors to four groups: physical, physiological, psychological and external conditions. Physical factors can be expressed in the form of health, growth and strength. The physiological ones include the access to oxygen, changes in pressure, perception capabilities, disorientation, fatigue, biorhythm disturbances, diet and alcohol effects. The psychological factors are: information processing and selection, error management, personality, self-discipline, motivation, operation under pressure, situational awareness, perception, safety awareness, threat identification, decision making and judgment of situation, attention distribution, coping with stress, interpersonal communication, leadership, adaptation capabilities, training, skills and experience. Finally the external conditions consist of workload and task demand, also the all meanings of culture (connected with profession, organization and safety) are included.

The literature mentioned above however, doesn't try to assess quantitatively the one given flight crew status in the context of the actual flight safety. In (Skorupski & Wiktorowski 2013) a proposal of the mathematical fuzzy inference model with the quantitative crew status assessment as the result is introduced. The estimation is expressed by linguistic variable value where the way leading to the final result takes into consideration many of the essential factors connected with crew's before flight preparation. The calculations consider also the operational and organizational environment influence. The model can become the base for creation of a decision support system that could be useful for people responsible for crew management process.

This paper is the extension of our previous work. It shows how the very important parameter—pilot's training—affects pilot's competency. It also shows how this relationship can be assessed quantitatively with the use of fuzzy sets theory.

The paper is organized as follows. In section 1 a short literature review on human factors in ATM is presented. Section 2 contains the short introduction to air carrier tasks connected with the crew resource management. In section 3 the literature review and general idea of fuzzy inference system for air crew status assessment is given. Section 4 presents one of the most important elements of this system—the local model, where the linguistic variable *Competency* is introduced. Then, in section 5 detailed description of training (represented by linguistic variable *Training*) as the very important part of competency model is given. Section 6 presents and discusses some experiments' results, that can be useful in everyday aircrew management. In section 7 a summary and concluding remarks are presented.

2 AIRLINE OPERATORS' TASKS IN THE AREA OF CREW RESOURCE MANAGEMENT

According to The Annex 6 of Chicago convention, the Safety Management System (SMS) was introduced. This triggered the situation where the airline operators are obliged to manage the safety, covering their all activities including every single flight. First of all, SMS deals with threat identification, ineligible events effects mitigation and risk estimation. The goals listed above can be assisted by the proposed model of the flight crew status in the context of safety. The risk connected with conducting the whole process of flight by the given crew will be easier to estimate in objective and quantitative way. The research of some flight operators (airlines) functioning in the area of SMS was presented in (Pei-Hui 2011). It was to be said that the idea of SMS was realized only partly, therefore some changes at the operational level are to be made. The model and the fuzzy inference system for the flight crew assessment, presented in the following sections, are going to work at the same level. Nowadays the risk management cards are widely used for the operational risk assessment, but they are not sufficient. The discussed model application can possibly extend the risk assessment idea by the whole human factor problem consideration. The flight crew assessment based on the presented method may improve crew resource management and planning process and in result will make the operators able to maintain high level of operational readiness especially in the area of crew availability.

3 THE FUZZY MODEL OF THE FLIGHT CREW STATUS ASSESSMENT IN THE CONTEXT OF AIR TRAFFIC SAFETY

The problem of the flight crew status estimation in the context of proper flight task realization

concerns the human factor that is hard to analyze in exact manner. That's why the problem is located in the area where the information is imprecise and uncertain. Therefore the fuzzy logic approach is used in this elaboration.

There are many papers that suggest the usage of the fuzzy logic methods and tools in the area of air traffic management. One of the most interesting (Hadjimichael 2009) describes the expert system that was created to assist the take-off and landing risk assessment. The human factor was taken into consideration however the problem was much simplified. The problem of flight crews duty hours planning was undertaken in the paper (Teodorovic & Lucic 1998). Psychological aspects of pilot's behavior where analyzed in (Wanyan et al. 2011). The research (Xianfeng & Shengguo 2012) includes the attempt of airport security assessment where the human factor was partly taken under consideration. The other examples of fuzzy methods utilization in the area of air traffic management can be found in (Babic & Krstic 2000) and (Netjasov 2004). The other technology sectors also use the fuzzy methods in risk assessment of key elements damage (Torshizi & Parvisian 2012), as well as human factor influence on reliability of system (Bertolini 2007).

In this research we are concentrated on hierarchic fuzzy structure creation considering any possible factors which can influence the crew (not single pilot) ability to perform the flight. We try to consider all the physical, physiological, psychological factors as well as the external conditions. The created model that is still being developed as well as its computer implementation in SciLab can be used to support the decision making process in crew selection.

The fuzzy set A we define as follows (Kacprzyk, 1986):

$$A = \left\{ \left(x, \mu_A(x) \right) : x \in X, \mu_A(x) \in [0,1] \right\} \tag{1}$$

where μ_A is the membership function of this set.

As a linguistic variable we define the variable which is expressed by words or sentences that we call linguistic values of linguistic variable. Our models assume that linguistic variables have *low, average* and *high* values.

The trapezoidal membership function for *low* value with trapezoidal shape and parameters (a,b,c,d) is defined as follows:

$$\mu_{low}(x;a,b,c,d) = \begin{cases} 0, & x < a = b \\ 1, & b \le x \le c \\ \dfrac{d-x}{d-c}, & c < x \le d \\ 0, & x > d \end{cases} \tag{2}$$

For value *average*:

$$\mu_{avg}(x;a,b,c,d) = \begin{cases} 0, & x \le a \\ \dfrac{x-a}{b-a}, & a < x \le b \\ 1, & b < x \le c \\ \dfrac{d-x}{d-c}, & c < x \le d \\ 0, & x > d \end{cases} \tag{3}$$

For *high* value:

$$\mu_{hgh}(x;a,b,c,d) = \begin{cases} 0, & x \le a \\ \dfrac{x-a}{b-a}, & a < x \le b \\ 1, & b < x \le c \\ 0, & x > c = d \end{cases} \tag{4}$$

In the reasoning process we use the input values fuzzification block, then inference block that uses a set of fuzzy rules, and finally defuzzification block of output values. The set of rules is being created with experts' opinions, in this case aircraft pilots and people responsible for Safety Management System (SMS) organization. As a inference rule for local models we will use the fuzzy rule *modus ponens*, as below (Kacprzyk 1986):

$$\begin{aligned} &I : x = A \Rightarrow y = B \\ &P : x = A' \\ &C : y = B' \end{aligned} \tag{5}$$

where I denotes implication, P—premise, C—conclusion. This rule gives us opportunity to conclude about the successor based on the predecessor logical value. The implication is treated as a fuzzy relation which means that A' doesn't have to be equal to A and B' doesn't have to be equal to B. It's fairly enough when A' is similar to A and this way B' is similar to B.

In the fuzzy inference systems the parameters listed below were chosen for determination of linguistic variable values concerning *CRM, Training* and *Experience*

– s-norm of maximum type:

$$\mu_{A \cup B}(x) = \max\left(\mu_A(x), \mu_B(x) \right) \tag{6}$$

– t-norm of minimum type:

$$\mu_{A \cap B}(x) = \min\left(\mu_A(x), \mu_B(x) \right) \tag{7}$$

– implication of algebraic product type:

$$\mu_{A \to B}(x,y) = \mu_A(x) \cdot \mu_B(y) \tag{8}$$

– rules aggregation of algebraic sum type:

$$\mu_{A\oplus B}(x) = \mu_A(x) + \mu_B(x) - \mu_A(x)\cdot\mu_B(x) \quad (9)$$

– defuzzification of center of gravity type:

$$Z^* = \frac{\int \mu_B(z)\cdot z dz}{\int \mu_B(z) dz} \quad (10)$$

The literature shows many different factors that influence human activity but only the most effective ones on flight crew performance were chosen for the analyses. We can point out three the most important factors describing the flight crew status. The first of them is competency (which among the others covers skills, experience and knowledge), the second one is situational awareness (that is determined mainly by communication and information processing) and the last one—motivation—the psychological side of performance (especially shows the difference between the actual results of activity and the theoretical abilities). The Figure 1 presents dependence scheme of the factors listed above.

The lack of situational awareness is one of the most important reasons of aviation negative events: incidents, serious incidents and accidents. The awareness is dependent on quality of information processing and communication, where the last one is strongly connected with competency and motivation. Information processing is dependent on fatigue and competency as well. As we can see the connections and dependencies are strongly complicated. This fact causes difficulties in the research and makes us to use expert estimated data, which are subjective and imprecise. Also that was the reason to use the fuzzy method in the research (Zadeh & Kacprzyk 1992).

The model of relations showed at Figure 1 determines the structure of local models. The every rectangle at this figure symbolizes the linguistic variable which is the output of a local fuzzy model with many inputs. The example of local models for *Competency* estimation will be shown in Chapter 4.

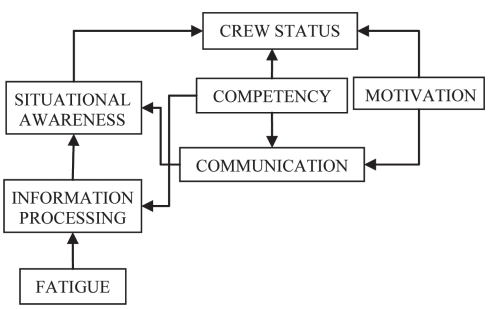

Figure 1. The general fuzzy model of factors that have influence on flight crew status.

4 THE FLIGHT CREW STATUS ASSESSMENT METHOD—LOCAL MODEL COMPETENCY

In this section we will concentrate on the local model destined to estimate the linguistic variable *Competency* which is the key factor for crew status assessment. That's because the *Competency* influence the linguistic variable of crew status directly and indirectly through the inputs to *Communication* and *Situational awareness* as well. Contributory factors of aviation events analysis indicate the last two factors are frequently direct reasons of flight incidents or belong to the circumstances that are conducive to negative events.

The linguistic variable *Competency* is determined by three input variables (Fig. 2): *Training, Experience* and *CRM* (Crew Resource Management), assumed as the ability of the crew to cooperation. We assumed the variable *Competency* will accept three values: *low, average* and *high*.

The three input variables influence the *Competency* in different manner. We assume the *Experience* has the highest weight because it mirrors crew flight capabilities with reference to their performance on current and the previous types of aircraft as well. The variables *Training* and *CRM* affect the *Competency* with the information about the so-called pilots currencies (length of breaks in flying) and important trainings participation which are

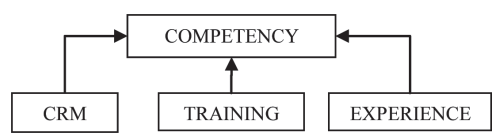

Figure 2. The local model *Competency*.

Table 1. The example of some fuzzy reasoning rules for *Competency*.

Rule	*CRM*	*Training*	*Experience*	*Competency*
10	*Average*	*High*	*Low*	*Low*

14	*Average*	*Average*	*Average*	*Average*
17	*Average*	*High*	*Average*	*Average*
18	*Average*	*High*	*High*	*High*
24	*High*	*Average*	*High*	*High*

especially key factors for young pilots. For more experienced pilots trainings and in-flight or simulator checks secure the safety from routine and conviction about their excellence that can become dangerous.

The Table 1 presents several fuzzy reasoning rules used in the fuzzy inference system for determining the *Competency.*

5 THE METHOD UTILIZATION EXAMPLE—TRAINING ASSESSMENT IN THE CONTEXT OF HIGH LEVEL OF CREW COMPETENCY

Between the others, the linguistic variable *Training* characterizes a member of flight crew in the area of currency in flying, and also accepts three linguistic values: *low, average* and *high*. One of the determinants can be the time that has passed since the last flight. The other one is the time (in months) since the last simulator training which is valuable index in relation to crew capabilities to cope with flight emergencies. Usually once a year every pilot is subjected to pass the checkride (an examination during flight) which causes the need to update and refresh his knowledge and this way improves his general professional performance in routine flights. That's why we can accept the time since the last checkride as the next *Training* determinant.

According to EU-OPS the every airline operator is responsible for implementation of procedures that guarantee their flight crews have all the proper licensees, suitable trainings, experience and are eligible to fulfill all the pilots duties (European Commission, 2008). Generally the every pilot is supposed to complete the aircraft class rating and aircraft type rating. Any change of operator by a pilot, forces him to complete the proper courses and trainings before he/she starts to fly without supervision.

The young pilots after completing suitable tests should execute minimum four flights under supervision in maximum 21 days period and 6 takeoffs and landings on simulator (sometimes the number of the operations can be flexible). The captains should have proper experience and they are obliged to complete aircraft commander training for multicrew operations that consists of:

- simulator training;
- captains airline training;
- captains skills examination;
- airports and en-route knowledge and competency training;
- CRM training.

Pilots should maintain their currencies (not to exceed maximal time between flights). The general rule is minimum 3 takeoffs and landings in the period of 90 days, but the period can be extended up to 120 days in cases pilots fly under supervision. When the break is longer, the compulsory additional flight under supervision or simulator training is required (European Commission, 2008). Not earlier than after 2 years of continuous flight operations, the periods of time listed above can be changed by the proper aviation authorities. In such cases ATQP (alternative training and qualification programme) and LOE (line oriented evaluation) allow the time spaces between checkrides to be extended to 12 months, and between emergency management checks-up to 24 months.

According to the previous assumptions and with respect to the flight crews operational rules we chose the input variables for linguistic variable *Training*:

- The period of time since the last flight: the *Pause* linguistic variable accepts three fuzzy values *low, average* and *high.* It's defined on the universe of discourse equal to the real numbers from the interval [0,90] days.
- The period of time since the last simulator training: the *Simulator* linguistic variable accepts three fuzzy values *low, average* and *high*. It's defined on the universe of discourse equal to the real numbers from the interval [0,12] months.
- The period of time since the last checkride in flight: the *Checkride* linguistic variable accepts three fuzzy values *low, average* and *high*. It's defined on the universe of discourse equal to the real numbers from the interval [0,24] months.

The Figure 3 shows the example of *Training* fuzzy model using the three listed above fuzzy variables as inputs. The Table 2 presents the trapezoidal membership functions parameters (a,b,c,d) of input variables while the trapezoidal membership functions parameters of output variable are shown in Table 3.

The factors listed above are searched for the importance and weigh that they have on *Training* and the results were taken into consideration in fuzzy reasoning rules creation. We assume the *Pause* is the most important. Pilots have to rely on their knowledge and experience and also they have to take care of the learnt good skills and habits. The longer the time since the last flight the faster proper skills and habits are forgotten. Less important are *Simulator* and *Checkride* while still they influence the output variable value. Some of the fuzzy reasoning rules are shown in Table 4. They were defined on the basis of expert evaluations. The group of experts consisted of pilots, safety managers and persons responsible for investigating the causes of air accidents.

6 THE RESULTS DISCUSSION

The example results of fuzzy inference system simulation for linguistic variable *Training* estimation, obtained with a computational tool created in SciLab 5.4 environment are shown on Figure 4.

In the case of *Training* and *Simulator* relationship (Fig. 4a) we can see in the results that the pilots with relatively short break from the last flights (up to 20 days) may extend the time between simulator trainings up to 6–7 months. The more frequent simulator trainings don't improve the *Training* value, which equals to 4.3 (the *high* linguistic value). For pilots with longer break from last flight (40 days and more) the simulator trainings should be organized more often (after about 3 months). The longer break results with the drop of *Training* value even to 0.8 (the *low* linguistic value). The observation is similar to intuitional approach but the model results give us quantitative assessment. The above experiment result can be treated as the element of the model validation process.

On the other hand the *Training* and *Checkride* relationship analyses (Fig. 4b) reveal a little amazing results. The simulation experiments results show, the *Checkride* in most cases doesn't influence the *Training* at all. This concerns the cases when the break from the last simulator training is longer than 1.5 month for any value of break in flights practicing. The only case (showed on Fig. 4b) the *Checkride* influence on the *Training* value, exists when a pilot has long break in flying (60 days or more) and the time from the last simulator training is shorter than 1 month. Then the checkride makes sense, but only if the break from the last one is more than 18 months. The observation is interesting because it indicates the checkride every 6 or 12 months (as requested by the regulations) may be needless because it doesn't improve the *Training* variable. In case the check-rides are to be continued they should be scheduled maximum every

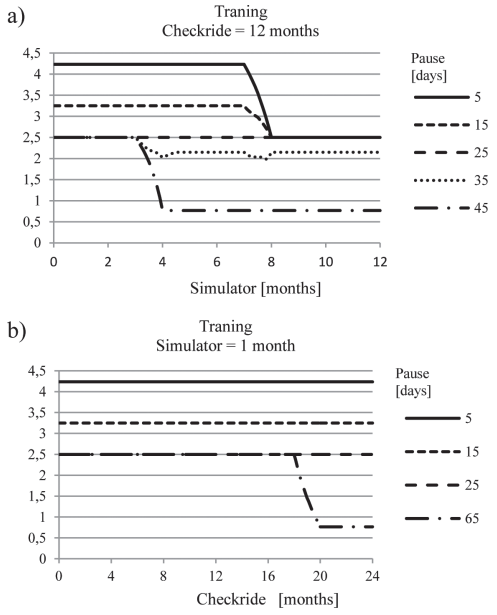

Figure 4. *Training* correlation with: a) *Simulator,* b) *Checkride.*

16–17 months. However further verification of the model, system and the results should be continued.

7 SUMMARY

The flight operators crew resources management is one of the most important factors that influence the air transport safety. The proper crew selection process is one of the key elements. The crew should have optimal performance that among the others mirrors their competency, motivation, communication skills or situational awareness. Those features are not constant and depend on many different factors such as current crew predisposition to perform the safe flight. The crew selection and assessment process in the context of flight safety is significantly difficult due to the imprecise, uncertain and incomplete information. In such a case the expert systems based on the fuzzy sets theory can become the meaningful and helpful assistance. The presented example of the fuzzy inference system assures the possibility of the presented approach utilization in flight operator assistance by crew reliability improvement.

