Primary biliary cirrhosis (with or without CREST)
Antiphospholipid syndrome
Membranous and membranoproliferative glomerulonephritis
Drugs (mostly used as immunosuppressants)
Vascular disorders of the liver
Portal vein agenesis
Portal vein thrombosis and other obliterative lesions (portal obliterative venopathy)
Patent ductus venosus
Congenital extrahepatic portosystemic shunts
Veno-occlusive disease
Budd-Chiari syndrome
Hepatic arteritis/vasculitis
Hereditary hemorrhagic telangiectasia
Hematologic disorders
Acute leukemias
Myeloproliferative disorders
Non-Hodgkin's lymphomas
Hodgkin lymphoma
Castleman's disease
Hypereosinophilic syndromes
Aplastic anemia
Immunodeficiency syndromes
Hypogammaglobulinemia
Solid organ and cell transplantation (post-transplant NRH)
Liver transplantation
Renal transplantation
Bone marrow transplantation
Infections
HIV infection
Tuberculosis
Hepatic granulomatous disorders
Sarcoidosis
Microcirculatory disorders caused by hepatic tumors or metastases
Thorotrastosis

(*continued*)

Other congenital disorders
Turner syndrome
Multiple malformations
Familial pulmonary fibrosis
Familial nodular regenerative hyperplasia

often the disorder treated with the implicated drugs. In fact, the drugs involved are mostly immunosuppressive agents used in the treatment of autoimmune disorders, inflammatory bowel disease and transplantation, and agents employed in cancer chemotherapy.

Classical thiopurines (azathioprine and 6-mercaptopurine) are commonly used as immunosuppressants in transplanted patients and patients with inflammatory bowel disease (IBD), in both Crohn's disease and ulcerative colitis. Hepatotoxicity is considered to be a relatively rare adverse event and is generally characterized by an increase in routine liver test parameters without clinical symptoms and signs. However, azathioprine (AZA) is well documented to cause NRH as a hepatic side effect (Duvoux et al. 1991; Mion et al. 1991; Russmann et al. 2001; Daniel et al. 2005; Seiderer et al. 2006; Schumann et al. 2008; Blogowski et al. 2011; Seksik et al. 2011; review: Musumba 2013). Male gender seems to be a major risk factor by providing a predisposing pharmacogenetic profile of purine analogue metabolism (Daniel et al. 2005). Several studies have shown NRH in IBD patients treated with AZA (Ehmsen et al. 2008), but has also been found in other disorders treated with this agent, including multiple sclerosis (Mion et al. 1991). In patients with inflammatory bowel disease treated with AZA, NRH is however an uncommon complication. In a study of 1888 consecutive IBD patients treated with AZA, the cumulative incidence of NRH was 1.28 % at 10 years (Seksik et al. 2011). A vascular effect may be involved in AZA-induced NRH, as NRH has been found in association with veno-occlusive disease in one patient with AZA-treated ulcerative colitis (Russmann et al. 2001).

NRH has been reported as a complication of 6-thioguanine therapy, both when used as a cancer therapy agent and as an immunosuppressive agent. In IBD patients, NRH has been increasingly found in azathioprine- or 6-mercaptopurine-intolerant patients using 6-thioguanine as a rescue drug (Shepherd et al. 1991; Dubinsky et al. 2003; Geller et al. 2004; Shastri et al. 2004; de Boer et al. 2005; Seiderer et al. 2005; De Bruyne et al. 2006; Ravikumara et al. 2006; Ferlitsch et al. 2007; Teml et al. 2007). 6-thioguanine is closely related to 6-mercaptopurine and azathioprine and has principally been used in the treatment of hematological malignancies. It has been reported to cause hepatocyte damage and necrosis and veno-occlusive disease, the latter being the most characteristic hepatic side effect caused by 6-thioguanine. The prevalence of NRH in patients treated with 6-thioguanine varies considerably, being 27.1 % (Teml et al. 2007), 39 % (Zech et al. 2007), and 76 % of patients undergoing liver biopsy in a group of IBD patients with hepatic laboratory abnormalities (Dubinsky et al. 2003). Among patients with inflammatory bowel disease treated with 6-thioguanine, 53 % of those who had a liver biopsy showed NRH in the reticulin stain, whereas only 11 % of the NRH cases were identified in H&E sections (Geller et al. 2004). It was proposed that NRH in the setting of 6-thioguanine therapy may well be dose or level dependent, NRH being less common under low-dose therapy. In a prospective multicenter study of inflammatory bowel disease patients using low-dose 6-thioguanine for at least 30 consecutive months, 28 liver biopsies were analyzed. In 93 % of biopsies, no signs of NRH were found, and in 2 patients the findings were not conclusive (de Boer et al. 2008a). On the other, NRH also develops in thiopurine-naïve patients with inflammatory bowel disease. In one study having analyzed 83 liver specimens (61 % of them from Crohn's disease patients), NRH was observed in 6 % of the samples, suggesting that NRH is occurring in IBD without specific therapy (de Boer et al. 2008b).

NRH occurs in patients with colorectal carcinoma liver metastases treated with cycles of neoadjuvant 5-fluorouracil and oxaliplatin before major liver surgery (Hubert et al. 2007; van den Broek et al. 2009; Wicherts et al. 2011; Morris-Stiff et al. 2014). Pathogenetically, a disturbance of hepatic microvascular circulation caused by chemotherapeutic agents may be considered. It was found that patients treated by oxiplatin more often had NRH compared with oxiplatin-naïve patients with metastatic colorectal cancer (Wicherts et al. 2011). Oxaliplatin-based chemotherapy has been shown to cause severe hepatic sinusoidal obstruction (the so-called sinusoidal obstruction syndrome; Arotçarena et al. 2006; Rubbia-Brandt et al. 2006; Rubbia-Brandt et al. 2010), and microvascular hepatic changes were found to be significantly associated with oxiplatin therapy in patients with metastatic colorectal cancer (Ryan et al. 2010).

Cytosine arabinoside and daunorubicine used for leukemia treatment has caused NRH (Rosen et al. 1991). Transcatheter arterial embolization therapy of hepatocellular carcinoma can be followed by NRH due to disturbance of vascular supply (Kobayashi et al. 1993).

NRH is observed in HIV-infected patients (Fernandez-Miranda et al. 1993; Arey et al. 2007; Tateo et al. 2008; Bihl et al. 2010; Kochin et al. 2010) and is thought to be related to antiretroviral drugs, e.g., ART therapy and IL-2 therapy, probably caused by the known capillary toxicity of high-dose IL-2 leading to decreased hepatic sinusoidal blood flow in murine models (Podevin et al. 2006; Arey et al. 2007; Sandrine et al. 2007; Maida et al. 2008). Didanosine therapy is implicated in HIV-associated NRH (Sood et al. 2014). NRH in HIV-infected patients seem to be related to age and the cumulative exposure to nucleoside and nucleotide analogues (Cotte et al. 2011).

Autoimmune and Related Disorders

NRH develops in several collagen vascular disorders and has been found in rheumatoid arthritis (Rauström 1953; Harris et al. 1974; Reynolds and Wanless 1984; Goritsas et al. 2001; Ebert and Hagspiel 2011) and in patients with Felty's syndrome (Ellman et al. 1955; Blendis et al. 1974, 1978; Reisman et al. 1977; Belaiche et al. 1978; Guarda and Hales 1981; Thorne et al. 1982; Young et al. 1992; Moots et al. 1994). Rheumatoid vasculitis accompanying these disorders seems to play a significant role in pathogenesis (Young et al. 1992). Several reports document the development of NRH in patients with systemic lupus erythematosus /SLE (Kuramochi et al. 1982; Klemp et al. 1986; Perez Ruiz et al. 1990; van Hoek 1996; Matsumoto et al. 2000; Horita et al. 2002; Park et al. 2006; Leung et al. 2009; Vaiphei et al. 2011; Grover et al. 2014). In an older study of 33 histologically proven cases of SLE, the spectrum of liver diseases included cirrhosis, but not NRH (Runyon et al. 1980). Pathogenetically, vasculitic changes induced by SLE may be considered. Some reports document NRG in the setting of systemic sclerosis (Friguet et al. 1984; Matsumoto et al. 2000) and Sjögren's syndrome (Gonzalez-Alvaro et al. 1994). Also the rare instance of NRH associated with mixed cryoglobulinemia, cryoglobulin-induced obliterative vasculitis may be pathogenetically involved (Garcia Buey et al. 1987).

NRH was observed in association with hepatobiliary autoimmune disorders. Numerous observations document the association between NRH and primary biliary cirrhosis, a disorder rather often associated with portal hypertension already in early-stage disease (Kew et al. 1971; Lebrec et al. 1976; Nakanuma and Ohta 1987; Nakanuma et al. 1989; Castellano et al. 1992; Sasaki et al. 2006). In part of the patients, CREST syndrome was found in association with NRH and primary biliary cirrhosis, suggesting an overlap syndrome (McMahon et al. 1989; Riviere et al. 2010). Patients with autoimmune disorders and other diseases of the bile duct system undergoing liver transplantation may present with portal hypertension already in the precirrhotic stage of liver disease. A study of 306 liver explants of such cases has shown that NRH is a major cause of this form of portal hypertension; in patients in whom portal hypertension was the major indication for OLT, NRH was detected in 73 % and

obliterative portal venopathy in 55 % of explants (Abraham et al. 2006).

NRH has been found in association with mesangiocapillary glomerulonephritis and idiopathic membranous glomerulonephritis (McCulloch et al. 1981; Haratake et al. 1987; Haboubi et al. 1991).

Antiphospholipid Syndromes

IgG and IgA antiphospholipid syndromes (APS) are systemic autoimmune disorders characterized by the combination of arterial and/or venous thrombosis, thrombocytopenia, and presence of antiphospholipid antibodies in serum. Antiphospholipid antibodies (aPL) form a heterogeneous group of circulating autoantibodies found in the sera of healthy individuals and patients with autoimmune and infectious diseases. aPL are directed against anionic phospholipids or protein/phospholipid complexes, usually containing beta2-glycoprotein I or prothrombin, but also other proteins involved in coagulation, including protein C, protein S, and annexin V. Several reports document the association of APS and NRH (Keegan et al. 1994; Cadranel et al. 1996; Perez-Ruiz and Zea-Mendoza 1998; Klein et al. 2003; Gaya et al. 2005). An association between NRH and circulating aPL was also observed in patients with systemic lupus erythematosus and suggested to play a role in the pathogenesis of NRH of the liver, probably via thrombotic obliterative changes taking place in small portal vein branches (Perez Ruiz et al. 1990). Part of HIV-infected patients show acquired autoimmune protein S paucity and secondary thrombophilia, associated with obliterative portal venopathy and NRH (Mallet et al. 2009).

Vascular Disorders of the Liver

NRH can develop in several types of portal venopathies. It has been found in portal vein thrombosis (Fukai et al. 1992; Terayama et al. 1995) and portal obliterative venopathy associated with myeloproliferative syndromes (Wanless et al. 1980; Wanless 1987). In a study of 64 NRH cases detected among 2500 autopsies, obliteration of many small portal veins was seen in all cases, but only 4.7 % of these had evidence of portal hypertension (Wanless 1990). Several studies reported on the development of NRH in congenital absence of the portal vein (Arana et al. 1997; Tanaka et al. 2003; Tsuji et al. 2005; Peker et al. 2009). Congenital absence of portal vein occurs in association with other hyperplastic hepatic lesions, specifically focal nodular hyperplasia/FNH (De Gaetano et al. 2004; Schmidt et al. 2006). Hepatic nodular lesions corresponding to NRH were seen in patients with patent ductus venosus (Kim et al., 2004a) and congenital extrahepatic portosystemic shunts (Abernethy type 2 malformation; Lisovsky et al. 2011). Congenital portosystemic shunts can be associated with NRH (Pupulim et al. 2013). NRH was also observed in obliterative portal phlebopathy, e.g., induced by macroglobulinemia (Wanless et al. 1981). Extensive obliteration of portal vein branches by cancer cell emboli can cause NRH (Turk et al. 2013). NRH can develop in Budd-Chiari syndrome (Castellano et al. 1989; de Sousa et al. 1991; Rha et al. 2000). In a systematic study of Budd-Chiari syndrome based on 17 explanted livers, obstructive portal venopathy associated with NRH was a constant finding, supporting the view that Budd-Chiari syndrome is associated with complex disturbances of hepatic arterial and portal circulation and their sequelae (Cazals-Hatem et al. 2003). However, large nodular hyperplastic lesions, FNH-like nodules, and FNH are more common complications of Budd-Chiari syndrome than NRH. A well-established cause of NRH is veno-occlusive disease involving the small and terminal hepatic veins (Snover et al. 1989). NRH can occur in the setting of hereditary hemorrhagic telangiectasia (Wanless and Gryfe 1986; Scardapane et al. 2013).

Hepatic vasculitis may cause NRH, including polyarteriitis nodosa (Nakanuma et al. 1984; Matsumoto et al. 2000; Tanaka et al. 2012), vasculitis in collagen vascular disorders, in particular SLE, but also vasculitis/hepatic arteritis in

rheumatoid arthritis (Reynolds and Wanless 1984), Felty's syndrome (Reisman et al. 1977), and microvasculitis in idiopathic hypereosinophilic syndrome (Baker et al. 1991). Similar to other vascular disorders, blood vessel stenosis or obliteration in vasculitis is thought to promote a hepatocyte regenerative response.

Granulomatous Hepatitis

NRH is known to develop in the setting of sarcoidosis of the liver (Devaney et al. 1993), likely due to obliterative (granulomatous) microvascular alterations.

Hypogammaglobulinemia

NRH can occur in the setting of primary hypogammaglobulinemia, e.g., caused by common variable immunodeficiency (Ravindran et al. 1995; Smith et al. 1995; Arenillas Rocha et al. 2003; Carbone et al. 2005; Ward et al. 2008; Fuss et al. 2013), and has been described as the main liver disease in these disorders (Malamut et al. 2008). In a systematic study, NRH in primary hypogammaglobulinemia was histologically associated with lymphocytic intrasinusoidal infiltrate and was found in 87 % of the patients with a liver biopsy. As other patients without liver biopsy often showed cholestasis (52 %) and splenomegaly (46.5 %) it was expected that the prevalence of NRH in hypogammaglobulinemia is high throughout. An association with intrasinusoidal T cells, portal vein endophlebitis, autoimmune diseases, and peripheral lymphocytic abnormalities suggest an autoimmune mechanism for NRH in this setting (Malamut et al. 2008).

NRH in the Setting of Cell and Organ Transplantations

NRH can develop de novo in liver grafts (Gane et al. 1994; Devarbhavi et al. 2007). The development of NRH after orthotopic liver transplantation (OLT) has usually been ascribed to the use of azathioprine. However, there are also reports showing that NRH can emerge in OLT patients in the absence of azathioprine therapy. Fourteen patients of one study developed NRH 3 months to 11 years after OLT; a total of ten patients developed NRH within 4 years (early onset), and four other patients showed the alteration beyond 4 years of OLT (late onset). These patients may later develop portal hypertension. A total of seven symptomatic patients, all in the early-onset group, had features of portal hypertension with vascular abnormalities on Doppler ultrasonography that were preceded by the diagnosis of NRH (Devarbhavi et al. 2007). At a certain stage, NRH occurring in the context of liver grafts becomes an irreversible lesion (gane et al. 1994). NRH has been observed in the setting of bone marrow transplantation (Pezzullo et al. 2000) and following renal transplantation, whereby azathioprine may play a role in at least part of the patients (Bredfeldt and Havey 1981; Morales et al. 1987; Buffet et al. 1988).

Hematologic Disorders

NRH occurs in the setting of various hematologic disorders (review: Al-Mukhaizeem et al. 2004). It can occur in reactive disorders such as aplastic anemia (Gonzalez-Huezo et al. 2006), but more commonly it develops in the setting of hematologic malignancies, including acute lymphoblastic leukemia (Mesa Latorre et al. 1990), myelofibrosis, polycythemia rubra vera, and other myeloproliferative syndromes (Shorey et al. 1979; Wanless et al. 1990; Al-Mukhaizeem et al. 2004). NRH occurring in myeloproliferative disorders may be caused by obliterative portal venopathy following venous thrombosis (Wanless et al. 1980). In myelofibrosis with hepatic extramedullary hematopoiesis, obstruction of small hepatic vascular channels by hematopoietic cells is thought to the pathogenic mechanism of NRH. A vascular pathogenic role is suggested by the observation of NRH in the setting of light

chain deposition in the liver in a patient with Waldenström's macroglobulinemia (Voinchet et al. 1988). NRH is a known complication of mastocytosis and is thought to be related to portal venopathy and veno-occlusive disease occurring in this disorder (Mican et al. 1995). NRH was also observed in patients with several types of Non-Hodgkin lymphomas, including macroglobinemia Waldenström and T-cell lymphomas, or with Hodgkin's disease (Wanless et al. 1981; Zuber et al. 1989; Gonzalez-Alegre et al. 2004; Kataoka et al. 2006; Ciria-Bru et al. 2014; Lopez et al. 2014). NRH was also found in association with Castleman's disease, with a possible pathogenic role of IL-6 (Kiyuna et al. 2005).

Gastrointestinal Disorders

NRH has been observed in children and adult patients with celiac disease and portal hypertension (Riestra et al. 2001; Biecker et al. 2006). IgA anticardiolipin antibodies were reported in celiac patients with NRH, suggesting a pathogenic role of these antibodies in celiac disease (Cancado et al. 2006). NRH can occur in the setting of Crohn's disease (Petrovic et al. 2011).

Hepatic Microcirculatory Disorders Caused by Tumors

Multiple hepatic metastases can compromise the microcirculation of the liver and induced NRH (Minato and Nakanuma 1992). NRH has been observed in a patient with an advanced carcinoid tumor, thought to be caused by vasoactive hormones secreted by the tumor followed by intrahepatic microcirculatory disturbances (Al-Hamoudi et al. 2009). In other situations, NRH associated with liver tumors, including hepatocellular carcinoma, may be caused by tumor treatment, in particular hepatic arterial infusion chemotherapy followed by vascular damage (Kobayashi et al. 1993).

Thorotrastosis

Thorotrast, following injection as contrast medium can damage portal vein radicles (Isner et al. 1978) and induce NRH (Dachman et al. 1987; Beer et al. 1998).

Infections

NRH was observed in association with subacute infectious endocarditis (Knowles et al. 1975) and following liver tuberculosis (Rougier et al. 1978; Boursier et al. 2005).

Congenital Metabolic Disorders

NRH can develop in patients with chronic granulomatous disease. In a study of 194 patients, NRH was seen in nine patients, including 6 of 12 autopsy specimens (Hussain et al. 2007). As venopathy of the portal vein was found in 80 % and venopathy of the central veins in 63 %, a vascular etiology of NRH has to be considered. Patients with cystinosis can develop noncirrhotic portal hypertension, mainly due to a sinusoidal block caused by accumulation of crystal-laden Kupffer cells in the sinusoids and deposition of collagens in Disse space (Klenn and Rubin 1994; DiDomenico et al. 2004; Rossi et al. 2005). But also NRH is a are late complication of cystinosis, with an undefined mechanism (O'Brien et al. 2006). NRH has been found in hyperhomocysteinemia associated with portal vein thrombosis and pronounced vascular lesions both in portal venules and in arterioles (Buchel et al. 2005).

Other Congenital Disorders

There are rare observations of NRH in the fetal liver, associated with severe malformations (Galdeano and Drut 1991). NRH can occur in patients with Turner syndrome, the pathogenesis being unknown (de Lédighen et al. 1994; Thevenot et al. 1998; Roulot 2013). There are

very rare instances of familial NRH (Albuquerque et al. 2013).

Pathogenic Pathways

Why Nodules

The pathogenesis of nodules in NRH has been discussed in detail (Reshamwala et al. 2006). For many cases of NRH, a common pathogenic pathway seems to involve hepatic obliterative vascular damage inducing a post-ischemic regenerative response of hepatocytes, although such vascular changes are lacking in other cases (Ibarrola and Colina 2003), rendering the definition of a common pathogenic pathway difficult. A blood vessel-based mechanism is rather well established for the microvascular vasculitis which often accompanies rheumatoid arthritis, Felty's syndrome, SLE, and other collagen vascular/immune-complex-mediated autoimmune diseases. But why should stenosing arterial lesions promote hepatocyte regeneration, as the hepatocyte parenchyma depends on portal blood flow, and not on hepatic arterial blood flow? Based on a morphometric study of the liver of a patient with rheumatoid vasculitis it was proposed that the arterial lesions caused secondary portal venous obliteration and portal hypertension followed by NRH (Reynolds and Wanless 1984).

Partial Nodular Transformation of the Liver

Introduction

Partial nodular transformation of the liver (PNTL) is a rare hepatic condition of still unknown pathogenesis, characterized by hepatocyte nodules that replace certain regions of the otherwise noncirrhotic liver. The perihilar region of the liver is predominantly affected, a but a subcapsular localization or a restriction to certain liver segments are also known. Many patients with PNTL have noncirrhotic portal hypertension and portal vein thrombosis.

Epidemiology and Clinical Features

In 1966, Sherlock and colleagues described four cases of a liver disease showing multiple hepatocyte nodules in the perihilar area of the liver associated with bleeding from oesophageal varices, the latter being caused by portal hypertension. The authors termed this constellation, partial nodular transformation of the liver/PNTL (Sherlock et al. 1966). In the following years, several other cases were reported (Maillard et al. 1967; Classen et al. 1970; Dick and Gresham 1972; Variend 1978; Donoso 1980; Fletcher and Wight 1980; Shedlofsky et al. 1980; Sansonno et al. 1981; Pedinelli et al. 1983; Terayama et al. 1995; Hoso et al. 1996; Takahata et al. 1997; Hytiroglou and Theise 1998; Simizu et al. 2006). PNTL is a rare disorder and an uncommon cause of noncirrhotic portal hypertension. In a study of 107 livers of patients with noncirrhotic, long-standing portal hypertension (92 wedge biopsies and 15 autopsy specimens), PNTL was found in only two cases and was much less common than NRH (Nakanuma et al. 1996). PNTL is often diagnosed at an early age and seem to be more common in females of childbearing age. In one review of the literature, the mean age at presentation was 35 years (Pedinelli et al. 1983), i.e., later then many types of liver cirrhosis. PNTL also develops in the pediatric liver (Tsui and So 1993). PNTL has been found in a patient with persistent ductus venosus and hypoplasia of the major intrahepatic portal veins (Wanless et al. 1985).

Pathology

Macroscopy

Patients with PNTL often show a grossly nodular region occupying the perihilar area, while more peripheral parts do not show nodular change. The diameter of the nodules ranges from a few millimeters to 4 cm. On cut surfaces of the liver, dilated vessels in the center of polygonal nodules may be seen, the adjacent parenchyma protruding above the periphery of the nodules (Classen et al. 1970). Typically, the parenchyma outside the nodular area does not show any nodular changes. Larger

nodules of the perihilar liver area may compress portal vein branches (Dick and Gresham 1972). However, other hepatic regions may also be involved, often with marked enlargement of the affected area, e.g., the caudate lobe (Fletcher and Wight 1980), and in some patients, nodules are mainly found in otherwise atrophic subcapsular parts of the liver. In PNTL, the extrahepatic portal vein usually exhibits evidence of old thrombosis, and distortions and stenosis of intrahepatic portal vein branches are often found. The extrahepatic portal vein can show wall thickening and calcifications, residual changes after organized thrombosis.

Histopathology

The regenerative nodules are composed of in part enlarged hepatocytes with irregular nuclei, liver cell plates often being thicker than two liver cells. Similar to NRH, the reticulin network may be compressed or condensed between nodules. The nodularity of the parenchyma causes an irregular arrangement of portal tracts, with abnormal portal tract spacing. Portal vein branches in nodular areas or in the vicinity of nodules may show intimal fibro-elastic thickening (Dick and Gresham 1972). Portal tracts with some fibrous extensions and abnormal vessels are often located in the centers of nodules, with a radiating arrangement of hepatocyte plates. Within the nodules, the number of branches of the hepatic vein are considerably reduced (Classen et al. 1970). Portal tracts situated in the perinodular tissue show minor degrees of ductular proliferation, caused either by compression of intrahepatic bile ducts by nodules, or by a progenitor cell reaction. In part of the cases, perihilar nodule formation is associated with portal tract fibrosis and septal fibrosis, causing interlaced "calloused" strands associated with some lymphocytic infiltration (Classen et al. 1970).

Differential Diagnosis

PNTL may histologically resemble nodular regenerative hyperplasia with a focal expression pattern, but nodules in PNTL are often larger than those in NRH and show a distinct spatial distribution pattern in the liver, e.g., with a perihilar predominance, or involvement of a segment or a lobe. Patients with noncirrhotic portal hypertension may, in the absence of clear-cut NRH or PNTL, show a vague nodular hyperplasia of hepatocytes not surrounded by fibrous septa, mainly in stages with subcapsular parenchymal atrophy (Nakanuma et al. 2001).

Is PNTL the Same Alteration as Incomplete Septal Cirrhosis of the Liver?

Incomplete septal cirrhosis (ISC) is an enigmatic disorder characterized by macronodular liver change and the development of fine, thin and incomplete septa taking their origin in portal tracts (review: Schinoni et al. 2004). Definition of ISC and the elucidation of its pathogenesis pose difficulties, because (1) ISC may be associated with other nodular liver lesions, including NRH, PNTL and some forms of true cirrhosis; (2) at least some ISCs may represent nonactive macronodular cirrhosis with signs of reversion of the cirrhotic process and vanishing of complete septa; and (3) different criteria and interpretations as to what ISC is have been formulated. In fact, it has been proposed that ICS is not a disease as such, but rather a stage of progression and regression of liver fibrosis (Schinoni et al. 2004).

In livers with ICS, abnormal spacing between portal tracts and veins, crowding of reticulin fibers between adjacent zones of hyperplastic parenchyma, and hepatocyte hyperplasia have been noted (Sciot et al. 1988), alterations known for nodular regenerative hyperplasia/NRH. Noncirrhotic nodular change with increased fibrosis of portal areas with the penetration of a few thin strands of connective tissue into the parenchyma and isolation of single nodules just under the liver capsule has been described in idiopathic portal hypertension (see below; Ziarkiewicz-Wroblewska et al. 2004). Such a nodular pattern resembles that of PNTL, which may also be associated with minor degrees of portal tract fibrosis. One may therefore consider that ICS, PNTL and

NRH share common pathogenic pathways, in particular hepatic vascular damage, and represent different manifestations of the same pathologic process.

Pathogenic Pathways

PNTL as a Disorder Caused by Vascular Abnormalities

It has been suggested that the pathogenesis of PNTL is similar to that of nodular regenerative hyperplasia (NRH) and focal nodular hyperplasia (FNH), i.e., a regenerative hepatocyte response in the vicinity of hypoperfused atrophic parenchyma (Wanless et al. 1985; Kondo 2001; Kondo et al. 2004). This suggestion is supported by the observation of portal vein thrombosis in the immediate vicinity of coalescent nodules at the liver hilus (Terayama et al. 1995) and by rare situations where PNTL and NRH synchronously develop in the same liver (Shedlofsky et al. 1980). Kondo (2001) developed the concept that congenital vascular anomalies are the origin of benign nodular hepatic lesions (the anomalous portal tract syndrome, APTS). It has later been proposed that the concept of APTS may be helpful in understanding the clinicopathological and radiological features of various hyperplastic liver lesions (Ueda et al. 2011). Irrespective of the concept of APTS, which implies a congenital base of vascular change, several acquired forms of obstructive vascular alterations, mainly of the portal vein system, have been implicated as a cause of nodular hyperplastic lesions of the liver. Slowly developing parenchymal ischemia not leading to acute mass necrosis or liver infarction is thought to be the driving force for the regenerative hepatocyte response. This is typically expected for obliterative portal venopathy. A postischemic pathogenic pathway may also be assumed for cases where PNTL emerges around intrahepatic portal venous emboli of tumors, e.g., hepatocellular carcinoma (Hoso et al. 1996). PNTL has also been observed in the setting of extrahepatic portal obstruction (Simizu et al. 2006). Why differ nodules in nodular regenerative hyperplasia/NRH from those in PNTL? It has been proposed that in NRH obliteration of small portal vein branches leads to uniform small hepatocyte nodules, whereas in most cases of PNTL portal vein thrombosis with irregular recanalization causes larger nodules often near large portal vein branches (Wanless et al. 1985).

One unresolved question is to explain why this hyperplasic response is nodular instead of diffuse or other patterns. As, in contrast to liver cirrhosis, the nodules developing in NRH, PNTL and FNH are not surrounded by fibrotic tissue, a scaffold effect exerted by extracellular matrix does not seem to be a likely pathway. A nodular hyperplastic response may, therefore, have several causes or combinations thereof, e.g., an effect reflecting the geometry of the damaged vascular network and its finest ramifications; the creation of an abortive, not well regulated liver lobule; or the outgrowth of clonal cells in the form of a nodular hepatocyte colony.

PNTL and Related Hepatic Hyperplastic Lesions as a Cause of Noncirrhotic Portal Hypertension

Banti, in 1889, published his research on splenomegaly and anemia, probably including a variety of disorders that we now classify as forms of cirrhosis with portal hypertension, and noncirrhotic portal hypertension (Banti 1889). Guido Banti (born 1852 in Montebicchieri; deceased 1925 in Florence, Italy) is considered to be the most eminent Italian pathologist of the early twentieth century who, in addition to histological works, published the first Italian textbook of bacteriological technique. From 1882 to 1904, Banti studied various forms of spleen enlargement, then called primitive splenomegalies (noninfectious splenomegalies). During these investigations, he found the intricate relationship between splenomegaly, anemia, and chronic liver disease, a constellation later termed Banti's disease or Banti's syndrome. These findings paved the way for the later understanding of portal hypertension, congestive splenic disease, and splenogenic hematological disorders, although Banti thought that this constellation was a primary splenic disorder, a view refuted by William Osler already in 1900 (Ravenna 1940; Costa 1958; Grannis 1975). In the sixties of the last century,

Indian investigators described a distinct group of adult patients having portal hypertension in the absence of liver cirrhosis (Ramalingaswami et al. 1962; Wig et al. 1966). In the same time period it was reported that patients with portal hypertension without cirrhosis can show concentric thickening or sclerosis of the portal vein and its radicles, a condition termed "hepatoportal sclerosis" (Mikkelsen et al. 1965). Boyer and coworkers identified patients having portal hypertension in the absence of liver cirrhosis and proposed the term "idiopathic portal hypertension" (Boyer et al. 1967). The authors compared patients with "idopathic portal hypertension" with those having cirrhosis or extrahepatic portal vein obstruction and found that patients with portal hypertension associated with hepatoportal sclerosis had a better prognosis. As suggested by the term "hepatoportal sclerosis," many cases of noncirrhotic portal hypertension were attributed to stenosing lesions of the portal vein and its large branches, but it later emerged that stenosing lesions in the hepatic microcirculation can cause, or be associated with, the same type of blood flow disorder, including the entire spectrum of hyperplastic lesions of the liver.

Serum Amyloid A-positive Hepatocellular Neoplasms/Nodules

Introduction

In patients with alcoholic liver cirrhosis, distinct hypervascular hepatocellular nodules or neoplasms resembling inflammatory hepatocellular adenoma (IHCA) were detected. These atypical nodules occurred more often in males than females, were multiple (more than 3 lesions) in all patients, and were serum amyloid A positive and in part CRP positive, thus resembling the phenotype of IHCA, but with certain differences (Sasaki et al. 2012, 2013, 2014). These nodules may coexist with focal nodular hyperplasia-like nodules in alcoholic cirrhosis, but these FNH-like lesions showed focal or no immunoreactivity for serum amyloid A (Sasaki et al. 2013). In small fraction (11.8 %) of serum amyloid A-positive nodules, STAT3 mutations were identified (Sasaki et al. 2014). These nodules developing in livers with alcoholic cirrhosis may represent a novel form of inflammatory hepatocellular neoplasm.

Pathology

Histologically, the nodules displayed a hepatocellular cell lineage, increased cellular density, inflammatory infiltrates, sinusoidal dilatation, arteries with abnormally thickened walls, variable ductular reaction, and positivity for serum amyloid A. In contrast to other hepatocellular neoplasms these nodules were negative for glutamine synthetase and glypican-3 (Sasaki et al. 2012). One serum amyloid A-positive abnormal nodule was CRP positive (Kim et al. 2004b).

Hypervascular FNH-Like Nodules in Alcoholic Liver Disease (ALD)

In patients with chronic alcoholic liver disease (ALD) and subsequent liver cirrhosis, distinct hypervascular nodules may develop, lesions that may be confounded with small hepatocellular carcinomas. In one type of such nodules, randomly distributed lesions measuring 9–21 mm in diameter were detected by ultrasonography during follow-up of cirrhosis as hypoechoic or isoechoic nodules, were high attenuated in early phase CT and iso attenuated in delayed phase (without wash-out in the venous phase), showed hypervascularity on angiography, and histologically shared features with focal nodular hyperplasia (Nakashima et al. 2004). Other types of hypervascular hepatic lesions occurring in ALD ("type 2") were described by Kim and coworkers (2004b). The authors found hypoechoic nodules measuring 2–4 cm in diameter that were isodense in early CT images, hypointense in T1-and T2-weighted MR images, and markedly hypervascular in angiograms. The differential diagnosis included HCC, FNH, and angiomatous tumors.

The nodular lesions described by Nakashima et al. (2004) were macroscopically encapsulated in part of the cases and showed scar-like fibrosis in

more than half of cases (one nodule with central stellate fibrosis). Histologically, the nodules were devoid of portal tracts but contained scar-like fibrotic tracts containing artery-like and vein-like anomalous vessels, and inflammatory cell infiltrate, and a ductular reaction along the interface of fibrotic tracts. Hepatocytes in the nodules showed iron overload, mainly in encapsulated nodules. Fatty change of Mallory-Denk bodies were not found. The lesions were interpreted as FNH-like nodules which are found in several types of liver cirrhosis (Nakashima et al. 2004). The lesions described by Kim and coworkers (2004b) either showed the histology of large hyperplastic hepatocyte nodules with hypercellularity and a trabecular pattern, or nodules showing fibrosis in the absence of hepatocyte hyperplasia, in part with stellate scar-like fibrosis, i.e., resembling FNH. It follows that larger hypervascular liver nodules developing in chronic ALD cover a spectrum of lesions ranging from hyperplastic nodules with increased vascularity to FNH-like lesions.

Regenerative Nodules in Alagille Syndrome

Introduction

Alagille syndrome (synonyms: arteriohepatic syndrome, arteriohepatic dysplasia, syndromatic hepatic ductular hypoplasia, Alagille-Watson syndrome) is a congenital mostly autosomal dominant disorder that manifests as cholestasis in infancy, related to progressive intrahepatic bile duct paucity. The syndrome is also characterized by a characteristic facies, vertebral malformations (butterfly vertebra), eye abnormalities (posterior embryotoxon), retarded physical, mental, and sexual development, and a mesosystolic murmur caused by pulmonary stenosis (Alagille et al. 1975). About 39 % of patients also have renal involvement, mainly renal dysplasia. Histologically, intrahepatic bile duct paucity and associated fibrosis increase with age and may result in secondary biliary cirrhosis (Emerick et al. 1999). Alagille syndrome is known to complicated by hepatocellular carcinoma (Rabinovitz et al. 1989; Le Bail et al. 1990; Perez Becerra et al. 1991), but also benign hyperplastic nodular lesions develop in this condition.

Alagille syndrome type 1 (ALGS1; OMIM 118450) is caused by mutations (haploinsufficiency) of the Jagged1/JAG1 gene located on chromosome 20p12.2. The JAG1 gene product is the ligand for the Notch receptor. Mutations in JAG1 can be found in more than 90 % of Alagille syndrome patients. ALGS2 (OMIM 600275) is caused by mutations in the NOTCH2 gene. Notch2 receptor mutations account for less than 1 % of Alagille syndrome patients. A very rare autosomal recessive variant of Alagille-like syndrome not related to a mutation of the JAG1 has also been reported (Dyack et al. 2007).

Regenerative Liver Nodules in Alagille Syndrome

A patient with Alagille syndrome died at age 17 years, autopsy showed liver cirrhosis and large hyperplastic liver nodule interpreted as a hamartoma resembling focal nodular hyperplasia/FNH (Nishikawa et al. 1987). A 6-year-old boy with liver cirrhosis caused by Alagille syndrome showed, on CT images, a high-density nodular lesion in the right liver lobe. In the liver explant of OLT, the nodular region was large and lobulated, clearly distinguished from the surrounding hepatic tissue. Histologically, the lesion consisted of hyperplastic hepatocytes (Torizuka et al. 1996). In a boy with ALGS1, pre-transplantation CT and MRI examinations revealed a large hepatic lesion associated with multiple small nodular lesions, representing hepatic nodular hyperplasia (Tajima et al. 2001). Hepatic hyperplastic changes were also observed in adults with ALGS1. Pseudotumorous hyperplasia of the caudate lobe has been found in an 31-year-old female patient with Alagille syndrome. The caudate lobe was increased in size (Tuset et al. 1995). Syed and coworkers (2008) reported the multimodality imaging features of two patients with Alagille syndrome and hepatic regenerative nodules. One patient had a lesion

with a diameter of 3.8 cm, while the second patient showed a mass of 10.5 cm diameter, illustrating that nodular regenerative lesions in Alagille syndrome can grow to large size and may be confounded with HCC.

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_119

Abstract

Pseudotumors and inflammatory pseudotumors form a heterogeneous group of lesions characterized by the presence of an inflammatory infiltrate and proliferations of fibroblasts and myofibroblasts. Pseudotumors are mass-forming lesions, also in the hepatobiliary tract, that may mimic diverse malignancies. Specifically, pseudotumors can grow in the walls of extrahepatic bile ducts, with formation of stenosing and obstructive lesions clinically similar to cholangiocarcinoma. The term inflammatory myofibroblastic tumor (IMT) has been proposed as synonym for pseudotumor, with a generally benign behavior. However, a subset of these lesions show an aggressive growth pattern and even malignant behavior, suggesting a neoplastic character of some pseudotumors. Furthermore, about half of recently analyzed cases of IMT carry rearrangements of the anaplastic lymphoma kinase (ALK) locus on chromosome 2p23, causing aberrant ALK expression. Based on these findings, the classification of so-called pseudotumors, mainly the identification of reactive versus neoplastic forms, requires revision. A variant lesion that is sometimes classified together with IMT is Epstein-Barr virus-positive inflammatory pseudotumor (inflammatory pseudotumor-like follicular dendritic cell tumor).

Hepatobiliary Pseudotumors: A Heterogeneous Group of Intriguing Lesions

Introduction

Hepatic lesions resembling or being identical with inflammatory pseudotumors observed in other organs and in particular the lung of young male patients are now well recognized. The first reports on primary hepatic inflammatory pseudotumor (HIP; synonyms: pseudolymphoma, fibroinflammatory tumor, inflammatory myofibroblastic tumor, plasma-cell granuloma, inflammatory pseudotumor-like granuloma) date back to the 1950s–1970s (Pack and Baker 1953; Hertzer et al. 1971; Someren 1978), the case of Pack and Baker representing a 40-year-old man. Since that time, many cases have been described, albeit mostly as single reports or small series hepatic inflammatory pseudotumors (HIP; review: Craig 1997) now become increasingly recognized because of the more frequent use of advanced abdominal imaging methods, in particular ultrasonography and CT. But what is a "pseudotumor" ?

Pseudotumors: A General Overview

The term pseudotumor is, as such, rather a misnomer and may in fact be a very inaccurate term: a tumor, in its original meaning, is a mass lesion of whatever cause and composition, although now being more and more reserved for a bona fide neoplasm; so, what is a "pseudo-mass," and what is an adequate definition of it ? "The term is typically employed to connote the presence of a mass lesion (which, by definition, is a tumor)" that on clinical or pathologic grounds, or both, is thought to represent a neoplasm. Thus, the name "pseudoneoplasm" would be more à propos under such circumstances (Wick and Ritter 1997). The two authors just cited employ the term, "pseudoneoplastic lesions," but they will be right in their introductory statement that, even though the term is utterly unsatisfactory, it will remain in the active medical literature, because of the difficulty that is generally encountered in challenging an established clinicopathologic rubric. First employed to denote orbital masses producing exophthalmos (Birch-Hirschfeld 1930), pseudotumors have later been subdivided in accordance with predominant histologic features, including "inflammatory," "granulomatous," "xanthomatous," " plasmacellular," and "fibrous" variants. It has to be emphasized that, even though such adjectives may offer some (primary or first line) help in classification, they unfortunately surmise that the lesions so denoted may represent "entities." This approach operates such as general pathology or pathophysiology would not exist: it is obvious that a reactive process driven by an

exuberant inflammatory response may later develop fibrosis, or may accumulate numerous lipid-laden macrophages subsequent to hemorrhage or necrosis, classifying adjectives and therefore identifying a type of response within a timely sequence rather than an inherent feature. More interesting (and probably also more important) is the phenomenon as to why such apparently nonneoplastic lesions exhibit excessive growth, may show invasive characteristics, and may or may not spontaneously regress, in some way reflecting the behavior of an abnormally healing wound.

Inflammatory Pseudotumor Versus Inflammatory Myofibroblastic Tumor

The term inflammatory myofibroblastic tumor (IMT) has been proposed as a synonym of inflammatory pseudotumor and characterized as lesions containing myofibroblastic spindle cells and a mixed pattern of leukocytic infiltrates, including plasma cells, and exhibiting a generally benign behavior. The majority of lesions previously described as inflammatory pseudotumors meet this definition, but cases reported in past decades were described as having "spindle cells" often interpreted as fibroblasts, because the myofibroblast concept and the immunohistochemistry to identify myofibroblasts were not yet developed. However, the spectrum of IMT and related lesions has recently evolved along several lines, causing some misconceptions or even confusion regarding classification. First, a subset of IMT show an aggressive growth pattern and a malignant behavior rather than a benign phenotype, sometimes with formation of metastases ("aggressive form of IMT"). Based on this behavior, some IMTs were classified as neoplastic lesions, or reactive lesions, that have undergone malignant transformation. Secondly, about half of recently analyzed cases of IMT carry rearrangements of the anaplastic lymphoma kinase (ALK) locus on chromosome 2p23, causing aberrant ALK expression. As these lesions markedly deviate from the "purely" inflammatory and mixed-cellular forms of inflammatory tumors, mainly due to their neoplastic nature, these lesions are treated in a separate chapter.

Pseudotumors as Neoplastic Versus Reactive Processes

Is HIP a reactive or a neoplastic process? Some features have been quoted that seemingly contradict the purely reactive/inflammatory nature of these lesions, including a progressive growth; a local recurrence; the development of noncontiguous, multifocal masses; an infiltrative border; the destruction of liver substance and bile ducts; and the vascular (portal-venous) invasion (Coffin et al. 1998). However, the histologic pattern of the majority of the lesions, lacking one typical target cell, their usually benign course, and the tendency for spontaneous regression do, on the other hand, not favor a bona fide neoplastic process. We therefore propose that the majority of HIPs are in fact reactive lesions, i.e., pseudotumors, but that a subset of hepatic lesions with a similar morphology have a neoplastic phenotype, in particular those with a proliferation of follicular dendritic reticulum cells. These lesions are discussed in the following chapter. In addition, there might be instances where part of a mass exhibits the histologic features of HIP, but this component may represent a reaction to a hidden and later overt malignant neoplasm, e.g., a sarcoma, thus initially causing the false impression of malignant HIP.

Inflammatory Pseudotumor of the Liver (Hepatic Inflammatory Pseudotumor, HIP; Hepatic Inflammatory Myofibroblastic Tumor, HIMT), Probably Reactive Forms (Excluding IgG4-Related Disease)

Introduction

The lesions described in this section comprise reactive phenotypes that, on the one hand, correspond to what has been described as inflammatory pseudotumors in the "pre-myofibroblast era" and

to lesions now termed inflammatory myofibroblastic tumors, however with the exception of those which have documented ALK gene rearrangements, expression of EBV, and/or signs of a bona fide neoplastic cell lineage. Also inflammatory pseudotumors developing in the setting of systemic IgG4 sclerosing disease are excluded from this section and are discussed in a separate chapter. As specified above, "type A" as a working formulation denotes a heterogeneous group of reactive and probably nonneoplastic lesions that awaits further classification. For this purpose, the older term, inflammatory pseudotumor, is employed in this section, also for comparative lesions in regard to the older literature.

Epidemiology

HIP has been first described in 1953 (Pack and Baker 1953) and has since been documented numerous times in the literature, mostly under the term inflammatory pseudotumor, notwithstanding the fact that the term inflammatory myofibroblastic tumor was already coined in 1995. HIP occurs at all ages. The age of the patients at presentation of the lesion ranges from infancy (3 months; Lee and DuBois 2001; 9 months; Lacaille et al. 1999) or early childhood up to more than 80 years, with a male to female ratio varying considerably from one series to other, from about 1:1 up to 8:1 (Horiuchi et al. 1990; Shek et al. 1993). HIP occurring in the pediatric age group has been reported several times (Someren 1978; Newbould et al. 1992; Passalides et al. 1996; Bankole-Sinni et al. 1997; Ueda et al. 2003; Swinney et al. 2006). The overall prevalence of HIP is not known, but in a study on 403 consecutive patients carrying a total of 717 focal liver lesions and undergoing liver resection, three patients proved to have HIP accounting for 0.7 % of all patients and 0.4 % of all focal liver lesions (Torzilli et al. 2001). The features of the lesions have been described in numerous reports.

et al. 2009; Ueda et al. 2009; Al-Jabri et al. 2010; Brage-Varela et al. 2010; Bruyeer and Ramboer 2010; Deng et al. 2010; Sari et al. 2010; Tang et al. 2010; Terada 2010; Faraj et al. 2011; Hasan et al. 2011; Herek and Karabulut 2011; Jerraya et al. 2011; Ntinas et al. 2011; Renzing et al. 2011; Kawaguchi et al. 2012; Patnana et al. 2012.

Clinical Features

The lesions are mostly solitary (multiple in about 20 %), more frequently right sided (about 60 %), and located within the liver substance or extended into the hilar/perihilar area. However, multiple nodules of HIP occur and may mimic liver abscesses, primary hepatic malignancy, or hepatic metastases. The size of the lesions is variable but may reach a diameter of up to 25 cm. HIP may clinically present as fever of unknown origin (FUO; mainly low-grade intermittent fever), malaise, vague abdominal symptoms and pain, an epigastric mass, a history of weight loss, jaundice, and/or laboratory data suggesting an inflammatory process (leukocytosis, raised erythrocyte sedimentation rate, polyclonal hyperglobulinemia). In part of the patients, HIP was asymptomatic and was detected as an "incidentaloma" or liver metastasis. In case the masses develop close to large bile ducts or within the bile duct wall, HIP may cause stenosis of intrahepatic bile ducts and sometimes obstructive jaundice, either due to involvement of the hilar compartment of the liver and/or large extrahepatic bile ducts, sometimes mimicking perihilar bile duct carcinoma, or as a disease centered around the intrahepatic biliary tree, or involving both the hepatobiliary and pancreatic system. HIP evolving with a ductocentric pattern can develop a hamartoma-like growth associated with fibrosclerosis, a lesion proposed to be termed "fibroductal variant" of HIP (Terada et al. 1992). HIP can develop in extrahepatic bile ducts, including the mid-portion, and closely mimic cholangiocarcinoma (Vasiliadis et al. 2014). HIP also occurs in the distal part of the common bile duct, i.e., close to the pancreatic head (Haith et al. 1964). A further distinct feature of HIP is endophlebitis, sometimes obliterative, involving medium-sized to large branches of the portal vein and eventually resulting in portal hypertension (Kaneko et al. 1984; Chen 1984; Heneghan et al. 1984; Horiuchi et al. 1990; Tsao et al. 1990), and also developing in young children (Someren 1978), sometimes with the angiographic demonstration of the portal vein draining into the lesion to be occluded (Hata et al. 1992).

In a minority of cases, HIP may undergo spontaneous regression. This regression process may take several months and can occur in the absence of any treatment, owing to unknown reasons, but it may be assumed that HIP regress when the causative factors, in particular infection, have disappeared (Gollapudi et al. 1992; Levy et al. 2001; Biecker et al. 2003; Druez et al. 2005; Koide et al. 2006; Tsou et al. 2007; Yamaguchi et al. 2007; Peddu et al. 2008; Chong et al. 2009; Brage-Varela et al. 2010; Jerraya et al. 2011). Regression of HIP has been achieved by treatment with nonsteroidal anti-inflammatory drugs (Colakoglu et al. 2005; Vassiliadis et al. 2007).

Imaging Features

Ultrasonography usually reveals hypoechoic and well-circumscribed masses (Abehsera et al. 1995; Nam et al. 1996; Sakai et al. 2002). As sonography sometimes reveals enlarged locoregional lymph nodes, a primary hepatic malignancy may be suspected (Fukuya et al. 1994; Schuessler et al. 2006). At non-enhanced CT, HIPs appear as an irregularly shaped, inhomogeneous mass with an internal low-density area in the delayed phase (Noi et al. 1994; Lim and Lee 1995; Lee and DuBois 2001; Nishimura et al. 2005; Goldsmith et al. 2009; Herek and Karabulut 2011) or ill-defined, hypoattenuating lesions, whereas at contrast-enhanced CT, the masses exhibit central hypoattenuating areas with an iso- or hyperattenuating and thickened periphery or a multiseptate appearance (Yoon et al. 1999). HIP may show calcifications (Lacaille et al. 1999). Changes in tumor size during relatively short

time periods are often observed in HIP, in contrast to most other hepatic mass lesions. An enhancement of the peripheral regions of HIP was often observed in the early phase of contrast medium dynamic CT, thought to be due to abnormal vessels located in peripheral parts of the lesions and to result from obliteration of preexisting vessels in portal tracts within the inflamed tissue (Seki et al. 2004). HIP may present capsular retraction as an uncommon imaging fining (Ganesan et al. 2009).

Findings at MRI have been reported several times (Flisak et al. 1994; Kelekis et al. 1995; Borgonovo et al. 1998; Yan et al. 2001; Sakai et al. 2002; Hasan et al. 2011), showing no early arterial enhancement (a key difference to hypervascular HCC), peripheral enhancement, septum and small nodular enhancement occurring in portal venous, and delayed phases. MRI with mangafodipir trisodium might help distinguish HIP from HCC (Materne et al. 1998; Mortele et al. 2002). On post-gadolinium gradient-echo (GE) images, an early, intense, and peripheral enhancement was followed by a homogeneous, complete, and persistent enhancement, and during follow-up, a peripheral intense rim appeared on precontrast T1-weighted images (Mortele et al. 2002). Due to the high content in metabolically active cells of diverse leukocyte lineages, HIP can be diagnosed by PET based on its markedly increased 18 F-FDG uptake (Kawamura et al. 2006; Chong et al. 2009). The high macrophage content of most HIP allows the detection of these lesions by use of ferumoxide-enhanced MR imaging (Kato et al. 2004).

Pathology

Macroscopy

At gross examination, HIPs are rather firm or even hard masses (depending on the collagenization) with usually sharp margins. The cut surface is variegated, gray to whitish or yellow, and sometimes with signs of hemorrhage and/or necrosis (Figs. 1 and 2).

Histopathology

Histologically, the "background" tissue consists of fibroblasts/fibroblastoid cells and myofibroblasts. The cellularity of the spindle cell component may be so abundant that these areas may be misdiagnosed as sarcoma. The spindle cell areas are frequently heavily collagenized, producing a hyaline or sclerosed aspect of the tissue. The vascularity may be high, reflected by the imaging presentation as a vascular tumor (Shek et al. 1993). The tissue is densely infiltrated by a mixed population of leukocytes, usually with a predominance of small lymphocytes. In some instances, the lymphocytic infiltration exhibits a density and a monomorphic presentation

Fig. 1 Inflammatory pseudotumor of the hepatobiliary tract. A whitish tissue has developed around intrahepatic bile ducts, causing duct stenosis

Fig. 2 Stenosing inflammatory pseudotumor of the extrahepatic bifurcation. The lesion macroscopically mimics stenosing cholangiocarcinoma

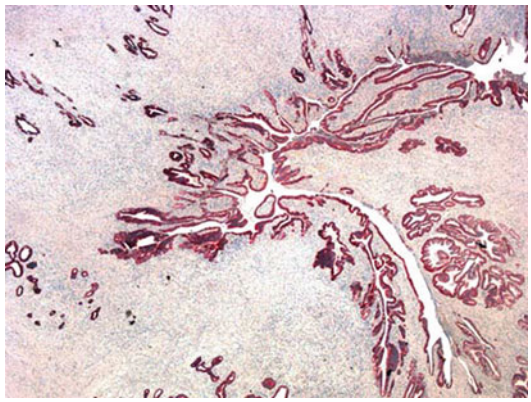

Fig. 3 The extrahepatic bile ducts are markedly stenosed by an inflammatory tissue (cytokeratin 7 immunostain)

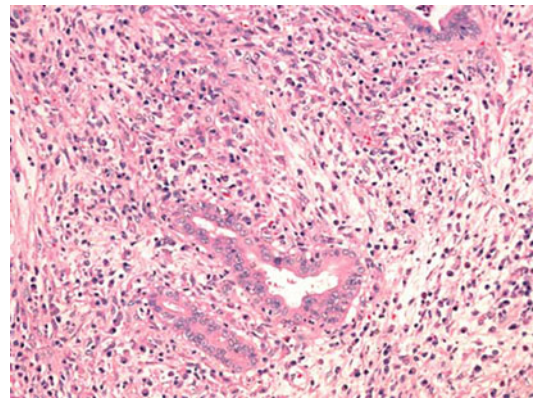

Fig. 4 Hepatobiliary inflammatory pseudotumor. The tissue surrounding bile ducts is infiltrated with lymphocytes, plasma cells, and macrophages, and there is an increase in fibroblastoid cells (hematoxylin and eosin stain)

reminiscent of malignant non-Hodgkin's lymphoma, one reason why such lesions have also been termed pseudolymphoma of the liver (Grouls 1987). Lymphocytes may be arranged as aggregates or lymph follicles, even with formation of germinal centers. In addition to lymphocytes, various amounts of mature plasma cells and plasmacytoid elements are regularly noted and may sometimes form dense clusters or aggregates mainly around blood vessels, previously having led to the term plasma-cell granuloma (Anthony 1993). Neutrophil and eosinophil granulocytes are mostly sparse, with the exception of cases with development of microabscesses or with cholangitic features. As a reaction to tissue breakdown, numerous foamy macrophages may be in evidence, sometimes resulting in a so-called pseudoxanthomatous reaction (Figs. 3, 4, 5, 6, and 7). Some of the tumors contain increased numbers of dendritic cells, including giant atypical reactive dendritic cell forms (Sturm et al. 2007).

Histopathologic diagnosis by needle biopsy is possible and has been reported (Irie et al. 1989; Nakama et al. 2000; Hosler et al. 2004; Sari et al. 2010; Kawaguchi et al. 2012). Fine-needle aspiration shows hypocellular smears with an admixture of various cell types including plasma cells, macrophages, lymphocytes, fibroblasts, and granulation tissue fragments. Foamy macrophages are a striking feature in some cases (Lupovitch et al. 1989; Yoshida et al. 2003; Hosler et al. 2004; Kawaguchi et al. 2012).

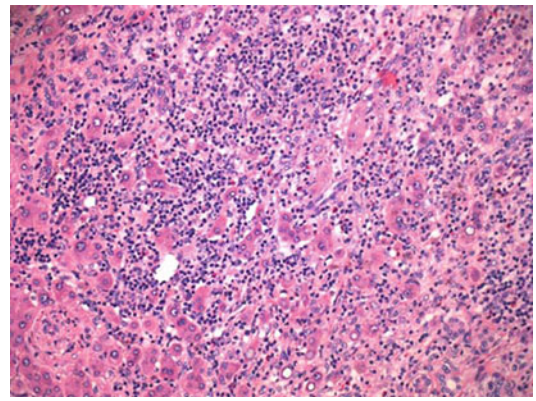

Fig. 5 Hepatobiliary inflammatory pseudotumor. An infiltrate rich in lymphohistiocytic cells has caused dissociation of hepatic parenchyma (hematoxylin and eosin stain)

Immunohistochemistry

The spindle cells found in HIP are vimentin positive, and at least part of them express alpha-smooth muscle actin (alpha-SMA), classifying these cells as myofibroblasts. In contrast to smooth muscle cells found in the muscle layer cells (Montani et al. 2010) and in leiomyomas and leiomyosarcomas of the gastrointestinal tract, the spindle cells of inflammatory pseudotumors are negative for the smooth muscle-specific cytoskeletal protein, smoothelin (Coco et al. 2009). Myofibroblasts do not seem

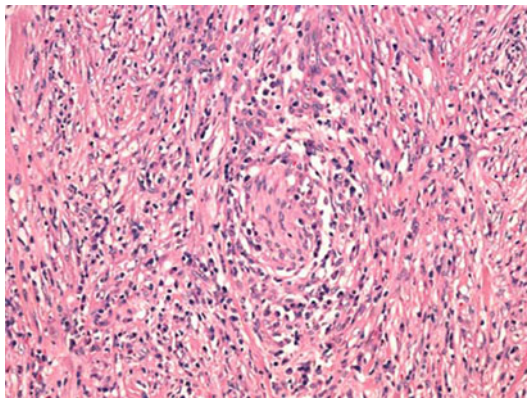

Fig. 6 Inflammatory pseudotumor of the liver. Lymphocytes, plasma cells, and macrophages infiltrate a tissue with abundant fibroblastoid cells and are present around a small nerve (center; hematoxylin and eosin stain)

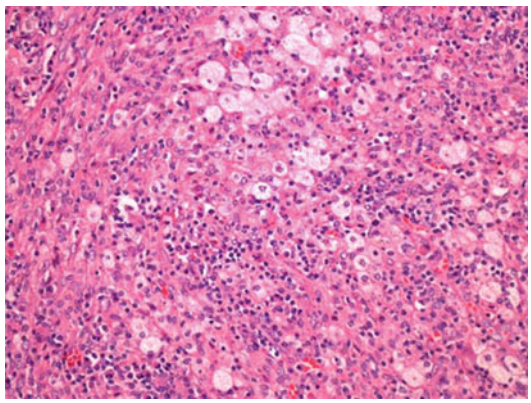

Fig. 7 Inflammatory pseudotumor of the liver. This lesion contains numerous lipid-rich, foamy macrophages (pseudoxanthoma cells; hematoxylin and eosin stain)

to express smoothelin (Nam et al. 2012). Immunohistochemically, the lymphocyte population is typically a mixture of T and B lymphocytes (Kim et al. 1999), even though T (in particular CD8-reactive) cells may predominate, also in portal tracts of the liver adjacent to the tumor, and the plasma cells are polytypic (Uccheddu et al. 1995; Sakai et al. 2001), showing a mixture of IgA-, IgM-, and IgG-producing cells and the expression of both lambda and kappa light chains (Tsao et al. 1990). However, in one reported case, most of the lymphocytes and plasma cells produced IgA and predominantly lambda light chains (Grouls 1987). Macrophages in the infiltrate are frequently activated and CD68-positive.

Attempts for a Histologic Classification of HIP

Referring to the predominant histologic patterns, attempts have been undertaken to classify the lesions in more detail. Someren categorized HIP into three morphotypes, i.e., hyalinized sclerosing, xanthogranuloma, and plasma-cell granuloma types (Someren 1978). As in other lesions with heterogeneity owing to an internal gradient of cellular responses, such a classification is prone to considerable sampling variation and therefore of doubtful significance. Based on 74 previously reported cases and an own pediatric patient, Lee and DuBois have recently proposed a novel classification (Lee and DuBois 2001). In contrast to histopathologic categories, they put emphasis on the clinical/radiologic presentation, i.e., solitary or multiple lesions. Their type 1 or solitary HIPs were typically large and centrally located lesions, exhibited a mean diameter of 7 cm, showed a low-density central core on CT representing necrosis, have a hypovascular or even avascular angiographic appearance, and were a predominant variant of HIP in children (16/18). The more central location of type 1 lesions may result in bile duct stenosis and portal venous and obliterative endophlebitis, as discussed below. Owing to these complications, type 1 according to Lee and DuBois may require surgery more frequently than other manifestations of HIP. Type 2 or multiple HIPs are typically smaller lesions (2–6 cm diameter) in a bilobar distribution, occur in adults and children, and are less likely to involve bile ducts and/or portal vein branches (Lee and DuBois 2001). In CT, the nodules are solid and exhibit a low but uniform density, similar to metastases, so that exclusion of malignancy is a major concern in case of type 2 lesions.

Differential Diagnosis

The differential diagnosis of HIP mainly includes chronic liver abscess, malignancy (sarcoma; malignant fibrous histiocytoma; lymphoma; desmoplastic carcinoma), benign mesenchymal tumors, and (sclerosed) vascular tumors.

Biology of Disease

In situations without biliary or vascular involvement and complications, or large lesions, the clinical course is usually benign and self-limiting; it sometimes even undergoes spontaneous regression (Gollapudi et al. 1992; Zamir et al. 1998; Young et al. 1998; Soudack et al. 2000; Nakama et al. 2000; Levy et al. 2001), but in patients with large and non-resolving lesions, hepatectomy is now advocated to be the treatment of choice in comparison with conservative therapy (Mangiante et al. 1997), even though selected patients may profit from conservative treatment, including antibiotics (Jais et al. 1995; Casassus-Builhe et al. 2002). The question as to whether HIP may undergo malignant evolution is not settled so far. A patient with HIP has been described where a subsequent evolution into malignant non-Hodgkin's lymphoma occurred (Pecorella et al. 1999).

Etiology and Pathogenesis

HIP is often associated with diverse conditions that may deliver clues as to pathogenic pathways involved (Lyons et al. 1993). In regard to pathogenic considerations, the apparently reproducible association of HIP and chronic cholangitis (Gough and Chakrabarti 1993; Nakanuma et al. 1994) or with recurrent pyogenic cholangitis (Yoon et al. 1999) merits particular attention. Yoon and coworkers investigated on 13 inflammatory hepatic pseudotumors evolving in 10 patients. All these patients had CT features of recurrent pyogenic cholangitis, such as hepatolithiasis, intrahepatic bile duct stricture and dilatation, common bile duct calculi, pneumobilia, or signs of atrophy/hypertrophy complex of the liver. The presence of chronically infected extrahepatic and/or intrahepatic bile ducts may, therefore, represent a risk factor for the development of IPTL, and a marked local host response to bacterial infection may in fact be the driving force for the establishment of a tumor-like, exuberant repair reaction, also involving strong immune reactions of both the cellular and humoral type. A causal relationship to local bacterial infection is further indicated by the observation of a spatial connection between HIP and adjacent abscesses (Jimenez-Mejias et al. 1989). Furthermore, situations with dilatation of bile ducts and frequently complicated by bacterial infection may later be accompanied by HIP (Terada et al. 1992; Kuhara et al. 1994). A possible significance of more remote visceral infections is indicated by the finding of HIP occurring together with diverticulitis (Coleman and Rees 1999) and with chronic abdominal abscesses followed by sepsis (White et al. 1997). In one case, fine-needle aspirate yielded a growth of *Klebsiella* organisms (Kafeel and Telesinghe 1997) and, in another, *Escherichia* and *Actinomyces* species (Schmid et al. 1996). In a patient with multiple HIP, *Enterococcus durans* bacteremia was detected (Jover Diaz et al. 2009). A further argument for the pathogenetic significance of infections is offered by the observation that HIP can regress under antibiotic therapy (Casassus-Builhe et al. 2002). HIP was also found in association with primary hepatic actinomycosis (Tamsel et al. 2004) and amebic infections (Alfieri et al. 2008) and with *Mycobacterium* tuberculosis infection in an immunocompetent child (Manolaki et al. 2009). The observation of HIP in association with HIV infection (Tai et al. 1998) might, if not a fortuitous coincidence, suggest a role of deranged immune responses to the more frequent bacterial infections in this disorder.

That immune or autoimmune mechanisms may play a role in the pathogenesis of HIP is suggested by the observation of such lesions in patients with primary biliary cirrhosis (Rai et al. 2003; Koide et al. 2006), primary sclerosing cholangitis (Toda et al. 2000), and after liver transplantation (Lykavieris et al. 2000); in patients with Crohn's disease (Papachristou et al. 2004; Mouelhi et al. 2009; Renzing et al. 2011) and rheumatoid arthritis (Diaz-Torné et al. 2007); and in the setting of Sjögren's syndrome (Hosokawa et al. 1998). HIP has been observed as the first manifestation of Crohn's disease (Amankonah et al. 2001), and it was speculated that the lesion may be related to underlying inflammatory bowel disease. Furthermore, inflammatory reactions

located elsewhere may be modified by the presence of HIP; e.g., both fever and recurrent arthritis related to gout completely resolved after surgery of HIP (Takahashi et al. 2001). HIP has been observed to complicate severe congenital neutropenia (Kostmann's disease; Hsiao et al. 1999; Schneider et al. 2003) and to occur in a hereditary disorder associated with the development of hepatic abscesses, Papillon-Lefevre syndrome (Czauderna et al. 1999).

Some pseudotumors seem to develop in association with collapsed liver cysts or form a residuum of biliary cystadenoma (Hoosein et al. 2007). HIP has been observed in association with gallstones (Al-Jabri et al. 2010), including hepatolithiasis (Ueda et al. 2009; Terada 2010); biliary atresia (Wang et al. 2002); intra-abdominal foreign bodies, e.g., intrahepatic wooden toothpicks or migrated fishbone (Del Fabbro et al. 2004; Perera et al. 2007); abdominal malignancy (Nishimura et al. 2005), GISTs (Lo et al. 2004); and leukemias (Isobe et al. 1991; Tajima et al. 1998). It has developed as a possible complication of percutaneous radiofrequency ablation of hepatocellular carcinoma (Lee et al. 2009). HIP was found during pregnancy (Maze et al. 1999).

Inflammatory Myofibroblastic Tumors of the Liver and Related Lesions

Introduction

Inflammatory myofibroblastic tumor (IMT) is a distinctive mesenchymal tumor that has emerged from within the heterogeneous group of inflammatory pseudotumors as an entity characterized by neoplastic features, a proliferation of myxoid spindle cells, an inflammatory infiltrate, and a rearrangement of anaplastic lymphoma kinase (ALK) in at least 50 % of the cases (reviews: Dehner 2004; Gleason and Hornick 2008). ALK rearrangement of the respective locus on chromosome 2p23 causes aberrant ALK expression in the neoplastic cells (Griffin et al. 1999). The term, IMT, implies that the neoplastic cell lineage characterizing IMT is a myofibroblast or a myofibroblast-like cell. However, alternative views regarding the cell of origin have been formulated, e.g., a proliferation of fibroblastic reticulum cells, a subtype of cell of the accessory immune system (Nonaka et al. 2005).

IMTs occur primarily during the first two decades of life (Coffin et al. 2007) and chiefly arise in the lung, retroperitoneum, and abdominopelvic region (Coffin et al. 1995). IMTs also occur in the pediatric age group (Mergan et al. 2005; Ernst et al. 2011). Less common localizations comprise the central nervous system, salivary glands, thyroid, larynx, breast, spleen, urinary bladder, and skin.

Inflammatory Myofibroblastic Tumors of the Hepatobiliary Tract

IMT of the liver is a rather common intra-abdominal manifestation of IMTs (Beauchamp et al. 2011). In a fine-needle aspiration cytologic study of 20 cases, nine were localized to the liver (Stoll and Li 2011). IMT of the liver was also found in children (Mergan et al. 2005). IMT very rarely develops in the bile duct system. The lesions developing in the distal part of the common bile duct usually make part of the syndrome IgG4-associated sclerosing disease (Yamamoto et al. 2009). IMTs not associated with IgG4 disease have very rarely been reported (Stamatakis et al. 1979; Bolla et al. 1988; Ikeda et al. 1990; Imafuku et al. 1990; Fukushima et al. 1997; Saint-Paul et al. 1999; Worley et al. 2001; Ashcroft et al. 2009) and also develop in the ampullary/periampullary region (Leese et al. 1986; Price et al. 1993). IMTs can develop in the hilar region, producing extending structures and mimicking a Klatskin tumor (Worley et al. 2001). Bile duct IMTs are usually lesions with a benign behavior, but aggressive forms have also been reported. In a 63-year-old female patient with aggressive hilar IMT, pulmonary metastasis developed (Kim et al. 2011).

Pathology

The typical feature is a growth of slightly eosinophilic spindle cells resembling fibroblasts, with bland-looking nuclei and absent mitoses or a low mitotic count. The spindle cells, which are immunohistochemically myofibroblasts, may be embedded in a myxoid or hypocellular fibrosclerotic matrix (Fig. 8). In a minority of cases, a round cell transformation of IMT was observed (Chen and Lee 2008). Cellular atypia is more frequent in aggressive variants of IMT. Cellular atypia was found in 69 % of tumors that recurred and in all cases showing malignant transformation (Hussong et al. 1999).

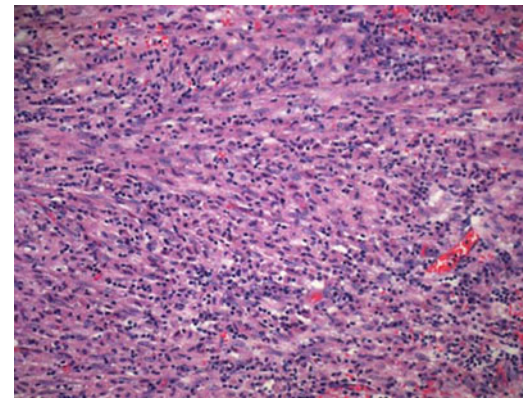

Fig. 8 Myofibroblastic pseudotumor of the liver. A dense collection of myofibroblasts and other spindle cells is infiltrated with lymphocytes (hematoxylin and eosin stain)

Immunohistochemistry

Apart from aberrant ALK expression (see below), hepatic IMT cells have been shown to be positive for alpha-SMA (Qiu et al. 2008) and actin (100 %; Stoll and Li 2011), supporting the myofibroblastic character of these cells (Fig. 9). Aggressive IMT may show nuclear p53 expression (Hussong et al. 1999).