Human Dependability Model for space application—the HuDeM project

T.M. Stene
NTNU Social Research, Trondheim, Norway

S.O. Johnsen
SINTEF, Trondheim, Norway

S. Ophof
ARGOTEC, Turin, Italy

ABSTRACT: This paper will present the HuDeM (Human Dependability Model) project financed by the European Space Agency (ESA). The project has focused on developing a Human Dependability Model to be applicable for space activities and projects. The project is based on relevant perspectives from other industries like aviation, petroleum, nuclear and railways. Human Dependability is described as the contribution of the human in a space system to safety and reliability, a subject to reduce the incidence of human error and minimize its effects. Existing literature suggests that there is a trend towards an understanding and acknowledgement of the importance of humans in accidents and recoveries. In addition to propose a Human Dependability Model, the project validated the implementation of one proposed method. The initial validation is based on a case study. The validation method focuses primarily on the use of scenarios and checklists. This paper will outline and discuss some experiences and key challenges.

1 INTRODUCTION

1.1 *Developing a human dependability model for space activities and projects*

In 2012 ESA initiated a one year project to review human dependability and identify relevant practices from other industries.

In general, the project is related to space control centres, integration facilities, and launch bases. Such technical infrastructures are all operated by human, and may constitute:

- Flight Segments: Manned Space Station and/or Modules; Satellite/Spacecraft etc.
- Ground Segments: Control or Test Centre; Launch Base etc.
- Recovery segments: Ground Vehicles; Ground Teams etc.

Even if the focus primarily is on activities and projects related to control centres human operated system in general are relevant.

1.2 *The consortium*

In defining a human error avoidance program, the Consortium constitutes three partners: NTNU Social Research, SINTEF and ARGOTEC. The former has been project manager and prime contractor.

NTNU Social Research has eight units, and the two involved in this project are CIRiS and Studio Apertura. CIRiS contribute, through the N-USOC (Norwegian User Support and Operations Centre), on a daily basis to support and operate research facilities and experiments on-board the International Space Station (ISS). The N-USOC is an important contributor during planning, development, integration and execution of the different experiments that utilizes the ESA Columbus laboratory on-board ISS. In addition to safety research in the petroleum sector, Studio Apertura has experience from sectors like transport and critical infrastructures. Many of the projects are of a cross-disciplinary character, often focusing on the interplay between formal and informal elements of organizations.

SINTEF is the largest independent research organization in Scandinavia. The research covers a diversity of domains; petroleum and energy, health, information and communications technology, marine activities, materials science and applied chemistry, technology management and building/construction. The Safety and Reliability department has expert knowledge in risk and reliability, having several publications in the field of human reliability, human errors, risk indicators, risk control methods and systems engineering.

ARGOTEC has experience from space operations through development of software displays, implementation of crew training as well as training and simulations for flight controllers, the company has identified and adopted processes and principles which contribute to the mitigation of human errors. In particular, the validation of the proposed methodology is based on experiences in the space domain.

1.3 *Key questions*

Although we have presented some background information for selecting one particular method applicable to space, this paper primarily describes the "initial validation" of the most central method in the HuDeM project.

Thus key questions in this article are:

- What human dependability methods are significant for control centre?
- How to validate a proposed human dependability model for space application?

2 THE HuDeM PROJECT

2.1 *The objective and tasks*

The main objective of the HuDeM project was to define a human dependability model, in addition to develop an analytical methodology and procedural approach for space system applications with emphasis on spacecraft operations and astronaut activities.

The HuDeM project covers the following five tasks: (1) Identification, Survey and Evaluation of the Most Meaningful Domains for Deriving a Consistent Human Dependability Model Applicable to Space Projects and Activities, (2) Definition of the Methodology for Development of Human Dependability Model(s), (3) Implementation of the Proposed Methodology, (4) Definition of the Analyses for Human Errors Identification and Avoidance, and (5) Management.

The objective of the tasks was respectively: (1) to investigate current existing practices in the industrial domain which use and apply human dependability approaches to their systems/activities. Literature from the following domains is used; aviation, nuclear power plants, oil/gas and railway. (2) To define a human dependability methodology suitable for space applications. (3) To define a human error avoidance program (methodology), in addition to validate the methodology with an example from ISS payload development, integration and operation (USOC). (4) To define the qualitative and qualitative analyses for human errors identification and avoidance or mitigation. (5) Project management.

2.2 *Experience form several domains*

In the first phase of the project experiences from other high technology industries like aviation, nuclear, marine and petroleum industry. In addition a survey in the space domain was conducted (see Johnsen & Stene, 2014).

Major accidents and mishaps have multiple systemic origins, i.e. origins and causes related to multiple factors such as technology, organisations, human factors and the interplay between them.

2.3 *Theoretical approach*

Human dependability encompasses the risk of human errors, but also the human capacity to perform well, even beyond expectations, and to anticipate and solve problems. Consequently the project addresses both human error and how it can be avoided, as well as how one can depend on humans to create safety in space operations. Thus, the project also includes theories and perspectives from resilience engineering and High Reliability Organizations (HRO).

To understand the ability of humans to perform safely in high technological organizations, it is necessary to study human action in light of technology and the organizational context. Errors do not happen in isolation, and there is a strong relationship between these factors. Consequently, human dependability is seen from a so called Man-Technological-Organisation (MTO) or Human-Organization-Technology (HOT) perspective in the project (Johnsen, Stene & Kongsvik, 2014).

When reviewing experiences from other industries, the development has gone from the perspective of "human errors" to looking at major accidents as having multiple interrelated causes from organisation, technology and human factors. Thus a key finding is the need to establish taxonomy to understand accidents and recoveries based on a causal chain avoiding to blame the human element if the causes were due to organisational or technical issues, as suggested by Dekker (2002).

In aviation, the taxonomy called Human Factors Analysis and Classification System (HFACS) has been established; see Shappell & Wiegmann (2000), to understand accidents based on several factors than mere human error. The HFACS taxonomy are based on the "Swiss Cheese Model" from Reason (1997), looking at accidents as unsafe acts based on preconditions, unsafe conditions and organisational influences, in order to avoid blaming the human element. However, the HFACS method has no exploration of resilience, and should be extended to cover resilient acts, based on preconditions of resilience, resilient conditions and High Reliable Organisational influences.

The HFACS method was initially developed to avoid mishaps in naval aviation, and has later been applied in several other domains similar to the space domain. Hence, it seems well suited to ESA. However, it should be adapted to the space environment. It consists of a comprehensive analysis of previous accidents, also identifying lacks in barriers that are more remote from the incident itself, as management or supervision or organisational causes Thus, taxonomy such as HFACS could be adapted and implemented in order to have an empirical background to implement and work with tools such as Human Reliability Analysis (HRA).

2.4 *Human dependability methods*

The project primarily focuses on control centre activities. The HuDeM project describes several theoretical perspectives and methodological approaches, and goes in depth of one particular human factor based approach—CRIOP—and both task 2 and 3 is dedicated to this.

CRIOP is Human Factors (HF) based method to verify and validate the ability of a human operated system to function reliable and safely during crises and during normal operations. CRIOP has been funded by the research council and it is a freely available method see, Aas et al. (2009), also www.criop.sintef.no. CRIOP is based on HF standards such as ISO 11064—"Ergonomic design of control centres".

CRIOP is performed to avoid accidents, based on risk analysis, and to build and support resilience (i.e. where resilience is considered as the ability to handle surprises and continue operations).

Good practice checklists, discussion in an expert team and exploration of scenarios are central elements. *Check lists* cover seven elements: Organisation and management. Procedures, work descriptions and workload, Competence and training, Communication/distributed situational awareness, Working environment, Layout, and Control and safety systems. The checklists explores key human factors (safety) issues in each area, i.e. when discussing control systems the use of alarms is explored and a question is the existence of an "alarm philosophy", and performance issues of alarm handling such as the acceptable number of alarms pr. hour.

Scenarios are used to highlight unwanted incidents, potential accident or loss of science in a particular project or activity. The scenarios are based on findings from the checklist, discussion with the design team to identify conditions where there are some unease or based on discussing key root causes from known documented accidents. The scenarios with errors and recoveries are modelled by using a simple STEP analysis, where critical steps are identified, selected and discussed in a workgroup meeting constituting *key stakeholders*: experts from management, operators, safety experts, designers and human factors experts. The purpose is to support both "bottom up" and "top-down" processes. Results, i.e. mitigating actions, are prioritized by experts in collaboration—ensuring that key issues are discussed and prioritised by different perspectives.

In addition to CRIOP, task 1 and 4 (see 2.1) of the HuDeM project describe several methods relevant for studying human dependability. In the following we mention relevant qualitative and quantitative methods.

Qualitative methods emphasized are Operational Condition Safety (OCS) and Operational Conditions in Control Room Organisations (OCCO). The OCS method is developed and frequently used in the petroleum industry. It is a counterpart to methods mapping the processing plant's technical safety condition. Five of seven elements constituting the whole OCS method in the petroleum sector, is operationalised to control room settings for space application; called OCCO. Prior to this project, a pilot study had operationalised four elements: Competence, Procedures and documentation, Communication and Management (Fossum et al., 2014). During the HuDeM project, a fifth element was added: Change management. Thus, two elements remain to be operationalised for space application: Work practice and Workload and practical working environment.

Quantitative methods emphasized are HRA methods based on a proposed set of selection criteria. We suggest SPAR-H as a simple and usable method for space. The method is developed for the US Nuclear Research commission. The method is applicable for selected scenarios to evaluate probabilities and areas of great concern for the space domain. SPAR-H accounts for the context associated with Human Failure Events (HFEs) by using Performance Shaping Factors (PSF) (Gertman et al. 2005).

3 VALIDATION OF THE METHODOLOGY

3.1 *Participants*

In addition to the consortium, the SPACE-CRIOP workgroup mainly included participants from one of ESA's control centre. N-USOC (Norwegian User and Operations Centre) is supporting biological experiments on-board ISS.

3.2 *Initial validation*

Validity assessment of the method is based on control centres within ESA and their collaboration

with space flights. The CRIOP method is in accordance with the European Cooperation for Space Standardization (ECSS) regulations.

Phases 0–2 of the CRIOP main phases are covered in the validation: (0) Preparation and organisation, (1) General analysis including checklists, (2) Scenario analysis, (3) Actions and (4) implementation and follow up.

The initial validation focuses primarily on the scenario and checklist methods. In addition to a real incident that occurred during real-time ISS operations, the validation includes a selection of standard checklist items as recommended in the general CRIOP method.

3.3 *Validation criteria*

The initial validation process aims to achieve the same analysis of real world ISS (International Space Station) operations anomalies by using the SPACE-CRIOP method. The CRIOP method should be able to identify weak points related to safety in advance of a real time operation.

In the project, we have used actual anomaly reports to validate the method. If the method is valid for the space domain, the identified weak points should be similar to actual anomalies cases from the real world.

Identified root causes to anomalies were used to find relevant validation cases. The project covers a survey, included in task 1, to identify meaningful anomalies during human spaceflight operations (Johnsen & Stene, 2014). The anomaly reports were related to control centres supporting ISS operations.

One of the registered anomalies was selected as suitable test scenario.

Validation criteria are:

- The *checklist process* was expected to identify similar causes to anomalies as the survey in task 1
- The *scenario process* was expected to identify weak points in line with the actual problems/ root causes according to the specific anomaly report.

4 RESULTS

In addition to results according to the stated validation criteria, this chapter presents experience with the validation process.

4.1 *The validation process*

The CRIOP method developed for the petroleum sector is used as a basis for development of a Human Dependability Model for space.

The purpose was to validate the methodology process and to test the specific results related to the checklists and scenarios. Thus, the project covers the first three of the following steps: (0) Preparation, (1) General analysis, (2) Scenario analysis, (3) Action and (4) Implementation and follow up.

The facilitator, in this case from Argotec, is in charge of the process. The facilitator chairs the meetings, provides all documentation and coordinates the discussion. The facilitator also selects the scenario and makes sure everything is performed within the time-limits.

Preparation and organisation phase: The scenario is briefed and all necessary documentation collected. During a teleconference the most applicable checklist items are selected. The final list included 34 relevant items.

Further, the scenario is briefed and discussed.

General analysis—Checklists: During a one day workshop the selected checklist items are discussed with all participants. Finally a prioritised list of the most important items is created.

Scenario analysis: The second day of the workshop is devoted to two scenario runs. All parties involved in designing the scenario and take a passive role. It is important that the involved people are not familiar with the specifics of the chosen scenario. In order to make a general process validation, the sequence is closed with a final debrief.

4.2 *Scenario selection*

The N-USOC participants in the validation are responsible for a biological payload (EMCS) onboard ISS. For the validation we chose a similar payload in ESA's Columbus laboratory. The German control centres MUSC is responsible for the Biolab payload (see Fig. 1). Both EMCS and Biolab allow biological and bio-medical experiments investigating the effects of e.g. weightlessness on plants.

We wanted to choose a scenario that was not known in advance to the participants, but where we had identified some anomalies and root causes. We chose the Waico experiment using Biolab.

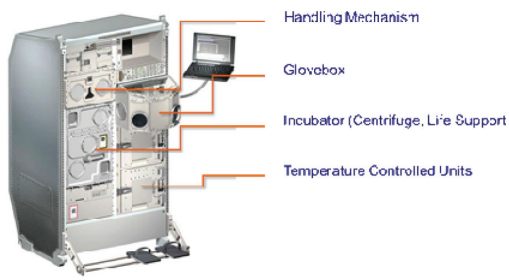

Figure 1. Caption of a typical figure.

Here the effect of gravity on the coiling of the roots was observed. Important information about the experiment set-up:

– Biolab contains two rotors inside its incubator that can simulate different levels of gravity. The Waico experiment required 4 different gravity levels and therefore required 2 separate runs. Each run contains 8 experiment containers on the rotors
– Video is taken every day to follow the growth
– Runs take 10–14 days

There were not enough resources to download all experiment containers to ground in cold stowage. Therefore crew was required to take high definition images to select prime samples.

The anomaly report for this scenario occurred during a rerun of the second Waico run. A rerun was required, because the Biolab handling mechanism failed to supply an Experiment Container (EC) with enough fixative at the end of Waico #1. The anomaly describes a failure from the crew to take pictures of a desirable quality, making it impossible for the scientist on ground to select the prime samples. Investigation following the anomaly showed a lack of crew training with this camera as the prime cause.

Using this scenario has several advantages for the initial validation. Firstly Biolab is very similar to the EMCS payload NUSOC is familiar with from their operations. Therefore, only a high level introduction to the payload and experiment is required to achieve the desired level of knowledge in the participants. Participants can explore the scenario from their own experience, requiring only a minimal amount of role-play. This ensures that the result will be more realistic.

Secondly, the anomaly is easier to include in a scenario. For the scenario we can take one run from start to finish with all the main activities as they were performed. All participants will be already familiar with the details of these activities and the actors involved, even though they have no intimate knowledge of Biolab and the failure.

4.3 *Validation criteria 1: Identification of weak points (relevant items form the checklist)*

An early phase of the CRIOP process is to pick relevant items from the total checklist. In our validation, the checklist items from CRIOP included potential incidents. These items were similar to the root causes identified in the survey.

The walk through of the 34 selected checklist items, in addition to prioritising the items, resulted in the following six most significant issues:

1. Alarm systems
2. No clear responsibility
3. High/Low mental workload

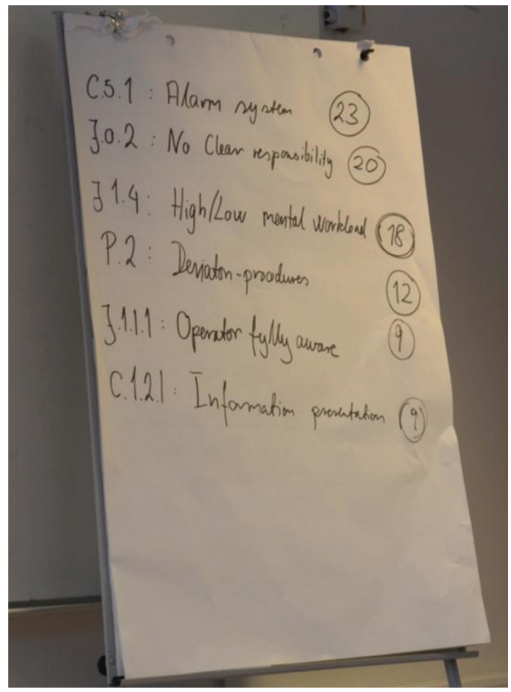

Figure 2. A selection of the flipcharts describing the key issues and their assigned priorities.

4. Deviation from procedures
5. Awareness of responsibilities
6. Information in graphs and telemetry

The list of the most significant issues is very similar to the survey results in task 1. The list of key root related to anomaly causes identified was:

A. Parallel tasks
B. Simple, repetitious tasks
C. Lack of domain knowledge on other systems
D. Long hours
E. Teleconferences on console
F. Lack of team support
G. Procedures

The only item not covered in the survey was the alarms (prioritized issue 1). Thus, the checklist method can be seen as validated. It helps to bring up similar issues that were brought up in an anonymous survey, together with some issues that are unique to the specific control centre.

4.4 *Validation criteria 2: Identification of critical steps in the experiment*

In order to validate the scenario method, the participants should at least identify the training of taking the pictures as a critical item,

since it has a strong impact on the entire Waico experiment.

As a secondary requirement, the participants were expected to indicate issues that were already indicated in the survey.

By going through the steps and actors involved in the scenario, the flow in Figure 3 was created. This was used to identify critical steps in this scenario. The specifications of critical actions should be describes as precise and objective as possible.