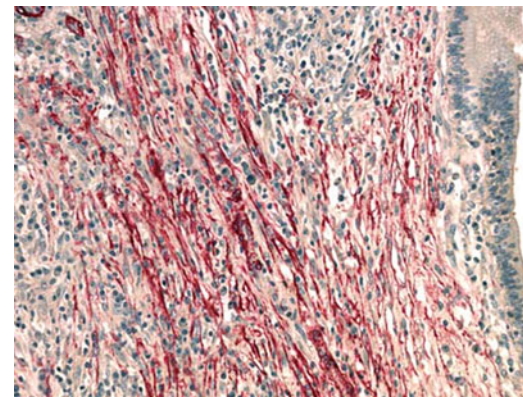

Fig. 9 Myofibroblastic pseudotumor of a bile duct. The inflamed tissue contains numerous spindle cells with reactivity for smooth muscle actin. The inflammatory infiltrate contains numerous plasma cells (alpha-SMA immunostain)

Biology of Disease

IMTs usually show a rather indolent course, but may exhibit invasive growth and spread. Currently, IMT is considered to be an intermediate-grade neoplasm that can recur in up to 25 % of cases (Hussong et al. 1999). However, in the subset of abdominal and pelvic IMTs, the recurrence rate was 85 % in one investigation (Coffin et al. 2007), suggesting an important role for the site of origin. Rarely, IMT can undergo malignant transformation, with locoregional and/or distant metastases (Hussong et al. 1999; Ernst et al. 2011). In a study of 24 cases, 8 % underwent malignant transformation (Hussong et al. 1999). Low-grade myofibroblastic sarcoma, which may be confounded with IMT, is currently not regarded as a member of the family of ALK-positive tumors (Qiu et al. 2008).

ALK Rearrangements in Hepatic IMT

IMTs primary to the liver may show ALK gene rearrangements with variable fusion partners. An unusual rearrangement is that between the Ran-binding protein 2 and ALK, associated with nuclear membrane expression of ALK (Chen and Lee 2008). Aberrant anaplastic lymphoma kinase (ALK) expression caused by ALK gene rearrangements is a frequent alteration in IMTs. ALK plays a significant role in the regulation of cell proliferation in several cell lineages and is the

partner of several fusion proteins in distinct chromosomal translocations (reviews: Ladanyi 2000; Palmer et al. 2009; Schonherr et al. 2012). ALK is a receptor tyrosine kinase that is highly related to leukocyte tyrosine kinase (Morris et al. 1997). ALK was expressed in 47.1 % of cases analyzed by fine-needle aspiration cytology (Stoll and Li 2011). In a study of 73 IMTs, immunohistochemical ALK positivity was detected in 60 % of cases. In contrast, all cases of nodular fasciitis, desmoid fibromatosis, and gastrointestinal stromal tumors were ALK negative (Cook et al. 2001). Among sixteen children (age range 1–15 years), aberrant ALK expression was detected in only 18.8 % of patients (Mergan et al. 2005). In one study, ALK-negative IMTs occurred in older patients and had a greater nuclear pleomorphism, atypia, and atypical mitoses, and all metastatic IMTs were ALK-negative, suggesting that ALK negativity is an indicator of an aggressive course and metastasizing disease (Coffin et al. 2007). The significance of ALK in the biology of IMT is highlighted by the observation that the ALK inhibitor, crizotinib, has led to a sustained partial response of IMT (Butrynski et al. 2010). Another myofibroblastic neoplasm that expresses ALK with a nuclear membrane or perinuclear expression pattern is epithelioid inflammatory myofibroblastic sarcoma, a predominantly intra-abdominal variant of IMT (Mariño-Enriquez et al. 2011).

Molecular characterizations have identified ALK fusions involving tropomyosins 3 and 4 (TPM-3 and TPM-4; Lawrence et al. 2000), clathrin heavy chain (CLTC; Bridge et al. 2001), cysteinyl-tRNA synthase (CARS), and Ran-binding protein 2 genes as fusion partners. IMTs with Ran-binding protein 2 (RANBP2/Nup358) fused with ALK are rare. The N-terminal 867 residues of RANBP2 are fused to the cytoplasmic segment of ALK in the RANBP2-ALK chimeric protein, and this chimerization causes ALK to be localized to the nuclear membrane (Ma et al. 2003). RANBP2 is a large (358 kDa) nucleopore protein (nucleoporin) localized at the cytoplasmic side of the nuclear pore complex. It is mutated in familial or recurrent acute necrotizing encephalopathy (Neilson et al. 2010; Loh and Appleton 2010), and the major component of the cytoplasmic filaments of the nuclear pore complex has a critical function in capturing recycling RanGTP-importin-beta complexes at cytoplasmic fibrils to allow for adequate classical nuclear localization signal-mediated cargo import (Hamada et al. 2011). The mediation of cargo processes is also related to the association of RANBP2, through its kinesin-binding domain, with kinesin-1, and RANBP2 is a positive allosteric activator of the kin2718esin-1 system (Cho et al. 2009). The protein is involved in the distribution of SR splicing factors enriched in nuclear speckles or interchromatin granule clusters and plays a role in the speckled distribution of phosphorylated pre-mRNA processing factors (Saitoh et al. 2012). RanBP2 contains a domain that catalyzes E3 ligase activity and forms a stable complex with SUMO-modified RanGAP1 and UBC9 at the nuclear pore complex (Gareau et al. 2012).

Epstein-Barr Virus-Positive Inflammatory Pseudotumor/ Inflammatory Pseudotumor-Like Follicular Dendritic Cell Tumor

Introduction

Lesions histologically resembling inflammatory pseudotumors have been found to be infected with Epstein-Barr virus (EBV), which is thought to play a role in the pathogenesis of these lesions. 18 inflammatory pseudotumor specimens (from lymph nodes, spleen, and liver) from 17 patients were studied by in situ hybridization for EBV RNA, and EBV virus RNA expression was detected in 41.2 % of cases, including one from the liver. Two morphologically different EBV-positive cell types, spindled and round cells, were evident, whereby the EBV-positive spindled cells were present exclusively in the extranodal lesions. Part of the EBV-positive spindled cells co-expressed smooth muscle actin, while others had immunohistochemical features of follicular dendritic cells (Arber et al. 1995). The presence of EBV virus in inflammatory

pseudotumors is an interesting finding regarding the pathogenesis of these lesions and has also been found in rare smooth muscle tumors in immunosuppressed individuals (reviews: Arber et al. 1998; Deyrup 2008). Since 1995, several examples of this distinct lesion have been reported for several organs, including the spleen (Yamaguchi et al. 2000; Kutok et al. 2001; Neuhauser et al. 2001; Lewis et al. 2003; Horigichi et al. 2004; Oz Puyan et al. 2004; Kiryu et al. 2009; Rosenbaum et al. 2009). In splenic lesions, two growth patterns have been noted, viz., a cellular spindle cell pattern and a hypocellular fibrous pattern, and immunohistochemistry revealed the myofibroblastic nature of the spindle cells (Neuhauser et al. 2001). Few examples in intracranial EBV-positive inflammatory pseudotumors are reported, one originating from the trigeminal nerve (Jung et al. 2006) and another showing an intraventricular site (Nishioka et al. 2009). A second splenic lesion that has been shown to express EBV RNA is sclerosing angiomatoid nodular transformation (SANT), a lesion which is thought by some authors to represent a final stage of splenic inflammatory pseudotumor (Weinreb et al. 2007, Kashiwagi et al. 2008).

Recently, the term inflammatory pseudotumor-like follicular dendritic cell tumor (IPL-FDCT) has been proposed to denote such lesions (Cheuk et al. 2001). The authors characterized a distinctive variant of FDCT morphologically mimicking inflammatory pseudotumor based on 11 patients (10 women, 1 man). All tumors occurred in intra-abdominal sites, i.e., liver (seven cases), spleen, and peripancreatic region, and were biologically classified as a low-grade malignant neoplasm. Of the nine patients with follow-up data, six were alive and well, one developed recurrence at 9 years, and two had repeated recurrences over many years. The term has recently been employed to denote splenic lesions formerly termed inflammatory pseudotumor (Horiguchi et al. 2004; Gong et al. 2008; Kiryu et al. 2009). Another term to denote such lesions was follicular dendritic reticulum cell tumor mimicking inflammatory pseudotumor, e.g., of the spleen (Brittig et al. 2004).

Hepatobiliary EBV-Positive Inflammatory Pseudotumors

In about the same frequency as the spleen, EBV-associated inflammatory tumors/IPL-FDCTs develop in the liver. In contrast to FDCTs in extrahepatic and extrasplenic areas, hepatic FDCTs have a strong association with EBV and a stronger inflammatory component and are more prevalent in females. FDCT not associated with EBV also occurs in the liver and is discussed in a separate chapter. The first EBV-positive hepatic inflammatory pseudotumor was described in 1995 (Arber et al. 1995). In the following year, an EBV-related clonal proliferation of follicular dendritic cells was described as follicular dendritic cell tumor of the liver (Shek et al. 1996). This tumor was initially reported as a hepatic inflammatory pseudotumor, but the lesion recurred as two separate tumor masses 30 months after complete resection. Histologically, the tumor contained bland-looking spindle cells amidst a background of lymphocytes and highly pleomorphic tumor cells reactive for CD21, CD35, R4/23, and Ki-M4. Both cell populations were positive for EBV-encoded RNA by in situ hybridization. The tumor cells expressed EBV latent membrane protein (LMP1), but not EBV-encoded nuclear antigen 2/EBNA2 (Shek et al. 1996). In this case, IPL-FDCT may have developed as a neoplastic lineage from an EBV-positive inflammatory pseudotumor. Again in 1996, Selves and coworkers described an "inflammatory pseudotumor" of the liver with a spindle cell component that was shown to be derived from follicular dendritic reticulum cells (FDRC). This cell population expressed the EBV receptor CD21 and contained clonal EBV genomes and EBV RNA transcripts (EBER) and expressed EBV latent membrane protein (Selves et al. 1996). In one young male patient with a large inflammatory pseudotumor of the liver (75 mm diameter) clinically associated with high fever and malaise, only EBV LMP1 was demonstrated within the lesion (Fritzsch et al. 2004). In a 30-year-old female patient, the 6 cm-sized hepatic tumor consisted of an admixture of spindle cells, lymphocytes, plasma cells, and macrophages. The spindle cells

were arranged in a wavy pattern, were immunoreactive for CD21 and CD68, and expressed EBV-encoded nuclear RNAs, leading to the diagnosis of FDCT (Bai et al. 2006). Further reported cases from the liver were identified as IPL-FDCT (Cheuk et al. 2001).

Pathology

Macroscopically, the neoplasms have been described as solitary and fleshy lesions with areas of hemorrhage and necrosis. Histologically, spindle cells are the predominant lineage, embedded in a tissue containing an inflammatory infiltrate consisting of lymphocytes, plasma cells, and macrophages. The proportion of spindle cells to lymphoid and plasma cells is variable in different areas, a typical finding in inflammatory pseudotumors. Parts of the spindle cells are bland looking, with a slightly eosinophilic cytoplasm and inconspicuous nuclei. These cells may be confounded with fibroblasts. A significant number of spindle cells show two nuclei, suggesting features of follicular dendritic cells. Sometimes, these large binucleated cells resemble Reed-Sternberg cells. Other spindle cells are atypical, with vesicular nuclei and distinct nucleoli. The spindle cells may be arranged in the form of fascicles, and a storiform pattern may be found. Atypical large ovoid cells are also noted. Immunohistochemically, the neoplastic cells are reactive for follicular dendritic cell markers, i.e., CD21 (C3d receptor), CD35 (C3b receptor), Ki-M4P, CD23, and CNA42, but only a fraction of cells are positive for DRC1 (Selves et al. 1996; Cheuk et al. 2001). The binucleated cells with large vesicular nuclei are consistently negative for CD15 and CD30. Normal-looking and atypical spindle cells express EBV markers, including immunoreactivity for LMP1 and EBNA2, and EBV-encoded RNA is detectable with in situ hybridization. Cells bearing EBV signals were CD21-positive by double immunostaining (Selves et al. 1996). Expression of EBV markers is also seen in those lesions that do not show clear-cut follicular dendritic cell features. Oval cells were negative for CD15, CD20, CD30, ALK protein, Bcl-2, S-100 protein, EMA, CD34, and HHV-8 (Rosenbaum et al. 2009). A small population of binucleated cells show an increased proliferative activity in Ki-67 immunostains. The lymphocytes are predominantly T cells, more CD8+ than CD4+ cells, while B cells are relatively scarce. The plasma-cell population is polytypic. Numerous CD68+ macrophages are commonly present (Selves et al. 1996).

Pathogenic Pathways

There is evidence that IPL-FDCT can develop from EBV-infected cells located in a primary inflammatory pseudotumor without clear frank signs of neoplasia (Shek et al. 1996).

Calcifying Fibrous Tumor (Calcifying Fibrous Pseudotumor) of the Hepatobiliary Tract

Introduction

Calcifying fibrous tumor/pseudotumor (CFT) is a unique, benign tumor or pseudotumor that was described as a childhood lesion in 1988 (Rosenthal and Abdul-Karim 1988) and later again in 1993 by Fetsch and coworkers, who first used the term calcifying fibrous pseudotumor (Fetsch et al. 1993). CFT most commonly occurs in soft tissues of the extremities and in the pleura, with a predilection for young individuals. According to the WHO classification, the lesion is now termed calcifying fibrous tumor. It is histologically characterized by the presence of hyalinized collagen with dystrophic calcifications (sometimes with psammoma bodies) and a mixed lymphocytic and plasmacytic infiltrate, with some contribution of IgG4-positive plasma cells (Kuo et al. 2009; Agaimy et al. 2010). About 10 % of the lesions showed recurrence (Fetsch et al. 1993), and about 10 % of the patients had multiple lesions (Pinkard et al. 1996). It has been discussed whether CFT might represent a late stage of

inflammatory myofibroblastic tumor (Van Dorpe et al. 1999; Sigel et al. 2001). In addition to soft tissues, CFT can also occur in visceral organs and tissues, including lung, heart, esophagus, stomach, omentum, mesentery, small intestine, rectum, fallopian tube, and adrenal gland. CFT also occurs in the gallbladder (Mourra et al. 2004). Calcifying fibrous tumor has been observed as multiple lesions of the peritoneum (Kocova et al. 1997; Farah et al. 2007), in one situation with familial occurrence (Chen 2003). Interestingly, abdominal CFT may be associated with sclerosing angiomatoid nodular transformation of the spleen (SANT). In a study of ten cases of SANT, five cases were associated with disseminated abdominal CFT, and IgG4-positive plasma cells were found in all SANT and CTF (Kuo et al. 2009), suggesting a possible relationship with sclerosing IgG4-related systemic disease.

Whether CFT is a pseudotumor or rather a neoplastic lesion is not yet settled. Based on 15 cases, it was proposed that CFT might represent a benign mesenchymal neoplasm with a low risk of recurrence (Nascimento et al. 2002).

Calcifying Fibrous Tumor of the Liver

CFT has rarely been observed in the liver substance (Jo et al. 2011; Nobili et al. 2011). Liver involvement has been observed in a patient with multiple nodules in several organs (Azam et al. 2014). On CT images, multiple laminated and amorphous calcifications are seen. Macroscopically, the masses are well circumscribed and exhibit a hard consistence due to multiple calcifications. The nodules reveal a fibrous texture and gray-white color and can reach a diameter exceeding 10 cm. The tumor may show a hardness that does not allow insertion of a biopsy needle (Jo et al. 2011). Histologically, the tumors are usually hypocellular and mainly consist of a vascularized collagenous mass with embedded spindle cells. The multiple calcifications are either amorphous or present as psammoma-like bodies. Lymphocytes and plasma cells are predominantly found in peripheral parts of the mass and in the peritumoral tissue.

Nonneoplastic Mass Lesions of the Hepatobiliary Tract

Ectopias and Heterotopies as Tumor-Like Lesions of the Hepatobiliary Tract

120

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_120

Abstract

Numerous types of ectopias and heterotopias located to the liver can result in tumor-like lesions. The presence of ectopic splenic tissue in various abdominal organs, including the liver, is termed splenosis. The liver can also contain various types of ectopic pancreatic tissue, ranging from exocrine lobules to small clusters of intrahepatic acinar cells. Adrenal cortex can ectopically adhere to the inferior-posterior capsule of the liver, a condition called adrenohepatic fusion. Other rare ectopic tissue components include thyroid gland ectopia, hepatogonadal fusion, hepatic endometriosis and endometrioma, and hepatic pregnancy.

Splenosis of the Liver

Introduction

Splenosis denotes the presence of splenic tissue in a more or less remote tissue compartment, most commonly occurring after traumatic splenic rupture and splenectomy, or due to overgrowth of congenitally ectopic splenic tissue. The histologic features of splenosis have been described in detail (Carr and Turk 1992), and splenosis is known to occur in the liver. Instead of splenosis, the term hepatic spleen nodules (HSN) has also been proposed (Mescoli et al. 2010).

The term splenosis was coined in 1939 (Buchbinder and Lipkoff 1939); however, autotransplantation of splenic tissue after trauma has been described much earlier, i.e., in 1910 (cited in Garamella and Hay 1954). It is now thought that, subsequent to splenic trauma, fragments of splenic pulp are seeded throughout the peritoneal cavity (Fleming et al. 1976; review: Fremont and Rice 2007). This view is supported by observations of splenosis occurring after laparoscopic splenectomy (Losanoff and Jones 2001), including growth of splenic tissue in a port site (Kumar and Borzi 2001). By use of an experimental rat model, it has been shown that the pneumoperitoneum may facilitate abdominal splenosis after laparoscopy if the splenic capsule is ruptured or if splenic tissue spills compared with surgery without gas (Espert et al. 2001). After trauma, splenic tissue embolization via the splenic vein or through other blood vessel routes may then result in remote manifestations, including the liver. Splenosis can, therefore, occur at numerous sites, intraabdominal and thoracic localizations being the most frequent (Kutzen and Levy 1978; Bizekis et al. 2003; Mavi et al. 2003). In the peritoneal cavity, the number of splenic nodules ranges from a few to hundreds, and their sizes range from a few millimeters to several centimeters. The implants can increase in mass and size, owing to stimulations that also produce splenomegaly in the original organ, and splenotic lesions can also induce recurrence of diseases related to splenomegaly having resulted in therapeutic splenectomy, including Felty's syndrome and idiopathic thrombocytopenic purpura. Rare locations of splenosis comprise the skin (subcutis; Velitchkov et al. 2000), the lung (Sarda et al. 2001), the brain (Rickert et al. 1998), and the liver. Splenotic lesions are not identical to accessory spleens, known as "splenculi," "splenunculi," "lienculi," and "splenules."

Ectopic splenic tissue was observed in 47 out of 250 (19 %) consecutive necropsies (Wadham et al. 1981). In a follow-up study, the incidence of splenosis was 66 % after splenic removal due to severe traumatic rupture (Ludtke et al. 1989). Improved detection methods include Tc-99 m sulfur colloid scintigraphy (Castellani et al. 2001), heat-denaturated Tc-99 m red blood cell scintigraphy (Laflamme and Boucher 2003), and combined transmission-emission tomography (TET, fusion of SPET and CT data; Horger et al. 2003). Splenosis post splenectomy may be suggested due to the absence of Howell-Jolly bodies in erythrocytes.

Splenosis of the Liver

A supernumerary spleen enclosed in the liver was reported already in 1914 (De Teyssieu 1914). The authors described an alteration that is still typical for many later cases of hepatic splenosis: the right

liver lobe showed, on its inferior surface, a cup-shaped depression of 4 cm diameter containing a well-delineated, egg-shaped focus of splenic tissue, in the presence of a normal-looking orthotopic spleen. Although rare, hepatic splenosis has since been reported several times.

(2007), Choi et al. 2008; Grande et al. (2008), Labat-Debelleix et al. (2008), Lu et al. (2008), Kashgari et al. (2009), Menth et al. (2009), Mescoli et al. (2010), Li et al. (2011), Liu et al. (2012a), Casella et al. (2013), Incedayi et al. (2013), Inchingolo et al. (2013), Röther et al. (2013), Chung (2014), Levi Sandri et al. (2014), and Sato et al. (2014).

Apart from hepatic splenosis, the term hepatic spleen nodules (HSN) has also been proposed (Mescoli et al. 2010). The timely delay between splenic trauma and the manifestation of hepatic splenosis may be considerable, reports indicating 20 years (Davidson and Reid 1997; Lee et al. 2002), 23 years (Yoshimitsu et al. 1993), 27 years (Gamulin et al. 2002), or even 34 years (De Vuysere et al. 2000).

Hepatic splenosis presents with two forms, namely, intrahepatic splenosis and perihepatic splenosis. In perihepatic splenosis, the splenic tissue foci are located to Glisson's capsule (Incedayi et al. 2013). Hepatic splenosis can occur as an isolated form of splenosis or occur in conjunction with splenosis synchronously situated elsewhere, e.g., the colon (Liu et al. 2012b). Intrahepatic lesions may present as an incidental finding, being somewhat similar to hemangiomas or other hepatic tumors on CT and MRI images, owing to hypervascularization/arterialization (Yoshimitsu et al. 1993; Izzo et al. 2004; Inchingolo et al. 2013), and remaining slightly hyperintensive relative to the hypointensive liver on T2WI after injection of superparamagnetic iron oxide (De Vuysere et al. 2000; Nakata et al. 2003). The lesions can be identified and diagnosed by means of selective Tc-99 m-labeled heat-denatured autologous red blood cells scintigraphy (Menth et al. 2009). However, hepatic splenosis may simulate an intrahepatic mass and can thus evoke differential diagnostic difficulties, including lesions mimicking hepatocellular carcinoma, especially in patients with viral hepatitis and cirrhosis (Yoshimitsu et al. 1993; Lee et al. 2002; Kim et al. 2003; Galloro et al. 2003; Zhao and Xu 2004; Di Costanzo et al. 2004; Abu Hilal et al. 2009; Kashgari et al. 2009; Menth et al. 2009; Chung 2014; Levi Sandri et al. 2014; Sato et al. 2014; Li et al. 2015; Liu et al. 2015) or liver cell adenoma (Gruen and Gollub 1997). Also perihepatic forms of splenosis can mimic a focal liver lesion (Casella et al. 2013). Apart from solitary lesions, instances of multiple hepatic splenotic nodules have been recognized (Di Costanzo et al. 2004). Such multiple splenotic foci may mimic hepatic metastatic disease (Foroudi et al. 1999; Kang et al. 2011; Li et al. 2012). In some situations of multiple intraabdominal splenosis, splenotic foci are distributed over the liver surface (Imbriaco et al. 2008).

At gross examination, intrahepatic splenosis presents as solitary or multiple nodules, sometimes presenting as a dark-red and angioma-like lesion (Cavallini 1958), and rarely a bilobed mass has been detected, in part projecting outward from the liver (Davidson and Reid 1997). The lesions are sharply delineated an exhibit a dark-red cut surface, i.e., the features of splenic pulp. The diameter of the lesions varies considerably, larger lesions having been reported as 3.5 cm (Lee et al. 2002; Kondo et al. 2004), the size of a "walnut" (Cavallini 1958), 4.8 cm (Galloro et al. 2003), 6 cm (De Vuysere et al. 2000), and 6.6 cm (Gamulin et al. 2002).

Histologically, intrahepatic splenosis has the characteristics previously described for splenosis

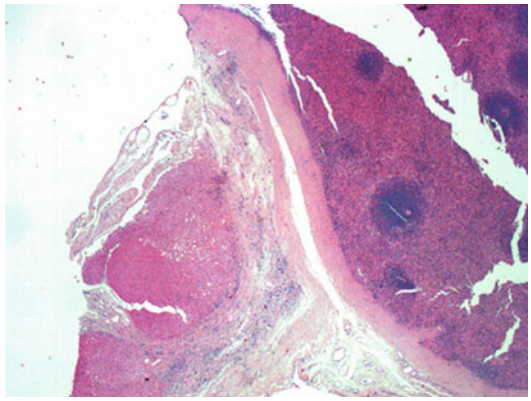

Fig. 1 Splenosis of the liver. Ectopic splenic tissue adheres to the liver tissue, whereby the capsule of the splenic tissue is interposed (hematoxylin and eosin stain)

at other sites (Carr and Turk 1992; Fig. 1). The ectopic splenic tissue is usually in direct contact with the adjacent liver substance, i.e., without intervening fibrous capsule (Davidson and Reid 1997), but a fibrous interface has also been described (Cavallini 1958). Typically, splenosis has no hilar structure, and the vascular supply is achieved from the periphery of the lesion. The splenotic tissue itself displays a texture with both red and white pulp, although sometimes the white pulp (including central arterioles) may be less prominent than usually known for the spleen. Germinal centers may occur in the white pulp. In one case, Gamna-Gandy bodies have been detected in the ectopic splenic tissue (Cavallini 1958). These bodies are well known from the orthotopic spleen and exhibit characteristic radiologic and histologic features. The first to describe Gamna-Gandy bodies was Marini in 1902 (Marini 1902). The authors giving the eponym reported on them only later; in 1905 for Gandy, in a patient with biliary cirrhosis (Gandy 1905), and in 1921 for Gamna, who used the term "siderotic splenogranulomatosis" (Gamna 1921). Hepatic splenosis may show marked iron overload, causing atypical MRI imaging (Nakajima et al. 2008). Immunohistochemically, splenosis has been shown to have a distribution of B- vs. T-lymphocytes not different from that of the normal spleen (Carr and Turk 1992). In case of splenosis growing out of the liver contour (abortive pedunculation), a common capsule enclosed the liver and the splenic tissue (Davidson and Reid 1997). Apart from a slight perifocal atrophy of parenchyma, the adjacent liver tissue does not show any relevant changes.

Ectopic Liver in the Spleen

Splenic hepatic ectopy is a much more uncommon event than splenosis. In one case, in a 69-year-old man, a large splenic tumor was detected and shown to be intrasplenic hepatocellular carcinoma, associated with heterotopic liver remnants (hepatocytes and biliary ductules) in the splenic capsule (Matsuyama et al. 2011). Foci of mature ectopic liver have been noted in the wall of an epithelial cyst of the spleen (Del Sordo et al. 2011).

Pancreatic Tissue Heterotopia of the Hepatobiliary Tract (Pancreas Aberrans; Pancreas Accessorium)

Introduction

Pancreatic heterotopia (heterotopic pancreas; pancreatic choristoma; pancreas aberrans; pancreas accessorium) is defined as the presence of any pancreatic tissue components in an abnormal location without parenchymal, stromal, or vascular connection with the main pancreas (Horgan 1921; Mobini et al. 1974). As cited by Hsia et al. (1999), Jean Schultz was the first to describe, in 1727, heterotopic pancreas in an intestinal diverticulum. This author found at the autopsy of a newborn child "wart similar to a gland" in the apex of a cone-shaped diverticulum of the ileum; no histologic confirmation was possible at this time (Schultz 1727). More than hundred years later, Klob (1859) reported the histologic proof of pancreatic heterotopia in two cases, using the term pancreas accessorium. This issue was further outlined in 1905 by Merkel (1905), Von Heinrich (1909), and, based on gastric pancreatic heterotopia, by Delhougne (1924). Instead of

heterotopic pancreas, the terms adenomyoma or myoepithelial hamartoma have been used to denote these lesions (Mitchell and Augrist 1943; Bill et al. 1982), but this might generate confusion, because adenomyoma of the ampullary region exists in the absence of pancreatic tissue elements.

Epidemiology

The lesion appears in 0.5–13 % of autopsies (Pearson 1951); this review also presented the first case with common bile duct obstruction caused by this type of heterotopia. Clinically, pancreatic heterotopia is identified with an estimated frequency of one in every 500 upper abdominal operations (Barbosa de Castro et al. 1946; Dolan et al. 1974; Lai and Tompkins 1986; Pang 1988; Tanaka et al. 1993; Zinkiewicz et al. 2003). Involved sites include the oesophagus, stomach (25.5 %), duodenum (27.7 %), ampulla of Vater, the main pancreatic duct, proximal jejunum (15.9 %), ileum, Meckel's diverticulum, and the hepatobiliary tract. Unusual sites are the umbilical region, Fallopian tube, mediastinum, salivary glands, tongue, and lymph nodes. The liver and the bile ducts are very rarely involved (Ballinger 1941; Barbosa de Castro et al. 1946; Gadrat et al. 1965; Mobini et al. 1974; Pujari and Deodhare 1979; Armstrong et al. 1981; Hsia et al. 1999; Fukueda et al. 2000). Stomach and duodenum together account for more than 50 % of heterotopic pancreatic tissue, also in the pediatric age group (Delhougne 1924; Ogata et al. 2008; Gokhale et al. 2010).

Classification and General Histologic Features

Depending on the pancreatic tissue components represented in the heterotopia, *classifications* have been proposed (Von Heinrich 1909; Gaspar-Fuentes et al. 1973; Table 1).

Histological features of pancreatic heterotopia show varying combinations of excretory ducts, glands of the exocrine apparatus (with a lobular or ill-defined architecture), and islets of Langerhans (Pang 1988). Pancreatic heterotopia can undergo secondary changes, including acute and chronic inflammation, fibrosis, duct obstruction with duct dilatation, and tumor development. Mucostasis in dilated ducts of heterotopic pancreatic tissue followed by mucus leakage and formation of mucus lakes may mimic colloid carcinoma (Teke et al. 2010). In the duodenal wall, heterotopic pancreas can undergo a complex change to so-called cystic dystrophy of the duodenal wall (Galloro et al. 2008).

Table 1 Classifications of pancreatic heterotopia

Von Heinrich classification (Von Heinrich 1909)	
Type I	Presence of all epithelial components of the normal pancreas
Type II	Pancreatic tissue without islets
Type III	The tissue only consist of (proliferated) ductules
Gaspar-Fuentes classification (Gaspar-Fuentes et al. 1973)	
Type I	Total heterotopia with all pancreatic components
Type II	Ductular proliferations only ("canalicular variety")
Type III	Acinar structures only ("exocrine pancreas")
Type IV	Islet tissue only ("endocrine pancreas")

Heterotopic Pancreas in the Liver

In the liver, pancreatic heterotopia usually manifests in the form of a solitary nodule. Gadrat and coworkers described two patients with liver cirrhosis in whom a hepatic needle biopsy revealed exocrine pancreatic tissue, one biopsy additionally with an islet of Langerhans. Hepatic pancreatic heterotopia may present as an abdominal mass (Mobini et al. 1974), because such tissue in the liver has been shown to rarely form a cystic mass of up to 7 cm diameter, almost completely covered by a smooth and transparent serosa and connected to the liver through a pedicle (Mobini et al. 1974). However, most lesions are much smaller, e.g., in the range of 2–3 cm (Pujari and Deodhare 1979). Intrahepatic pancreatic tissue

can consist of acini, ducts, and islets, but some authors specify that only acinar cells, but not islet tissue, were present (Mobini et al. 1974; Suzuki et al. 1999). In one early reported case, islet cell carcinoma causing hypoglycemia apparently developed from hepatic pancreatic heterotopia, implying a preexisting islet-containing lesion (Ballinger 1941). Rarely, ectopic pancreatic tissue in the liver undergoes secondary changes, e.g., resulting in large pseudocysts (Kralik and Pesula 1993). The heterotopic lesions are usually circumscribed, but, in some instances, small foci of pancreatic tissue are scattered in the adjacent liver substance, in addition to the main heterotopia (Mobini et al. 1974). The heterotopic pancreatic tissue may undergo atrophy, with remaining duct and ductule profiles.

Pancreatic Metaplasia in the Liver

A distinctive situation is the presence of numerous microscopic foci of exocrine pancreatic tissue in the liver, instead of one grossly visualized mass (Terada et al. 1990; Wolf et al. 1990; Kuo et al. 2009; Fig. 2). Terada and coworkers (1990) identified foci of exocrine pancreas in 41 of 1,000 consecutive autopsy livers (4.1 %) and regarded these foci as heterotopic pancreas, but the morphology of the lesions they described together with their localization in large portal tracts and the lack of islet cells rather suggest acinar metaplasia. In the patient reported by Wolf and coworkers (Wolf et al. 1990), a nodular liver with septal fibrosis contained acinar cell and ductule containing pancreatic structures embedded in fibrous tissue (but not encapsulated). The foci measured 0.1–1.0 mm (average: 0.4 mm), clearly separated from hepatocytes and with an estimated frequency of one focus per 4.3 cm^2. Some of the pancreatic foci displayed a lobular construction. Alpha-amylase-reactive acinar cells were detectable, while islet cells or endocrine cells were lacking. In a study analyzing 382 liver explants from 1995 to 2000, 16 livers (4.2 %) contained pancreatic acini-like tissue. Fifteen of these liver were cirrhotic. The pancreas tissue foci appeared as small clusters of

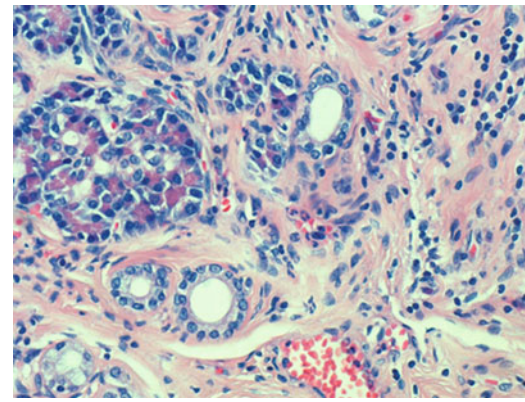

Fig. 2 Intrahepatic ectopic pancreatic acini (hematoxylin and eosin stain)

compactly packed cells that either blended imperceptibly with or were in close proximity to adjacent bile ducts or ductules. The acinar tissue was positive for pancreatic alpha-amylase and weakly positive for cytokeratin 8, but negative for cytokeratins 7 and 19, in contrast to the adjacent biliary-type epithelium, but the close spatial relationship with small bile ducts and ductules suggested a metaplastic process in the pathogenesis of these lesions, derived from a hepatic progenitor cell lineage (Kuo et al. 2009). On the other hand, acinar cells may be derived from the remodeling ductal plate (Terada 2012).

Heterotopic Pancreas in the Biliary Tract

Apart from ectopia within the liver substance itself, ectopic pancreatic tissue has been observed in intra-or/and extrahepatic bile ducts. According to a distributional analysis on 471 cases of pancreatic ectopia/heterotopia of Barbosa de Castro and coworkers (Barbosa de Castro et al. 1946), 0.4 % were located to the common bile duct, where it can induce stenosis or even obstruction (Pearson 1951; Weber et al. 1968; Sabini et al. 1970; Lehur et al. 1983; Pang 1988; Schu et al. 1988; Thognon et al. 1998; Molinari et al. 2000; Maisonnette et al. 2004; Karahan et al. 2006; Yan et al. 2012), in case of a localization in the distal common bile duct associated

with marked bile duct dilatation (Tsunoda et al. 1990; Molinari et al. 2000). In MR cholangiopancreatography, a hypointense nodular filling defect was detected in one patient, associated with dilatation of the intrahepatic biliary tree (Karahan et al. 2006). When the heterotopic pancreatic tissue is located in the extrahepatic bile duct bifurcation, a filiform stenosis mimicking Klatskin tumor has been described (Heer et al. 2010). Obstruction of the common hepatic duct by ectopic pancreas has been reported (Schu et al. 1988). Involvement of intra- and extrahepatic ducts was detected in patients with choledochal cysts (Suzuki et al. 1999; Prasad et al. 2001; Bahadir et al. 2006) and with congenital biliary dilatation (Kattepura et al. 2010). Heterotopic pancreas has also been observed in the cystic duct wall, causing duct stenosis and gallbladder hydrops (Inceoglu et al. 1993; Bhana and Chetty 1999; Weppner et al. 2009). The heterotopic tissue is situated deep in the submucosa or may occupy a larger part of the duct wall (Mrak et al. 2010). In a 45-year-old female patient with a 3 cm-sized mass in the bile duct of the left liver lobe near the hepatic hilum, histology showed that an adenocarcinoma had arisen from heterotopic pancreas, with perineural invasion in the hilar region (Yan et al. 2012).

Heterotopic Pancreas of the Gallbladder

Misplaced pancreatic tissue also occurs in the wall of the gallbladder, first described by Poppi in 1916 (Fig. 3). Since this report, numerous descriptions of this clinic-pathologic entity have appeared (Cerullo et al. 2011; Gucer et al. 2011). This issue is discussed in detail in the chapter on pseudotumors of the gallbladder.

Heterotopic Pancreas Associated with Choledochal Cysts

In a 36-year-old female patient with intra- and extrahepatic bile duct cysts and abnormal arrangement of the pancreatobiliary junction region, pancreatic tissue with acinar cells, centroacinar cells, and ductal elements but without Langerhans islets was scattered along the abnormal biliary tract. The pancreatic foci ranged from 200 to 800 μm in size (Suzuki et al. 1999).

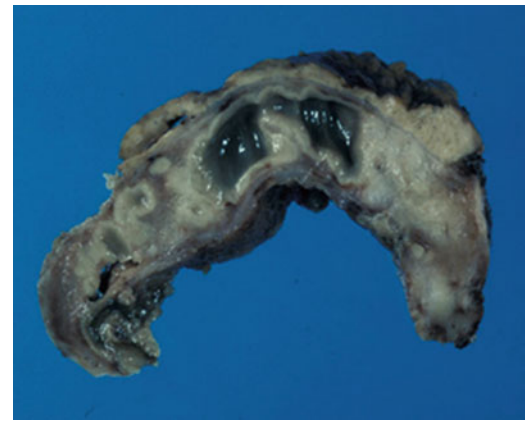

Fig. 3 Ectopic pancreas of the gallbladder

Pancreatic Metaplasia of the Biliary Tract

Pancreatic metaplasia with formation of acinar and/or ductal cells in a glandular mucosa is well known to occur in the stomach and in Barrett's mucosa, but less often also develops in the biliary tract. Pancreatic acinar metaplasia has been observed in up to 10 % of cases of end-stage primary sclerosing cholangitis (Lewis et al. 2010).

(1968), Paraf et al. (1970), Sabini et al. (1970), Berenguer et al. (1972), Laughlin et al. (1983), O'Reilly et al. (1983), Coupland et al. (1987), Hammarström and Nordgren (1999), Molinari et al. (2000), Chen et al. (2001), Contini et al. (2003), Maisonnette et al. (2004), Wagle et al. (2005), Chou et al. (2006), and Filippou et al. (2006).

Differential Diagnosis

Radiologically, hepatobiliary ectopic pancreas should not be confounded with heterotopic pancreas located to the retroperitoneal space, where it may eventually produce lipoma-like tumors owing to massive pancreatic lipoatrophy (Moriki et al. 2004). Remnants of pancreatic tissue located to the retroperitoneal space vary considerably in size and may, e.g., present as small nests in the periaortic space (Heller et al. 2010).

Heterotopic Liver in the Pancreas

Pathogenetically interesting is the reverse situation, i.e., heterotopic liver in the pancreas, sometimes giving rise to hepatocellular carcinoma in the pancreas (Cardona et al. 2007; Kubota et al. 2007).

Pathogenic Pathways

Proposals reported so far include (a) incomplete regression of the ventral anlage; (b) regression to more primitive distribution pattern of pancreatic tissue, resembling the pattern in lower vertebrates, with a diffuse distribution of pancreatic tissue foci in the liver, intestinal wall, and peritoneum; (c) aberrant differentiation of a displaced pluripotent cell system; (d) separation of pancreatic anlage from the orthotopic pancreas by the rapidly growing intestine; (e) metaplasia; and (f) transdifferentiation.

The liver and pancreas develop in close proximity, and very early developmental defects in humans can therefore involve both systems together, e.g., combined absence of bile ducts and pancreatic ducts (Nakamura et al. 2003). The pancreas develops from the dorsal and ventral pancreatic buds of endodermal cells arising from the caudal part of the foregut, the bulk of the pancreas deriving from the dorsal bud, while the ventral bud gives rise to the uncinate process. Recent studies show that the pancreatic progenitor cells first give rise at the ventral endoderm prior to the formation of dorsal and ventral pancreatic buds (Yoshida et al. 2009). Early progenitors seem to be bipotential, i.e., pancreatobiliary progenitor cells which coexpress the transcription factors PDX1 and SOX17 (concept of hepatic and pancreatic stem cells; Burke and Tosh 2012; Arndtfield and van der Kooy 2013). The subsequent lineage segregation of these cells produces a PDX1+ ventral pancreas and a SOX17+ biliary primordium, and this pathway is SOX17-dependent (Spence et al. 2009). It has been postulated that prior to fusion of the pancreatic buds, small branches of the anterior and posterior pancreatic buds may become attached to the gut wall at various locations, these branches eventually remaining grafted to the gut wall and thus giving origin to heterotopic tissue (Derbyshire 1940). That displacement of bud components may occur is illustrated by a bifid ventral bud resulting in annular pancreas, and the frequent location of pancreatic heterotopia in the duodenal wall, probably via fragmentation of the ventral bud. It may be surmised that such cellular fragments may be integrated into the hepatic primordium and then be translocated to the definitive liver.

Is hepatic pancreatic heterotopia caused by metaplasia and/or transdifferentiation?

Metaplasia has been suggested in the rare situation where hundreds of pancreatic foci have been found to be distributed within the liver (Wolf et al. 1990). A metaplastic change of hepatocytes into pancreatic cells is known from animal observations, in particular liver tumors induced by carcinogens (Kimbrough 1973; Rao et al. 1986; Lee et al. 1989). Another concept refers to transdifferentiation, i.e., a change in the cell lineage program. The plasticity of both liver and pancreas in regard to mutual transdifferentiation has been studied in several models, demonstrating a biochemical shift of liver to pancreas, but so far not a structurally identifiable transdifferentiation. Recombinant-adenovirus-mediated gene transfer of PDX-1 to the livers of mice activated expression of the endogenous, otherwise silent genes for mouse insulin 1 and 2 and prohormone convertase one third, indicating the capacity of a major pancreatic developmental regulator to reprogram extrapancreatic tissue toward a beta cell

phenotype (Ferber et al. 2000). In subsequent experiments in mice, it surfaced that PDX-1 triggers a long-lasting process of liver to pancreas developmental shift, chiefly in perivenous hepatocytes, demonstrating that PDX-1 possesses an instructive role in pancreas differentiation also when ectopically expressed in mature fully differentiated tissue such as the liver (Ber et al. 2003). In transgenic Xenopus tadpoles carrying a modified Pdx-1 homolog (Xlhbox8), part or all of the liver was converted to pancreas, containing both exocrine and endocrine cells, and this same construct also brought about transdifferentiation of human hepatocytes in culture, with formation of exocrine and endocrine pancreatic cells (Horb et al. 2003). Adult hepatic stem cells can transdifferentiate in vitro into pancreatic endocrine hormone-producing cells, forming self-assembled 3D islet cell-like clusters expressing islet cell differentiation-related transcripts, e.g., PDX-1, PAX-4, PAX-6, and Nkx2.2 (Yang et al. 2002a). The "mirror situation" is transdifferentiation of pancreas into the liver, early been detected by the observation that the pancreas can almost completely convert to the liver in the adult rat (Rao et al. 1988) and recently reviewed with respect to the mechanisms involved (Shen et al. 2003a). The temporal and hierarchical control of transdifferentiation of liver to pancreas is regulated by distinct transcription factors, including Pdx1, Pax4, and Mafa/3pTs (Berneman-Zeitouni et al. 2014). The glucagon-like peptide-1 antagonist, exendin-4, promotes liver cell proliferation and enhances the Pdx-1-induced liver to pancreas transdifferentiation process (Aviv et al. 2009). What are the cellular sources of hepatic metaplasia in the pancreas? Rat and human pancreatic islets and ducts contain a distinct population of cytokeratin-19 and peptide hormone-negative cells expressing the neural stem cell-specific marker, nestin. These nestin-positive islet-derived progenitor (NIP) cells seem to be multipotential and are able to differentiate into cells that express liver and exocrine pancreas markers (Zulewski et al. 2001). More recently, it has been shown that glucocorticoids induce the appearance of hepatocyte-like cells of islet origin in organ cultures of embryonal rat pancreas based on the expression of liver markers, albumin, alpha-1-antitrypsin, and transthyretin, associated with a downregulation of Pdx-1 and an upregulation of the transcription factor, C/EBPbeta (Shen et al. 2003b). It remains to be shown whether transdifferentiation mechanisms are involved in the pathogenesis of nodular or multifocal hepatic pancreas heterotopias in humans.

Thyroid Gland Ectopia in the Hepatobiliary Tract

Introduction

Thyroid tissue ectopias chiefly occur along the developmental axis of this organ, i.e., in the posterior part of the tongue (area of the foramen caecum; lingual thyroid) and in salivary glands, and in association of the descending pathway of the thyroid anlage. However, thyroid primordia may also be displaced together with other organs undergoing a physiologic descent during ontogenesis, resulting in intrathoracic thyroid ectopia, e.g., the lung, the oesophagus, and the heart (struma cordis). Thyroid ectopia may even extend to compartments below the diaphragm, e.g., in the duodenal wall, pancreas, hilum of the spleen, small intestinal mesentery, adrenal gland, vagina, and liver and gallbladder. Even thyroid ectopias outside the thorax and abdomen have been observed, e.g., in the axilla. Malignant transformation of thyroidal ectopias (papillary carcinoma of thyroid) is extremely rare (Michigishi et al. 1991; Zink et al. 1991; Hari et al. 1999; Matsumoto et al. 1999).

Thyroid Ectopia in the Liver

Ectopic thyroid tissue in the liver is a very unusual alteration, and most patients displayed the tissue in or near the porta hepatis. In one instance, where the thyroid features of the tissue were confirmed by immunohistochemistry, displaced thyroid tissue was detected in a fetus with trisomy 18, who showed a eutopic thyroid gland without changes,

and a focus (2 mm) follicular, thyroglobulin-reactive thyroid tissue (immunohistochemically without calcitonin-reactive cells) at the porta hepatis, close to a bile duct (Sekine et al. 2000). Five additional published observations on thyroid ectopia at the hepatic porta are available (Schubert 1957; Rahn 1959; Strohschneider et al. 1993; Jamshidi et al. 1998; Ghanem et al. 2003).

In the case of Strohschneider and coworkers, the thyroid ectopia produced a mass of 4.5 cm diameter, and the tissue was identical to normal thyroid gland tissue. In contrast, another case was characterized by the presence of nodular goitrous tissue at the porta hepatis, producing a mass (Jamshidi et al. 1998). The case of Ghanem and coworkers (Ghanem et al. 2003) refers to a 24-year-old female patient who was admitted to the hospital to explore an incidentally detected subhepatic tumorous lesion in the porta hepatis via routine abdominal ultrasonography. CT revealed an inhomogeneous, slightly attenuated, lobulated lesion measuring up to 10 cm, with some calcifications. Fine needle aspiration yielded typical thyrocytes and thyroid follicles. A subsequent 123-I-scintigraphy confirmed the diagnosis of thyroid ectopia. The lesion was resected, weighed 580 g, and exhibited a nodular structure as seen in nodular goiter, further exemplifying that strumigenic factors may also act in ectopic thyroid tissue. Hepatic thyroid ectopia may be mimicked by metastasis of well-differentiated follicular carcinoma of the thyroid (Kondo et al. 2000).

Thyroid Ectopia in the Biliary Tract

Few reports have described thyroid ectopia in the gallbladder (Curtis and Sheahan 1969; Harach 1998; Ihtiyar et al. 2003; Cassol et al. 2010; Liang et al. 2010). In all but one case, thyroid ectopia was an incidental finding. In the case of Harach (1998), a spheroid nodule up to 7 mm was found lying within the fibrofatty tissue adjacent to the neck of the gallbladder, containing thyroid follicles of various sizes filled with colloid and lined by typical thyrocytes. The follicular cells and the colloid showed patchy thyroglobulin immunoreactivity but were negative for calcitonin. In one reported patient, the ectopia presented as a gallbladder mass (Liang et al. 2010).

Endometriosis of the Liver

Introduction

Endometriosis, first described by Rokitansky in 1860, is a condition in which endometrial tissue becomes implanted on extrauterine sites (reviews: Giudice and Kao 2004; Clement 2007; Baldi et al. 2008), most commonly within the pelvis, but rarely also in foregut derivatives, i.e., the pancreas and the liver. Albeit as such a benign lesion, endometriosis is a condition that predisposes to cancer.

Epidemiology

As endometriosis is strongly associated with abdominal trauma and abdominal-pelvic surgery, reliable informations concerning its incidence are difficult to obtain. The literature shows around 25 published cases of hepatic endometriosis. Hepatic endometriosis predominates in the right liver lobe and was mostly detected in patients younger than 60 years of age. In more than 50 % of patients, hepatic endometriosis was detected before menopause (Fluegen et al. 2013).

Clinical and Imaging Features

Hepatic endometriosis is clinically silent in most of cases, but some of the patients reported so far had several symptoms and signs, including chronic epigastric (right) pain or upper abdominal tenderness, and nausea. The disorder can also cause cyclic right subcostal pain (Cravello et al. 1996; Verbeke et al. 1996; Watari et al. 2012) or, rarely, obstructive jaundice (Jeanes et al. 2002; Khan et al. 2002). In one patient, hepatic endometriosis progressed to the hepatic hilar region, causing obstructive jaundice and portal vein thrombosis (Khan et al. 2002). Hepatic

endometriosis is rarely associated with involvement of the falciform ligament (Weinfeld et al. 1998). The majority of published cases of hepatic endometriosis had no past history of pelvic endometriosis. As a complication, hepatic endometriosis can give rise to bronchobiliary fistula (Schuld et al. 2011). Apart from the liver substance, endometriosis occurs in a perihepatic distribution (Weinfeld et al. 1998), including the diaphragm (Kalkur et al. 2013). Endometriosis also occurs in the gallbladder and can cause occult bleeding (Saadat-Gilani et al. 2007).

The ultrasonographic and imaging features have been specified (Grabb et al. 1986; Nakanishi et al. 1994; Inal et al. 2000). Apart from solid liver manifestations (hepatic endometrioma; Groves et al. 2003), hepatic endometriosis presents in the form of cystic hepatic lesions, sometimes with (punctate) calcifications of the cyst wall and with or without septation (Finkel et al. 1986; Cravello et al. 1996; Verbeke et al. 1996; Chung et al. 1998; Inal et al. 2000; Huang et al. 2002; Reid et al. 2003; Tuech et al. 2003; Kouto Fichet et al. 2004; Nezhat et al. 2005; Goldsmith et al. 2009; Roesch-Dietlen et al. 2011; Bouras et al. 2013; Fluegen et al. 2013). Radiologically, the intrahepatic lesion can closely mimic hepatobiliary cystadenoma (Rivkine et al. 2013). The size of hepatic endometriotic cysts ranges from 50 to 240 mm in diameter, and the cysts are either solitary or multilocular. On contrast-enhanced CT images, a heterogeneous mass with both solid and cystic parts is typical, while on MR images, hemorrhagic parts are low-signal intense on T1-weighted and high-signal intense on T2-weighted images (Zawin et al. 1989; Inal et al. 2000). The differential diagnosis of endometriotic hepatic cysts chiefly comprises hemorrhagic simple cysts (Vilgrain et al. 1993; Hanazaki et al. 1997; Hagiwara et al. 2001). Multiple foci of hepatic endometriosis can mimic metastatic liver disease (Asran et al. 2010).

Pathology

At gross examination, hepatic endometriosis occurs in the left or right liver lobe, and bilobar manifestation is exceptional (Khan et al. 2002) and is mostly manifest as a cystic lesion (see above) with fresh or altered blood in the cavity or the features of a so-called chocolate cyst, as known for genital endometriosis, and may produce a liver mass ("endometrioma"; Grabb et al. 1986; Rovati et al. 1990; Inal et al. 2000; Bohra and Diamond 2001). The cystic structures are sometimes multiloculated. The diameter of endometriotic foci in the liver can exceed 20 cm in diameter (30 cm: Tuech et al. 2003). Solid variants of hepatic endometriosis present as an expanding, well-delineated and sometimes multilobated mass of dark-red to red-brown color. A spongy texture may occur, and on cutting, fresh and old blood or a brownish fluid with suspended cholesterol crystals may ooze from the cut surface. The perifocal liver substance is atrophic. Histologically, a typical bimodal morphology with both endometrium-type epithelium and cellular stroma is in evidence, sometimes with secondary changes such as hemorrhage and deposition of stainable iron. The lesions are well delineated and may develop a capsule-like structure with variable inflammatory changes. In old cysts, much of the epithelium may have decayed, and the stroma may be atrophic and/or fibrosed, rendering the histologic diagnosis more difficult. Subsequent to necrosis and/or hemorrhage, nodules containing numerous lipid-laden macrophages ensue in part of the cases (necrotic pseudoxanthomatous nodules in endometriosis; Clement et al. 1988).

In endometriosis, acellular, laminated, ring-like, eosinophilic, and in part PAS-positive structures called Liesegang rings can develop (Schwartz and Bellin 1991; Perrotta et al. 1998), occurring also in other situations of tissue damage, and thought to result from a periodic deposition of proteins within a colloid-like matrix (Cartwright et al. 1999; Henisch 2002). Liesegang rings are named after the German scientist Raphael Eduard Liesegang (1869–1947), an extraordinary and multi-interested personality who translated a Malay grammar when still in school, was formed as a painter, published in 1891 the probably first

article on "the question of electric television" (the "Phototel"), was active in the photographic factory of his father, became an outstanding colloid scientist, visualized neuronal ramifications by use of the Golgi impregnation technique, reported in 1896 periodic phenomena occurring in colloids (later called "Liesegang rings" by Wilhelm Ostwald), and became director of the colloid science branch of the Kaiser-Wilhelm Institute of Biophysics in Frankfurt in 1937.

Immunohistochemically, the glandular epithelium is reactive for Ca19-9 and the stromal cells for CD10 (Carbone et al. 2004). CD10 is known to be a marker for normal and neoplastic endometrial stromal cells (Toki et al. 2002) and may be used in detecting occult or inconspicuous endometrial stromal cells in presumptive endometriosis (Groisman and Meir 2003). The stromal cells of hepatic endometriosis show strong nuclear reactivity for estrogen receptor protein (Carbone et al. 2004).

Hepatic Endometriosis and Malignancy

Both gonadal and extragonadal endometriosis can be complicated by malignancy (ovary 80 %, extragonadal sites 20 %; Heaps et al. 1990; Leiserowitz et al. 2003). Endometrioid adenocarcinomas account for 69 % of the lesions, clear cell carcinomas 13 %, and adenosarcomas 12 % (Clement and Scully 1990). Adenocarcinoma in situ has been found in cystic liver endometriosis (Sanchez-Perez et al. 2006). One report documents squamous carcinoma in hepatic endometriosis (Weinfeld et al. 1998). Adenosarcoma arising in liver endometriosis has also been reported (N'Senda et al. 2000; Jelovsek et al. 2004). There is also one reported observation of low-grade endometrial stromal sarcoma arising in hepatic endometriosis, manifest in the form of a large mass lesion occupying the entire right liver lobe (Khan et al. 2002). Primary extrauterine endometrial stromal sarcoma is known to occur at several sites, in part related to endometriosis (Chang et al. 1993).

Differential Diagnosis

Differential diagnostically, endometriosis of the liver has to distinguish from endometriosis and endometriomas developing in the perihepatic compartment. Endometriosis occurs in the diaphragm (Vercellini et al. 2007), where it can mimic Fitz-Hugh and Curtis syndrome (Takeuchi et al. 2005), and endometrioma has been observed in the subhepatic retroperitoneal space (Lolis et al. 2007). Hepatic endometriosis may histologically be confounded with endometrial stromal sarcoma which can metastasize to the liver (Ramia et al. 2012).

Adrenal Ectopia, Adrenohepatic Fusion (AHF), and Adrenohepatic Adhesion (AHA)

Introduction

Whereas ectopic adrenal tissue is widely recognized in many sites of the body, and in particular the urogenital system, ectopic adrenocortical tissue in the liver is exceedingly rare. In the context of hepatic tumors, ectopic or fused adrenal tissue is of certain significance insofar as these misplaced tissues can give rise to intrahepatic adrenocortical tumors. The complex issue of adrenal rest tumor of the liver is discussed in a separate chapter.

Adrenal Ectopia

In a neonate, a small nodule of adrenal cortical tissue situated deep within the liver has been observed, the cortex consisting of both fetal and adult types (Vestfrid 1980). In another pediatric patient with undifferentiated embryonal sarcoma of the liver, ectopic adrenal cortical tissue was detected under the Glisson's capsule (O'Sullivan et al. 2001). Ectopic adrenal tissue has also been identified in the gallbladder wall (Busuttil 1974). Conversely, heterotopic liver has been observed within the adrenal gland (Honoré 1985; Buck and Koss 1988).

Ectopic adrenocortical neoplastic lesions have been observed in the liver. In a small boy with signs of virilism and Cushing's syndrome, a calcified tumor was detected in the liver, in the absence of the right adrenal gland. The large tumor (8 cm) was embedded within the liver substance and in fact occupied much of the right liver lobe. Histologically, the tumor was composed of large cells typical for an adrenocortical neoplasm (Wilkins and Ravitch 1952).

Adrenohepatic Adhesion

Adrenohepatic adhesion (synonyms employed in the literature: adrenohepatic fusion; adrenohepatic union; hepatic adrenal dystopia) denotes tissual continuity between an entire or a part of the adrenal gland (or glands) with the liver's surface (Schmorl 1891; Oberndorfer 1900; Miloslavich 1914; Weller 1925; Cullen 1925; Hamperl 1970; Dolan and Janovski 1968; Honoré and O'Hara 1976; Honma 1991; O'Sullivan et al. 2001; Figs. 4 and 5). The several terms sometimes used as synonyms may in fact represent different changes caused by different mechanisms. In a first critical review of the issue, adrenal heterotopia was defined as partial or complete fusion of the adrenal with the kidney or liver, the amount of adrenal medulla present being roughly inversely proportional to the degree of fusion (Weller 1925). Later, true adrenorenal heterotopia and accessory or aberrant adrenal rests were clearly distinguished (Culp 1939). Three reports in the literature refer to the incidence of this phenomenon; in one study, 4 among 510 necropsy cases (08 %) were observed (Schmorl 1891), while another study documented 2 among 115 cases (1.7 %; Dolan and Janovski 1968), and a third 63 among 636 nonselected autopsies (9.9 %; Honma 1991). It therefore appears that adrenohepatic adhesion is a rather common incidental finding in autopsy material. In one autopsy series, the incidence of AHF was much higher in older age group, interpreted to suggest that AHF may be an ageing phenomenon (Honma 1991).

Fig. 4 Adrenohepatic fusion. Yellow adrenocortical tissue (*right half of figure*) adheres to the the liver capsule

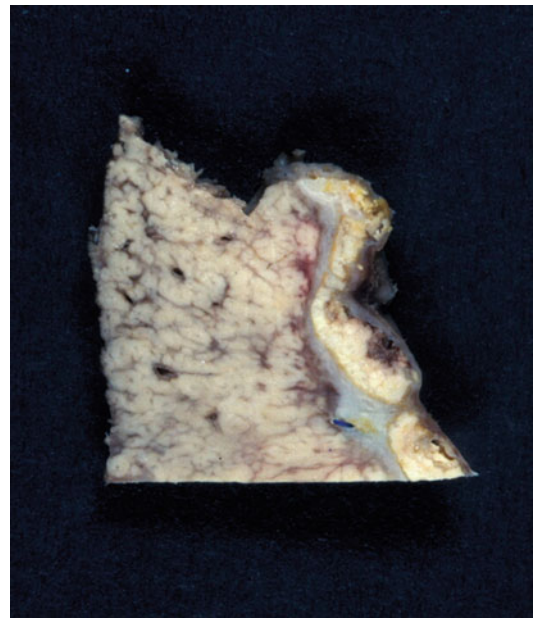

Fig. 5 Adrenohepatic fusion. A *yellow* rim of adrenal tissue is in direct contact to liver tissue

Pathology

At gross examination, heterotopic adrenal tissue may be in evidence in form of clearly identifiable yellow adrenal cortical tissue adherent to the inferior surface of the liver, more frequently on the right side, but rarely also in a bilateral position. Histologically, a broad spectrum of spatial

relationships between the two tissues in question can be observed, having resulted in a more specific nomenclature and views regarding pathogenic pathways. The heterotopic adrenal tissue consists of lipid-rich, typical cortical cells, mostly of the spongiocytic type. The adjacent liver tissue shows only minor changes, compatible with perifocal atrophy, and sometimes ectatic blood vessels. In one systematic study, adrenohepatic fusion (AHF) was distinguished from adrenohepatic adhesion (AHA), AHF being characterized by parenchymal intermingling, whereas AHA was defined as firm attachment of both organs without evidence of parenchymal intermingling (Honma 1991). In more detail, AHF was defined as union of the liver and the right adrenal with close intermingling of the respective parenchymal cells, with or without partial absence of a fibrous organ capsule (Honma 1991; Fig. 5). This author also identified three types of AHF: (a) adrenocortical cells within the liver, (b) hepatocytes and/or bile duct epithelium within the adrenal, and (c) bidirectional intermingling showing features of both (a) and (b). Extrahepatoparenchymal adrenocortical nodules may occur (Honma 1991). In 71 % of AHF cases, adrenocortical hyperplasia was detected, but the significance of hyperplasia for the genesis of AHF is not known (Honma 1991). The histologic separation between AFH and AHA depends on the number of sections performed to identify parenchymal intermingling. AHA and adrenorenal fusion may occur as combined alterations (Miloslavich 1914).

Adrenal Tumors Arising in the Setting of Adrenohepatic Fusion

AHF may be associated with neoplastic processes. In few patients, AHF harbored adrenal cortical adenoma (Woo et al. 2007; Park et al. 2009). In one patient, CT revealed a nodule in the posterior section of the right liver, and the surgeon found that the right adrenal was adherent to a subcapsular nodule of 1.5 cm diameter, which was a lipid-rich adrenocortical adenoma (Woo et al. 2007). In a second patient, a solid hepatic tumor was incidentally detected at ultrasound examination for an unrelated lesion. At surgery, the neoplasm was a lipid-rich cortical adenoma deeply situated within adrenohepatic fusion tissue (Park et al. 2009). In a 69-year-old female patient with a diagnosis of primary aldosteronism, enhanced CT scan before surgery revealed a right adrenal tumor (aldosteronoma) located to an adrenohepatic fusion (Takeuchi et al. 2013).

Adrenal Metastases Developing Through an Adrenohepatic Fusion

Metastasizing hepatocellular carcinoma may use the vascular connections situated within an adrenohepatic adhesion to form metastases in the adrenal gland (Okano et al. 2004). In one patient with a right-sided periadrenal metastasis of hepatocellular carcinoma, this metastasis was supplied by the hepatic artery. It was suggested that cancer cell invasion through an adrenohepatic fusion was the most likely mode of periadrenal metastasis in this case (Iwamoto et al. 1997).

Hepatogonadal Fusion

Introduction

Fusion of the gonadal anlagen with other embryonal organs is a rare but well-described condition. Clinically important is splenogonadal fusion, first described by Pommer in 1889 and characterized by the presence of heterotopic masses of aberrant splenic tissue adherent to the gonads (Putschar and Manion 1956; Kocher et al. 2014). Classical splenogonadal fusion clinically manifests as a palpable, painless left scrotal swelling. Three types of splenogonadal fusion have been described: continuous, discontinuous, and combined, what is of some importance for the understanding of hepatogonadal fusion. In the continuous variety, the main spleen remains connected to the left gonadal mesonephric structures by a continuous cord, which may be completely splenic, fibrous, or beaded with

multiple nodules of splenic tissue. In the discontinuous variety, discrete masses of aberrant heterotopic splenic tissue are found fused to the same structures (Putschar and Manion 1956). In the combined variety, there is an extension of functional splenic tissue from the orthotopic spleen into the abdomen, but there is no connection to the ectopic spleen near the gonad.

Hepatogonadal Fusion

Fusion of a liver component with testis is highly unusual and has only reported few times. It is a form of ectopic liver tissue (Ferro et al. 1996; Fan et al. 2012). A 4-month-old boy operated for right inguinal hernia with completely patent processus vaginalis showed a reddish nodule adherent to the upper pole of the right testicle. This nodule continued upward in a thin fibrous pedicle found to enter the porta hepatis. Histology revealed a small lobe of hepatic tissue that contained several portal tracts of different sizes. The hepatic parenchyma consisted of liver cell plates and intervening sinusoids, and the portal tracts contained interlobular bile ducts. In a second patient, a 3-month-old boy showed an unusual spermatic cord-like structure connecting the liver and right testis. Liver tissue was found along the entire length of this structure (Fan et al. 2012).

Pathogenic Pathways

Gonadal fusion events may be better understood owing to increasing knowledge of gonadal development and gonadal descent (Byskov 1986; Werdelin and Nilsonne 1999). The testis begins its descent at about the eighth week, when the liver, spleen, and adrenal anlagen are already formed. In regard to splenogonadal fusion, it has been suggested that, owing to the close spatial relation between the developing spleen and the left gonad during rotation of the dorsal mesogastrium, adhesion between the splenic peritoneum and the gonadal ridge may occur and result in fusion (Gouw et al. 1985; Carragher 1990).

Hepatic Pregnancy

Hepatic pregnancy is briefly discussed here because of the focal hepatic or perihepatic changes and potential mass effects induced by this disorder, resulting in a complex differential diagnosis. Primary peritoneal pregnancy is rare, and implantation may occur anywhere but most commonly on the surface of the pelvic peritoneum. The four chief criteria to be fulfilled in order to diagnose primary peritoneal pregnancy comprise (a) normal tubes and ovaries without evidence of injury, (b) no evidence of utero-peritoneal fistula, (c) pregnancy-related exclusively to the peritoneal surface, and (d) pregnancy at an early enough stage of gestation to exclude the possibility of a secondary implantation following initial eliminated primary tubal nidation (Studdiford 1942). The liver, respectively, its visceral peritoneum, is an exceptional site of implantation (Mear et al. 1965; Kirby 1969; Luwuliza-Kirunda 1978; Gordeev 1980; Hietala et al. 1983; Mitchell and Teare 1984; Shukla et al. 1985; Paulino-Netto and Roselli 1986; Veress and Wallmander 1987; Borlum and Blom 1988; Schlatter et al. 1988; Harris et al. 1989; De Almeida Barbosa et al. 1991; Leshchenko et al. 1994; Kato 1995; Nichols et al. 1995; Delabrousse et al. 1999; Chui et al. 2001; Jané et al. 2008). Hepatic pregnancy may present as a bleeding mass of several centimeters diameter, with angiographic features similar to those in tubal pregnancy (Hietala et al. 1983), but hepatic implantation may also be compatible with a living infant (Mear et al. 1965; Shukla et al. 1985). Exceptionally, hepatic pregnancy is diagnosed after long delay, i.e., in a state of lithopedion (Luwuliza-Kirunda 1978). Lithopedion (Greek: lithos, stone; paidion, child) designates a fetus that has become bony or calcified after death (Fagan et al. 1980) and has apparently first been described in the tenth century by an Arab surgeon named Albucasis (cited in Lachman et al. 2001). In the late nineteenth century, lithopedion has been classified based on the kyemal components involved by calcification/ossification (Küchenmeister 1881; Hemley and Schwinger

1951), i.e., lithokelyphos (stone sheath or egg shell; Kelyphos, Greek, = husk, shell; calcified membranes forming a hard shell surrounding the fetus), lithokelyphopedion (stone sheath child; both membranes and fetus are calcified), and true lithopedion (stone child; fetus, but not membranes, is calcified). The clinical and radiologic differential diagnosis of hepatic pregnancy comprises, apart from other heterogeneously structured masses, hepatic hemorrhage occurring during pregnancy.

Fetus in Fetu

An extraordinary cause of an abdominal mass in infancy is fetus in fetu (FIF), FIF being "applied to any structure in which the fetal form is in a very high development of organogenesis and to the presence of a vertebral axis" (Gonzales-Crussi 1982). FIF was first described by Meckel in 1800 and defined by Willis (1953). FIF is thought to arise from inclusion of a monozygotic diamniotic twin where the parasitic twin installs and grows in the body of its partner (Gürses et al. 1990; Hoeffel et al. 2000; review: Brand et al. 2004), although it has been proposed that FIF may represent a fetiform, highly organized teratoma (a "pseudofetus"; de Lagausie et al. 1997). FIF is distinguished from bona fide benign teratoma by the presence of an amniotic or at least amnion-coated cavity and of a vertebral axis with limb buds (present in 91 % and 82.5 %, respectively; Hoeffel et al. 2000) or other appropriately situated bones or organs. FIF is extremely rare; the estimated incidence is 1 per 500,000 births (Grant and Pearn 1969). In almost 90 %, there was a single parasitic fetus apart from five reports in which the number of the fetus ranged from 2 to 5 (Hoeffel et al. 2000). Most of the FIF reported were cases of pedunculated masses within a capsule containing fluid and with an umbilical cord containing only two vessels. The typical site of FIF is the upper retroperitoneal space, but very rare other sites include the pelvic area, the ileal mesentery, the cranial cavity, the scrotum, and the liver. FIF may undergo postnatal growth (Kim and Shinn 1993).

FIF in the right liver lobe presented as a sac containing the fetus (Al-Baghdadi 1992). In one patient, a fetal liver abnormality was detected during routine ultrasound examination, and postnatal examinations allowed the diagnosis of three lesions of intrahepatic fetus in fetu, associated with multiple small subcapsular and perimass vascular hamartomas. The surgically removed specimen (hemihepatectomy) revealed two lesions with an amnion-lined cavity and one lesion with the features of benign teratoma (Magnus et al. 1999).

Ectopic Cartilage of the Hepatobiliary Tract

Foci of hyaline and mature cartilage at the porta hepatis have been described in patients with extrahepatic biliary atresia (EHBA) (Hassab et al. 1996; Mirkin and Knisely 1997; Kashiwagi et al. 2007; Stahlschmidt et al. 2008). Several band-like portions of hyaline cartilage were present in the adventitia of the nearly obliterated bile duct, while other patients revealed small nodules of hyaline cartilage adjoining residual peribiliary glands. The chondroid tissue exhibited a rich development of cartilage matrix, and the foci were demarcated by perichondrium. Respiratory-type epithelium was not detected, although the cartilaginous structures were sometimes reminiscent of the bars and plates seen in bronchi. In one case, the cartilage islands closely followed the lumens of small bile ducts (Hassab et al. 1996). In a 3-month-old infant with biliary atresia, islets of hyaline cartilage were found in the wall of a stringlike gallbladder, whereas the porta hepatis did not show cartilage in this case (Altamirano and Drut 2008).

Heterotopias that contain hyaline cartilage may occur as a result of developmental malformation or as a result of connective tissue metaplasia. It has been suggested that chondroid heterotopia in EHBA may result from long-standing inflammation inducing a metaplastic response, similar to the cartilage observed in renal cystic dysplasia (Bernstein 1971; Mirkin and Knisely 1997).

Tumor-Like Lesions of the Hepatobiliary Tract: Anatomical Variations and Malformations Resulting in Hepatic Mass Effects or Focal Defects

121

Contents

Abstract

Gross malformations of the liver can result in mass effects or focal defects that can resemble tumors or hepatic changes induced by tumors. Accessory liver lobes characterized by solitary or multiple parts of liver substance connected to the main liver by a bridge or stalk can mimic a pedunculated liver tumor. One well-known example is Riedel's lobe, an inferior, tongue-like projection of the anterior border of the right liver lobe. Several anomalies of the caudate lobe of the liver can also resemble tumorous growths. A similar effect can be produced by subdiaphragmatic and supradiaphragmatic ectopias of the liver.

Anatomic Variations of the Liver Mimicking a Hepatic Tumor

Albeit rare events, gross malformations of the liver may pose considerable differential diagnostic problems, even in the present time with its sophisticated imaging techniques; hence, misinterpretations of anatomic anomalies as neoplastic lesions have occurred and still occur. It therefore seems appropriate to summarize important aspects of liver substance abnormalities and to give an overview on the spectrum of the lesions in question.

How to classify hepatic malformations? In what follows we summarize what is, according to our view, the still best classification system

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_121

Table 1 The Jacquemet classification of malformations (listed in Cullen 1925)

1. Liver modified in form and in dimensions but retaining its place in abdomen
1.1. Anomalies by reduction
1.1.1. Diminution of the left lobe
1.1.2. Diminution of the right lobe
1.2. Anomalies through increase in size of the liver
1.2.1. Increase involving right lobe
1.2.2. Increase involving right lobe
1.2.3. Increase of Spiegel's lobe
1.2.4. Increase involving quadrate lobe
1.3. Modifications in form of the liver without any sensible augmentation in volume
1.3.1. Incised liver (furrowing of parenchyma; one or more fissures)
1.3.2. Liver with multiple lobes (accessory lobes)
1.3.2.1. Accessory lobe attached to the liver by a pedicle of liver tissue
1.3.2.2. Accessory lobe connected with the liver by a mesohepaticum ("mesentery" in the original text, this being a misnomer)
1.3.3. Isolated accessory livers
1.3.4. Isolated nodules of liver tissue in the suspensory ligament
1.4. Liver modified in form and in dimensions and out of place
1.4.1. Liver misplaced and rotated to a vertical axis
1.4.2. Liver almost free in the abdominal cavity owing to loss of the greater portion of its ligamentous attachment
1.5. Elongated right lobe of the liver (Riedel's lobe)
2. Liver not modified in form but displaced
2.1. Anomalies of the liver in abnormal subjects
2.1.1. Thoracic displacement of the liver
2.1.2. Portion of the liver in amniotic hernia
2.1.3. Accessory lobe of the liver springing from the surface of the gallbladder

(Jacquemet 1896; Cullen 1925), which is based on a purely phenotypic approach to the question. In the future, modern embryological aspects of hepatic morphogenesis will certainly alter, expand, and refine such an attempt at classifying these lesions.

Selected References Meckel 1822a; Wagner 1861; Vegandt 1876; Toldt and Zuckerkandl 1876; Calori 1880; Gruber 1880; Broca 1880; Duchesne 1881; Tarenetzki 1883; Musser 1888; Grenet 1895; Thomson 1898; Moser 1898; Chiari 1899; Tarozzi 1904; Barclay-Smith 1908; Inglis 1911.

The Jacquemet system (listed in Cullen 1925) is shown in Table 1.

It is important to note that hepatic anatomic variations are not stable features, but rather represent changes submitted to a dynamic evolution. In a study on 52 perinatal livers, remarkable discrepancies between the adult and perinatal incidences of various anomalous manifestations were noted (Parke et al. 1996). In particular, ectopic accessory lobes were very rare in the adults analyzed in this study and in other groups reported in the literature. They were, in contrast, a relatively common finding in the perinatal group as were gallbladder bridges of hepatic tissue, hypertrophic papillary lobes, and marked accessory fissures, but marginal accessory lobes were not observed in perinatal livers. This may be due to postnatal gross liver remodeling, with most of the ectopic lobes, bridges of liver substance, hypertrophic caudate lobe extensions, and accessory fissures disappearing after birth (Parke et al. 1996).

Accessory Lobes of the Liver

Accessory lobes of the liver are developmental anomalies of the liver characterized by solitary or multiple parts of liver substance, of variable size, usually covered by a liver capsule, and connected to the main, orthotopic liver by a bridge or a stalk (Meckel 1822b; Gruber 1849; Wagner 1861). Most of the cases reported in the nineteenth century and before have been compiled in 1915 (Forni 1915). The cases described in the literature are, based on the descriptions, not always attributable to accessory lobes sensu stricto or to liver ectopia; this mainly holds true for hepatic masses situated in hepatic ligaments, where the descriptions sometimes do not allow to reconstruct the type of connections to the main liver. Accessory lobes are, with one exception (Riedel's lobe), rare alterations (Cullen 1925; Chouke 1932; Watson and Lee 1964); in a series of 5500 autopsies, 13 children with

supernumerary lobes have been identified (Eiserth 1962). It has to be emphasized that liver furrowing is rather frequent in the newborn and infancy periods, and mostly involves superficial parts of the right liver lobe (Jacquemet 1896), but part of these changes seem to be reversible (Parke et al. 1996). The issue of accessory liver lobes has been discussed in a comprehensive review (Cullen 1925). Cullen described all degrees of hepatic lobation, from multiple deep furrowing to complete separation of parts of hepatic tissue from the main, orthotopic liver. Some supernumerary lobes (or rather lobe equivalents) were attached to the main liver mass by a pedicle of hepatic tissue, while others were attached by some sort of a meso (a "mesohepaticum") containing blood vessels and bile ducts only. Pathogenetically related may be the situation where the right and left liver lobes are completely separated, with a fibrovascular plate separating the two parts (Kschischo 1912). Multiple accessory lobes result in congenital hepar lobatum, and the liver may then consist of more than ten lobar units. Cullen (1925) cites the remarkable case of Moser who had found the liver to be partitioned into no less than 16 lobes, in some way reflecting the situation frequently found in some mammals, such as the pig and the dog.

Riedel's lobe (RL) is an inferior, tongue-like projection of the anterior border of the right liver lobe, to the right of the gallbladder, termed after the author of the first description (Riedel 1888). Already in 1903, the term, Riedel's lobe, was employed (Lockwood 1903). Riedel observed this change in seven females who had palpable masses in the right hypochondrium, and the abnormal "lobe" was subsequently confirmed at surgery. Probably, two other authors have described and reported this change in the same year, in one patient as a hepatic lesion simulating movable kidney (Pichevin 1888; Musser 1888). In the early nineteenth century, some surgeons had surmised that RL was due to tight corseting (Finney 1925), and already Riedel himself thought of this possibility (Riedel 1888). RL has since been documented and discussed several times.

Selected References Lockwood 1903; Wilhelmi 1923; Reitemeier et al. 1958; James et al. 1963; Lane 1966; Keyloun and Pinkernell 1967; Couinaud et al. 1968; Baum et al. 1982; Kudo 2000.

What is the incidence of RL in the adult population? In a review of 2604 patients, RL as identified by technetium scintigraphy was present in 86 (3.3 %). In a second study of 564 patients, the prevalence of RL was 14.5 %, however, defined by liver scintigraphy only (Baum et al. 1982). The reasons for such differences in prevalence are, on the one hand, related to definition of what RL is and, on the other hand, linked to age-related changes of the liver and its anatomy (see below; Gillard et al. 1998). In a larger series, no significant differences in the prevalence of RL between the sexes were found (Gillard et al. 1998). RL is usually an asymptomatic lesion presenting as a palpable mass in the right hypochrondrium, but it may lead to possible confusion with a hepatic or renal tumor or with right-sided nephroptosis (Wilhelmi 1923; James et al. 1963; Kudo 2000). RL can exert compression effects on neighboring organs, e.g., gastric outlet obstruction (Akbulut et al. 2011). In a study on 31 patients with RL (age at diagnosis ranging from 31 to 77 years), a palpable mass in the right side of the abdomen was present in 18 patients, and the existence of a mass was known before the diagnosis of RL in seven. In contrast with the series described by Riedel, no gallbladder was palpable in these 31 patients (Reitemeier et al. 1958). Clinically significant lesions originating within RL are extremely rare but include cirrhosis and metastatic lesions (Soo and Adatepe 1990). In 30 of the 86 individuals analyzed by Sham and co-workers, RL was found to be hypertrophic, more frequently in females (Sham et al. 1978). Therefore, particularly RL hypertrophy makes part of the differential diagnosis of a right-sided abdominal mass. RL is readily diagnosed by ultrasonography (Chaulieu et al. 1982), CT, and MRI (Yano et al. 2000) and has distinctive angiographic features (Lipchik and Schwartz 1967). Radiologically, RL necessitates an extended sequence of sectional imaging in order

not to miss lesions in its most distal parts (Gillard et al. 1998). The morphological presentation of RL has been studied in detail (Gillard et al. 1998). As a secondary phenomenon, the apex of RL can be attached to the right (hepatic) colonic flexure, but these adhesions may be much more extended, involving almost the entire undersurface of RL, connecting RL with both the right colon and the duodenum and causing kinking of the colon (Figs. 11, 12, and 13 in the work of Cullen 1925). Similar to other anatomic anomalies of liver lobes, RL seems to be a lesion subject to a dynamic evolution. For example, the proportion of individuals in whom the most caudal margin of the liver was inferior to the most caudal costal margin was age dependent and increased to 65 % in the 50–59-year age group; moreover, the craniocaudal dimension of the liver decreased with age, overall suggesting that the prevalence of RL is dependent on age-related changes in liver size and skeletal shape (Gillard et al. 1998).

What is the possible fate of RL? Riedel reported that there was an apparent regression of the abnormal lobe after cholecystectomy (Riedel 1888). RL can be complicated by torsion, with necrosis and signs of acute abdomen (Lefaucher et al. 1978). It has also been theorized that RL, or at least parts of this lobe, may undergo atrophy, resulting in a hanging spheroid lobe of liver tissue connected with the lower end of the right liver lobe by a fibrovascular band. Such a hanging lobe, with two associated satellite nodules, has already been described in 1880 (Taruffi 1880).

It is still debated whether RL is a congenital change (Reitemeier et al. 1958; Farmer et al. 1969; Sham et al. 1978) or an acquired change (Riedel 1888; Reitemeier et al. 1958). It has been proposed that RL is, in fact, not a bona fide malformation but rather a simple variant of clinical anatomy (Lane 1966), all the more so as the change can be subject to regression. Very rarely, two inferior accessory lobes, each one somewhat resembling a RL, have been found, right and left to the round ligament, a "double RL" (Giacomini 1884). Moreover, tongue-like projections with a configuration similar to RL occur in the left liver lobe (Chiba et al. 1991). Rarely, RL is the site of cancerogenesis, e.g., hepatocellular carcinoma (Zamfir et al. 2008).

Anomalies of the Caudate Lobe of the Liver

The caudate lobe (CL) of the liver has a complex anatomy with five surfaces that is clarified by embyrologic and anatomic analysis (Van Minh et al. 1992; Couinaud 1998; Abdalla et al. 2002; Murakami and Hata 2002). In some contrast to the concept of Couinaud (see below; Couinaud 1998), some authors state that the CL consists of three parts, i.e., (a) the Spiegel's lobe (the caudate lobe plus papillary process of the anatomists), (b) the caudate process, and (c) the paracaval portion corresponding to the dorsally located parenchyma in front of the inferior vena cava. All three parts are supplied by primary branches originating from the left and right portal veins, including the hilar bifurcation area. The hilar bifurcation branch often (50 %) supplies the paracaval portion, and it sometimes (29 %) extends its territory to Spiegel's lobe (Murakami and Hata 2002). The CL belongs, according to Couinaud (1998), to the so-called posterior sector of the liver which is, in its development and anatomy, independent of the right and left liver and the main portal fissure. In particular, the CL is the midportion of the posterior liver and the only part of the liver that is in contact with the caval vein, except at the entrance of the main hepatic veins into the vena cava. This dorsal sector extends in front and to the sides of the inferior vena cava, separating the caval axis from the main liver, resulting in a single unit composed of the dorsal sector itself and the retrohepatic portion of the caval vein (Couinaud 1998). In contrast to the three-part concept of the CL as outlined above, Couinaud's view is that the dorsal sector is made of two segments: left (segment I) larger than the Spiegel lobe and right (segment IX) incorporated in the posterior surface of the right liver, where the caudate process is not regarded as a peculiar element but rather the inferior margin of segment IX. The vascular and bile duct anatomy related to CL has been studied in detail.

Selected References Couinaud 1998; Filipponi et al. 2000; Kanamura et al. 2001; Kwon et al. 2002; Sato et al. 2002; Bargallo et al. 2003;

Kitami et al. 2004; Lee et al. 2004; Ortale and Borges Keiralla 2004; Takamatsu et al. 2004; Tohma et al. 2005.

Alterations of the CL may mimic a mass or space-occupying lesion in the portocaval space. Specifically, the variable anatomy of the papillary process may cause misinterpretations of the gross morphology of the posterior sector. In an ultrasound study of 400 patients, the papillary process appeared to be separate from the liver in 15.5 % and had an egg shape with a maximum transverse diameter of 8–39 mm. In this subfraction of patients, the papillary process appeared above and in front of the common hepatic artery close to the portal vein and pancreatic isthmus, and enlarged papillary processes were more frequently seen in patients with chronic liver disease (Donoso et al. 1989). Hypertrophy of the papillary process of CL can mimic a liver mass (Reuther 1992). The papillary process may also be separated from the caudate lobe as such by a fissure, thus leading to erroneous sonography interpretation as a space-occupying lesion (Korn et al. 1991). But also the caudate process of the caudate lobe can undergo pseudotumorous hyperplasia (Kwak et al. 2000). Other mass-inducing changes of the CL is, e.g., a pseudotumorous hyperplasia of this lobe that has been seen in Alagille syndrome (Tuset et al. 1995).

Other hepatic malformations of the liver are characterized by additional lobes or lobe-like formations.

Very rare malformations include small ectopic livers (Marquand et al. 1980), a pendulated accessory liver lobe (Fogh et al. 1989), anomalous lobes displacing stomach and duodenum (Meyers and Jacobson 1958), and juxtacholecystic hepatic nodules (Perez Ara and Silva Ruiz 1954).

Atrophy, Hypoplasia, and Aplasia/Agenesis of Liver Lobes

This issue of gross disorders of lobar or segmental development of the liver has been reviewed (Champetier et al. 1985). Congenital hypoplasia of the right hepatic lobe with compensatory hypertrophy of the left lobe and of the left liver lobe has been described (Heller 1870; Krauspe 1923; Morgenstern and Mazur 1959); it is sometimes associated with a so-called floating gallbladder (Kabaroudis et al. 2003). In some cases, atrophy subsequent to ischemia or birth trauma may be more likely than hypoplasia, a question already raised in an early report on liver hypoplasia (*Vitium primae formationis* vs. acquired alteration; Heller 1870; Lancereaux 1899). Hepatic lobar agenesis is exceedingly rare (Reddy 1954; Auguste et al. 1955; Bertrand 1963) but can cause portal hypertension (Negre et al. 1962; Bertrand et al. 1962).

Subdiaphragmatic and Supradiaphragmatic Ectopias of the Liver

Subdiaphragmatic Ectopias

Liver ectopias are, in contrast to accessory lobes, usually not in connection via liver substance with the main liver, but may be supplied by liver vessels and drained by bile ducts. Subdiaphragmatic locations include the left triangular ligament, supraumbilical part of the round ligament, hepatoumbilical ligament, omentum majus, pancreas, spleen, retroperitoneal space, and gallbladder (Eiserth 1940; McCreadie and Burkhardt 1965; Cardona et al. 2007; Kanzaki et al. 2010; Matsuyama et al. 2011; Zonca et al. 2013). In connection with the transient omphalic cleft during ontogeny, ectopic liver has been observed in the umbilicus, in the absence of an umbilical hernia (Shaw and Pierog 1969; Park et al. 1991), in one instance in the form of a separate hepatic lobe (D'Agostino et al. 1989), as ectopic liver in the umbilical cord (Preminger et al. 2001; Wax et al. 2007; Lara-Diaz et al. 2011; Vaideeswar et al. 2011), and as a supernumerary liver lobe within omphalocele (Fock 1963; Louda and Baumelt 1981; Charbonnet et al. 1988; Festen et al. 1988).

In Fock's two cases, the liver tissue within the omphalocele was completely separated from the

intra-abdominal liver. In the case described by Shaw and Pierog (1969), a 2 cm reddish-purple, pedunculated mass was present, attached to the depths of the umbilicus of a baby. A dark-red drainage was noted to be coming from this umbilical tissue mass. Histology revealed a polypoid fragment of liver covered by capsule, with diffuse hepatic fibrosis and ductular proliferation (Shaw and Pierog 1969). A different situation was described in a newborn infant with a 7.5 cm sized ectopic mass of liver tissue connected to the orthotopic liver by blood vessels traversing an otherwise normal umbilicus (Nora and Carr 1946). These authors cite a similar case (a "duplicated liver") that had already been described in the eighteenth century by Morgagni (De sedibus et causis morborum 1767). In the case of omphalocele, an accessory liver displaced into the cell may be connected to the right liver lobe by a vascular stalk (Kleinhaus et al. 1968). Aberrant ectopic liver tissue has been detected as a nodule attached to the edge of the gastrohepatic omentum along the anterior border of Winslow's foramen (reported by H.N. Costello, Hartford Hospital; cited by Cullen 1925). A small ectopic liver nodule had been found in the greater omentum, with cirrhotic change (Brühl 1926), an early observation of a phenomenon that has been discussed again in the recent years. Foci of ectopic liver were found in an epithelial cyst of the spleen (Del Sordo et al. 2011).

Similar to cholecystic pancreatic heterotopia (Jarde et al. 1989; El Mezni et al. 1993), varying amounts of liver substance are known to occur as ectopic tissue (hepar succenturiatum) close to the gallbladder, within the wall of this organ, or in the tissue surrounding the cystic duct.

Selected References Henle 1866; Moore 1882; Tarenetzki 1883; Corsy 1922; Walzel and Gold 1925; Cullen 1925; Eiserth 1940; Ashby 1969; Torchio and Maconi 1978; Natori et al. 1986; Fellbaum et al. 1987; Tejada and Danielson 1989; Watanabe et al. 1989; Castro Viera et al. 1990; Hamdani and Baron 1994; Acar et al. 2002; Sakarya et al. 2002.

Liver Ectopia of the Gallbladder

Liver ectopia of the gallbladder presents as variably sized and encapsulated nodules at the serosal surface (Fig. 1), with (Ashby 1969) or without a mesohepatic ligament, may be situated within the wall itself, protruding into the lumen or forming a spur-like structure adjacent to the gallbladder wall. In case of a mesohepatic ligament (first described for such an ectopia by Henle in 1866, based on a museum specimen), this may contain a branch of the cystic artery and a small bile duct (Ashby 1969). The ectopic tissue can form a pedunculated mass covered by serosa (Corsy 1922). The ectopic tissue has a lobular architecture and bile ducts, but may undergo cirrhotic change similar to that of the main organ. These lesions may, in dependence to their size, lead to

Fig. 1 Liver ectopia in the gallbladder. A pedunculated elliptic, encapsulated nodule of liver tissue is connected with external structures of the gallbladder through a thin vascular stalk

differential diagnostic problems in a clinical workup of a mass lesion in this area.

Supradiaphragmatic Ectopias

Supradiaphragmatic ectopic liver tissue has been found in the extrapulmonary and mediastinal spaces (Naganuma et al. 1993; Han and Soylu 2009), within the lungs (Iber and Rintala 1999; Babu and Van der Avoirt 2001; Mehta et al. 2010; Bannon et al. 2013), within the pleura (Rodriguez-Perez 1955), and in the chest wall (Chalak and Parham 2007). Intrathoracic livers may be connected with the main liver via a vascular and biliary pedicle traversing the diaphragm (Rendina et al. 1989). Ectopic liver in the lungs can form a mass resembling a primary pulmonary tumor (Wang et al. 2010), and pulmonary and pleural liver ectopia can present as multiple nodules mimicking metastatic disease (Song et al. 2011). In very rare instances, ectopic liver was found in the heart cavities, mainly in the atria (Trocciola et al. 2011; Xu et al. 2012).

Intravascular Liver Ectopia

In very rare situations, ectopic liver tissue is present within the lumen of large veins. Ectopic intracaval liver, sometimes presenting as a floating intracaval mass, has been described (Chapman-Fredricks et al. 2010; Morris et al. 2012; Rafiei et al. 2012). The intravenous liver tissue can be attached to the vein wall by a thin stalk (Morris et al. 2012) and may extend to the right atrium, producing a pedunculated intracardiac mass (Chapman-Fredricks et al. 2010). Pathogenetically, a deranged morphogenesis of the caudate lobe of the liver with aberrant migration of hepatocyte precursors into the developing retrocaudate vena cava was proposed (Chapman-Fredricks et al. 2010). Intracaval ectopic liver may be confounded with retrohepatic invasion of the inferior vena cava by well-differentiated hepatocellular carcinoma (Ohwada et al. 1994; Kaneko et al. 1996; Uemura et al. 2004). A further differential diagnosis of intravenous liver ectopia is traumatic dislocation of liver tissue into the vena cava.

Gallbladder Ectopia

Gallbladder ectopia can occur in an intrahepatic location (Galli and Donati 1968; Zhuravlev 1968; Mincsev 1968; Maekawa et al. 1978; Lloyd 1979; Schmahmann et al. 1982; Lusink and Sali 1985; Matsuzaki et al. 1995; Guiteau et al. 2009), also as an accessory organ (Wolnicki et al. 1974), and results in an area of decreased tracer concentration in liver scans (Wysong and Gorten 1980; Dumont and Danais 1984; Velchik and Noel 1987; Soudry et al. 1995) with a characteristic focal defect in 99mTc-sulfur colloid imaging (Schulz et al. 1975), eventually leading to the suspicion of an intrahepatic neoplasm. Intrahepatic gallbladders may undergo inflammatory and fibrous changes resulting in intrahepatic porcelain gallbladder (Smith et al. 2012).

There are several other situations of congenital or acquired gallbladder disease which may produce differential diagnostic problems at imaging. A suprahepatic or retrohepatic gallbladder is usually combined with hypoplasia or even agenesis of the right liver lobe (Faintuch et al. 1980; Youngwirth et al. 1983; D'Araujo and Coelho 1992; Sheu et al. 1995; Hsu et al. 1997), but rarely both parts are found in a supradiaphragmatic position without hepatic hypoplasia (Organ and Hayes 1980). The gallbladder is rarely situated to the left side (sinistroposition; Large 1963; Siebermair 1986; Banzo et al. 1990; Idu et al 1996; Fujita et al. 1998), sometimes associated with hypoplasia of the right liver lobe (Stankovic et al. 1998) or with duplication of the common bile duct (Bender et al. 2007). A hepatic tumor may be suspected in case of gallbladder duplication (McDonald and Lwin 1986; Nursal et al. 2007; Pitiakoudis et al. 2008). In case of missed double gallbladder, perforation can occur after laparoscopic cholecystectomy (Borghi et al. 2008). False-positive hepatobiliary imaging can be caused by congenital absence of the gallbladder (Dickinson et al. 1984). The Phrygian cap anomaly of the

gallbladder can simulate a hepatic mass lesion (Smergel and Maurer 1984).

Apart from congenital malformations, the gallbladder can also be displaced in patients with liver cirrhosis (Owshalimpur and Karimeddini 1982). An enlarged gallbladder filled with blood has been shown to result in nonvisualization, with a rounded photon-deficient area (Davis et al. 1993). Gallbladder perforation has been shown to rarely result in tumor-like, large pseudocyst (Fernandez et al. 2000).

Solitary Necrotic Nodule of the Liver 122

Contents

Abstract

Solitary necrotic nodule of the liver (SNNL) is a rare benign lesion defined as a reactive circumscribed nodule characterized by a central coagulative necrosis and a fibrous demarcation. Most cases of SNNL are clinically silent and are incidental findings in the setting of liver resections or autopsies. SNNL can grow to important size, but can also undergo spontaneous regression. Macroscopically, SNNL are round to ovoid well-delineated lesion showing a whitish to yellowish central part and a capsule-like fibrous peripheral sheath. Most cases are solitary, but multiple lesions have also been reported. SNNL may contain calcifications and cholesterol crystals. Rarely, a foreign body-type reaction with giant cells is noted. Accumulation of lipid-rich foamy macrophages is a common finding. Etiology and pathogenesis of SNNL are still not clarified.

DOI 10.1007/978-3-319-26956-6_122

Introduction

Solitary necrotic nodule of the liver (SNNL) is a rare benign lesion, initially reported in 1983 (Shepherd and Lee 1983). SNNL is defined as a reactive and benign, circumscribed nodular liver lesion characterized by a central coagulative necrosis and a fibrous demarcation. Since 1983, several other reports have confirmed the existence of this lesion (about 50 cases reported) and have further characterized it, including its radiologic features. Most SNNL are clinically silent or are incidental findings. However, SNNL can mimic a primary liver neoplasm, as it can grow to important size, but it can also undergo spontaneous regression.

Selected References Berry 1985a, b; Shepherd 1990; Berry and Shepherd 1990; Sundaresan et al. 1991; Tsui et al. 1992; Carella et al. 1993; Clouston et al. 1993; Di Stasi et al. 1993; Desai et al. 1995; Nakanuma 1995; Alfieri et al. 1997; Grazi et al. 1998; Yoon et al. 2000; De Luca et al. 2000; Iwase et al. 2002; Colagrande et al. 2003; Koea et al. 2003; Marongiu et al. 2004; Glas et al. 2006; Kondi-Pafiti et al. 2006; Zuo et al. 2006; Chen et al. 2007, 2010; Shonaka et al. 2007; Wang et al. 2007; Koea and Smith 2008; Zhou et al. 2008; Delis et al. 2009; Choi et al. 2010; Deniz and Coban 2010; Deniz et al. 2011).

Epidemiology

The prevalence of SNNL is difficult to estimate; in one study, seven nodules were retrieved from 4000 necropsy and surgical liver specimens coming to light over 5 years (Tsui et al. 1992). All these lesions were incidentally detected, the patient ages ranging from 48 to 79 years (mean: 63.7 years), without gender predilection. SNNL occur as solitary lesions or are multiple nodules. They may occur more frequently in anterior portions of the liver (Shepherd and Lee 1983; Berry 1985a; Sundaresan et al. 1991) and are more common in the right liver lobe (Kondi-Pafiti et al. 2006). In a recent Chinese retrospective study of 51 patients with histologically confirmed SNNL, the mean age at presentation was lower (45.3 years; the youngest patient 5 years old), with a clear male preponderance (68.6 %; Zhou et al. 2008).

Imaging Features

As the lesions range in size from few mm to more than 8 cm, many can be detected by modern imaging methods. Hepatobiliary ultrasonography reveals a hypoechogenic, target-appearing nodular formation, which appears as a perfusion defect in contrast-enhanced ultrasonography (CEUS) (Wang et al. 2007). Doppler examinations display a lack of flux within the lesion (De Luca et al. 2000; Yoon et al. 2000; Colagrande et al. 2003; Koea et al. 2003). Lesions thought to have undergone dehydration of the coagulative necrosis may show central hyperechogenicity on US, with a rough patchy core (Colagrande et al. 2003). CT scans usually show a hypodense nodular lesion without enhancement after contrast media injection, whereas MR exhibits low signal in the weighted T1 images, hyperintensity on T2WI, and isointense in the later echoes of the SE sequences. In a study of 33 pathologically proved lesions, MR revealed hypointense nodules on T1-weighted images in 93.9 % and isointense lesions in 6.1 % only, while the nodules were hyperintense on T2-weighted images in 36.4 %, isointense or invisible in 45.4 %, and hypointense in 18.2 %. After injection of gadopentetate, all lesions were hypointense and none of them showed enhancement (Geng et al. 2012). Calcifications are frequent and were noted in more than half of the cases (Kondi-Pafiti et al. 2006). On F-18 FDG PET, SNNLs are hypermetabolic lesions (Chen et al. 2010). At imaging, SNNL may mimic liver metastasis (Shepherd and Lee 1983; Carella et al. 1993; Yoon et al. 2000; Colagrande et al. 2003). Primary malignancy may be suspected, including hepatocellular carcinoma (Kondi-Pafiti et al. 2006; Shonaka et al. 2007; Delis et al. 2009), in particular because in some instances SNNL may show rapid growth

(Imura et al. 2006). Imaging differential diagnosis chiefly comprises inflammatory pseudotumor, regressing angiomas, rare infections producing masses in the liver (tuberculosis; mycoses; pneumocystosis), and the rare rheumatoid hepatic nodules.

Macroscopic Pathology

At gross examination, SNNL are spheroid to ovoid, well-delineated lesions that display a whitish to yellowish central part, representing coagulation necrosis, and a capsule-like fibrous demarcation zone at the periphery (Fig. 1). The average diameter of the lesions was 23 mm (range: 10–55 mm) (Zhou et al. 2008). Although the term, SNNL, expectedly indicates that we deal with single lesions, there are few instances where the lesion was not solitary but multiple (less than 10 % of the cases; Kondi-Pafiti et al. 2006). The lesions tend to more commonly occupy the subcapsular area of the liver than deeper parts of the liver substance (almost 87 % in one study; Kondi-Pafiti et al. 2006), but large masses (8.5 cm; Imura et al. 2006) grossly mimicking malignancy are also encountered. Subcapsular SNNL causes a typical, flat retraction of the capsule, the adjacent lesion then assuming a roughly triangular shape. SNNL may be hard and gritty, owing to extensive mineralization/calcification. In large masses, the calcification pattern may be reticular and chiefly localized to central parts of the lesion. Such lesions grossly mimic metastasis of colorectal cancer. Rarely, a small cystic space may be found in the center of the lesion (Iwase et al. 2002).

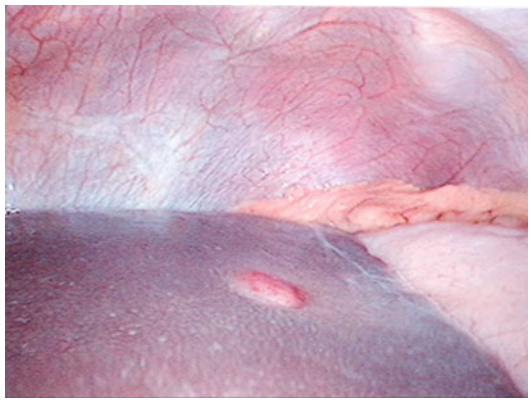

Fig. 1 Solitary necrotic nodule of the liver

Histopathology

Histologically, the inner part of SNNL is occupied by a necrotic mass consisting of an eosinophilic, partly granular material of widely variable necrotic cellularity ("ghost cells"), depending on the cause of the lesion. Descriptively, the central mass histologically represents the nonspecific features of coagulation necrosis, but not of caseification, nuclear debris usually not being prominent. SNNL sometimes contain calcifications and cholesterol crystals. In rare instances, almost the entire nodule may be calcified. Accumulations of foamy macrophages are a relatively frequent finding, and cholesterol granulomas may be observed, also at the interface between the necrosis and the peripheral fibrous tissue. Multinuclear giant cells of the foreign-body type have been observed (Iwase et al. 2002). Typically, the necrotic eosinophilic core is surrounded by a hyalinized fibrotic tissue of variable thickness, with or without a cellular infiltrate (Figs. 2 and 3). This strip of fibrous tissue is visualized at ultrasonography (De Luca et al. 2000, their Fig. 1). SNNL may show varying numbers of small mural vessels with intimal fibrosis and

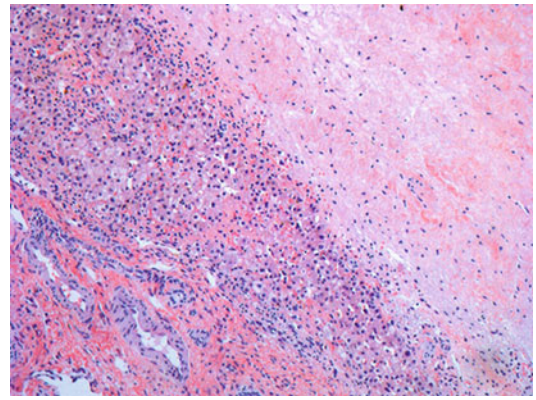

Fig. 2 Solitary necrotic nodule of the liver. The nonencapsulated nodule (right half of figure) consists of hypocellular fibrous tissue with focal necrosis (hematoxylin and eosin stain)

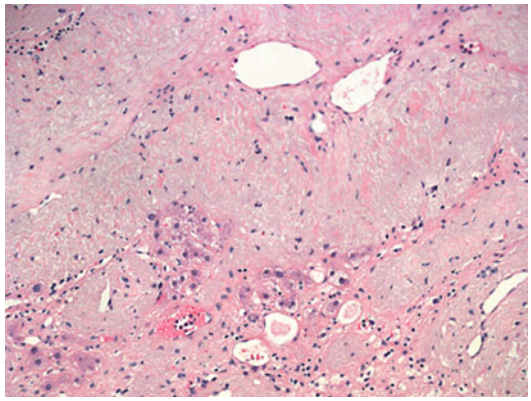

Fig. 3 Solitary necrotic nodule of the liver. In this case, fibrous tissue of the nodule displays elastosis, a secondary change of collagenous matrix. Note three enclosed nests of hepatic parenchyma (hematoxylin and eosin stain)

obliteration. In case of doubt about the nature of a given nodule, a reticulin stain showing a characteristic fiber network in case of SNNL is helpful. In particular, this stain will in most cases allow the distinction between a benign SNNL and a necrotic malignant tumor, the most important differential diagnosis. In a minority of cases, remnants of metastatic carcinoma or fragments of echinococcal membranes were found within a lesion otherwise fulfilling the criteria of SNNL (Deniz and Coban 2010), suggesting that copious sampling for histology should be performed. In one case, remnants of not further specified larval infestation were detected (Chen et al. 2010).

Differential Diagnosis

Several other benign nodular liver lesions are known that may mimic SNNL at imaging and in part also histologically (nonneoplastic nodular lesions of the liver, NNNLL; Nakanuma 1995). A particularly important group includes nodular lesions characterized by a granulomatous reaction and scarring, because such changes occur in SNNL. Rarely, the liver is involved in rheumatoid arthritis, with formation of hepatic rheumatoid nodules (rheumatoid nodulosis) showing a central fibrinoid necrosis and peripheral palisading histiocytes/epithelioid macrophages (Smits and Kooijman 1986; Fitz et al. 1987). Manifestations of sarcoidosis in the liver can produce confluent and sometimes rather large granulomatous lesions that typically produce scarring, but no significant necrosis (nodular hepatic sarcoidosis; Bilir et al. 2000; Thanos et al. 2002; Sartori et al. 2002). Tuberculosis, morphologically characterized by a granulomatous reaction and a distinctive type of coagulative necrosis (caseification), occurs in the liver in the form of several phenotypes according to Levine: (1) miliary tuberculosis, (2) pulmonary tuberculosis with liver involvement, (3) primary liver tuberculosis, (4) tuberculoma, and (5) tuberculous cholangitis (Levine 1990). Hepatic tuberculosis rarely results in large hepatic lesions, termed tuberculomas, nodular, or pseudotumoral tuberculosis (Belloir et al. 1988; Oliva et al. 1990). Macronodular hepatic tuberculomas (Levine 1990; Moskovic 1990; Kawamori et al. 1992; Murata et al. 1996; Ohta et al. 1996; Amaris et al. 1997; Tan et al. 1997; Fan et al. 1998) or giant tuberculomas of the liver (Chan and Pang 1989) may resemble SNNL at imaging. In particular, tuberculomas are hypodense on CT, as SNNL usually are. Contrast enhancement occurs in the peripheral granulomatous tissue while the central low density caseation necrosis shows less enhancement (Levine 1990; Mercusot et al. 1995). As in some SNNL, tuberculomas exhibit calcifications visualized at imaging; they may increase in number, enlarge, or remain unchanged at different stages of healing (Belloir et al. 1988; Chan and Pang 1989; Moskovic 1990), so that the features of calcifications as such will not help in the differential diagnostic judgments. Nodular lesions in the liver with necrosis, and with or without purulent inflammation, can occur in hepatic nocardiosis (Nocardia brasiliensis, N. asteroides, and Rhodococcus equi; Pretet et al. 1979; Akan et al. 1998), aspergillosis (Aspergillus (A.) israelii, A. viscosus, A. naeslundii, A. odontolyticus, A. meyeri, A. gerencseriae, A. terreus; Roesler and Wills 1986; Kazmi and Rab 1989; Ow et al. 1991; Vargas et al. 1992; Miyamoto and Fang 1993; Nazarian et al. 1994; Trachana et al. 2001), brucellosis (brucelloma; Colmenero et al. 2002), cat scratch disease (Danon et al. 2000), and amebiasis (Yeoh et al. 1997).

Etiology and Pathogenesis

What are the causes of SNNL ? The possible origins of these lesions are still debated and theoretically include hematomas, necrotic parasites (e.g., liver flukes, or Armillifer armillatus/pentastomiasis), trauma (owing to the frequently anterior position of the lesions), old hepatic infarctions, and regressing benign tumors. Already in 1985, Berry hypothesized that SNNL might represent an evolution of hepatic hemangioma, based on the observation of a sclerotic and calcified hemangioma, and the detection of a "feeding vessel" (Berry 1985a, b). In a larger histologic study, an origin in hemangiomas of the liver has been confirmed for most of the lesions studied (Sundaresan et al. 1991). Arguments to propose an origin from hemangiomas comprised that SNNL had, in the latter study, a feeding vessel consisting of a muscular artery and that reticulin stains revealed traces of preexisting hemangioma components. However, it was later concluded that the etiology is in fact multifactorial, several lesions having a similar endpoint with the features of SNNL, including regressing hemangiomas, infected abscesses, parasitic granulomas, hematomas, and benign tumors (i.e., not preferentially hemangiomas). In one case, *Clonorchis sinensis* was identified within a lesion (Tsui et al. 1992), and in another patient, a central coiled nematode was detected (Clouston et al. 1993). The presence of *Capillaria hepatica* in SNNL was histologically confirmed in one case (Koea and Smith 2008). Fragments of echinococcal membranes were identified in two cases (Deniz and Coban 2010). An ischemic origin of SNNL was suggested based on the observation of subtotal stenosis of the celiac tripod in one case, followed by progressive reduction of the lesion's diameter upon surgical correction (De Luca et al. 2000).

Abstract

Various types of mineral dust can induce tumor-like lesions in the liver. A nowadays rare form is hepatic silicosis or anthracosilicosis, a condition usually combined with splenic silicosis. Silicium dioxide crystals are probably transported to the liver by macrophages and induce, within parenchyma and portal tracts, a vigorous inflammatory reaction similar to that found in the bronchopulmonary tract. Asbestosis is rarely associated with a circumscribed fibroinflammatory reaction in the liver. Similar changes may be observed in talcosis. Thorotrastosis, caused by deposition of highly radioactive thorium dioxide particles in tissues following radiographic examinations, was an important cause of morbidity in former times but is now no longer observed. Thorotrastosis caused a vigorous and sometimes tumor-like fibrotic reaction in the hepatobiliary tract and is a well-known example of radiation-induced carcinogenesis.

Hepatic Anthracosis, Anthracotic Liver Nodules, and Cirrhosis Hepatis Anthracotica

Hepatic anthracosis has not well been studied, although coal pigment can sometimes been found in hepatic macrophages, usually in conjunction with marked pulmonary anthracosis (Weigert 1883; Welch 1891; Chiari 1907; Orth 1917; Hanser 1930; Heggie 1946; Anderson 1971; Beckert 1972; Pounder 1983; Cabarcos and Gomez Dorronsoro 1984; Sampedro Nuño et al. 1985).

The earliest recorded instance of so-called blood anthracosis is that of Soyka in 1878 (cited by Weigert 1883), in which carbon pigment was found in the spleen, liver, and kidneys of a man of 70 years, suffering from anthracosis of the lungs. Soyka formed the hypothesis that the coal particles had passed through the lymph nodes and thoracic duct into the blood stream. Anthracotic pigment may be found in hepatic macrophages in patients with silicosis, a pneumokoniosis which is known to favor spread of coal particles owing to a markedly altered lymphatic drainage. Among 100 liver biopsies from patients with pulmonary silikotuberculosis, 35 biopsies showed coal dust particles, in 24 of them with pigment deposits in portal tract macrophages. Coal particles were also found in intrasinusoidal macrophages (Kupffer cells; sometimes with formation of black nodules in lobular zone 3) and in endothelial cells of central/terminal veins (Beckert 1972). Some of the macrophages contain hemosiderin together with coal particles. Apart from Welch's patient (1891; discussed below), only one report described the gross features of hepatic anthracosis. The autopsy of an 81-year-old male patient with severe anthracosilicosis showed the liver to have a general grayish color due to marked pigment accumulation. On section the lobular pattern was rendered unusually distinct by the black deposits of carbon in the portal tracts, while the intervening parenchyma was yellowish gray (Heggie 1946). It is thought that hepatic anthracosis results from the systemic dissemination of carbon pigment following rupture of a thoracic anthracotic lymph node into a pulmonary vessel, the transmigration of coal-laden macrophages through pulmonary venous wall, or the transport of pigmented macrophages via the lymph stream into the blood circulation (the Soyka hypothesis). Arnold has pointed out the frequent association of emphysema of the lungs with the presence of coal pigment in the spleen, liver, and elsewhere. Weigert has shown that adhesions and destructive inflammations may open the way for the passage of coal pigments from bronchial lymph nodes into the circulation and from there to remote organs and tissues (Weigert 1883). Cirrhosis hepatic anthracotica is a term coined in 1891, based on the observation of a peculiar form of liver cirrhosis associated with the massive deposition of coal pigment in the liver (Welch 1891). The patient was a 70-year-old German who had lived for many years as a farmer in the neighborhood of Mercersburg, Pa, and had formerly been a weaver in Germany. After having been in good health, he began to suffer from vomiting, loss of appetite, and severe abdominal pain. He developed ascites, became emaciated,

and expired. An autopsy was performed. The peritoneal surface, the omentum, the mesentery, and superficial parts of the liver were massively involved by nodular growths of a carcinoma of unknown origin (the necropsy was incomplete). The liver cut surface showed numerous black specks and small streaks. These little black dots and lines were present everywhere throughout the liver scattered irregularly at intervals not more than 0.5–1 mm apart. The black structure was not present in the cancer nodules and was not more abundant in the neighborhood of cancer than elsewhere. Around many of the black specks, the tissue had a grayish color. Histologically, the black structures were accumulations of black granular pigment identical with the coal pigment found in the lungs. The pigment resisted treatment of tissue with concentrated sulphuric acid, nitric acid, and hypochloric acid. The black granules occurred both free and enclosed in cells. Dense accumulations of black pigment separated unchanged hepatocytes, and the pigment was in part accumulated within Kupffer cells and other macrophages, the latter situated within fibrous bands, but was never found in hepatocytes. Hepatocyte nodules as in cirrhotic remodeling were in evidence. The fibrous areas differed in distribution and in appearance from the fibrous tissue in ordinary liver cirrhosis, in that the bands never completely surrounded a lobule, but were also present within lobules and around the central veins, producing a peculiar type of micronodular ("monocellular") cirrhosis. A ductular reaction was almost lacking. Overall, the picture resembled that of indurative anthracosis of the lungs (Naeye 1971). It is assumed that in such situations, anthracotic pigment may harbor another toxic substance transported together with the coal into target organs.

Hepatic Silicosis and Anthracosilicosis

Introduction

Involvement of the liver in silicosis (chalicosis) is not uncommon and is usually associated with splenic involvement (hepatosplenic silicosis). In the two largest published series, the prevalence of hepatic involvement in pulmonary silicosis was 6/60 (Ambrosi 1965) and 13/93 (Cisno et al. 1971).

Selected References Uchiyama 1928; Giese 1931; Lynch 1942; Cioni 1943; Polachek and Pijanowski 1960; Argento et al. 1962; Ambrosi 1965; Cisno et al. 1971; Ortuno Pacheco and Sampedro Nuno 1974, 1975; Langlois et al. 1977; Pimental and Menezes 1978; Gong and Tashkin 1979; Carmichael et al. 1980; Slavin et al. 1985; Liu et al. 1991; Oswald et al. 1995.

Liver Lesions: Silicotic Hepatic Nodules

Macroscopically, hepatic silicosis manifests as nodular and firm lesions consisting of sclerotic tissue, sometimes with black pigmentation. There is no evidence that these lesions may undergo so-called callosity liquefaction (called phthisis atra in pulmonary silicosis). In the lung, callosity liquefaction is caused by loss of silicotic and necrotic tissue via the bronchial tree (Breining 2003), and a similar mechanism may be expected to occur in case the invasive and destructive hepatic silicotic lesions obtain access to the biliary draining system. Histologically, the lesions correspond to typical silicosis nodules at various stages of development. The spectrum ranges from granulomas to nodules of almost acellular hyaline collagenous nodules with central densely calcified cores that contain no or little quartz crystals (Uchiyama 1928; Arai 1931; Giese 1931; Ritterhoff 1941). In a patient with fatal silicosis and hepatic involvement, liver biopsy showed numerous noncaseating granulomas scattered throughout the hepatic lobules. These granulomas were associated with various amounts of fibrous tissue. Smaller nodules were composed of epithelioid macrophages and lymphocytes, while larger nodules were hyalinized, with a fibrous core surrounded by lymphocytes and macrophages, without giant cells. Polarizing microscopy revealed rare needle-shaped birefringent particles within the hyalinized nodules (Carmichael et al. 1980).

In an autopsy study of 21 patients with hepatic silicosis, liver granulomas with various amounts of fibrosis were present in 20 cases, and portal tract fibrosis was seen in ten. Intralobular silicotic nodules tended to be more frequent close to the terminal vein (Ortuno Pacheco and Sampedro Nuno 1975). Intermediate lesions in the liver usually are surrounded with an outer rim of fibroblasts and quartz-containing macrophages (Langlois et al. 1977). In a detailed study of extrapulmonary manifestations of silicosis, silicotic nodules in the liver were coniotic and fibroconiotic lesions recognized in portal tracts and within parenchyma. Sclerohyaline nodules were, in contrast, only found in portal tracts. The fibrosed portal tracts were sometimes associated with incomplete and complete, portal-to-portal septa. Silicotic nodules enlarged as they progressed, ranging from 0.1 mm (coniotic nodules) to 1.7 mm (silicosclerohyalinized nodules). Nodules containing silica and other dusts (mixed dust coniotic nodules) were also encountered (Slavin et al. 1985). Macrophages with coal particles are sometimes seen. Silicotic nodules have experimentally been produced in rodents by intraperitoneal injection of silica (Mosinger et al. 1957), and a hepatic granulomatous reaction to silica has been observed in an experimental rat model (Kanta et al. 1986). In patients with hepatic silicosis, lymph nodes located to the hepatic hilar/perihilar area may be markedly enlarged, being extensively replaced by conglomerated silicotic nodules (Slavin et al. 1985). Generally, reports of autopsies in patients with hepatic silicosis also mention silicotic lesions in portal and abdominal lymph nodes (Giese 1931; Polachek and Pijanowski 1960; Langlois et al. 1977). The demonstration of typical eggshell calcifications of silicosis in perihilar/portal lymph nodes by abdominal radiographs in patients with pulmonary silicosis (Polachek and Pijanowski 1960; Langlois et al. 1977; Gong and Tashkin 1979) might indicate concomitant silicotic lesions in the liver (Slavin et al. 1985). Anthracosilicosis of the liver may also present in the form of mainly subcapsular, partly calcified nodular lesions, similar to what can develop in the spleen (Vanhoenacker et al. 2001). Such macroscopically black nodules can also develop on the hepatic visceral peritoneum (Miranda et al. 1996). In a study of 21 patients, three patients showed numerous, lead gray to black nodules measuring 0.1–0.3 mm on the hepatic capsular surface, and one patient exhibited larger capsular nodules, up to 8 mm diameter, with a gray center and a black peripheral rim. At some places, these nodules coalesced to form conglomerate, plaque-like lesions (Ortuno Pacheco and Sampedro Nuno 1975). Experimentally, hepatic silicosis associated with cirrhosis, liver cell adenoma, and carcinoma develops in nude mice given silicon dioxide (quartz) by the subcutaneous and intraperitoneal routes (Williams and Knapton 1996).

Pathogenically, it is thought that quartz crystals enter the liver via circulating monocytes/macrophages that change into Kupffer cells or deliver their phagocytosed crystals to already resident Kupffer cells. The uptake of silica particles by macrophages is receptor mediated (Kolb-Bachofen 1992). Specifically, the binding of crystalline silica particles is mediated by the macrophage scavenger receptors (SR; review: Murphy et al. 2005). SR are cell surface receptors that bind a wide variety of ligands, including bacteria, nonopsonized particles, modified lipoproteins, and inorganic substances. There are eight known classes of SR designated A through H, which are dissimilar in structure, but related in ligands recognized. Known class A SR comprise three splice variants SR-AI (CD204), SR-AII, and SR-AIII, MARCO (macrophage receptor with collagenous structure), SRCL, and SCARA5. The SR most associated with macrophage silica binding are SR-AI, SR-AII, and MARCO (Hamilton et al. 2006, 2008). MARCO is a critical binding receptor for nonopsonized inhaled environmental particles and bacteria (Palecanda et al. 1999; Arredouani et al. 2004), and MARCO-null mice are unable to clear silica particles from lung alveoles (Thakur et al. 2009). Macrophages having engulfed silica become activated and secrete cytokines, including fibrokines (TNF-alpha, IL-1, and TGF-beta; Schmidt et al. 1984; Piguet et al. 1990; Williams and Knapton 1996; Hamilton et al. 2008), thus

mediating the fibrogenic reaction in silicosis. Exposure to silica particles induces activation of NF kappaB and AP-1 (activator protein-1) and the associated signaling pathways in macrophages. Activation of AP-1 causes a decrease in cyclin-dependent kinase 4/CDK4, mediated by the ERK and JNK pathway (Shen et al. 2008). In addition, silica is involved in the cellular production of reactive oxygen/nitrogen species (review: Castranova 2004).

Asbestosis

Introduction

In asbestosis, asbestos fibers are known to be transported to numerous organs and tissues in addition to the bronchopulmonary compartment, including the liver (Pollice et al. 1997). Fibers can be dragged from the lung interstitium by pulmonary lymph flow (primary translocation), wherefrom they can reach the blood stream and subsequently distribute to the whole body (secondary translocation). Fiber concentration in organs correlates with specific conditions of interstitial fluid dynamics, in line with the notion that in all organs microvascular filtration occurs from capillaries to the extravascular spaces. Concentration of fibers is high in the kidney (high perfusion pressure and flow) and in the liver (high microvascular permeability). Ultrafine fibers (length <5 μm, diameter <0.25 μm) can travel larger distances due to low steric hindrance. For example, in mesotheliomas, 90 % of the fibers are ultrafine (review: Miserocchi et al. 2008). In contrast, it has long been uncertain whether asbestos *bodies* found in extrapulmonary sites have been transported as mature structures from the lung or formed de novo at the extrapulmonary site. One study has, however, shown that asbestos bodies can in fact be formed in extrapulmonary sites, but that the coating efficiency (coating of asbestos fibers by a cellular iron- and protein-rich matrix) in the lung is much greater than that within the liver or spleen (Williams et al. 2001).

Asbestosis of the Liver

In most cases, deposition of fibers in the liver will not cause visible hepatic lesions, but a fibroinflammatory reaction may rarely ensue to even produce nodular lesions. Asbestosis can seldom cause calcified fibro-hyaline plaques on the liver (Fondimare et al. 1974; Andrion et al. 1983) that may be confounded with other circumscribed sclerotic lesions in the liver's periphery.

An autopsy study has revealed that there is a correlation between peritoneal and liver plaques and asbestos exposure (Mollo et al. 1993). Pulmonary asbestos can also be associated with a generalized fibrotic tissue reaction, and this fibrosis, including liver fibrosis, is accompanied by the accumulation of asbestos bodies in the fibrotic tissue (Kobayashi et al. 1983). Asbestosis can involve locoregional lymph nodes of the liver, as these nodes are connected with intrathoracic nodes. Silicosis of retropancreatic lymph nodes has been found to block the common bile duct and to cause obstructive jaundice (Chassagnon and Silie 1966). Asbestos is known to induce mesotheliomas and other cancers. In an autopsy study of 525 cases of asbestosis in Japan, there were 174 lung cancers (33.1 %), 73 malignant mesotheliomas (13.9 %), 29 stomach cancers (5.5 %), but also 14 liver cancers (2.7 %) (Murai and Kitagawa 2000). Primary malignant biphasic mesothelioma of the liver has been observed in a patient with asbestosis (Sasaki et al. 2009). Asbestos bodies have been found in a cholangiocarcinoma of a patient with asbestosis (Szendröi et al. 1983).

Talcosis

Introduction

The mineral talc is a soft, hydrous magnesium silicate known to have the physical characteristic of birefringence. Generally, talc in the liver is highly suggestive of intravenous drug abuse (Min et al. 1974; Molos et al. 1987; Sherman

et al. 1995) but may also occur in the absence of an abuse history (Klatskin 1977). When drugs containing talc (e.g., "Blue Velvet") are injected intravenously, they pass to the pulmonary vascular bed that retains most of the crystalline particles, but part of the crystals escape this filter via pulmonary arteriovenous shunts caused by lung disease, or via cardiac shunts, to be spread to parenchymatous organs.

Hepatic Talcosis

In an autopsy study of 273 drug addicts, 38 % of the patients had talc in their liver. Those with hepatic talc were older and had a longer history of i.v. drug abuse, and the presence of birefringent particles in the liver was always associated with a nonspecific portal tract lymphocytic infiltration (Kringsholm and Christoffersen 1982). Among 70 patients with chronic hepatitis and a history of active or past i.v. drug abuse, birefringent crystalline particles consistent with talc were found in liver tissue in 63 % (Allaire et al. 1989). Histologically, talc microcrystals are situated predominantly in activated portal tract macrophages. The crystals observed in the liver are birefringent and unevenly green, needle or rod shaped, and arranged singly or in clusters, with a mean length of 3 mm (Liu et al. 1991). Electron microscopy of involved macrophages reveals the characteristic "flake-pastry" appearance of this ingested mineral (Allaire et al. 1989). Ultrastructurally, the crystals are 5–12 mm, elongated with sharp edges, electron-dense, laminated, and located in phagosomes of macrophages (Buschmann and Mir 1979). Liver biopsies show birefringent crystals also in Kupffer cells within lobules (Molos et al. 1987). Deposition of talc in the liver can induce a granulomatous reaction, with formation of talc granulomas (Groth et al. 1972; Min et al. 1974; Szanto 1975; Mariani-Costantini et al. 1982; Kringsholm and Christoffersen 1982; Lewis et al. 1985; Molos et al. 1987; Racela et al. 1988; da Cunha et al. 1999).

Thorotrastosis

Introduction

Thorotrast is or was the trade name of a 25 % colloidal aqueous solution of thorium (Th232) dioxide. Thorium-containing contrast media, first called Umbrathor and Thordiol, were introduced 1927 in Japan and 1928 in Germany (Frik and Blühbaum 1928; Kalbrenner 1928; review: Oka 1930). Then, in 1930, Thorotrast, developed by the German firm Heyden, was preferentially used. Thorotrast was an excellent contrast agent that could be administered intravenously and intraarterially and was first thought to have no side effects. Th(232) only exists as a radioactive substance (predominantly an alpha particle emitter, 90 %; beta and gamma, 10 %) with a physical half-life of $1.4 \times 10(10)$ years. The biologic half-life is about 400 years. It is estimated that up to 100,000 patients worldwide were exposed to Thorotrast from 1930 to 1964. The carcinogenic action of colloidal thorium dioxide was recognized in 1934 in rat experiments (Roussy et al. 1934, 1936), and the risk of employing this contrast medium was already recognized in 1933 by the FDA, and in the years to come, a broad array of Th232-induced late effects were identified (Boyd et al. 1968; Horta et al. 1972).

The first case of angiosarcoma of the liver in a Thorotrast patient was published in 1947, and the first report concerning Thorotrast-induced late effects in Japan dealt with a case of liver cirrhosis in observed in 1945 (Shimauchi et al. 1949). The use of intravascularly administered Thorotrast was discontinued when it was recognized that its radioactivity caused long-term deleterious effects, most notably hepatic and hematologic malignancies and hepatic fibrosis (da Silva Horta 1967; Abbatt 1979; Bo et al. 2001; Lipshutz et al. 2002). A German study of 2326 originally exposed subjects revealed that median life expectancy was shortened by 14 years (German Thorotrast Study; Becker et al. 2008). But, for instance, in Japan, the use of Thorotrast continued until about 1954 (Mori et al. 1999a,b). The history

of Thorotrast use and toxicity has been reviewed (Abbatt 1979).

Thorotrast-Induced Liver Malignancy

The Thorotrast-induced changes cause a rise in overall mortality, essentially due to malignant neoplasms and specifically those of the liver. Thorium dioxide-induced hepatic carcinogenesis has also been studied in experimental animal models (Grampa 1967; Okamoto 1974; Wesch et al. 1985; Taylor et al. 1993).

Selected References Bauer 1943; Matthes 1956; Baserga et al. 1960; Dahlgren 1961; Nettleship and Fink 1961; Suchow et al. 1961; Batzenschlager et al. 1963; Möbius and Lembke 1963; Leitner 1965; Mori et al. 1967; Tsukamoto 1968; Visfeldt and Poulsen 1972; Faber 1978; Farid 1982; Yamada et al. 1983; Kato and Kido 1987; Andersson et al. 1994; Lee et al. 1996; Mori et al. 1999a; dos Santos Silva et al. 1999; Travis et al. 2001; Lipshutz et al. 2002; Nyberg et al. 2002; Sharp 2002; Becker et al. 2008.

In the liver, Thorotrast has been found to induce three major types of neoplasms, namely, angiosarcoma, cholangiocarcinoma, and hepatocellular carcinoma (reviews: Ito et al. 1988; Sitarik et al. 1999; Lipshutz et al. 2002). There is a latency period of 16 to >45 years for the development of hepatic malignancy after Th232 administration. In the German Thorotrast Study, 899 patients and 662 controls had follow-up every 2 years, beginning in 1969. Results in 1991 showed a high rate of liver cancer (410 in the Thorotrast group, 2 in the control group) observed after the 15th year of Thorotrast exposure. The frequency of tumor development was correlated with the cumulative dose, not the age at injection (Van Kaick et al. 1991). In a Swedish study of patients exposed to Thorotrast, the relative cancer risk at any site was 3.0, and the relative risk for primary liver and gallbladder cancer was 39.2 (Nyberg et al. 2002). In the Danish National Study of 1003 patients, 584 were alive 15 years later, and 40 remained alive at the end of the follow-up period. Among these 584 patients, 127 liver cancers were detected (45 HCCs, 41 cholangiocarcinomas, and 33 hepatic angiosarcomas). The median time from injection to diagnosis of liver cancer was 35 years, with a range of 18–48 years (Andersson et al. 1994). In a Japanese study, the risk of death from any cause was threefold greater, and the risk of liver cancer was 47-fold greater than in unexposed individuals (Kato and Kido 1987; Mori et al. 1999a). In regard to liver malignancies, the updated (1998) Japanese Thorotrast study revealed, in the autopsy analysis, that Th (232)-induced liver malignancies showed remarkable differences in the proportions of histologic types of tumors from those of non-Thorotrast liver malignancies since 1975, and the results showed 523 liver malignancies per 10(4) person Gy for Japanese male Thorotrast carriers (wasted dose 10 years; Mori et al. 1999b). From the studies of Travis et al. (1992) and Andersson et al. (1994), it was estimated that the excess lifetime risk of developing liver cancer is 260–712 patients/10,000 persons/Gy. Among 157 Japanese autopsy cases of thorotrastosis, there were 102 cases of thorium dioxide-associated hepatic malignancies: 43.1 % cholangiocarcinomas, 38.3 % angiosarcomas, 15.7 % HCCs, and 2.9 % double cancers. The average age for thorium-associated cholangiocarcinoma patients was significantly lower than that for cholangiocarcinomas in the non-thorium series. Peripheral intrahepatic cholangiocarcinomas were much more frequent than hilar carcinomas in comparison with non-Thorotrast cases (Ito 1988).

The development of Thorotrast-induced malignant tumors requires a long incubation period. Exceptions are known, e.g., one of the first reported Thorotrast-related hepatic angiosarcomas was detected 3 years and 2 months after Thorotrast injection (Da Silva Horta 1953). Reasons for the phenomenon of delayed hepatic cancer seem to include an uneven distribution of radionuclide, the limited range of radiation, and the movement of tumor precursor cells. Target

cells susceptible to malignant transformation may undergo one event and may then migrate outside of the range of alpha particles, thereby avoiding immediate induction of successive additional events that would lead to cell death or neoplastic change (Yamamoto et al. 2009). In the liver, Th (232) induces foci of altered hepatocytes that may represent early lesions in a carcinogenic pathway (Kopp-Schneider et al. 2006).

Angiosarcoma of the Liver

Hepatic angiosarcoma is one of the most important malignancies caused by Thorotrast and is, in some way, a "marker tumor" for thorium dioxide-induced late effects. 7–10 % of hepatic angiosarcomas were Thorotrast-related in the time period when Th(232)-exposed individuals were alive. Epidemiologic data showed that previously thorium 232 dioxide was the most iatrogenic cause of hepatic angiosarcoma (MacMahon et al. 1947; Falk et al. 1979; van Kampen et al. 2007). Thorotrast-related hepatic angiosarcoma was found in conjunction with combined HCC and cholangiocarcinoma in a single patient (Masamichi et al. 1982).

Selected References MacMahon et al. 1947; Da Silva Horta 1953; Lüdin 1953; Tesluk and Nordin 1955; Caroli et al. 1956; Grampa and Tomamasini-Degna 1958; Rosenbaum 1959; Vallenga 1962; Rakov et al. 1963; Heger and Bayindir 1970; Howard et al. 1971; Futh and Pietzke 1974; Quinlan and Scopa 1976; Jennings and Priestley 1978; Popper et al. 1978; Underwood and Huck 1978; Telles et al. 1979; Baxter et al. 1980; Hiraoka et al. 1981; Benjamin and Albukerk 1982; Silverman et al. 1983; Mohr et al. 1984; Kojiro et al. 1985; Abe and Wakasa 1987; Schmid and Beham 1987; Hardt and Geisthövel 1988; Ito et al. 1988; Azodo et al. 1993; Arteche et al. 2007.

Hepatocellular Carcinoma

Hepatocellular carcinoma related to hepatic Thorotrast deposition is a well-known complication and was in some studies observed more often than cholangiocarcinoma and angiosarcoma (Morgan et al. 1958; MacKay and Ross 1964; Person and Isaac 1964; Akagi et al. 1966; Kuisk et al. 1967; Forbes et al. 1968; Smoron and Battifora 1972; Kiely et al. 1973; Espasa et al. 1981; Lageron et al. 1984; Lally 1993; Andersson et al. 1994). There are no data as to whether the types and grades of Thorotrast-associated HCCs are the same as or different from those of nonirradiated individuals.

Other Liver Tumors

In addition to these three major malignancies induced by Thorotrast, several other hepatic malignant neoplasms occur in association with hepatic Thorotrast deposits. Cholangiocarcinoma has been reported several times (Heitmann 1954; Roberts and Carlson 1956; Stemmermann 1960; Batzenschlager et al. 1961; Ellis 1964; Yuda et al. 1969; Rota et al. 1971; Johnson and Babb 1975; Vanhaecke et al. 1979; Rubel and Ishak 1982; Sakai et al. 1984; Ito 1988; Masbou et al. 1995; Sahani et al. 2003; Zhu et al. 2004). Less common hepatobiliary cancers apparently induced by Thorotrast comprise gallbladder carcinoma (Hashizume et al. 1980), primary squamous cell carcinoma of the liver (Larson 1963), and mucoepidermoid carcinoma of the liver (Lambrianides et al. 1986).

Nonneoplastic Liver Changes

Apart from overt malignancies, Thorotrast induces focal and sometimes nodular reactive lesions in the liver ("Thorotrast-related hepatosis"). In Thorotrast patients, abdominal radiography shows typical depositions of thorium dioxide in liver, spleen, and locoregional lymph nodes. The hepatic distribution patterns markedly depend on the amount of injected Thorotrast. Type 1 has agglomerates of thorium dioxide in periportal lymph nodes; type 2 shows, in addition, dot-like deposits in the spleen; type 3 additionally reveals shell-like deposits beneath the liver capsule; types 4–6 exhibit a progressive deposition in the liver, ranging from a fine network to coarse

and conglomerate lesions (Van Kaick et al. 1999). These hepatic changes are associated with a shrinkage of the organ, with a mean atrophy of 260 g in one study (Bast et al. 1995). In hilar/perihilar lymph nodes, Thorotrast-induced fibrotic lesions may cause sclerosed conglomerate lesions (Poti et al. 1980) that mimick perihilar malignancy, in particular Klatskin tumor.

Thorotrast Deposition and Turnover in the Liver

Histologically, deposition of Thorotrast in the liver presents in the from of dark pigmented granules that are situated either within macrophages or in the extracellular space (Figs. 1 and 2). The strong ionizing radiation emitted by these particles is clearly demonstrable by use of autoradiography preparations (Fig. 3). In cases with induced malignancy, Thorotrast particles may be present adjacent to tumor tissue (Fig. 4).

The liver is particularly involved in thorotrastosis owing to its position as an important

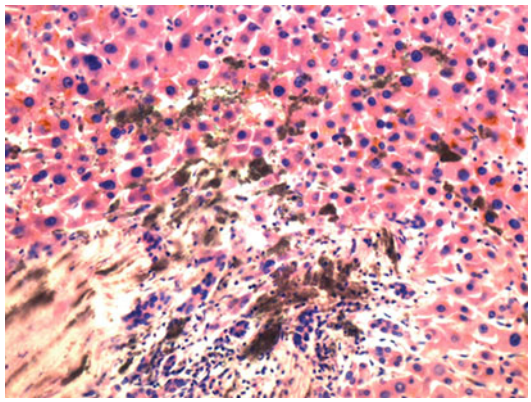

Fig. 1 Thorotrastosis. Accumulation of dark pigment in liver tissue, in part within phagocytes (hematoxylin and eosin stain)

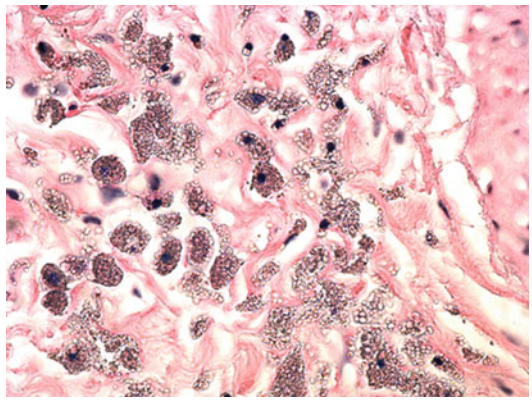

Fig. 2 Thorotrastosis of the liver. In this area, thorium dioxide particles are stored within macrophages (hematoxylin and eosin stain)

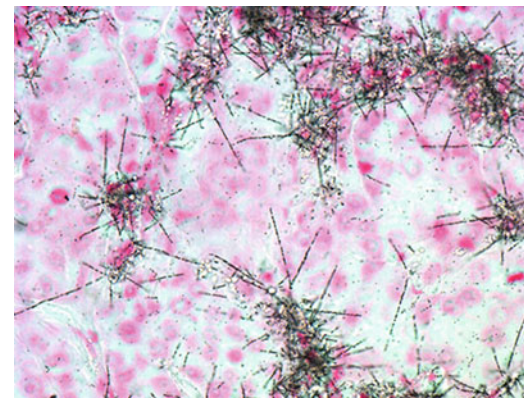

Fig. 3 Thorotrastosis. In this autoradiograph, silver grain tracts of high-LET radiation emerge from thorium dioxide particles. Note that the tract length does not exceed 5–8 cell diameters (photoemulsion autoradiography)

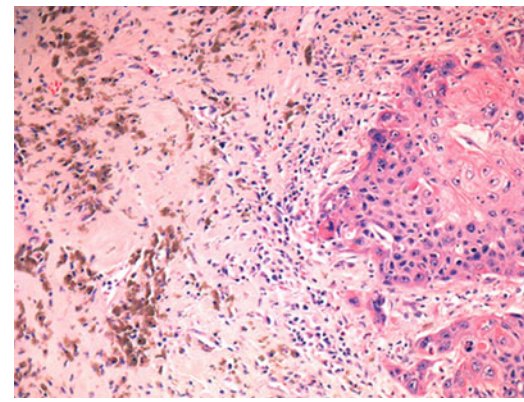

Fig. 4 Thorotrastosis of the liver. Long-lasting ionizing radiation from Thorotrast depositions is associated with biliary squamous cell carcinoma in this case (hematoxylin and eosin stain)

target of Th(232) (review: Tavares et al. 1979). Thorium dioxide depositions in the liver have first been reported in 1944 (Lüdin and Scheidegger 1944). In 1946, von Meyenburg reported on liver cirrhosis diagnosed 5 years following Thorotrast angiography (von Meyenburg 1946). It is estimated that the annual dose to the liver from a typical 25 ml of Thorotrast injection is 0.0025 Gy (Travis et al. 1992). This is mainly due to the liver's high content in macrophages (Kupffer cells) capable of phagocytosing Thorotrast particles (Tessmer and Chang 1967; Wegener et al. 1976; Kaul et al. 1979; Irie and Mori 1987), where Thorotrast particles can also be detected by autoradiography (Yasumizu et al. 1999) and by X-ray microanalysis (Terzaksi et al. 1974; Odegaard et al. 1978). In an assessment of the whole-body distribution of thorium and its daughters in a patient injected with Thorotrast 36 years prior to her death, approximately 45 % of all the activity was retained in the liver, and 3.5 % in a thorotrastoma (McInroy et al. 1992). In a later study, organ partition of Th(232) revealed a revised estimate of the relative partition of (232) Th in the liver, spleen, bone marrow, and other tissues of 53:14:25:8, respectively (Ishikawa et al. 1999). That Thorotrast phagocytosed by macrophages can locate from extrahepatic compartments to the liver has also been demonstrated in a patient with a liver allograft who had received intraarticular Thorotrast 36 years prior to transplantation. A liver graft biopsy performed 10 years posttransplant showed typical Thorotrast particles in macrophages in portal tracts and around central veins (Krasinskas et al. 2004).

CT findings of thorium dioxide deposition are pathognomonic. High-density deposits are seen in the liver, spleen, and lymph nodes, often associated with fibrosis-induced atrophy of the tissues involved. CT and MRI of the liver provide, therefore, an excellent method of early detection of thorium-related tumors (Brecht et al. 1980; Dunky and Klumair 1980; Silverman et al. 1983; Rao et al. 1986; Findley and Childress 1987). Also scintigraphy reveals characteristic findings of liver thorotrastosis (Oliveira et al. 1979).