For each critical issue the group identified barriers for mitigation of risks. Only issues related to human dependability were considered. Figure 4 show the identified issues. It is worth commenting that the possible issues at step 5 are in accordance with anomalies reported in the Waico experiment.

Figure 3. Complete flow of the Waico scenario.

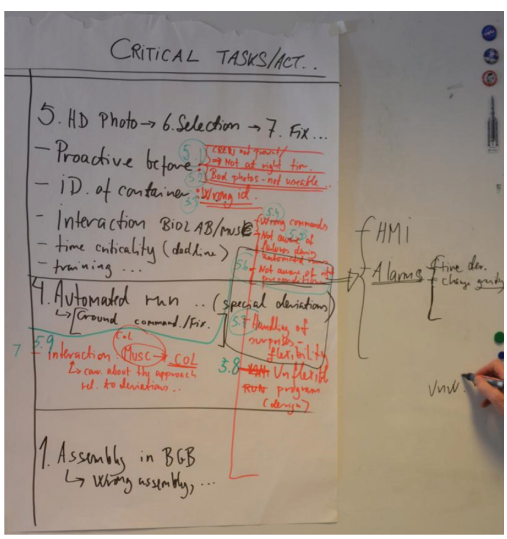

Figure 4. Critical issues identified and analysed.

In this scenario workshop, training was one barrier that should be empathized to cope with this critical step.

It can therefore be assumed that the run of this scenario would have resulted in the same conclusion as the analysis of the anomaly afterwards. This is a strong case for the validity of this method.

Interestingly, the time criticality of the fixation and the stowage afterwards was also identified as a critical issue to be checked. This time criticality is what eventually leads to the requirement of a second Waico experiment, since there was not enough time to recover from the fixation error that occurred in Waico #1.

The results from this study indicate that the method would have possibly mitigated the occurrence of both anomalies. Therefore from this perspective the method is regarded as validated.

5 CONCLUSION

5.1 *Human dependability study*

This paper describes an implementation of the SPACE-CRIOP method from start to finish. The application of the method is originally developed and applied in the petroleum sector. Deviations from the standard are clearly stated. Thus, results from the initial validation can be used as a guide to the practicalities of implementing and facilitating the method.

The project gives a good understanding of how the method may work in space control room settings.

5.2 *Recommendations—theoretical and methodical approach*

In addition to describe common pitfalls, suggestions are gives on how to improve results and implements lessons learned.

Recommendations are given to ensure the applicability of the method for space application. We have suggested that an improvement of human dependability should be based on the following prerequisites:

- Improved understanding of human errors and human recoveries
- Model errors and recoveries through scenario analysis and practice as described in the CRIOP method
- Selection of a HRA method based on a rigorous set of selection criteria—suggesting SPAR-H as a simple and usable method

– Explore the suggested methods in design and operation to support human dependability as a result of improved design and operations, based on best practices in human factors in organisation, technology and humans.

5.3 *Recommendations—process performance*

The preparation is done via telecom in this case, but should be performed in a face-to-face meeting in a normal SPACE-CRIOP process.

The selection of checklist items was very useful, but quite a long process. A longer meeting would help to relieve some of the time pressure.

In addition, it was agreed that a teleconference is not sufficient for a preparation meeting. A meeting face to face would facilitate a less formal feeling, would improve the ability to collaborate on drawings and other inputs, remove problems with sound quality and similar and have an overall positive effect on the quality of the discussions.

However, the item list selected was in the right range of size, the scenarios where selected, the schedule finalized and all questions clarified, so the meeting met its objectives.

Finally, it was clear that a facilitator needs to be familiar with the method, or receive some sort of training, to be able to chair this meeting. Specific domain knowledge of the control center is however not required.

FURTHER WORK

The suggested methods should be used and evaluated, in order to ensure that human dependability is increasing. Further, the methods should be used as early as possible—in design, through engineering; building and operation.

The results from the analysis performed by CRIOP, OCCO and SPAR-H may influence human dependability. We suggest that further work in the space domain perform several pilot projects exploring CRIOP, OCCO and SPAR-H.

Towards safer air traffic: Optimizing ATC controller workload by simulation with reduced set of parameters

B. Számel & G. Szabó
Department of Control for Transportation and Vehicles, Budapest University of Technology and Economics, Hungary

ABSTRACT: The workload of air traffic controllers plays a crucial role in the safety and efficiency of air traffic as it is the prime factor to determine airspace capacity. Workload is the result of traffic complexity which can be described by different sets of parameters. In order to find a small, yet reliable set of complexity parameters that describe controller workload in the Hungarian Air Traffic Control system, a study with multiple steps was conducted and the results are presented in this paper. Information on the most important complexity factors was aquired from experts through interviews and questionnaires and as a result, different sets of parameters were created. To validate the method for gathering information as well as the applicability of complexity factors for airspace capacity estimation, a neural network based model was used. The results indicate that even smaller sets of parameters can be helpful in estimating workload.

1 INTRODUCTION

The safety of air traffic can be defined as the optimal operability (and the probability of maintaining it) of airspace and aerodrome movements under given circumstances. This level of operability is the result of the complex actions of human and technological factors concerned with air transportation. Owing to its complexity, air traffic safety has many different aspects, which led to different approaches in the research area of analyzing and improving it. These approaches may involve the following:

- Mathematical modeling and/or simulation of the movement of aircraft and air traffic flows (e.g. Skorupski (2010) presents a quantitative description for air traffic safety based on the incidence rate of disturbed flights)
- Modeling or simulating automation systems and the behavior of human operators in aircraft or in ATC (Air Traffic Control) (e.g. Inoue et al. (2010) present a model of knowledge in ATC operations, Yemelyanov (2009) introduces a complex method for modeling operator performance and analyzing error)
- Analysis of the effect of design, implementation and maintenance on the reliability of technical system elements
- Analysis of the effect of regulations, training and work environment on the performance of humans in the system (e.g. Martinie et al. (2010) propose an integrated model of the ATC system and operator training)

In our present study, we introduced a functional relationship diagram showing technical and human subsystems affecting air traffic safety at ATC side, then we focused on the human operators in the system of ATC and their impact on the safety (and efficiency) of air traffic. We examined the factors that influence the workload of air traffic controllers working in the Flight Information Region (FIR) of Budapest (BUD) and analyzed how different sets of such factors can be used to predict the optimal number of controllers needed to handle a certain traffic situation.

In Section 2, we provide a brief description of the structure of a general ATC system and the safety analysis techniques related to the system elements focusing on human components. In Section 3, a method is presented for the determination of the set of air traffic complexity parameters to be used for sector capacity estimation. In Section 4 we summarize the results of a neural network based sector capacity estimation model with different sets of complexity factors as input parameters and in Section 5, we give final conclusions.

2 HUMAN FACTORS IN THE SYSTEM OF ATC

When talking about the different parties involved in air transportation, a key area related to the safety of the entire system is Air Traffic Control (or Air Traffic Management in a broader scope). The system of Air Traffic Management consists

of various technological and human components. We created a model to show the components and their relationship. The model can serve as a basis for investigation of a given component malfunction. Figure 1 shows this model with some simplification and thus presents a brief overview of the most important and most common components involved in the Air Traffic Control department of a general ATM system. The safety of ATC is affected by the reliability of both the technological elements and the humans operating the system.

Examining the contribution of technology to the safety of the entire system is usually done by applying safety-, reliability- and risk analysis techniques developed in past decades. Technical system components can be broken down into subcomponents, the structure of which can be unambiguously defined (i.e. what kind of input data they receive, what functions they use to process data and what kind of output data they provide). For example, a primary radar data processing unit may get the time of transmission and time of reception (obtained using a digital timer) of an analogue electromagnetic pulse along with the sign of a digital counter that is reset after each turn period of the antenna and provide digital signs correspondent to the difference of the two times (thus the distance of the aircraft) and the counter's value (thus the azimuth angle). This makes the applicability of traditional safety and risk analysis methods such as failure mode and effects analysis possible, taking into account different function degradations and malfunctions.

When it comes to the estimation of human reliability, the available methods are not as straightforward as those applied for technological systems. Problems are brought on by the fact that human behavior is influenced by lots of different factors that are hard to describe using formal methods (mainly factors that belong to the area of psychology, medicine or social science). This makes the performance of human operators barely predictable and therefore traditional safety analysis methods inapplicable.

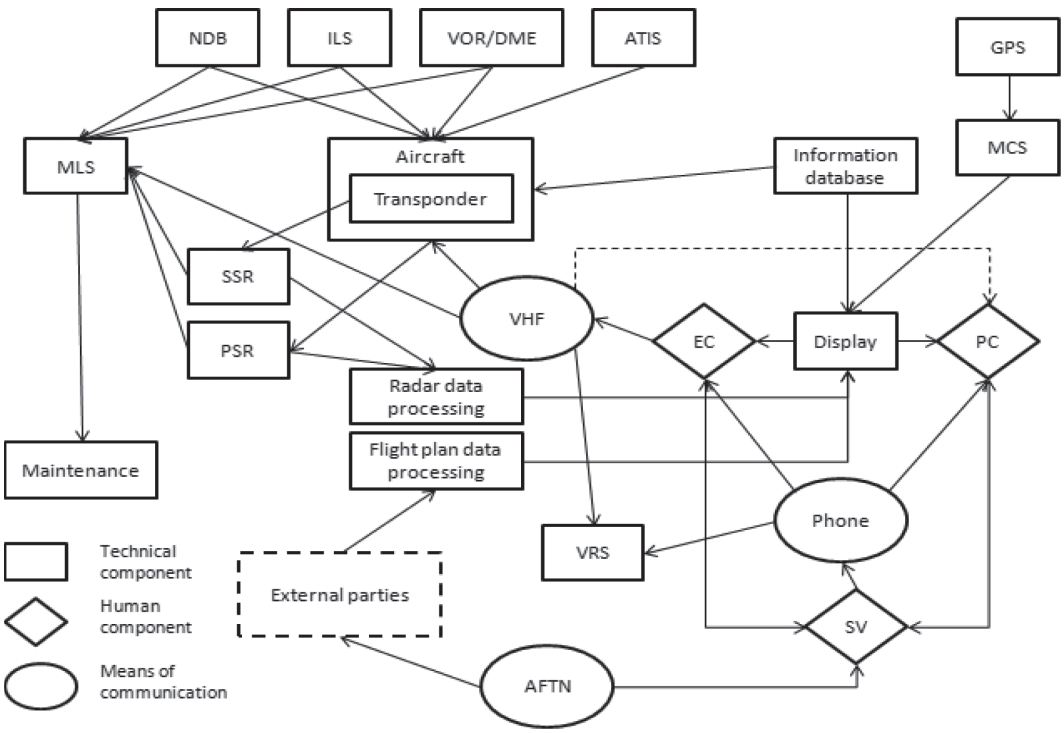

Figure 1. Structure of the ATC system (abbreviations: EC: Executing Controller, PC: Planning Controller, SV: Supervisor, VHF: Very High Frequency (radio), AFTN: Aeronautical Fixed Telecommunication Network, PSR: Primary Surveillance Radar, SSR: Secondary Surveillance Radar, ILS: Instrument Landing System, VOR/DME: VHF Omni-directional Radio Range and Distance Measuring Equipment, NDB: Non-directional Beacon, ATIS: Automatic Terminal Information System, MLS: Microwave Link System, VRS: Voice Recording System, MCS: Master Clock System, GPS: Global Positioning System).

The above statement however does not mean that there are no similarities between the analysis of the impact on safety for humans and for technology. The work of a human operator can also be broken down into a functional group of macroscopic actions (i.e. externally observable actions, not cognitive ones that are executed "inside" the operator) like gathering certain information, processing it and executing actions. For example, in the case of an air traffic controller in a common work situation, there is a traffic monitoring activity which means gathering visual information from the display and audio information from communication with pilots. Based on this, the controller executes actions by issuing orders to aircraft. This enables some kind of analysis for human reliability (e.g. when analyzing operator error, the erroneous macroscopic activity can be determined), but the retrievable information is insufficient as the most important causes of human behavior (and human error) dwell within the microscopic cognitive processes.

Modeling the microscopic information processing activities for humans is much harder than it is for technological elements but there are several methods developed for the task. The most well known models of cognitive human behavior include the information processing model in Wickens (1992), the Step Ladder Model presented in Rasmussen (1986), the Generic Error Modelling System in Reason (1987), the Contextual Control Model and Simple model of Cognition in Hollnagel (1993) and the model of situational awareness in Endsley (1999).

When modeling or analyzing operator error or performance in order to aid the improvement of system safety, it is usually not enough to uncover the area of human cognition which is responsible for the erroneous behavior (e.g. by using one of the above mentioned models). In most cases, the root cause of human error (or a certain type of human behavior) does not lie solely in the problems of the operator's information processing, as human behavior is always influenced by environmental effects which are usually called Performance Shaping Factors (PSFs) in literature. PSFs may include the operator's inner conditions (e.g. hunger or fatigue), hardware environment (quality and condition of equipment used), organizational issues (e.g. regulations, work atmosphere), social environment (e.g. operator's interpersonal relations) etc. An example for the classification of PSFs (for nuclear power plant operators) is given in Blackman et al. (2008).

When it comes to the analysis of the performance of operators in safety critical systems, perhaps the most emphasized of PSFs is workload (as seen in e.g. the operator performance model of Strenzke & Schulte (2011)). In the case of air traffic controllers, workload can be defined (according to Flynn et al. (2005)) as the amount of time in a certain time interval that the controller spends on activities directly related to controlling air traffic (i.e. gathering information, interpreting situations, developing and executing plans). Using this definition, workload can be measured in absolute time (mostly in minutes) or relative time. The latter is a percentage value representing how big a part of work time is spent on the above activities (e.g. 30 minutes in an hour equals to a 50% workload level).

While operator workload is an important factor in every safety related area, in the case of ATC it is even more essential. In the present state of air transportation systems worldwide, the capacities of airspaces are determined by the capacity of the local ATC center. The capacity of ATC centers is in turn based on the level of traffic that controllers can handle, which is heavily influenced by the controller workload generated by the given traffic level. The rule of thumb dictates that the larger the traffic, the higher the workload and although some doubt it (Stager & Hameluck (1990)), higher workload leads to more frequent and more severe controller errors. This means that if the workload generating characteristics of certain air traffic situations could be calculated, then it could be decided whether the given situations can be handled by ATC with controller workload not reaching an undesired level or not. In other words, this would enable determining how many air traffic controllers (airspace sectors) would be optimal to handle the given traffic in a safe and efficient way.

It is also worth noting, that not only high levels of workload can lead to more controller errors but very low workload situations as well. The presence of different PSFs is one explanation for this. It is assumed, that if an air traffic controller works under medium or high workload, then he or she will not pay attention to other internal or external effects that could otherwise hinder work efficiency. When workload drops however, these other factors may become predominant and cause error. Further problems can occur at low workload situations, if it is not obligatory for air traffic controllers to guide flights using only the standard routes in the airspace. If regulations allow and there are not many aircraft present in their sector, controllers will often direct flights to waypoints on non-standard routes. Doing so however means that the flight requires constant attention from the controller until it reaches a standard route again. This, of course leads to increase in workload in situations that would normally induce only a moderate workload level.

Earlier in this Section, we mentioned that larger traffic leads to higher workload. It is important

to state, that large traffic does not simply mean a large amount of aircraft in this context. It means instead, that the traffic is hard to handle for controllers due to the number of aircraft as well as the complexity of both traffic and the airspace.

3 METHOD FOR SELECTING COMPLEXITY PARAMETERS

3.1 *Querying experts' opinions*

There is an enormous number of possible parameters to describe the complexity of air traffic and airspace sectors. This makes it necessary to narrow the set of parameters to a level at which they still provide a good description about the controller workload caused by the given traffic situations but do not lead to unnecessarily complicated and time consuming calculations in mathematical models and simulation.

The first step in determining the optimal set of complexity parameters is figuring out which are the characteristics of air traffic that active air traffic controllers find the most burdensome. In order to realize this, we first made an interview with an expert in the topic of organizing air traffic control as well as the characteristics of the airspace and air traffic in Hungary. The interview was unrestricted, so first we avoided using guidewords and yes or no questions and simply asked, what are the factors of air traffic and airspace that have the biggest impact on controller workload and therefore decisions about the sector configuration to use.

The interview served a double purpose. The first and more obvious one was helping us filter the set of all possible complexity factors we gathered from past studies (e.g. Gianazza & Guittet (2006), Kopardekar & Magyarits (2002) or Christien & Benkouar (2003)), thus generating a smaller set that was not hard to use for the remainder of the survey. The second purpose was to get some guidance for describing complexity factors with words as well as mathematical formulae. For example, the fact that the interviewed expert mentioned descending aircraft among the first workload generating factors and talked about climbing aircraft much later indicates that the number of descending and climbing aircraft should be used as two different complexity factors instead of using only the number of aircraft changing altitude.

In the second step, we broadened the scope of the experts whose opinions were taken into consideration while narrowing the list of parameters using the information gathered in the first step. After the interview, the following parameters of the airspace and air traffic seemed to be the major factors to influence controller workload.

- Number of climbing aircraft
- Number of descending aircraft
- Direction of aircraft movement relative to one another
- Variability of aircraft velocity
- Relative number of arriving, departing and cruising aircraft
- Number of aircraft pairs flying on crossing routes
- Smoothness of the distribution of aircraft in the airspace (flatness of traffic density)
- Number of pilot requests
- Number of intersection points of standard routes
- Number of available flight levels
- Number of special (e.g. military) airspaces used in the given sector or its neighboring sectors
- Weather
- Congestion of frequency
- State of technological system components

Based on this list, a questionnaire was created and given to several air traffic controllers and supervisors. The average experience of controllers to provide answers was 24.3 years and the average experience of supervisors was 5.6 years.