Fibrotic Changes Induced by Thorotrast and "Thorotrastomas"

The morphology and the pathogenesis of these reactive alterations have been studied in detail (Dahlgren 1967; Visfeldt and Poulsen 1972; Helpap and Tschubel 1980). In the liver, Thorotrast particles concentrate, via phagocytosis, in Kupffer cells/hepatic macrophages, first within the sinusoids, where the particle-containing macrophages can form plug-like structures (Irie et al. 1986). A focal or diffuse proliferation of hepatic macrophages seems to be an typical phenomenon and has been described in early reports of Thorotrast liver damage (Lüdin and Scheidegger 1944; Schmidt et al. 1950; Obiditsch and Obiditsch-Mayer 1954; Hackenthal 1956; Selmair and John 1970). This phenomenon may cause sinusoidal obstruction and eventually nodular regenerative hyperplasia (Beer et al. 1998). A first report regarded granuloma-like lesions caused by Thorotrast in the liver as a foreign body-type reaction ("foyers granulomateux"; Lanari et al. 1937). The production of granuloma-like liver lesions caused by Thorotrast irradiation and containing epithelioid macrophages plus thorium dioxide granules was then reported in 1950 (Rotter 1950). The macrophages then congregate in the parenchyma and later in the portal tracts, forming aggregates of Thorotrast-laden cells (Kaul et al. 1979; Irie et al. 1986). Some of these aggregates have the features of so-called Thorotrast granuloma, a feature already published in 1950 (Rotter 1950; Polacarz et al. 1992; Srinavasan and Dean 1997). Thorotrast granulomas have also been found in locoregional lymph nodes, caused by translocation of Thorotrast particles by migrating and transported phagocytes (Danese and Mollura 1974; Wegener and Wesch 1979). Conglomerates of such confluent lesions may cause a mass effect, a lesion pattern called "thorotrastoma." The stable deposition of macrophages with Thorotrast particles will lead to high-LET irradiation of the tissue compartment for long time periods. Alpha particles have a range of only up to 100 mm, resulting in local doses as much as 100 Gy/year at points 20 mm from a deposit of Thorotrast 5 mm in

diameter (Kaul et al. 1979; Dagle et al. 1992). The radiation tracks can histologically be visualized by use of slide autoradiography and imaging plate autoradiography (Hassler et al. 1964; da Silva Horta and Nunes 1973; Polacarz et al. 1992; Goto et al. 2002). Pathogenetically, and owing to the laden macrophages' preferential localization around blood vessels and bile ducts in the liver, the highest concentration of thorium dioxide is found in paravascular deposits (van Kaick et al. 1999). The mean dose rate in these areas was calculated to be 5 Gy/year (van Kaick et al. 1999). This irradiation will induce a fibrosis reaction which, together with the macrophage accumulation, may result in macroscopic nodular lesions termed thorotrastoma (Duriez et al. 1973). Larger lesions of this type may form "fibroadenomatoid" growths (Krücke 1950). In addition to tumor-like lesions, node-shaped histiocytic proliferations with characteristic eosinophilic substance around Thorotrast deposits have also been described (Levy 1960). On the other hand, septal fibrosis and cirrhosis of the liver may ensue (Aizawa et al. 1960; Momose et al. 1966; Ueda et al. 1966; Takagi and Hasebe 1972; Vanhaecke et al. 1979; Mori et al. 1983; Morant and Rüttner 1987; Marti Vicente et al. 1993; Sharp 2002), with an often coarsely nodular pattern (Krasinskas et al. 2004). In regard to cirrhosis, a 20-fold increase in risk has been calculated (Kato and Kido 1987). The Thorotrast-induced fibrosis can induce biliary obstruction and cholangitis (Malamud and Berra 1964; da Silva Horta 1967) which may, in its turn, cause secondary hepatic changes.

Thorotrast-Induced Vascular Lesions

Fibrosclerotic reactions caused by Thorotrast induce vascular obstructive lesions, including veno-occlusive disease (Dejgaard et al. 1984) and hepatoportal sclerosis. Nodular regenerative hyperplasia (Dachman et al. 1987) and focal nodular hyperplasia (FNH)-like lesions of the liver associated with thorotrastosis (Sano et al. 1985) may be caused by such vascular anomalies. Pronounced changes can be found in sinusoidal endothelial cells in hepatic thorotrastosis (Helpap and Tschubel 1980), and this injury to sinusoidal endothelia is thought to cause peliosis that has been observed after Thorotrast exposure (Okuda et al. 1981; Dejgaard et al. 1984). It has been suggested that advanced so-called micropeliosis might be a precursor lesion for hepatic angiosarcoma in thorotrastosis (Tateno et al. 1984). Veno-occlusive disease has been found in association with Thorotrast administration and was found in conjunction with peliosis hepatis (Dejgaard et al. 1984).

Thorotrast Deposits in Thorotrast-Induced Tumors

Thorotrast deposits can also be detected in Th232-induced tumors. Thorotrast particles, in part within macrophages, have been observed in the tissue surrounding the tumor and also in regions of tumor necrosis, where macrophages harboring particles accumulate. Also free Thorotrast particles can be seen in tumors, and some tumor cells seem to take up the particles (Visfeldt and Poulsen 1972).

Pathogenic Pathways

There is a relationship between the tissue compartments loaded with Thorotrast particles and carcinogenesis. Autoradiographic studies have shown that cancer was rarely in the center of fibrotic and macrophage-rich regions with heavy Thorotrast deposition, but rather at a distance from the deposits, suggesting mechanisms more complex than a mere local effect of alpha particles (Yamasaki et al. 2004; Yamamoto et al. 2009). The mechanisms causing the marked delay between thorium dioxide injection and manifestation of liver cancer have not been fully elucidated. One model proposed that target cells susceptible to malignant transformation may undergo one event by alpha particles and may then migrate outside of the range of alpha particles, thereby avoiding immediate induction of successive additional events for neoplastic change (Yamamoto et al. 2010). Thorium dioxide is also transported within organs via migration of macrophages that have ingested the Thorotrast particles

(Goto et al. 2002), microdistribution therefore being markedly influenced by the migration dynamics of phagocytosing cells. The distribution of colloidal thorium dioxide within the liver has been studied in a rat model of hepatic carcinogenesis (Grampa 1967).

Thorium dioxide induces chromosomal anomalies (Kemmer et al. 1973), and Th232-induced cholangiocarcinomas exhibit microsatellite instability (Liu et al. 2002). Genetic changes induced by Thorium dioxide have been detected in several hepatic tumors induced by this agent (Kamikawa et al. 1999; Liu et al. 2004; review: Ishikawa et al. 2001; Andersson 1997). LOH analysis revealed Thorotrast-induced intrahepatic cholangiocarcinomas (ICC) share some LOH features with ICC and HCC that were not induced by Thorotrast (Liu et al. 2004). Frequent and multiple point mutations in K-ras-2 were found in Thorotrast-induced hepatic angiosarcomas (Przygodski et al. 1997). Alpha particles such as thorium dioxide cause p53 gene mutations (Hollstein et al. 1997; Iwamoto et al. 1999).

Tumor-like Mineralizations/ Calcifications of the Liver

Introduction

Rarely, calcification (or mineralizations, as it is also termed) of the liver can result in mass-forming pseudotumoral lesions that can be confounded with calcified benign or malignant neoplasms (Fig. 5; early reports on liver calcification: Kaufman 1951; Bruce 1957; Schröder 1959; Reeder 1975; Darlak et al. 1980; Pounder 1985; reviews: Paley and Ros 1998; Stoupis et al. 1998). In what follows, the most important situations of hepatic calcifications are summarized.

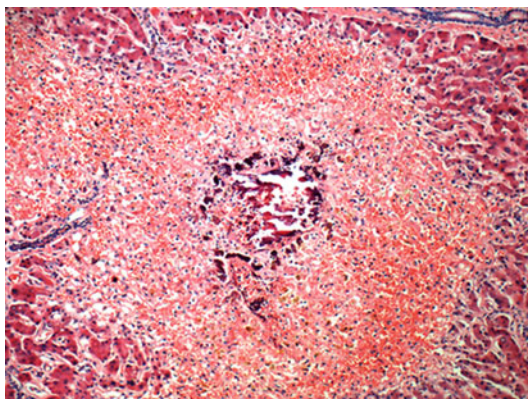

Fig. 5 Calcium granuloma in a necrotic area of the liver (hematoxylin and eosin stain)

Hepatic Calcification in Ischemia of the Liver

Diffuse dystrophic parenchymal calcification of the liver has been observed subsequent to ischemic hepatic necrosis (Nguyen and Leonard 1986), including shock (Shibuya et al. 1985b). Yet, there are also more complex situations with a mixed pathogenesis, such as combined hepatic ischemic injury and hypercalcemia due to chronic renal failure (Milstein and Moulton 1993).

Hepatic Calcification in Uremia

Uremia can cause extraosseous calcification, sometimes massive (Floege 2004). The pathogenesis may, at least to a good part, involve hypercalcemia, i.e., causing metastatic calcification (Ibels 1980). Calcification of liver tissue in uremia has rarely been reported (Shibuya et al. 1985a; Ladefoged and Frifelt 1987; Milstein and Moulton 1993; Kinjo et al. 2007), also in patients treated with peritoneal dialysis (Abbas et al. 1996). Calcifications were found in damaged parenchyma in the centrilobular to midzonal areas of liver lobules, but uremia-induced hepatic calcifications involving the epithelia of proliferated bile ductules have also been described (Kurumaya et al. 1989). Centri- and midzonal hepatic necrosis with intracellular and extracellular calcifications of round or rod-like shape was seen in uremic patients who had received hemodialysis, necrotic hepatocytes sometimes being almost completely replaced by calcium salt deposits (Sugiura et al. 1987; Kinjo et al. 2007).

Postinflammatory/Postnecrotic Hepatic Calcification

Several types of hepatic infection causing inflammation and necrosis are known to be accompanied, or followed, by hepatic calcification. They include placental infections spreading through the venous system to the liver (Arda et al. 2000), tuberculosis (Stoupis et al. 1998), calcified granulomas in hepatic brucellosis (Pons et al. 1981), and in cat-scratch disease (Talenti et al. 1994). Tuberculoma (macronodular tuberculosis) of the liver produces large and sometimes round hypointense nodules that may show calcifications at imaging (Chan and Pang 1989; Levine 1990; Fan et al. 1998). Amoebic liver abscesses older than 7 years have been found to undergo calcification (Blessmann et al. 2006). Liver calcification was also noted in neonates after transplacental infection (Shackelford and Kirks 1977).

Calcified Parasites

Parasites can, following their death, accumulate calcium salts in their necrotic tissue and cause circumscribed calcified masses. This phenomenon is known for hepatic schistosomiasis (Radhakrishnan et al. 1988) but has also been observed in liver fluke disease (fascioliasis, infestations with *Clonorchis* and *Opisthorchis*).

Calcified Necrosis, Infarcts, and Hematomas

Small and large hepatic necroses and infarcts can undergo dystrophic calcification, as insoluble calcium salts tend to accumulate in necrotic tissues. Also hematomas, as soon as they dehydrate and leave a mass of blood cell proteins, can calcify (Krivokhizh et al. 1983).

Hepatic Calcification After Liver Transplantation

Postoperative ectopic calcification located to several tissues seems to be rather subsequent to liver transplantation and appears to be caused by intraoperative manipulations of serum calcium levels, renal failure, ischemia, and other factors (Wachtel et al. 1992). An important mechanism of liver calcification posttransplantation is mediated by ischemia-reperfusion injury (Kalantari et al. 2007). Masses of posttransplantation lymphoproliferative disorder in a liver graft may primarily calcify (Lecouvet et al. 1996).

Hepatic Calcification Due To Amyloidosis

Marked hepatic calcification can develop in conjunction with amyloidosis of the liver, amyloid being known to have an affinity for calcium salts (Kennan and Evans 1991; Gibson et al. 1992; Jacobs et al. 1997).

Metastatic Calcification of the Liver

Liver cell calcification has been observed both in primary hyperparathyroidism (parathyroid adenoma; Monma et al. 1987) and in secondary hyperparathyroidism caused by renal failure (Ladefoged and Frifelt 1987). In the case published by Ladefoged and Frifelt (1987), the necropsy of a 20-year-old female who had had renal, cardiac failure and secondary hyperparathyroidism showed chronic passive congestion of the liver, associated with severe centrilobular necrosis and calcification. The calcium phosphate deposits stained black with the von Kossa stain (which stains phosphates) and orange red with the Alizarin-Red S method for calcium. The hepatocytes near the central vein were totally replaced by calcium phosphate, forming a black von Kossa-positive ring around the vein, while hepatocytes in the peripheral zone of the lobule showed calcium-containing granules in their cytoplasm. On the other hand, there are primary hepatic tumors inducing hypercalcemia (Oldenburg et al. 1982), for example, cholangiocarcinoma (Naide et al. 1968; Hirano et al. 1978; Davis et al. 1994) and hepatocellular carcinoma (with parathyroid hormone activity; Knill-Jones et al. 1970), including the sclerosing variant (Omata et al. 1981).

Hepatic Calcification in Other Metabolic Disorders

Hepatic calcification develops in the autosomal recessive connective tissue disorder, pseudoxanthoma elasticum (OMIM 264800) (Vanakker et al. 2006). This disorder has the phenotype triad of popular lesions and increased skin laxity in the flexural areas of the body, angioid streaks in the ocular fundus, and accelerated atherosclerosis leading to cardiovascular complications. Alterations of the elastic fibers in several tissues cause progressive fiber fragmentation and mineralization, which is the histologic hallmark of the disease. Aberrant mineralization of connective tissues has also been detected in a mouse model of pseudoxanthoma elasticum (Jiang et al. 2007). The responsible gene (termed ABCC6, multidrug resistance protein 6) is located on chromosome 16p13.1, encodes an ATP-dependent transmembrane transporter of substrate, is mainly expressed in the liver, and reveals numerous mutations in pseudoxanthoma elasticum (Ringpfeil et al. 2001; Li et al. 2009; Ratajewski et al. 2009; Costrop et al. 2010; Uitto et al. 2010). In murine hepatic Abcc6 expression, HNF4alpha and NF-E2 are the key transcriptional regulators (Douet et al. 2006), and in cultured human hepatocytes, the ERK1/ERK2-HNF4alpha axis regulates ABCC6 expression (De Boussac et al. 2010). In the liver, vitamin K precursor is secreted by ABCC6 as a glutathione or glucuronide conjugate, and the lack of ABCC6 may prevent the liver from providing sufficient amounts of vitamin K to the periphery (Borst et al. 2008). Low serum vitamin K in pseudoxanthoma elasticum results in defective carboxylation of mineralization inhibitors, and this is thought to play a role in the pathogenesis of ectopic calcifications (Vanakker et al. 2010).

Hepatic Calcification in Cystic Lesions of the Liver

Calcification, sometimes ring-like, in cyst walls of hepatic hydatid disease is well established and occurs in 10–20 % of cases (Scherer et al. 1978; Darlak et al. 1980; de Diego Choliz et al. 1982; Beggs 1983; Pandolfo et al. 1984; Kalovidouris et al. 1986; Stoupis et al. 1998). Hereditary polycystic liver disease is a very rare cause of intrahepatic calcification (Travers et al. 1983).

Hepatic Arterial Calcification

In contrast to the mesenteric and splenic arteries, the hepatic artery is seldom calcified. Calcification of this artery has been noted in a liver transplant recipient 13 years after transplantation (Eisele et al. 2009). It may sonographically mimic intrahepatic biliary calculi (White and Wilson 1994) or pneumobilia (Pai and Bude 2002). Calcifications have also been found to involve the ductus arteriosus and the ligamentum botalli (Currarino and Jackson 1970).

Calcification of Venous Vessels of the Liver

Most venous calcifications occurring in the liver are based on mineralization of venous thrombi or thromboemboli, well documented for the portal vein (Friedman et al. 1981; de Filippi and betta 1988). Calcifications can occur in the ductus venosus and veins of the ligamentum teres hepatis (Beluffi et al. 1998). The radiologic localization of calcifications to the structures of this compartment may be difficult (Lafortune 1990; Abu-Yousef 1990). A calcified ductus venosus associated with "tram-track" calcifications have been seen in neonates and suggested to be caused by catheterism (Rizzo et al. 1989).

Calcifications of the Bile Ducts

Biliary wall calcification has been found in Langerhans cell histiocytosis (Caruso et al. 2008).

Peritoneal Calcification

Peritoneal calcification (progressive calcifying peritonitis) can develop in patients with uremia

on continuous ambulatory peritoneal dialysis/CAPD (Dejima et al. 2008) and may involve the hepatic peritoneum.

Tumor-Like Calcification of the Liver

Solitary necrotic nodules of the liver are typically calcified (Colagrande et al. 2008). Mineralized conglomerates of hepatic granulomas may present as a calcified pseudotumor of the liver (Yuan et al. 1988; Fig. 6). Large calcifying granulomatous and necrotic masses are characteristic for hepatic brucelloma (Ruiz Carazo et al. 2005).

Calcified Tumors in the Liver

Focal nodular hyperplasia (FNH) is rarely associated with calcific deposits within the nodular lesion (Caseiro-Alves et al. 1996). In FNH, calcifications were found in the form of small, solitary spots located centrally or peripherally within the lesions, and the calcified foci were similar to those encountered in fibrolamellar carcinoma (Caseiro-Alves et al. 1996). Calcifications are rarely encountered in liver cell adenoma. Calcifications may be solitary or multiple and are usually located excentrically within a complex heterogeneous mass (Stoupis et al. 1998). In a multiphase CT study of 25 patients, calcifications were uncommon in liver cell adenoma (5 %; Ichikawa et al. 2000). Calcification has also been noted in liver adenomatosis (Khan et al. 1992). Tumor calcification also occurs in bile duct adenoma (Maeda et al. 2006). A distinct type of peripheral calcification occurs in mesenchymal hamartoma of the liver (Steiner and Giles 2008). Tumor calcification, often punctate, is regarded as rather typical for fibrolamellar hepatocellular carcinoma and occurs more frequently than calcification in ordinary hepatocellular carcinoma. The prevalence in published observations is given as 38 % (Friedman et al. 1985), 40 % (Soyer et al. 1991), 55 % (Brandt et al. 1988), and 68 % (Ichikawa et al. 1999). Calcification in untreated hepatocellular carcinoma has been reported to be rare, with most patterns fine granular, single, or multiple punctate and coarse and conglomerate (Weiss et al. 1972; Itai et al. 1979; Kunstilger et al. 1980; Scatarige et al. 1983; Teefev et al. 1987;) In part of the tumors, calcification involves the neoplasm's stroma (Moenandar 1974). In a CT study, calcific deposits were noted in 15.3 % of patients with hepatocellular carcinoma (Scatarige et al. 1983). Few HCCs show a rim or ring calcification that may mimic parasitic hydatid disease (Mitchell et al. 1994; Fukuya et al. 1999). Calcified cholangiocarcinomas seem to be rarer than calcified hepatocellular carcinomas (Hall et al. 1970; Yamasaki et al. 1977; Nagakura et al. 1999; Kitade et al. 2005), but in the intrahepatic variants, calcifications have been noted in up to 18 % (Stoupis et al. 1998). There are exceptional situations where psammoma body formation is a feature of cholangiocarcinoma (Yamada et al. 2000). Secondary calcification is well known in carcinoma metastases, in particular colorectal carcinoma (CRC) metastases (Miele and Edmonds 1963; Green and Stephens 1971; Kutzner and Wagner 1973; Sanchez Perez et al. 1995; Easson et al. 1996). Calcified hepatic metastases may be the first manifestation of CRC (Sanchez Perez et al. 1995), and they have characteristic CT features. By use of CT examination, 18.3 % of patients with CRC hepatic metastases showed calcific deposits (Scatarige et al. 1983). Among

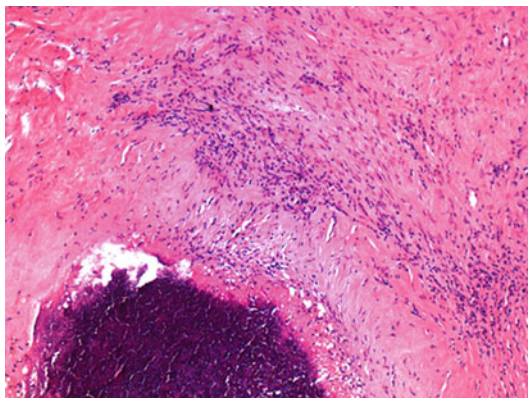

Fig. 6 Tumor-like calcification of the liver. The large accumulation of calcium salts (*bottom*) is associated with a fibrosed epithelioid cell reaction (hematoxylin and eosin stain)

265 patients with hepatic CRC metastases, 11 % had calcified metastases at presentation and 4 % developed calcification during chemotherapy (Hale et al. 1998). Calcification in colorectal hepatic metastases has been found to correlate with longer patient survival (Easson et al. 1996). Calcifications are also rather typical for certain vascular tumors. Cavernous hemangiomas, especially giant hemangiomas, may contain large, coarse calcifications that are centrally located in areas of fibrosis (Aspray 1945) and may be seen at CT (20 % of cases) or radiography (10 % of cases; Stoupis et al. 1998). Calcification is known for epithelioid hemangioendothelioma (Den Bakker et al. 1998),

Pathogenic Pathways

A crucial component of mineralization (both *loco classico* and ectopic) is the collagen fibril. During mineralization the fibril is formed first and then water within the fibril is replaced with mineral. The collagen fibril therefore provides the aqueous compartment in which mineral grows. Size exclusion experiments have shown that molecules smaller than a 6-kDa protein diffuse into all of the water within the collagen fibril, whereas molecules larger than a 40-kDa protein are excluded from this water phase. Large nondiffusible molecules can, however, initiate mineralization by forming small apatite crystal nuclei that diffuse into the fibril (Toroian et al. 2007). Other molecules inhibit the extra-fibril formation of apatite crystal, especially the serum inhibitor of apatite growth, fetuin-A, a protein synthesized in the liver (Toroian and Price 2008; mineralization by inhibitor exclusion, Price et al. 2009).

Cells involved in the initiation of mineralization in newly formed bone and in areas with ectopic mineralization/calcification release a distinct microstructure called matrix vesicles (MVs). MVs are extracellular, lipid bilayer-enclosed microstructures that are enriched in several phospholipids, especially phosphatidylserine (PS), a lipid with high affinity for Ca^{2+}. PS/Ca^{2+}.inorganic phosphate complexes (CPLXs) have been found in calcifying tissues, including bone, cartilage, and tumors. Critical components of MVs are the annexins II, V, and VI, and types II and X collagen are associated with MVs, and these interactions mediated by annexin V stimulate Ca^{2+} uptake and mineralization of MVs. The formation of annexin II, V, and VI Ca^{2+} channels in MVs together with stimulation of annexin V channel activity by collagens II and X binding provide the MVs with the ability to rapidly uptake calcium and to initiate the formation of the first crystal phase (Kirsch et al. 2000; Genge et al. 2007). Annexin V (A5) has the ability to bind in a calcium-dependent manner to phosphatidylserine, which is located in the inner leaflet of the plasma membrane. By this binding, A5 can form a membrane-bound two-dimensional crystal lattice (van Genderen et al. 2008). In calcification developing in and around hepatic necrosis, myofibroblasts play a pathogenic role. They have been shown to express bone-specific proteins, such as osteopontin, type I collagen, and bone sialoprotein. In addition, TGFbeta-1 and BMP2, two growth factors implicated in osteoblast differentiation, and Runx2 and Msx2, two transcription factor targets of TGFbeta-1 and BMP2, were also expressed in these cells (Kalantari et al. 2007).

Tumor-Like Lesions of the Hepatobiliary Tract Caused by Gallstones, Foreign Bodies, and Bile

124

Contents

Abstract

Gallstones, foreign bodies, and bile can induce tumor-like lesions in the hepatobiliary tract. Dropped or impacted gallstones can induce a vigorous inflammatory reaction followed by fibrosis and scarring, and eventually production of a pseudotumor. Medical material can elicit a foreign body reaction in the hepatic area, sometimes imitating a neoplastic process. Materials known to be involved include cotton pledgets, cloth, cottonoids, and several textiles, giving rise to "textilomas" and "gossypibomas." Similarly, ingested foreign bodies that migrate to the hepatic area can induce mass-forming foreign body reactions. Other materials that elicit such reactions comprise embolized particulate materials and bile accumulations (bilomas).

Gallstones and Gallstone Fragments

Some authors reported that as many as a third of all laparoscopic cholecystectomies are complicated by dropped gallstones (Sathesh-Kumar et al. 2004; Lohan et al. 2005; Tumer et al. 2005). Gallstones may also be dropped in the course of open cholecystectomy, but they are easier to retrieve due to larger operating field (Sathesh-Kumar et al. 2004). The main complications of dropped gallstones include localized or systemic infections, abscess formation, adhesions, fibrosis, ileus, and formation of fistulas

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_124

(Zamir et al. 1999). It was estimated that dropped gallstones cause an intra-abdominal abscess in 0.6–2.9 % of cases of dropped gallstones and bile spillage (Rice et al. 1997; Morrin et al. 2000; Lohan et al. 2005). The abscesses can obstruct the digestive tract or drain into the digestive tract to cause a communicating abscess. Abscesses may open into the peritoneal cavity and hence cause an empyema (Roberts and Chun 2005). Dropped gallstones can favor the development of actinomycosis (Ramia et al. 2004). Draining abscesses and their fistulas can cause communications of abdominal hollow organs with each other or create communications between bowel and skin (enterocutaneous fistula) and rarely between the abdominal cavity and the bronchial tree with formation of broncholithiasis (Noda et al. 1998). Gallstone-associated abscesses may develop with considerable delay, e.g., 5 years after laparoscopic cholecystectomy (Awwad et al. 2010). Due to inflammatory infiltrates with foreign body reaction and subsequent fibrosis, dropped gallstones can produce mass lesions that may mimic tumors, e.g., colon cancer (Perl et al. 2009). Intraperitoneal gallstone granulomas can be formed (Warren and Wyatt 1996; Tham and Ng 2001). Intraperitoneal abscesses developing around gallstones can invade the liver substance (Mahmood et al. 2008). In the liver, late abscesses after spilled gallstones can induce a liver mass mimicking malignancy (Casillas and Kittur 2003). Gallstone-induced abscesses rarely encircle the extrahepatic bile ducts, causing stenosis and obstructive jaundice (Stevens et al. 2003).

Hepatic Foreign Body Reactions Caused by Medical Material

Among surgical hemostatic agents, some are nonresorbable and are removed (various types of cotton pledgets; cloth such as muslin; synthetic rayon hemostats, such as cottonoids and kites). Muslin is a cotton fabric used to provide reinforcement, e.g., of vessel walls, and is composed of transparent fibers that are apparent under polarized light. Cottonoids and kites are synthetic strips and pledgets composed of rayon fibers containing a filament or strip impregnated with radiopaque barium sulfate. Conversely, bioabsorbable hemostats are often left in the surgical bed. They mainly include gelatin foam (Gelfoam), oxidized cellulose (Oxycel), and microfibrillar collagen. Nonresorbable material left in the body will produce a marked foreign body reaction, and this inflammation together with subsequent fibrosis can induce a pseudotumor. Several terms have been coined to denote these lesions, depending on the material involved. A textiloma is a mass ("oma") developing around a retained textile. The term, gossypiboma, is more complex and somewhat exotic; it derives from a genus of cotton plants, *Gossypium*, and a Kiswahili term, "borna," meaning "a place of concealment." A gauzoma contains surgical gauze, and a muslinoma is a pseudotumor induced by retained muslin (Ezaki et al. 1994; Farina et al. 1995; Zbar et al. 1998; Rajagopal and Martin 2002; Tacyildiz and Aldemir 2004). Pseudotumorous subhepatic gauzomas have been observed postcholecystectomy (Sok et al. 1989). Retained surgical swabs prodding a gossypiboma can produce a distinct CT features characterized by a calcified reticulate rind sign (Cerwenka et al. 2005; Lu et al. 2005). In case gossypibomas or gauzomas are located to the liver's surface, they may mimic a hepatic tumor, and intrahepatic foreign body granulomas may be confounded with liver metastasis (Poyanli et al. 2005). Oxidized cellulose ("Oxycel") can induce a granulomatous reaction in the liver, with formation of a pseudotumor (Bradley and Singh 1991). Thick gelfoam slurry used to embolize a hepatic needle biopsy tract was found to migrate to the common bile duct and the gallbladder (Riddle et al. 2008). Subcapsular hepatic abscess has been described as a rare complication of ventriculoperitoneal shunt (Reddy 1987). Also embolized foreign material particles can produce masses (see below; Murakata et al. 2006). Hepatic seed implant embolization was observed after prostate brachytherapy (Nguyen 2006).

Hepatic Inflammatory Masses, Abscesses, and Pseudotumors Caused by Ingested Foreign Bodies

Rarely, sharp objects may penetrate the intestinal tract and subsequently involve the liver, a complication already described in 1955 (Griffiths 1955). About 80–90 % of ingested foreign bodies pass through the gastrointestinal tract within 1 week, and perforation has been observed in less than 1 % of the patients. In the majority of cases, the left liver lobe is involved (Horii et al. 1999). Most foreign bodies migrating to the liver take their origin from the stomach and the duodenum, but the gut (Harjai 2000; Kumar and Gupta 2000) and colon (specifically the transverse colon) are also known as a source (Houli et al. 2003). A small set of foreign bodies clearly dominate the situation. Toothpicks can penetrate the upper GI tract and migrate into the liver, often causing a marked inflammatory reaction or even a liver abscess (Rafizadeh et al. 1981; Tsuboi et al. 1981; Bloch 1984; Pedersen et al. 1986; Cheung et al. 2000; Kanazawa et al. 2003; Chiang et al. 2006; Serwe et al. 2007; Stoica et al. 2007; Ammari et al. 2009; Liu et al. 2009; Glick et al. 2012). Migrating toothpicks can, in case of marked inflammatory response with fibroplasia, induce a hepatic pseudotumor (Del Fabbro et al. 2004). Hepatic complications with abscess formations are well known after migration of entire bones and bone fragments (particularly, fishbone) migrating from the stomach or the duodenum to the liver (Gower et al. 1961; Aron et al. 1966; Berk and Reit 1971; Gonzalez et al. 1988; Iwasa et al. 1988; Masunaga et al. 1991; Chan et al. 1999; Horii et al. 1999; De la Vega et al. 2001; Kessler and Kourtis 2001; Theodoropoulou et al. 2002; Goh et al. 2005; Starakis et al. 2005; Santos et al. 2007; Clarençon et al. 2008). Migrated fishbones are the most frequent cause of liver abscess (Gundara and Harrison 2010; Chen et al. 2011; Ng et al. 2011), sometimes with rupture (Kadowaki et al. 2007). Migrated fishbone was shown to induce a hepatic pseudotumor (Perera et al. 2007).

Ingested intact or broken needles can migrate from the stomach or the duodenum into the liver and cause an inflammatory response, sometimes with abscess formation (Abel et al. 1971; Acosta and Lantz 1996; Omejc 2002; Chintamani et al. 2003; Rahalkar et al. 2003; Azili et al. 2007; Akçam et al. 2009; Feng et al. 2009; Saitua et al. 2009; Jutte and Cense 2010; Senol et al. 2010). In few instances, intrahepatic sewing needles were found to remain for years without harm (Saitua et al. 2009; Senol et al. 2010). Exceptionally, ingested plant twigs such as rosemary can dislocate to the liver (Karamarkovic et al. 2007). Sometimes, unusual swallowed objects have caused colonohepatic penetration, e.g., a toothbrush (Lee et al. 2006). There are unusual types and origins of ingested foreign material. Systemic and particularly liver granulomatosis with noncaseating, giant cell-containing granulomas has been observed in a patient with malocclusion, bruxism, and worn dental prostheses, the foreign material in the granulomas being feldspars as a principal component of porcelain (Ballestri et al. 2001).

Metallic and Other Foreign Bodies Migrating From Places Other than the Digestive Tract

Apart from ingestion, needles may locate to the liver via penetration through the skin (Nishimoto et al. 2003; Azili et al. 2007). Hypodermic needles have been observed in peripheral parts of the liver, without marked foreign body reaction (Muddaiah and Varghese 2008). Dropped clips at laparoscopic interventions can cause infection, inflammation, intra-abdominal abscesses, and eventually sepsis (Labuski and Wise 1999; Hussain 2001). Ventriculoperitoneal shunts can show intrahepatic dislocation (Berkmann et al. 2011). They can also pass through the liver and diaphragm and migrate to the lung (Nazaroglu et al. 2009). Penetration of a fractured Bird's Nest filter strut into the liver substance has been described (Maleux et al. 2011). Dissemination of wear particles of the liver has been found in patients with hip or knee replacement (Urban et al. 2000).

Inflammatory Hepatic Mass Lesions Subsequent to Embolization of Particulate Matter

Embolotherapy of liver tumors has gained a role in the treatment of several neoplastic hepatic lesions. The embolization of particulate matter induces a foreign body reaction which is thought to contribute to the so-called postembolization syndrome (Siskin et al. 2003). Histologically, particles are found within the vascular lumina (sometimes with stretching of the vessels) and are in contact either with an intact endothelial layer, a denudated inner vascular surface, or with cells of the foreign body reaction. In situations of inflammation, the outer contour of the spherical particle may be irregular and in direct contact mainly with lymphocytes, monocytes/macrophages, and multinucleated giant cells. The thickness of the cellular rim encircling the particle is highly variable. At the periphery, the leukocytic and giant cell reaction is followed by a zone of fibroblast and myofibroblast proliferation, sometimes forming small nodular masses. In marked fibroplastic reactions, the contained vessels are deformed, causing a cobblestone shape or even a threadlike appearance of the remaining embolized particles (Stampfl et al. 2009). In rare situations, embolized material causes an inflammatory pseudotumor, e.g., cyanoacrylate hepatic pseudotumor (Velasco et al. 2005).

Biloma and Other Bile Accumulations

Introduction

Biloma is defined as an extraductal collection of bile within a newly formed intrahepatic or extrahepatic space. It is thought that biloma starts with bile leakage forming first a bile lake, which then increases in size to become a space-occupying lesion, viz., a biloma. Due to their presentation as a cystic mass, bilomas can mimic a hepatobiliary neoplastic process.

Causes and Clinic-Radiologic Features of Bilomas

A common basic mechanism and cause of bilomas is a defect in the biliary tract, induced by trauma, necrosis, and inflammatory changes. Bilomas have been observed in the setting of postoperative bile leakage after surgery (Vazquez et al. 1985), postcholecystectomy (Antonopoulos et al. 2009; Kannan et al. 2009), liver trauma (Esensten et al. 1983; Cañete Gomez et al. 2009), acute cholecystitis with gallbladder perforation (Tsai et al. 2009), bile duct necrosis secondary to transcatheter arterial chemoembolization for hepatocellular carcinoma or liver metastases (TACE; Kobayashi et al. 1993; Komatsu et al. 1998; Sakamoto et al. 2003; Chen et al. 2005), microsphere usage (Huang et al. 2007), radiofrequency ablation of hepatocellular carcinoma (Chang et al. 2010), endoscopic retrograde cholangiopancreatography (ERCP; Dupas et al. 1988), metastatic liver disease (Hiraki et al. 1998), hepatocellular carcinoma (Fritz et al. 1989), and bile leak from the duct of Luschka (Neumann et al. 2010). Liver infarction can rarely be associated with biloma. Sickle cell disease is known to produce several complications in the liver, such as cholelithiasis, intrahepatic cholestasis, hepatic crisis, cirrhosis, and infarction (Schubert 1986). An expanding intrahepatic bile-filled cyst representing a biloma has been reported, suggested to a consequence of liver infarction (Middleton and Wolper 1984; Lebensburger et al. 2008).

Ultrasound of bilomas shows cystic and well-circumscribed lesions with the echogenicity of protein-containing fluid (Gould and Patel 1979; Esensten et al. 1983; Kuligowska et al. 1983; Mueller et al. 1983). On CT, intrahepatic biloma appears as a more or less spherical, solitary, or multiple cystic area. But there are also cases which present as a branching appearance of hypoattenuating areas along Glisson's sheaths (Mueller et al. 1983; Sakamoto et al. 2003). Subcapsular hepatic cysts are also a known manifestation of biloma. Radiologically, a subcapsular

fluid collection is defined as fluid deep in the liver capsule and superficial to the liver parenchyma without rupture into the peritoneal cavity (Chen et al. 2009).

Pathology

Macroscopically, biloma is round or irregularly shaped collections of thin or sometimes viscous bile, resembling a bile-containing cyst. The color of the biloma fluid varies markedly, depending on the concentration of bile pigments and the contribution of exudate, blood, pus, and mucus, hence ranging from deep green yellow to brownish or reddish. Sometimes, intrahepatic bilomas are visualized as circumscribed bile accumulation with a bile duct in the center, i.e., bile collection within a Glisson tract.

Bile can flow from the biloma to adjacent tissue compartment, such as Glisson's sheaths and the subcapsular hepatic space. In bilomas developing secondary to bile duct and liver necrosis, e.g., post-chemoembolization, bile accumulates within the coagulative parenchymal necrosis (bile-stained or "yellow" necrosis). In case of neutrophil reaction, the histologic picture may resemble Charcot infarction. Bile accumulation is later demarcated by a fibrosing granulation tissue of variable thickness, with perifocal infiltration of lymphocytes and macrophages. The latter may pinocytose bile and eventually form bile granulomas. In case of biloma infection, there is a fibrin-containing exudative reaction with variable amounts of neutrophils and, later in the process, plasma cells as a local humoral immune response.

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_125

Abstract

The hepatobiliary tract can develop tumor-like lesions or pseudotumors that consist of hematopoietic tissue or macrophage accumulations. Extramedullary hematopoiesis can occur in the liver and may result in macroscopically visible nodular lesions (nodular extramedullary hematopoiesis). Macroscopically, the lesions may have several cm in diameter and usually show a red-brown or tan color. One variant is characterized by the production of an abundant fibrous stroma (sclerosing extramedullary hematopoietic tumor). The liver can be the site of various eosinophilic pseudotumors and eosinophilic necrosis. Macrophage-rich lesions of the liver that can result in tumor-like nodular lesions comprise lipogranulomas, xanthomatous lesions, rheumatoid nodules, malakoplakia, and accumulations of Gaucher cells in Gaucher's disease.

Hematopoietomas and other Nodular Manifestations of Extramedullary Hematopoiesis in the Liver

Introduction

Extramedullary hematopoiesis (EMH) refers to the production of blood cells outside the bone marrow and is often a compensatory response to cope with marrow infiltration, marrow depletion, or marrow hyperactivity seen in certain chronic anemias (review: O'Malley 2007). Moreover, EMH is a typical feature of several myeloproliferative disorders. Mostly, EMH is a diffuse or "microfocal" process. However, there are situations where EMH presents in the form of gross nodular lesions or tumorous masses. Tumor-like extramedullary hematopoiesis (nodular EMH) was originally described in 1945 (Ask-Upmark 1945) and occurs at several sites, including the spleen, the kidney (Moskovitz et al. 1991; Tamiolakis et al. 2003), the intrathoracic compartment (Malamos et al. 1962), the adrenal gland (Ask-Upmark 1945), and the liver. Based on the cases reported so far, an intrathoracic paravertebral location seems to prevail (Verani et al. 1980). Nodular EMH has been observed in several hematologic and bone marrow disorders, including sickle cell disease (Verani et al. 1980; Lemos et al. 1997), congenital dyserythropoietic anemia (Heimpel et al. 2009), thalassemia major (Papavisiliou and Sfikakis 1964; Kumar et al. 1995), beta-thalassemia intermedia (Wong et al. 1999), beta-thalassemia trait (Ma and Au 1999), hemoglobin E-thalassemia disease (Da Costa et al. 1974), myelofibrosis (Navarro et al. 2000) as a manifestation of thymoma (Hervé et al. 2001), and medullary tuberculosis (Ben Rejeb et al. 1992).

Nodular Extramedullary Hematopoiesis of the Liver

Since the liver is a site for early hematopoiesis, it is not surprising that it is a relatively frequent site of extramedullary hematopoiesis. In pediatric patients, EMH is considered normal up to about 5 weeks of age. Nodular extramedullary hematopoiesis of the liver (NEMH-L) occurs in the form of solitary or multiple lesions of highly variable size, involving one or both liver lobes (Kopecky et al. 1986; Wiener et al. 1987; Abbitt and Teates 1989; Dewar et al. 1990; Bradley and Metreweli 1990; Warshauer and Schiebler 1991; Kumar et al. 1995; Tamm et al. 1995; Lemos et al. 1997; Aytac et al. 1999; Wong et al. 1999; Kwak and Lee 2000; Navarro et al. 2000; Hervé et al. 2001; Gil-Fernandez et al. 2001; Parwani and Ali 2003; Tamiolakis et al. 2004; Gupta et al. 2004; Jelali et al. 2006; Lee et al. 2008). Among eight cases with sufficient data compiled from the literature, five were multiple and three solitary lesions (Wong et al. 1999). NEMH-L can present as a solitary space-occupying lesion mimicking a primary liver neoplasm, mainly HCC, metastatic disease, FNH, or an atypical hemangioma (Wiener et al. 1987; Bradley and Metreweli 1990; Gil-Fernandez et al. 2001; Tamiolakis et al. 2004), thus promoting diagnostic fine needle aspiration (Dardi et al. 1990; Raab et al. 1993; Lemos et al. 1997). Metastatic disease may in particular be suspected in case NEMH-L produces

several lesions with nodular hepatomegaly (Hervé et al. 2001). Sizes of the nodules have been reported to range from tiny lesions mimicking microabscesses (Kopecky et al. 1986) to 1.5 cm (Hervé et al. 2001), 3 cm (Wong et al. 1999), 7 cm (Parwani and Ali 2003), and 8 cm (Ma and Au 1999). Massive solitary NEMH-L has been observed in thalassemia (Dewar et al. 1990) and in myelofibrosis (Navarro et al. 2000). The masses may grow rather rapidly; particularly post-splenectomy; in one observation, the first hepatic manifestation was a 3 cm lesion, growing to 6 cm within 3 months (Wong et al. 1999). On the other hand, even very large lesions have been reported to remain unchanged for 4 years (Ma and Au 1999).

At ultrasound examination, the lesions are usually hypoechoic (Bradley and Metreweli 1990; Dardi et al. 1990; Dewar et al. 1990; Aytac et al. 1999; review: Wong et al. 1999). CT shows fairly well-defined, homogeneously low attenuated masses. On contrast-enhanced portal venous phase CT, most of the lesions show intense enhancement (Wong et al. 1999; Kwak and Lee 2000; Lee et al. 2008). The appearance of the lesions on MR consists of slightly increased signal on T2-weighted images with heterogeneous enhancement of some of the lesions during bolus infusion of gadolinium, while the T1-weighted images post-gadolinium showed no delayed enhancement (Warshauer and Schiebler 1991; Jelali et al. 2006). The imaging features for Doppler US (Aytac et al. 1999) and for Technetium-99 m red blood cell SPECT (Tamm et al. 1995) have been reported. When using the latter method, NEMH-L may mimic hepatic hemangioma (Tamm et al. 1995). Radiologically, NEMH-L can present as a fatty lesions, thus causing differential diagnostic difficulties (Gupta et al. 2004).

Macroscopically, NEMH are generally described as nodular and sometimes bulky, rather well-defined lesions, that are of medium consistency and show a cut surface that varies from red-brown or tan (in case of high vascularity and/or iron deposition) to grayish-white. Histologically, NEMH-L is composed of normal-looking hematopoietic tissue consisting of all three lineages (Figs. 1, 2, and 3). Few small cells

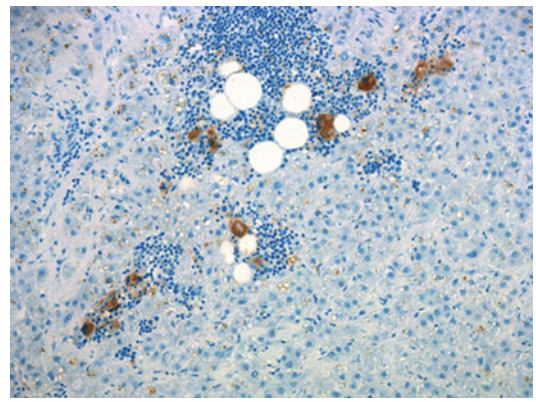

Fig. 3 Extramedullary hematopoiesis of the liver with production of megakaryocytes (CD61 immunostain)

with a lymphoid morphology may be present. It is not yet known whether such cells may, in addition to a lymphocyte population, represent hematopoietic stem cells. Similar to bone marrow, the hemopoietic tissue contains scattered macrophages with or without stainable iron. In addition, cells with a spindle-shaped morphology are detectable in small numbers (an analogue to marrow stromal cells?). In larger lesions, extracellular matrix may be increased, sometimes with focal fibrosis or sclerosis. In fact, NEMH-L can produce stellate scars visible in MRI and CT (Wong et al. 1999). The adjacent liver substance is compressed in large lesions, and perifocal hepatocytes may show iron overload (Ma and Au 1999). The morphologic differential diagnosis of NEMH-L chiefly includes hepatic myelolipoma and malignant tumors of the hemopoietic lineage.

Sclerosing Extramedullary Hematopoietic Tumor of the Liver

Sclerosing extramedullary hematopoietic tumor (SEMHT) is a rare lesion that typically arises in patients with chronic myeloproliferative disorders (Remstein et al. 2000; Yang et al. 2002; Sukov et al. 2009). Multiple intra-abdominal nodules of SEMHT can develop after splenectomy in patients with chronic myeloproliferative syndrome (Gualco et al. 2010). Macroscopically, these lesions are soft to firm, gray-white to yellow-tan nodular masses. Histology reveals extramedullary hepatopoiesis with atypical megakaryocytes, granulocytic precursors, and erythroid precursors set in a background of dense collagenous sclerosis. SEMHT has been observed in the ligamentum teres of the liver, in one patient in association with chronic idiopathic myelofibrosis (Kwon et al. 2004).

Benign Extramedullary Hematopoietic Proliferations of the Biliary Tract

In very rare instances, benign extramedullary hematopoiesis develops in and around the walls of large bile ducts. These foci of hematopoiesis occur in myeloid neoplasms destroying the bone marrow and in certain other situations of marked secondary extramedullary hematopoiesis. In massive forms, the intrahepatic biliary tract may be encased by the hematopoietic tissue, causing hepatic failure (La Fianza et al. 2010).

Hepatic Myeloid Hyperplasia in Caffey's Disease

Infantile cortical hyperostosis (ICH; Caffey's disease; OMIM 114000) was described in 1945 (Caffey and Silverman 1945). The disorder is characterized by cortical thickening of affected bones (mainly diaphysis of long bones) and inflammatory swelling of the contiguous soft tissues (reviews: Glorieux 2005; Kamoun-Goldrat and le Merrer 2008). The acute manifestations are usually inflammatory in nature, with fever and hot swelling of involved bones, clinically suggesting osteomyelitis. ICH usually manifests in young infants (the classical infantile form), but is sometimes also seen in neonates and in fetuses as early as 20 weeks of gestation (Herman 1996; Schweiger et al. 2003). A distinct variant is early-onset prenatal ICH (Lecolier et al. 1992). The classical form reveals autosomal-dominant inheritance (Fried et al. 1981), whereas autosomal recessive inheritance has been suggested for the early-onset prenatal variant. The disorder is assigned to chromosome 17q21-31-q22. Patients with classical ICH have been shown to have a 3040C>>>T mutation in the COL 1A1 gene (Gensure et al. 2005; Cho et al. 2008; Kamoun-Goldrat et al. 2008). Early-onset prenatal ICH, the form which shows liver alterations, is divided into two forms, a severe form with onset before 35 weeks of gestation, associated with polyhydramnios, lung disease, hydrops fetalis, anasarca, hepatomegaly, prematurity, and high lethality, and a mild form, with onset after 35 weeks of gestation and lack of complications (Schweiger et al. 2003). In a detailed autopsy analysis of a patient with early-onset prenatal ICH, hepatomegaly was found to be

caused by marked myeloid hyperplasia. Myeloid hyperplasia was most prominent in the tissue surrounding the portal tracts, and myeloid precursors were located within hepatic sinusoids. In contrast, an increase in erythropoiesis was not noted. This extramedullary myeloid hyperplasia was suggested to be caused by the generalized skeletal inflammatory process characterized by ICH, with microabscess formation and widespread granulation tissue at the interface between bone and periosteum (Wright et al. 2005).

Focal Eosinophilic Infiltration of the Liver

Introduction

Hypereosinophilia is associated with several conditions, comprising allergic reactions, parasite infestations, connective tissue diseases, and neoplastic processes, but idiopathic forms are also recognized. Idiopathic hypereosinophilic syndrome (HES) is a heterogeneous group of disorders that has been defined as peripheral eosinophilia $>1500/mm^3$ for at least 6 months and evidence of end-organ involvement in the absence of an identifiable cause (Leiferman and Gleich 2004). A subset of patients with a myeloproliferative variant of hypereosinophilic syndrome (MHES) is characterized by elevated serum tryptase levels, increased atypical mast cells in the bone marrow, tissue fibrosis, and the presence of the fusion tyrosine kinase, Fip1-like 1 (FIP1L1) – PDGFRalpha (generated by a cryptic interstitial deletion on chromosome 4q12; del (4)(q12q112)), a therapeutic target of imatinib mesylate (Griffin et al. 2003; Klion et al. 2003; Cools et al. 2003; Pardanani et al. 2003; Klion et al. 2004a). This novel fusion kinase is detectable in chronic eosinophilic leukemia (CEL), MHES, and systemic mast cell disease (Coutre and Gotlib 2004; Cools et al. 2004; Gotlib et al. 2004). Recently, familial eosinophilia (FE; OMIM 131400) has been characterized, a disorder that can also cause end-organ damage (Klion et al. 2004b).

Liver Alterations in Hypereosinophilic Syndromes

Hypereosinophilic syndrome may cause eosinophil-related tissue alterations in various organs, including the gastrointestinal tract (eosinophilic gastrointestinal disorders, EGID; Rothenberg 2004) and the liver (Table 1).

In a study on 13 patients, mild to moderate hepatomegaly was found in all cases, and seven patients exhibited multiple round or oval hypoechoic or variably echogenic lesions measuring 1–2 cm with poorly defined margins in both lobes of the liver, but four patients showed lesions of up to 4 cm diameter. The number of lesions and the extent of diffuse lesions seemed to be proportional to the degree of eosinophilia (Nam et al. 1999). The lesions may mimic multiple liver metastases or hepatocellular carcinoma (Won et al. 1999; Jang et al. 2002; Kwak et al. 2004). CT demonstrates well-defined, homogeneous, or heterogeneous low attenuation with a straight margin limited to a hepatic lobe, segments, or subsegments, in the latter situation with multiple, ovoid, or wedge-shaped lesions (Lim et al. 2000; Yoo et al. 2003).

Pathologically, hypereosinophilia causes several groups of hepatobiliary lesions. In cases of low to moderate eosinophilia, an infiltrate dominated by eosinophils is chiefly identifiable in portal tracts, but the number of these cells is also increased within sinusoids and around the central veins (Fig. 4; Lim et al. 2000). The liver involvement in marked peripheral eosinophilia can present as cholestatic liver disease (Valente et al. 1997). In case of direct hepatic involvement

by parasites (fasciola, clonorchis, and other liver flukes; visceral larva migrans, e.g., *Toxocara* or *Ascaris suum*; *Capillaria*; echinococcosis), the dense eosinophilic infiltrate is found in close association with the parasite, sometimes to a degree to form a focal eosinophilic infiltration, an eosinophilic abscess, or an eosinophilic pseudotumor (Pulpeiro et al. 1991; Han et al. 1993, 1996, 1999; Bhatia and Sarin 1994; Murrell et al. 1997; Kim et al. 1999, 2002; Hayashi et al. 1999; Andresen et al. 2000; Azuma et al. 2002; Sakakibara et al. 2002). These lesions are further discussed in another chapter.

The hypereosinophilic lesions may contain accumulations of Charcot-Leyden crystals (CLC; Fig. 5). These crystals accumulate in any situation where numerous eosinophils are present in tissues, including eosinophilic abscess (Fig. 6). The crystal constituents show indirect lysophospholipase activity (galectin-10, CLC protein; chromosome 19; Mastrianni et al. 1992; Zhou et al. 1992; Leonidas et al. 1995). The galectins form a family of proteins playing a role in myeloid differentiation (Dyer et al. 1997; Abedin et al. 2003) and include, apart from the CLC galectin-10, the placental protein 13 (galectin-13) that also has lysophospholipase activity. The CLC protein, galectin-10, is not a lysophospholipase as such, as has been sometimes reported, but a protein that binds a lysophospholipase inhibitor in a distinct structural fashion (Ackerman et al. 2002). CLC are not only

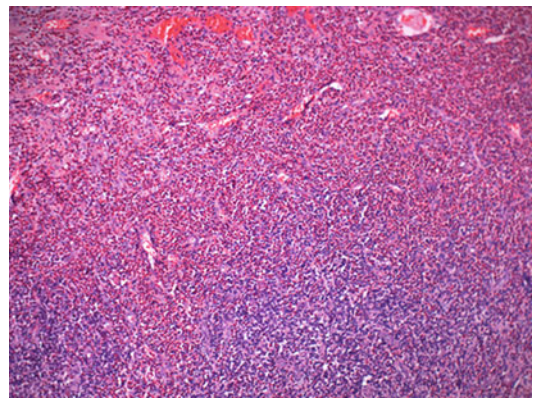

Fig. 6 Eosinophilic abscess of the liver. The abscess mainly consists of eosinophil granulocytes, with cell decay and nuclear debris in the center (hematoxylin and eosin stain)

formed by eosinophils but also by basophil granulocytes (Ackerman et al. 1982).

Focal Eosinophilic Necrosis of the Liver (FEN)

A second and distinct situation occurs when eosinophil infiltration of the liver is associated with tissue necrosis, a condition termed focal of eosinophil-related necrosis, eosinophilic hepatic necrosis (Figs. 7, 8, and 9; Ung et al. 2000; Hur et al. 2005; Laghi et al. 2010), focal eosinophilic necrosis (FEN; Jang et al. 2002), or focal eosinophilic liver disease (FELD; Kim et al. 2010). FEN

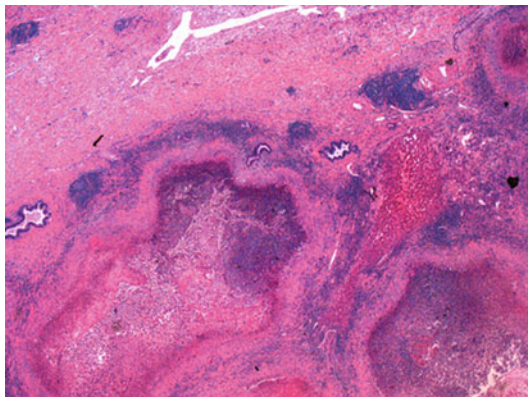

Fig. 7 Focal eosinophilic necrosis of the liver. Collapsed areas of necrosis with eosinophilia and nuclear debris are important features (hematoxylin and eosin stain)

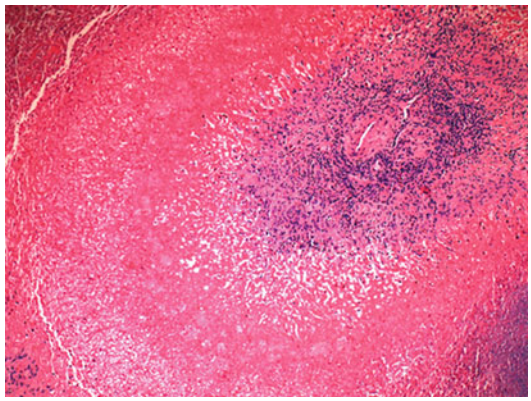

Fig. 8 Focal eosinophilic necrosis of the liver. The necrotic aspect of the lesion is more prominent in this case (hematoxylin and eosin stain)

is a descriptive term based on pathologic features and has not yet been clearly defined (Jang et al. 2002). In principle, FEN is a distinct type of parenchymal necrosis (mostly periportal), associated with eosinophilic infiltration. The main difference to focal eosinophilic infiltration and eosinophilic abscess is the presence of necrosis, thought to be caused by cytotoxic proteins released from eosinophils, but necrosis also occurs in abscesses and the separation of the entities is therefore somewhat arbitrary. FEN seems to almost always be accompanied by peripheral eosinophilia, and it occurs in several conditions causing eosinophilia, including lymphoma, leukemia, and carcinomas (Lee et al. 1999, 2011); Jang

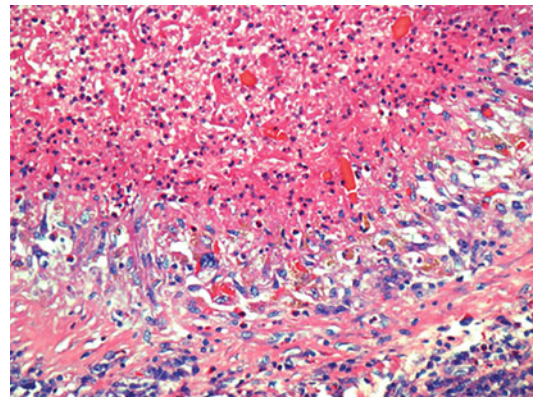

Fig. 9 Focal eosinophilic necrosis of the liver. The area of eosinophilic necrosis is demarcated by activated, epithelioid macrophages. Note few Charcot-Leyden crystalloids within the necrosis (hematoxylin and eosin stain)

et al. 2002; Yu et al. 2005; Choi et al. 2009, 2010. In these instances, eosinophil-recruiting facts such as tumor-associated eosinophil-chemotactic factor are thought to be involved (Wasserman et al. 1974).

Pathologically, FEN is characterized by focal coagulative necrosis of hepatic parenchyma associated with an infiltration of eosinophils. The necrosis is, due to high protein content, markedly eosinophilic, but this oxyphilic staining features may also be caused by the high content of the necrosis of eosinophil granules and debris. In the adjacent tissue and particularly in portal tracts, an eosinophilic infiltration is noted.

Xanthomatous Lesions of the Liver

Introduction

Xanthomas are solitary or multiple lesions characterized by grossly yellowish to frankly yellow plaques (Greek: xanthos, yellow) histologically consisting of an accumulation of lipid-rich macrophages/histiocytes. Xanthomas chiefly occur in several types of hyperlipidemia/hyperlipoproteinemia and mainly involve the skin and the soft tissues, but may also involve deep-seated tissues. In periocular areas, the term xanthelasma is employed (Greek: elasma, plaque; yellow

plaque). Xanthomas were first described by Rayer under the term "plaques jaunatres des paupières" (what exactly means, "yellowish plaques," i.e., xanthelasmas; Rayer 1835). In 1851, the same type of lesions was described under the term "vitiligoidea," with a "plana" and a "tuberosa" variant (Addison and Gull 1851). The term, xanthelasma, was coined in 1863 by Wilson, while the tumor-like appearance of some of the yellow nodules led to the name xanthoma by Smith in 1869.

Liver Xanthomas

Xanthomas and xanthogranulomas of the liver are rare lesions, but may produce multiple nodular changes suggesting manifestations of a neoplastic process (Figs. 10, 11, and 12; Tanino and Ohta 1981). Probably the first description of hepatic xanthoma is the report by Chvostek in 1911, who also used the term *xanthoma of the liver* (Chvostek 1911). Before, other terms had been used, such as "xanthomatous tubercles" (Hardaway 1884). A similar case has been described in 1938, based on a partial autopsy (performed by Ludwig Aschoff) of a patient with liver cirrhosis and partially eruptive skin xanthomas (Thannhauser and Magendantz 1938). In part of the cases, the hepatic xanthomatous reaction was suggested to be caused by hyperlipidemia. For example, multiple liver xanthomas have been found in multiple myeloma associated with hyperlipidemia (Yim et al. 1995). In proliferative plasmacytic disorders, xanthomas are known to occur in other locations, and lipid deposits may, apart from hyperlipidemia, be caused by paraprotein Ig-mediated complexing of lipoproteins (Moschella 1970; Roberts-Thomson et al. 1975; Taylor et al. 1978). A xanthomatous mass at the liver hilum has been described in a 9-year-old boy with generalized xanthomatosis and xanthoma tuberosum (Weidman and Freeman 1924). Xanthomas may also involve the liver capsule (Weidman and Boston 1937). In

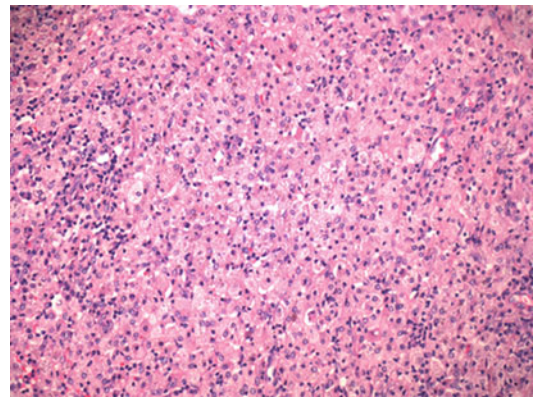

Fig. 11 Xanthoma of the liver. Numerous lipid-rich foamy macrophages occupy the tissue, associated with focal lymphocytic infiltration (hematoxylin and eosin stain)

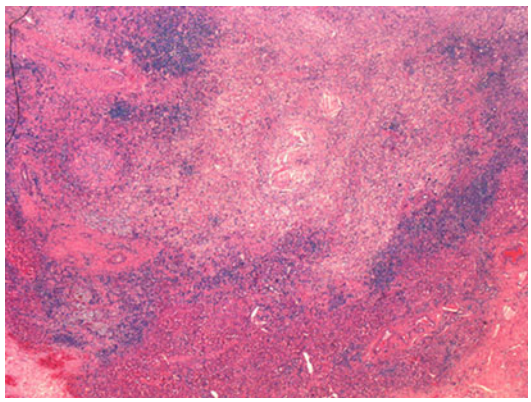

Fig. 10 Tumor-like hepatic xanthoma (hematoxylin and eosin stain)

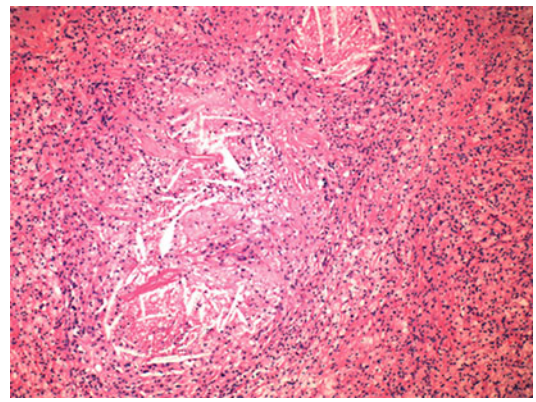

Fig. 12 Hepatic xanthoma. In this lesion, numerous cholesterol clefts are noted (hematoxylin and eosin stain)

hyperlipoproteinemia associated with extensive xanthoma tuberosum, hepatocytes in addition to macrophages may take part in lipid storage, sometimes resulting in parenchymal changes reminiscent of adrenocortical tissue (Weidman and Stokes 1937). Xanthomatous lesions of the liver parenchyma itself also occur in obstructive cholestasis; the lesions are characterized by the accumulation of foamy macrophages chiefly in the periportal zone ("xanthomatosis of the liver," Thannhauser and Magendantz 1938; Desmet 1995; Woollons and Darley 1998). Multiple xanthomatous foci have been reported to occur in the liver in the systemic form of juvenile xanthogranuloma (Chantranuwat 2004), a disorder further discussed in the chapter of Langerhans cell histiocytosis.

Xanthomatous Cholangitis (Xanthomatous Cholangiopathy)

An interesting group of lesions has been termed *xanthomatous cholangitis,* now rarely found in the current literature. The lesion spectrum has been summarized under the term "xanthomatosis of the bile ducts" (Thannhauser and Magendantz 1938). Early reports go back to the end of the nineteenth century (Moxon 1873) and the beginning of the twentieth century (Futcher 1905). We propose the term *xanthomatous cholangiopathy*, to denote these lesions, as this alteration is not primarily an inflammatory disorder, but rather a lesion characterized by the focal accumulation of lipid-laden macrophages within the inner parts of medium-sized and large bile ducts, albeit usually with some lymphocytic infiltration. This lesion has mainly been seen in patients with biliary cirrhosis or diabetes mellitus and usually eruptive, sometimes papulopustular, skin xanthomas. At gross examination, the lesions are spheroid to oblong, elevated, rather sharply delineated spots or patches, sometimes showing a dimple in the center (molluscum-like lesions). In some patients, the involved bile ducts were dilated, had thickened walls, and were lined by bright yellow granular incrustive material (Weidman and Boston 1937). In an another patient, the walls of the bile ducts were of a deep yellow color, and there were minute yellow flecks in the mucosa of the bile ducts (Futcher 1905). Histology is characterized by a patchy accumulation of foam cells involving the mucosa and, in larger lesions, inner parts of the bile duct muscularis. The lesions may be accompanied by impressive hyperplasia of the peribiliary glands (Weidman and Boston 1937) and by scarring causing stenosis or even obstruction (Weidman and Boston 1937; Thannhauser and Magendantz 1938). The pathology has already been described in early reports. It is difficult to judge of what these patients had suffered, but reading the original works suggests that most of them may have had primary or secondary biliary cirrhosis, or diabetes mellitus. In one patient with xanthomata diabeticorum, the postmortem examination showed dilated bile ducts with white to yellowish, opaque, xanthelasma-looking patches on the mucosal surface of the ducts (Moxon 1873). In another patient, the xanthomatous lesion was located to the bifurcation of the hepatic duct (Thannhauser and Magendantz 1938). The striking resemblance of bile duct xanthomas to the respective skin lesions, or to atheromas, has been acknowledged in an early report ("Patches precisely like those in the eyelids and hands were found on the surface of the spleen and in the mucous membrane of the dilated hepatic ducts." "The patches in the ducts looked just like atheroma in the artery with which condition, indeed, they correspond histologically"; Pye Smith 1873). The xanthomatous patches may cause stenosis or occlusion of bile ducts involved (Futcher 1905; Weidman and Stokes 1937).

Hepatic Xanthomatous Reactions in Xanthomatous Cholecystitis

In severe xanthogranulomatous cholecystitis, the massive macrophage reaction with production of foamy cells can extend into the gallbladder bed and from there into the liver substance of the right lobe, mimicking cancer (Pinocy et al. 2003; Yang et al. 2007). Xanthogranulomatous cholecystitis, treated in more detail in a separate chapter, was first described in 1970

under the term fibroxanthogranulomatous cholecystitis (Christensen and Ishak 1970), while the term xanthogranulomatous cholecystitis was coined in 1976 (McCoy et al. 1976). Alternative terms include biliary granulomatous cholecystitis, ceroid-like histiocytic granuloma, and ceroid granuloma. The change is found in 1.2 % of cholecystectomy specimens. It is not yet clear whether the incidence of carcinoma is increased in the presence of this distinct type of inflammation (Benbow 1990; Franco et al. 1990; Reed et al. 1994; Parra et al. 2000). Histologically, three different types of xanthogranulomatous cholecystitis are distinguished, i.e., multinodular, focal, and diffuse, the latter being the least common (Franco et al. 1990). Apart from an extension of the xanthomatous (or better pseudo-xanthomatous) reaction into the liver, this type of cholecystitis has been reported to be associated with liver abscess (Eriguchi et al. 2002).

Xanthomatous Inflammatory Pseudotumors

A further group of masses located to the liver and sometimes containing large numbers of lipid-laden, foamy macrophages are the several variants of inflammatory pseudotumor, discussed in more detail in a separate chapter. The accumulation of fatty macrophages can result in xanthomatous features; therefore, these lesions have also been termed xanthogranuloma of the liver. In some situations, the masses are large and present as lobulated, yellowish tumors measuring up to 7 cm in diameter, with septate fibrotic bands, or are manifest as multiple yellow nodules of few cm size, with or without abscesses in the vicinity (Noi et al. 1994; Tai et al. 1998; Yoon et al. 1999; Yoshida et al. 2003). Histology is characterized by a complex mixture of foamy macrophages, plasma cells, lymphocytes, and granulation tissue. A high lipid content of pseudotumors are in part due to accompanying purulent changes with massive decay of lipid-rich granulocytes, such as pyogenic cholangitis (Yoon et al. 1999).

Hepatic Lipogranulomatosis (Farber's Disease)

Disseminated lipogranulomatosis Farber or Farber disease is a rare inherited autosomal recessive disorder of lipid metabolism in the childhood population due to a genetically determined defect in ceramide degradation (acid ceramidase deficiency), with ceramide accumulation in the lung, liver, bowel, skeletal muscle, cartilage, and bone. Ceramidase splits ceramide into free fatty acids and sphingosine. The storage cells show lysosomal inclusions containing lamellar and curvilinear membrane profiles, zebra structures, and banana bodies (Farber bodies). This storage process is followed by a sometimes massive lipogranulomatous reaction associated with the presence of macrophages, lymphocytes, and fibroblasts. Liver involvement is clinically manifest as hepatomegaly and histologically in the form of dense focal infiltrations of ceramide-containing storage cells (histiocytes/macrophages). Lipid-containing foam cells can form hepatic granuloma-like lesions (Koga et al. 1992). The multiple, up to pinhead-sized lesions in the liver, may already be evident in the newborn period (Schäfer et al. 1996). Type 4 disease (see below) is particularly prone to develop marked lipogranulomatous changes in the liver, sometimes forming tumor-like masses. Liver involvement in type 4 Farber's disease can cause neonatal liver failure (Willis et al. 2008). Lipid-laden foam cells in Farber's disease may develop in suture foreign body granulomas of the liver (Koga et al. 1992).

Farber's lipogranulomatosis (Farber disease; ceramidase deficiency; OMIM 228000) is a rare genetic, autosomal recessive lysosomal storage disease caused by acid ceramidase (E.C. 3.5.1.23) deficiency, which leads to ceramide accumulation in several organs (Koch et al. 1996; review: Ehlert et al. 2007). Farber's disease presents with six phenotypes. Type 1 is the classic variant with early subcutaneous nodules and joint involvement, and often progressive neurologic involvement and lung disease. Type 2 and 3 patients show only slight alterations of the central nervous system, but severe manifestations in the soft tissues. Type 4 patients show severe

neurologic deterioration and marked hepatosplenomegaly already in the neonatal period. Type 5 is characterized by progressive CNS dysfunction, beginning already at 1–2 ½ years of life. Finally, type 6 is a combination of Farber's disease and Sandhoff's disease. Ceramide is an important cellular lipid involved in signal transduction, the synthesis of complex sphingolipids, and in apoptosis pathways (el Bawab et al. 2002; Pettus et al. 2002). The Farber phenotype has been divided into seven different subgroups that differ in the age of onset, severity of symptoms and signs, and tissue involvement of ceramide storage. The acid ceramidase gene has 14 exons and 13 introns, and mutations so far described in humans have recently been reviewed (Zhang et al. 2000; Bar et al. 2001; Muramatsu et al. 2002). In the mouse, insertional mutagenesis of the acid ceramidase gene cause early embryonic lethality in homozygotes and progressive lipid storage disease in heterozygotes (Li et al. 2002).

Differential Diagnosis

Hepatic xanthomas have to be distinguished from situations where visible depositions of cholesterol-rich lipids involve liver cell systems in a diffuse distribution pattern (e.g., "hepatic cholesterolosis" in hepatic cholesterol storage disease; a minor variant of Wolman's disease; Verola et al. 1983). This distinct type of lipid accumulation in several hepatic cell systems has also been observed in the respective animal model, the Wolman's disease rat or Yoshida rat (Kuriwaki and Yoshida 1999).

Lipogranulomas, Lipogranulomatosis, and Mineral Oil Granulomas of the Liver

Hepatic Lipogranuloma

Hepatic lipogranulomas in a wider sense of the term are focal accumulations of macrophages that have pinocytosed neutral fat and other lipids. Lipogranulomas are well known to occur in adipose tissue following adipocyte damage with release of neutral fat from injured or dead cells, but they also occur in fatty livers subsequent to steatotic hepatocyte injury and death. In case of numerous such lesions, the term lipogranulomatosis is sometimes used. Clusters of hepatic lipogranulomas can be identified in vivo by means of modern imaging techniques and may present as small tumor-like lesions.

The morphologic definition of lipogranulomas led to the inclusion, apart from those caused by neutral fat, also of reactions to exogenous substances inducing a similar or the same histology, e.g., mineral oil. Lipogranulomas sensu stricto represent a macrophage- and lymphocyte-driven reaction to triglycerides (neutral fat) (Iversen et al. 1970; Christoffersen et al. 1971). They mainly occur in the setting of hepatic steatosis of any cause (Christoffersen et al. 1971; Andersen et al. 1984; Ferrell et al. 1995). In a study of 61 morbidly obese patients, patients showing lipogranulomas in liver biopsies were significantly more obese than patients without this change (Andersen et al. 1984). In a study comparing patients with nonalcoholic steatohepatitis (NASH) and alcoholic steatohepatitis (ASH), lipogranulomas were more remarkable in the ASH group (Morita et al. 2005). The etiology of hepatic lipogranulomas depends, however, markedly on epidemiological factors. Lipogranulomas are also a features of some types of chronic HCV infection. Among 376 sequential, archival liver biopsy specimens examined in New York, 58 (15.4 %) had hepatic lipogranulomas, including 46 patients with hepatitis C and 14 patients with fatty liver disease. Hepatic lipogranulomas were more often seen in patients with hepatitis C (21 %) and fatty liver disease (18 %). Therefore, hepatitis C, which can be associated with hepatic steatosis, is an additional important cause of lipogranulomas (Zhu et al. 2010).

The prevalence of hepatic lipogranulomas is only partially known, and the data are markedly related to the sampling used (biopsies vs. autopsies) and to the histologic methods employed (paraffin sections vs. lipid staining). Part of the investigations include lesions that may have been caused by exogenous oily

substances, such as mineral oil, hence not representing true lipogranulomas. In liver biopsies, lipogranulomas have an estimated frequency of 2.4–5 % (Delladetsima et al. 1987; Scheuer and Lefkowitch 2006). Portal tract lipogranulomas were recognized in 2.4 % of biopsies and were consistently associated with hepatic steatosis (Delladetsima et al. 1987). In an autopsy study (465 autopsies), they were found in 48 %, which is a very high figure that may markedly depend on the autopsy material and the criteria used (Wanless and Geddie 1985). In this study, hepatic lipogranulomas were more common in portal tracts than adjacent to the terminal hepatic venules and more frequent in older subjects (especially men). These two findings suggest that, in addition to neutral fat, mineral oil exposure (see below) may have played a significant role in the etiology of the lipogranulomas found in this investigation (what also the authors took into consideration).

Pathology

In case of larger lipogranulomas, the yellowish cut surface of steatotic livers may show discrete spots of a darker yellow, usually of the size of 1–2 mm. Numerous lipogranulomas forming dense clusters appear as yellow granular collections of coalescing lesions. As in other organs and tissues, lipogranulomas of the liver are histologically defined as roughly spheroid accumulations of activated macrophages and lymphocytes. In early lesions, the macrophages (Kupffer cells) surround extracellular lipid droplets (vacuoles in paraffin sections). The macrophages may show discrete epithelioid changes in some cases. The periphery of lipogranulomas mostly exhibits only few lymphocytes. Older lesions reveal less vacuoles, but the macrophages have pinocytosed the lipid and have become lipophages (foamy cells). Some lipogranulomas may contain multinucleated giant foam cells of the Touton type (Touton giant cells; see below), although Touton cells are more frequently encountered in xanthomatous lesions described in the previous chapter. Hepatic lipogranulomas are usually microscopic, but they may grow to macroscopically recognizable size and, in case they form conglomerate lesions, may be seen radiologically. Rarely, lipogranulomas result in a generalized process in the liver, progressively replacing the liver parenchyma and portal tracts.

Where are lipogranulomas typically located within the liver? Many authors noted that hepatic lipogranulomas are usually located in portal tracts (Stryker 1941; Goldberg and Saphir 1960; Boitnott and Margolis 1970; Nochomovitz et al. 1975; Blewitt et al. 1977), which may more often represent mineral oil granulomas, while other authors found most lipogranulomas in the pericentral lobule zone 3 (Christoffersen et al. 1971; Klatskin 1977; Dincsoy et al. 1982). True neutral fat lipogranulomas will probably develop at sites where most steatotic hepatocytes are damaged or are decaying. Ultrastructurally, fat droplets in severely fatty livers are encircled by lymphoid cells and histiocytoid cells. There was evidence that fat droplets protruded through the cell membranes of hepatocytes, followed by settling of macrophages/histiocytes and lymphocytes around such fat protrusions. Remnants of liver cells may be seen between the fat droplets and the macrophages (Petersen and Christoffersen 1979). Lipogranulomas consist of lipid-storing macrophages that are CD68-immunoreactive. It is not yet known whether cells of the hepatic macrophage system, i.e., Kupffer cells, are recruited to form granulomas, or whether blood-borne monocytes attracted to lipid accumulations are involved. However, prominently enlarged and aggregated Kupffer cells were observed in steatohepatitis, with a predominantly perivenular distribution, suggesting a potential direct Kupffer cell role in hepatic lipid processing (Lefkowitch et al. 2002).

Hepatic Phlebocentric Lipogranulomatosis

This is a very rare disorder of unknown cause that has first been described based on autopsy findings in two patients with no history of liver disease (Keen et al. 1985). The livers showed congestive alterations caused by a process mimicking veno-occlusive disease. In both patients, central veins

were occluded by an inflammatory and fibrosing process, with a striking accumulation of lipid-containing macrophages showing large fat vacuoles (Oil Red O-positive and osmiophilic). Giant cells were also noted. In one of the patients, the process had extended into the sublobular venous radicles, where intimal proliferation and sclerosis were present. The etiology of these lesions remained unknown, but an environmental insult such as a drug or toxin were suspected.

Other Types of Granulomas Containing Neutral Fat

An increased prevalence of hepatic lipogranulomas (56 %) was observed in patients with rheumatoid arthritis who had been routinely biopsied to evaluate side effects of methotrexate therapy. The lipogranulomas contained a dark pigment shown, in few cases, to represent gold-containing particles (chrysiasis). It was, therefore, assumed that lipogranulomas were caused by the frequent administration of gold in an oily vehicle (Landas et al. 1992).

Mineral Oil Granulomas

Lipogranulomas in the liver can be induced by exogenous lipoid-like substances or substances histologically mimicking lipid accumulation, such as mineral oil (Stryker 1941; Boitnott and Margolis 1970; Nochomovitz et al. 1975; Dincsoy et al. 1982; Fleming et al. 1998) or paraffin oil (Trivalle et al. 1991). This issue has already been discussed briefly above. Mineral oil has been used or is still used for the treatment of constipation and enters the food chain owing to its use as a lubricant for machines, e.g., in bakeries.

What Are Touton Giant Cells?

Touton giant cells are large and multinucleated cells resembling foreign body-type giant cells, but usually with a ringlike arrangement of the nuclei and a central vacuolated area containing numerous lipid droplets. Although not investigated so far, it is assumed that these giant cells, similar to other multinuclear giant cells, develop via fusion of macrophages mediated by several cytokines/lymphokines (McNally and Anderson 1995; Anderson 2000). The eponymic designation goes back to Karl Touton (1858–1934), a German dermatologist. Student of Ernst Ziegler, Moriz Kaposi, Albert Neisser, and Isidor Neumann, and after studies in Augsburg and Breslaw, he settled in Wiesbaden as a dermatologist and built up an international reputation (Herxheimer 1935; Gougerot 1935; Gans 1964; Holubar 1990). In this function, he published several articles on phytodermatosis and described his "xanthelasmic giant cell" (Touton 1885; Aterman et al. 1988). Touton wrote his survey on xanthomas when he was only 25 years of age. Touton described the characteristic features of multinucleated giant cells occurring in xanthomatous lesions, but the presence of such cells in lesions, then called "endothelioma adiposo," had been noted earlier already by an Italian author, who noted large cells showing numerous nuclei "da impartire loro la forma de celluli giganti" ("rendering them the feature of giant cells"; De Vincentiis 1883; reviewed in Aterman et al. 1988). Apart from Touton's activities as a physician and professor of medicine, he was an outstanding botanist specialized mainly in the composite genus, *Hieracium*. He published numerous botanical works and left a *Hieracium* herbarium consisting of about 20,000 specimens, now kept in the Botanical Museum Berlin-Dahlem, Germany (Vogt 1998). Among this genus of hawkweed, one species has his name (*Hieracium toutoni*).

Necrobiotic Granulomas of the Liver (Rheumatoid Nodules, Rheumatoid Nodulosis, Rheumatismus Nodosus Hepatis)

Introduction

Patients with seropositive rheumatoid arthritis develop rheumatoid nodules (RN; Hart 1994). RN have already been recognized as a soft tissue

manifestation of rheumatoid arthritis in the nineteenth century (Hilliers in 1868 and Jacoud in 1874), but the first detailed description is by Meynet (1875). The pathology of rheumatism was studied in detail by the pathologists Aschoff, Klinge, and Gräff (review: Keitel 2008). The term, rheumatismus nodosus, had been coined by Rehn. Classic RN occur in approximately 20–25 % of patients with seropositive rheumatoid arthritis and are the most common extra-articular manifestation of this disease (Kaye et al. 1984; Ziff 1990). A much greater incidence (75 %) is observed in patients with rheumatoid arthritis-associated Felty syndrome. The HLA-DR4 haplotype is predictive of the risk of subcutaneous RN in rheumatoid arthritis. Homozygosity for HLA-DRB1 *0401 makes rheumatoid arthritis patients susceptible to major organ involvement. These nodules may evolve very rapidly, within few hours to days, and grow up to few cm in diameter, may form conglomerate lesions, and are known to also develop in visceral organs and tissues. The nodules can undergo accelerated growth (subsequent to therapy, e.g., with methotrexate), but can also regress spontaneously (McCarty 1991; Garcia-Patos 2007; Highton et al. 2007).

Rheumatoid Nodules of the Hepatobiliary Tract ("Rheumatismus Nodosus Hepatis")

RNs (nodulosis) in the liver are very rare (Fig. 13). An autopsy report referring to a patient with chronic rheumatoid polyarthritis documented, apart from widespread amyloidosis, numerous grayish-white nodules with a peripheral zone scattered throughout the liver, their maximum diameter being 5 mm. Histologic analysis of these nodules disclosed a central necrosis surrounded by histiocytes/macrophages in a palisade arrangement, and peripheral fibrosis associated with chronic inflammation. This morphology closely resembled that of typical rheumatoid nodules in observed in the subcutis (Smits and Kooijman 1986). RN rarely also develop in the mesentery and may mimic an intra-abdominal malignancy (Thinda and Tomlinson 2009).

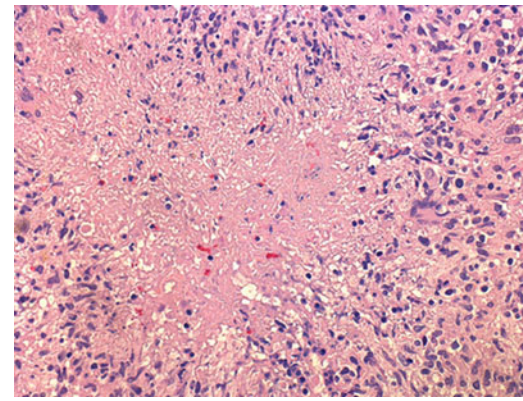

Fig. 13 Rheumatoid nodule of the liver. A focus of fibrinoid necrosis (*center*) is surrounded by a palisading granuloma (hematoxylin and eosin stain)

What Are Rheumatoid Nodules?

Rheumatoid nodules (RN, tumefactive necrobiotic granulomas; nodulosis) are histologically characterized by a central, so-called fibrinoid, necrosis showing a typical, "geographic" shape, a demarcation zone consisting of epithelioid macrophages (sometimes arranged in a typical palisading, radial, or corona-like pattern), and a peripheral rim of fibrosclerotic tissue (Ziff 1990). The histopathologic progression of RN occurs in three stages: an acute inflammatory stage, a granulomatous stage, and finally a necrotic stage. In the acute inflammatory stage, a nonspecific granulation tissue develops as a reparation response. The second or granulomatous stage is the stage of massive macrophage reaction with palisading. Fibrinoid necrosis develops in the preexisting collagenous tissue, but also involves the macrophages of the granulomas. The most prominent cells of the rheumatoid nodule belong to the monocyte/macrophage lineage. These cells migrate from the vascular periphery of the nodule toward the central palisade layer (Palmer et al. 1987a). The migrating cells undergo differentiation to epithelioid macrophages (so-called maturation) and release cytokines and the

MRP-8/MRP-14 heterodimer, labeling them as newly arrived activated macrophages (Palmer et al. 1987b; De Rycke et al. 2005). The immigrating macrophages and their epithelioid offspring accumulate in the palisade interspersed with myofibroblasts and fibroblasts. In addition to monocytes /macrophages, lymphocytes are present in and around the RN. Both CD4 and CD8 subtypes are detectable in the nodules, and these cells tend to accumulate around blood vessels and in the area immediately outside the palisade (Highton et al. 2007). Lymphoid cells in this tissue space are attracted by chemokines produced by the nodules, including CCL21, CXCL12, and CXCL13. The peri-palisade compartment also contains dendritic cells (Highton et al. 2000). In contrast to T cells, B lymphocyte density around RN is more variable, and B cells in RN are mostly sparse and sometimes almost undetectable, but B cell signaling and the formation of germinal centers has been reported. The markedly eosinophilic necrosis was initially interpreted to contain large amounts of fibrin (Fahr 1918), finally resulting in the term fibrinoid necrosis to denote the fibrin-like staining of the central necrosis. The name "fibrinoid" goes back 1880, when Neumann described a new picrocarmine staining to demonstrate the features of "fibrinoid degeneration" (Neumann 1880; reviewed in Bajema and Bruijn 2000). A change from "degeneration" to "necrosis" appeared in 1932 (Klinger 1932), and still later, several morphologic variants of fibrinoid necrosis were distinguished (Zeek 1952). In regard to the composition of fibrinoid necrosis, it was first assumed that precipitation of fibrin and/or other coagulation factors, necrosis of collagen, and coagulation of the intercellular ground substance, or a combination of these, were involved (Altshuler and Angevine 1949). In fact, fibrin is one component that is detectable in this type of lesions (Gitlin et al. 1957). But later it was found that the eosinophilic material of fibrinoid at least in part consists of fibronectin isoforms indicating that the lesion is actually part of a wound-healing process (Bajema et al. 1998). RN are also termed tumefactive necrobiotic granulomas, or nodulosis (Riedlinger et al. 2005), and rheumatoid nodulosis employed for variants of rheumatoid arthritis with numerous soft tissue nodules and an unusual, rather benign course (Ginsberg et al. 1975; Wisnieski and Askari 1981; Couret et al. 1988; Goni et al. 1992).

Malakoplakia of the Hepatobiliary Tract

Introduction

Malakoplakia (Greek: soft plaque; frequently used term: malacoplakia, von Hansemann's disease) is an unusual inflammatory process that was first described in the early 1900s (Michaelis and Gutmann 1902), although the discovery of the lesion as such goes back to Michaelis and Gutmann's senior colleague, von Hansemann (reviews: Damjanov and Moriber Katz 1981; Stanton and Maxted 1981; Dasgupta et al. 1999). Malakoplakia is mostly known from the urinary tract, but it may also involve extra-urinary sites (Yousef and Naghibi 2007), including the appendix, colon, spleen, skin, frontal and ethmoidal sinuses, tongue, lungs, lymph nodes, and brain.

The eponymic designations go back to Carl Gutmann (born 1872), a German physician, and Leonor Michaelis (1875–1947). Leonor Michaelis, an assistant of Paul Ehrlich, is particularly known for his role in the formulation of the Michaelis-Menten law, equation, and constant in enzymology (1913). Maud Leonora Menten (1879–1960), one of the first Canadian women to become a doctor, came to Berlin in 1912 to work together with Michaelis on invertase enzyme activity, and together they developed their now famous equation. Michaelis also discovered Janus green as a supravital stain for mitochondria. Together with Sam Granick, he furthermore characterized ferritin and apoferritin. However, the first human case of malakoplakia was in fact seen by von Hansemann in 1901, who had read about a similar disease described by Olt in a veterinary magazine in 1900. von Hansemann provided his assistant, Dr. Gutmann, with the details of his case, as Dr. Michaelis had agreed to investigate the disease in a collaborative approach. von Hansemann himself published

this index case 1 year after Michaelis and Gutmann (Von Hansemann 1903; review: Dasgupta et al. 1999). Malakoplakia may, hence, be called von Hansemann's disease.

Malakoplakia of the Hepatobiliary Tract

Malakoplakia of the liver is a rare condition (Moldavskii and Rustamov 1984; De Saint-Maur and Gallot 1990; Robertson et al. 1991; Boucher et al. 1994; Chen et al. 1994; Hartman et al. 2002; Botros et al. 2014). Hepatic malakoplakia may be detected as an incidental alteration at autopsy (Botros et al. 2014). Reported cases of liver malakoplakia were associated with immunosuppression and liver abscess (Robertson et al. 1991), perforated colonic diverticulum (Boucher et al. 1994), small bowel ileus in conjunction with *Klebsiella* sepsis (Hartman et al. 2002), hepatic invasion by renal parenchymal malakoplakia (Chen et al. 1994), hepatic multichamber pseudocyst in miliary tuberculosis (Moldavskii and Rustamov 1984), infected polycystosis (De Saint-Maur and Gallot 1990), and systemic lupus erythematodes (Botros et al. 2014). It is seen that in part of cases, bacterial infection seems to have been involved. Malakoplakia also occurs in the bile duct system and in the gallbladder (Sahel et al. 1976; Charpentier et al. 1983; Hide et al. 2001; Regragui et al. 2003; Agnarsdottir et al. 2004; Di Tommaso et al. 2005). Interestingly, renal and intestinal malakoplakia has been repeatedly observed in patients after liver transplantation (Rull et al. 1995; Kamishima et al. 2000; Weinrach et al. 2004), but this association is likely to be based on immunosuppression, because a similar association has been seen in renal graft recipients (Ourahma et al. 1996; Berney et al. 1999).

Lesions of malakoplakia are variably sized yellow to brownish plaques or nodules that are usually soft (malakos, soft) and friable, sometimes with central liquefaction and frequently with a peripheral rim of inflammatory hyperemia. Malakoplakia in the liver appears to follow a sequence of changes also seen in other locations of this disorder. There are three phases in the histopathologic evolution, originally defined for urinary tract malakoplakia (Smith 1965). In the early phase, plasma cells and the distinct macrophages (the so-called von Hansemann cells) prevail, and classic Michaelis-Gutmann bodies are not usually seen. In the second or classic (granulomatous) phase, large macrophages with Michaelis-Gutmann bodies, lymphocytes, and occasional giant cells are found. The third phase is the "healing" phase, which consists of fibroblasts and collagen deposits around macrophages, along with rather few and sometimes extracellular Michaelis-Gutmann bodies. In the liver, the fully developed lesion shows a rather circumscribed accumulation of histiocytes/macrophages with an admixture of plasma cells and lymphocytes. Already in the H&E preparation, targetoid cytoplasmic inclusions are seen in the macrophages, which represent the Michaelis-Gutmann bodies which have distinct histochemical and ultrastructural features (McClure et al. 1981; Robertson et al. 1991). In a liver biopsy specimen, portal and periportal regions showed scattered small, round to oval targetoid structures consistent with Michaelis-Gutmann bodies that stained with PAS (with and without diastase treatment), von Kossa calcium stain, and colloidal iron stain. CD 68 immunohistochemistry identified the bodies to be situated within macrophages (Hartman et al. 2002). In late stage, fibrosed lesions of malakoplakia and Michaelis-Gutmann bodies tend to accumulate in the extracellular space, both in hepatic malakoplakia (Robertson et al. 1991) and in extrahepatic malakoplakia (Esparza et al. 1981). In malakoplakia of the gallbladder wall, yellowish plaques or nodules are noted, with a histology as outlined above, whereby the targetoid Michaelis-Gutmann bodies may be crowed just beneath the mucosal epithelium (Di Tommaso et al. 2005).

Etiology and Pathogenesis

Malakoplakia is usually associated with bacterial or fungal infections, in particular infections with *Klebsiella* and *Escherichia coli*, suggesting a

pathogenetic relationship between bacterial antigen and a functional disorder of the macrophage system. Apart from *Klebsiella* and *Escherichia coli*, germs found in conjuncture with malakoplakia include mycobacterium tuberculosis, *Rhodococcus equi* (mainly pleuropulmonary lesions in AIDS patients), *Shigella boydii*, and paracoccidioidomycosis (Yuoh et al. 1996; Rocha et al. 1997; Raguin et al. 1999; Altwegg and Hinrickson 1999; Guerrero et al. 1999; Caterino-de-Araujo et al. 2000). The reason why macrophages react in a particular way in infected patients developing malakoplakia is not known, but functional and structural monocyte abnormalities are suspected to play a role (van Crevel et al. 1998). The morphogenesis of Michaelis-Gutmann bodies has been studied (Ho 1979; Yuoh et al. 1996). Immature or early Michaelis-Gutmann bodies consist of a circular, electron-dense core containing bacteria and parts thereof, whereas mature Michaelis-Gutmann bodies have a concentric, trilaminated structure with a central mineralized core and usually no remnants of bacterial cell walls. These findings suggested that the bodies are formed around undigested or incompletely digested bacteria as a seemingly alternative pathway for bacterial destruction (Yuoh et al. 1996).

Hepatic Gaucher Cell Pseudotumors ("Gaucheroma")

Introduction

Gaucher disease is autosomal recessive glucocerebrosidosis and is the most common lysosomal storage disease (reviews: Rosenbloom and Weinreb 2013). It is caused by deficiency of the lysosomal enzyme, beta-glucocerebrosidase, leading to the accumulation of the substrate, glucocerebroside, in the monocyte/macrophage system of many tissues and organs. Glucocerebrosidase normally splits the glycolipid, glucocerebroside, into ceramide and glucose (Chen and Wang 2008). Based on the age of manifestation and clinical presentation, three types of Gaucher disease are recognized, all localized to the same chromosomal region and involving the same gene. Type 1 (the non-neuropathic type; OMIM 230800) is the most frequent form of the disease. Type 2 (acute infantile neuropathic Gaucher disease; OMIM 230900) typically begins within 6 months of birth and has a rapidly progressive course with unfavorable outcome. Type 3 (chronic neuropathic Gaucher disease; OMIM 231000) begins at any time in childhood or even adulthood. It has a milder phenotype than type 2 and shows a slow progression. Type 3 predominates in the northeastern part of Sweden, Norrbotten (Norrbottnian type; Erikson 1986). Around 300 unique mutations have been reported in the glucocerebrosidase gene (GBA), with a distribution that spans the entire gene.

More than 200 of these mutations are missense mutations, while nonsense mutations and splice junction mutations each account for less than 20 mutation types. Thirty-six small insertions or deletions that lead to either frameshifts or in-frame alterations have been found. Recombination events with a highly homologous pseudogene downstream of the GBA locus have been identified, resulting from gene conversion, fusion, or duplication (Hruska et al. 2008). Mutant glucocerebrosidase variants present variable degrees of endoplasmic reticulum (ER) retention and undergo ER-associated degradation (ERAD) in the proteasome (Bendikov-Bar and Horowitz 2012). The degree of ERAD of the mutant enzyme correlates with and is one of the factors that determine Gaucher disease severity (Ron et al. 2010). Gaucher cells typically accumulate in the bone marrow, causing severe bone complications (Poll et al. 2010).

Liver Manifestations of Gaucher's Disease

Among 500 patients with Gaucher disease, 7.8 % had sonographic evidence of hepatic disease. Hepatomegaly is a well-known feature and is sometimes marked with rounded or blunt liver margins (Gruber 1930). The color of the involved liver is variable, in children sometimes pink yellow in case of marked. In long-standing cases, the

liver is grayish yellow, tan, or, rarely, chocolate brown.

Gaucher Cell Infiltration

Pick noted a characteristic whitish network in the parenchyma resulting in a geographic lesion pattern. Focal accumulations of Gaucher cells can produce nodules of variable diameter. These lesions are usually hyperechoic and slowly evolving (Hadas-Halpem et al. 2010).

Accumulation of cerebroside-laden macrophages (the Gaucher cells) in hepatic sinusoids and portal tracts are a typical feature of this storage disorder. In the course of the disease, chiefly in patients without adequate therapy, inflammation, septal fibrosis, and cholestatic liver cirrhosis may develop (Bothe et al. 2013; Debnath et al. 2013). Under enzyme replacement therapy, the number of Gaucher cells is markedly decreased (Hulkova et al. 2009). Large accumulations of Gaucher cells with nodules formation may develop central necrosis (Gruber 1930).

Patients with Gaucher disease type 1 show a frequent iron overload of both hepatocytes and Kupffer cells (Bohte et al. 2013). This alteration is associated with hyperferritinemia (with a mean 3.7-elevation of serum ferritin), and prior splenectomy is associated with most severe hyperferritinemia. This iron overload is not related to HFE mutations (Stein et al. 2010).

Gaucher Cell Pseudotumors (So-Called Gaucheromas)

Gaucher cell pseudotumor is defined as a mass-like accumulation of Gaucher cells (cerebroside-containing macrophages). This lesion occurs in the liver, where pseudotumors of this type within or adjacent to parenchymal tissue are a common finding (Poll et al. 2000). Sometimes, gaucheromas grow to important size. In a 23-year-old male patient with Gaucher disease presented with hepatomegaly, an ultrasound of the abdomen showed a hyperechoic mass of up to 9 cm in diameter. Liver MRI demonstrated a well-delineated mass, which appeared hyperintense in comparison to adjacent liver substance on T2-weighted images. A central hypointense scar was detected, suggestive of focal nodular hyperplasia. Biopsy of the lesion revealed accumulation of typical Gaucher cells (Poll and vom Dahl 2009).

Differential Diagnosis

Storing macrophages resembling Gaucher cells can occur in the bone marrow and probably also in visceral organs of some patients with hematologic malignancy or anemia. These cells are termed pseudo-Gaucher cells. The cells have also been found in large numbers in the liver following chemotherapy and bone marrow transplantation (Stenzel and Weeks 2013). In case of large Gaucher cell nodules, hepatocellular carcinoma (HCC) should be excluded in this situation, because HCC without preexisting cirrhosis is increased in Gaucher disease (Breiden-Langen et al. 1991; Xu et al. 2005; De Fost et al. 2006). Cholangiocarcinoma has also been reported (Hulkova et al. 2009).

Neutrophilic Dermatoses/Systemic Neutrophilic Diseases: Manifestations in the Liver

Introduction

Neutrophilic dermatoses (systemic neutrophilic diseases) constitute a group of related and in part hereditary disorders which comprise pyoderma gangrenosum, Sweet's syndrome, erythema elevatum diutinum, subcorneal pustular dermatosis, acute generalized exanthematous pustulosis (AGEP), pustular vasculitis, and CANDLE syndrome. There are phenotypical overlaps between part of these diseases (review: Cohen 2009). The most important members of this group of disorders are pyoderma gangrenosum and Sweet's syndrome, both characterized by dense dermal inflammatory infiltrates composed of neutrophils, usually with little evidence of a primary vasculitis

(review: Lear et al. 1997). Part of these disorders are associated with visceral aseptic abscesses, including the liver. Such abscesses are deep, sterile, round lesions consisting of neutrophils that do not respond to antibiotics but improve rapidly with corticosteroids.

Pyoderma Gangrenosum

Pyoderma gangrenosum (PG) is a neutrophilic dermatosis of unknown etiology (review: Wollina and Haroske 2011). In its classical clinical presentation, the main feature of PG are pustules or plaques that rapidly progress painful skin ulcers with a necrotic center and red to violaceous undermined margins. PG is typically associated with systemic inflammatory disease, but particularly with inflammatory bowel disease and arthritis, including juvenile rheumatoid arthritis. It has been reported that PG develops in 30–60 % of patients with inflammatory bowel disease (Powell et al. 1996). PG can be associated with visceral manifestations, including cavitating nodular pulmonary inflammation (the lung being the most frequent internal organ site of PG), aseptic splenic abscess, pancreatitis, and focal liver inflammation.

Involvement of the Liver and the Biliary Tract

In PG, focal and sometimes multiple liver lesions representing aseptic abscesses can develop (Urano et al. 1995; Ferrazzi et al. 1996; Hastier et al. 1996; Rodot et al. 1996; Vadillo et al. 1999; Delbrel et al. 2001; Matsumura et al. 2011). At imaging the nodular liver lesions show up as cystic, well-circumscribed foci with cystic change (Vadillo et al. 1999). Aseptic abscesses of the liver in PG are often associated with analogous lesions in the spleen (hepatosplenic abscesses; Vadillo et al. 1999). Fine needle aspiration of the liver lesions yielded purulent, neutrophil-rich fluid, Gram and Ziehl-Neelsen stains being negative (Vadillo et al. 1999).

PG is sometimes associated with other hepatic disorders, including chronic active hepatitis (Byrne et al. 1976; Marshall et al. 1978; Burns and Sarkany 1979; Sampson et al. 1982; Banerjee 1990) and chronic persistent hepatitis (Green et al. 1985).

DOI 10.1007/978-3-319-26956-6_126

Abstract

An important hepatic lesion that produces masses that may mimic cancer is pyogenic liver abscess. Liver abscesses are caused by diverse bacterial organisms, but certain bacteria are prominent inducers of liver abscesses, such as *Klebsiella* and *Staphylococcus*. The spread of bacteria to the liver follows hematogenous or ascending routes, sometimes associated with infectious pylephlebitis. Pyogenic liver abscesses exhibit a characteristic macroscopic presentation, with a purulent center followed to the periphery by a belt of granulation tissue and a hyperemic demarcation zone. In the curse of fibrous repair, pyogenic abscesses can collapse and leave a scar-like lesion. Distinct variants of bacterial liver abscesses and related lesions are caused by *Salmonella* species. In case of infection with anaerobic germs, and in particular *Clostridium* species, complex morphologies ensue, in part with prominent gas formation.

Classical Pyogenic Liver Abscess

Introduction

Pyogenic liver abscess (PLA) is a potentially life-threatening disorder that may, owing to the invasive and destructive mode of presentation in the liver, be confounded with malignancy. PLA develops in a wide variety of patients (Branum et al. 1990; Huang et al. 1996; Seeto and Rockey 1996; Johannsen et al. 2000; Alvarez Perez et al. 2001).

Epidemiology

PLA is usually found in elderly patients with biliary tract disease, and males predominate in all major studies (Frey et al. 1989; Kurland and Brann 2004; Chan et al. 2005). There are marked differences in epidemiology and etiology between western countries and tropical countries, in particular what regards the contribution of amebic infections. A study performed in India has shown that 51.2 % of all abscesses were amebic, 23.2 % were PLA, and 25.6 % had unknown causes (Mohan et al. 2006). In contrast, most liver abscesses in the West are in fact PLA. The epidemiology of PLA has markedly changed in recent years, in that the incidence of PLA is rising in numerous countries and that the etiology is changing (Land et al. 1985; Seeto and Rockey 1996). This is also specifically due to the emergence of *Klebsiella*-associated PLA, a distinct syndrome (Lederman and Crum 2005). Whereas PLA formerly was mainly associated with preexisting hepatobiliary disease and polymicrobial infections, dominated by *Escherichia coli*, more and more patients with PLA have no preexisting hepatobiliary disease, but suffer, e.g., from diabetes mellitus and have PLA caused by *Klebsiella*. A nationwide analysis of PLA in Taiwan from 1996 through 2004 showed that the annual incidence of PLA increased steadily from 11.15/100,000 population in 1996 to 17.59/100,000 in 2004. Diabetes mellitus, malignancy, renal disease, and pneumonia were associated with a higher risk for PLA (Tsai et al. 2008).

Clinical Features

Malaise, anorexia, abdominal pain (mainly focal abdominal tenderness), and night sweats are the leading symptoms in patients with PLA. Up to 60 % of patients present with these nonspecific features, which have been specified in numerous reports, while fever was noted in up to 80 % (less often chills), and a variable number of patients show hepatomegaly and weight loss. Jaundice is usually only present in case of simultaneous biliary obstruction (Warren and Hardy 1968; Young 1976; Perera et al. 1980; Rubin et al. 1981; Kandel and Marcon 1984; Beaumont and Davis 1985; Gyorffy et al. 1987; Hau and Hartmann 1987; Bansal and Prabhakar 1988; Frey et al. 1989).

In PLA not caused by *Klebsiella* (see below), the most common coexisting diseases are diabetes mellitus, followed by biliary stone disorders and other types of biliary tract disease (Rockey 2001),

and intra-abdominal infectious and neoplastic disease (Lin et al. 2011a; Law and Li 2012), in particular colonic disease (McDonald et al. 1984), including colorectal cancer (Lonardo et al. 1992; Yokota et al. 2005; Pisano et al. 2007, Lee et al. 2008). Silent colorectal cancer (CRC) can manifest as PLA in the absence of metastasis (Teitz et al. 1995; Fernandez Ruiz et al. 2007; Giuliani et al. 2007; Hiraoka et al. 2007; Chen et al. 2012; Jeong et al. 2012; Qu et al. 2012), a constellation which is an important cancer-inflammation syndrome (the CRC-PLA syndrome, as I tend to call it). PLA has also found to be the initial manifestation of hepatocellular carcinoma (Yeh et al. 1998; Lin et al. 2011a). Diabetes mellitus is a very important risk factor for PLA, as poorly controlled diabetic patients are immunocompromised and are susceptible to bacterial infections. In a large study, persons with diabetes mellitus had a 3.6-fold increased risk of experiencing PLA in comparison with a control population, and patients with PLA who had diabetes mellitus had a higher 30-day post-discharge mortality rate, compared with patients with PLA who did not have diabetes (Thomsen et al. 2007; Tian et al. 2012). On one study, 10–16 % of patients with PLA had diabetes mellitus (McDonald et al. 1984). There are less common predisposing conditions for PLA, such as pylephlebitis in pancreatitis (Rustagi et al. 2012) and Crohn's disease (McGreal et al. 2012). In case no infectious cause is identified, the term cryptogenic liver abscess is used (Stokes 1960).

PLA are usually more often solitary than multiple lesions; among 483 patients with PLA, 343 PLA were single lesions, 140 multiple abscesses. In this study, single abscesses were usually larger than 5 cm, whereas multiple abscesses were usually smaller than 5 cm. Solitary abscesses were predominantly located to the right liver lobe. Multiple PLA were more often associated with preexistent biliary tract disease (Chou et al. 1997). Abdominal pain was more frequent in case of single PLA than with multiple PLA, but jaundice was more often found in multiple PLA. However, there are also series where solitary and multiple PLA had about the same prevalence (Strong et al. 2003).

Complications

Portal and/or hepatic vein thrombosis can be caused by PLA (Syed et al. 2007). Sometimes, the classical Budd-Chiari develops (Karadag et al. 2005). Such thrombotic events can extend into the inferior vena cava and/or the right atrium (Bagri et al. 2013). Abscess rupture causes subdiaphragmatic abscess (specifically, this is an empyema per definition), and such a process can penetrate through the diaphragm and pericardial wall to induce pyopericardium (Chong et al. 2010). PLA can cause septic pulmonary embolism (Lin and Chang 2008). This complication is more common in patients with diabetes mellitus (Yang et al. 2008). A subset of PLA is characterized by gas formation (gas-containing PLA; Hayashi et al. 1989; Ukikusa et al. 2001; Chen et al. 2008a; Chong et al. 2008; Huang et al. 2009; Oh et al. 2011; Safe et al. 2013). In part of these PLA, the bacteria causing the infection express formic hydrogen lyase, leading to mixed acid fermentation and gas formation. Etiologically, classical gas-forming bacteria may be involved (such as Clostridia; Kahn et al. 1972; Ogah et al. 2012), but at least 75 % of all gas-containing PLA have been found to be caused by *Escherichia coli* and *Klebsiella* (Zhang et al. 2013). Other germs inducing gas-forming PLA are *Salmonella enteritidis* (Tee Yu et al. 2013) and diverse anaerobic bacteria. Gas-forming PLA, which are rare variants of liver abscesses, most often occur in patients with diabetes mellitus (Yang et al. 1993) and are associated with a high mortality rate. In case a gas-forming PLA ruptures, pneumoperitoneum ensues (Matsuyama et al. 1994; Ukikusa et al. 2001).

There is evidence that patients with PLA have a higher rate of primary liver cancer than matched controls, suggesting that PLA is a warning sign for liver cancer (Huang et al. 2013). In a study of 1257 PLA patients from Taiwan, 186 were diagnosed with cancer after a median follow-up of 3.33 years, including 56 liver cancer, 22 biliary tract cancer, and 40 colorectal cancer patients: The highest standard incidence ratio/SIR of all cancers, hepatocellular carcinoma, biliary tract

cancer, and colorectal cancer, occurred within 90 days of follow-up (Kao et al. 2012).

Pathology

Macroscopy

Non-gas-containing PLA are usually spherically, wedge-shaped or irregular mass-producing lesions varying in diameter from few millimeter to more than 20 cm (Figs. 1, 2, 3, and 4). PLA can present as solitary or multiple lesions, sometimes involving both liver lobes. In case the PLA extends to the liver capsule, the capsule may be thinned, a yellowish or hemorrhagic mass being visible through the transparent capsule, and the capsular surface can be eroded or covered by an exudate (fibrinous or fibrinopurulent), or coagulated blood. On cut surfaces, the center of PLA is occupied by thick, viscous, or liquefied pus that flows off the cut surface and sticks to the knife. In contrast to tuberculosis, the purulent material is never cream white, but has several shades of yellow to yellow green, a greenish tinge being caused by neutrophil myeloperoxidase, a green enzyme, or by pyocyanin in case of *Pseudomonas*

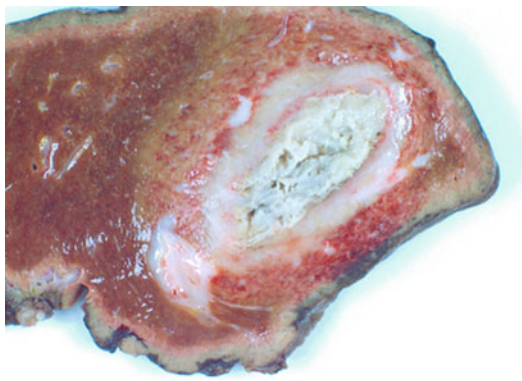

Fig. 1 Pyogenic liver abscess. On cut surfaces, hepatic abscesses frequently show a distinct concentric structure, as in this case. The innermost part is occupied by pus (whitish-yellow mass), followed by a zone of granulation tissue and scar tissues (white rim) and a peripheral hyperemic zone

Fig. 2 Pylephlebitic liver abscess. The pyogenic abscess in this case displays the distribution of portal veins with infectious pylephlebitis, through which the pyogenic infection has spread to the liver substance

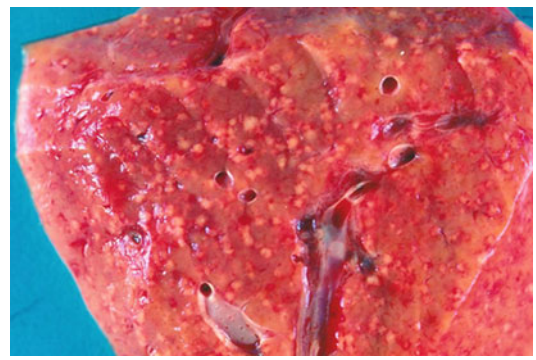

Fig. 3 Multiple miliary abscesses of the liver in a patient with septicemia. The lesions are evenly distributed

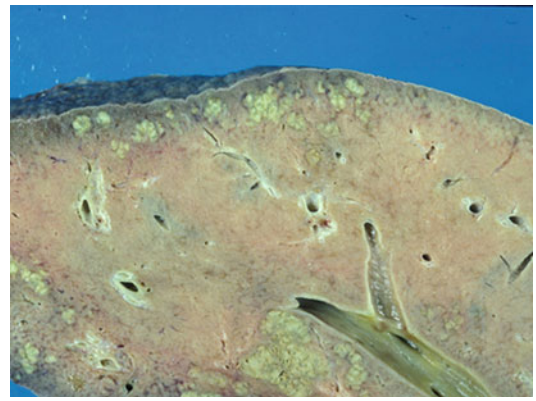

Fig. 4 In this case, small or miliary abscesses accumulated in terminal ramifications of the intrahepatic portal venous system

aeruginosa infection. In some cases, the central part of the abscess exhibits a fluid-filled cyst in which purulent exudate flakes may float. Part of PLA contain hemorrhagic pus. In acute PLA, the purulent material directly contacts the adjacent liver substance, while older lesions show a dark-red demarcation zone mainly consisting of a wall of granulation tissue. In PLA undergoing contraction, this vessel-rich zone collapses and shows a wavy contour. The parenchyma surrounding a PLA may contain spotty hemorrhage and sometimes a perifocal steatosis. PLA may destroy the walls of intrahepatic bile ducts and discharge the pus into the ductal lumina. Bile may flow back into the abscess cavity, greenishly discoloring the purulent exudate. PLA can break through the organ's limits and give rise to fistulae entering diverse tissues and organs in the vicinity of the liver. In PLA caused by gas-forming bacteria, the tissue may produce a blistering or crackling sound on palpation, and the cut surface shows a foamy or spongy appearance due to the presence of gas bubbles. Sometimes, gas bubbles float within the pus, an effect difficult to distinguish from artificial air entering upon cutting the tissue.

Macroscopically, the etiology of PLA is difficult to assess. A foul and feculent odor indicates *E. coli* infection, while in case of *Pseudomonas aeruginosa* infection, the pus may have a bluish-green tinge due to accumulation of pyocyanin. Gas production suggests anaerobic infections.

Histopathology

Histologically, the purulent exudate reveals the classical composition of neutrophils and macrophages in all stages of decreasing viability. Many of the phagocytes remain only as shadow cells or nuclear debris, specifically in the central, older parts of the abscess. Bacteria are shown by use of bacterial stains and are either present as free organisms or bacteria located within phagocytic cells. Viable phagocytic cells are usually seen at the periphery of the lesion, where active leukodiapedesis from blood vessels of the granulation tissue takes place. The granulation tissue itself is nonspecific and lacks an epithelioid cell reaction of granulomas. At the parenchymal face of granulation tissue, dilated blood vessels entering the parenchyma are seen. The sinusoidal vascular bed is usually hyperemic in the area surrounding the PLA. The suppurative process may cause damage of adjacent intrahepatic bile ducts, followed by bile leakage (Fig. 5). Abscesses may be associated with peliosis hepatis (Van Schil et al. 1988). In healing PLA, the purulent exudate becomes more viscid and histologically dense, with less and less phagocytes being visible. The wall of granulation tissue transforms into a less vascular scar tissue, associated with focal hemosiderosis. Through organization, the exudate may completely vanish at the end, but in large PLA, a cyst may remain, as the granulation tissue is unable to form a bridge through large exudate masses.

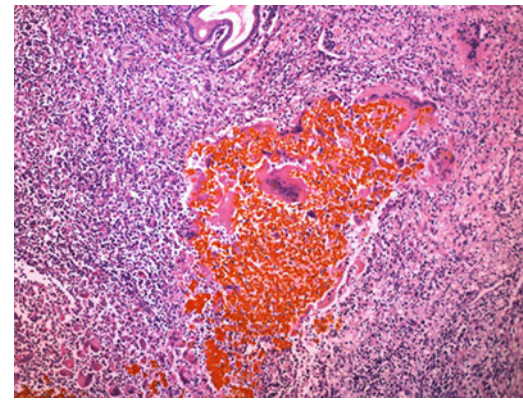

Fig. 5 Intrahepatic bile duct damage due to purulent inflammation. There is marked bile leakage with induction of a foreign body reaction (multinucleated giant cells; hematoxylin and eosin stain)

Differential Diagnosis

Radiologically, PLA can mimic massively necrotic primary liver cancer or necrotic metastases (Klotz and Penn 1987), in particularly those of tumors with a high tendency of necrosis, such as colorectal, pancreas, and bronchopulmonary primaries. It is important to note that PLA may hide a primary malignant liver tumor, in particular necrotic HCC (Yeh et al. 1998).

Biology of Disease

The Acute Physiology and Chronic Health Evaluation II (APACHE II) classification system (Knaus et al. 1985; Knaus 2002) has been evaluated in patients with PLA and found to be useful in predicting in-hospital mortality of PLA (Levison and Zeigler 1991; Hsieh et al. 2006). In a multivariate analysis, it turned out that the mortality from PLA was associated with gas-forming abscess, multidrug-resistant isolates, anaerobic infection, APACHE II score > or = 15, and blood urea nitrogen level > 7.86 mmol/l (Chen et al. 2008b). The cumulative recurrence rates of PLA were lower in both the cryptogenic and diabetic groups than in the underlying biliary tract disease group (Cheng et al. 2008).

Pathogens Causing PLA

Worldwide, causative agents of PLA mostly include *Escherichia coli* (*E. coli*), *Klebsiella pneumoniae*, *Enterococcus* species, *Staphylococcus* species, *Streptococcus* species, *Bacteroides* species, and a large group of other organisms (Gyorffy et al. 1987; Chou et al. 1997), but *E. coli* and *Klebsiella* are by far the most common pathogens, with *Klebsiella* having a specific role in that it causes as distinct syndrome of invasive infection.

Over the past years, a new type of invasive *Klebsiella pneumoniae* disease (*Klebsiella* liver abscess syndrome, KLAS; invasive *Klebsiella pneumoniae* liver abscess syndrome), which typically manifests as a community-acquired primary liver abscess associated with bacteremia, has been identified, first in Taiwan (Wang et al. 1998; Rahimian et al. 2004; Lee et al. 2010), but then also in other countries (Saccente 1999; Lederman and Crum 2005; Gomez et al. 2007; Keynan and Rubinstein 2007; Casella et al. 2009; Frazee et al. 2009; Pope et al. 2011; Fung et al. 2012; Moore et al. 2013). KLAS is caused by the *Klebsiella* capsular phenotype K1, magA KP, which confers a unique hypermucoviscous phenotype to the bacterium (see below). Community-acquired primary liver abscess caused by *K. pneumoniae* or KLAS mainly occurs in diabetic patients without previous hepatobiliary or intra-abdominal infection. Patients with this type of infectious syndrome can present with or without hepatic metastatic complications, but the development of metastatic infections is a typical feature in part of the patients, and 10–20 % of reported cases developed metastatic meningitis, endophthalmitis, endocarditis, and metastatic manifestations in other organs (Wang et al. 1998; Fung et al. 2002; Chan et al. 2007, Cheng et al. 2007; Chen et al. 2008a). There are certain clinical differences between KLAS patients from Eastern Asia, South Africa, and western countries (Ko et al. 2002). *Klebsiella pneumoniae* causing this syndrome has several distinct microbiologic features and a distinct genomic signature based on complete genome sequencing (Wu et al. 2009a). The main feature is the HMVKp (hypermucoviscous *Klebsiella pneumoniae*) phenotype, caused by the capsular serotype K1, magA + Kp. The mucoviscous phenotype is seen when contacting a bacterial colony in culture with a probe, resulting in the production of a viscous thread between the probe and the colony. The mucoviscosity-associated gene A, magA (wzy_K1), is the K1 polymerase gene, which encodes a 43 kDa outer membrane protein involved in the synthesis of exopolysaccharides (Fang et al. 2010; Yeh et al. 2010). *Klebsiella pneumoniae* isolates causing KLAS carry three rmpA/A2 genes, two large-plasmid-carried genes (p-rempA and p-rampA2), and one chromosomal gene (c-rmpA) (Hsu et al. 2011). Hyperviscosity, an extremely sticky phenotype of K. pneumonia, is associated with this destructive abscess syndrome (Kawai 2006; Lee et al. 2006; Yu et al. 2006; Pan et al. 2008). The K antigen, a capsular polysaccharide, is a very important virulence factor for *K. pneumoniae*. Expression of the rmpA and magA genes is associated with the hypermucoviscous phenotype and is linked to *Klebsiella* virulence and an aggressive clinical presentation (Yu et al. 2006). Capsular polysaccharide production leading to the hypermucoviscous phenotype is linked to the expression of genes regulating *Klebsiella* biofilm formation, treC (encoding trehalose-6-phosphate

hydrolase) and sugE (Wu et al. 2011). The pathogenic mechanism by which this distinct *Klebsiella* phenotype is related to the unique clinical presentation is only partially known. Expression of K1 antigen hampers complement- and neutrophil-mediated killing of *Klebsiella*, a mechanism thought to promote an invasive phenotype (Lin et al. 2010; Fung et al. 2011). In fact, capsular serotypes K 1 and K2 impair *Klebsiella* phagocytosis in type 2 diabetic patients (Lin et al. 2006), and phagocytosis-resistant *Klebsiella* serotypes are highly prevalent in PLA (Lin et al. 2004). Antibodies directed against capsule polysaccharide protect the host from magA+ *Klebsiella pneumoniae*-induced lethal disease by evading Toll-like receptor 4 signaling (Wu et al. 2009b). Other virulence factors that markedly influence the aggressiveness of *Klebsiella* include the expression of FimH as an adhesive subunit of type 1 enterobacterial fimbriae (Stahlhut et al. 2009). Fimbriae play an important role in target cell adhesion and invasion of the host. The expression of *Klebsiella* fimbriae is highly associated with K1 serotype isolates. The genome of *Klebsiella pneumoniae* contains nine fimbrial gene clusters, comprising type 1 and type 3 fimbriae and a group of fimbriae termed Kpa, Kpb, Kpc, Kpd, Kpe, Kpf, and Kpg. The Kpc fimbriae are regulated by the site-specific recombinase Kpcl (Wu et al. 2010). *Klebsiella pneumoniae* must acquire iron for replication; for this, it utilizes iron-scavenging siderophores, such as enterobactin, glycosylated enterobactin (salmochelin), and yersiniabactin. Siderophore-dependent iron acquisition systems are implicated in *Klebsiella* virulence, and three are upregulated in *Klebsiella* strains causing KLAS, *Yersinia* high-pathogenicity island, lucABCDiutA, and iroA(iroNDCB) (Hsieh et al. 2008). Yersiniabactin is a virulence factor that is prevalent among *K. pneumoniae* carbapenemase (KPC)-producing strains (Bachman et al. 2011). Hypervirulent *K. pneumoniae* secretes more and more active iron-acquisition molecules than classical *K. pneumoniae*, and this enhances virulence (Russo et al. 2011). The uptake of iron from extrabacterial compartments is regulated by the ferric uptake regulator Fur, which also modulates *Klebsiella* capsular polysaccharide biosynthesis via repression of the expression of rmpA, rmapA2, and rcsA (Lin et al. 2011b). Another *Klebsiella* species that much less commonly causes PLA is *K. ozaenae*, which is generally considered an opportunist of low virulence and colonizer of the respiratory tract implicated in atrophic rhinitis/ozaena (Chowdhury and Stein 1992).

PLA Caused by *Escherichia coli*

In an investigation of 72 patients with *E. coli* PLA, the majority of the abscesses were solitary, involved the right lobe of the liver, and comprised polymicrobial infections. The local cause of PLA involved the biliary tract in 66.7 % of the patients, and the most concomitant diseases were diabetes mellitus (30.6 %) and underlying malignancy (30.6 %) (Chen et al. 2005). Among 202 patient with PLA, there was no significant difference in mortality between patients with *E. coli* and those with *Klebsiella pneumoniae* infections, although for patients with PLA caused by *E. coli*, the APACHE II score at admission, malignancy, and right lobe abscess were significant predictors of death (Chen et al. 2007).

PLA Caused by Other Bacteria

Less common bacteria causing or having been isolated from PLA comprise *Staphylococcus aureus* (Smith et al. 2007), *Pseudomonas aeruginosa* (Goldani et al. 2005), *Enterococcus* species (Thomas et al. 1983), *Bacteroides fragilis* (Lonardo et al. 1992), *Streptococcus mitis* (Sarthe and DiBardino 2013), *Streptococcus anginosus* (Giuliano et al. 2012), *Aeromonas sobria* (Kamano et al. 2003), *Citrobacter koseri* (Gupta et al. 2013), *Aggregatibacter aphrophilus* (Tsui et al. 2012), *Yersinia enterocolitica* (Pulvirenti et al. 2007), *Fusobacterium necrophorum* (Hagelskjaer and Pedersen 1993; Athavale et al. 2002; Thatcher 2003), periodontal bacteria (*Fusobacterium nucleatum*, *Treponema denticola*, *Prevotella intermedia*, *Porphyromonas*

gingivalis; Ohyama et al. 2009), several anaerobic bacteria (Sabbai et al. 1972; Ogah et al. 2012), and a large number of other germs, which have in part been observed in immunocompromised patients.

Staphylococcus aureus is a well-known cause of solitary or multiple pyogenic liver abscesses and is estimated to account for 7 % of infectious liver abscess in case of non-mixed infection. Also other *Staphylococcus* species, e.g., *S. epidermidis*, were identified as causative agents, but much less often. Pyogenic liver abscess may be caused by mixed bacterial infections, a frequent partner of *S. aureus* being *Escherichia coli*. Staphylococcal liver abscesses are commonly medium-sized to large solitary lesions with indistinct ("invasive") borders, but multiple smaller abscesses or even a miliary abscess pattern (so-called microabscesses) has also been encountered. Multiple hepatic microabscesses caused by *S. aureus* can radiologically mimic *Candida* abscesses. An increasing number of hepatic abscesses is caused by the highly virulent methicillin-resistant *Staphylococci*/CA-MRSA, which can cause liver abscesses also in previously healthy adult individuals and in children. PLA caused by *Staphylococcus aureus* seems to be more common in patients with schistosomiasis (Teixeira et al. 2001). An association between schistosomiasis and *Salmonella* infection is also well documented (Lambertucci et al. 2001). In rare instances, PLA contained *Ascaris lumbricoides* (Hamid et al. 2013), a parasite which either induces PLA or moved into an abscess cavity.

Liver Abscesses in Crohn's Disease

Perforating Crohn's disease is characterized by the formation of intra-abdominal abscesses which develop in 20–24 % of patients. However, liver abscess represents a rare complication of Crohn's disease (Fagge 1870; Taylor 1949; Lerman et al. 1962; Watts 1978; Macpherson and Scott 1985; Mir-Madjlessi et al. 1986; Vakil et al. 1994; Kreuzpaintner et al. 2000). In a review of 59 cases (Kreuzpaintner et al. 2000), 72.9 % were men. 62.2 % of the patients suffered from active and 37.8 % from inactive Crohn's disease. In 52.9 % of the patients with active disease, the liver abscess presented as the initial manifestation of Crohn's disease. 47.2 % had a solitary abscess, 9.4 % double abscesses, and 43.4 % multiple abscesses. Microbiological analyses revealed that *Streptococcus milleri* was the dominating pathogen, followed by other streptococci, anaerobes, and enterobacteriaceae.

Pyogenic Abscesses and Necroses Caused by Gas-Forming Bacteria: *Clostridium* Liver Abscess

Introduction

Clostridium infections cover a broad spectrum of illnesses ranging from tetanus and severe and highly dangerous food intoxications to diarrheal disorders and highly aggressive organ and tissue lesions characterized by necrosis and gas-forming lesions (reviews: Maclennan 1962). Certain *Clostridium* species can cause large hepatic abscesses or abscess-like lesions that may mimic hepatic malignancy.

Liver Abscess

Clostridium species are a known cause of liver abscesses, in part with gas formation (Fiese 1950; Kivel et al. 1958; Sarmiento and Sarr 2002; Kurtz et al. 2005; Tabarelli et al. 2009; Ng et al. 2010; Rajendran et al. 2010; Huang et al. 2012; Ogah et al. 2012). Clostridial species causing liver abscess include *C. perfringens*, *C. clostridioforme*, *C. baratii*, *C. septicum*, and *C. welchii*. Among 83 patients with gas-forming pyogenic liver abscesses, 85.5 % of the patients had diabetes mellitus (Chou et al. 1995). The development of a clostridial liver abscess may be favored by the development of a hypoxic/anoxic hepatic area. For example, an abscess caused by *Clostridium perfringens* together with *Hafnia* and *Enterobacter cloacae* infection developed after obliteration of the portal vein by pancreatic cancer tissue (Tabarelli et al. 2009). Gas-forming hepatic abscess can develop as a complication of arterial

infusion chemotherapy (D'Orsi et al. 1979). Clostridial hepatic abscess may show a highly aggressive course, with extension of the abscess into adjacent organs (including the right kidney and the intestinal tract) and induction of portal vein thrombosis (Ogah et al. 2012). Liver abscess caused by C. perfringens can be followed by massive intravascular hemolysis (Kreidl et al. 2002; Au and Lau 2005; Ng et al. 2010), or intravascular hemolysis and septicemia (Rajendran et al. 2010).

Hepatic Gas Gangrene

Hepatic gas gangrene (gangrenous clostridial hepatitis) is an uncommon condition mainly caused by bacterial infection by *C. perfringens* (Fig. 6). It is a life-threatening disorder associated with a mortality rate (Ashley 1965; Birnbaum et al. 2012). The pathologic features of this rare disorder are characteristic. At autopsy, the liver is enlarged, pale, and fatty and feels crepitant. When this liver is put into water, it floats. On sections through the organ, multiple gas-filled spaces or cysts of variable sizes are noted, and sometimes the entire organ has a foamy aspect ("foamy liver"). Histologically, the liver exhibits separation of the hepatocyte plates, similar to far advanced autolysis. The gas-filled spaces are lined by flattened liver cells, and a leukocyte-mediated inflammatory reaction is lacking. Pressure exerted by the gas bubbles may cause crowding of the hepatocyte remnants, with formation of highly cellular areas without any lobular architecture. Gram-positive rods are present in this severely damaged tissue, sometimes in enormous numbers (Ashley 1965).

Clostridial Infection of Liver Metastasis

Colorectal liver metastases undergoing necrosis and forming an anaerobic niche can undergo infection with *Clostridium* followed by tumor abscess and eventually gas formation (Kahn et al. 1972; Saleh et al. 2009; Sucandy et al. 2012). Gas accumulating in the abscess may enter the peritoneal cavity and produce pneumoperitoneum (Urban et al. 2000; Fondran and Williams 2005; Sucandy et al. 2012). In one patient, infection of a hepatic CRC metastasis by *C. septicum* took place following alcohol injection into the liver lesion (Saleh et al. 2009). *C. septicum* infection presenting as a liver abscess has also been observed in a case of choriocarcinoma with liver metastasis (Lee and Hsieh 1999) and in metastases of breast carcinoma (Thel et al. 1994).

Microbiology

Clostridium is a genus of Gram-positive, rod-shaped bacteria belonging to the family *Clostridiaceae*, order *Clostridiales*. The genome of *C. perfringens* has been sequenced, and its genome analyzed in regard to toxin expression

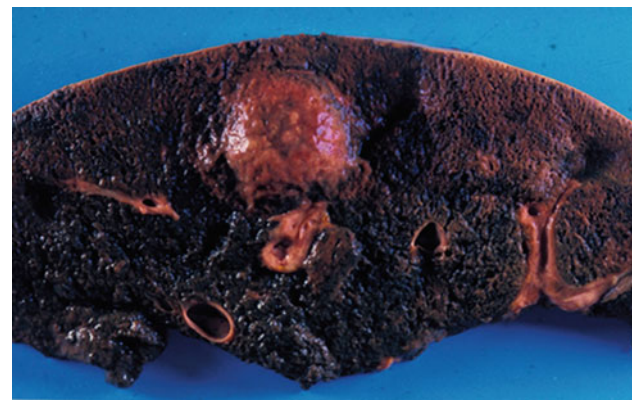

Fig. 6 Tumor-like, bulging, and hemorrhagic liver abscess associated with gas-forming *Clostridium* infection causing numerous gas bubbles in hepatic parenchyma

patterns (Myers et al. 2006). It is an obligate anaerobic group of microorganisms capable of developing endospores. There are about 100 clostridial species, of which a subset is pathogenic to humans, including *C. botulinum* (the cause of botulism), *C. tetani* (the causative agent of tetanus), *C. difficile* (bacterial diarrhea and antibiotic-induced enterocolitis), *C. perfringens/welchii* (gas gangrene), and *C. sordellii*. An increasing number of other *Clostridium* species have recently been isolated from humans, both with clinical manifestations and as isolates from apparently healthy individuals (*C. aldanense*, *C. amygdalinum*, *C. asparagiforme*, *C. baratii*, *C. celerecrescens*, *C. clostridioforme*, *C. fallax*, *C. glycolyticum*, *C. glycyrrhizinilyticum*, *C. hathewayi*, *C. intestinale*, *C. leptum*, *C. scindens*, *C. sphenoides*, and *C. symbiosum*. The clinically important taxon, *C. clostridioforme*, is now a mixture of three species that are different in terms of 16S rRNA sequences, phenotypic characteristics, and antimicrobial susceptibility (Finegold et al. 2005).

Pathogenic Pathways

Clostridium species are commonly found in soil, leaf litter, animal feces, and freshwater sediments, from where they can enter the human organism, either as complete viable bacteria or as spores. In the human host, they most commonly inhabit the intestinal tract.

Virulence Factors

C. perfringens has a variegated system of virulence factors, regulated at the transcriptional level by the products of the virR and virS genes that mainly comprise numerous extracellular toxins including alpha-toxin (phospholipase C), beta-toxin, theta-toxin (perfringolysin), kappa-toxin (a collagenase), and a sporulation-associated enterotoxin (reviews: Smith 1979; Rood and Cole 1991; Rood 1998). The global VirRS two-component signal transduction pathway regulates gene expression of alpha-toxin and perfringolysin O. In this regulatory pathway, the response regulator VirR regulates directly the expression of the theta-toxin/perfringolysin O gene and ccp, encoding the cysteine protease alpha-clostripain (which is not essential for *C. perfringens*-induced tissue necrosis), and indirectly regulates the expression of plce gene encoding the alpha-toxin, the colA gene (kappa-toxin of collagenase), and other genes. Alpha-toxin is a zinc-metallophospholipase C toxin mainly produced by *C. perfringens* and is responsible for necrosis and gas gangrene. It also possesses hemolytic activity and is the key virulence factor of *C. perfringens* infections. It induces the release of IL-8 from host cells through a dual pathway via tyrosine kinase A/TrkA acting on the ERK1/2/NF-kappaB and p38 MAPK pathways (Oda et al. 2012).

C. perfringens toxins affect the function of blood platelets and neutrophils and cause a reduction in blood supply to affected tissues (Hickey et al. 2008), a mechanism that may be important in the pathogenesis of *Clostridium*-induced tissue necrosis. *C. perfringens* beta-toxin is a necrotizing agent and is capable to release catecholamines from the host. The toxin forms potential-dependent, cation-selective channels in lipid bilayers and is a pore-forming agent with cytopathic effects. The *C. perfringens* iota toxin, only produced by type E strains, is an ADP-ribosyltransferase that induces ion-permeable channels in cells. The theta toxin of *C. perfringens* is also termed perfringolysin O. Perfringolysin O is a member of the cholesterol-dependent cytolysin family and a pore-forming agent that requires high concentrations of cholesterol to insert into host cell membranes. After binding to membrane cholesterol and transmembrane protein rafts, it oligomerizes into a prepore structure containing around 50 monomers followed by structural changes to create a rigid transmembrane beta-barrel (review: Nelson et al. 2010). *C. perfringens* epsilon-toxin is produced by type B and D strains and belongs to the aerolysin-like family of pore-forming toxins and is one of the most potent bacterial toxins that can cause fatal toxinemia in animals and eventually humans. Its expression is regulated by the agr operon (Chen et al. 2011). *C. perfringens* produces an

enterotoxin (CPE) which is responsible for the diarrheal signs and symptoms of *C. perfringens* type A food poisoning and antibiotic-associated diarrhea. CPE is 35 kDa polypeptide with an N-terminal toxicity domain that binds to tight junctions and damages their structure and function (McClane 2001). In tight junctions, CPE interacts with occludin, forming a complex that causes the internalization of occludin into the cytoplasm, followed by disruption of the normal paracellular permeability barrier (McClane and Chakrabarti 2004). CPE is a potent cytolytic agent and has been shown to rapidly and specifically destroy cancer cells expressing the CPE receptors, the tight junction proteins claudin-3 and claudin-4 (Kominsky et al. 2004, 2007; Kominsky 2006). *Clostridium* species produce several pore-forming toxins involved in the induction of host cell death and necrosis. The pore-forming alpha-toxin of *C. septicum* can induce programmed cellular necrosis, a distinct form of cell death described also in ischemia/perfusion injury and mediated by a disordered Ca^{2+} flux in target cells (Kennedy et al. 2009). Enterotoxic *C. perfringens* causing disease in birds and particularly in poultry produces a necrotic enteritis B-like toxin or NetB, a member of the beta-barrel pore-forming toxin family (Keyburn et al. 2010). *C. perfringens* strains also express up to three different sialidases which affect the host cell adherence and epsilon-toxin-induced cytotoxicity (Li et al. 2011), but as such are not decisive virulence factors (Chiarezza et al. 2009). Apart from the VirRS virulence factor system briefly discussed above, *C. perfringens* has a second important virulence effector and response regulator termed RevR, which affects cell morphology and regulates the expression of alpha-clostripain, hyaluronidase, and sialidase (Hiscox et al. 2011).

Liver Abscesses and Other Hepatobiliary Lesions in Salmonellosis

Introduction

Salmonella (S.) species cause both acute and chronic infections, depending on bacterial species, strains, virulence, and the host's immune defense system. Salmonellosis is the main cause of bacterial enteritis in humans and animals, and it is estimated that 1.4 million cases of salmonellosis occur among humans in the USA. Chronic infections increase the risk of inflammatory bowel disease and cancer. Typhoid (enteric) fever or *Typhus abdominalis* ("Typhus" in German, not to be confounded with the English term, typhus, which denotes a rickettsial disease) is a severe acute septicemic infectious illness caused by *S. typhi* (typhosa) and *S. paratyphi* A, less often by *S. paratyphi* B and C, and uncommonly by other S. species (review: Bhan et al. 2005). In typhoid fever, involvement of the liver can result in the development of focal lesions that may mimic hepatic malignancy.

Hepatobiliary Involvement

Pathologically, typhoid fever is characterized by a severe and diffuse enterocolitis, associated first with hyperplasia/hypertrophy of the intestinal (Peyer's patches) and lymphonodal lymphatic tissue (during the invasion phase) and then with necrosis and ulcerations of the Peyer's patches toward the end of the fastigium phase. In the course of typhoid septicemia, marked splenomegaly develops.

Salmonellosis and in particular typhoid fever can be associated with several forms of hepatobiliary disease (Table 1). These liver alterations were described in detail in the older literature, but have become uncommon due to the potent treatment modalities now available. The lesions can, however, be still encountered in

Table 1 Hepatobiliary involvement in salmonellosis

regions with poor medical care and/or high exposition to *Salmonellae*.

Miliary Typhoid Granulomas and Salmonellotic Granulomatous Hepatitis

In the course of typhoid fever (*Typhus abdominalis*), submiliary or miliary nodules of whitish to gray-white color (so-called typhomas or typhoid pseudotubercles; Fig. 7) can develop in the liver, often in association with similar nodules in the subperitoneal tissue and the kidneys. In the original observation, these nodules were compared to "lymph follicles" owing to similarities in size, color, and shape (Friedreich 1857; Wagner 1860, as cited in Mallory 1898) and have been related to lymphomas ("miliary lymphomas"; Gruber 1916), but were later found to be specific nodular lesions not exclusively composed of lymphocytes (Fraenkel and Simmonds 1886), but histologically presenting two patterns, i.e., liver necroses surrounded by a neutrophil reaction (Reed 1895) or lesions resembling granulomas as seen in tuberculosis (Joest's "pseudotubercles"; Joest 1914).

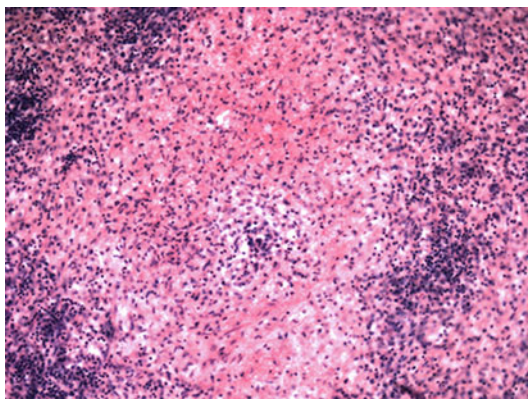

Fig. 7 Hepatic typhoid nodule (typhoid pseudotubercle; "typhoma") in *Salmonella typhi* infection. The granulomatous lesion shows central necrosis and exudation and a peripheral lymphocytic reaction (hematoxylin and eosin stain)

Histologically, these lesions chiefly consist of activated macrophages similar to those found in other tissues in the invasion and fastigium phases of disease (Mallory 1898). These macrophages are sometimes highly activated and enlarged. These are the so-called Rindfleisch cells which may phagocytose *Salmonellae* and/or erythrocytes. These large macrophages were originally described by Georg Eduard von Rindfleisch (1836–1908), a scholar of Virchow who was active in the then Breslau (now Wroclaw), Zurich, and Bonn and intensely worked on typhoid fever (Rindfleisch 1867). Stimulated macrophages may be associated with multinucleated giant cells (derived from macrophages), elements that occur in Peyer's patches, mesenteric lymph nodes, and liver, and detected by Billroth and Grohe in 1861 and Hoffmann in 1869 (cited in Mallory 1898). In the fastigium phase, and similar to Peyer's patches and mesenteric lymph nodes, the macrophage nodules undergo necrosis, sometimes with a central focus of coagulation necrosis, however without caseification, in contrast to tuberculosis. The necroses may a contain a filamentous, slightly eosinophilic network of fibrin-containing filaments, and the granulomas often show a peripheral infiltrate of lymphocytes in a rim of atrophic or decaying hepatocytes (Fraenkel and Simmonds 1886; McCrae and Klotz 1908; Büchner 1956). In case of septicemia and reduced monocyte activated, necrosis of the lesion can increase, associated with epithelioid cell loss, resulting in miliary hepatic necroses that may or may not contain bacteria (Kaiserling et al. 1972). In patients with an intact cell-mediated immunity, and in later stage disease, activated macrophages can form epithelioid cells and granulomas, usually without multinucleated giant cells or only very few giant cells. The granulomas may have direct contact with the lining of terminal vein ("nodular endophlebitis typhosa circumscripta"). These phlebocentric lesions can cause thrombosis of terminal veins and terminal vein obliteration.