The substantive part of the questionnaire contained the possible air traffic complexity factors listed above and the respondents were required to rate them subjectively (relying on their own experience) based on two aspects. The first aspect was the extra workload generated by the unfavorable state of the given parameter. The respondents were asked to mark each parameter with a number from 1 to 5 based on their thoughts about the workload generated (with 1standing for no or very low workload and 5 for very high workload).

The second aspect was the variability in the values of the given factor. The respondents were once again asked to give marks from 1 to 5 depending on the variability of the parameters. A mark of 1 meant that the parameter's value could be considered constant; 2 meant that the value is not constant but changes significantly only 1–5 times a day; 3 meant that the value changes every 1–2 hours; 4 meant that the value can change multiple times in an hour; 5 meant that the value changes randomly and its change is hard to predict.

This information was necessary in order to determine whether it is important to take the given factor into consideration for the rest of the research process. If a complexity factor has a high impact on workload but its value does not change frequently or greatly, then it should not be used in sector capacity estimation models. One reason behind this is the fact that air traffic controllers will probably adapt to the presence of the given factor which would result in lesser influence on workload.

We also assumed that controllers can even adapt to frequent changes in complexity factor values at a certain level, if the changes are predictable. This is why we asked the respondents to give 5 (the mark representing the worst case) to parameters the changes of which are not regular. The respondents were informed about the aim of the questionnaire and received detailed instructions about providing the answers properly. Although we could not establish personal contact with all the air traffic controllers and supervisors that filled the questionnaire, the feedbacks indicated that the questions, the instructions and the additional information were clear and professional.

3.2 *Results of the questionnaire*

The results obtained from the questionnaire are presented in Table 1. The table shows the mean value and standard deviation of the marks given to the different workload affecting parameters. The parameters are the same as those listed above but this time we used shorter names for the sake of simplicity.

It is worth noting that some of the complexity parameters used had a similar meaning to others and in some cases, a logical relationship can be found between two parameters. For example, arriving and departing aircraft increase complexity because they are usually descending and climbing aircraft respectively and the frequency in the given sector gets overloaded when there are bad weather conditions or failure in technology. These parameters were left in the list for two reasons. Reason number one was that we did not want to combine complexity factors that were stated as different during the interview, regardless if they differed only slightly. Reason number two was the will to create an opportunity to check the coherence of answers given in the questionnaire.

3.3 *Creating final set of parameters*

The results of the questionnaire showed us that the parameters with similar or relational meaning received similar ratings, so the respondents had probably given thought-out answers instead of random marks.

The results summarized in Table 1 indicate that the most important complexity factor according to air traffic controllers is unsurprisingly weather with a mean value well above 4 in both categories. Other major factors based on the mean value of extra workload rating are the numbers of climbing and descending aircraft, the relative number of arriving, departing and cruising aircraft, the aircraft pairs on crossing routes (i.e. pairs with a possibility of conflict), the smoothness of the distribution of aircraft, the number of route intersections, the available flight levels, the number of active special airspaces, the congestion of frequency and the state of technological system components. Density, intersections, flight levels and state of technology however received a mean value below 3 for variability so these can be considered factors that are easier to adapt to than others, therefore they are less significant. The complexity factors that do not seem to have much relevance

Table 1. Ratings of complexity factors based on subjective opinions.

	Extra workload		Variability	
Parameter	Mean	Deviation	Mean	Deviation
Climbing aircraft	3.71	0.53	3	0.88
Descending aircraft	3.57	0.58	3.14	1.15
Relative heading	2.29	1.03	2.43	1.63
Speed variability	2.57	1.05	3	1.25
Arriving/departing/ cruising aircraft	3.86	0.97	3.57	1.23
Aircraft pairs on crossing routes	3.57	0.85	3.43	1.37
Flatness of density	3.71	0.53	2	1.25
Pilot requests	2.86	0.75	3.43	0.85
Route intersections	3.43	0.58	2.43	1.51
Available FLs	3.29	0.82	2.43	1.51
Special airspaces	3.57	0.85	3.29	1.5
Weather	4.57	0.58	4.29	1.03
Frequency congestion	3.71	0.82	3.57	1.22
State of technology	3.14	1.31	2.71	1.84

to controller workload in Hungarian airspace are the variance of aircraft speed and heading and the number of pilot requests.

The standard deviation for the extra workload generated by the different factors is small (does not exceed 1 in most cases), so most answers were close to one another indicating that controllers have a uniform opinion about the complexity factors' effect on workload. In the case of variability, the deviation values are much greater in general (this time they are above 1 for almost every parameter). This indicates that the answers were not as unified as they were to the question about extra workload. The reason behind this may either be that controllers' opinions differed more on this question or more probably, the meaning of variability was not clear (regardless of the information provided to the questionnaire) and/or it was not easy to estimate the variability of different complexity factors.

The primary goal of the information acquiring process about complexity factors was to use them as parameters for mathematical modeling of the relationship between air traffic characteristics and controller workload. The aim of such a model in turn was serving as a basis for a decision support tool that would help supervisors in making decisions about the optimal sector configuration for various traffic situations.

With the above aims in sight, it was necessary to consider other aspects beside the opinion of ATC experts when trying to determine which would be the optimal set of parameters to be used in the model. One of these aspects was the issue of predictability. An automated decision support system could not be operable without receiving reliable information about the anticipatory values of complexity factors in the near future. In the case of our research, this meant that only parameters with confidently predictable values could be taken into consideration. This resulted in the exclusion of the number of pilot requests and the state of equipment from the parameters (which is hard to predict even though the ATC system is equipped with diagnostics tools) as well as the most important workload affecting factor: weather.

The latter decision may seem neglect, but it is important to note, that weather is hard to predict even on short terms and hard to describe by mathematical formalization that would be essential for usage in automated decision support (although there may be methods to do so, like modeling thunderstorm areas as restricted airspaces and treating them similarly). We can also assume that supervisors would not rely on decision support systems when weather conditions in the airspace are harsh.

The other complexity factors were more or less included in our first set of parameters to be used for modeling. The term "more or less" refers to the fact that some of the parameters were used with a meaning slightly different from what can be presumed from the name that was used in the earlier list while others were included implicitly as parts of other complexity factors. For better understanding, the actual complexity parameters that were included in our largest parameter set are listed below with a short explanation, where needed:

- Number of aircraft
- Number of climbing aircraft
- Number of descending aircraft
- Percentage of climbing aircraft among all aircraft
- Percentage of descending aircraft among all aircraft
- Standard deviation of aircraft velocity (to represent variability in aircraft speed)
- Flatness of traffic density (indicates whether the aircraft are distributed equally in the given sector or they are concentrated in small, high density areas)
- Divergence of traffic (to represent relative heading and speed of aircraft)
- Convergence of traffic (to represent relative heading and speed of aircraft)
- Insensibility of traffic divergence (the insensibility of divergence to changes in aircraft speed and heading)
- Insensibility of traffic convergence (the insensibility of convergence to changes in aircraft speed and heading)
- Number of aircraft pairs on crossing routes with the possibility of conflict
- Number of intersections of standard routes
- Sector volume (geographical area of a sector multiplied by the standard flight levels in the sector)
- Number of available flight levels
- Number of temporary restricted airspaces (TRAs) (in the given sector as well as its neighboring sectors)
- Number of climbing aircraft in Budapest Terminal Maneuvering Area (TMA) (to represent if the given traffic situation has a "departing" nature)

Traffic density, divergence, convergence and the insensibility of divergence and convergence were calculated using the formulae presented in Delahaye & Puechmorel (2000). Relative heading of aircraft were included implicitly in convergence and divergence. The proportion of departing, arriving and cruising aircraft is represented by climbing and descending aircraft as well as by climbing aircraft in the TMA. When calculating the number of aircraft pairs on crossing routes, only those were considered, where both aircraft would reach the

intersection point in no more than 720 seconds with a time difference less than 90 seconds (based on the current speed and heading).

4 MODEL CREATION AND RESULTS WITH DIFFERENT SETS OF COMPLEXITY PARAMETERS

4.1 *Data and structure of the neural networks*

In order to examine the applicability of the complexity factors introduced in Section 3, we decided to use a neural network based approach similar to the one seen in Gianazza & Guittet (2006). To provide input data to our networks, air traffic data of the Hungarian airspace was obtained for two days in the past (29th July 2011 and 30th July 2012) and a few more hours from 25th October 2012 when military TRAs were in use. We took snapshots of the radar data every 30 minutes for the two full days and every 10 minutes for the time when TRAs were open. After taking these samples, we had radar data for 107 different air traffic situations which included a wide variety of traffic levels.

Based on the radar data and data regarding sector structure of the airspace, values of the complexity factors listed in Section 3 were calculated for the different traffic situations. Calculations were made for the entire airspace, for elementary sectors (sectors that cannot be split) and for sector blocks that are currently used in Hungarian ATC.

The input values of the neural network were obtained by applying principal component analysis on the set of complexity parameter values. We had 17 principal components in the case of elementary sectors and sector blocks, and 15 principal components in the case of the entire airspace (sector volume and intersections of standard routes were constant, therefore the principal component analysis was performed on a set of only 15 parameters).

The output values of the networks were numbers indicating the optimal state of the given sector in the given traffic situation. Still sticking to the path laid by Gianazza & Guittet (2006), sectors had two or three possible states. The airspace could be split or armed, elementary sectors could be armed or merged and sector blocks could be split, armed or merged. Each possible state was represented by a node in the output layer of the neural network that could take on a real value between 0 and 1. In an ideal case, the node of the optimal state would have a value of 1 and the other or others 0. In practice however, error can never be completely eliminated during the training of a neural network and in some cases it is hard to tell even for experienced human supervisors what the optimal state of a sector would be. These problems usually lead to values between 0 and 1 on two or more output nodes. In such a case, the node with the greatest value is considered the node of the optimal state.

For the training of our neural networks we needed information about the optimal state of sectors in reality, which required supervisory know-how. Once again active supervisors with high experience were asked to state their opinions about different traffic situations and tell what the best sector configuration would be for the safest and most efficient control. To achieve this, they were shown radar pictures of the historical air traffic data of the traffic situations in scope. Although the situations were shown in chronological order, they were asked to look upon them "out of context" and tell what the optimal configuration would be if the given situation lasted for a long time and not only a couple of minutes as it was the case in some situations.

Neural networks were trained by using about 80% of the available data, while the remaining 20% was used as query data. For the training we used off the shelf software which prevented us from fully recognizing or modifying training logic, but network size and training parameters were still settable. The networks had twice as many hidden layer nodes as input nodes and the training of a network was considered complete once at least 95% of the output nodes' values was within 5% range of the expected value. Time limit for training was also used to avoid too long training periods. Validation of the networks was done using both query data and the same data that had been used for training.

4.2 *Results of the neural networks*

In order to examine how the results of a neural network analysis depend on the set of parameters used as input, we performed our analysis for three different sets of parameters. The first and largest one (named Set A) contained every complexity parameter described in Section 3. The second set (Set B) was created by removing the least significant parameter (according to the subjective opinion of experts), which was relative heading. Since relative heading was present in Set A as a latent parameter included in divergence and convergence, these parameters were the ones to be excluded (along with their corresponding insensibility values). Set B therefore had 13 parameters (11 in the case of the entire airspace). The third set (Set C) was obtained by the exclusion of the second least important parameter: the standard deviation of aircraft velocity. We also removed the percentage of climbing and descending aircraft as these parameters seemed to be redundant. This resulted in 10 parameters for Set C.

For the analysis of the applicability of neural network modeling for sector capacity estimation in Hungarian airspace, we examined the reliability of the results by comparing the results calculated by the network with those provided by supervisors. Results of a certain network for a certain set of parameters in a certain sector type (i.e. airspace, elementary sector or sector block) can be characterized by the percentage of results that were correct (equal to those obtained from supervisors).

The neural network calculations using Set A provided the results summarized in Table 2. Calculations were done with different amounts of principal components, but Table 2 lists only the results obtained using the maximum amount. The "Validation data" column shows what type of data was used for validation of the network with Q standing for query data and T standing for training data.

As it is seen in Table 2, the results for sector blocks are far from satisfactory. This is a problem that may have several causes (e.g. the geometrical diversity of different sector blocks or the quality of the neural network planning software used) which are out of the scope of this paper and are to be dealt with in another research project. To eliminate the problem temporarily, a smaller set of sector blocks was considered, which involved only the West (W) and East (E) sector blocks, each built up of five elementary sectors. For the neural networks of Set B and Set C these were the only sector blocks used by default.

Tables 3 and 4 show the neural network results for Set B and Set C respectively.

Tables 2–4 show us that although there is a slight decrease in the accuracy of neural network results when the number of input parameters (complexity factors) is reduced, the results can still be considered satisfactory as they rarely drop below 80%. The seemingly strange increase in accuracy in the case of sector blocks in Table 3 can be explained by the parameters we used for training our networks. In both cases, training was stopped after the fixed time limit but since Set C had a simpler network (due to the lower number of input parameters) its training was probably in a more advanced state already than it was for Set B.

Table 2. Results of neural network calculations for Set A.

Sector type	Validation data	All (%)	Split (%)	Armed (%)	Merged (%)
Airspace	Q	100	100	100	–
Airspace	T	100	100	100	–
Elementary	Q	96.5	–	56.3	99.5
Elementary	T	97.8	–	81.8	99
Block	Q	57.2	69.9	4.6	59.7
Block	T	72.2	88.5	8.1	77.7
Block W&E	Q	95.2	100	91.7	83.3
Block W&E	T	97.7	100	92.1	100

Table 3. Results of neural network calculations for Set B.

Sector type	Validation data	All (%)	Split (%)	Armed (%)	Merged (%)
Airspace	Q	100	100	100	–
Airspace	T	95.5	95	100	–
Elementary	Q	82.1	–	82.4	82.1
Elementary	T	88.1	–	86.7	88.2
Block W&E	Q	73.8	82.6	63.6	62.5
Block W&E	T	96.9	98.7	97.5	86.7

Table 4. Results of neural network calculations for Set C.

Sector type	Validation data	All (%)	Split (%)	Armed (%)	Merged (%)
Airspace	Q	100	100	100	–
Airspace	T	100	100	100	–
Elementary	Q	93.5	–	75	95
Elementary	T	93.8	–	73.9	95.3
Block W&E	Q	82.9	85.2	81.2	66.7
Block W&E	T	93.8	97.2	94.6	78.9

5 CONCLUSIONS

In an attempt to enhance the safety of air traffic control in Hungarian airspace, we conducted a study to examine the possibility of using a neural network model as a basis for a supervisory decision support tool that would be able to estimate the optimal number of ATC sectors for a given traffic situation based on its complexity. Data about the importance of different complexity parameters was gathered using a simple method that focused on finding out the subjective opinions of ATC experts. To validate our method, we used neural network calculations with different sets of complexity parameters.

The results obtained using reduced parameter sets indicated that the complexity factors that air traffic controllers did not find important are not important indeed, so the method used for gathering information on complexity factors was proven suitable. It was also proven that complexity factors that are calculated through complicated mathematical formulae (divergence, convergence and insensibility) are not indispensable for neural network

calculations with satisfactory results. This makes it inadvisable to use such parameters in a decision support tool as they would only lead to lower software performance with not much increase in reliability.

As the method of selecting complexity factors seems to be proven adequate, it is advisable to use it in similarly themed studies in the future. The reduced sets of complexity parameters seem to lead to a similar outcome as the full set when used in neural network calculations, therefore it is worth considering to use these instead.

ACKNOWLEDGMENT

The authors would like to return thanks to AMKMA (Foundation for the Hungarian Transportation Engineering Education) for supporting the project presented in this article and Hungaro-Control Hungarian Air Navigation Services Co. for providing radar data and contributing to the selection of complexity factors by consultation.

ABSTRACT: There are the very important problems about the lack and veracity of the basic data in Human Reliability Analysis (HRA). In order to resolve the problems, the task process operations in manned spaceflight are analyzed, and "Meta-Operation" is defined. The eleven kinds of "Meta-Operations" are given which cover both the rule type and skilled cognitive type, including six operations for one person, five operations for two persons, then classify the process of tasks related to the multi-factor. According to these eleven kinds of "Meta-Operation", the test environments and the groups of experimental persons are designed. Through five different groups of experimental persons, over ten thousand valid experimental data are obtained. The analysis of these experimental data reveals that there is no significant difference among the different groups at the "Meta-Operation" level. From the analysis, the eleven kinds of Human Cognition Reliability (HCR) model basic parameters are gotten.

1 INTRODUCTION

At all times, HRA is regarded widely in the fields of nuclear power human operations, fighter operations and astronaut operations. The foreign and domestic scholars have focused a growing amount of research efforts in this direction [He X.H., et al., 2007, Huang J., Huang X.R. and Shen Z.P., 1999, Li B.F., Song B.F. and Xue H.Q., 2005, Thomas A.B., 2012, etc]. Yang Yi, Liu Weibo & Kang Rui (2012) researched into the overview of human reliability which has produced basic models to solve certain problems and assess complex manipulation task reliability, especially for "Meta-Operation". The work has laid a solid foundation for further study in the field of Human Reliability Analysis. However, due to the particular nature of different manned missions, data tends to be unreliable and limited. Solutions to the problems of Human Reliability Analysis must satisfactorily solve the problems arising from limited and unreliable sample data. So Yang Y., Chen S.G., Zheng W.X. & Kang R. (2013) gave the "Meta-Operation" of the single-factor of one person, the test environment, the valid experimental data, and the parameter estimates of HCR (Weibull distribution). This paper further attempts to use the results of "Meta-Operating" analysis to identify the multi-factor of one person and multi-person for "Meta-Operation", and design appropriate test environment for reliability data accumulation, obtain the test data and the parameter estimates of the multi-factor HCR, thus developing the ability to evaluate complex task operation reliability.

2 MULTI-FACTOR "META-OPERATION" ANALYSIS

Using the results of Yang Yi, Liu Weibo & Kang Rui (2012), the single factor in feeling can be divided for visual expression, listening comprehension, smell and touch, classification can sort out two factors at the same time, such as visual and smell, visual and listening, visual and touch, and so on, classification can sort out three and four factors at the same time. A single factor, two factors, three factors and four factors constitute the basic classification judgment. The same way considers the classification of body movement, which can be divided into the upper limb movement, lower limb movement, upper and lower limb coordination

Table 1. Meta-Operation summary in the manned space mission operations.

Operation test content	Factors	Meta operational motion
Suit A worn operation	Vision-Hearing-Touch (three factors)	Coordinated action of upper and lower limbs
Suit B worn operation	Vision-Hearing-Touch (three factors)	Coordinated action of upper and lower limbs
Suit C worn operation	Vision-Hearing-Touch (three factors)	Coordinated action of upper and lower limbs
open/close doors operation	Vision-Hearing-Touch (three factors)	Coordinated action of upper and lower limbs
Piping layout operations	Vision-Hearing-Touch (three factors)	Coordinated action of upper and lower limbs
Two players together remove a seal operation	Vision-Hearing-Touch (three factors)	Upper limb movement
Two players together install a seal operation	Vision-Hearing-Touch (three factors)	Upper limb movement
Two players together a seal adjustment	Vision-Hearing-Touch (three factors)	Upper limb movement
Two players together measuring	Vision-Hearing-Touch (three factors)	Coordinated action of upper and lower limbs
Two players remove/install beams together	Vision-Hearing-Touch (three factors)	Coordinated action of upper and lower limbs
Two players together install floor block operation	Vision-Hearing-Touch (three factors)	Coordinated action of upper and lower limbs

actions, etc. The classification of the judgment is combined with the body movements' classification. All of the contents of the specific procedures for the flight event classification are given, the classification reflects the operation types, also is the base of main model.

2.1 *Building method of "Meta-Operation" set*

With the increase of task difficulty, the type of Meta-Operation also increased, from simple single-factor type into multi-factor of one player type, such as: the operation of filling in, switching operations, pick and place operations, connectors join operations, extravehicular suits worn operation, physiological clothing and protective clothing worn operation, cabin clothes worn operation, open/close doors operation and pipeline connection operation and so on.

For complex manned space mission, we need to consider more than two players in collaborative multi-factor "Meta-Operation" type. For example, in typical operation of replacing the door seals, "Meta-Operation" type include two players together remove seal ring operation, two players collaborative installation seal ring operation, two players at the same time to adjust the position operations and so on.

According to astronauts normal flight manuals and operating instructions in a certain manned space mission, action items astronauts were to be carried out are detailed analyzed and generalized from the beginning to the spacecraft to return astronauts landing, 11 kinds of Meta-Operation includes: clothing worn operation, open/close doors operation, piping connection operation and some collaborative operations, see Table 1.

3 MULTI-FACTOR "META-OPERATION" PERSONNEL RELIABILITY TEST

Yang Yi, Chen ShangGuang, Zheng WeiXing & Kang Rui (2013) detailed analysis of personnel operating activities during manned spaceflight missions, known as "Meta-Operations". Using "Meta-Operation" the basic categories, and combining related the main operating classification in the multi-factor test of one player and two players, we can determine the main type of operation and the main equipment. It can be seen that personnel operations involved in the upper and lower limb coordination actions. All types of multi-factor are shown in Table 2.

Aimed at the above operations, these main factors are considered in the test:

a. Suit A, B, C worn operation;
b. Open/close doors operation;
c. Piping layout operation;
d. Two players collaboratively a seal operation;
e. Two players collaboratively measuring operation;
f. Two players collaboratively remove/install beams;
g. Two players together install the block.

The testing environmental and implementation can straightway use the results of Yang Yi, Chen ShangGuang, Zheng WeiXing & Kang Rui (2013).

Table 2. Personnel operation factor.

Categories	Subclass of similar operation time	HCR type
The upper and lower limb coordination actions for one player	Suit A worn operation Suit B worn operation Suit C worn operation Opening/closing doors operation Pipeline connection operation	Regular skill
The upper and lower limb coordination actions for two players	Two players together remove a seal Two players collaborative installation a seal, Two players at the same time to adjust the seal positions Two players together measuring Two players remove/install beams together Two players together install the block operation	Regular skill

4 MULTI-FACTOR TEST PARAMETERS IDENTIFICATION

4.1 *HCR model*

In order to carry out the personnel operating reliability analysis in complex task, we have already arranged the experiments of "Meta-Operation", and obtained a large amount of data. If these data can be used for predicting the personnel operating reliability in complex task, we must determine the each reliability of "Meta-Operation". According to the reliability model in the HRA, we considered HCR model has the standard expression form and clear meaning. Especially it could reflect the comprehensive effect of cognitive rules. So we selected HCR model as the basic paradigm of "Meta-Operation" reliability model.

He X.H., et al. (2007) illuminated in the detail that Weibull distribution is the most broad model in the HRA. Then Assuming the time to complete a "Meta-Operation" meets Weibull distribution, then

$$R(t)=\begin{cases}\exp\left\{-\left(\dfrac{t-\gamma}{\eta}\right)^{\beta}\right\} & t\geq\gamma\\ 0 & t<\gamma\end{cases} \tag{1}$$

where $R(t)$ is the probability for completing a "Meta-Operation" at t. γ is location parameter, η is dimension parameter, β is shape parameter.

Furthermore, we can get that

$$\ln\left[\ln\frac{1}{R(t)}\right]=\beta\ln(t-\gamma)-\beta\ln\eta \tag{2}$$

In order to reduce the inherent time differences, the operation time to completion is normalized. Standardized time is defined as $t/T_{0.5}$, where t is the operation completion time for the operator to complete a certain operation time.

$$T_{0.5}=\gamma+\eta(\ln 2)^{1/\beta} \tag{3}$$

Using $T_{0.5}$ to normalize the processing operations time, we get:

$$R(t)=\begin{cases}\exp\left\{-\left(\dfrac{(t/T_{0.5})-C_{\gamma}}{C_{\eta}}\right)^{\beta}\right\} & t/T_{0.5}\geq C_{\gamma}\\ 0 & t/T_{0.5}<C_{\gamma}\end{cases} \tag{4}$$

where $C_{\gamma}=\gamma/T_{0.5}, C_{\eta}=\eta/T_{0.5}$, β is constant.

Through the test, we can use fitting method to get estimated values of the above parameters. For the same set of test data in ascending order, $t_1, t_2, t_3, \ldots, t_N$, $R_i=i/N+1$ is the estimation of the operating task when t_i complete probability value. By the preceding definitions, we have:

$$\ln R(t)=-\left(\frac{t-\gamma}{\eta}\right)^{\beta} \tag{5}$$

$$\ln\left[\ln\frac{1}{R(t)}\right]=\beta\ln(t-\gamma)-\beta\ln\eta \tag{6}$$

According to the equation (2) and test data we can get the fitted values of β, η and γ by the method of least squares. Then, the fitted values of $T_{0.5}$, C_{γ} and C_{η} can be obtained.

4.2 *Multi-factor test data identification results for one player*

Tables from 3 to 8 provide HCR model parameter identification results of the clothing worn operation test, open/close doors operation test and piping connection operation test.

Figures 1 to 6 reveal the estimated probability curve of tests 1 though 6. Grouping trends were similar according to probability estimation value curves. The analysis of the parameters identified in

the table showed that individual areas also showed some differences, but the fundamental differences reflect the different team level, then from the evaluating requirements the differences are acceptable. The results can be used as the base for human reliability evaluation.

4.3 *Multi-factor test data identification results for two players*

Tables from 9 to 14 provide HCR model parameter identification results of two players together removing a seal test, two players together installing a seal test, two players together to adjust the seal position test, Two players together measuring test, Two players removing/installing beams test together, and Two players together installing the block test.

Figures from 7 to 12 give the curves of probability evaluation for the 6 experimental data. From the curves, the differences are small among the different groups and conditions. The results of parameters identification are concentrative, and then can be used as the base for human reliability evaluation.

5 CONCLUSION

The study is just a simple study attempting to put forward the basic method of human operation reliability testing and parameter identification for multi-factor, given the 11 categories of the test as well as test data. Compared the test results with the data of engineering, the tests are coincident. Because of the lack for the data of engineering, the statistical consistency cannot been given, the data also must be got together. However the results of parameter identification, experimental design and data processing method are scientific and reasonable. The study's results can support the study of the complex task of reliability assessment, as comparisons of task execution differences between personnel need further analysis, and further work will be required to expand this subject.

Statistical analysis of past accidents and a methodology (MEDIA) for Human and Organizational Factors assessment in process industries

M. Ahmad & M. Pontiggia
D'Appolonia S.p.A., Milan, Italy

M. Demichela
Politecnico di Torino, Turin, Italy

ABSTRACT: This paper presents a statistical analysis of past accidents occurred between 1983–2013 reported to European Major Accidental Reporting System (EMARS) across seven industries for Human and Organizational Factor (HOF) assessment. The main purpose of this analysis is to provide guidelines for the HOF analysis and its quantification in chemical process industries. Five identified organizational factors have been chosen as performance shaping factors for human actions/interventions which are quantified using analysis of past accidents. The relation between organizational and human factors is developed and quantified using a newly developed methodology MEDIA.

A case study is carried out for a pig launcher that is widely used in oil and gas facilities during pigging operations. Failure Mode, Effects and Criticality Analysis (FMECA) approach is used to identify the potentially critical human actions/interventions based on guided brainstorming. After that, these identified actions/interventions analyzed using conventional FMECA approach and MEDIA. FMECA can provides a qualitative results, while MEDIA can provides quantitative results and also demonstrates the influence of an organization on human reliability.

1 INTRODUCTION

1.1 *Statistical analysis of past accidents*

One of the concerns during Human and Organizational Factor (HOF) assessment in process industries is the absence of a database for HOF quantification. Therefore, for an effective HOF assessment, it is required to rely on an authentic source for quantification. In this work, it was decided to rely on data from past accidents for HOF quantification. IEC Standard (2009, p. 15) also illustrates the use of relevant historical data to predict the probability of occurrence for events in future.

European Major Accidental Reporting System (EMARS) is selected to recover the historical data of accidents for 30 years from 1983 to 2013. The EMARS was established by the EU's Seveso Directive 82/501/EEC in 1982. The purpose of this reporting system is to facilitate the exchange of lessons learned from accidents and near misses involving dangerous substances in order to improve chemical accident prevention and mitigation of potential consequences (EMARS). At the moment, only accidents are considered in this analysis with a possibility to add near misses in future.

Reporting an event to EMARS is compulsory for EU member states when a Seveso establishment is involved and the event meets the criteria of a "major accident". This criteria of major accident has been defined in the annex VI of the Seveso III Directive (2012/18/EU) and also highlighted below:

- Dangerous substances involved;
- Injury to the person and damage to real estate;
- Immediate damage to the environment;
- Damage to property;
- Cross-border damage.

In this analysis seven different types of industries have been considered to increase the number of accidents and available accidental data. These seven types of industries have been selected due to similarities in their organizational and operative structures. The following self explanatory industrial types as reported in EMARS have been considered in this analysis:

- Petrochemical/Oil Refineries;
- Chemical installations—ammonia;
- General chemical manufacture (excluding H2, SO_x, NO_x, F_2, Cl, NH_3 & CO);
- Wholesale and retail storage and distribution (excluding LPG);
- Production of basic organic chemicals;
- LPG production, bottling and distribution;
- Power supply and distribution.

A preliminary assessment is used to identify those accidents caused by the HOF. Once these accidents have been identified, a detailed analysis was carried with HOF action taxonomy. Accidents were classified according to their major root causes, after reading accidental reports from EMARS. Table 1 illustrates the factors used for the accidental classification. In the first column, plant's operational conditions are listed and in subsequent columns HOF are highlighted.

During the accidental analysis it was also examined if an accident was caused solely either by human error or by an organizational fault or by both.

1.2 *New HOF assessment methodology: MEDIA*

Method for Error Deduction and Incident Analysis (MEDIA) is a newly developed taxonomy based HOF risk quantification technique (Ahmad et al. 2014) and shown in Figure 1. MEDIA is based on newly developed HOF taxonomy which is illustrated in Table 1. At present, only organizational factor is considered as a Performance Shaping Factor (PSF) for human actions.

MEDIA assumes that humans inherit a tendency to make errors even in an ideal working condition, these errors entitle as inherit human error in MEDIA. It also assumes that human reliability fluctuate with the given organizational characteristics. Meanwhile, effect of Safety Instrumented Functions (SIF) is also important to consider in overall HOF assessment by using their risk reduction factor. Guidelines of these safety function and their risk reduction is provided in IEC Standard (1999).

1.2.1 *Organizational factor*

In MEDIA five organizational factors are considered as illustrated in Table 1. Øien (2001) described

Table 1. Criteria for accident classification.

Plant's operational stage	Human factor taxonomy	Organizational factor taxonomy
Normal	Monitoring (M)	Training (T_O)
Start up	Control room	Design (D_O)
Shut down	Actions (A)	Procedures (P_O)
Maintenance	Communication (C)	Management (M_O)
	Manual on-field (F) operations	Safety culture (C_O)
	Reporting (R)	

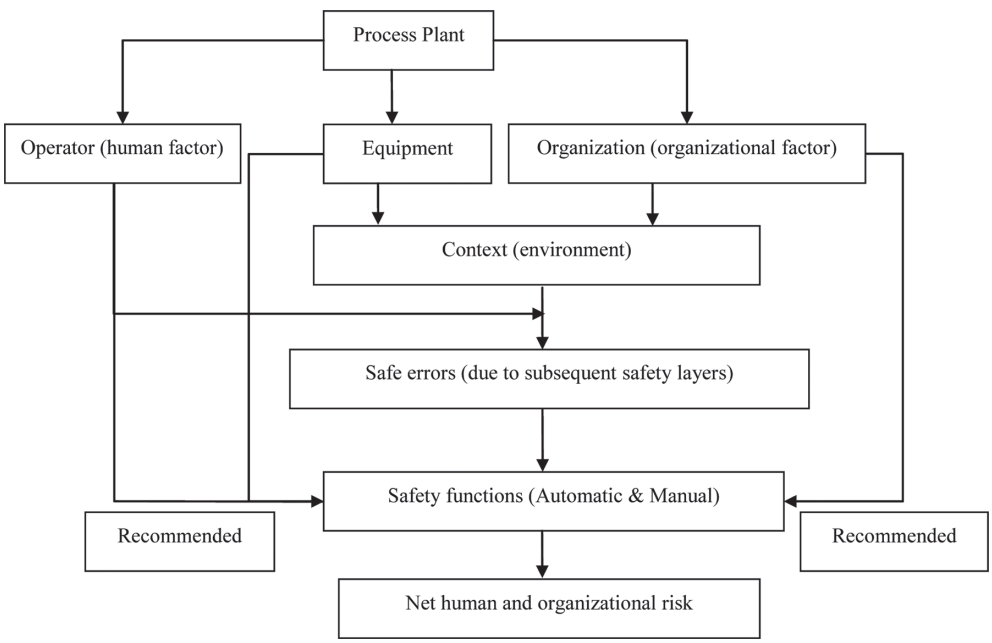

Figure 1. Method for Error Deduction and Incident Analysis (MEDIA) framework.

six organizational factors in his model. During accidental analysis all the Organizational Factors (OF) leading to accidents are recorded and listed in Table 3. OF can be assessed in an organization/company using safety audit/review procedures in order to assign them a level. During proposed safety audit/review, points mentioned in Table 3 will be examined in an organization to check if precautionary measures are in place to minimize the effect of an organization on human actions. If an organization meets all the criteria, then its level is defined by a lower number than if it does not meet these criteria.

Table 3 only illustrates the points that were directly involved in an accident but not those organizational aspects which were improved after the accident.

1.2.2 *Human factor*

In human factor analysis five human factors are considered based on an action based taxonomy as shown in Table 1. A Similar taxonomy is used in SPEAR and reported by Stanton et al. (2005). For each of the factors inherit error frequency/year/plant was calculated based on the accidental analysis. Table 4 shows the basic human errors that led to an undesirable situations during past accidents.

1.2.3 *Quantification of organizational effect on human behavior*

The effect of an organizational characteristics on human behavior is the main feature of this methodology. It is also reported by Daniellou et al. (2011) that organizational factors can influence the human actions. Accidents were observed in a way to account for all the human failure and number of times these failure were caused due to an organizational factor. This quantification analysis can provides the limits to what extent organization can influence the human behavior and cause an accident.

2 STATISTICAL ANALYSIS OF PAST ACCIDENTS

In this section the results of the analysis are presented. Table 2 shows the main features of this analysis. In this analysis 470 accidents from 30 years were considered, of which 90 of them caused by the HOF as mentioned in EMARS database.

It was also recorded if an accident is caused solely either by HF, OF or by both factors. The determination of causal factors to an accident is based on subjective judgment after reviewing the detail report of an accident.

Table 4 lists all the human actions that have led to accidents in the past. Therefore, during a human factors assessment an analyst can know what kind of potential failure events can happen and can consider them accordingly. Since all the human actions are grouped into five main classes, therefore frequencies of human failures are determined across these five classes.

Table 2. Features of accidental analysis.

Description	Number
Time duration (years)	30
Total no. of accidents	470
No. of times HOF involved	90
Accidents in petrochemical/oil refineries	27
Accidents in ammonia installation	2
Accidents in gen. chem. production plants	42
Accidents in wholesale and retail storage and distribution	5
Accidents in organic chemical production installation	6
Accidents in LPG production, bottling and distribution	1
Accidents in power supply and distribution	7
Accidents caused solely by Human Factor (HF)	11
Accidents caused solely by Organization Factor (OF)	17
Accidents caused by both Human and Organizational (HOF)	62

2.1 *Plant's operational stage*

As mentioned earlier, all possible plant stages are considered in this analysis, since risk can be associated with each of the operational stages of the plant as illustrated in Table 1.