Miliary Hepatic Necroses

In some patients with typhoid fever, small and round intra-acinar foci of coagulation necrosis are present in the absence of a significant macrophage reaction. These lesions may have pathogenesis similar to other so-called areactive necroses occurring in the setting of infections, e.g., peracute forms of tuberculosis, and are probably related to a distinct immune status of the host.

Hepatic Macroabscesses and Microabscesses in Typhoid Fever

Liver abscess is a rare, but well-known complication of both enteric typhoid fever and non-enteric *Salmonella* infections. In salmonellosis, liver abscesses are caused by *S. typhi* (Rodriguez and Undurraga 1955; Penaloza et al. 1974; Chogle et al. 1981; Rovito and Bonanno 1982; Petersen 1984; Matar et al. 1990; Soni et al. 1994; Ciraj et al. 2001; Rogers and Wadula 2001; Chaudhry et al. 2003; Chou et al. 2006; Kabra and Wadhwa 2006), *S. paratyphi* A (Rajagopal et al. 2002; Chaudhry et al. 2003; Jeans and McKendrick 2007), *S. enteritidis* (Hirschowitz 1952; Collazos et al. 1991; Elias et al. 1996; Vidal et al. 2003; Sheikh et al. 2011), *S. infantis* (Simmers et al. 1997), *Salmonella* group D non-typhi (Choi et al. 2006), *S. choleraesuis* (Luong and Fournier 1960), and *S. bareilly* (Allegra and Niutta 1957).

Salmonella abscess of the liver may develop within necrotic hepatic tumor metastases (Modol et al. 2006) or hepatocellular carcinoma (Elias et al. 1996; Lee et al. 2002), in intrahepatic hematoma (Cerwenka et al. 1997), via secondary infection of an amoebic liver abscess (Essien et al. 1965; Mansharamani et al. 1971; Marr and Haff 1971; Jeans and McKendrick 2007), and as a late complication of simple liver cyst infection (Gömceli et al. 2006; Sangwaiya et al. 2009). Hepatic *Salmonella* abscess can follow *Salmonella cholangitis* (Holler and Starlinger 1954) and may be combined with splenic abscesses (Chaudhry et al. 2003).

Typhoid Hepatitis

In the course of typhoid fever, a form of acute hepatitis may develop, mimicking viral hepatitis or leptospirosis and rarely ending up with fulminant hepatitis, liver failure, and encephalopathy (Ramachandran et al. 1974; Pais 1984; Ramanathan 1991; Husain 2011; Karoli et al. 2012).

Cholestatic Typhoid Hepatitis

A minority of patients with typhoid fever can develop cholestatic hepatitis, the pathogenic mechanism being unknown (Arabaci et al. 2003; Albayrak et al. 2011; Ratnayake et al. 2011).

Cholangitis Typhosa (Typhoid Cholangitis)

Cholangitis associated with hepatic microabscesses was observed in infections with *Salmonella enteritidis* serovar Choleraesuis (Vogel et al. 2007).

Cholecystitis Typhosa (Typhoid Cholecystitis)

Cholecystitis caused by *Salmonella* is a rare but clinically important complication of *Salmonella typhi* infection (Bender 1946; Avalos et al. 1992; Lai et al. 2006; Ruiz-Rebollo et al. 2008; Ali et al. 2013).

Differential Diagnosis

The main differential diagnosis of hepatic *Salmonella* abscess is abscess formation caused by other bacterial species. In most cases, salmonellosis is nowadays promptly diagnosed, but there are rare situations where liver abscess caused by *Salmonella* may be attributed to other types of hepatic

mass-forming lesions. In patients with septic salmonellosis, hepatic malignancies may mimic (expected) liver abscesses, as the necroses that develop in malignant tumors may resemble cavitated *Salmonella* abscesses on CT images (Hagiwara et al. 2009). Conversely, liver abscesses in septic salmonellosis may be confounded with multiple hepatocellular carcinomas (Simmers et al. 1997).

Microbiology

Salmonella is a genus of rod-shaped, Gram-negative, chemoorganotrophic, predominantly motile bacteria of the family *Enterobacteriaceae*. The bacteria are peritrich, i.e., they have flagella all around their body. *Salmonella* is very closely related to *Escherichia* and occurs worldwide in the environment and in cold- and warm-blooded animals. Most species are facultative intracellular pathogens. There are about 2500 serotypes (serovars) of *Salmonella*, which are allocated to few species. The taxonomy and nomenclature of *Salmonella* species have evolved from an initial one serotype-one species concept, and each serotype was previously considered a separate species, but taxonomy has undergone several revisions. *Salmonella* species formerly included five species, namely, *S. arizonae*, *S. choleraesuis* (the type species of the genus), *S. enteritidis*, *S. typhi*, and *S. typhimurium*. According to the Centers for Disease Control and Prevention (CDC), the genus *Salmonella* contains only two species, each of which contains multiple serotypes. The two species are termed *S. enterica* and *S. bongeri*. *S. enterica* contains the subspecies referred to by a Roman numeral and a name: I, *S. enterica* subsp. *enterica*; II, *S. enterica* subsp. *salamae*; IIIa, *S. enterica* subsp. *arizonae*; IIIb, *S. enterica* subsp. *diarizonae*; IV, *S. enterica* subsp. *houtenae*; and VI, *S. enterica* subsp. *indica* (review: Brenner et al. 2000). Clinically well-known "species" are in part distinct serovars, e.g., the former *S. typhi* is now *S. enterica* subsp. *enterica* ser. Typhi.

What Is Typhoid Fever?

Typhoid fever may present as diarrhea followed by sustained fever, anorexia, vomiting, abdominal distention, headache, and apathy. The illness usually starts after an incubation of 10–14 days, but it ranges from 5 to 30 days, chiefly depending on the size of the infectious dose and the strain's virulence. In the classical medical literature, the first week of clinically manifest infection was termed *Stadium incrementi* ("stage of increase"), characterized by step-wise increase of fever, while the severe *Stadium fastigii* was defined as the stage with continuous high fever (typically 39–40 C). The *Stadium amphibolicum* (third week) was defined as disease with end of continuous fever, with high evening fever and low temperature in the morning. The *Stadium decrementi* ("stage of decrease") was typically in the fourth week of illness and was characterized by lytic fall of fever and decrease of splenomegaly. Today, untreated typhoid fever is usually classified to progress through five stages, i.e., incubation, invasion, fastigium, lysis, and convalescence. In the course of active invasion, patients experience a stepwise elevation in body temperature from day to day, and part of the patients develop rose-colored skin spots grossly resembling petechiae, the roseoles of typhoid fever which have a histologic substrate of perivascular cellular infiltrates, but only rarely minor bleedings. Symptoms and signs are maximum in the fastigium stage, which is also characterized by a continuous fever with only minor daily fluctuations (the well-known "febris continua" or briefly, "continua" of typhoid fever). In the lysis stage, the symptoms start to wane and the fever slowly falls, however still with sometimes extreme daily fever fluctuations. In the convalescence stage, the condition of the patient improves, but fatigue and weakness can continue for a long time period.

Typhoid fever can show several complications, including septic metastases in several organs, osteomyelitis typhosa, nephritis, meningitis, parotitis, orchitis, pneumonia, and hepatobiliary disease. About 3 % of patients develop chronic

typhoid cholecystitis after 1 year, the infected gallbladder forming a reservoir for viable *Salmonellae* (the carrier state).

Pathways of Infection

Salmonella species adhere to host cells through fimbrial adhesins. In the course of cellular invasion, *Salmonella* species interact in a complex manner with the actin cytoskeleton of host cells. Rearrangements of the actin cytoskeleton are brought about by elements of the bacterial type III protein secretion system, a virulence complex which activates the regulatory proteins, Cdc42 and Rac, to produce membrane ruffles that engulf the bacteria, while the pathogenicity island 2/SPI2 translocates effectors that promote intracellular survival and growth, associated with focal actin polymerization around the *Salmonella*-containing vacuole of the host cell (Guiney and Lesnick 2005). *Salmonellae* can also be taken up by host cells through macropinocytosis and phagocytosis, e.g., by luminal neutrophils in the inflamed gut during early infection (Loetscher et al. 2012). Replicating bacteria within host cells can counteract the autophagy pathway and evade elimination via the induction of aggresome-like induced structures through the action of a translocated virulence protein, deubiquitinase (Thomas et al. 2012).

The *Salmonella* type II secretion effector protein AvrA is a multifunctional enzyme having important roles in inhibiting inflammation, regulating apoptosis, and increasing proliferation. In a mouse model of salmonellosis, AvrA expression suppressed intestinal inflammation and inhibited the secretion of the cytokines, IL-12, IFN-gamma, and TNF-alpha. On the other hand, AvrA promoted the bacterium's invasion and was associated with *Salmonella* translocation to the gallbladder and liver abscess formation (Lu et al. 2010).

Host cell death plays a significant role in *Salmonella* infections (review: Guiney 2005). *Salmonella* species can induce cell death through apoptosis, a process dependent of the type III secretion system of the bacterium (Boise and Collins 2001). In particular, intestinal epithelial cells/enterocytes are killed by caspase-dependent apoptosis in salmonellosis, while macrophages undergo a caspase-1-dependent proinflammatory programmed cell death called pyroptosis (Monack et al. 2001; Fink and Cookson 2007).

Tumor-Like Lesions of the Hepatobiliary Tract Caused by Mycobacterial Infections: Tuberculosis and Lepra

127

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_127

Abstract

Primary and secondary tuberculosis of the liver can result in several types of tumor-like lesions. A common manifestation of hepatic tuberculosis is miliary hepatic tuberculosis and granulomatous hepatitis. Tumor-like lesions mainly include local forms of hepatic tuberculosis, with conglomerate tubercles, tuberculomas (macronodular tuberculosis), and nodular tuberculous pseudotumors. Hepatobiliary tuberculosis can also involve the biliary tract proper, with ulcerating and granulomatous cholangitis resulting in significant strictures. The infection also causes distinct vascular changes, such as granulomatous vasculitis and tuberculous pylephlebitis. A second mycobacterial infection that may involve the liver is leprosy, causing granulomatous hepatitis and the formation of so-called lepromas.

Tuberculosis and Tuberculomas

Introduction

Tuberculosis is a still widespread mycobacterial infectious disease that belongs to the most intensively studied pathologies, numerous detailed studies already being available from the nineteenth to early twentieth centuries (Louis 1825; Lorentz 1913; Liebermeister 1921; Saphir 1929; Morris 1930; reviews: Yew and Leung 2008). Abdominal forms of tuberculosis can cause impressive tumor-like lesions in the liver that may closely mimic hepatic primary malignancy or metastatic disease of the liver. The basics of microbiology are briefly summarized at the end of the chapter.

Epidemiology

About one-third of the world's population is infected with *M. tuberculosis*, and the WHO estimates of 1.6 million deaths were caused in 2005 by *M. tuberculosis*. Hepatic tuberculosis is also known in the pediatric age group (Praharaj et al. 1979; Moskovic 1990). A very large number of individuals in the world have latent tuberculosis, caused by a complex interaction between viable bacteria and a host with a potent immune system. These numerous persons with latent tuberculosis represent an enormous reservoir of potential tuberculosis cases, because any transient or persisting failure of controlling immune reactions can lead to outbreak of clinically manifest disease (reviews: Tufariello et al. 2003; Cardona 2007). On the other hand, *M. tuberculosis* itself can become a latent *bacillus*, meaning that it can adapt to the stressful conditions generated by the immunocompetent host.

Latent mycobacteria can downregulate their metabolism, alter their antigenic profile, transiently lose their invasive features, and hence appear "silent" to the immune system. This dormant state can persist for many years, but may not be longer than 10 years. When the properties of the niche harboring silent or dormant mycobacteria alter in favor of a "resuscitation" of the bacteria (e.g., in case of poor immune response), silent bacteria can resume their fully virulent state, but this readaptation requires longer time periods (Cardona and Ruiz-Manzano 2004; Zhang 2004; Sridhar et al. 2011).

Classifications of Hepatic Tuberculosis

During the long period of investigations on tuberculosis of the liver, both primary and secondary resulted in several variants of classification. These classifications are in part a mixture between clinical and radiological findings, and of pathologic-anatomic changes observed at surgery or autopsy, rendering some of the classifications complicated and difficult to reproduce. The diagnostic elements that enter a given classification have been worked out in detail, but as such cannot deliver the skeleton usable for classification. An often-used system of criteria is that of Maharaj et al. (1987), which consists of detection of acid-fast bacilli in liver tissue; tubercle bacilli elsewhere, plus hepatic granulomas with or without Langhans-type giant cells, and/or caseation; typical

Table 1 Forms of hepatic tuberculosis

Miliary hepatic tuberculosis and granulomatous hepatitis (lesions/tubercles 0.6–2 mm in diameter)
Liver involvement in Landouzy's sepsis (sepsis tuberculosa acutissima)
Local hepatic tuberculosis (lesions larger than 2 mm in diameter)
Conglomerate tubercles
Tuberculomas (macronodular hepatic tuberculosis)
So-called tuberculous abscesses
Nodular tuberculosis pseudotumors
Tuberculous caverns of the liver (cavernous hepatic tuberculosis)
Bile duct tuberculosis
Tuberculous vascular lesions of the liver
Granulomatous vasculitis
Tuberculous pylephlebitis
Portal vein thrombosis
So-called tuberculous cirrhosis

macroscopic appearance on laparotomy or peritoneoscopy; and response to antituberculous therapy. A novel classification of secondary hepatic tuberculosis is proposed in Table 1.

An old classification as of 1929 divided hepatic tuberculosis into miliary and local forms (Rolleston and McNee 1929). A later approach as of 1984 separated miliary hepatic tuberculosis associated with generalized miliary tuberculosis, primary miliary tuberculosis of the liver without involvement of other organs, and a primary nodular hepatic lesion termed tuberculoma or frank tuberculous abscess (Spiegel and Tuazon 1984). The nomenclature of these lesions has not been employed in a consistent way, some definitions lacking for a long time period. For example, the so-called tuberculous abscess has been used to denote tuberculoma, but these lesions are clearly different. What has probably been meant with "abscess" are large nodular tuberculous lesions with partial colliquation of the necrosis, rendering the lesion similar to pyogenic abscess at imaging. However, and in contrast to other bacterial infections, tuberculosis does not induce suppuration which characterized abscess, but a distinct type of coagulation necrosis (caseiform necrosis). In rare instances, superinfection of a tuberculous necrosis with pyogenic bacteria may add a suppurative component, but this is always a secondary phenomenon.

Clinical Presentation of Hepatic Tuberculosis

Apart from hepatomegaly, many patients usually do not show symptoms or signs of their liver disease (Gold et al. 1957). Common symptoms and signs are weight loss, loss of appetite, abdominal pain, fever, abdominal distension, and jaundice (Cruice 1914; Pariente et al. 1963; Saluja et al. 2007; Chong 2008; Hwang et al. 2009). In a study of 200 patients with hepatic tuberculosis, hepatomegaly was the most striking and constant physical sign and was present in 71 % of patients with miliary tuberculosis and 95 % of those with focal tuberculosis (Hersch 1964). On the other hand, some authors found that patients complain of upper abdominal tenderness in addition to liver enlargement (Lichtman 1949; Maharaj et al. 1987). In the study of Hersch (1964), clinical jaundice was noted in 15.4 % of patients.

Patients with hepatic tuberculosis often show elevated serum alkaline phosphatase (Klatskin and Yesner 1950; Korn et al. 1959). Among 96 patients with tuberculous hepatitis, the characteristic serum profile included hyponatremia (64 %), raised alkaline phosphatase (83 %) and gamma-glutamyl transferase (77 %), hypoalbuminemia (63 %), and hypergammaglobulinemia (83 %). In 78 %, serum aminotransferases were moderately elevated (Essop et al. 1984). In few cases, hepatic tuberculosis was associated with marked hyperferritinemia masquerading adult-onset Still's disease (Manoj et al. 2012). In generalized miliary tuberculosis with bone marrow involvement, miliary liver tuberculosis with jaundice can be accompanied by pancytopenia (Evans et al. 1998). There are several causes of obstructive jaundice in hepatobiliary tuberculosis, discussed in more detail in later paragraphs. In case of extensive liver involvement, tuberculosis can cause portal hypertension (Bruguera et al. 1968; Mojtahedzadeh et al. 2012). Rare manifestations of tuberculosis involving the liver include hepatic failure in extensive miliary liver

tuberculosis (Asada et al. 1991; Godwin et al. 1991) and hemophagocytic syndrome (Balasubramanian et al. 2008; Lee et al. 2008).

Primary (Isolated) Hepatic Tuberculosis

In comparison with secondary hepatic tuberculosis, primary tuberculosis of the liver is nowadays less common, but has been reported many times in the preantibiotic era. More recent reports described the principal morphology of primary hepatic lesions and in part emphasize the tumor-like presentation of primary hepatic tuberculosis (Fig. 1; Essop et al. 1983a,b; Nagai et al. 1989; Oliva et al. 1990; Errougani et al. 1991; Emre et al. 1992; Kok and Yapp 1999b; Sheen-Chen et al. 2001; Chen et al. 2003; Varela et al. 2003). Primary hepatic tuberculosis radiologically manifests as echogenic masses in ultrasonography and hypodense, tumor-like masses on CT images (Kok and Yapp 1999b; Chen et al. 2003). Focal hepatic tuberculosis forming a mass or tuberculoma (pseudotumor) can closely mimic primary hepatic malignancy at imaging (Sheen-Chen et al. 2001; Varela et al. 2003) or may resemble hepatic metastatic disease (Zipser et al. 1976; Achem et al. 1992). Mixed attenuation lesions in primary hepatic tuberculosis can grow to impressive size, e.g., occupying a good part of a liver lobe and sometimes confounded with hepatocellular carcinoma (Brookes et al. 2006). Primary hepatic tuberculosis can also present as miliary tuberculosis, i.e., in the form of a specific granulomatous hepatitis (Cinque et al. 1964; Terry and Gunnar 1957). In case of bona fide primary hepatic tuberculosis, the spread of disease to locoregional lymph nodes situated in the perihilar area and the hepatoduodenal ligament has been observed (the "tuberculous primary complex" of the liver; Nordmann 1927).

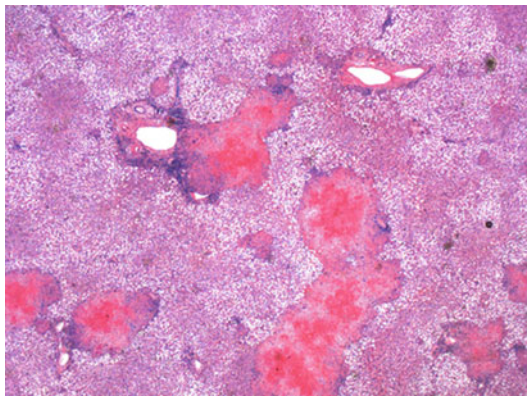

Fig. 1 Hepatic tuberculosis. Several and in part confluent caseous necroses (strongly eosinophilic areas) with a peripheral granulomatous reaction are present. The lesions are in contact with portal tracts. Hepatocyte steatosis surrounds the lesions (hematoxylins and eosin stain)

Secondary Hepatic Tuberculosis

Most cases of hepatic tuberculosis are secondary forms (Amarapurkar and Agrawal 2006). Formerly, this was a rather common complication of tuberculosis. In the time period before efficient antituberculosis treatment, hepatic involvement was found clinically in 50–80 % of all patients dying of pulmonary tuberculosis and in up to 91 % at autopsy (Gelb et al. 1973; Leder and Low 1995). It has been proposed to differentiated secondary hepatic tuberculosis into several forms (Hersch 1964).

Granulomatous Hepatitis

Miliary tuberculosis is a severe and often generalized manifestation of tuberculosis, characterized by the development of multiple necrotizing granulomas in diverse organs and tissue, the lesions usually containing visible mycobacteria (Auerbach 1944; Proudfoot et al. 1969; Kim et al. 1990; Siemann et al. 1999; Mert and Ozaras 2005; Tajiri et al. 2011). In generalized tuberculosis, tuberculous granulomatous hepatitis was one of the most common manifestations of the infection in the preantibiotic era (Arnold 1880). The liver substance is either reached by bacteria circulating in the blood or by the hepatic homing of infected monocytes to become macrophages. In many instances, pulmonary tuberculosis with tuberculous phlebitis of pulmonary veins with subsequent invasion of the bloodstream was a significant pathogenic mechanism (Silbergleit 1905).

Based on detailed autopsy studies, Silbergleit (1905) could detect yellowish, elongated, and prominent lesion on the intima of pulmonary veins, sometimes associated with smaller and gray, milium-sized nodules in the venous intima. These lesions are regarded as the source of mycobacterial spread through the bloodstream in miliary tuberculosis. Miliary hepatic tubercles have been observed in various forms of tuberculosis, including acute disseminated miliary tuberculosis and extrapulmonary tuberculosis, and in fatal cases of pulmonary tuberculosis. It is estimated that the liver as part of generalized miliary tuberculosis is involved in 50–80 % of all patients dying from pulmonary tuberculosis (Morris 1930). Similar figures have later been found (Glaus 1919; Terry and Gunnar 1957; Korn et al. 1959; Bottiger et al. 1962; Cinque et al. 1964; Steniu-Aarniala and Tukiainen 1979; Sharma et al. 2005; Amarapurkar et al. 2008; Kumar and Pandey 2008; review: Alvarez and Carpio 1983). Among 200 cases of hepatic tuberculosis studied in the time period 1955–1961, only miliary tuberculosis of the liver was found in the pediatric cases, whereas in adults miliary hepatic tuberculosis was present in 86 % and focal hepatic tuberculosis in 14 % of the cases (Hersch 1964). In a series of 38 patients with generalized miliary tuberculosis, hepatomegaly was found in 37 % (Mert et al. 2001). Severe forms of hepatic miliary tuberculosis can cause jaundice (Curry and Alcott 1955) or hepatic failure (Sharma et al. 1981; Hussain et al. 1995). Miliary liver tuberculosis is rarely a primary form of tuberculosis, in the absence of active pulmonary disease (Terry and Gunnar 1957; Pitzus and Verme 1960; Traissac et al. 1961; Cinque et al. 1964; Tritou et al. 2000). Hepatic miliary tuberculosis has also been described in congenital tuberculosis with multiorgan involvement (Chou 2002). Apart from *M. tuberculosis*, hepatic granulomas can also be induced by *M. scrofulaceum* (Patel 1981).

Ultrasonographically, multiple granulomas result in a "bright liver," although one may note hypoechoic or hyperechoic lesions. In CT images, miliary granulomas are visualized as multiple low-density lesions with small calcifications, usually with attenuation values in the range of +35 to +45 Holmstrom units with peripheral contrast uptake (Kohli et al. 1996; Yu et al. 2004). Angiographically, miliary liver tuberculosis displayed abnormalities of the distal arterioles, with small, nodular, and irregular formations, while the portal and hepatic veins were normal (Rémond et al. 1976; Dwek et al. 1981). Most cases of tuberculous granulomatous hepatitis are caused by *M. tuberculosis*, but other species have also caused a granulomatous reaction in livers, mostly in immunosuppressed hosts, including *M. avium* complex (MAC) bacteria (Farhi et al. 1986; Ruiz et al. 2002; Akhtar and Shaheen 2007; Todd et al. 2007; Laramore et al. 2009), *M. gordonae* (Kurnik et al. 1983; den Broeder et al. 2003), *M. mucogenicum* (Goldblatt and Ribes 2002), and *M. chelonae* (Fernandez-Rodriguez et al. 2004). Hepatomegaly associated with deranged liver function tests suggesting hepatitis was observed in *M. fortuitum* infection (Zainal Muttakin and Tan 2006).

The gross visualization of miliary liver tuberculosis depends on the number of granulomas and their size. It is generally agreed that submiliary, i.e., also very early, lesions may not be visible with the naked eye. Miliary lesions are best recognized when, in the setting of generalized miliary tuberculosis, they are situated as numerous lesions just beneath the liver capsule, where they are seen in the form as whitish or opaque nodules of 1–2 mm diameter. The granulomas are less easily recognized on cut surfaces, particularly in case of liver steatosis. By use of a magnifying glass, granulomas are often seen to be situated close to blood vessels in Glisson's sheaths. Extensive miliary liver tuberculosis can be associated with enlarged, caseous lymph nodes at the porta hepatis (Arends 1950; Leggat et al. 1953).

Histopathologically, tuberculoid granulomas have been recognized as a key element in miliary tuberculosis. Early lesions are characterized by small accumulations of macrophages/Kupffer cells (the "Retothelknötchen/retothel nodules" of older nomenclature; Hamperl 1953; Ringleb 1953). The lesions consist of nodular accumulations of epithelioid macrophages with a central caseiform coagulation necrosis. The earliest

lesions are characterized by tiny accumulations of lymphocytes and a central group of three to five larger and pale cells representing macrophages. In fully developed granulomas, lymphocytes form a layer of variable width surrounding the macrophage nodule. The granulomas are situated within the hepatocyte parenchyma, portal tract spaces, or in the adventitia of blood vessels. In some cases, granulomas are present in the intima of hepatic veins (endophlebitis granulomatosa tuberculosa). Many tuberculoid granulomas contain Langhans-type giant cells which develop via macrophage fusion. The morphology of the Langhans giant cell has been studied in detail (Herxheimer 1914; Haythorn 1929). Typically, the nuclei which have more or less the same structure as those found in epithelioid macrophages are arranged at the cell body periphery, often with an anuclear gap which shows up as a "horseshoe-like" arrangement in tissue sections. The central part of the cytoplasm may contain a foamy structure with tiny dots representing the numerous centrosome/centriole stacks ("centrosome swarm"; sometimes with a central astrosphere) arranged in the center of the cell body. The tissue occupied by granulomas is usually necrotic or shows signs of hepatocyte atrophy and disintegration of hepatocyte plates. By use of special stains, acid-fast bacilli are present in the granulomas, often in the border zone between necrosis and preserved macrophages. Tuberculoid granulomas in tuberculosis are readily diagnosed in liver biopsies (Schinnerling 1966), but in order to obtain a reasonable chance to find the lesion, a large amount of granulomas must be present in the liver. It is estimated that, for having around three granulomas in the section of biopsy cylinder of 2.5 cm length, approximately 100,000 randomly distributed granulomas must have developed in the entire liver.

Liver Involvement in Landouzy's Sepsis (Sepsis Tuberculosa Acutissima)

Landouzy's sepsis (LS; generalized nonreactive tuberculosis, sepsis tuberculosa acutissima, Landouzy's typhobacillosis) is severe, acute, or peracute (fulminant) systemic disease caused by widespread infection with *M. tuberculosis* in the absence of an adequate macrophage-mediated defense reaction of the host (Landouzy 1891; Eckel 1929; Arends 1950; Von Knorre 1950; Jenss et al. 1981). LS as the most devastating form of areactive tuberculosis has also been called acute caseating tuberculosis by Rich (1944), the Yersin type of tuberculosis, and generalized nonreactive tuberculosis, a term coined by Siegmund (1939). Rennen called the disorder sepsis tuberculosa gravissima (Rennen 1922).

LS is named after Louis Théophile Joseph Landouzy (1845–1917), a French physician who was influenced by Jean-Martin Charcot and was a coworker of Déjérine's studies on the muscular disorder having the latter's eponym. Landouzy was the first to suggest the infectious nature of herpes. Landouzy published his work on LS 1891, under the title "Bacterial pretuberculous fevers with a typhoid presentation: typhobacillosis" (Landouzy 1891). LS is mostly caused by *M. tuberculosis* but has also been encountered with other mycobacterial species. The clinical course of LS is usually that of an acute, overwhelming infectious disease. Less commonly, patients with LS present with subacute pyrexia of unknown origin (FUO). The main pathogenic feature is the virtual absence of a monocyte/macrophage response to mycobacteria spread to tissues. Histologically, the hallmark is a multifocal coagulative, caseous necrosis without associated macrophage reaction, i.e., without tuberculoid granulomas. This areactive state is caused by failure of monocyte stimulation by primed T lymphocytes or by secondary deficiency of immunocompetent effector cells. LS can, therefore, develop in immunosuppressed individuals (Jenss et al. 1981). As LS is a generalized disorder, liver involvement is to be expected in most patients and has in fact been documented at autopsy (Arends 1950; Moriwaki 1959; Rodin and Hnatko 1963).

At autopsy, only splenomegaly may be seen, as the whitish-gray miliary lesions found in miliary tuberculosis are lacking. Some patients showed hepatomegaly, up to 2600 g (Arends 1950). The liver showed some fibrinous epicapsular exudates in one case (Arends 1950). By use of magnifying

glass, the tiny necroses may be visualizing as white pinhead-sized spots less than 1 mm diameter. Less commonly, larger yellowish necroses of 1 cm diameter may be observed, probably resulting from coalescence of numerous and densely packed small lesions. Draining lymph nodes are either normal or show multiple necroses, but no granular aspect of the cut surface, because granulomas are absent (Pagel and Woolf 1949). Histologically, the leading feature is that of a focus of coagulative necrosis, often with "ghost cells" reflecting the original parenchyma. The necrosis may contain nuclear debris (karyorrhexis), similar to caseous necrosis found in miliary tuberculosis, and may be rich in fibrin and blood (Arends 1950). Typically, the lesions contain large amounts of acid-fast bacilli packed together (Rodin and Hnatko 1963), resulting in what has been called "felt-like masses" (O'Brien 1954). The tissue around these lesions is mostly normal and either completely lacks any lymphoid cell or monocyte infiltrates or shows a few scattered lymphocytes surrounding the necrosis (Gibson 1946; Arends 1950), reflecting a certain variation in immune reaction failure, ranging from complete to partial areactivity. In one autopsy, few Langerhans-type giant cells were found around the necroses (Arends 1950), again suggesting a certain monocyte-mediated reaction.

Hepatic Tuberculoma (Macronodular Hepatic Tuberculosis)

Hepatic tuberculomas or macronodular hepatic tuberculosis (MNHT) is a rare form of liver tuberculosis in Western countries, but may be more commonly seen in tropical areas with a high prevalence of tuberculosis (Figs. 2, 3, and 4). Even in Europe of the nineteenth and early twentieth centuries, when tuberculosis was a common disease, macronodular liver tuberculosis was rarely reported; in 1912, Lotheissen could only extract 34 observations from the literature (cited in Culp 1921). It is characterized by the presence of solitary or multiple, macroscopically visible nodules consisting of a caseous necrosis and surrounding tuberculoid granulomas. MNHT is chiefly a

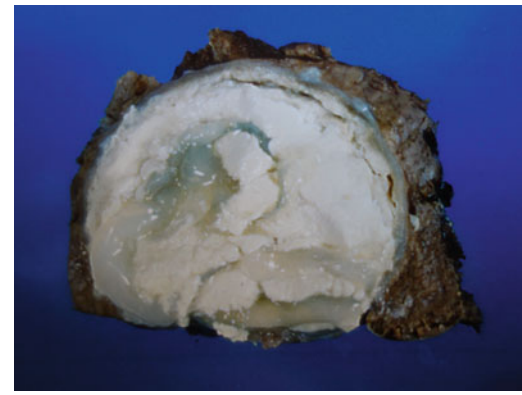

Fig. 2 Tuberculoma of the liver. The tumor-like mass mainly consists of caseous necrosis, which is macroscopically *whitish* in contrast to *yellow* pus. The cream-like mass typically shows cracks and fragmentation

disease of adults, but has also been diagnosed in children (Daynes 1971; Moskovic 1990; Kohli et al. 1996). MNHT uncommonly develops in the absence of abdominal tuberculosis (Desai et al. 2006). On plain radiographs, hepatic tuberculosis often shows calcifications, in the form of large "chalky" and confluent calcifications, nodal-type calcifications along the course of bile ducts, or smaller mineralizations of flecks and speckles (Maglinte et al. 1988). Ultrasonography showed hypo- or hyperechoic, ill-defined masses in the liver (Brauner et al. 1989; Tan et al. 1997). CT images show variably sized tumor-like lesions of low density, sometimes with multiple flecked calcifications (Small 1974; Brauner et al. 1989; Levine 1990; Buxi et al. 1992; Kawamori et al. 1992; Denton and Hossain 1993; Mercusot et al. 1995; Yu et al. 2004). Rarely, a honeycomb appearance has been found on CT. MR images showed low signal intensity on both T1-and T2-weighted images (Murata et al. 1996; Fan et al. 1998). Large mass lesions, sometimes exceeding 10 cm in diameter, mimic primary hepatic cancer (giant tuberculoma; Chan and Pang 1989; Achem et al. 1992; Brookes et al. 2006; Malik et al. 2011) or gallbladder cancer (Bikhchandani et al. 2005). Tuberculoma located to the porta hepatis can clinically and radiologically resemble Klatskin tumor (Arora et al. 2008). Multiple MNHT is also known and may present as calcified lesions (Chan and Pang

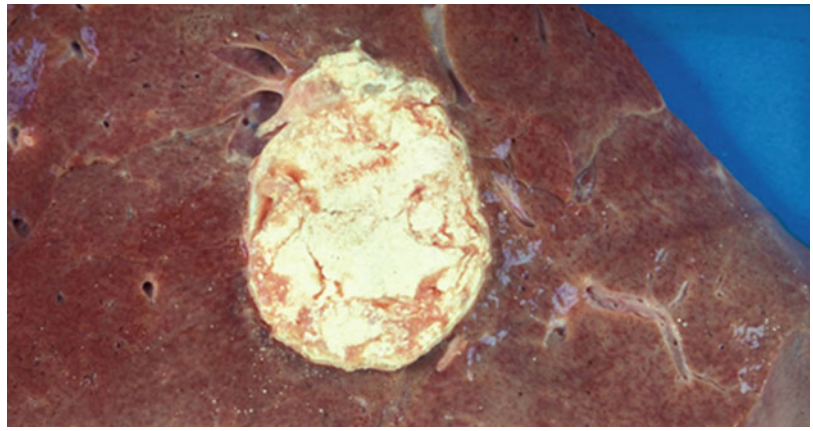

Fig. 3 Tuberculoma of the liver. Old lesions become sticky masses with a chalk-like aspect

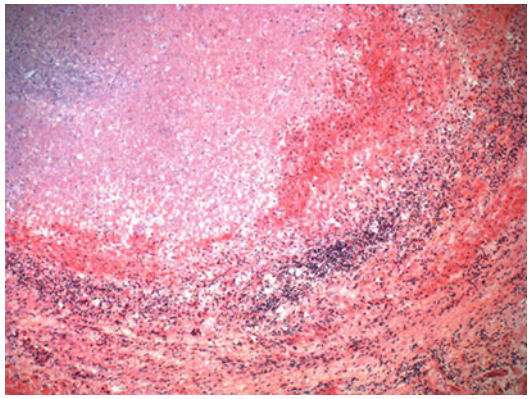

Fig. 4 Tuberculoma of the liver. The center of the lesion exhibits typical coagulation necrosis with nuclear debris. At the periphery of the lesion, a rim of epithelioid cells is observed. The *crescent-shaped* strongly eosinophilic structure is a zone of freshly necrotic epithelioid macrophages. The interface between the granulomatous belt and adjacent liver shows a lymphocytic infiltration and fibrosis (hematoxylin and eosin stain)

1989). These multiple nodules can closely resemble metastatic cancer foci at imaging (Fernandes et al. 1984; Wei et al. 2012). In case the tuberculoma is situated close to the gallbladder fossa, gallbladder cancer may be mimicked (Ben et al. 1995; Bikhchandani et al. 2005). MNHT is sometimes centered around intrahepatic bile ducts (Rosenkranz and Howard 1936).

In active hepatic tuberculosis, the histiodestructive process of a tuberculoma can extend beyond the anatomical limits of the liver, e.g., invading the pericardium (Mutreja et al. 2010). Tuberculomas can undergo or cause complications. MNHT can undergo secondary hemorrhage, similar to tumors (Prochazka et al. 1986), and was associated with portal vein thrombosis and portal hypertension (Ka et al. 2004; Venkatesh et al. 2005). Hepatic tuberculoma has also been detected after orthotopic liver transplantation (Berzigotti et al. 2006). In the past literature, part of hepatic tuberculous mass necroses now called tuberculomas have also been termed tuberculous liver abscesses. This designation is to be understood in a clinical-radiological setting, because necrotic lesions occurring in tuberculosis are, by definition, not true (pyogenic) abscesses, because an abscess is defined as a necrotic lesion with a dense granulocyte/neutrophil exudate, what is not the case in tuberculosis (Kanagaraj et al. 2008).

Apart from *M. tuberculosis*, tuberculomas, sometimes mimicking liver cancer or hepatic metastatic disease, have also been found in infections with other mycobacteria, including *M. kansasii* (Kaur et al. 2011) and *M. avium* (Hurley et al. 2011).

et al. 1959; Chimene et al. 1965; Gracey 1965; Grave 1972; Gattegno et al. 1973; Rab and Beg 1977; Rosin 1978; Siwach and Srivastava 1978; Jain et al. 1981; Purhoit and Verma 1982; Bhargava et al. 1983; Spiegel and Tuazon 1984; Gallinger et al. 1986; Mustard et al. 1986; Goh et al. 1987; Stevens and Little 1987; Chan and Pang 1989; Levine 1990; Oliva et al. 1990; Reed et al. 1990; Asada et al. 1991; Wilde and Kueh 1991; Achem et al. 1992; Emre et al. 1992; Purl et al. 1994; Ben et al. 1995; Chien et al. 1995; Herman et al. 1995; Nampoory et al. 1995; Amaris et al. 1997; Tan et al. 1997; Hickey et al. 1999; Jain et al. 1999; Agrawal et al. 2001; Rahmatulla et al. 2001; Huang et al. 2003; Mert et al. 2003; Ardiles et al. 2004; Hayashi et al. 2004; Köksal et al. 2006; Hassani et al. 2010; Abe et al. 2011; Singh et al. 2011).

Macroscopically, tuberculomas (hepatic tubercles) are pea-sized to walnut- or apple-sized solitary or multiple masses that may present as tumor-like lesions (Figs. 2, 3, and 4). In several investigations, multiple lesions were more common than solitary lesions. The nodules are usually well delineated and have a whitish-dull to gray-green color. Large and solitary masses are often bile stained ("green tubercles"), due to erosion of intrahepatic bile ducts and extravasation of bile into the necrotic areas. It is this type of greenish nodule that might macroscopically be confounded with a bile-storing liver cancer. Histologically, most of the mass of hepatic tubercles or tuberculomas consists of caseiform necrotic masses. These are pale eosinophilic and finely granular masses that may contain shadow cells and nuclear debris. Typically, these necrotic areas show fissures as an artifact occurring during tissue processing. Calcification is often seen, either in the form of tiny basophilic depositions or dense accumulations of calcified matter. The periphery of these areas is occupied by an epithelioid cell wall of variable thickness, without palisading. In smaller lesions, the micronodular aspect of this wall which results from fused granulomas is still seen, while large lesions often only show a very thin rim of epithelioid cells.

Nodular Tuberculous Pseudotumors

Large and in particular conglomerate focal lesions may give rise to tumor-like nodular masses (giant solitary liver tubercles, conglomerated tubercles, nodular tuberculous pseudotumors; NTPT). Almost all of these usually solitary tumor-like lesions seem to develop through coalescence of several preexisting tubercles. This pathway is likely because there are transition forms between several discrete nodules and a solitary pseudotumor, in which a coalescence of spherical necrosis with visible overlaps is easily seen, with the remaining epithelioid cell wall forming a peripheral structure resembling a fortification structure. Large tuberculous pseudotumors can progress to multilobulated masses strikingly resembling hepatic malignancy at gross examination. In rare instances, large areas of caseification may undergo condensation to thick and viscous homogeneous, grayish masses similar to those seen in renal tuberculosis ("putty tubercles of the liver"). The epidemiology of tuberculous pseudotumors is not well known. Among 682 patients from China who had undergone liver resection, eight were confirmed pathologically as having hepatic tuberculous pseudotumors (Xing et al. 2005). In some cases, NTPT are manifest as so-called hepatic pseudometastases, lesions that cause diagnostic difficulties, in particular, as they may coexist with true hepatic carcinoma metastases (Sen et al. 2004). NTPT may cause compression of bile ducts and lead to biliary obstruction (Wee et al. 1995).

Tuberculous Caverns of the Liver (Cavernous Hepatic Tuberculosis)

In pulmonary cavernous tuberculosis, the morphogenesis of caverns requires that the bronchus system is connected with large necrotic lesions in order air can get access to the lesions that may afterwards drain, with formation with a fluid-air interface. Cystic tuberculous lesions of the liver have been described as intrahepatic tuberculous biliary caverns (Sergent 1895; Jacobson 1897; Fletcher 1899; Rauber et al. 1956; Kemeny et al. 1981), In one patient, necropsy showed multiple biliary caverns of the liver, measuring 1–2 cm in diameter, with a grayish-greenish content (Kemenyi et al. 1981). Pathologenetically, the cavernous aspect, in contrast to tuberculous lung caverns, was probably caused by biliary drainage of necroses, leaving a fluid-filled cystic space.

In rare cases, tuberculosis restricted to intrahepatic bile ducts can mimic, due to wall destruction and dilation of ducts, alterations previously observed in bronchial tuberculosis and termed "Röhrentuberkulose" (tube-type tuberculosis; Hall 1911). Macroscopically, dilated intrahepatic bile duct protrudes from the liver's cut surface due to their markedly inflamed walls and the accumulation of caseiform necrosis in the walls. Histologically, the picture is dominated by a severe ulcerating granulomatous cholangitis with increase in duct wall thickness and sometimes sickle-shaped caseiform necrosis occupying sectors of the duct walls (Orth 1876; Gruber 1930). The necrotic bile duct may contain concrements, resulting in the effacement of the bile duct structure.

Tuberculous Vascular Alterations of the Liver

Invasive tuberculomas can involve the wall of the portal vein and induce so-called tuberculous thrombosis (pylephlebitis tuberculosa; Fig. 5). Tuberculous pylephlebitis is a very rare complication, sometimes also associated with tuberculous lymphadenitis of the hepatic hilum (Caroli and Paraf 1956; Savioz et al. 1993). In situations of pylephlebitis associated with hilar tuberculous lymphadenitis, it is assumed that inflamed nodes with granulomatous perilymphadenitis adhere to the adventitia of the portal vein, followed by transmural inflammation of the vein and thrombogenic endothelial damage. Another potential thrombogenic mechanism is endophlebitis tuberculosa of the portal vein, with formation of subendothelial tuberculoid and caseating granulomas. Perihilar tuberculous lymphadenitis can also cause bland, i.e., noninfected portal vein thrombosis and portal hypertension (Caroli-Bosc et al. 1997). In rare instances, tuberculosis manifests in the wall of the hepatic artery and its branches, sometimes causing hepatic artery aneurysm and associated hemobilia (Klepetko et al. 1986).

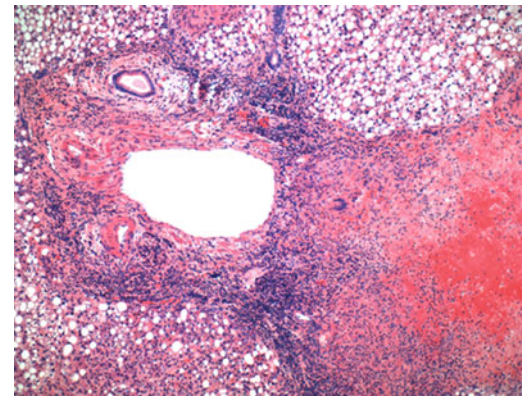

Fig. 5 Pylephlebitis tuberculosa. A sector of the portal vein is involved with tuberculosis. A granuloma with a typical Langhans giant cell has destroyed the venous wall (*right of the middle*). This lesion is in continuation with a large necrosis (hematoxylin and eosin stain)

Hepatic Tuberculosis in the Absence of Disseminated Abdominal Tuberculosis

In a series of seven patients, all presented with fever and hepatomegaly, five complained of pain in the upper abdomen and vomiting, and two patients were jaundiced. On ultrasonography,

two had multiple hypodense lesions, one showed a coarse echotexture of the liver, and one had a hypoechoic pattern (Desai et al. 2006). The lesions may mimic hepatic metastases (Kok and Yapp 1999b).

Associated Liver Alterations

Patients with tuberculosis often show, apart from specific hepatic lesions, a broad array of other liver alterations, in part related to the infections itself, in part caused by antituberculosis therapies (side effects of tuberculostatic drugs). In an autopsy study of 150 adult patients with tuberculosis, the liver showed granulomas in 42 %, fatty change in 32.6 %, portal tract inflammation in 40 %, sinusoidal congestion in 32 %, and fibrotic changes in 16 % (Amarapurkar and Agrawal 2006). In disseminated tuberculosis, small punctiform hemorrhages can develop in the liver, of unknown pathogenesis (Mittasch 1920; Peltason 1921). Tuberculous lesions of the liver can induce parenchymal atrophy and vascular alterations followed by nodular hypatocyte hyperplasia (Wegerle 1913). The liver capsule might be involved in encapsulating peritoneal sclerosis that has been found in *M. fortuitum* infection in peritoneal dialysis patient (Simbli et al. 2012).

Tuberculous Cholangitis, Biliary Stenosis, and Strictures

In abdominal tuberculosis, four mechanisms have been described to cause obstructive jaundice: (1) mass-producing tuberculosis of the pancreatic/peripancreatic region, (2) periductal/peripanceatic or retroperitoneal tuberculous lymphadenitis, (3) tuberculosis of the bile ducts, and (4) retroperitoneal tuberculosis with mass formation. Tuberculosis of the bile ducts causing ulcerations (Fig. 6), biliary stenosis, or strictures is a rare form of hepatobiliary tuberculosis that may mimic biliary tract malignancy. In a review of 17 cases (Iwai et al. 2006), six involved the common hepatic duct, six the common bile duct, one both the common hepatic and common bile duct,

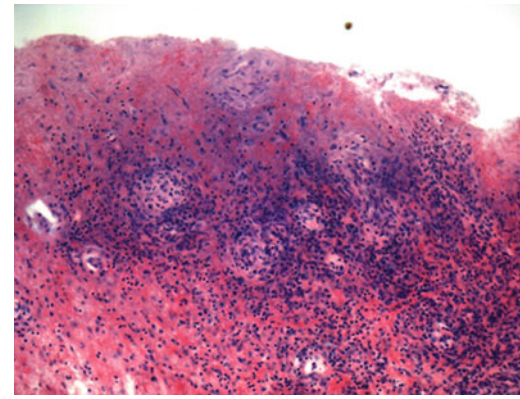

Fig. 6 Cholangitis tuberculosa ulcerosa. The wall of this bile duct is destroyed by tuberculous inflammation, leaving an ulcer covered with a necrotic matter. Deeper parts of the ulcer show several granulomas (hematoxylin and eosin stain)

one both the right hepatic duct and the common bile duct, one the hepatic duct, and two multiple strictures. Tuberculosis of the bile ducts can radiologically present with multiple flecked calcifications (Yu et al. 2004). The diagnosis can be confirmed by the finding of *M. tuberculosis* in bile duct by the use of PCR (Iwai et al. 2006) and by the histologic visualization of bile duct granulomas (Kotlar 1894). In one patient, stenosing biliary tuberculosis was associated with ampullary carcinoma (Chong et al. 2009), and tuberculosis can also involve the ampulla as an isolated lesion causing bile duct stenosis (Ricci et al. 2000). The coexistence of cancer and tuberculosis is not unexpected and occurs in several organs, probably owing to the fact that patients with tuberculosis are immunocompromised. Periampullary carcinoma has also been observed in coexistence with peripancreatic tuberculous lymphadenitis (Desai et al. 2004). The pathogenesis of bile duct tuberculosis has not been clarified in detail. Several pathogenic mechanisms have been proposed, including an infection of the duct mucosa from intraluminal bacteria eliminated from the liver ("Ausscheidungstuberkulose/excretory tuberculosis"; Lichtenstein 1912). Tuberculosis can also affect the gallbladder (Goyal et al. 1998; Gupta et al. 1998; Abu-Zidan and Zayat 1999; Banerjee and Sen 2003; Ruhl et al. 2003; Leong et al. 2011), an issue discussed

in another chapter. Macroscopically, the granulomatous and later fibrosing inflammation of the bile ducts is characterized by stenosis, strictures, and saccular dilatations (Abascal et al. 1988).

Selected References (Stemmerman 1941; Autio et al. 1963; Bergdahl and Boquist 1972; Gupta et al. 1985; Abascal et al. 1988; Bonnel et al. 1988; Fan et al. 1989; Ratanaparee and Pausawadi 1991; Bearer et al. 1996; Behera et al. 1997; Hickey et al. 1999; Kenneth et al. 1999; Kok and Yapp 1999a; Valeja et al. 1999; Yeh et al. 1999; Inal et al. 2000; Prasad and Pandey 2001; Alsawat and Aljebreen 2006; Iwai et al. 2006; Chong et al. 2009).

Bile Duct Perforation Due to Tuberculosis

Common bile duct perforations and fistula formation due to tuberculosis has mainly been observed in HIV-infected patients (Desta et al. 1998; Patino et al. 2003; Jarmin et al. 2004). Tuberculous fistulas may connect the bile duct with the duodenum (Patino et al. 2003) or with the small intestine (Desta et al. 1998).

Biliary Obstruction Due to Tuberculosis of Adjacent Organs

Tuberculous lymphadenitis, e.g., involving retropancreatic or periportal lymph nodes, can cause compression of the common bile duct and obstructive jaundice. The tuberculous lymph nodes may coalesce to form a multinodular mass that can mimic cancer of the pancreatic head. Sometimes, a single and markedly enlarged tuberculous lymph node situated posterior to the pancreatic head can result in perilymphadenitis, fistulation, and stenosis of the distal bile duct (Colovic et al. 2008). The resemblance to malignancy is furthered by the trend of these inflamed lymph nodes to adhere to adjacent structures, mimicking cancer invasion. Tuberculous lymph nodes, in the form of a coalesced mass, can compress the entire hepatic pedicle (Francillon et al. 1970). In tuberculous hepatic parenchymal disease, lymph nodes draining the liver and situated in the periportal area or the hepatoduodenal ligament may show enlargement due to granulomatous lymphadenitis and cause duct stenosis (Schmid 1957; Stanley et al. 1984; Mathieu et al. 1986; Pombo et al. 1990; Iglesias Castañon et al. 1995; Inal et al. 2000; Peyré et al. 2004; Kimura et al. 2005; Liew et al. 2011). The first case of periportal tuberculous lymphadenitis, causing obstructive jaundice in a child, had been reported in 1895 (Knight 1895). Tuberculous lymphadenitis has also been found to involve the cystic duct node (de Melo et al. 2004; Sidhu et al. 2007). Peritoneal tuberculosis may cause choledochal and duodenal stenosis (Paris et al. 1966).

Selected References (Päzolt 1968; Kohen and Altman 1973; Landa and Kravetskaia 1973; Jakab and Gönci 1974; Martinon and Aurousseau 1976; Murphy and Gray 1980; Alvarez and Carpio 1983; Lafay and Fouet 1983; Stanley et al. 1984; Mathieu et al. 1986; Arlandis Félix et al. 1990; Queralt et al. 1992; Arrese et al. 1997; Poon et al. 2001; Obama et al. 2003; Patino et al. 2003; Xia et al. 2003; Peyré et al. 2004; Saluja et al. 2007; Colovic et al. 2008).

The pancreas itself and/or the peripancreatic region can be involved by tuberculosis and lead to obstruction of the distal-most part of the common bile duct, mimicking malignancy of the pancreatic head (Queralt et al. 1992; Weiss et al. 2005; Foo et al. 2007). Tuberculosis can rarely involve the pancreatic substance itself and exert pressure on the traversing bile duct followed by obstructive jaundice (Crowson et al. 1984; Leborgne et al. 1989; Chen et al. 1999; Shan et al. 2000; Singh et al. 2002; Kumar et al. 2003). Pancreatic tuberculosis may spread to pancreas-associated lymph nodes and induce peripancreatic tuberculous lymphadenitis (Xia et al. 2003). Tuberculosis of the duodenum has been found to cause obstructive jaundice (Shah et al. 1991). Tuberculosis of the duodenum causes choledochoduodenal fistula and obstructive jaundice (Caudhary et al. 1989; Miyamoto et al. 2001).

Hepatic Fibrosis in Tuberculosis

The granulomatous response and associated portal tract inflammation can elicit diverse grades of liver fibrosis, ranging from simple portal tract fibrosis to incomplete and complete septal fibrosis, and eventual extensive fibrosis associated with hepatic remodeling/cirrhosis. Periportal fibrosis in hepatic tuberculosis is an observation already found in early literature (Lavenson and Karsner 1909). The advanced type of liver fibrosis with formation of nodular regenerative changes has either been termed cirrhosis or pseudocirrhosis (Egeli 1953). A peculiar type of liver fibrosis has been described in patients with *M. kansasii* infection (Listwan et al. 1975).

Silicotuberculosis of the Liver

Retropancreatic tuberculous lymphadenitis associated with lymph node silicosis has been shown to cause obstructive jaundice (Chassagnon and Silie 1966).

Liver Involvement in Generalized *Bacillus* Calmette-Guérin (BCG) Infection

Involvement of the liver in generalized BCG infection is a very rare disorder sometimes associated with so-called "BCGitis," mainly in children (Göttke et al. 2000; Karpelowsky et al. 2008; Li et al. 2010). An analysis of 830 pediatric autopsies in Canada revealed that 26 of the 36 infants given BCG vaccine shortly after birth exhibited tuberculoid granulomas in various organs, including the liver. In part of the cases, *M. bovis* BCG type could be isolated (Trevenen and Pagtakhan 1982). BCG as such is an invasive organism in immunocompromised organisms. In SCID mice having a severe T-cell defect, BCG bacteria caused hepatic parenchymal cell destruction in the absence of a protecting macrophage reaction (Mills et al. 2001).

Liver Involvement Following Intravesical *Bacillus* Calmette-Guérin Instillation

Intravesical instillation of BCG has been used as a therapy for superficial bladder cancer. Severe adverse reactions are uncommon in this treatment modality, but in rare instances, this treatment was complicated by disseminated BCG infection associated with sepsis, pancytopenia, abscess formation, mycotic aneurysms, hemolytic uremic syndrome, and multiorgan failure (Lamm et al. 1986). Clinical liver involvement with hepatomegaly and jaundice was sometimes found (Korac et al. 2009), and in some patients with this complication, granulomatous hepatitis was identified (Dederke et al. 1998; Hristea et al. 2007; Kaklamanos et al. 2011).

Microbiology of Tuberculosis

The genus *Mycobacterium* (M.) comprises more than 100 species and belongs to the family Mycobacteriaceae, suborder Corynebacterineae, and order Actinomycetales. One clinically relevant classification of mycobacterial species is based on the growth features of the bacteria. The *slowly growing group* (*generation time 6–24 h*) contains the *M. tuberculosis* complex (MTBC; *M. tuberculosis*, *M. bovis*, *M. bovis* BCG, *M. microti*, *M. africanum*, and others); the *M. avium* complex (MAC; *M. avium*, *M. paratuberculosis*, and others); the *M. gordonae* clade (*M. gordonae*, *M. asiaticum*); the *M. kansasii* clade (*M. kansasii*, *M. gastri*); and several other clades. The *group with intermediate growth rate* comprises *M. intermedium*. The *group of rapidly growing mycobacteria* (*generation time about 1–4 h*) contains numerous species grouped into several clades, of which some are human pathogens, e.g., *M. fortuitum*. Many mycobacterial species are currently ungrouped. Another classification of mycobacteria is based on the capability to synthesize carotenoid pigments in the presence or

absence of light. Photochromogens (group I; e.g., *M. kansasii*) have nonpigmented colonies in the dark and pigmented ones after light exposure. Scotochromogens (group II; e.g., *M. gordonae*, *M. scrofulaceum*) produce brisk yellow to orange colonies both in the dark and in the presence of light. Non-chromogens (groups III and IV; e.g., *M. tuberculosis*, *M. bovis*, *M. avium* intracellulare, *M. ulcerans*) only have a pale yellow or tan pigment that does not intensify following light exposure.

M. tuberculosis is a nonmotile aeorobic bacterium requiring high oxygen levels and is a member of a mycobacterial species group with a complex phylogeny (Hartmans et al. 2006). The bacterium, which had been detected by Robert Koch in 1882 (the reason why the agent is sometimes called, Koch's *bacillus*), possesses a wax-like coat containing mycolic acid, this coat rendering it impervious to Gram staining. The bacterium is therefore neither Gram-positive nor Gram-negative, i.e., the germ does not retain crystal violet or only to a very minor degree ("ghost bacteria"). The germ can be identified due to its acid-fast features in stains. The most commonly used stain is the Ziehl-Neelsen stain, other stains being Chen's modification of Ziehl-Neelsen stain (2012), modified Schaeffer and Fulton stain, Fite's stain, Kinyoun stain (1915; the "cold staining method," because it omits the heating step of the Ziehl-Neelsen stain), and the auramine O fluorescence method. Morphologically, *M. tuberculosis* is a fairly large thin rod 2–4 μm in length, often with a slightly curved and twisted shape. Following division, the two daughter bacteria may stick together for a short time at one end, resulting in a V-shaped structure. Smears from old in vitro colonies often reveal serpentine cords, caused by the expression of cord factor, a virulence factor already found by Robert Koch. Ultrastructurally, the bacterium contains and has a slightly irregular contour, sometimes rendering it finely "granular" or "beaded" in the Ziehl-Neelsen stain.

Leprosy: A Rare Cause of Large Hepatic Mass Lesions (Lepromas)

Introduction

Leprosy is an infectious disease caused by *Mycobacterium leprae* (review: Eichelmann et al. 2013). This multifaceted disorder is known since antiquity; Egyptian papyri dating back to 4000 BC make reference of the disease. Millions of persons with leprosy, and pejoratively called lepers, suffered a terrible destiny during thousands of years, being disfigured by skin nodules, loss of facial structures, deformation of limbs, and autoamputation caused by neuropathic sensory loss. It is well known that lepers were separated from society, had to announce themselves, e.g., by bells when underway, and were forced to live in specific buildings well outside cities and villages. It is estimated that, in the middle ages, 190,000 such leper hospitals and sanctuaries had been constructed in Europe. A review on some historical aspects is presented at the end of this chapter.

In the environment, *M. leprae* is present in certain mammals (e.g., the nine-banded armadillo), but the bacterium can also been taken up and stored in viable condition by free-living pathogenic amebas. Although the transmission mode has not been clarified, it is assumed that *M.leprae* is spread from person to person in respiratory droplets and by close contact. The probability of an infectious hit upon close contact varies considerably and seems to also depend on the infection dose, genetic background of hosts, and possibly on virulence. Incidence studies have shown that infection rates from contacts of lepromatous leprosy range from 6.2 per 1000 in Cebu (the Philippines) to 55.8 per 1000 per year in Southern India. The incubation period may be as short as few weeks and exceed 30 years. The entry rout of *M. leprae* is thought to be the skin and upper respiratory mucosae. Interaction of *M. leprae* with respiratory epithelial cells is mediated by a cell surface proteome of at least 11 potential adhesins. An important biological niche for *M. leprae* is the macrophage, where acid-fast bacilli can survive and proliferate, depending on the

host's immune defense. *M.leprae* can also invade other cell systems, whereby Schwann cells play a central role in lepric lesions of the peripheral nerve system (review: Polycarpou et al. 2013). *M. leprae* has a unique predilection for Schwann cells and employs distinct entry pathways to parasitize these cells. There is evidence that invasion of Schwann cells by *M. leprae* reprograms these cells to stem-like cells for promoting the dissemination of infection (Masaki et al. 2013). Invasion of Schwann cells is the main mechanism for the pathogenesis of the characteristic, mutilating neuropathy of leprosy (review: Rambukkana 2001).

Clinical Features

Clinically, leprosy is divided into two major forms of presentation, viz., the tuberculoid leprosy and the more malignant lepromatous (Virchowian) leprosy (Rabello 1937), a classification which reflects the host's defense reactions and illustrates opposite poles of the patient's response, i.e., efficient defense versus anergy (Ridley and Jopling 1966). An intermediate form, called borderline (dimorphous), develops in patients whose immune response is situated between the two major types. When leprosy is too early in stage or too mild for classification, it is called "indeterminate leprosy." Based on the Ridley-Jopling proposition, the principal groups employed now include tuberculoid, borderline tuberculoid, borderline, borderline lepromatous, and lepromatous leprosy. In tuberculoid leprosy, host defense is maximal, while in the polar form, lepromatous leprosy, it is minimal.

Another classification divides leprosy into multibacillary and paucibacillary groups, this classification determining the duration of treatment. Paucibacillary leprosy is characterized by one to five lesions and includes the tuberculoid and borderline tuberculoid forms (ICD-10 A30.1. A30.2). Multibacillary leprosy has usually more than five lesions and includes two Ridley-Jopling groups, i.e., midborderline or borderline (ICD-10 A30.3) and borderline lepromatous and lepromatous (ICD-10 A30.4, A30.5). These clinical presentation patterns are highly reflective of a Th1 (cell-mediated) or Th2 (humoral) immune response, respectively (Parkash 2009). There is also a humoral immune response in leprosy that leads to distinct inflammatory skin nodules, a condition termed erythema nodosum leprosum, a lesion that may result in nerve and organ damage (Voorend and Post 2013).

General Pathology of Leprosy

The first detailed descriptions of the pathology of leprosy were published in 1848 and 1895 (Danielssen and Boeck 1848; Hansen and Looft 1895). The histopathologic patterns in leprosy reflect the type and magnitude of the host's immune reactions directed against *M.leprae* and its antigens (Ridley and Jopling 1966; Turk and Waters 1969). Activation of the monocyte/macrophage system with formation of granulomas is, similar to tuberculosis, a hallmark of certain evolution stages of leprosy (Adams and Krahenbuhl 1996). In tuberculoid leprosy, the host displays near maximum resistance to the leprosy *bacillus*, and this is histologically seen in the presence of activated, epithelioid macrophages forming granulomas and a varying amount of lymphocytes, mainly of the T class. In these lesions, bacilli are typically not found, owing to the successful elimination of the germ. In the other polar form of leprosy, lepromatous (Virchowian) leprosy, cell-mediated immune reactions are deficient, allowing marked proliferation of *M.leprae* within the macrophage system. This results in the accumulation of enlarged and usually foamy (vacuolated) macrophages in involved tissues. Numerous acid-fast bacilli are detected in lepromatous leprosy, in contrast to the tuberculoid form (Mahlberg and Levis 2008). For the intermediate stages of leprosy, the bacterial load, lymphocyte responses, and recruitment and activation of the macrophage system correlate with the progression of disease. Apart from the skin and neural lesions, leprosy can involve mucosal surfaces and visceral organs, including the oral cavity/tongue (Bétourné et al. 1964) and the liver. In the liver,

lesions in general correspond in morphology to the skin infiltrates in lepromatous leprosy.

Hepatobiliary Manifestations

The spectrum of hepatic alterations caused by, or associated with, leprosy comprises nonspecific hepatomegaly, acute reactive (immune-mediated) hepatitis, granulomatous hepatitis, mass lesions (lepromas), fibrosis, cirrhosis, amyloidosis, fatty liver (mainly in patients with poor general health caused by leprosy), and drug-induced liver disease. Apart from the type of immune reaction and defense, and therefore the type of leprosy present, the probability of lepric liver lesions strongly depends on the efficiency and duration of treatment (Chen et al. 1976). The hepatic lesions occurring in leprosy have been reviewed (Browne 1964).

Granulomas

In tuberculoid leprosy, epithelioid cell granulomas have been detected in the liver in 1936 (Arning 1936). This visceral tuberculoid leprosy was first put in doubt, but the findings were subsequently confirmed (Campos and Molina 1950; Okada 1954; Verghese and Job 1965), also in puncture biopsy specimens of the liver (Okada 1954; Verghese and Job 1965). Among ten biopsied cases of tuberculoid leprosy, four showed paraportal granulomas, but only about 30 % of all the portal tracts were involved. The granulomas consisted of epithelioid cells and lymphocytes, but not of foamy cells, and no acid-fast bacilli were found. Rarely, granulomas were also observed in other areas of the liver. In addition to granulomas, small accumulations of non-epithelioid macrophages associated with lymphocytes and few neutrophils, but only very occasional plasma cells were noted in parenchyma (Sood and Grueber 1969). The latter lesions correspond to the so-called "retothel" nodules of older reports on tuberculosis and are focal immune reactions involving the macrophage-lymphocyte lineages (Hamperl 1953; Ringleb 1953). However, in a an autopsy study of 37 cases, no liver lesions were found in non-lepromatous cases (Desikan and Job 1968), and in an investigation of 21 more recent autopsies of tuberculoid leprosy, no leprous lesions were found in the liver, while biphasic leprous lesions may be found in borderline leprosy in several organs (Liu and Qiu 1984).

Lepromatous Lesions (Foamy Cells, Virchow Cells, Leprosy Cells)

It seems that most findings of significant liver lesions observed in leprosy are in patients with the lepromatous (Virchowian) form. In a study of 19 patients (11 lepromatous, five borderline, and three tuberculoid types) where puncture biopsies of the liver were performed and which is presented as an example well reflecting the situation, eight of 11 lepromatous patients showed numerous granulomas; in the borderline group, four out of five patients showed multiple hepatic granulomas, and also the tuberculoid cases showed granulomas (Verghese and Job 1965). There were histological differences as a function of the leprosy types. In lepromatous leprosy, the granulomas were usually in a paraportal position consisted of collections of foamy macrophages and lymphocytes. In fact, when one focuses on studies where lepromatous cases have been investigated, liver involvement is a rather frequent event in leprosy (Riecke 1928; Black and Denny 1936; Mitsuda and Ogawa 1937; Kean and Childress 1942; Fite et al. 1947; Ferrand 1954; Powell and Swan 1955; Battaglia 1960; Dogliotti and Fazio 1960; Bétourné et al. 1964; Garcia Perez et al. 1966; Desikan and Job 1968; Contreras and Val Bernal 1969; Sood and Grueber 1969; Agarwal et al. 1970; Bernard and Vazquez 1973; Chen et al. 1976; Kumar and Corder 1979; Liu and Qiu 1984; Azulay 1987; Ferrari et al. 2002; Singh et al. 2006). In 13 patients with lepromatous leprosy where liver biopsies had been performed, all 13 showed granulomatous involvement with accumulation of foamy cells and/or epithelioid cells.

Foamy cell lesions of the liver in lepromatous leprosy may be seen macroscopically as small yellowish foci that may render the liver surface spotty (von Bergmann1897). Histologically, the macrophages have a markedly vacuolated cytoplasm and small nuclei pushed to the periphery. Numerous acid-fast bacilli are found in the macrophages, where they are often arranged parallel in bundles. Bloated macrophages (foamy macrophages) are termed Virchow lepra cells. Older and markedly enlarged cells may contain so-called globi ("Keimkugeln"; "Zoogloea-Massen"; Wynne 1890; Storch 1897; Gurd 1911; Cowdry 1940), spherical fatty structures up to 100 μm in diameter containing masses of bacilli that replace most of the cytoplasm. Gurd (1911) was the first to recognize that the spherical spaces called globi were situated within the so-called lepra cells. The ballooned and often damaged macrophages contain a paranuclear clear space that contains compacted acid-fast bacilli (the globus), whereby the dark and compact inner part may be lobulated or show spikes ("cactus globi," Cowdry 1940). Between the bacterial accumulation and the peripheral border of the body, a halo may be present. After decay of the cell, the bacterial masses enter the extracellular space and form large acid-fast masses that may be phagocytosed by multinuclear giant cells.

In the borderline and tuberculoid cases, granulomas are small and composed of epithelioid cells, Langhans-type giant cells, and lymphocytes. In these two situations, no acid-fast bacilli were detected. In no case caseification was found. The granulomas occurring in lepromatous leprosy, characterized by foamy cells, were called "miliary lepromas" or foam cell granulomas (Bernard and Vazquez 1973; Chen et al. 1976). The very small hepatic granulomas arising in tuberculoid leprosy were almost always formed during exacerbation of the disease following a generalized spread, suggesting a macrophage-driven immune reaction, while in lepromatous leprosy, infected granulomas are the leading lesions. The diameter of lepromatous granulomas in portal tracts varied from 45 to 180 μm, and the granulomas were eccentrically placed in the portal tracts or involved the entire portal tract space. Eight of the 13 cases showed acid-fast bacilli in the granulomatous lesions and/or foamy cells (Sood and Grueber 1969). Among 75 autopsy cases, 64 cases (85.3 %) had leprous liver lesions, dominated by miliary lepromas consisting of bacilli-positive foamy macrophages and hyperplastic Kupffer cells with a foamy appearance and some bacilli in their cytoplasm. The miliary lepromas were mainly located in portal tracts or near the central veins (Liu and Qiu 1984). Leprosy can undergo so-called reactions (or acute exacerbation), caused by a change in the host's immune responses. In tuberculoid leprosy, reactions reveal reddening and elevation of skin lesions, new lesions, painful neuritis, and eventually the emergence of bacilli in lesions that were previously abacillary. In lepromatous leprosy, reactions are clinically characterized by bouts of high fever, enlargement and reddening of all lesions, an enormous increase in bacteria with bacillemia, and the emergence of new lesions. Liver histology in reaction states of lepromatous leprosy shows lepromatous lesions with foam cells, sometimes infiltrated by neutrophils, epithelioid granulomas, exudative lesions, and portal vasculitis in some cases (Patnaik et al. 1989). In a study of 30 patients of lepromatous leprosy in a state of reaction, hepatic involvement in the form of foam cell granulomas was observed in all, and 93.3 % of the cases exhibited the presence of acid-fast bacilli in the lesions (Zawar et al. 1983). Instead of fully developed granulomas, small hepatic accumulations of macrophages/Kupffer cells (sometimes only a few grouped cells) with a clear and vacuolated cytoplasm and numerous mycobacteria can be noted (Bétourné et al. 1964). Lepromatous patients who had the infection for shorter duration showed acid-fast bacilli in their Kupffer cells but lacked hepatic granulomas (review: Verghese and Job 1965). There may be transition forms that are difficult to classify in regard to bacterial load, because there are few reports of tuberculoid leprosy showing acid-fast bacilli in hepatic granulomas (Bru and Rollier 1957; Garcia Perez et al. 1966). In a study of 21 patients, it was shown that the prevalence of hepatic granulomas correlated with the cutaneous reactions in lepromatous leprosy, but the association was poor for

other stages of disease. Hepatic involvement varied with the severity of cutaneous infection and with the frequency and intensity of bacteremia. An estimated 1000–10,000 acid-fast bacilli/ml blood was required to induce the hepatic infiltrate (Chen et al. 1976).