Figure 2 shows that major share of accidents (about 67%) occurred during the normal operating conditions while maintenance operations caused about 23% of accidents. Start up operations also led to a noticeable fraction of accidents.

This analysis proposes to consider not just normal operating conditions but also other conditions during the plant's life.

During HF analysis potential failure events can be identified by considering different plant's operational stages and frequencies of events can be adjusted accordingly.

2.2 *Human and organizational factor quantification*

In order to perform integrated HOF assessment, it is important to identify and quantify the effect of different organizational factors on human factors. Table 5 illustrates the effect of different organizational factors on human actions.

Table 3. Organizational factors audit/review points.

Organizational factors	Description
Training	To provide training about most hazardous scenarios;
	To provide training to workers for daily operations;
Design	To check equipment requirements and specifications (e.g. flanges, heat exchangers);
	To provide necessary interlocks (verification of shutting time provided by interlocks);
	Risk should be calculated for all the operations and incorporate during design phase (i.e. loading op.);
	To consider Periodic maintenance of units and adjusted accordingly in design phase of a plant;
	To consider potential human errors and included in design phase of plant;
	To consider vibrations of units and pipelines due to diversions;
	To provide redundancy (e.g. double alarms and interlocks) for high risk operations (e.g. loading and unloading operations);
	To consider proper type/class of an equipment (e.g. pumps, heat exchangers) depending upon the operations and involved substances;
Procedures	To provide necessary operational procedures for operators;
	To provide proper procedures for the start-up operations (i.e. need to consider metrological conditions if seems influencing);
	To provide procedures for carry out maintenance/modifications operations (i.e. procedures to provide work permits to consultants);
	To provide updated operative procedures for the potential hazardous substances and also for the critical operations (e.g. cleaning of high flammable liquid tanks);
	To provide strict procedures for hot work applications (i.e. maintenance and normal operations);
Management	To ensure plant's manning level as considered during the risk assessment;
	To verify knowledge about properties of all the chemicals use in a plant and their potential propagation to certain explosive scenarios (e.g. domino effect);
	To ensure the handling and communication of process modifications (e.g. management of change) to all involved parties;
	To ensure steps to adopt enhanced (latest) safety and performance standards;
	To ensure that Periodic maintenance/inspection of equipments is devised with care;
	To ensure safety and proper management during contractors' work (i.e. normal, maintenance operations) to issue work permit to contractors;
	To ensure necessary communication between different parties involved in different phases of a plant;
Safety culture	To ensure the development and maintaining of safety culture across a facility.

Table 4. Human factor analysis points.

Human factors	Description
Monitoring	Monitoring of vibrations (i.e. vibration in pumps);
	Visual checks for leaks;
	Monitoring of automated safety functions (e.g. not disarmed);
	Constant monitoring of high pressure alarms and indicators;
	Supervision for potentially wrong sequence of operations;
Control room actions	Unintentionally change (i.e. increase or decrease) in plant parameters (i.e. pressure, temperature and flow etc);
Communication	Communication between shifts;
	Communication among and between operators and supervisors;
	Communication between control room operator and manual on-field operator;
Manual on-field operations	Repetition of an action;
	Manual operation of valves;
	Switch-off an alarm unintentionally/intentionally;
	Error of commission (i.e. wrong valve, wrong fluid, wrong equipment etc);
	Error of omission (i.e. violations, slips);
	Error to recover from a faulty state;
	Operator left valve open/close after an operation;
Reporting	Not informing management about the state of a component/accident.

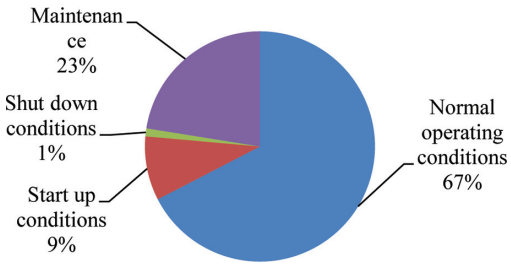

Figure 2. Accidents in different operational stages of a plant caused by HOF.

Table 5. Effect of organizational factors on human factors.

	Organizational factors				
Human factors	T_O	D_O	P_O	M_O	C_O
Monitoring	0.44	0.30	0.36	0.34	0.33
Control room actions	0.00	0.00	0.04	0.00	0.00
Communication	0.33	0.09	0.13	0.09	0.00
Manual on-field operations	0.88	0.60	0.77	0.43	1.00
Reporting	0.11	0.04	0.00	0.00	0.00

Table 6. Human factor inherit error frequencies, HEP and organizational influencing factor.

Human factors	Inherit human error (event/plant/year) (HEP)	Human error probability factor (PSF*)	Organizational influencing
Monitoring	4.96E-04	6.38E-02	3.2
Control room actions	7.09E-05	4.26E-03	1
Communication	2.13E-04	2.55E-02	3
Manual on-field operations	6.38E-04	1.17E-01	5.1
Reporting	7.09E-05	6.38E-03	2

*PSF: Performance Shaping Factor.

Table 5 quantifies the conditional occurrence of human factor errors given the faulty organizational factors. For example: in column 2 and row 1, 0.44 shows that in past accidents whenever there was a problem with the "Training (T_O)", this scenario had 44% potential to led to an error in "Monitoring" activates performed by operators and subsequently caused an accident.

Since organizational "Training (T_O)" has great effect on the "Monitoring" activities, therefore in order to improve the operator's "Monitoring" activities, "Training (T_O)" of operators should be improved.

Table 5 also shows that all five organizational factors had a huge influence on "Manual on-field operations" in a plant. Therefore "Manual on-field operations" errors can't be reduced without proper organizational improvement.

On the other hand, "Control room actions" did not showed much influence from organizational factors except from the "Procedures (P_O)".

Hence, this analysis can provide quantification estimates of organizational influence on the human actions. After this analysis, industrial human actions can be improved by improving the right kind of organizational factor.

Table 6 demonstrates the human error frequencies which had led to notifiable accidents without having any influence from organizational factors (as per EMARS accidental reports); therefore these human error are called inherit human errors.

Table 6 provides the inherit error frequencies for different kinds of human actions. These inherit human error frequencies are calculated by considering only the accidents caused solely by human failures without any involvement of organizational factors.

Organizational influencing factor in Table 6 shows the number of times inherit human error frequencies can be increased considering a conservative approach.

3 HUMAN AND ORGANIZATIONAL FACTOR ASSESSMENT

In this section, the "Method for Error Deduction and Incident Analysis" (MEDIA) methodology is applied to human and organizational factors assessment. A combination of Failure Mode, Effects and Criticality Analysis (FMECA) and MEDIA will be presented for pigging operations. Risk quantification of this assessment is based on the results of statistical analysis of past accidents as explained in section 2.

3.1 *A case study: Pig launcher (pigging operation)*

Pigging operations are used in oil & gas sector for pipeline cleaning. A pigging operation consists of launching and receiving traps. In this study only

launching trap (launcher) is considered for HOF assessment. Figure 3 shows the pig launcher in a simple process flow diagram. Launching operation consists of number of properly sequenced human actions like purging, pressurization, venting, scraper loading and launching. Valves used in this operations are provided with an interlock therefore minimizing the risk of HOF failures.

A sample FMECA worksheet is used for the HOF analysis as reported in Table 8. In order to screen the risk through FMECA, a risk matrix is used extracted from IEC Standard (2000, p. 24) as shown in Table 7. Risk matrix in Table 7 ranks the risk according to frequency and consequence of failures and classify it in terms of high, medium and low risk.

FMECA sheet is slightly modified in order to use MEDIA along with conventional method for risk analysis as shown in Table 8.

In order to calculate the HOF risk through MEDIA, Equation 1 (Ahmad et al. 2014) is used.

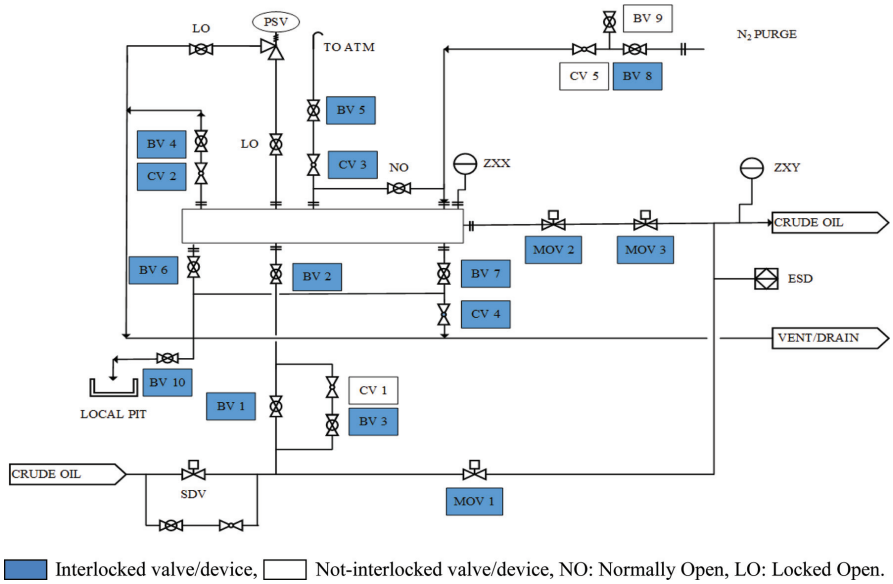

Figure 3. Pig launcher of a pigging operation.

Table 7. Risk matrix use in FMECA.

Consequence					Increasing probability			
Severity rating	People	Assets	Environment	Reputation	A	B	C	D
					Occurred in E&P industry	Occurred in operating company	Occurred several times a year in a company	Occurred several times a year in location
0	Zero injury	Zero damage	Zero effect	Zero effect	LR	LR	LR	LR
1	Slight injury	Slight damage	Slight effect	Slight effect	LR	LR	LR	LR
2	Minor injury	Minor damage	Minor effect	Limited impact	LR	LR	MR	MR
3	Major injury	Local damage	Local effect	Considerable impact	LR	MR	MR	HR
4	Single fatality	Major damage	Major effect	Major national impact	MR	MR	HR	HR
5	Multiple fatalities	Extensive damage	Massive effect	Major international impact	MR	HR	HR	HR

*LR: Low Risk (manage for continued improvement); MR: Medium Risk (incorporate risk-reducing measures); HR: High Risk (fails to meet screening criteria).

Table 8. HOF assessment through FMECA and MEDIA.

Task/action class	Potential failure of task	Plant's state	Potential effect (s) of failure (local)	Severity	Occurrence	Risk (from matrix)	Human Error Prob. (HEP) Table 6	Updated HEP (plant's state)	$Risk_{HOF}$ (Eq. 1) P = 0	$Risk_{HOF}$ (Eq. 1) P = 1
Monitoring	1: Fails to detect rupture of crude oil pipeline.	Normal	Potential explosion event	1	B	LR	6.38E-02	4.27E-02	4.24E-05	1.82E-04
	2: Fails to detect pressure rise in crude oil pipeline.	Pigging	Damage of pipeline	2	B	LR	6.38E-02	1.47E-02	1.46E-05	6.24E-05

$$Risk_{\mathrm{HOF}} = E \cdot e^{\mathrm{P}.\ln(X/E)} \cdot \left(\sum_{i=1}^{4} (N\ I\ Si \cdot i) \cdot R \right) \qquad (1)$$

where:
E = Inherit human errors (ev/plant/year);
P = Probability of human action failure given organizational characteristics, $0 \le P \le 1$;
X = Total number of human errors (ev/plant/year);
i = No. of safety layer associated to human actions;
$N\ I\ Si$ = Number of human action associated to ith safety layer;
R = Human Error Probability (HEP).

Equation 1 is developed using definition of risk (i.e. frequency × consequence). Number of factors were identified and recorded while conducting the analysis of past accidents with regard to HOF. These factors relate together in Equation 1 using iterations in order to ensure the theoretical concepts behind MEDIA.

1st term in Equation 1 represents the frequency as listed in Table 6, while 2nd term is the calibration term for this model which also consider the organizational influence through "*P*" value. The last term in this equation is the consequence term which involves the characteristics of a specific plant by taking into account the number of human interventions at each safety layer and also the failure probability of these human interventions.

In this analysis all the potential human interventions are categorized into five main classes as identified in Table 8.

Nine potential human interventions have been selected for further analysis. HOF risk is evaluated qualitatively by using the conventional risk matrix approach as indicated in Table 8 column 7. On the other hand, same interventions are also evaluated quantitatively using MEDIA approach as indicated in columns 10 and 11 of Table 8.

3.2 *MEDIA HOF risk quantification*

HOF risk can be quantified using Equation 1 as proposed by MEDIA. MEDIA also accounts for the criticality of an action by considering the associated safety layer of an action. Figure 4 illustrates the HOF risk associated to nine identified potentially critical human actions for zero organizational influence on human actions. X-axis shows the number of an action and Y-axis shows the obtained risk.

Action 3 has the highest associated risk since failure of this action had led to extensive accidents in the past. While, lowest risk is obtained for action 9 which is associated to "reporting" failure to management. Risk from action 5 to action 8 almost remains the same since it all involved the manual on-field operations.

3.3 *Comparison of risk at different levels of organization*

As mentioned earlier, an organization has an influence on human reliability, therefore in Figure 5 MEDIA model will be tested against four organizational influence levels to see the final obtained risk.

Figure 5 illustrates the effect of an organization on human actions. Associated risk to human actions increases as the influence of an organizational increases as represents by "P" values.

The curve with minimum level of organizational effect (P = 0) has lowest risk, while curve with the maximum level of organizational effect (P = 1) has the highest risk. The extent of change in risk with change in organizational level is determined by the calibration term in Equation 1. This calibration term is calculated from the analysis of past accidents across selected five type of human factor taxonomy.

Therefore, MEDIA model can provide consistent results against different influencing levels of an organization.

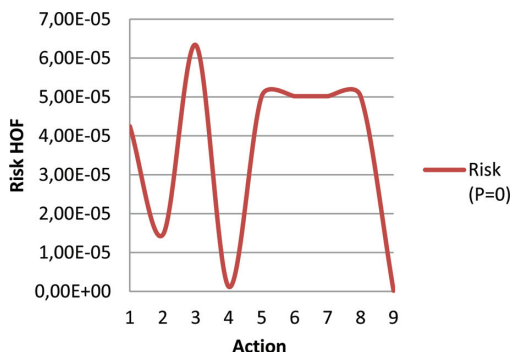

Figure 4. Chart of human factor risk with zero organizational influence.

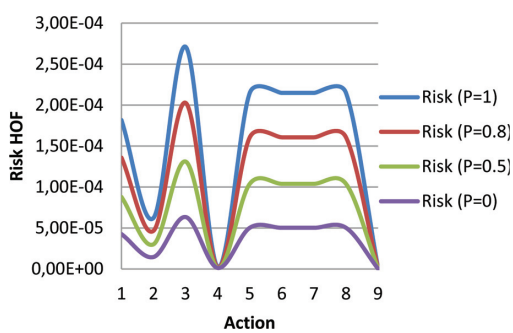

Figure 5. Chart of human factor risk with four organizational influencing levels.

4 DISCUSSION

It is very important to consider HOF in overall risk management. Major hurdle in HOF analysis arise due to lack of human unreliability database. Statistical analysis of past accidents can provides good estimates for potential human failures and effect of an organization on the outcome of human actions.

The statistical analysis of past accidents (1983–2013) confirmed the importance of organizational influence on human actions.

"Design" and "procedures" organizational factors have high degree of influence on human actions. Meanwhile, output from "Manual on-field" human actions has maximum tendency to be influenced from organizational factors.

Concluding the statistical analysis of past accidents, frequencies and probabilities of human failure were obtained for selected human factor taxonomy. This analysis is strongly based on data obtained from past accidents, therefore it will provide the fewer estimates of HOF errors compare to normal operational situation where near-miss events are also an important aspect to be considered.

In the second part of this study, a newly developed methodology "MEDIA" is applied to a case study.

Primarily, MEDIA is a methodology to quantify the human failure actions based on the past accidental database. At the same time, MEDIA also provides an added value to the analysis since it can also incorporate the organizational influence on human actions. This methodology is developed keeping in mind today's practical constraints posed by lack of information flow from a company to an outsource contractor about HOF analysis. P&ID's, cause & effect diagrams and organizational & human factor reviews can provide the necessary information for MEDIA human factor analysis, however results can be more precise with any other relevant information depending upon company's regional or international standards.

Various organizational factors have different influence on different kinds of human actions. Therefore, this analysis can provides the information about the right kind of organizational factor to be improved in order to improve the human factor.

Furthermore, in future it is expected to include the guidelines to use HOF as an extra safety barrier in order to optimize the existing resources.

Predictive Human Error Analysis in Permit To Work system in a petrochemical plant

M. Jahangiri
Department of Occupational Health, School of Health, Shiraz University of Medical Sciences, Shiraz, Iran

F. Zare Derisi & N. Hobobi
Student Research Committee, Shiraz University of Medical Sciences, Shiraz, Iran

ABSTRACT: Permit To Work (PTW) is a means of safety system to coordinate different work activities. However, it may be susceptible for human error. The purpose of this study was identification and analysis of human errors in PTW system using Predictive Human Error Analysis (PHEA) technique. The most important identified errors were; inadequate isolation of process equipments, inadequate labelling of equipment, and delay in starting the work after issue the work permit, improper gas testing, inadequate site preparation measures etc. Finally for preventing and recovering from the identified errors, site work permit form and its procedure was revised.

1 INTRODUCTION

According to industrial accident's investigation 60 to 90% of all accidents have directly been caused by human errors (Brazier et al. 2000). Increasing interest in this area has arisen partly from occurrence of a number of major accidents such as Flixbrough (1974), Seveso (1976), Tree Mile Island (1974), Bhopal (1984), Chernobyl (1986) and many other accidents where human error has played a significant role.

Human error defined as any situation in which an operator fails to do an activity within the tolerance of the system that can result in unacceptable or undesirable results (Roger et al. 2001).

Permit to work (P.T.W) is a formal written system to control certain types of work which are identified as potentially hazardous. This system may need to be used in high-risk jobs such as hot works, confined space entry, carrying hazardous substances, and electrical or mechanical isolation. In this system, responsible persons should assess the work and check safety at all stages. Moreover, permits are effectively a means of communication between site management, plant supervisors and operators, and those who carry out the work. The people doing the job sign the permit to show that they understand the risks and precautions necessary.

Although P.T.W is an integral part of a safe system of work and can help to properly manage the wide range of activities, it may be susceptible for human error itself. The purpose of this study was identification and analysis of human errors and proposing proper solutions for prevention of errors and reduction of theirs consequences in a petrochemical plant.

2 METHOD

In this cross-sectional study, permit to works system procedure in a petrochemical plant were studied for potential human errors. For this purpose, in the first stage occupational tasks in P.T.W procedure were analyzed using Hierarchal Task Analysis (HTA) (Stanton 2004).

Task analysis is description of the observable aspects of operator behaviour at various level of details together with some indications of the structure of the task (Embery 2000).

HTA is a systematic method to describe how work is organized in order to meet the overall objective of the job. It involves identifying in a top down fashion the overall goal of task, then various subtasks and the condition under which they should be carried out to achieve the goal (Stanton 2000). In this study all tasks that were selected as critical and susceptible to human error consequences were analyzed by HTA method and its information was gathered through observation method, interviewing with workers and reviewing procedures and documents.

In the second stage, Predictive Human Error Analysis (PHEA) technique was used for

predicting and analysis of human errors in each task. In PHEA worksheets, all possible errors in the selected occupational tasks were predicted and proper solutions for their preventing were determined. This technique is systematic and easy to learn and recommended for chemical process. Moreover, it is based upon HTA and error taxonomy and predict errors and their consequences (CCPS 2004, Brazier 2000).

Error classifications in PHEA are as follows (Kirwan 1997);

– Action errors (e.g. pressing a button or pulling a switch): Action too late/early; action too fast/ slow; action in wrong direction; action too little/much; wrong action on right object, action omitted, action incomplete
– Retrieval errors (e.g. getting information from a screen or manual): information not obtained; wrong information obtained; information retrieval incomplete.

Checking errors (e.g. conducting a procedural check): check omitted; check incomplete; right check on wrong object; wrong check on right object; checking too late/early.

Selection errors (e.g. choosing one alternative over another): selection omitted; wrong selection made.

Information communication errors (e.g. talking to another party): information not communicated; wrong information communicated; information communication incomplete.

In PHEA, each task analysed step by step in term of error type, error description and error consequences. Moreover, error reduction strategy and proper solutions for prevention and recovering from errors were determined and presented in PHEA worksheets.

3 DISCUSSION

Table 1 shows the hierarchical task analysis of P.T.W system procedure in the studied petrochemical plant. As it can be seen, 11 main tasks and 4 subtasks were identified in HTA process. Task No. 3 (Inspecting the workplace and complete the checklist section in the permit) had 4 subtask including venting process equipments from flammable and toxic materials, lock out and tag out the electrical equipment, cleaning the work area from flammable material and isolation of process equipment.

A sample of PHEA worksheet for prediction of human errors in each task has been presented in Table 2. As shown, in PHEA worksheets, apart from errors and their description, consequences of error occurrences and error reduction strategy for each task are determined. Error types and frequency of predicted errors in permit to work system in the studied petrochemical plant has shown in Table 3.

Table 1. Hierarchical task analyses of work permit system in the studied petrochemical plant.

1. Site inspection
2. Description of hot/cold work
3. Site preparation
   3.1. Venting process equipments from flammable and toxic materials
   3.2. Lock out and tag out the electrical equipment
   3.3. Cleaning the work area from flammable material
   3.4. Isolation of process equipment
4. Flammable gas testing
5. Oxygen and toxic gas testing
6. Specify the protective devices in the permit
7. Specify safety measures in the permit
8. Showing work area to operator
9. Site inspection by shift control
10. Signing the permit
11. Validation and revalidation after shift handover

Totally 67 errors were identified in all permit to work system tasks including 28 action error, 23 checking error, 8 retrieval error, 5 selection error and 3 information communication error.

Some of the most important errors identified in the PHEA worksheets were; inadequate isolation of process equipments, inadequate labelling of equipment, delay in starting the work after issue the work permit, improper gas testing, inadequate site preparation measures etc. 32% of predicted errors, were related to inadequate isolation of process equipments and hazardous energy source which are one of the main causes of accidents in process industries.

For preventing and recovering from identified errors, proper solutions were proposed. These solutions were mainly focused to;

1. Training: Inadequate training has been found to be one of the failures relating to the operation of P.T.W system (HSE, 2005). Effective training is essential to achieve quality and consistency in the use of the permit-to-work system. Some of human errors identified in the PHEA worksheets, were because of inadequate and shortcomings in training programs. Therefore, training needs in P.T.W system were determined specifically for each task in PHEA worksheets.
2. Work procedures: Studies have showed that 11 to 24% industrial accidents occurred due to lack and weaknesses related in procedures (Peterson 1996). Rasmussen's classified these errors as rule based errors (Kirwan 1997). In this study, some of human errors identified in the PHEA worksheets, were because of shortcomings in

Table 2. Sample of PHEA worksheet for prediction of human errors in permit to work system.

Task step	Error code	Error description	Error consequences	Control strategy
6. Specify required protective equipment in the permit	A3	Operator does not specify required protective equipment the permit	Workers may not use the protective equipment specified in the permit	Training and check the permit by supervisor
	A6	Operator specify required protective equipment too much	Unnecessary protective equipment specify in the permit and workers may not use tem	Training and check the permit by supervisor Revision of work permit form
	A7	Operator forgot to specify some of required protective equipment in the permit	Workers may not use all required protective equipment	Training and check the permit by supervisor

*For error codes refer to Table 3.

Table 3. Predicted human errors in permit to work system in the studied petrochemical plant.

Error types	Code	Description	No. of predicted errors
Action errors	A1	Action too late	–
	A2	Action too early	–
	A3	Action omitted	17
	A4	Action too fast	1
	A5	Action too slow	–
	A6	Action too much	1
	A7	Action too little	1
	A8	Action incomplete	8
	A9	Action in wrong direction	–
	A10	Wrong action on right object	1
Checking errors	C1	Checking too late	5
	C2	Checking too early	1
	C3	Right check on wrong object	2
	C4	Check incomplete	7
	C5	Checking omitted	8
Retrieval errors	R1	Information not obtained	5
	R2	Wrong information obtained	–
	R3	Information retrieval incomplete	3
Information communication errors	I1	Information not communicated	1
	I2	wrong information communicated	–
	I3	Information communication incomplete	2
Selection errors	Sel1	Selection omitted	1
	Sel2	Wrong selection made	3

P.T.W procedures. For this reason, proper solutions were proposed for revising P.T.W procedures and work permit form.

3. Hardware change in equipment design: The most effective way for preventing human errors is design plants and working methods to remove opportunities for error or provide opportunities for recovering them (Kletz 2000). Therefore for some of errors identified in PHEA worksheet, measures including labelling and colouring of process equipments, installing acoustic telephone booths for better communication in the site etc were proposed.

Finally for preventing and recovering from the identified errors, site work permit form and its procedure were revised totally.

4 CONCLUSIONS

Permit To Work (P.T.W) is a means of safety system to coordinate different work activities, but

it may be susceptible to human error. Predictive Human Error Analysis (PHEA) technique could be applied for prediction and analysis of human errors and providing proper solutions for preventing and recovering from the identified errors. These solutions could be in the area of training, labeling of equipments, coloring pumps and process equipments, installing acoustic telephone booths in the site for better communication etc.

Anticipating impacts of change on individual behaviors within a perspective of safety management

T. Côte, E. Rigaud & E. Garbolino
Mines ParisTech, CRC Sophia Antipolis, France

ABSTRACT: Technological or managerial changes aim improving a dimension of performance of sociotechnical systems, generally productivity, profitability or quality. In some circumstances changes can affect, as a side effect, system safety properties and facilitate occurrence of crisis situations or by decreasing system ability to mitigate crisis situations. Anticipating potential consequences of change on sociotechnical systems safety properties requires knowledge, method and tools covering the complexity of sociotechnical system. Objective of this paper is to present and apply a methodological framework aiming supporting the identification of impact of a change on individual and collective behaviors within the perspective of safety management.

1 INTRODUCTION

Organizational changes, defined as a "process of radical or marginal transformation of structures and skills that punctuates the process of evolution of organizations" (Grouard et al. 1998) or "any relatively permanent modification in a subsystem of the organization, provided that such modification can be observed by its members or people who are related to this system" (Collerette et al. 1997) are omnipresent in enterprises.

Among the diversity of these changes, some are injunctions coming from the strategic apex with a strong constraint of realization and relatively weak margins of manoeuvre (Autissier et al. 2012). Consequences are the launch of change management project aiming to transform the organisation as whished by the strategic apex.

Changes can affect safety performance. Several examples can be found where new technologies, new rules, new work organisation led to system failure, misunderstanding of situation by agent, creation of new system dependencies, loose of flexibility, etc.

Technology assessment (Westrum 1991) aims considering the potential consequences of new technological system. Several methods and tools exist to support such assessment. In the context of safety and security, brainstorming, expert groups and traditional risk assessment methods such as FMECA (Failure Mode, Effects and Criticality Analysis) are often used with the purpose of identifying potential risks related to the adoption of a new technology.

Objective of this paper is to present initial results of a research project aiming to understand and improve safety management tasks to be achieved during change processes.

First section is related to the presentation of the context of the project. Second section aims describing basis of the framework currently developed. Third section presents an inventory of dimensions to be considered by the assessment of potential consequence of a change on socio technical system safety performance. Fourth part describes a module aiming to support assessment of consequences of change on system situation awareness performance.

Some lessons of the realization of assessment on different cases are summarized in the conclusion and perspectives of development are presented.

2 CONTEXT OF THE RESEARCH

Occurrence of a change can affect safety performance of a system. In order to prevent them, risks analyses are conducted. In some industry like train transportation, studies is mandated by a regulation, in other industries studies are voluntary done.

In order to define the context of the project, empirical studies are conducted to understand practices and issues related to the realization of those studies.

A set of studies is conducted in order to understand safety issues of change management. Main results of those studies are:

– **Impact of change on safety performance is a key issue for safety management systems.** Changes occur everyday (new tools, new technology, new organization of work, etc.). Management of

related safety issues is mandatory or voluntary done.
- **Absence of global methods.** Analyses are done using methods like brainstorming; experts group or with the application of risks analysis methods but no global methodological guideline exist.
- **Technological dimension are well considered, study of human and organizational factors has to be improve.** Anticipation of potential technological failures well considerate but analyses of consequences of a change on human and organizational factors has to be improved.
- **Analyses are generally realized to late.** Risks analyses are considered by change management people as constraints and therefore are planned near the end of the process. Consequences are tensions when safety manager identify potential risks and ask to revise the change process.
- **Decisions are trade-off between conducting change and maintaining safety.** When change management process has to be modified for safety issues, a trade off between the two dimensions is searched between change and safety managers.
- **Safety management does not consider all changes.** There are rules to decide if an event is considered as a change and consequently studied by risk analyses.

Those empirical results structure methodological development in order to provide a method aiming to support change management based risk analyses with the finality to improve the consideration of human and organizational factors.

3 THE IMPACT FRAMEWORK

The IMPACT method aims providing a set of recommendations for a change process management before, during and after its realisation. It is based on a risk analyses approach. Consequences are identified through the application of an assessment strategy that is defined alongside an examination of the change considered.

Methodological guidelines support the application of the different steps to be achieved and a toolbox offers data acquisition processes and performance indicator assessment guidelines.

3.1 *Methodological guidelines*

The IMPACT method is structured with four phases.

- **Phase 1**: *General Outline*. Definition of an assessment strategy based on the description of the change studied, the system impacted and the selection of assessment modules.
- **Phase 2**: *Consequence identification*. Application of assessment modules with the perspective of identifying potential pacts of the change.
- **Phase 3**: *Risks and opportunities analysis*. Evaluation of risks and opportunities of each consequence.
- **Phase 4**: *Recommendations for decision-making*. Definition of recommendations for change management process and system safety management.

In order to support the application of the method a toolbox has to be developed.

3.2 *IMPACT toolbox*

The IMPACT toolbox aims to be constituted of two types of guidelines: data collection processes and performance indicator assessment processes.

A preliminary survey supports the identification of dimensions to be considered by process of definition of modules.

Three types of data collection processes are suggested:

- **Risk assessment**. Traditional risk assessment processes based on different methods (FMECA, HAZOP, THERP, CREAM, etc.).
- **Focus groups**. Focus groups is an approach that consists of asking a group of people about their feelings, opinions, and beliefs concerning an idea, a concept, a product, etc.
- **Simulation**. Simulation can be an efficient way to identify the consequences of a change on a system. Simple role-playing games or more elaborate simulations using technological facilities such as bridge, flight or crisis management simulators can be used in order to acquire information about the consequence of a change by, for example, comparing the execution of a given scenario with and without the application of the change.

Two levels of safety performance indicators are suggested based on the safety I versus Safety II theoretical context (Hollnagel 2014).

- **Safety I based consequences**. Consequences related to failure of a dimension of the system (technological, human or organizational) including change acceptance, non-technical skills definition and assessment; research and development activities, e.g. situation awareness, decision-making, communication, teamwork, leadership, stress, fatigue (Flin et al. 2008); control performance assessment (Hollnagel & Woods 2005); and risk governance e.g. pre-assessment, management, appraisal, characterization, evaluation and communication (Renn & Walker 2008).
- **Safety II based consequences**. Consequences related to capabilities of a system to sustain

required operations under both expected and unexpected situations. It includes resilience capabilities e.g. Respond, Learn, Monitor and Anticipate (Hollnagel et al. 2011); HRO abilities, e.g. Preoccupation with failure, Reluctance to simplify interpretations, Sensitivity to operations, Commitment to resilience, Deference to expertise (Weick & Sutcliffe 2001); Efficiency Thoroughness Tradeoff model i.e. Work ETTO, Psychological ETTO, and Organizational ETTO (Hollnagel 2009).

Research and development activities are conducted with the perspective of developing a first prototype of assessment module dedicated to the assessment of impact of change on human behaviour.

4 HUMAN—BASED CONSEQUENCES OF CHANGE ASSESSMENT INDICATORS

Objective of the module is to support assessment of potential impact of a change on the diversity and complexity of individual behaviors. Two preliminary assessment modules are considerate:

- **Societal and practical acceptance of change impacts assessment.** This module aims assessing the potential of the change to be at the origin of rejection by people for general or practical concerns.
- **Individual characteristics impacts assessment.** This module aims assessing the potential of the change to affect individual characteristics (stress, fatigue, etc.) and behaviors (observe, interpret, plan, etc.).

For each dimension, a list of preliminary indicators is proposed.

4.1 *Societal and practical acceptance of change conceptual model*

Societal and practical acceptance of change issues concern mainly innovative technology and are related to the question of acceptance of a technology.

4.1.1 *Societal acceptance of a new technology*

Societal acceptability is related to the potential of an innovation to be at the origin of a social problem. Social problem can be defined as "a condition that undermines the well-being of some or all members of a society and that is usually a matter of public controversy" (Macionis 2005) or as "the activities of individuals or groups making assertions of grievance and claims with respect to some putative conditions" (Spector & Kituse 1977). Social problem life cycle can be structured with six phases (Best 2008):

- **Claims making**. People make claims that there is a social problem, with certain characteristics, causes and solutions.
- **Media coverage**. Media report in claims makers so that news of the claims reaches a broader audience.
- **Public reaction**. Public opinion focuses on the social problem identified by the claims makers.
- **Policymaking**. Lawmakers and others with the power to set policies create new ways to address the problem.
- **Social problem work**. Agencies implement the new policies, including calls for further changes.
- **Policy outcomes**. There are various responses to the new arrangements.

In order to assess the potential of a change to be at the origin of social problems, a set of dimensions are considered. Table 1 presents dimensions that are considered.

4.1.2 *Practical acceptability of a new technology*

Practical acceptability is related to the perception by users of the utility of a technology for achieving their goals. This perception can be studied "a priori", assessment is based on the subjective representation of the technology and characterized its acceptability. It can be studied with an experimental use of the technology and characterized its acceptation. Finally it can be studied once

Table 1. Societal acceptance indicators.

Indicators	Description
Privacy	Concern over our accessibility to others: the extent to which we are known to others, the extent to which others have physical access to us, and the extent to which we are the subject of others' attention'
Confidentiality	Status accorded to data or information indicating that it is sensitive for some reason, and therefore it needs to be protected against theft, disclosure, or improper use, or both, and must be disseminated only to authorised individuals or organisations with a need to know"
Safety	Condition of being protected against physical, social, spiritual, financial, emotional, occupational, psychological, educational or other types or consequences of failure, damage, error, accidents, harm or any other event, which could be considered non-desirable.

integrated in users activities and characterized its appropriation (Terrade et al. 2009).

In order to assess the potential of acceptability, acceptance and appropriation of a change a set of dimensions are considered (Table 2).

Dimensions to be considerate by a diagnostic of a change potential of acceptance or of reject by society and end users have been presented in this section. These dimensions can be used, as basement by data collection processes.

4.2 *The individual perspective*

This is related to the presentation of a set of factors to be used for the diagnostic of potential impacts of a change on individual functions and characteristics.

Four individual functions are firstly considerate: Observe, Interpret, Plan and Communicate. Then individual characteristics of human stress and fatigue are discussed.