Lepromatous Hepatic Mass Lesions (Lepromas; Leprosy Tumors)

Lepromas are large nodular lesions that occur in several organs in conjunction with lepromatous or histoid leprosy (Figs. 7 and 8). Apart from the skin, lepromas have been observed in the soft tissue, bone, tongue, and breast, where they can mimic primary malignancy or metastatic disease. Histologically, these masses chiefly consist of bacteria-containing macrophage accumulations with or without necrosis. There are relatively rare situations where lepromatous liver lesions coalesce to larger nodules or grow to tumor-like lesions, called leprosy pseudotumors or lepromas. Larger nodular lesions may be visualized by ultrasonography (Taneja et al. 1990). Abscess-like cavitations with numerous leprosy cells in the wall have been described (Arning 1884).

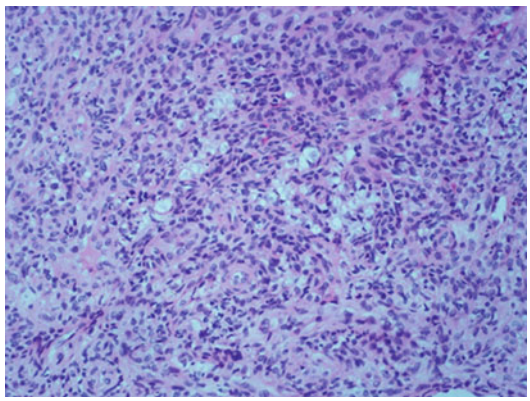

Fig. 7 Lepromatous lesion of the liver with a granulomatous reaction and several ballooned Hansen cells (hematoxylin and eosin stain)

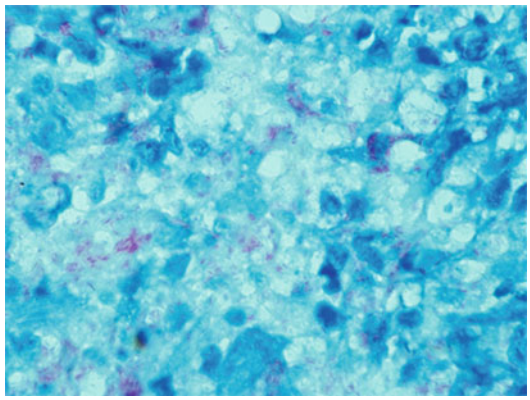

Fig. 8 Hepatic lepromatous lesion with numerous mycobacterial organisms (*red rods*). The large pale cells are Hansen cells (Ziehl-Neelsen stain for acid-fast organisms)

Liver Involvement in Lucio's Leprosy (Lazarine Leprosy)

Lucio's leprosy (diffuse leprosy of Lucio-Latapi, Lucio-Alvarado-Latapi form of leprosy, Mal de San Lazaro, diffuse lepromatous leprosy with erythema necroticans/Lucio's phenomenon, lepra manchada, "pretty leprosy," spotted or Lazarine leprosy) is an unusual manifestation of lepromatous leprosy that is or was mainly observed in Latin America, in particular Mexico (reviews: Wade 1949; Saul and Novales 1983; Diogenes et al. 2001; Kaur et al. 2005). It is a diffuse necrotizing or spotted type of leprosy originally reported in 1852 (Lucio and Alvarado 1852) and subsequently in 1948 (Latapi and Zamora 1948). Lucio's leprosy is often unmasked by a specific reactional state, the Lucio phenomenon, characterized by well-shaped erythematous spots which later become necrotic with ulcerations and later scars (Donner and Shively 1967; Moshella 1968), akin to type II lepra reaction. It is currently thought that Lucio's phenomenon, the hallmark of Lucio's leprosy, is caused by deposition of immune complexes (IC) in vessel walls, followed by IC-mediated vasculitis. In Lucio's leprosy, the skin histologically shows ulceration and necrosis of the upper layers, and beneath the necrotic area, there is an extensive inflammation of the dermis and the underlying subcutis, associated with proliferation of small blood vessels (angiogenesis), angiectasia, thrombosis of small vessels, and necrotizing vasculitis. Numerous vacuolated

macrophages containing large numbers of acid-fast bacilli are seen, and these bacilli may also be found in endothelial cells of damaged blood vessels (Vargas-Ocampo 2007). The distinct form of panvasculitis chiefly involves medium-sized arteries which histologically show necrosis, a granulomatous reaction, and clusters of intramural macrophages with large numbers of bacilli (Magaña et al. 2008). In one patient, liver biopsy disclosed multiple scattered granulomas distributed along portal tracts and within the lobules. Small epithelioid cell granulomas were in part located to dilated sinusoids, while larger granulomas appeared as coalescent lesions with Virchow-type foamy cells and numerous acid-fast bacilli (Kramarsky et al. 1968).

Liver Involvement in Histoid Leprosy (Wade's Histoid Variety of Lepromatous Leprosy)

Histoid leprosy is a rare variant of lepromatous leprosy with specific clinical, pathological, and bacteriological features. The disorder has been described in 1963 (Wade 1963) and is characterized by firm, reddish, skin-colored, dome-shaped, or oval papules and/or nodules (lepromas), with a translucent shiny and stretched overlying skin. Sometimes, sharply demarcated plaques are noted. Few to numerous (6–50) lesions may be found over the lower back, buttocks, face, and extremities. As these lesions protrude from the skin, a tumor-like appearance may result (Sehgal et al. 2009). Several reports have confirmed this entity (Mansfield 1969; Rodriguez 1969; Sehgal et al. 1987; Seghal and Srivastava 1988; Kalla et al. 2000; Pereyra et al. 2007; Kaur et al. 2009). Histoid leprosy is uncommon. Among 962 leprosy patients having attended the Hansen Clinic in New Delhi from June 2000 to June 2009, 11 cases were diagnosed as histoid leprosy (prevalence of 1.1.4 %; Mediratta et al. 2011). The disorder prevails in females, and most patients were between 16 and 35 years of age. Macroscopically, histoid lepromas are expansively growing, tumor-like lesions, in contrast to the infiltrative lesions in lepromatous leprosy (Wade 1963; Seghal and Srivastava 1987; Sehgal et al. 1987; Seghal and Srivastava 1988; Bakry and Attia 2012). Histologically, the lesions show numerous spindle-shaped histiocytes/macrophages forming interlacing bundles and bands or whorls. The cells show a vacuolated cytoplasm (Mansfield 1969), but much less than the foamy macrophages of lepromatous leprosy. The lesions contain numerous bacilli, which are detectable as needle-shaped negative images within macrophages/histiocytes in H&E-stained sections and are acid-fast in the Ziehl-Neelsen stain. Interestingly, many of these bacilli are longer than the usual leprosy bacilli seen in other lesions. These abnormally sized bacilli have been interpreted to be mutant forms resulting from the development of drug resistance (review: Seghal et al. 2009). Histoid leprosy may be the expression of an enhanced immune response to multibacillary disease, with an increase in both cell-mediated and humoral responses (Sehgal and Srivastava 1987).

Amyloidosis

Similar to other long-lasting infections and inflammatory disorders, leprosy can often be complicated by amyloidosis (Shuttleworth and Ross 1956; Garcia Perez et al. 1966). As in other forms of hepatic amyloidosis, the amyloid is localized to the spaces of Disse, associated with marked atrophy or destruction of hepatocyte plates (Garcia Perez et al. 1966). Amyloidosis is a frequent secondary change in chronic untreated or incompletely treated leprosy and is in fact the most common hepatic alteration in some studies. Among necropsies of leprosy patients, amyloidosis was detected in 38/89 cases (Hansen and Looft 1894), 17/50 cases (Powell and Swan 1955), 12/109 cases (Inaba 1940), 9/16 cases (Tilden 1945), and 14/60 cases (Bernard and Vazquez 1973).

Other Liver Alterations in Patients with Leprosy

Steatosis of the liver is seen in part of patients with leprosy. As in other individuals, the causes and morphology of liver steatosis are highly variable,

but small-droplet fatty change (microvesicular steatosis) seems to be a feature more common in leprosy (Singh et al. 2006). Significant hepatic steatosis was found in 4/12 biopsied cases, usually multifocal and in part of the microvesicular type (Garcia Perez et al. 1966). In an necropsy study of 60 leprosy patients, steatosis of the liver was noted in ten cases, three being massive (Bernard and Vazquez 1973). Peliosis hepatis has been observed in a patient with lepromatous leprosy (Furuta et al. 1982). Leprosy can elicit a form of immune-type (interstitial) hepatitis, which was detected in 9/12 biopsied patients in one series (Garcia Perez et al. 1966). In the quiescent stage of lepromatous leprosy of the liver, periportal and septal fibrosis as a fibrogenic end result of immune reactions (immune-mediated hepatitis) can develop, sometimes with hepatic remodeling or even cirrhosis. Among 75 autopsy cases with examination of the liver, formation of pseudolobules was found in three cases (Liu and Qiu 1984).

Locoregional Lymph Nodes of the Liver

Involvement of hepatic lymph nodes was always associated with lepromatous lesions of the liver (Liu and Qiu 1984). Whereas lymph nodes in tuberculoid leprosy may not show any alterations or then signs of immune stimulations, lymph nodes in lepromatous leprosy show epithelioid cell accumulations (also in the paracortex), epithelioid foam cells (sudanophilic Virchow cells), and microgranulomas, and acid-fast bacilli are detectable.

Historical Aspects of Leprosy

In the eighteenth century, a leading figure in leprosy research was the Norwegian Daniel Danielssen, the head of the Bergen leprosy hospital. Together with Carl Boeck, he published the work, On Leprosy, containing the hypothesis that leprosy was inherited rather than transmitted. In 1866, another Norwegian from Bergen (born 1841), Gerhard Henrik Armauer Hansen (1841–1912; Grzybowski et al. 2013), became the collaborator of Danielssen and worked in the Bergen Lundegaard Leper Hospital. Here he started to analyze the pathologic features of leprosy. In 1874, he published findings that completely changed the views one had on leprosy so far; he described ". . .in every leprous tubercle extirpated from a living individual. . .small staff-like bodies, much resembling bacteria, lying within cells; not in all, but in many of them." These organisms were *M. leprae*, and leprosy is often termed Hansen's disease in honor of Hansen's discovery. Hansen could not isolate the germ and fulfill Koch's postulates and failed to grow the bacterium on artificial media or in live rabbits. After autoinoculation experiments had not caused the disease in him and Danielssen, Hansen performed human experimentation in 1879 by cutting the eye of a female patient, without consent, with a cataract knife which just previously had been used to cut a nodule from a patient with lepromatous leprosy. Hansen was accused and found guilty for failure to obtain consent and lost his position (cited from Tan and Graham 2008). Leprosy in all its aspects was the issue of many reviews (Arnold and Fasal 1973; Scollard et al. 2006; Hussain 2007; Misch et al. 2010; Piris et al. 2010; Walsh et al. 2010; Rodrigues and Lockwood 2011).

Abstract

An invasive and aggressive hepatic infection of the hepatobiliary tract that can mimic malignancy is actinomycosis, caused by *Actinomyces* species. This severe bacterial infection can present in the form of several and distinct clinico-pathological phenotypes. The most common form is primary and secondary abscess-forming hepatic actinomycosis with solitary, multiple, or fistulating abscesses. Similar to other organs involved in this infection, hepatic abscesses may contain yellow bacterial colonies called "sulfur granules." *Actinomyces* infection of the liver can also cause mass-forming lesions and actinomycomas. The latter can resemble cholangiocarcinomas, because they sometimes occupy the hilar region of the liver. Chronic actinomycosis of the liver may result in a marked inflammatory reaction with granulation tissue and fibrosis, a lesion termed actinomycotic inflammatory pseudotumor.

Hepatobiliary Actinomycosis

Introduction

Actinomycosis (first described in 1878 by Israel) is an acute to chronic infectious disease characterized by abscess formation, invasiveness mimicking malignancy, draining sinuses, and subsequent fibrosis/scarring (review: Smego and Foglia 1998). It is caused by several species of the genus *Actinomyces*, encompassing a taxonomically heterogeneous collection of anaerobic and aerotolerant, nonspore-forming, nonacid-fast, Gram-positive rod-shaped organisms. Actinomycosis of the hepatobiliary tract is an important differential diagnostic issue in the setting of liver tumors, because this infection is known as the "great imitator" owing to its invasive features and its remarkably varied clinical presentation. Three main clinical types of actinomycosis are recognized, i.e., cervicofacial (the most common), thoracic, and abdominopelvic, hepatobiliary manifestations almost always occurring in conjunction with the abdominopelvic form. Actinomycosis causes a destructive inflammatory process with a sometimes impressive induration of the diffusely involved soft tissues (the so-called wood-like phlegmonous induration, the "ligneous phlegmon"). In chronic forms, the diagnosis may be difficult and thus delayed, sometimes with delays of months to years from onset of symptoms and signs to correct diagnosis. As specified in a later paragraph, the clinical entity of actinomycosis can be caused by other bacteria, specifically *Propionibacterium propionicum* (formerly, *Arachnia propionica*). In contrast, infections caused by *Nocardia* species do not closely mimic the typical presentation of actinomycosis.

Microbiology

Actinomyces is a bacterial genus of anaerobic to microaerophilic, Gram-positive non-motile microorganisms that do not form endospores. While individual *Actinomyces* bacteria are rod-shaped, their colonies form fungus-like branched networks of filaments that resemble fungal hyphae. Individual rods are straight or slightly bent, with a thickness of 0.2–0.3 μm. Taxonomically, *Actinomyces* belongs to the family *Actinomycetaceae*. This family also includes the genera *Actinobaculum*, *Arachnia*, *Arcanobacterium*, *Mobiluncus*, and *Varibaculum*. Recently, molecular taxonomy has added much to aid in the identification and classification of *Actinomyces*-like organisms, the recognition of novel species, and the elucidation of clinical phenotype-genospecies relationships (Goodfellow et al. 1999; Clarridge and Zhang 2002; Hall et al. 2003). Of all the known species and culture isolates not yet allocated to species, less than ten preferentially cause disease in humans, including *A. israelii*, *A. gerencseriae*, *A. naeslundii*, *A. odontolyticus*, *A. viscosus*, *A. massiliensis*, *A. meyeri*, and *A. gerencseriae* (Schaal and Lee 1992; Smego and Foglia 1998). However, *A. israelii* and *gerencseriae* remain the principal causative agents of actinomycosis (review: Hall 2008). *Actinomyces israelii* is an organism typically found in soil and in decaying organic matter including wet hay and straw, where a

microaerophilic environment prevails. The germ is also a commensal and normal inhabitant of the oropharynx. Apart from the oral cavity, this bacterium is also a member of the natural genital tract flora in mammals. *A. israelii* is common in women with intrauterine devices, and in fact 85 % of cases of pelvic actinomycosis, a rare infection, are in women with IUDs. A distinct partner of *Actinomyces*, *Actinobacillus actinomycetemcomitans* (the Latin adjective meaning "accompanying *Actinomyces*," the bacterium often accompanying *Actinomyces israelii*; Zambon 1985), now assigned to a novel genus name, *Aggregatibacter* (Norskov-Lauritsen and Kilian 2006), was first isolated from a cervicofacial actinomycotic lesion in 1912 and initially termed *Bacterium actinomycetemcomitans*. In 1921, the organism was referred to as *Bacterium comitans* by Lieske and finally named *Actinobacillus actinomycetemcomitans* in 1929. In a more recent study analyzing genotype diversity of *Actinomyces* species, *Actinomyces israelii* was in fact the only *Actinomyces* species co-isolated with *Aggregatibacter actinomycetemcomitans* (Clarridge and Zhang 2002). It is strongly associated with localized aggressive periodontitis (LAP) and adult periodontitis and is the causative agent for some severe systemic infections (Fives-Taylor et al. 2000). *Actinomyces* species associated with mucosal and dental surfaces are members of complex biofilms (Yeung 1999). Biofilms containing *Actinomyces* preferentially develop on surfaces with specific physical properties, such as teeth or, for *Actinomyces israelii*, intrauterine devices/IUDs. In the oral cavity, and specifically in dental plaques and the parodontal space, *Actinomyces* species exist in close association with other microorganisms, often in mutual dependence and as members of complex biofilms (review, Hall 2008). The oral biofilm is a complex microbial community comprising more than 700 bacterial species belonging to 11 divisions of phyla of which, however, about 50 % are known only by 16SrRNA gene sequences (so-called phylotypes; Siquera and Roças 2005). While *A. odontolyticus* dominates at the tongue surface, *A. naeslundii* genospecies 1 and 2 colonize plaque and buccal surfaces but with different patterns (Hallberg et al. 1998; Mager et al. 2003). In this biotope, they attach to tissue surfaces by means of fimbriae.

Actinomycosis of the Hepatobiliary Tract

Actinomycosis induces a whole spectrum of clinico-pathologic conditions in the liver and biliary tract (Table 1).

Actinomycosis of the Liver Proper

Several early reports have documented liver involvement in actinomycosis, which makes part of the abdominopelvic form out of four known clinical forms of actinomycosis. In fact, the liver was found to be involved in the first human cases of actinomycosis (Israel 1878). It is of interest to note that, only shortly after Israel's report, relatively numerous cases of hepatic actinomycosis were reported toward the end of the nineteenth century. Hepatic lesions are estimated to occur in about 15 % of cases of abdominal actinomycotic infections and in 5–20 % of all cases of actinomycosis. The liver is frequently reached via spread from abdominal infection, e.g., subsequent to appendiceal actinomycosis, colonic diverticular disease (Joshi et al. 2010), or uterine actinomycosis caused by long-standing intrauterine anticonceptive devices (Ramirez Sanchez et al. 1997; Tamsel et al. 2004), but apparently, primary hepatic actinomycosis in the absence of such an infection elsewhere has also been described (Meade 1980; Hisaoka et al. 1991; Lai et al. 2004). Hepatic actinomycosis has been

Table 1 Clinico-pathologic forms of hepatobiliary actinomycosis

Actinomycotic cholecystitis and pericholecystitis
Cystic stump actinomycosis
Common bile duct actinomycosis
Primary and secondary hepatic abscess-forming actinomycosis
Solid or tumorous/pseudotumorous actinomycosis
Actinomycotic inflammatory pseudotumor

suspected to have its starting point in periodontitis (Uehara et al. 2010). Hepatic actinomycosis very uncommonly occurs in the pediatric age group, where it may mimic a wide variety of diseases (Rabusin et al. 1996; Lin et al. 2001; Buyukavci et al. 2004). It was reported that only 4 out of 56 hepatic actinomycosis were pediatric cases (Sharma et al. 2002). Actinomycosis of the pediatric liver has been observed following other infections, e.g., varicella (Guven et al. 2008). Primary hepatic actinomycosis is caused by *A. israelii* and other common species causing actinomycosis, but unusual species such as *A. odontolyticus* have also been found to cause hepatic abscess (Chao et al. 2011).

Selected References Zemann 1883; Heller 1884; Grill 1895; Barth 1890; Baumgarten 1890; Taylor 1891; Koch 1894; Leith 1894; Grill 1895; Habel 1896; Abée 1897; Isemer 1878; Poncet and Bernard 1898; Litten 1900; Yamada et al. 1971; Mir et al. 1978; Chandarlapaty et al. 1975; Golematis et al. 1976; Mir et al. 1978; Miyamoto and Fang 1993; Tamsel et al. 2004; Schmeding et al. 2005; Chen et al. 2006; Braun et al. 2009; Cetinkaya et al. 2010; Kanellopoulou et al. 2010; Lall et al. 2010; Wang et al. 2012.

In the meta-analysis on 13 published cases of pseudotumoral hepatic actinomycosis by Lai and coworkers (Lai et al. 2004), the mean age of patients at presentation was 43 years, with a male preponderance. The most common presenting manifestations were fever, abdominal pain, and weight loss. Hepatomegaly was present in 38 %. Larger lesions may mimic liver tumors (Lange et al. 2009), and multiple lesions simulate hepatic metastatic disease (Kanellopoulou et al. 2010). The lesions were solitary in three and multiple in ten cases, with bilobar involvement in seven. Extension into the gallbladder or the common bile duct, and/or to surrounding organs, was a common finding. Due to the highly invasive features of actinomycosis, the process may fistulate through the abdominal wall (Saad and Moorman 2005), can be associated with, or cause, right-sided pleural empyema (Kocabay et al. 2006), and may penetrate through the diaphragm to invade the lung (Kasano et al. 1996; Islam et al. 2005). On CT images, hepatic actinomycosis presents as solitary or coalescing hypodense lesions (Boucenna and Arrivé 1999; Lakshmana Kumar et al. 2005), and MRI images revealed irregularly shaped, inhomogeneous, and hypointense lesions (Lange et al. 2009). The rather aggressive lesions may communicate among others and develop fistulation, also detectable in CT scans (Roesler and Wills 1986). Angioinvasive actinomycosis can induce portal vein occlusion (Cheng et al. 1989) and like this clinically resemble an aggressive cancer. Clinico-pathologically, actinomycosis of the liver proper can be divided into several phenotypes (Table 2).

Table 2 Clinico-pathologic phenotypes of actinomycosis occurring in the liver substance

Primary and secondary abscess-forming hepatic actinomycosis
Solitary abscess
Multiple abscesses
Fistulating abscesses
Solid/mass-forming hepatic actinomycosis (actinomycoma)
Actinomycotic inflammatory pseudotumor of the liver

Primary and Secondary Abscess-Forming Hepatic Actinomycosis

Actinomycosis of the liver substance proper can present as a solitary abscess or as multiple abscesses in up to half of the patients. Actinomycotic abscesses of the liver are found to be male predominant (70–97 %) with 30–50 years as the most common age group (Miyamoto and Fang 1993; Sugano et al. 1997; Sharma et al. 2002). The imaging presentation is that of space-occupying lesions (Meade 1980; Jacobs et al. 1981; Roesler and Wills 1986; Felekouras et al. 2004).

et al. 2004; Saad and Moorman 2005; Chen et al. 2006; Wong et al. 2006.

Solid/Mass-Forming Actinomycosis of the Liver (Hepatic Actinomycoma)

Hepatic actinomycosis can cause large hilar and/or intrahepatic tumor-like lesions mimicking cholangiocarcinoma and other liver malignancies and termed mass-forming actinomycosis, solid actinomycosis, actinomycoma, or actinomycosis with pseudocancerous features. One particularly detailed report summarized here as a typical example refers to a 42-year-old patient having a solid space-occupying lesion in the right liver lobe. Due to suspected cholangiocarcinoma, the mass was resected. The liver specimen showed a huge tumor-like mass with a nodularly structured periphery and a yellowish cut surface. The lesion had extended beyond the organ's limits and had infiltrated the diaphragm and the abdominal wall. The histology was typical for actinomycosis, most of the mass being necrotic tissue and abscesses. In another patient, isolated actinomycosis of the liver also involving large bile ducts was manifest at necropsy in the form of firm and yellowish tumoral nodes, of the size of duck's eggs. The cut surface disclosed several yellow foci. The process had invaded the liver substance and followed the intrahepatic periductal tissue, including here a nodular, firm sheath having caused biliary stenosis (Schmeding et al. 2005).

Actinomycotic Inflammatory Pseudotumor of the Liver

Cases of hepatobiliary inflammatory pseudotumor caused by *Actinomyces* have been reported, sometimes presenting as a mass of more than 10 cm diameter and again mimicking liver malignancy (Kim et al. 2007). Histologically, there is an overlap between the tumor-like lesions described in the previous paragraph and actinomycotic inflammatory pseudotumors; hence, they might be lumped together. In a meta-analysis of 13 published cases of pseudotumoral hepatic actinomycosis (Lai et al. 2004), the average age of patients at diagnosis was 43 years, with a male preponderance. The most common presenting manifestations were fever, abdominal pain, and weight loss. Hepatomegaly was present in 38 %. The lesions were solitary in three and multiple in ten cases, with bilobar involvement in seven. Extension into the gallbladder or the common bile duct, and/or to surrounding organs, was a common finding. In one instance, a mixed infection was found in the lesion, i.e., *Actinomyces* associated with *Bacteroides caccae* (White et al. 1997).

Macroscopic Pathology

The morphology of hepatic actinomycosis is highly variable. Already Israel described multiple miliary-like foci in the liver substance (Israel 1878). But the solitary or multiple necroinflammatory lesions produced in hepatic actinomycosis may grow to impressive size, sometimes via formation of conglomerate masses, as outlined in the previous paragraph. Macroscopically, small to large nodular lesions induced by *Actinomyces* infection are yellowish-gray to

hemorrhagic and friable masses, which sometimes present as a typical abscess. The cut surface may bulge and reveal a variegated texture, with friable masses of necrotic and massively infiltrated tissue. Langhans noted the interesting finding that large actinomycomas may show, on their cut surface, a microalveolar-like texture in some way reminiscent of alveolar echinococcosis or of lung tissue, with numerous densely packed abscesses (Langhans 1888). This honeycomb-like structure of the cut surface has been confirmed in a subset of cases (Diehl 1911; Tiling 1912; Roth 1921). It was also noted that the abscess cavities may be arranged in a particular way, forming branching structures (Langhans 1888). When performing necropsies of patients with liver actinomycosis, Langhans noted that notwithstanding hot ambient temperature, autolysis was unusually delayed, what he suspected to be caused by an "antiseptic" action of *Actinomyces* (Langhans 1888). This suggestion is of some actuality insofar as members of *Actinomycetales* are now known to produce an array of antibiotic agents. Large actinomycomas may be associated with smaller lesions ("satellites") in their vicinity (Diehl 1911). In case of portal vein invasion, hematogenous spread starting from infected and puriform venous thrombi results in disseminated liver abscesses (Kramer 1911; Diehl 1911). Involvement of the portal had previously been documented at necropsy. One patient described by Israel (1878) showed actinomycotic pus flowing off the opened portal vein which also contained infectious thrombi. The shape of actinomycotic abscesses and large actinomycomas ranges from almost spherical lesions, usually in case of smaller abscesses, to irregularly delineated masses resembling a necrotic malignant tumor, and to ill-defined or ramified lesions, the ramification pattern thought to reflect the architecture of large intrahepatic veins (Israel 1878; Abée 1897; Diehl 1911). The abscesses may bulge from the organ's surface ("tuberous actinomycosis"). Peripheral masses may form umbilication of the hepatic capsular area, similar to tumor metastases (Tiling 1912). Macroscopically, the purulent material of actinomycotic abscesses was described as unusually thick and viscid, and more transparent than common pus, greenish in color, and with a foul odor (Langhans 1888). A striking green color of the actinomycotic pus was also noted by another author of an early documentation of actinomycosis, Habel (1896). The commonly aggressive lesions of actinomycosis may communicate among each other and develop fistulations, also detectable in CT scans (Roesler and Wills 1986).

In the purulent material, sulfur granules typical but not pathognomonic for actinomycosis can be identified. The color of these granules is in fact often brightly yellow or golden, as the term "sulfur" suggests (Diehl 1911), but the granules, which consist of bacterial radiating colonies admixed with debris, exudate proteins, and leukocytes, are sometimes dark or even greenish-blackish (Israel 1885; Askanazy 1913). In his later work on human actinomycosis, Israel described the granules as highly variable in color, ranging from colorless or sago-like to brightly yellow, green-yellow, dark green to sepia brown (Israel 1885). He noted that the granules were firmer than pus (he compares them to sebum particles) and could, therefore, easily be taken out from pus by use of a needle's tip. The granules were most numerous in the grayish-red and viscid pus that was obtained by applying pressure on the abscess (the so-called pus crudum of the historical medicine), i.e., the older and compact pus sticking to the abscess capsule, whereas the granules were rarer in the more liquid pus spontaneously flowing off the incised lesions. This finding of an outstanding clinical observer has a modern pathophysiological facet, as it is known that growth of *Actinomyces* can occur under microaerophilic conditions, which may prevail only in certain regions of an abscess, e.g., between central and peripheral parts rather than in the center with its toxic neutrophil products or the periphery, where oxygenation by the granulation tissue is stronger. Israel also observed that, when he let actinomycotic pus flow over a glass plate, the grains stuck to this surface (Israel 1878), suggesting distinct adhesion properties of the bacterium required for biofilm formation. By the use of low magnification, Israel recognized that, under gentle pressure under the cover slide, the

granules had a central brownish-yellow, slightly glistening core surrounded by a dark ring composed of leukocytes with fatty change suspended between long and tortuous bacterial filaments. In his later work on human actinomycosis, Israel described the granules as highly variable in color, ranging from colorless or sago-like to brightly yellow, green-yellow, dark green to sepia brown, yellow being more common with small grains and darker color with grains of increasing diameter (Israel 1878, 1885). Langhans described the granules as clearly black in one of his cases of hepatic actinomycosis but noted that the color faded in alcohol (Langhans 1888). The latter author observed that most of the small abscess cavities contained one granule, but purulent lesions with two or three granules were also encountered. He reported that, at higher magnification, the granules are speckled, with the blackish color being restricted to certain areas of the granules. Langhans, as an excellent observer, saw that subsequent to spreading of the pus with a knife, the granules were separated from the pus by a transparent zone. I presume that this zone corresponds to the macroscopic aspect of what has later been described as the Splendore-Hoeppli phenomenon (see below). The granules may better be visualized by running sterile water or saline over the gauze used to cover a lesion: the water washes away the purulent material leaving the granules on the gauze.

Why are sulfur granules pigmented? *Actinomyces* species are known to produce colored agents, including yellow substances (the yellow *Actinomyces* group), melanin-like or melanoid pigments, iron-containing green pigments, and colored antibiotics (flavofungins, flaveolins, flavacid), also rendering *Actinomyces* cultures pigmented, colors ranging from creamy pinkish, yellowish to gray-violet or even dark gray (Naidenova and Vladimirova 2000). The distinct microstructure of sulfur granules is caused, apart from the microbial growth pattern, by the distinct surface structure of *Actinomyces*, the cell surface showing a dense array of hair-like fimbriae protruding through a thick fuzzy surface coat (Figdor and Davies 1997). Noninfectious pseudoactinomycotic radiate granules (PAMRAGs) can mimic actinomycotic sulfur granules (Pritt et al. 2006).

Histopathology

Histologically, the abscesses consist of a purulent exudate which is peripherally demarcated by a rim of granulation tissue. The adjacent tissue commonly contains increased numbers of macrophages and plasma cells. Granules suspended in the pus contain the characteristic Gram-positive branched filaments that also form the interior part of the microbial drusen grossly seen as sulfur granules. The microbial core of the granules is visualized by Gram stains, modified Fite-Faraco stain, or Grocott's hexamine-silver stain. The Gram-positive filamentous branching rods show peripheral clubbing. The granules are sometimes associated with the Splendore-Hoeppli phenomenon (Fig. 1).

The Splendore-Hoeppli phenomenon denotes eosinophilic, pseudomycotic structures composed of necrotic debris, granulocyte proteins, and immunoglobulins forming a characteristic radiating structure, the "rays" consisting of eosinophilic or amphophilic rods of variable length (see above; Hamann et al. 1989; Rodig and Dorfman 2001). Some of the sulfur granules exhibit a corona of

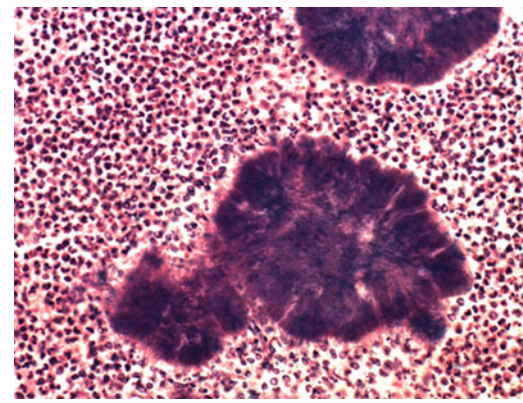

Fig. 1 Actinomycosis of the liver. Basophilic microbial drusen, macroscopically visible as sulfur granules, float within a purulent exudate. The periphery of the granules shows a thin rim of eosinophilic club-shaped bodies. This is the Splendore-Hoeppli phenomenon (hematoxylin and eosin stain)

neutrophil granulocytes, sometimes separated from the more compact pus of the abscess by a slit-like artifact. Fistulation of actinomycotic abscesses of the liver may result in destructive mine-like conduits which can reach the bile ducts or medium-sized to large hepatic veins, followed by mycotic thrombosis.

Auxiliary Methods for the Identification of *Actinomyces* in Tissues

The specific identification of bacteria with a filamentous morphology can be difficult, particularly for Gram-positive bacteria growing in the form of threads or long chains. In situ hybridization employing DNA probes directed against the variable regions of 16S ribosomal RNA genes of *Actinomyces* is a rapid and specific technique also suitable for culture-negative or clinically difficult cases of infection (Isotalo et al. 2009).

Actinomycosis of the Extrahepatic and Intrahepatic Bile Ducts

Relatively few cases of actinomycosis have been observed in the common bile duct (Kühn and Fleischer 1974; Hadley et al. 1981; Bledsoe et al. 2008; Thadani et al. 2010), intrahepatic ducts (Jung et al. 2005), and the cystic duct (Ormsby et al. 1998). Actinomycosis of the common bile duct ranging from the pancreatic head to the porta hepatis was diagnosed in one patient by the use of endoscopic ultrasound (EUS) fine-needle aspiration. EUS showed a heterogeneous isoechoic mass abutting the portal vein and the common bile duct (Thadani et al. 2010). Actinomycosis of the common bile duct can masquerade as cholecystitis. In a 56-year-old male patient with epigastric pain and fever, oral cholecystography failed to visualize the gallbladder, and intravenous cholangiography revealed a 10 mm common bile duct without visualization of the gallbladder. At cholecystectomy, operative cholangiography disclosed a persistent filling defect in the distal common bile duct. Choledochoscopy showed a firm, frond-like mass attached to the mucosal surface of the common bile duct, and histology exhibited actinomycosis, culturally confirmed to be caused by *Actinomyces israelii* (Hadley et al. 1981). Actinomycosis of the extrahepatic bile ducts can cause cholecystocholedochal fistulas (Bledsoe et al. 2008). Actinomycosis of intrahepatic bile ducts was found in association with hepatolithiasis (Jung et al. 2005).

Actinomycosis of the Gallbladder Bed, the Pericholecystic Space, and the Cystic Stump

Actinomyces naeslundii infection of the cystic stump has been reported (Ormsby et al. 1998). In this patient, stump actinomycosis emerged after a complicated history of fistulating cholecystitis. Abdominal and retroperitoneal actinomycotic abscesses can occur after laparoscopic cholecystectomy, again with infection with *A. naeslundii* (Vyas et al. 2007). Interestingly, such complications are sometimes related to retained/dropped gallstones (Ramia et al. 2004), raising the question whether gallstones might form an adhesive surface for *Actinomycetes*.

Hepatic Actinomycosis Caused by *Propionibacterium* (Arachnia) *propionicum*

Arachnia was originally identified as a propionic acid-producing *Actinomyces*-like microorganism (*Actinomyces propionicus*). Arachnia propionica was shown to be related to propionibacteria (Propionibacterium Orla-Jensen 1909) and has been renamed *Propionibacterium propionicum* (Summanen 1993). *P. propionicum* can cause an infection which clinically and morphologically resembles actinomycosis proper (Brock et al. 1973). The organism has been isolated from hepatic abscesses occurring in disseminated

Propionibacterium-type actinomycosis (Garcia-Martos et al. 1992).

Differential Diagnosis

Microbial drusen or granules can be produced by the growth of microorganisms other than *Actinomyces* species. In botryomycosis, *Staphylococcus aureus* has been shown to produce granules in the tissue, with an eosinophilic rim at the periphery and being Gram-positive (see the respective chapter). As this morphology resembles actinomycosis grains, these alterations have been proposed to be called granular bacteriosis on descriptive terms (Waisman 1962; Tomb et al. 2009). The Grocott stain is helpful in these settings, as actinomycotic colonies are Grocott-positive but not colonies seen in botryomycosis.

The Detection of *Actinomyces* and of the Distinct Sulfur Granules: A Historical Résumé

The index species of the known species, *A. israelii*, is named after James Adolf Israel (1848–1926, born in Berlin), one of the leading kidney surgeons of his time, who also made several important contributions to maxillofacial surgery (Bloch 1983; Knöner and Schultheiss 2003). After having studied medicine in Berlin, he went to Vienna, where he became a resident in the surgery division of the Jewish Community Hospital, a division headed by the famous surgeon, Bernhard von Langenbeck. Interested in antisepsis, he worked for a while with Joseph Lister in Edinburgh. In 1877, Israel detected yellowish grains in the pus of certain chronic abscesses, the later sulfur granules. In his work of 1878 (published in Virchows Archiv, Israel 1878), he personally illustrated the microscopic features of these unique grains, characterized by filamentous microorganisms (interpreted to be a mycosis by him), forming colonies which are called "drusen" in German (in mineralogy, a "druse" is an incrustation of small crystals on the surface of a rock or mineral; the term was used to denote the radial structure of the bacterial colonies owing to the resemblance with such crystalline formations). On Israel's published drawings, one microbial colony already clearly shows a distinct radial symmetrical corona with terminal club-shaped structures, a feature later described as Splendore-Hoeppli phenomenon (for details, see the chapter on botryomycosis). Based on their striking yellow color, the grains are termed sulfur granules. Sulfur granules have, however, already been documented about 30 years earlier, in fact not referred to in texts on actinomycosis. In the appendix to Israel's seminal publication of 1878, Israel mentions that the surgeon von Langenbeck had already seen in 1845 similar grains located in a vertebral abscess examined in Kiel. He cites von Langenbeck's report in its complete version, and it is remarkable to note that the surgeon's description of the objects clearly represents what has later been described by Israel (in the original German text: "Dem ziemlich dünnen, übelriechenden Eiter sind rundliche, gelblich aussehende Körperchen von der Grösse von Mohnsamenkörnern in grosser Menge beigemischt. Unter dem Deckgläschen leicht comprimiert zeigte sich jedes Klümpchen aus feinen, cylindrischen, radienartig aneinander geordneten Stäbchen von sehr regelmässiger Gestalt und ziemlich konstanter Grösse zusammengesetzt " [Admixed to the rather thin and foul-smelling pus are numerous spherical, yellowish-looking bodies of the size of poppy seeds. Gently compressed beneath a cover slid, each globule is seen to be composed of thin, cylindrical, ray-like arranged rodlets of very regular shape and rather constant size]). We owe to the recognition by von Langenbeck of these "ray-like rodlets" the terminological roots for *Actinomyces*, the "ray-like fungus." Are sulfur granules seen in all forms of actinomycosis ? In a detailed study, clear-cut sulfur granules were only detected in infections caused by *A. israelii* and *A. meyeri* (Clarridge and Zhang 2002), but it may be assumed that other species may produce similar microbial colonies.

Hepatobiliary Nocardiosis

Introduction

Nocardiosis is a mixed suppurative and granulomatous inflammatory disease caused by numerous species of the Gram-positive bacterium genus, *Nocardia*. The majority of infections are caused by the *N. asteroides* complex which includes *N. asteroides* sensu stricto, *N. farcinica*, and *N. nova*. The first human infection with *Nocardia* was reported in 1924.

Microbiology

Nocardia is an aerobic Gram-positive member of the family *Nocardiaceae* within the order *Actinomycetales*. There are currently more than 30 species of nocardiae of human clinical significance, and current molecular taxonomy approaches will augment this number in the future (Brown-Elliott et al. 2006). The optimal growth of *Nocardia* in tissues requires iron, which is accumulated by nocardial siderophores. *N. brasiliensis* produces the siderophore brasilibactin A, a membrane-bound siderophore with structural similarity to the mycobactin class of siderophores in mycobacteria.

Epidemiology and Main Clinical Phenotypes

Human *Nocardia* infections are rare, with an estimated incidence in the USA of 1,000 cases per year. Nocardiosis is in principle an opportunistic infection mainly described in immunocompromised individuals, although several cases have been described in immunocompetent hosts (Harris 1980; Beaman and Beaman 1994; Lederman and Crum 2004; Filice 2005). In a retrospective study covering the years 1997–2003, all patients had active comorbidities at the time of infection (Munoz et al. 2007). In organ transplant recipients, receipt of high-dose steroids, history of cytomegalovirus disease, and high levels of calcineurin inhibitors were found to be independent risk factors for *Nocardia* infection (Peleg et al. 2007). Nocardiosis is an infection complicating chronic granulomatous disease (Bassiri-Jahromi and Doostkam 2011). The respiratory tract is the most commonly involved system, followed by CNS and cutaneous infections and, less commonly, other sites. Skin infections are divided into three types, i.e., nocardial mycetoma/actinomycetoma, localized cutaneous nocardiosis, and a type typically associated with painful locoregional lymphadenopathy, the lymphocutaneous type of nocardiosis (reviews: Harris 1980; Kalb et al. 1985; Lerner 1996; Saubolle and Sussland 2003; Wilson 2012).

Hepatobiliary Nocardiosis

Nocardia species (e.g., *N. asteroides* and *N. brasiliensis*) have been reported to cause liver abscesses (Pretet et al. 1979; Salfield et al. 1983; Cockerill et al. 1984; Roman et al. 1991; Ramseyer and Nguyen 1993; Elliott et al. 1997; Benes et al. 2003; Nakahara et al. 2011). The hepatic lesions may radiologically resemble amebic abscess (Pretet et al. 1979). Liver abscess caused by *N. farcinica* has been observed in patient following multivisceral transplantation (Wiesmayr et al. 2005). In one patient with nocardiosis, multiple liver abscesses developed in association with Crohn's disease treated with infliximab (Nakahara et al. 2011). In addition to abscesses, focal collections of granulomas forming multiple small hypodense lesions on CT images may develop (Akan et al. 1998).

Pathology

Macroscopically, liver abscesses in nocardiosis do not show the features described for actinomycosis. The lesions rather resemble abscesses caused by bacterial infections than actinomycetomas (see the respective paragraph). Histologically, a fibrinopurulent exudate with a marked peripheral macrophage and plasma cell reaction prevails, encircled by a granulation tissue, but often without granuloma formation. In the Gram stain, the

organism is visualized as clusters of short, beaded, variably Gram-positive, sinuous non-branching rods within the suppurative areas. The organisms stain red purple in the Ziehl-Neelsen stain. Depending on the immune reaction of the host, hepatic nocardiosis can also present in the form of a granulomatous hepatitis (Akan et al. 1998), sometimes with conglomerates of granulomas that form multiple liver masses resembling metastatic disease.

Differential Diagnosis

The main differential diagnosis consists of other purulent focal lesions of the liver containing filamentous Gram-positive bacterial elements, in particular actinomycosis and infections with *Candida albicans*.

Botryomycosis and Botryomycomas

Introduction

Botryomycosis is characterized by a chronic, suppurative, more or less granulating (not granulomatous, as it is sometimes stated) bacterial-induced but not fungal inflammation in which the specific feature is the presence of fungus-like grains or granules (microbial drusen) which contain, unlike actinomycosis, non-branching bacteria (Winslow 1959; Greenblatt et al. 1964). These grains are called Bollinger grains (not to be confounded with Bollinger bodies, which are cellular inclusion bodies occurring in avian pox/fowl pox and containing fowl pox virus). Botryomycosis is named after the Greek word "botrys," meaning "bunch of grapes," and mycosis because of the initially supposed fungal origin of the disease. Synonyms of the disorder include bacterial pseudomycosis (Greenblatt et al. 1964), staphylococcic actinophytosis (Berger et al. 1936), granular bacteriosis (Waisman 1962; Tomb et al. 2009), and actinobacillosis (Beaver and Thompson 1933).

Botryomycosis was first described in 1870 in a horse with a pulmonary infection then thought to be a true mycosis (Bollinger 1870). Otto Bollinger (1843–1909) was a German pathologist considered to be one of the founders of comparative pathology. In 1876, he also discovered actinomycosis in cattle. The term, botryomycosis, was coined 14 years after Bollinger's description by Rivolta under the impression that it was caused by a true fungus, based on observations on botryomycotic lesions in stallions after castration (Rivolta 1884). Botryomycosis has formerly also been termed the "champignon de castration," because of original descriptions of this disease after castration in horses (Finegold et al. 1978). The first human case of botryomycosis was published in 1910 (Archibald 1910). In 1913, Opie published the first report of a human case of botryomycosis in the USA, which was also the first account of liver involvement (Opie 1913). Botryomycoma has to be separated from telangiectatic granuloma. Telangiectatic granuloma was previously described under the term human botryomycosis by Poncet and Dor in 1879, but in 1899, Sabrazès and Laubie denied a relation with botryomycosis and created the name telangiectatic granuloma (cited in Hagedoorn 1934). Botryomycosis was originally thought to be caused by fungus-like organisms, and several now obsolete terms were employed to denote putative causative agents, including Zoogloea pulmonis equi (Bollinger 1870) and Dyscomyces equi (Rivolta 1884).

Microbiology

Botryomycosis can be caused by a wide range of bacteria, but *Staphylococcus aureus*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Neisseria mucosa*, and certain fungi are particularly important causes. Rarer etiologies include *Propionibacterium acnes*, *Serratia marcescens*, *Moraxella nonliquefaciens*, and fusobacteria. The pathogenesis of this unique tissue reaction is still unknown, but low-virulent strains of bacteria together with a distinct immune reaction of the host are discussed. In early animal experiments done in the French Pasteur Institute, it was shown that the number of microorganisms inoculated

into healthy test animals was critical to induce botryomycosis. Very high and very low concentrations of bacteria were not effective, whereas intermediate concentrations resulted in granules as seen in human botryomycosis (Magrou 1919).

Hepatobiliary Botryomycosis and Botryomycoma of the Liver

Botryomycosis is known to involve visceral organs and has been reported for the liver (Opie 1913; Beaver and Thompson 1933; Fink 1941; Schlossberg et al. 1980, 1988; Omar and Cooper 1995). In the liver, botryomycosis can present as a sometimes huge hepatic abscess, as described in the first report on hepatic botryomycosis (Opie 1913). Staphylococcus as the causative agent of hepatic botryomycosis was first reported in 1941 (Fink 1941). In one patient, abdominal CT showed multiple low-density nodular lesions ("botryomycomas") throughout the liver, measuring up to few cm in size (Schlossberg et al. 1998). Densely placed lesions may coalesce, and fistula formation may develop. The botryomycotic lesions can induce obstructive jaundice (Bagby and Gunning 1978) and have sometimes been misinterpreted as malignancy, including hepatocellular carcinoma (Omar and Cooper 1995). Histology shows purulent inflammation, sometimes presenting as an active abscess, demarcated by a granulation tissue of variable thickness, and in the exudate, different kinds of bacteria may be detectable by the use of special stains or microbial culture. Between the exudate rich in intact and decaying neutrophils and the granulation tissue, varying amounts of macrophages, including foamy cells, are in evidence, and even a pseudoxanthomatous reaction may ensue in disease of longer-standing duration. Bollinger bodies may be directly visualized in the purulent exudate, but they can more easily be recognized in wet mounts subsequent to clarification of the tissue by means of 10 % potassium hydroxide (KOH) treatment followed by examination with polarized light. Similar to botryomycosis in other locations, hepatic botryomycosis may show the Splendore-Hoeppli phenomenon associated with Bollinger granules (Schlossberg et al. 1998; case of streptococcal botryomycosis of the liver). The liver tissue adjacent to botryomycomas is atrophic, and scattered leukocytes are seen in the perifocal sinusoids and also in portal tracts situated in the vicinity of the lesions.

Pathology of Botryomycosis

Bollinger grains, an eponym linked to the discoverer of botryomycosis (see above), are small, yellowish to white granules in mulberry-like masses, usually with a diameter of 1–3 mm, hence visible with the naked eye. The granules consist of intact and decaying leukocytes (mostly granulocytes) and are rich in non-branching bacteria, which may form a radiate pattern and therefore representing so-called microbial drusen. Histologically, Bollinger granules resemble pseudoactinomycotic radiate granules (PAMRAGs) found in the lower female genital tract (Bhagavan et al. 1982). Instead of white to yellow Bollinger granules, botryomycosis may sometimes show granules that are red (so-called red grain botryomycosis), caused by *Actinomadura pelletieri* (Gerber 1971) and *Actinomadura vinacea* (Maiti et al. 2003). In *Actinomadura*-induced red grain botryomycosis, the red color of the bacterial drusen is caused by synthesis of prodigiosin, an antibiotically active red pyrrole alkaloid of the prodigiosin-roseophilin family (Gerber 1971; Bennett and Bentley 2000; Fürstner 2003). Red grain botryomycosis has also been observed in a *Staphylococcus aureus*-induced lesion (Katkar et al. 2009). Prodigiosins and roseophilins can also be synthesized by cocci, e.g., *Streptococcus* species (Kawasaki et al. 2008).

Splendore-Hoeppli Phenomenon

The bacterial colonies may be encircled by a distinct hyaline, eosinophilic corona with a radial symmetry, the Splendore-Hoeppli phenomenon. This phenomenon is named for the two scientists who described it in 1908 and 1932, respectively. In 1908, Splendore described in human tissues

what he regarded as a new species of *Sporotrichum*, and he named this structure "*Sporotrichum asteroides*" (aster, star) owing to the star-like configuration of the coating around it (Splendore 1908). In 1912, de Beurmann and Gougerot reexamined Splendore's material and listed the "germ" in their work on sporotrichosis under the name "*Sporotrichum beurmanni* variété asteroides" (De Beurmann and Gougerot 1912). Almost 25 years later, Hoeppli reported the same phenomenon seen around schistosomal ova in rabbit tissues but made no reference to Splendore's observations (Hoeppli 1932). The occurrence of clubs and knobby or smooth shells formed around microorganisms was reported by Meyer in 1934 (Meyer 1934). The Splendore-Hoeppli phenomenon is also termed pseudoactinomycotic radiate granules, radiate granules, actinophytosis, pseudo-sulfur granules, Splendore-Hoeppli radiate reaction, and pseudoactinomycotic sulfur granules, sulfur granules being reserved for actinomycosis proper (Padberg et al. 2002). Actinophytosis is a term that has to be rejected, because it signifies a lesion characterized by ray formation produced by any microorganism, and it may be confounded with actinomycosis (Winslow 1959). The latter author, in his seminal work on botryomycosis, has referred to the occurrence of "clubs" and knobby or smooth shells which form around microorganisms in certain cases of botryomycosis, with deposition of an eosinophilic and safranophilic material, without referring to the reports of Splendore and Hoeppli, but cites works describing clubbing in actinomycosis going back to 1925 (Winslow 1959). Histologically, the phenomenon is characterized by an eosinophilic to amphophilic material composed of hyaline rods of variable length (sometimes with slight peripheral clubbing) arranged in ray-like fashion around deposits of microbes, parasite/parasite eggs, or foreign material (Hussein 2008). The inner zone of the material contains diastase-resistant PAS-positive, safranophilic material and lipids and is acid-fast and autofluorescent. The outer zone is less reactive to stains and is not autofluorescent (Johnson 1976). Electron microscopically, the material shows signs of protein precipitation and exhibits a fibrillary material suggesting the presence of fibrin (Padberg et al. 2002). It is thought that Splendore-Hoeppli phenomenon represents a distinct type of antigen-antibody reaction with local activation of the complement cascade and of coagulation factors. The Splendore-Hoeppli phenomenon is not unique to botryomycosis but can be seen in actinomycosis, mycetoma, phycomycosis, coccidioidomycosis, sporotrichosis, and even around foreign bodies, including intrauterine devices and silk sutures.

It has been suggested that the granule-associated Splendore-Hoeppli phenomenon, with a hyaline matrix rich in IgG and complement C3, may be associated with maximum host reactivity through antigen-antibody interaction (Williams et al. 1969).

Tumor-Like Lesions of the Hepatobiliary Tract: Granulomatous Masses in Syphilis, Brucellosis, and Cat-Scratch Disease

129

Contents

Abstract

Venereal syphilis caused by *Treponema pallidum* induces a complex spectrum of lesions in the hepatobiliary tract, ranging from a distinct fibrosing disease in connatal syphilis to gummatous hepatitis in adult patients. Early syphilis of the liver is characterized by syphilitic hepatitis, a disorder well known in patients with HIV infection. In later stages of the infection, i.e., in tertiary syphilis, hepatic mass lesions can develop. These include syphilomas and gummas. The latter are macroscopic inflammatory lesions of a firm consistence, an irregular rather than spherical shape, and a geographic pattern on cut surfaces. Mass lesions of the liver can also occur in brucellosis. These lesions are spherical, may have a diameter of more than 5 cm, and are characterized by central necrosis, several layers of granulomatous inflammatory reaction, and a peripheral fibrous demarcation. Necrotic and inflammatory nodular lesions with a granulomatous reaction in the liver also occur in cat-scratch disease.

Syphilis and Hepatic Gummas

Introduction

Venereal syphilis (lues) is a complex infectious disease caused by the spirochete *Treponema pallidum* (reviews: Singh and Romanowski

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_129

1999; Antal et al. 2002; LaFond and Lukehart 2006; Lee and Kinghorn 2008).

Treponema is a helical spirochete that belongs to the family *Spirochaetaceae*, order *Spirochaetales*. *Primary syphilis* is the stage of infection when the bacterium penetrates surfaces of mucosae or microabrased skin, this first contact resulting in a lesion called chancre, a painless and later indurated ulcer at the inoculation site. As *T. pallidum* is a highly invasive organism, it spreads already at the primary stage of disease to numerous tissues and organs. Within 3 months of primary infection, manifestations of this spread in the form of a multisystem disorder are in evidence, the *secondary syphilis*. The manifestations of secondary syphilis appear in the form of a characteristic rash, initially roseolar or macular, long-standing lesions then becoming papular or even nodular. In rare situations, the skin lesions become necrotic, a condition termed lues maligna. After this stage of disease, patients enter latent syphilis. Latent syphilis is a form of the disorder that is diagnosed serologically, at least in the asymptomatic phases of this stage. Early latent syphilis, occurring within the first 2 years after infection, is asymptomatic. Late latent syphilis is either asymptomatic or symptomatic. In about one-third of patients having late latent syphilis, symptomatic disease develops. This is also called *tertiary syphilis*.

Epidemiology

Syphilis remains a very common infectious disease. Humans are the only source of *T. pallidum* infection; there are no known nonhuman reservoirs. The WHO estimates that there are 12 million new cases of syphilis per year worldwide. Social disruption, poverty, and changing sexual behaviors have contributed to the sometimes epidemical increase of infections. Also the incidence of congenital syphilis is increasing in many resource-restricted countries.

Liver Involvement in Syphilis

In the course of syphilitic infection, liver involvement occurs in three distinct periods, i.e., congenital (usually transplacental) infection, in the secondary period when treponemes reach the liver via the portal venous blood within a few weeks to a few months after the initial chancre, and in the tertiary (symptomatic latent) period, when after a variably latency interval, manifestations of late syphilis such as gummas develop. Syphilis can induce a broad array of hepatobiliary diseases including hepatitis. Visceral and specifically hepatic manifestations are variable and may mimic several other disorders; this is the reason why this infection has been termed by Sir William Osler, the great imitator (of other diseases; Witkowski and Parish 2002).

Syphilitic Hepatitis

Syphilitic hepatitis is a typical manifestation of early (secondary) syphilis, owing to the spread of numerous viable spirochetes during this stage of disease. Syphilitic hepatitis is common among HIV-infected individuals (Lynn and Lightman 2004; Crum-Cianflone et al. 2009). Among a total of 62 HIV-infected patients with early syphilis, 19.3 % demonstrated abnormal liver enzymes consistent with syphilitic hepatitis (Manavi et al. 2012). Another investigation on 100 HIV-infected patients with acute syphilis revealed 19 patients with laboratory parameters of liver involvement (Jung et al. 2012). Studies with higher incidences of hepatitis in HIV-infected patients with early syphilis have been reported, e.g., 38 % (Crum-Cianflone et al. 2009). Syphilitic hepatitis was also detected after liver transplantation (Camara et al. 2007).

Selected References Baker et al. 1971; Sherlock 1971; Sobel and Wolf 1972; Bhowmick et al. 1975; Feher et al. 1975; Hanchard et al. 1978; Campisi and Whitcomb 1979; Roge et al. 1979; Tiliakos et al. 1980; Agrawal et al. 1982; Echard et al. 1982; Keisler et al. 1982; Petersen et al. 1983; Perrin et al. 1985; Vas et al. 1985; Veerahu 1985; Fischer et al. 1986; Rampal et al. 1986; Archambeaud-Mouveroux et al. 1987; Bukharovich et al. 1989;

Granicki et al. 1990; Relvas et al. 1992; Young et al. 1992; Gschwantler et al. 1996.

Symptomatic syphilitic hepatitis with or without cholestasis is a well-recognized, albeit uncommon complication of early/secondary syphilis (Hahn 1943; Parker 1972; Morrison et al. 1980; Archambeaud-Mouveroux et al. 1987; Schossberg 1987; Young et al. 1992). Cholestatic forms of syphilitic hepatitis are well recognized (Kim et al. 2010), and the cholestasis is sometimes severe ("Icterus syphiliticus praecox"; Michael 1914; Fuhs and Weltmann 1922; Ridruejo et al. 2004) and jaundice marked (Icterus gravis syphiliticus; Wile and Karshner 1917). Already the famous clinician, F. Parkes Weber, described a severely jaundiced patient with secondary syphilis (disseminated lobular necrosis of the liver with jaundice/hepar necroticum cum ictero of Curschmann and Oertel; Weber 1909), relating his observations to a publication of Oertel (1906). Syphilitic hepatitis is usually characterized biochemically by a markedly increased ALP and a minor increase in the aminotransferases. However, syphilitic hepatitis can rarely also result in fulminant hepatic failure (Lo et al. 2007). Histologically, one notes a usually mild lymphohistiocytic portal tract inflammation, sometimes associated with vacuolization and regenerative changes in the interlobular bile duct epithelium. It has been reported that *Treponema* is detectable in the liver lesion in 70 % of the patients (Buschke and Fischer 1905; Jozsa et al. 1977).

Hepatic Mass Lesions in Syphilis: Gummas and Syphilomas

Tertiary syphilis is, in contrast to the preantibiotic era, a rather rare disease, although, e.g., more than 25,000 cases of primary or secondary syphilis are diagnosed annually in the United States. In the early- to mid-twentieth century, the liver was regarded as the commonest internal organ to harbor a syphilitic gumma (Rolleston and McNee 1929), although the clinical diagnosis of hepatic gumma was rarely made in this time period (Tucker and Dexter 1946; Neuner 1950; Nicol and Terry 1951; Viranuvatti and Kochaseni 1953; Ito et al. 1963). The frequency of tertiary liver involvement in syphilis (identified at necropsy as hepar lobatum) as based on necropsies is given in the literature as 0.45 % (66 cases among 14,561 autopsies performed between 1908 and 1941; Hahn 1943) and 0.42 % (102 cases among 23,792 autopsies; Symmers and Spain 1946) and was found to be 0.3–1.5 % of cases in a nonselected autopsy series (Kellock and Laird 1956). Due to the less efficient diagnostic techniques available those days, it is thought that many of the commonly silent gummatous liver lesions were not detected in living patients (Shapiro and Weiner 1951). The more potent treatment measures available have caused tertiary liver syphilis to be a rare disease, but the rapidly increasing frequency of syphilis in certain regions of the world is expected to cause more of these lesions in the future.

Gummatous Syphilis of the Liver

Gummatous syphilis of the liver (hepatitis gummosa), a visceral manifestation of tertiary syphilis, is characterized by the development of solitary or multiple luic gummas in the liver substance.

Selected References McRae and Caven 1926; Hahn 1943; Symmers and Spain 1946; Shapiro and Weiner 1951; Viranuvatti and Kochaseni 1953; Kellock and Laird 1956; de Gouveia et al. 1961; Gencsi 1962; Ito et al. 1963; Salembier 1967; Parnis 1975; Naveau et al. 1982; Shapiro and Gale 1987; Cronin et al. 1987; Fischbach et al. 1991; Dämmrich et al. 1992; Rossi et al. 1992; Maincent et al. 1997; Peeters et al. 2005; Chen et al. 2008.

Tertiary liver involvement was found at postmortem examinations in 4.9 % of 1,165 adults suffering from syphilis at any stage (Hahn 1943), in 16 % for another series of 314 patients with tertiary syphilis (Symmers and Spain 1946), and in 0.3–1.5 % of cases in a nonselected necropsy series (Kellock and Laird 1956). Hepatic gummas

have also been recognized in congenital syphilis (Whitehouse and Macfarlane 1958; Debré et al. 1962), a currently resurgent disorder (Dobson 2004; Walker and Walker 2007), although congenital gummatous hepatitis was identified to be an exceptional finding in an extensive compilation on congenital syphilis (Nabarro 1954), and was not found in a study on 22 children with this disease (Flegel 1951). In adult patients, these mass lesions may cause differential diagnostic difficulties in relation to suspected malignancy, in particular multinodular metastatic disease (Rampal et al. 1986; Fischbach et al. 1991; Maincent et al. 1997; Shim 2010). On CT, gummas have a low-density appearance with slight peripheral enhancement upon contrast (Fischbach et al. 1991; Dämmrich et al. 1992). In contrast to tuberculosis, calcifications are seldom seen (Alergant 1956; Rampal et al. 1986; Shapiro and Gale 1987). The presence of several or numerous luic/syphilitic lesions in tertiary syphilis can result in syphilitic multinodular liver that may mimic malignancy (Gruber 1930; Alergant 1956; Rampal et al. 1986). Sclerogummatous hepatitis in syphilis may be associated with amyloidosis (Naveau et al. 1982). Upon successful treatment, liver gummas leave a small scar on CT scans (Peeters et al. 2005).

The gummas are usually firm nodes of irregular rather than spherical shape that are situated within the liver substance, close to the hilar area, or in the subcapsular compartment. They can reach a diameter of 2.5 cm or more (Maincent et al. 1997). The cut surface is either homogeneous gray to gray reddish or with a geographic pattern (reviewed by Gruber 1930). Gummatous lesions may develop along the intrahepatic bile ducts (pericholangitis gummosa) or along the intrahepatic portal vein branches (peripylephlebitis gummosa). Sometimes, the process involves the inner parts of venous walls (Chiari's endophlebitis luica hepatica), causing venous obliteration (endophlebitis hepatica obliterans). In the portal venous system, an obliterative sclerosing process with vein atrophy may ensue (pylephlebosclerosis). Gummas located close to the liver surface may be associated with fibrosing perihepatitis, fibrosis of Glisson's capsule (Nicol and Terry 1951), and fibrous adhesions between the liver and adjacent organs. Gummas can also be associated with syphilitic artery disease (endarteritis and mesoarteritis luica hepatica). Liver shrinkage/atrophy caused by gummous lesions can elicit a marked compensatory hypertrophy/hyperplasia of the liver substance (Reinecke 1898; Schorr 1907).

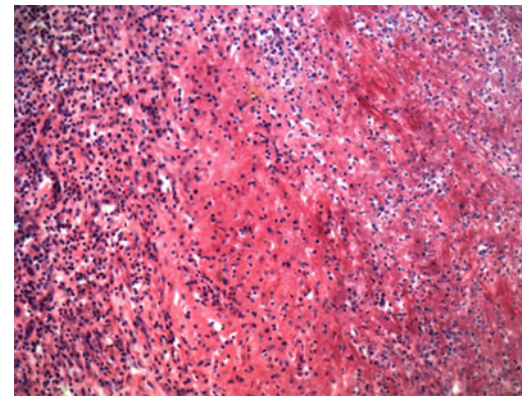

Fig. 1 Gumma in hepatic syphilis. The *right* of the figure shows necrosis with nuclear debris. In the *middle*, fresh eosinophilic necrosis is noted, however without associated granulomas. The *left* part shows fibrosing granulation tissue (hematoxylin and eosin stain)

Histologically, hepatic gummas show a central necrosis with a usually still preserved reticulin fiber network (Fig. 1). The necrosis is sometimes described in the literature as caseous, but close examination will uncover certain differences, mainly a lack of the numerous nuclear debris typically found in tuberculosis. At the border of the lesions, a granulomatous reaction is seen, commonly in the form of a band of loosely arranged epithelioid cells with confluent small and sometimes blurred granulomas. Langhans-type giant cells are rare (Binder 1904). A cellular infiltrate of variable density forms the interface to scarred zone surrounding the gumma. Around small vessels there is sometimes a lymphocytic and plasmacellular infiltration suggesting vasculitis. The adjacent liver tissue may show lymphocytic portal tract infiltration (accompanying portal hepatitis; similar to what is seen in secondary syphilis).

Typically, and in contrast to early syphilis, gummas contain morphologically detectable spirochetes in 0–5 % of cases only. Within the same liver, the entire spectrum of gummatous lesions may be found, ranging from cellular lesions (so-called active gumma or syphiloma) with poor fibrosis, to markedly fibrosclerosed nodules (sclerogummas). The centripetal sclerosis (or scarring) of gummas leads to retraction of the liver substance, the pathogenic mechanism leading to hepar lobatum (Nicol and Terry 1951; Cronin et al. 1987; Peeters et al. 2005). Grossly, hepar lobatum is characterized by a coarse nodular deformation of the organ with usually deep furrows between the lobe-like parts of the liver substance caused by the retracting scars. The resulting picture may mimic metastatic disease. On the other hand, metastatic carcinoma itself may cause hepar lobatum owing to stromal reactions of scarring necroses (Klinge and Ormann 1988; Gravel et al. 1996), also after chemotherapy (hepar lobatum carcinomatosum; Chin et al. 1987; Qizilbash et al. 1987; Uhlmann et al. 1996). In situations where only one liver lobe is involved, the contralateral liver lobe may undergo compensatory hypertrophy, resulting in the atrophy/hypertrophy complex. Scarring lesions close to the liver hilum can comprise the portal vein and cause portal hypertension (Berthelot et al. 1964), sometimes with formation of portal vein cavernoma (Hunt 1961).

Hepatic Syphilomas

The term, syphiloma, has been coined by Wagner in the nineteenth century (Wagner 1864) to denote focal lesions different from gummas. Miliary syphilomas have chiefly been observed in patients with congenital syphilis. These lesions are commonly associated with hepatomegaly, a firm liver, and sometimes with fibrous perihepatitis, this capsular fibrosis containing stainable spirochetes. Syphilomas are grossly ill defined and small yellowish to gray lesions which may seldom reach the size of a pea, but commonly show the size of a milium (hence the term, miliary syphilomas). The smallest lesions have been compared to semolina grains (grains de semoule; Gubler 1852). They are sometimes diffusely scattered through the liver. Superficial syphilomas may bulge through the liver capsule (Gruber 1930). Owing to their color, syphilomas are easily recognizable against the darker color of the parenchyma. Miliary syphilomas are histologically characterized by a central, non-caseous necrosis containing remnants of hepatocytes (with fatty change, causing the grossly yellowish color of the lesions; Fig. 2) and usually showing nests of stainable spirochetes, the bacteria being visibly damaged in the center of the lesion in comparison with microorganisms in the periphery (Gruber 1930). The necrotic foci are either surrounded by a dense granulocyte reaction (so-called abscess-like miliary syphilomas; Müller 1883; Aschoff 1903) or one notes an epithelioid cell reaction or even a granulomatous reaction around the necrosis (miliary granuloma or miliary gumma; Gruber 1930), this granulomatous form usually lacking multinucleated Langhans-type giant cells. Miliary syphilomas are commonly located within the lobules and are preferentially situated close to the terminal veins (Gruber 1930). Syphilomas may form confluent grapelike clusters surrounded by fibroblastoid granulation tissue. Hepatic syphilomas developing in congenital syphilis may contain numerous spirochetes (see below).

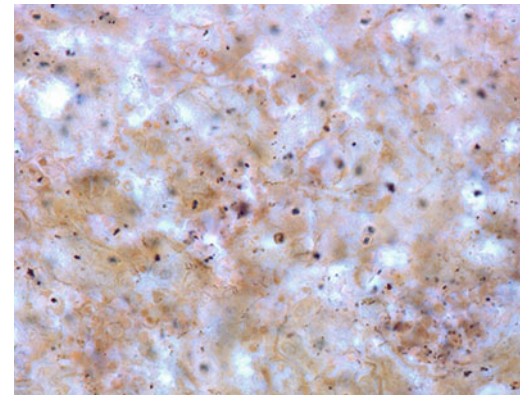

Fig. 2 Syphiloma of the liver. Within a background of necrosis, few *Treponema* organisms are seen (thin waved rods of dark color; Warthin-Starry stain)

Hepatic Pseudotumors in Syphilis of the Liver

Inflammatory pseudotumor of the liver has been observed in secondary syphilis (Mahto et al. 2006). Gummatous syphilis of the liver is seldom associated with peliosis hepatis and has been found to cause tumor-like lesions (peliosis hepatis pseudotumor) of several cm size (Chen et al. 2008).

Syphilis of the Bile Duct System

Rarely, syphilitic gummata may develop along the biliary tract and cause biliary obstruction (gummous cholangiopathy; Rolleston 1907; Edwards and Weir 1964). Syphilitic gumma of the pancreas may involve the most distal part of the common bile duct (Lelong et al. 1952). Gummous lesions can involve the gallbladder (cholecystitis luica gummosa). In early syphilis, *Treponemas* may colonize vascular structures in hepatic portal tracts and are thought to induce a vasculitis followed by epithelial damage of small bile ducts and ductules (Romeu et al. 1980). This process can end up with non-syndromic small duct ductopenia. Bile duct paucity has been found in a 2-week-old girl with congenital syphilis. She presented with jaundice and hepatosplenomegaly and has a high titer of IgM antibody to *Treponema pallidum*. The patient died of respiratory failure and autopsy showed syncytial giant cell hepatitis and paucity of small intrahepatic bile duct, associated with marked ductular proliferation (Sugiura et al. 1988).

Brucellosis and Brucelloma

Introduction

Brucellosis is a zoonotic disease caused by intracellular bacteria of the genus *Brucella* (reviews: Pappas et al. 2005; Ficht 2010). Regions where brucellosis is endemic are the Mediterranean basin, the Middle East, Russia, Mongolia, Latin America, the Caribbean, and Mexico. Brucellosis in humans is characterized by a greatly varied clinical image, and the course of the disease may be acute, subacute, or chronic. Patients often present with a febrile illness, in part of the patients associated with organ involvement, including severe liver disease. The infection in humans is mainly observed in specifically exposed persons, such as veterinarians, veterinary technicians, insemination service employees, zoo technicians, farmers working on multi-herd farms, slaughterhouse employees, and persons working in meat, milk, or fur processing enterprises (Galinska and Zagorski 2013).