4.2.1 *Observe, interpret, plan and communicate*

Observation function aims gathering information by perception in the current situation (Endsley 1995, Flin et al. 2008). Failure modes of observation process are (Hollnagel 1998):

- **Observation can be missed**. A signal, an event or a measurement is missed.
- **A false observation can be made**. A response is given to an incorrect stimulus or event, an event or some information is incorrectly recognized or mistaken for something else.
- **Wrong identification can be made**. A signal or a cue is misunderstood as something else, the identification of an event or some information is incomplete or incorrect.

Information gathered by the observation process has to be processed to make sense of the situation in order to understand what is going on and the significance of data observed (Flin et al. 2008). Failure modes of interpretation process are (Hollnagel 1998):

- **Diagnosis is false**. Diagnosis of the situation is incorrect or incomplete.
- **Reasoning is false**. Induction or Deduction reasoning process lead to invalid results, Selection among alternatives is achieved with using incorrect criteria, hence leading to incorrect results.
- **Decision is false**. Agents are unable to make a decision; decision is wrong, decision does not completely specify what to do.
- **Interpretation is delayed**. Identification is not made in time or not made fast enough.
- **Prediction is incorrect**. A change not anticipated occurred, event developed in the main as anticipated but some side effects has been missed, speed of development has been misjudged.

Interpretation and prediction of the evolution of the events to be controlled information is used for planning decisions and actions to be performed (Flin et al. 2008). Failure modes of planning process are (Hollnagel 1998):

- **Plan is inadequate**. Plan is not complete, does not contain all the details needed or is wrong.
- **Selection of goals is wrong**. Priorities followed are wrong and goals have been wrongly selected.

Communication refers to the exchange of information, feedback, response, ideas and feelings. Failure modes of communication process are (Hollnagel 1998):

- **Communication failed**. The message or the transmission of information did not reach the receiver, the message was received, but it was misunderstood.
- **Information is missing**. Information is not being given when it was needed or requested, the information being given is incorrect or incomplete, there is a misunderstanding between sender and receiver about the purpose, form or structure of the communication.

4.2.2 *Stress and fatigue*

Stress is a "particular relationship between the person and the environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being" (Lazarus et al. 1984). Two types of stress are considered (Flin et al. 2008). Acute stress is sudden, novel, intense and of relatively short duration. It disrupts goal-oriented behaviour and requires a proximate response (Salas et al. 1996). Chronic stress is related to reactions of individuals of the variability of its environment such as an increase of the

Table 2. Practical acceptance indicators.

Indicators	Description
Utility	Utility is related to the total or partial correspondence between functions provided by the innovative system and actual and future users' needs.
Usability	Usability is related to a set of dimensions characterizing the ease of use of system functionalities (efficiency, ease of learning, man machine interface, errors prevention, satisfaction, etc.).
Acceptability	Acceptability is related to users' attitude and the correspondence between users' values and the innovative technology properties.

demand or a perception of having not enough time or resource to perform goals correctly.

With the perspective of assessing impact of change on stress of individual, source, symptoms and effects of stress are considerate (Flin et al. 2008).

Factors related to activities, demands, individual perception or work and general environment of the individual can create stress (Table 3).

Stressor Factors can create both individual and organisational symptoms. (Table 4).

Effects of stress can also be both individual and organisational. (Table 5).

All these indicators can be used to assess potential impacts of a change on the stress of individuals.

Fatigue can be define as "the state of tiredness that is associated with long hours of work, prolonged periods without sleep, or requirements to work at times that are 'out of synch' with the body's biological or circadian rhythm" (Caldwell et al. 2003). With the perspective of assessing impact of change on individual's fatigue, cause and effects of fatigue are considerate (Flin et al. 2008).

All these indicators can be used to build assessment process for assessing potential impacts of a change on human performance variability.

Table 3. Stressors factors.

Indicators	Description
Job demands	Too much, or too little time to complete tasks
	Too little or too much training for the job
	Boring or repetitive work, or too little to do
	Working environment (temperature, noise, etc.)
Control	Lack of control of work activities
	Lack of involvement in decision making
Superviser/ manager	Lack of support from manager and co-workers
	Unrealistic goals
Relationships	Poor relationships with others
	Bullying, racial or sexual harassment
Role	Uncertainty about work objectives and lack of clarity about responsibilities
	Staff feeling the job requires them to behave in conflicting ways
Change	Uncertainty about what is happening at work
	Fears about job security
	Restructuring of the job
Home: work interface	Family problems
	Dual-career marriages
	Life crises

Table 4. Symptoms factors.

Indicators	Description
Individual	Behavioral (absenteeism, abuse of drugs or alcohol, hostile behavior, apathy, distracted, etc.)
	Emotional (anxiety, cynicism, depression, irritability, etc.)
	Somatic (decline in physical appearance, chronic fatigue, infections, health complaints, etc.)
	Thinking (lack of concentration, reduced attention, difficulty in remembering, failures in planning, etc.)
Organizational	High absenteeism
	High labor turnover
	Poor quality control

Table 5. Effects of stress factors.

Indicators	Description
Individual	Physical ill-health
	Mental ill-health
	Burn out
Organizational	Apathy
	Chronically poor performance
	Frequent/severe accidents
	Prolonged strikes

Table 6. Fatigue cause and effect factors.

Indicators	Description
Cause of fatigue	Long hours of work
	Lack of sleep
	Stress
	Temperature extremes
	Noise
	Physical work
	Vibration
Effect of fatigue	Cognitive performance (reduced ability to cope with unforeseen rapid changes, less able to adjust plans, tendency to adopt more rigid thinking and previous solution, acceptability of lower standards of performance, etc.)
	Motor skills (less coordination, poor timing, etc.)
	Communication (difficulty in finding and delivering the correct word, speech is less expressive, etc.)
	Social (become withdrawn, more acceptance of own errors, less tolerant of others, neglect smaller tasks, less likely to converse, increasingly irritable, distracted by discomfort, etc.)

Next section will be dedicated to the presentation of a set of data collection process that can be used to structure assessment.

5 HUMAN—BASED CONSEQUENCES OF CHANGE ASSESSMENT MODULES

Indicators characterized in the precedent sections are used for realizing assessment modules.

Three types of assessment are considered:

- **"Before change" assessment**. Identification of potential consequences of change on system safety performance is realized before the occurrence of the change. Identification process of potential impact is based on systems' experts and end users perceptions of the change and of its potential consequences.
- **"During change" assessment**. Identification of potential consequences of change is realized during the change management process. Identification is based on the study of systems' experts and end users perceptions after the start of the change process or on the conduct of a pilot study.
- **"After change" assessment**. Identification of potential consequences of change is realized after the change management process. Identification is based on the study of systems' experts and end users perceptions after the change.

Two types of methods are proposed for building the assessment modules. Focus Group for studying impacts of change before, during and after the conduct of the change and human factors assessment methods for assessing impacts of changes during and after the conduct of the change.

5.1 *Focus group*

Focus groups are structured, attentively moderated group discussions that reveal a target audience's conscious preferences, recalled experiences, and stated priorities (Goodman et al. 2012).

Focus groups are good for finding desires, motivations, values and firsthand experience; Understanding fundamental issues and perceptions; Get attitudes and perceptions, thoughts and feeling; Identify and prioritize features of a product and Brainstorming.

Focus groups are not good for getting general information on usability as this can vary much among individuals and getting numerical results, which can be generalized, to a larger public.

The organization of a Focus Group requires defining:

- **The schedule**. In order to be successful, a focus group requires time for preparation and time for data analysis. The definition of a schedule allowing appropriate time for each step is important.
- **The target audience and scope**. The selection of the people that will participate to the focus group and the definition of the groups are important to have a climate allowing free exchanges and discussions.
- **The topics**. The definition of the topics of the focus group, based on the strategy of assessment will support the writing of the discussion guide that will help the animation of focus group.

With the perspective of identifying consequences of change, focus group can be used to get people perceptions about the new technology, the new organization or the new regulation. Organizing Focus Groups with representative of the different activities of a domain allows collecting elements about their perception about the pertinence of the change, the potential change resistances forces or the complementary actions to be followed in order to support the change process.

Focus group dedicated to the identification of potential consequences of change can be completed with the application of specific human factors assessment methods

5.2 *Human factors assessment methods*

Various human factors assessment methods can be applied with the perspective of identifying consequences of changes. Situation awareness measurement techniques and discusses in this section.

Situation awareness is related to the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning and the projection of their status in the near future (Endlsey 1995a). Different methods exist for studying situation awareness three approaches are presented thereafter.

SART (Situation Awareness Rating Technique) method (Taylor 1990) aims to assess ten dimensions related to situation awareness: Familiarity of the situation, complexity of the situation, focusing of attention, variability of the situation, information quantity, arousal, instability of the situation, information quality, concentration of attention and spare capacity.

Participants of the assessment perform a scenario and at key moments they are asked to rate the ten dimensions with a scale of one (low) o seven (high).

SAGAT (Situation Awareness Global Assessment Technique) method (Endsley 1995b) aims to assess three key dimension of situation awareness: Perception of the elements, Comprehension of their meaning and Projection of future status. A set of questions is defined after a task analysis and participants are asked to answer to them during freezes time of a simulation scenario.

SACRI (Situation Awareness Control Room Inventory) method (Hogg et al. 1995) is an adaptation of SAGAT method to assess situation awareness in control rooms. Assessment is based on three types of questions: Comparison between the current situation with that of the recent past, Comparison between the current situation with normal operations and Prediction of future situation developments.

5.3 *Preliminary experimentations*

Experimentation has been conducted with preliminary version of the method and of assessment modules.

First application was the study of a prototype of 3D chart for transport industry. Diagnostic of technology acceptance issues with focus group sessions and a set of simulation for assessing potential impacts on human factors in general and more specifically on operator situation awareness were conducted (Rigaud et al. 2012).

Second application was the study of the use of drones to monitor pipeline threats. Study of technology acceptance issues with focus group sessions and the potential of occurrence of emerging risks with role games were conducted (Zarea et al. 2013a, Zarea et al. 2013b).

Experimentations demonstrate the relevance of the approach. Nevertheless, dimensions to be improved have been identified related to the definition of experimentations protocol and of the use of the data collected to define recommendation for the change management process.

6 CONCLUSION AND PERSPECTIVES

Finality of this paper is to present preliminary results of a research project aiming to understands risks analysis during change issues and to develop a methodological framework to support assessment in helping to take in consideration human and organizational factors.

A methodological framework structured with four main phases is proposed. Application of the method is based on a set of data collection and performance modules. Current status of the development of the modules is discussed in the paper with the identification of dimensions to be considered for assessing impacts of a change on human performance and with the definition of an assessment framework aiming to support the assessment of impact on change on the Situation Awareness non technical skill before, during after the change conduct process.

Next phases of the work are the development and the experimentation of equivalent module for other non-technical's skills and for organizational capabilities.

Modeling and assessment of Performance Shaping Factors in construction

Y. Xenidis & K. Giannaris
Department of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece

ABSTRACT: Human reliability is a key issue for ensuring safety in all industries; however, while it has been thoroughly studied in other industries, limited research has been conducted in the construction industry. This paper constitutes a first step towards the development of a methodology for identifying, analyzing and calculating the significance of Performance Shaping Factors (PSFs) in the context of worksite operations of civil engineering projects. The adopted approach differs from the established methods, in terms of architecture and concept. The method classifies PSFs in three categories, namely organizational, human and environmental and maps with the help of network analysis their relations in respect with the occurrence of a specific human failure incident. The method's last stage is to quantify the significance of each PSF to the occurrence of the human error. It is anticipated that further development of this method will allow HRA's successful application in the construction industry.

1 INTRODUCTION

Human reliability is a critical parameter for safety and security in all industries. It is estimated that 70%–90% of all types of failures in all types of activities are directly or indirectly related to human error (Li et al. 2012). In the nuclear industry human-induced failures are 90% of the total recorded failures (French et al. 2011); this percentage is more than 80% for the chemical and petrochemical industry (Kariuki & Löwe 2007, French et al. 2011, El-Ladan & Turan 2012), 80%–90% for the marine and offshore industry (El-Ladan & Turan 2012, Kounavos 2012, Sundaramurthi & Smidts 2013), 60%–90% for the aviation industry (French et al. 2011, El-Ladan & Turan 2012), and 75% for infrastructure such as water supply, dams, buildings and bridges (French et al. 2011, Kounavos 2012).

Although automation would be expected to reduce the effect of human reliability on production processes, simply because it limits both the presence of humans and their level of impact on production, it seems that the exact opposite happens. On the one hand, the complexity and power of technological, automated and information systems is constantly raising, thus hardening their use and increasing the requirements for employees with special knowledge, skills and training to operate these systems; on the other hand, the increased level of control of several processes, which is achieved due to automation exceeds by far the level of control of the rest, human-dominated, processes, thus rendering the latter more critical than in the past. Therefore, Human Reliability Assessment (HRA) remains a critical parameter in production processes.

The last 50 years extensive research has been conducted with regard to HRA, focusing on various aspects, such as definition and modeling of human error, data and information collection and evaluation, HRA techniques, etc. (Groth & Swiler 2013, Kirwan et al. 2008). Several tools and methods have been developed, broadly grouped in three generations (Bell & Holroyd 2009). ATHEANA, CREAM, HEART, OHPRA, and THERP are some of the most applied HRA methods. Despite, the extensive research on the field, the following issues remain challenging and even controversial for researchers and practitioners (Groth & Swiler 2013, Colombo & Demichela 2008, Kennedy et al. 2007, Trucco & Leva 2007):

- Quality of Data. It is widely accepted that various data are required in HRA, which need to be retrieved from various sources such as related data and knowledge bases, experiments, and analysis of the organizational and behavioral structure of the specific organizations investigated per case. So far, a methodology for the integration of data sources for HRA has not been achieved, thus retaining the use of methods, which deal only with a small part of the data required for HRA.
- Inefficiency of exerts' judgments. Data inconsistency and fragmentation frequently renders

experts' judgments as an alternative for conducting HRA. The lack, however, of a robust methodology for the definition and quantification of the various parameters involved results to uncertain outcomes that depend on the experts involved, and the method adopted.
- Lack of consistent human error definition. Human error is defined in many similar yet distinct manners, thus resulting to the lack of a consistent approach for identification and, consequently, taking of response measures.
- Lack of integration of framework factors. It is acknowledged that human error is heavily affected by the working environment, the organizational structure and culture, and cognitive reasons. The difficulty in quantifying these factors results to their indirect introduction in the assessment of human reliability; moreover, these factors are, frequently, introduced to the analysis after the human error quantification stage, thus leading to an inconsistent consideration of the interdependencies between the factors that affect human error.
- Inefficiency in the presentation of human error root-causes. The identification and presentation of the root-causes of human errors would considerably improve HRA, because it would allow deeper understanding of the error-making process, more accurate quantification of the contributing factors, and less subjectivity in the analysis. The difficulties in the systematic and clear mapping of the cause-and-effect relations between technological, human and environmental factors in an error-making process has resulted to their partial inclusion in current HRA methods.
- Inadequate inclusion to the analysis of the positive impact from health and safety measures and proactive human actions. HRA methods, systemically, tend to overlook the effect of precautionary measures, actions and behaviors in the error-making process. This results to the exclusion from HRA of a significant part of the analysis, which renders the whole approach incomplete.
- Inadequate modeling of Errors of Commission (EoC). The number of inappropriate actions or performance failures by humans that may result to human errors, the difficulty of tracking down the impact of such events to an error-making process, and the difficulty to clearly identify the context wherein EoCs occur has resulted to their incomplete and inadequate modeling in current HRA methods.

The challenge to deal with the abovementioned issues motivated the research effort presented in this paper; however, HRA methods' improvement was not the single goal to pursue in this research. A literature review revealed that HRA methods are scarcely applied in the construction industry, which is an unexpected observation given that construction is: a) the sector with the worst performance in terms of occupational safety and health, worldwide (Eurostat Statistics Explained 2014, OSHA 2014), and b) a field of activity where human errors are by far the first reason for the occurrence of failures and accidents (Health and Safety Executive 2003).

Construction industry processes differ significantly from chemical, nuclear or aviation industry processes, where current HRA methods are mainly applied. A construction site is completely different from a nuclear or chemical plant in the following terms:

- Construction works are not automated, since normal construction equipment is mainly operated by humans.
- Construction site conditions are dynamic in nature and develop rapidly, thus limiting the capacity to response, in case of failures or accidents. Moreover, construction site conditions, are mainly determined by the performance and actions of the construction site personnel; in most of the cases, these actions and performance are neither standard, nor predictable due to the nature of the work that allows even for ordinary workers a certain level of initiative in everyday practice.
- Construction sites are open systems, which are affected by factors that very often are not controllable (e.g. supply chains) and even not predictable (e.g. weather).

Based on all the above, it is inferred that the application of HRA in construction industry is a challenging task, since it requires innovation to, concurrently: a) form an approach that will try to overcome the various inherent deficiencies of existing HRA methods, and b) apply it on a field where little, if any, experience is available. This paper is a step in performing this challenging task that focuses on the identification and modeling of Performance Shaping Factors (PSFs) in construction. The remaining of this paper is organized in the following way: Section 2, provides some necessary background in HRA that sets the theoretical framework of this research. Section 3 presents the proposed method for modeling PSFs in construction, while Section 4 presents a demonstration example of the method. The conclusions of this work are presented in Section 5.

2 BACKGROUND IN HUMAN RELIABILITY ASSESSSMENT

HRA has attracted much interest from researchers and practitioners, which have formed a theoretical

and methodological background that is not always clear even with regard to the fundamentals (e.g. definitions). This is normal, especially when the field is highly complicated and involves many uncertainties. In these cases, any new attempt to apply HRA requires first a brief review of the existing working definitions. Subsections 2.1 and 2.2 serve this requirement.

2.1 *Definition and classification of human error*