The cause of Malta fever was identified by the Scottish military physician, bacteriologist, and pathologist, David Bruce (1855–1931), during his stay in the Valetta Hospital in Malta. Bruce was impressed by Robert Koch's discovery of the tubercle bacillus and decided to investigate Malta fever which affected many soldiers of the British garrison. Late in 1886 he found, by means of a purchased microscope, enormous numbers of single, gentian violet-positive and Gram-negative micrococci in the spleen of a fatally ill patient. Bruce inoculated three monkeys with the organisms cultured in peptone broth, and 16 days later one monkey's temperature rose to 41 centigrades and the animal died. From several inoculated monkeys, the organism could be cultivated in pure culture, hence fulfilling Koch's criteria (Bruce 1887; 1888). The genus *Brucella* belongs to the alpha2 subdivision of proteobacteria, together with *Ochrobactrum*, *Rhizobium*, *Rhodobacter*, *Agrobacterium*, *Bartonella*, and *Rickettsia*. Transmission of *Brucella* species to the human host occurs through the consumption of infected, unpasteurized milk products, through contact with infected animal parts and through the inhalation of *Brucella*-containing aerosolized particles. Brucellosis is also an occupational disease (shepherds, abattoir workers, dairy-industry professionals). *Brucellae* can enter the human host via the oral and respiratory tracts and can also penetrate the mucous membranes covering the conjunctiva and vagina as well as non-damaged skin, similar to *Leptospira* pathogens. On surfaces in the environment and in the host, *Brucella* produces complex populations, including biofilms,

subject to quorum sensing. After invasion of mucosal surfaces, phagocytes (mainly macrophages) ingest the organisms. Most of the ingested *Brucellae* are killed, but 15–30 % survived in gradually evolving *Brucella*-containing compartments. These surviving organisms proliferate within the macrophage system without affecting host cell integrity. In macrophages, *Brucella* dwells in a parasitophorous vacuole derived from membranes of the endoplasmic reticulum of the host cells via subversion of the host's cell secretory pathway.

Clinical Features

Brucellar infection is a disease of protean manifestations, but fever is invariably present (spiking, relapsing, or protracted). Malodorous perspiration is regarded as almost pathognomonic. Lymphadenopathy, hepatomegaly, and splenomegaly are frequently present. The most common complication of brucellosis is inflammatory osteoarticular disease (mainly peripheral arthritis, sacroiliitis, and spondylitis). The second most common site of focal brucellosis is the reproductive system (epididymoorchitis). Brucellosis during pregnancy is characterized by invasion of the trophoblast by *Brucella* and confers a significant risk of abortion. Hepatitis is common, but mass-producing lesions (see below) are rare. Involvement of the central nervous system (neurobrucellosis) occurs in 5–7 % of cases. Endocarditis (mainly of the aortic valve) is the main cause of mortality. As the organism tends to persist in the macrophage system, long-lasting infection is a well-recognized feature of brucellosis. *Brucella* DNA load persists for years after clinical cure (Vrioni et al. 2008). Relapses, at a rate of about 10 %, usually occur in the first year after infection and are often milder than the initial disease.

Tumor-like Liver Involvement in Brucellosis: Hepatic Brucelloma

Hepatic brucellar lesions (abscesses and necroses) are a manifestation of chronic hepatosplenic brucellosis (Ariza et al. 2001; Shouval 2010). No distinction is usually made in the literature between small multifocal hepatosplenic abscesses, detected rather in acute brucellosis, and larger lesions that are usually caseiform necroses with calcification. Small purulent lesions can develop in relatively early phases of brucellosis already, chiefly in severe infection with multiple visceral manifestations. However, mass-producing (pseudotumoral) caseiform necroses with calcification typical for brucellosis of the liver usually emerge in chronic infection. These pseudotumoral brucellar lesions are now termed brucelloma. The term, hepatic brucelloma, had been coined by Davion and coworkers in 1987 who reviewed 14 cases from the literature and added an own observation (Davion et al. 1987). Previously, brucelloma has been described under a wide range of terms (pseudotumoral brucellar caseous necrosis of the liver; chronic hepatosplenic suppurative brucellosis; caseiform necrotizing brucellar hepatitis; hepatic brucellar abscess; necrotizing hepatic granulomatosis; brucellar caseiform hepatic abscess), based on numerous old and recent published observations, the first report probably dating from 1957 (Spink 1957), followed by numerous other observations. Hepatic brucelloma is known to be caused by *Brucella melitensis*, but similar lesions have also been observed in conjunction with *Brucella* suis infection (Spink 1957; Paton et al. 2001). The delay between the primary infection and the diagnosis of brucellomas ranges between few months and more than 40 years (Davion et al. 1987). Clinically, liver brucellomas may be latent lesions, detected during laparotomy for other reasons or in context with abdominal imaging. It can also be the cause of fever, malaise and abdominal discomfort, and pain. In a review of 14 cases, abdominal pain was present in 8 cases (Davion et al. 1987). Hepatomegaly due to larger lesions has been reported. Imaging studies revealed that the lesions are single in about two-thirds and multiple in one-third of the cases. With ultrasonography, the lesions are iso- or hypoechoic with respect to the surrounding parenchyma and have poorly defined borders. Some lesions contain multiple, small anechoic areas (Meloni et al. 2008). In

Fig. 3 Tumor-like manifestation of hepatic brucellosis (brucelloma). The encapsulated lesion displays central laminated and partially calcified necrosis and concentric layers of inflammation

contrast-enhanced CT, brucellomas are predominantly solid with irregular borders, and the majority are hypodense with the liver. A constant finding is the presence of hypodense solid areas and/or tiny cystic areas separated by fine or thick enhancing trabeculations (Arcomano et al. 1977; Pons et al. 1981; Cosme et al. 2001; Sisteron et al. 2002; Ruiz Carazo et al. 2005; Chourmouzi et al. 2009). A unique type of calcification in the necrotic foci is typical for hepatic brucelloma and occurs in 80–100 % of reported cases (Williams and Hara 1967; Bastin et al. 1973; Arcomano et al. 1977; Pons et al. 1981; Ruiz Carazo et al. 2005; Ennibi et al. 2010). They may be single or multiple, sometimes exceeding 1 cm in size. Their shape varies from flocculant densities to crescent-like structures or a dense central calcification surrounded by one or several concentric halos.

Small and early hepatic brucellar lesions are either single or multiple abscess-like foci, sometimes with a red rim reflecting active hyperemia or grossly resemble miliar lesions of tuberculosis. Brucelloma is circumscribed tumor-like lesion with a diameter of 1 cm to several cm (Fig. 3). In hepatic resection specimens, peripheral brucellomas situated close to the liver capsule may be associated with marked capsular thickening and fibrosing perihepatitis, eventually with formation of a whitish firm plaque resembling so-called pseudocartilaginous perihepatitis. The cut surface of large brucellomas has highly characteristic features. The center of the mass is commonly occupied by a white to yellowish-gray necrosis, with accumulation of a crumbling, "cloudy," and friable material that is rather sharply demarcated and tends to bulge. However, this type of necrosis is not creamy white and sticky as in tuberculous caseification necrosis. Surrounding this central necrosis, one notes a striking sequence of circular complete or incomplete lamellae of yellowish to reddish-brown color, likely to reflect the growing phases of the lesion, and also clearly seen at imaging. In some cases, the mass contains grossly visible hemorrhages. Flocculent or crescent-shaped calcifications are found, and sometimes calcification is extensive, not permitting to cut

the mass with a knife before decalcification. Large brucellomas may be surrounded by satellite nodules of variable size.

In brucelloma, a purulent inflammation (suppurative hepatic brucellosis) is usually only seen in early phases of the disease or in small lesions developing in the course of the infection. Therefore, the term "hepatic abscess," previously employed in several publications on large hepatic lesions, is misleading in a considerable number of cases. Necrosis in brucelloma is, at low magnification, characterized by an amphophilic or even slightly basophilic mass, this staining feature being caused by the accumulation of numerous nuclear debris. At the periphery of this caseiform coagulation necrosis, a red rim is regularly observed, caused by a protein-rich exudative reaction. Calcifications are noted within the necrosis and/or the fibrosed peripheral parts of it (Figs. 4, 5, and 6). The necrosis is surrounded by a rim of epithelioid macrophages, often without isolated granulomas. This zone is followed to the periphery by a cellular immune reaction, containing numerous lymphocytes and sometimes lymph follicles. Most of the lymphocytes are CD3-positive T cells, but CD79a- and CD20-positive B cells are also in evidence. A striking feature is the high content of plasma cells (CD38 positive), usually not seen in caseiform tuberculosis. A granulation tissue develops around the lesion, and the inflammatory process blends into the adjacent liver tissue, with formation of interface lesions. In large and older brucellomas, the necrosis is progressively replaced by a hypocellular collagenous tissue that still reflects the circular lamellar pattern and contains calcifications.

There is some controversy in the literature regarding granuloma formation in hepatic brucellosis (Nagalotimath et al. 1979; Young 1979; Ledro et al. 1983), but this may be due to differential epithelioid cell production as a function of

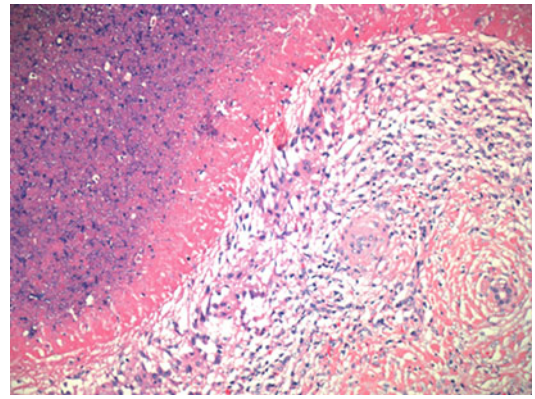

Fig. 5 Brucellosis of the liver. A zone of basophilic necrosis with high density of nuclear debris (*left upper* corner) blends into a zone of fresh eosinophilic necrosis showing shadow epithelioid cells. Note the well-developed granulomatous rim in contact with a portal tract (*right lower* corner; hematoxylin and eosin stain)

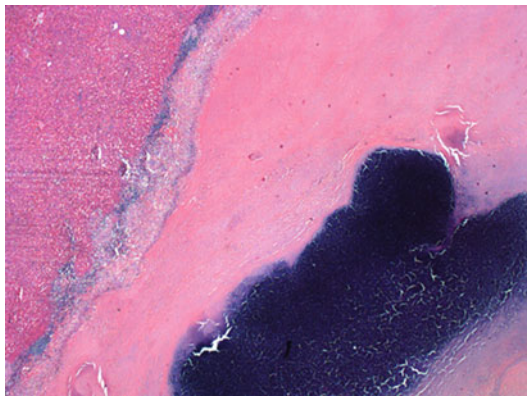

Fig. 4 Hepatic brucelloma. The strongly eosinophilic necrosis reveals marked central dystrophic calcification. Necrosis is peripherally demarcated from liver tissue by a granulomatous rim (to the *left*; hematoxylin and eosin stain)

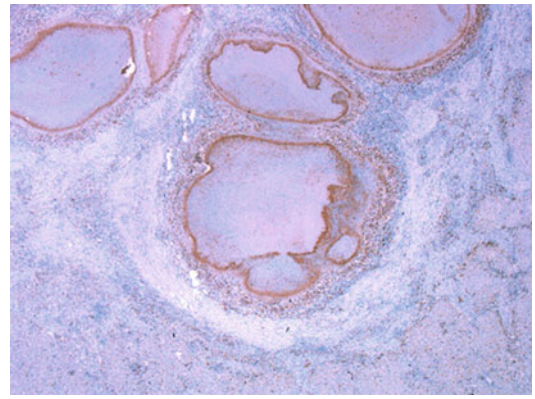

Fig. 6 Nodular lesions in hepatic brucellosis are surrounded by numerous activated macrophages (brown rims; CD68 immunostain)

the antigenic profile of *Brucella* strains, the immune status of the host, and the phase of the infectious disease at the time point of sampling. In forid caseiform necrosis, an epithelioid cell reaction with or without epithelioid cell micronodules (granulomas) at the peripheral interface of the necrosis is an almost constant feature.

Other Hepatic Manifestations of Brucellosis

Rarely, brucellosis is associated with febrile illness, hepatomegaly, cholestasis, and the presence of small hypodense rounded lesions in the liver and the spleen (Fernandez Fernandez et al. 2010; Schmid and Birkenfeld 2010). This damage pattern may in part be caused by liver cells themselves, as *Brucella*-infected hepatocytes mediate tissue-damaging immune responses, in that they secrete IL-8, express ICAM-1, attract neutrophils, and induce the expression of MMP-9 in neutrophils (Delpino et al. 2010).

Cat-Scratch Disease: Hepatobiliary Manifestations

Introduction

Cat-scratch disease (CSD; synonym: cat-scratch fever) is caused by *Bartonella* (*B.*) *henselae*, a worldwide distributed zoonotic pathogen (Zangwill 2013). CSD is therefore classified as a bartonellosis. The term, cat-scratch fever, is now obsolete, because not all patients with CSD show a febrile course, and the term might be confounded with cat-bite fever (rat bite fever; Sodoku). As a function of the immune status of the host, *B. henselae* can cause a broad spectrum of clinical manifestations, the most important being CSD usually occurring in immunocompetent hosts and bacillary angiomatosis, which is typically seen in immunocompromised hosts (Carithers 1985; Maguiña et al. 2009; Kaiser et al. 2011).

CSD was first described in 1950 (Debré et al. 1950; Keefer and Greer 1950), although Parinaud described similar symptoms in the context of oculoglandular syndrome in 1889 (Parinaud 1889). In the publication of Keefer and Greer (1950), it is noted that "cat-scratch fever" is a term that was first used by Dr. Lee Foshay of the University of Cincinnati College of Medicine to describe lymphadenitis of unknown etiology following cat scratches. Keffer and Greer obtained a vial from Lee Foshay containing "cat fever antigen" prepared from a former patients' bubo, heated to 60 centigrades on two subsequent days, and performed an intradermal injection to their patient, followed by itching, redness, and swelling at the injection site. This seems to be the first skin test performed for an agent that was unknown those days. CSD as a disease entity was then described in detail in 1951 (Greer and Keefer 1951).

Microbiology

In 1983, a report described a small, pleomorphic Gram-negative bacillus detected by the Warthin-Starry silver stain in infected lymph nodes of patients with cat-scratch disease (Wear et al. 1983). The organism was successfully isolated and cultured about 5 years later (English et al. 1988), and in 1991 Brenner and coworkers coined the taxon name *Afipia felis* to denote this bacterium, after the Armed Forces Institute of Pathology (Brenner et al. 1991). In 1992, *Rochalimaea henselae* was isolated from HIV-infected patients with bacillary angiomatosis, peliosis hepatis, and fever syndromes, and it was noted that the majority of the patients with clinically suspected cat-scratch disease studied had high serum titers to the *Rochalimaea henselae* antigen (Regnery et al. 1992). Later, *Afipia felis* was refuted and the genera *Bartonella* and *Rochalimaea* were united, the genus *Bartonella* having precedence (Brenner et al. 1993; Bowman 2011).

Clinical Presentation

B. henselae can cause two different pathologic reactions, depending on the immune status of the host: CSD and bacillary angiomatosis. The latter

condition, characterized by abnormal angiogenesis, is treated in a separate chapter. CSD typically starts as localized papule of the skin appearing 3–5 days after a cat scratch or bite and progresses into a pustule. Within 2 weeks, a tender locoregional lymphadenitis develops. In several reports it was stated that most patients remain afebrile and do not show systemic symptoms and signs. However, an analysis of 130 seropositive patients from Japan revealed that 77 % had general symptoms, such as fever, headache, and malaise. 20.8 % of the cases were classified as atypical CSD (Murakami et al. 2002). CSD is, in most cases, a self-limited illness resolving in 2–4 months, with locoregional unilateral lymphadenitis as its hallmark. However, some immunocompetent patients may show atypical CSD caused by systemic *B. henselae* infection, including prolonged fever or fever of unknown origin (FUO), malaise, headache, sore throat, myalgia, arthralgia, erythema nodosum-like skin eruptions, and parotid gland swelling, features that may lead into another diagnostic direction. Complications occur in about 2 % of the patients (Adal et al. 1994) and comprise Parinaud's oculoglandular syndrome, signs of encephalopathy, neuroretinitis with occlusive vasculitis, cat-scratch optic neuropathy (CSON), valvular endocarditis and myocarditis, osteolytic lesions, mesenteric lymphadenitis, and hepatosplenic involvement. Among 27 Japanese patients with atypical CSD, 37 % had FUO, 22.2 % neuroretinitis, 14.8 % encephalopathy, and 11.1. hepatic lesions (Murakami et al. 2002). The diagnosis is made in the appropriate clinical setting by finding an inoculation site, a positive skin test, positive serology and indirect immunofluorescence assay, and eventually a PCR-based typing. Real-time PCR assay targeting the groEL gene has been developed as a rapid and sensitive method for the detection of *Bartonella* species (Diederen et al. 2007).

Hepatic Manifestations of Cat-Scratch Disease

Hepatic and/or splenic involvement has more often been described in children, adolescents, and young adults than in older individuals. CSD of the liver is often associated with splenic lesions (hepatosplenic CSD; Belvisi et al. 2012), although involvement of the spleen is more common than that of the liver. In patients in whom the diagnosis was made by skin testing, splenomegaly was observed in 12 % (Margileth et al. 1987). Hepatic infection with *B. henselae* can present in several forms, including a distinct form of exudative granuloma-like masses, granulomatous hepatitis (Lenoir et al. 1988), focal inflammation (anicteric hepatitis; Korbitz 1973; Katner et al. 1986), peliosis hepatis, and bacillary angiomatosis, the latter two manifestations being seen in immunosuppressed patients. The first hepatic focal lesions were described in 1950 as "visceral granulomatous lesions" (Inglis and Tonge 1950). Since then, numerous cases of CSD-induced granulomatous hepatitis and tumor-like masses of the liver have been reported. These forms of CSD are mostly associated with CSD having systemic signs including a febrile course. Early reports identified hepatomegaly in association with classical CSD, in association with lymphadenopathy (Rocco et al. 1985), and as the sole focus of involvement in FUO (Malatack and Jaffe 1993). Typical CSD-associated liver masses have also been found in transplanted livers (Bonatti et al. 2006; Thudi et al. 2007). The mass lesions have in part been described as hepatic abscesses, but as outlined below, the histomorphology of the lesions is not exactly that of abscesses in the proper sense of the term.

Selected References Rocco et al. 1985; Rizkallah et al. 1988; Port and Leonidas 1991; Rappaport et al. 1991; Cataldi et al. 1995; Vanlemmens et al. 1995; Lamps et al. 1996; Siret and Hardy 1996; Danon et al. 2000; Le Tallec et al. 2003; Ishikawa et al. 2006; Liao et al. 2006; Marsilia et al. 2006; Renou et al. 2010; Vanderheyden et al. 2012.

In mass-forming hepatic CSD, ultrasonography revealed multiple round hypoechoic lesions of variable size, but up to 3 cm diameter and rarely more (Rocco et al. 1985; Port and Leonidas 1991; Rappaport et al. 1991; Stuart and Nowicki 1998), while CT examination both before and after IV

contrast administration has shown multiple, well-defined, low-attenuation lesions, ranging in diameter from 3 to 2 cm (Delbeke et al. 1988; Rappaport et al. 1991). Larger lesions can show peripheral enhancement after injection of contrast material (Rappaport et al. 1991). The nodules may form confluent masses (Kahr et al. 2000) and can form calcifications as a late change (Talenti et al. 1994). Hepatic masses in CSD may be associated with involvement of periportal, periaortic, and peripancreatic lymph nodes. Involvement of the gallbladder has been reported in one case (Marsilia et al. 2006).

Pathology

Laparoscopy in a pediatric patients with hepatosplenic manifestations of CSD revealed multiple soft, whitish-tan lesions (Liao et al. 2006). In the course of open liver biopsy, well-demarcated nodules of several mm diameter were seen, the lesions having slightly hyperemic margins (Rappaport et al. 1991). Yellowish stellate (collapsed) abscess-like alterations may be seen. In some cases, the abscess-containing granulomatous lesions grow to tumors of up to 3.5 cm diameter (Murano et al. 2001).

The histologic hallmark of CSD is a complex granuloma-like lesion termed necrotizing granuloma (Figs. 7 and 8; Rizkallah et al. 1988; Rappaport et al. 1991; Malatack and Jaffe 1993; Vanlemmens et al. 1995; Lamps et al. 1996; Liston and Koehler 1996; VanderHeyden et al. 2012), a lesion which may grow to large, tumor-like masses (Murano et al. 2001). This unique lesion patterns mainly occurring in lymph nodes of patients with pseudotuberculosis had previously been termed reticulocytic absceding lymphadenitis (Masshoff 1953). It is characterized by a central and often stellate (star-shaped) abscess-like exudate containing variable numbers of neutrophils and numerous nuclear and cellular debris, resulting in a basophilic area at low magnification and a stippled appearance at higher magnification. Apoptosis of leukocytes causes the large amounts of cell fragments and condensed nuclear remnants. In principle, this complex composition of the exudative reaction does correspond neither to typical abscess nor to necrosis. Parts of the lesion are not stellate shaped but rather exhibit a cerebriform or garland-like morphology. The inflammatory reaction around this focus typically shows three layers. Just outside this stellate exudate, one notes a rim of palisading epithelioid macrophages/histiocytes, sometimes with interspersed multinucleated giant cells of the Langhans type. This is followed by a zone rich in lymphocytes, non-epithelioid macrophages, and few plasma cells. The outermost layer has less infiltrate cells and shows fibrosis. It is assumed that the characteristic stellate morphology of the inner part of the lesion results from the

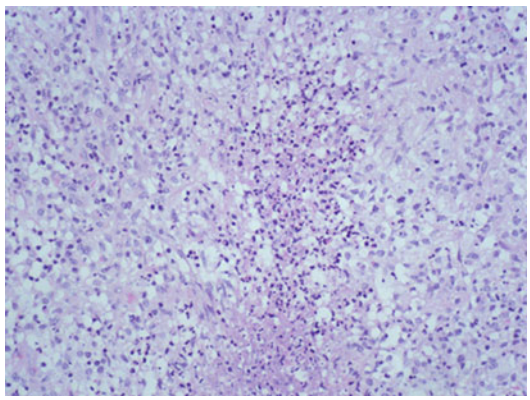

Fig. 7 Cat's scratch disease of the liver. Central slit-like (collapsed) abscesses are surrounded by a granulomatous reaction (hematoxylin and eosin stain)

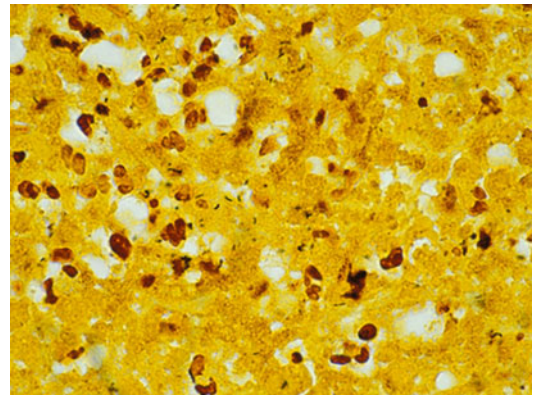

Fig. 8 Cat's scratch disease of the liver. *Bartonella* organisms are visible as short black rods (Warthin-Starry stain)

lesion's collapse. Within the lesions, but mainly in the transition zone between the central stellate focus and epithelioid cells, short rodlike bacteria can be found by use of the Warthin-Starry and Steiner silver stains. The Steiner silver stain seems to be the most sensitive test but is the least specific in comparison with immunofluorescence and PCR. It was found that granulomas in CSD consist of S100A8-, S100A9-, HLA-DR+, CD40+, and TNFalpha+ macrophages, while macrophages embracing the granulomas were S100A8+ and S100A9+. It was shown that the latter macrophages continuously migrate to granulomas, where part of the macrophages undergo apoptosis (Schweyer and Fayyazi 2002). By use of specific antibodies, *B. henselae* can immunohistochemically be detected in the lesions (Reed et al. 1992; Min et al. 1994; Caponetti et al. 2009). The bacteria can also be diagnosed in formalin-fixed tissue via PCR assays (Qian et al. 2005).

Tumor-Like Lesions of the Hepatobiliary Tract: Specific Abscess-Forming Bacterial Infections

130

Contents

Abstract

Several types of specific abscess-forming bacterial infections induce mass lesions in the liver. Yersiniosis is associated with hepatic miliary necroses (necrotizing hepatitis), miliary abscesses, macroabscesses, pseudotuberculoma, and granulomatous hepatitis. In tularemia, caused by *Francisella tularensis*, mild hepatitis is a common feature. Less frequently, focal suppurative hepatitis with abscess formation develops, usually without granulomatous reaction. Large necrosis and abscess of the liver are caused by melioidosis, caused by *Burkholderia pseudomallei*. The multifocal hepatic necrotizing and suppurative inflammation often results in large abscesses. Abscesses that may resemble tumors are also induced in the liver by listeriosis and glanders.

Yersiniosis (Pseudotuberculosis)

Introduction

Yersinia (*Y.*) *enterocolitica* and *Y. pseudotuberculosis* are two species that are very similar to the causative agent of plague, *Y. pestis*. These two enterobacteriacean germs most often cause self-limiting enteritis and mesenteric lymphadenitis, subsequent to ingestion of contaminated food or water. *Y. enterocolitica* is a zoonotic agent that causes gastrointestinal disease in humans as well as reactive arthritis and erythema nodosum. However, systemic infections

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_130

with septicemia are observed in patients with diabetes mellitus, liver cirrhosis, and, in particular, iron overload (Ljungberg et al. 1995). In addition, sudden onset of pseudotuberculosis in humans, in the form of small epidemics, has been reported in Japan, Russia, and France, probably related to contaminated water and plants (review: Vincent et al. 2008). Enteric yersiniosis disseminating systemically may have a case fatality of up to 70 % (review: Barnes et al. 2006). As the clinical presentation and hepatobiliary manifestations of the two *Yersinia* species are very similar, their clinicopathologic features are described together, except where the histology is different under certain circumstances.

Microbiology

Y. enterocolitica and *Y. pseudotuberculosis* belong to the genus *Yersinia*, which also contains *Y. pestis* and more than 15 other species. *Yersinia* is a member of the family Enterobacteriaceae, order Enterobacteriales. The organisms are rod-shaped, nonmotile, Gram-negative, facultatively anaerobic bacteria. *Yersinia* is a microorganism living in various habitats of the environment, e.g., on diverse plants and their leaf litter, vegetables, and soil, where the bacteria can resist low temperatures. Upon entry into a warm-blooded organism, yersiniae have to adapt their biochemical machinery to the suddenly higher temperature. They can do this by using the *Yersinia* virulence regulator, RovA, which acts as a protein thermometer. Thermal shifts encountered in the host lead to reversible conformational changes of the autoactivator, which reduces its DNA-binding functions and renders it more susceptible for proteolysis.

Clinical Features

Infection with both organisms leads to a febrile enteritis associated with right-sided abdominal pain. Enteric infections with *Y. enterocolitica* are usually self-limiting (review: Fabrega and Vila 2012). In *Y. pseudotuberculosis* infection, however, the diarrheal component is often absent, and this infection may mimic acute appendicitis, predominantly in children and young adults, because mesenterial lymphadenitis located in the region of the terminal ileum and the periappendiceal space is a prominent feature of pseudotuberculosis. *Y. pseudotuberculosis* can cause septicemia and septic arthritis associated with high mortality. Reactive arthritis caused by *Yersinia* infections is a well-recognized complication, but septic arthritis is observed at a much lower frequency. Severe forms of *Yersinia* infections, in particular septicemia, are often associated with iron overload (Mischnik et al. 2012).

In 1959, an epidemic of *Y. pseudotuberculosis* infections on the Pacific coast of Russia was called Far East scarlet-like fever (FESLF) or scarlatinoid fever for its clinical similarity to scarlet fever caused by group A streptococci. This infectious disease is severe and may result in toxic shock syndrome. The *Y. pseudotuberculosis* strains causing FESLF have acquired an altered genomic composition via horizontal acquisition and incorporation of different genetic information into the chromosome, two plasmids (pVM82 and pIB), and the capability to produce the superantigenic exotoxin, *Y. pseudotuberculosis*-derived mitogen (Eppinger et al. 2007; Nörenberg et al. 2013).

Hepatobiliary Yersiniosis

In the hepatobiliary tract, *Yersinia* species can induce several types of lesions that exert a mass effect and can thus mimic neoplastic disease (Table 1). The size of the focal lesions ranges from tiny, miliary necroses and microabscesses to large purulent and granulomatous lesions. Most of these focal liver lesions developing in the setting of *Yersinia* infections are encountered in septicemic forms of yersiniosis.

Miliary necroses (necrotizing hepatitis)
Microabscesses (miliary abscesses)
Macroabscesses
Pseudotuberculoma
Granulomatous hepatitis

Miliary Necrosis/Necrotizing Hepatitis

This form of liver disease found in septicemic yersiniosis is characterized by several to numerous foci of parenchymal necrosis. Macroscopically, the liver shows tiny to millet seed-sized nodules that are diffusely distributed in the hepatic parenchyma. These nodules are whitish-yellowish and show, on the cut surface, a slightly concave center. A hyperemic rim surrounding the lesions may be noted. Aschoff, in his handbook, described the nodules as very similar to small tuberculous lesions (miliary tuberculosis) with a perifocal macrophage reaction, sometimes with formation of epithelioid cells. In contrast to lymph node lesions in pseudotuberculosis, fully developed granulomas are not a feature of the hepatic lesions (Schneider 1915; Dubois et al. 1982; Collazos et al. 1995).

Hepatic Abscesses

Liver abscesses as a complication of septicemic yersiniosis mostly occur in adult patients, but pediatric cases are known as well, sometimes in association with hematologic disorders causing iron overload, including sideroblastic anemia or thalassemia (Leighton and MacSween 1987; Brunel et al. 1993; Grigull et al. 2005). Yersiniotic liver abscesses are mostly associated with systemic infection (i.e., septicemia and multiorgan involvement; Saebe and Lassen 1992), but rare instances of liver abscess subsequent to portal venous transfer of *Yersinia* in the absence of systemic manifestations are known (Viteri et al. 1981). Also in adults, the development of hepatic abscess in yersiniosis may be favored by iron overload, e.g., primary hemochromatosis (Olesen et al. 1989; Watson et al. 1989; Santoro et al. 1994; Vadillo et al. 1994; Abdelli et al. 1996; Zapata and Garcia 1997; Bergmann et al. 2001; Höpfner et al. 2001; Mennecier et al. 2001), hepatic hemosiderosis of unknown cause (Beeching et al. 1985), or subsequent to long-term blood transfusion (Schuchmann et al. 1997) or iron injections (Leighton et al. 1987). When reviewing the literature, one notes that both *Y. pseudotuberculosis* and *Y. enterocolitica* produce liver abscesses. Hepatic abscesses caused by *Y. pseudotuberculosis* seem to be less common than those caused by *Y. enterocolitica* and may occur after yersiniotic terminal ileitis.

The lesions are sometimes solitary lesions that can grow to large size, but multiple yersiniotic liver abscesses are more common (Beeching et al. 1985; Hopwood and Riddle 1986; Ismail et al. 1987; Leighton et al. 1987; Leyman et al. 1989; Nemoto et al. 1992; Vadillo et al. 1994; Schuchmann et al. 1997; Zapata and Garcia 1997; Grigull et al. 2005). Abdominal ultrasound reveals solitary or multiple fluid-filled lesions in which Doppler ultrasound fails to show flow (Schuchmann et al. 1997). Ultrasonographically, hypoechogenic liver abscesses may be accompanied by ascites and signs of pseudoappendicitis (Grigull et al. 2005). Liver CT scans show solitary or multiple low-density areas (Leyman et al. 1989; Nemoto et al. 1992).

Selected References Fraenkel 1914; Capron et al. 1981; Beeching et al. 1985; Farrer et al. 1988; Ljungberg et al. 1995; Mennecier et al. 2001; and Navascues et al. 2005. Liver abscess caused by *Y. enterocolitica* is predominantly found in association with septicemia (Viteri et al. 1981; Hopwood and Ridddle 1986; Ismail et al. 1987; Leyman et al. 1989; Olesen et al. 1989; Nemoto et al. 1992; Santoro et al. 1994; Vadillo et al. 1994; Collazos et al. 1995; Strungs et al. 1995; Abdelli et al. 1996; Schuchmann et al. 1997; Zapata and Garcia 1997; Bergmann et al. 2001; Mennecier et al. 2001; Benbrika et al. 2005; Grigull et al. 2005; Navascues et al. 2005; Pulvirenti et al. 2007).

Macroscopically, the smaller abscesses are grayish-white lesions with a soft, yellowish center (Fig. 1). The lesions are described to be pea sized or bean sized; they may be accompanied by miliary, i.e., smaller, lesions. Large abscess may grow to diameters of several centimeters; these abscesses are often wax yellow and have a softened, puriform center. In the case of multiple lesions, the abscesses may show confluence,

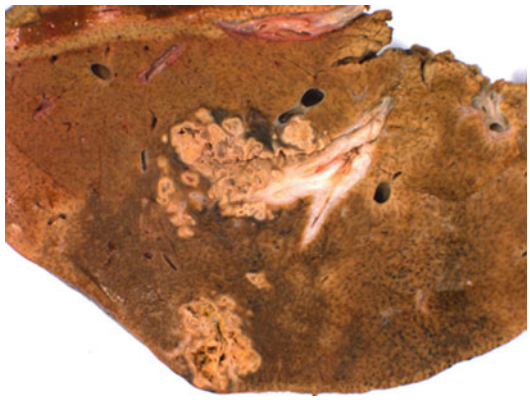

Fig. 1 Yersiniosis (pseudotuberculosis) of the liver. The distribution of the grape-like abscesses reflects bacterial spread through the portal venous system

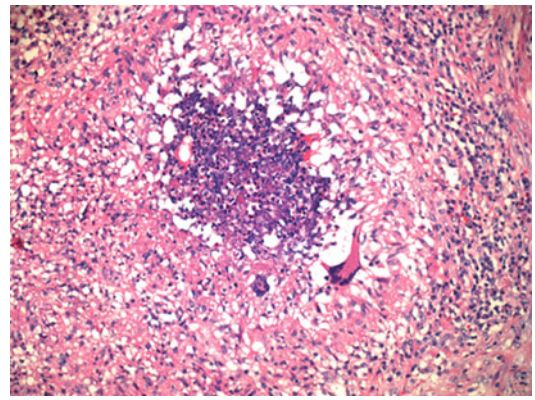

Fig. 2 Yersiniosis (pseudotuberculosis) of the liver. Typically, the lesions show a central abscess instead of coagulation necrosis. This abscess is surrounded by a granulomatous reaction with Langhans-type giant cells (hematoxylin and eosin stain)

resulting in large conglomerate lesions. Usually, abscesses located in peripheral parts of the liver are larger than centrally placed lesions, and sometimes large peripheral abscesses are accompanied by miliary lesions situated in the core of the liver (Roman 1916; Fraenkel 1924). Needle biopsy may reveal pus which grows *Yersinia* (Strungs et al. 1995). Histologically, the lesions have a central part consisting of coagulation necrosis (but without caseification), neutrophils, neutrophil debris with abundant nuclear fragments, and macrophages (Fig. 2). This part is demarcated by a rim of various thicknesses, showing an infiltrate of lymphocytes and macrophages, sometimes with epithelioid cell change. Plasma cells are rare of lacking. This presentation resembles the alteration seen in the appendix and ileum in cases of yersiniosis and the lymph node changes formerly termed "reticulocytic abscedent lymphadenitis."

Pseudotuberculomas

In analogy to large, tumor-like masses seen in caseating tuberculosis, conglomerate lesions formed by confluence of several large yersiniotic liver abscesses with extensive central necrosis and suppuration may form large masses, which mimic malignancy and may be termed "pseudotuberculomas."

Granulomatous Hepatitis

In part of patients, hepatic manifestations of yersiniosis are characterized by granulomatous hepatitis, sometimes with suppurative granulomas (Dubois et al. 1982; Piéron et al. 1983; Guarga et al. 1984; Stjernberg et al. 1987; Drebber et al. 2008).

Differential Diagnosis

Multiple liver abscesses in yersiniosis may radiologically mimic metastatic liver disease (Leighton et al. 1987).

Tularemia

Introduction

Tularemia is a zoonotic disease caused by the Gram-negative bacterium, *Francisella tularensis* (reviews: Oyston 2008; Splettstoesser et al. 2008; Harik 2013). Other names of this contagious disease include Ohara's disease, Francis disease, rabbit fever, deer fly fever, and marketmen's disease. Tularemia is a predominantly Northern Hemispheric disorder and is widely endemic throughout North America,

continental Europe, Russia, China, and Japan. The greatest numbers of human cases reported are from northern and central Europe (in particular Scandinavia), from Russia, and more recently also from certain Balkan regions. In these areas, tularemia sometimes presented as large-scale epidemic outbreaks. Increased concerns about the potential use of *Francisella tularensis* as a bioterrorism and bioweapon agent led, in 2000, to the reinstatement of tularemia on the list of notifiable disease in the USA after it had been removed in 1994. In the early twentieth century, a Japanese physician, Hachiro Ohara, described a disease affecting those who hunted or ate rabbits (yato-byo, meaning rabbit fever in Japanese), endemic to the Abukuma Mountains in Japan. There are certain clinical differences between the Japanese yato-byo and North American tularemia.

Microbiology

Deer fly fever was described in 1910 by the Utah physician R.A. Pearse, and in 1912, McCoy and Chapin isolated the causative agent of this plague-like disease from California ground squirrels and named it *Bacterium tularense*, after Tulare County where the work was performed. Dr. Edward Francis identified the cause of deer fly fever as *Bacterium tularense* in 1928. The genus was later changed into *Francisella*, in honor of Edward Francis. *F. tularensis* is a member of the family *Francisellaceae*, which in turn belongs, together with *Thiotrichaceae* and *Piscirickettsiaceae*, to the order *Thiotrichales* (bacterial class *Gammaproteobacteria*). The *Francisellaceae* family is composed of a group of closely related organisms that are widespread in nature. Apart from the few *Francisella* species (see below), the family also includes *Wolbachia* species and several *Francisella*-like endosymbionts (Kugeler et al. 2005; Escudero et al. 2008). The natural reservoir chiefly consists of small mammals (mice, water rats, voles, squirrels, rabbits, and hares; overall more than 250 species), and diverse arthropods are vectors transmitting the infection among susceptible mammals. The human host is infected in rural environments by infected arthropod bites, handling of infected animals or parts thereof (e.g., hunters and trappers), ingestion of contaminated water or soil, and inhalation of infective aerosols. Infection of the human host may occur after exposure to as few as ten bacteria. The incubation period is about 3–5 days but can take as long as 2 weeks for symptoms and signs to appear. Uptake of the bacterium into monocytes/macrophages occurs by so-called looping phagocytosis, in which the bacterium is engulfed in a spacious, asymmetric pseudopod loop. Contact with and trafficking in host cells critically depend on the features of the bacterium's surface membrane proteins, the membrane complexome (Dresler et al. 2011).

Clinical Presentation

The clinical presentation is variable and depends on the infection mode (Evans et al. 1985; Ellis et al. 2002); several presentation forms of tularemia are recognized (ulceroglandular, glandular, oculoglandular (Parinaud's oculoglandular syndrome), oropharyngeal, pneumonic, and typhoidal tularemia and visceral and septic forms). In humans, ulceroglandular tularemia is the most common form of the disease and is usually a consequence of a bite from an arthropod (tick) vector which has previously fed on an infected animal. An ulcer, which can persist for several months, forms at the site of infection (usually a tick bite site), soon associated with lymphangitis caused by local bacterial spread and locoregional lymphadenitis with lymph node enlargement (hence the term ulceroglandular form). Lymphadenomegaly may be impressive and resemble that in bubonic plague. Ulceroglandular tularemia may show a protracted course and recovery, but is seldom fatal. The oculoglandular form is rare and characterized by primary conjunctival infection followed by lymphadenitis. From the lymph node reservoirs, the infection may spread to internal organs and eventually produce sepsis. The dangerous pneumonic form of the disease occurs rarely but is the likely form of disease should the causative

bacterium be used as a category A bioterrorism agent (Ellis et al. 2002).

Hepatic Manifestations of Tularemia

Hepatitis, usually of a mild degree, is common (Evans et al. 1985). Hepatomegaly was found in two of three patients with pulmonary tularemia, and the results of liver function tests were abnormal in all three (Martone et al. 1979). It was suggested that dissemination to the liver in tularemia may be more frequent than has been recognized. In regard to focal liver lesions, the most frequently observed alteration is coagulative necrosis with associated sinusoidal dilatation and suppurative inflammation, the latter chiefly found in larger lesions (Francis 1928; Foulger et al. 1932; Foshay 1937; Pullen and Stuart 1945; Dienst 1963; Gourdeau et al. 1983; Zaidi and Singer 2002). Focal suppurative hepatitis with abscess formation has become uncommon under modern antibiotic treatment strategies, except in septicemic tularemia.

Liver abscesses in tularemia are histologically characterized by a central suppurative focus with necrosis and nuclear debris, followed at the periphery by a zone of better preserved leukocytes (neutrophils and macrophages). The lesions are separated from liver tissue by a rim of inflammatory infiltrate rich in macrophages, lymphocytes, and sometimes also plasma cells (Baskerville et al. 1978; Gourdeau et al. 1983; Zaidi and Singer 2002; Lamps et al. 2004). Epithelioid cell and giant cell granulomas are rare findings (Ortego et al. 1986). In a murine model of tularemia, lysis of infected hepatocytes was mediated by leukocytes (Conlan and North 1992).

Melioidosis

Introduction

Melioidosis (burkholderiosis) is caused by the Gram-negative bacterium *Burkholderia pseudomallei*, a germ which is found in damp soil, paddy water, and stream banks mainly in Southeast Asia (White 2003; Leelarasamee 2004; Wiersinga et al. 2006; Gilad 2007). This infection was first reported in 1912 based on the observation of a hitherto undescribed, glanders-like disease occurring among the population of Rangoon (Whitmore and Krishnaswami 1912). Clinically, melioidosis is most frequently recognized as a respiratory infection that varies in severity from a mild tracheobronchitis to an overwhelming and frequently fatal pneumonia. Due to its often very aggressive course, melioidosis is a potential biothreat.

Microbiology

B. pseudomallei belongs to the family *Burkholderiaceae*. The genus *Burkholderia* contains more than 30 species, many of them being environmentally adaptable plant-associated bacteria and some species being bacterial endosymbionts of plant-associated insects and of plant-pathogenic fungi, such as *Rhizopus microsporus*, the causal agent of rice seedling blight. Some *Burkholderia* species are nonphytopathogenic and beneficial microorganisms associated with the phytosphere and the rhizosphere, involved in the important mechanism of leguminous plant root nodulation. The most pathogenic members of this genus are *B. pseudomallei*, *B. mallei* (the cause of glanders), and, in certain conditions such as cystic fibrosis, *B. cepacia*. *B. pseudomallei* is a saprophyte and resilient microorganism that is capable of surviving hostile environmental conditions, including nutrient deficiency; antiseptic, acid, and detergent exposure; and dehydration, but the factors that determine whether an environment is suitable for the organism remain poorly understood. It has been discussed that *B. pseudomallei* may exist in a viable, non-cultivable state in the environment, that it probably forms biofilms, and that interactions with other organisms, particularly protozoa, might explain the adaptation of this bacterium to an intracellular niche. The transfer of *B. pseudomallei* from environmental reservoirs to attachment and invasion of phagocytic cells and epithelial cells is a complex sequence of events that is closely linked to the expression of

virulence factors (reviews: Inglis et al. 2001; Compant et al. 2008; Adler et al. 2009; Lazar Adler et al. 2009; Allwood et al. 2011).

Clinical Features

The lung is the most commonly involved organ, and lung imaging shows acute pulmonary consolidation, multiple nodules, and abscesses. The most dreaded form of melioidosis is a fulminant septicemic infection, striking as severe diarrhea, massive pneumonia, and sometimes visceral manifestations, including the liver (Sheehy et al. 1967; Brundage et al. 1968; Weber et al. 1969; Puthucheary et al. 1992; Dance 2002; White 2003; Cheng and Currie 2005; Inglis 2011; Limmathurotsakul and Peacock 2011; Torres and Steinmetz 2012). In this form, death may follow within few days. The clinical definitions of melioidosis have recently been reported (Cheng et al. 2013). Melioidosis also exists in an encephalomyelitic form.

In a study of ten patients with acute melioidosis, the average duration of illness was 14 days and ranged from 3 to 42 days (Piggott and Hocholzer 1970). Apart from these acute courses, chronic melioidosis may ensue, characterized by predominant involvement of the lung, lymph nodes, skin, or bone (Kingston 1971). Chronic cavitary pulmonary melioidosis mimics tuberculosis clinically and radiologically (Spotnitz et al. 1967). In endemic regions, apparently not all persons exposed to this bacterium develop clinical melioidosis, as, e.g., surveys in Malaysia and Thailand have found circulating antibodies to *B. pseudomallei* in as much as 30 % of the normal population (Nigg 1963). Melioidosis is known to often show recurrence caused by two different mechanisms, i.e., relapse and reinfection. A study on 140 patients with disease recurrence showed that similar patterns of organ involvement occurred during the first and second episode of infection, independent of whether this was caused by relapse or reinfection (Limmathurotsakul et al. 2009). An intriguing phenomenon in this infection is the long incubation period in recrudescent melioidosis, sometimes exceeding 10 or even 20 years (review: Gan 2005).

Liver Manifestations of Melioidosis

Liver involvement in *B. pseudomallei* infection is chiefly characterized by a multifocal necrotizing and suppurative inflammation, commonly leading to the formation of sometimes large abscesses (Greenawald et al. 1969; Atisook and Panyathanya 1988; Thurnheer et al. 1988; Puthucheary et al. 1992; Vatcharapreechasakul et al. 1992; Wong et al. 1995; Ben et al. 2004; Machado Braga and Carvalho de Almeida 2005; Apisarnthananarak et al. 2006; Cheng and Johnson 2006; Lee et al. 2006; Azali et al. 2007; Mukhopadhya et al. 2007; Laopaiboon et al. 2009; Lim and Chong 2010; Apisarnthanarak et al. 2011; Rajadhyaksha et al. 2012). In a study of 16 bacteriologically proven cases accessioned to the Armed Forces Institute of Pathology during a 25-year period (1944–1968), liver involvement was detected in seven patients (Piggott and Hochholzer 1970). The etiology of hepatic necroabscesses in melioidosis has been confirmed by the cultural identification of *B. pseudomallei* in aspiration material (Mukhopadhya et al. 2007). *B. pseudomallei* abscesses are significantly associated with the presence of poorly controlled diabetes mellitus (Chong 2006).

Imaging of *B. pseudomallei*-induced hepatic mass lesions shows the typical features of hypodense abscesses with variable peripheral enhancement at CT. The lesions may be multiloculated and multiseptated, with a so-called honeycomb appearance, and a "necklace sign" may be seen in lesions greater than 5 cm in diameter (Vachara-preechasakul et al. 1992; Wibulpolprasert and Dhiensiri 1999; Ben et al. 2004; Apisarnthananarak et al. 2006). In a comparative study, it was shown that liver abscesses in melioidosis can be distinguished from non-melioidosis abscesses based on distinct features of size, enhancement patterns, and organ distribution (Laopaiboon et al. 2009).

Pathology

Early hepatic melioidosis presents in the form of few to numerous small yellowish to tan lesions

resembling small pyogenic abscesses, usually measuring 0.1–0.5 cm (Greenawald et al. 1969). As the disease persists, these focal lesions increase in size and become large and in part coalescing necroses with a purulent center. Early lesions in acute melioidosis are characterized by a suppurative inflammation, with formation of small, well-circumscribed abscesses, 1–3 mm in diameter rand sharply delineated from the surrounding tissue. These abscesses may be found in many organs, but are most often seen in the lungs, liver, spleen, and lymph nodes. In a given organ, they are usually multiple (Piggott and Hochholzer 1970; Wong et al. 1995). In small and early hepatic lesions, a mixture of neutrophils and macrophages predominates, and necrosis is a feature almost from the beginning, while larger and older lesions chiefly contain neutrophils intermingled with nuclear debris and necrotic tissue (Fig. 3). A rim of necrosis surrounding the central pus is frequently noted. Within the purulent masses, bacteria can be demonstrated, often in large numbers, best visualized by the use of the Brown-Hopps tissue Gram stain, but also reliably detectable in the Warthin-Starry and Goodpasture stains. The bacteria are not well demonstrable in the Brown-Brenn and silver methenamine preparations (Piggott and Hochholzer 1970). In case the illness persists more than several days, the abscesses tend to enlarge and often coalesce, forming complex clusters or conglomerates of nodular lesions. Large lesions commonly contain a fibrinous exudate, whereas hemorrhage is not a prominent feature in liver lesions (Piggott and Hochholzer 1970).

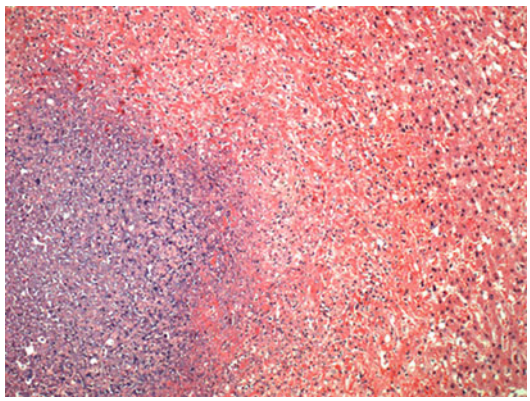

Fig. 3 Tumor-like melioidosis of the liver. The lesions are characterized by massive necrosis which rapidly extends into hepatic parenchyma, leaving shadow structures of hepatocyte plates. Central parts are basophilic due to numerous nuclear debris (karyorrhexis, hematoxylin and eosin stain) monocytogene organisms (hematoxylin and eosin stain)

In chronic melioidosis, visceral involvement is more seldom seen. The lesions present as a combination of necrosis and an epithelioid cell or granulomatous reaction, often with formation of Langhans-type giant cells. Perifocal fibrosis develops. The central necrosis of the nodules may contain pus, but a coagulation necrosis looking like tuberculous caseification may also develop, such lesions markedly resembling tuberculosis, tularemia, or brucelloma.

Glanders

Introduction

Glanders (glanders disease; Malleasmus; *Malleus humidus* of Vegetius; Latin, malleus (hammer, mallet); German (Rotz, Mürde); French (morde, farcin)) is an aggressive infection mainly of horses and other equids, caused by *Burkholderia mallei* (reviews: Strube 1900; Neubauer et al. 2005; Gilad 2007; Whitlock et al. 2007; Dvorak and Spickler 2008; Van Zandt et al. 2013).

Glanders is known since antiquity, and Aristotle (c. 350 BC) gave it the name melis (Greek melis later transformed into Latin malleus; citation from Aristotle's *Historia Animalium*: "The ass suffers chiefly from one particular disease which they call melis. It arrives first in the head, and a clammy humour runs down the nostrils, thick and red; if it stays in the head the animal may recover, but if it descends into the lungs the animal will die. . ."). This observation is still nowadays valid because it described the dismal outcome in case glanders spreads to internal organs. It has also been hypothesized that Achaean disease, a mortal illness described in the first book of Homer's Iliad, was glanders (Urso 1993). Until the beginning of the twentieth century, glanders was widespread among army horses, with a last

important peak during World War II, followed by a decline due to rigorous testing (Wilkinson 1981; Blancou 1994). However, glanders is again increasing since the 1990s, mainly among racing horses and army horses in the Middle East, South Asia, and South America. Owing to the highly aggressive course of the infection caused by *B. mallei*, this bacterium may serve as a means of bacterial warfare and terrorism (*B. mallei* is a category B biothreat agent).

In equids, acute glanders is characterized by high fever, a distinct form of ulcerating rhinitis (*Malleus humidus*), pharyngolaryngitis and tracheobronchitis, and locoregional lymphadenitis. The acute glanders syndrome is more common in mules and donkeys than in horses. Chronic glanders, which predominates in horses, is characterized by ulcerous skin manifestations (called farcy or glanders of the skin, *Malleus farciminosus*) and inner organ spread with development of pneumonia (glanders pneumonia, Lungenrotz in German). In humans, glanders manifestations can be variable. At least six forms of infection have been described, including nasal and pharyngolaryngeal, localized, pulmonary, septicemic, disseminated, and chronic infections. The variety of these forms is explained by various routes of infection, the virulence of the bacterial strain, the immune status of the host, and modes of spread within the body.

Clinical Features

An acute infection with *B. mallei* is characterized by an erysipelas-like inflammation of the nasal skin and adjacent regions of the face (sometimes followed by hemorrhagic necrosis, also involving the upper lip and the gingiva), a necrotizing inflammation of the tracheobronchial tree, multiple and sometimes numerous pustular skin lesions, and either a febrile pneumonia if the organism was inhaled or sepsis with multiple abscesses if the skin was the portal of entry (review: Srinivasan et al. 2001). The purulent nodular lesions in the skin form craterlike ulcers forming chains along the lymphatic vessels, the so-called farcy pipes. Chronic glanders in humans presents with lymphadenitis, ulcerating or necrotizing nodules in the alimentary and respiratory tracts (visceral glanders), weight loss, and numerous subcutaneous abscesses (Robins 1906). The chronic, sometimes nonclinical glanders in humans is also termed farcy.

Liver Lesions in Glanders

In generalized *B. mallei* infection, abscesses and leukocyte-rich necroses can develop in multiple organs, most notably the lungs, liver, and spleen. The pathologic features of liver involvement are mainly found in the older literature (Sommerbrodt 1864; Bollinger 1874, 1876; Strube 1897, 1900; Koch 1902; Helly 1907; Bernstein and Carling 1909; Jochmann 1914; Spinner 1926). Because untreated human glanders is almost uniformly fatal and imaging appearances of hepatic involvement may mimic echinococcal or amebic infection, a high index of suspicion is mandatory and requires knowledge of the imaging features (Georgiades and Fishman 2001). In contrast-enhanced CT, cystic and sometimes multiseptate, low-attenuation lesions of variable size have been observed (Georgiades and Fishman 2001; Srinivasan et al. 2001).

The liver is usually enlarged (Sommerbrodt 1864; Bollinger 1874; Jochmann 1914). The lesions range in size and shape from miliary foci without central liquefaction but with a red hyperemic rim to medium-sized nodules of gray-yellow color (sometimes coalesced to form clover leaf-shaped structures) or to large abscesses or necroses with perifocal atrophy of the liver substance (Sommerbrodt 1864). In the autopsy case of a 29-year-old farmer with septicemic glanders, reported by Spinner (1926), the liver was scattered with millet-sized purulent foci with a hyperemic rim. Helly (1907) reported on the necropsy of a patient who had attracted *B. mallei* infection in the laboratory. The liver showed an arborizing cavity containing pus, associated with thrombophlebitis of the portal vein. Large purulent hepatic lesions may communicate with intrahepatic bile ducts (Sommerbrodt 1864). Older necrotic lesions are

described to by dry on the cut surface and to resemble compact tuberculous caseification necrosis (Spinner 1926). In extended hepatic disease with multiple lesions, hepatomegaly may be a striking feature (Spinner 1926). In one case, a large abscess cavity of variegated or arborescent shape was spatially associated with portal vein thrombophlebitis (Helly 1907).

Histopathology

Postmortem examinations of livers involved with glanders showed several types of lesions, depending on the phase of infection and the severity of involvement. The early pattern is characterized by the formation of epithelioid cell granulomas, sometimes with a miliary pattern (Fig. 4). This is followed by enlargement of these lesions, resulting in numerous, small necrotizing and sometimes caseating nodules, similar to lesions that are well known in glanders pneumonia. The so-called glanders nodule (Rotzknötchen) was first described by Virchow in 1854. The centers of these nodules exhibit nuclear debris and decaying granulocytes, forming sometimes large basophilic foci surrounded by inflammatory cells (Spinner 1926). In the center of the nodules, numerous glanders bacteria are found. This pattern shows a striking similarity to both brucelloma and the lesions seen in melioidosis (see the respective chapters). Larger nodules show a central, caseiform necrosis containing numerous debris of granulocytes and their nuclei, surrounded at the periphery by a rim of epithelioid macrophages. Epithelioid macrophages in fact dominate the histologic picture in glanders (Strube 1897). Giant cells may be found, but are generally rare in glanders (Strube 1897). In the vicinity of the lesions, vascular damage and thrombophlebitis are common alterations. The lesions may contain necrotic liver cell plates, and in the parenchyma surrounding the lesions, fatty change of hepatocytes is noted. As a function of disease advancement, these nodules may coalesce into larger, confluent necroses with or without marked pus formation, but occasionally forming large abscesses.

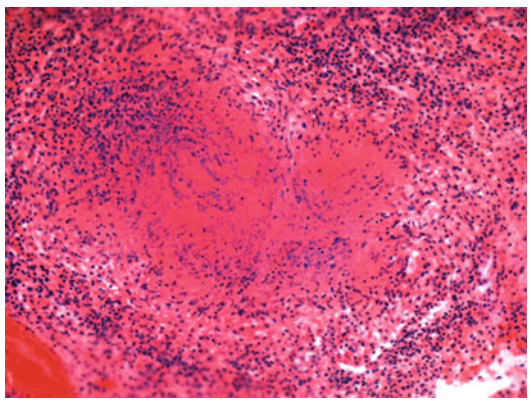

Fig. 4 Necrotic and granulomatous hepatic lesion in septicemic glanders (hematoxylin and eosin stain)

Glanders may also involve the bile ducts. A tubular-shaped intrahepatic cholangitis of larger ducts has been described, with ulcers and so-called diphtheroid lesions (Sommerbrodt 1864).

Listeriosis

Introduction

Listeria monocytogenes is an opportunistic bacterial pathogen that causes food-borne illnesses and is well known to cause neonatal and adult sepsis, recognized in 1929 already. The pathogenic spectrum in humans is rather broad and comprises meningitis, septicemia, abortion, and gastroenteritis. *L. monocytogenes* is widely distributed in the environment and also occurs in the intestinal tract of healthy animals and humans (Barbuddhe and Chakraborty 2009). *Listeria* can be isolated from sources as diverse as wild and domestic animals (including insects), soil, stale water supplies, waste water, vegetation (typically grazing areas), and food (particularly dairy products).

L. monocytogenes is a typical example of a bacterium that can switch from a saprophytic organism to a virulent mammalian pathogen. The microorganism is capable to live and survive in several environmental niches, is resistant to dry and cold environment, and can grow at temperatures as low as 3 C in high-salt or acid-stress environments, permitting replication in refrigerated processed

food. As a result, *Listeria* may be transmitted in ready-to-eat foods that have been kept properly refrigerated and heated before use. *L. monocytogenes* grows best at −18–10 C but is also able to grow and survive at relatively high temperatures.

Epidemiology

It has been suggested that up to 5 % or more of normal healthy people harbor *Listeria*, usually in the gut, where the germ can stay for long time periods without causing harm. Listerial infections occur most frequently in neonates and in adults with immunosuppression, in pregnancy, advanced age, HIV infection, alcoholism, kidney diseases, or diabetes mellitus, with an estimated incidence in adults of less than 1/100,000. In a French study, patients with chronic lymphocytic leukemia had a more than 1,000-fold increased risk of acquiring listeriosis, and a 100–1,000-fold increased risk of listeriosis was observed in patients with liver cancer, myeloproliferative disorders, multiple myeloma, acute leukemias, immune complex vasculitis, dialysis, several types of solid cancers, brain tumors, liver cirrhosis, and pregnancy (Goulet et al. 2012). *L. monocytogenes* causes a variety of diseases, including infection in pregnancy, the manifestations here ranging from mild chill to severe illness precipitating miscarriage or premature birth, and meningitis in the newborn. Meningoencephalitis and sepsis are particularly well-known manifestations of listerial infection in adult individuals.

Liver Involvement in Listeriosis

Liver involvement in listerial infections probably has its origins either in a primary bacteremia (septic listeriosis), the spreading to different organs, or through the portal venous system after enteric colonization. This is the reason for the development of several patterns of clinical presentation for listerial liver disease (review: Scholing et al. 2007). Transplacental transmission of *L. monocytogenes* causes a distinct prenatal/perinatal syndrome called granulomatosis infantiseptica (septic granulomatosis of the infant). This severe disorder is characterized by disseminated, *Listeria*-containing abscesses and/or granulomas mainly involving the fetal liver, lung, spleen, brain, and skin. In contrast, the predominant clinical manifestations in the adult patients comprise CNS involvement or a primary bacteremia. In adults, it is the latter presentation which will most commonly cause liver disease, which is however not common. One reason for the relative rarity of hepatic listerial infection in adults may be related to the distinct defense environment of the liver, complex interactions in this organ between resident cells and immigrating lymphocytes, and monocytes and neutrophils providing a strong innate defense and immunity to listerial infection (Cousens and Wing 2000; Gregory and Wing 2002).

Listerial Liver Abscesses

Purulent hepatitis with abscess formation is an uncommon manifestation of hepatic listeriosis. Solitary liver abscess, multiple liver abscesses, or supramiliary purulent hepatitis (microabscesses) are recognized.

Selected References Seeliger et al. 1961; Yu et al. 1982; Al Dajani and Khati 1983; Herreman et al. 1990; Ribière et al. 1990; Bugnon et al. 1991; Beaufigueau et al. 1993; Manian 1994; Marino et al. 1996; Brönnimann et al. 1998; and Lopez-Prieto et al. 2000.

Based on a literature review (Scholing et al. 2007), *solitary* listerial liver abscesses had an average patient age of onset of 59 years (range: 28–77 years) and were, among ten cases reviewed, exclusively found in patients with diabetes mellitus. The clinical signs are variable, but often mimic malignancy, with fever, epigastric pain, night sweats, and weight loss. Solitary listerial liver abscess is not associated with extrahepatic manifestations of listeriosis. In extended perifocal liver disease, jaundice and abnormal liver function tests may ensue, causing the presentation of acute icteric hepatitis (Yu et al. 1982). In a review, 11 patients (8 males and 3 females) with *multiple* listerial liver *abscesses* were

identified (Manian 1994; Marino et al. 1996; review: Scholing et al. 2007). The average age of onset in this group was also 59 years (range: 22–81 years), i.e., the same as in solitary listerial hepatic abscesses. The majority of the patients had underlying conditions such as diabetes mellitus, grafts with immunosuppression, or chronic steroid use. In 80 % of the patients, blood cultures were positive for *L. monocytogenes*, and slightly more than a third had concomitant meningitis. In contrast to solitary abscess, multiple abscesses carry a poor prognosis, with a mortality of about 70 %, causes of death including septic shock, meningitis, and multiorgan failure (Scholing et al. 2007). The abscesses were recognized as miliary lesions ("miliary abscesses") in two reports (Simpson et al. 1967; Yu et al. 1982).

Macroscopically, solitary listerial liver abscesses range in diameter from 1 to 20 cm, whereas multiple abscesses are usually smaller, most lesions not exceeding 2 cm in diameter (review: Scholing et al. 2007). The lesion in part resembles pyogenic liver abscess, but pus formation is often less prominent, and tissue necrosis dominated the presentation. Histologically, listerial abscesses commonly present as necrotic foci with shadow cells, nuclear debris, and variable numbers of viable or decayed phagocytes, both neutrophils and macrophages, but sometimes necrosis prevails, with few infiltrate cells (Fig. 5). By the use of bacterial stains, *Listeria* organisms may be detectable as thin, Gram-positive rods, either within phagocytes or situated in the necrotic masses.

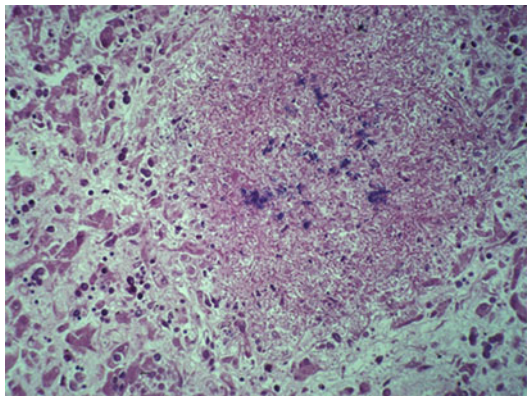

Fig. 5 Hepatic necrosis in listeriosis. The lesion is poor in leukocytic infiltrates and contains numerous *Listeria* organisms (hematoxylin and eosin stain)

Nodular Hepatic Listeriosis

Nodular hepatic lesions have been noted at necropsy of two adult patients dying from listeriosis (Seeliger et al. 1961). The lesions represent coalesced necroses and abscess with a demarcation zone of granulation and fibrous tissue.

Miliary Granulomatous Hepatitis

Listeriosis may induce a cell-mediated immune reaction with strong macrophage activation and formation of epithelioid cell granulomas (Seeliger et al. 1961; Henderson and Ramsey 1967). These granulomas may cause miliary lesions resembling those in tuberculosis (Henderson and Ramsey 1967). Necrosis can develop in the center of the granulomas, and *Listeria* organisms have been identified in macrophages surrounding the necrotic foci (Kumada et al. 1989).

Diffuse Listerial Hepatitis

Listerial diffuse hepatitis was observed in patients with alcohol abuse, underlying viral hepatitis, pregnancy, or steroid treatment, but not in patients with diabetes mellitus. Almost all of these patients had listerial bacteremia, and almost half suffered from meningitis (Yu et al. 1982; De et al. 1992; Teodor et al. 2012).

DOI 10.1007/978-3-319-26956-6_131

Abstract

Systemic *Candida* infections (candidiasis), most commonly observed in immunosuppressed and/or neutropenic individuals, can induce several types of hepatic lesions. They comprise disseminated or miliary hepatic candidiasis, granulomatous hepatitis, candidal liver abscess, *Candida* pseudotumor ("candidoma"), and candidal cholangitis. Large nodular lesions show a complex histology with necrosis, purulent inflammation, and eventually a granulomatous reaction. A similar spectrum of lesions is induced by cryptococcosis, with formation of miliary lesions, abscesses, and hepatic cryptococcoma. Macroabscesses and pseudotumors of the liver are also induced in the setting of zygomycosis including mucormycosis and in systemic aspergillosis. In the latter, aspergillomas and hepatic pseudotumors are sometimes associated with angioinvasive mycosis.

Hepatobiliary Candidiasis

Introduction

Candida species are diploid fungi that cause the dominant fungal disease, invasive candidiasis (review: Rueping et al. 2009). Candidiasis is most commonly observed in immunosuppressed and/or neutropenic individuals and occurs as acute, smoldering, or chronic forms (Swerdloff et al. 1993). In the liver, *Candida* infections can produce mass lesions that may be confounded with hepatic neoplasias.

The genus *Candida* belongs to the family *Saccharomycetaceae* of the order *Saccharomycetales* and phylum *Ascomycota*. The main *Candida* species of clinical relevance includes *C. albicans*, but an increasing number of non-*albicans Candida* (NAC) have been reported (Krcmery and Barnes 2002; Chen et al. 2009).

Epidemiology

Candida albicans is a commensal yeast colonizing the gastrointestinal tract and being detectable in the oral cavity in about one-third to one-half of the healthy population. Apart from effects of the composition of the oral microbial community, salivary factors seem to be involved in oral *Candida* colonization. Saliva of *Candida*-free subjects inhibits the blastoconidial growth more than that of *Candida* carriers, suggesting that salivary components modulate persistent oral *Candida* carriage (Hibino et al. 2009). Invasive candidiasis as a condition of great medical importance has shown a dramatical increase in incidence over the last 50 years. *Candida* species are regularly reported to be the fourth commonest cause of bloodstream infection (fungemia), but the incidence of infections with *Candida albicans* is falling in recent years, while other *Candida* infections are on the rise (Hobson 2003). In fact, the epidemiology has recently changed with regard to *Candida* species involved. In a US study on 2019 patients with candidemia, the incidence of candidemia caused by non-*albicans Candida* species (54.4 %) was higher than the incidence of candidemia caused by *C. albicans* (45.6 %). Patients with *C. parapsilosis* candidemia had the lowest mortality rate and were less likely to be neutropenic compared with patients infected with other *Candida* species. *Candida krusei* candidemia was most commonly associated with prior use of antifungal agents, hematologic malignancy, stem cell transplantation, or neutropenia, and patients infected by this fungus showed the highest crude 12-week mortality (Horn et al. 2009).

Hepatobiliary Candidiasis

Hepatobiliary candidiasis is increasingly seen in recent years due to factors already briefly discussed above. It predominantly occurs in immunocompromised patients and cancer patients (Lewis et al. 1982; Haron et al. 1987; Thaler et al. 1988; Carstensen et al. 1990). It presents as

Table 1 Phenotypical classification of hepatobiliary candidiasis

Disseminated ("miliary") hepatic candidiasis
Granulomatous hepatitis
Candidal liver abscess
Focal hepatic candidiasis (candidoma of the liver, *Candida* pseudotumor)
Candidal hepatic thrombovasculitis
Candidal cholangitis
Candidal cholecystitis

several forms of hepatic tissue damage associated with inflammatory changes (Table 1). In an autopsy study, hepatic granulomas and microabscesses were the two most common histologic lesions attributable to *Candida* infection (Lewis et al. 1982). The emergence of a given phenotype of hepatic infection depends on *Candida* virulence, *Candida* species, the neutrophil and immune status of the host, duration of disease, and effects of treatment measures. Part of the inflammatory and necrobiotic alterations cause mass lesions that may mimic hepatic malignancy. Hepatic candidiasis is often associated with manifestations in the spleen (the hepatosplenic candidiasis syndrome), particularly in patients with acute leukemia and those with neutropenia (Miller et al. 1982; Fenaux et al. 1989; von Eiff et al. 1990; Loeliger et al. 1992; Anttila et al. 1994, 1997; Colovic et al. 1999; Sallah 1999; Rammaert et al. 2012). There are also patients showing a protracted from of hepatic/hepatosplenic candidiasis (chronic disseminated candidiasis; Blade et al. 1992; Pagano et al. 2002; Masood and Sallah 2005). In hepatic candidiasis, *C. albicans* is a dominant causing agent, but other *Candida* species are also involved, including *C. glabrata* (Pinès et al. 1994) and *C. tropicalis* (McGuire et al. 1992).

Disseminated ("Miliary") Hepatic Candidiasis

This phenotype of candidiasis is characterized by small abscesses spread throughout the organ. The

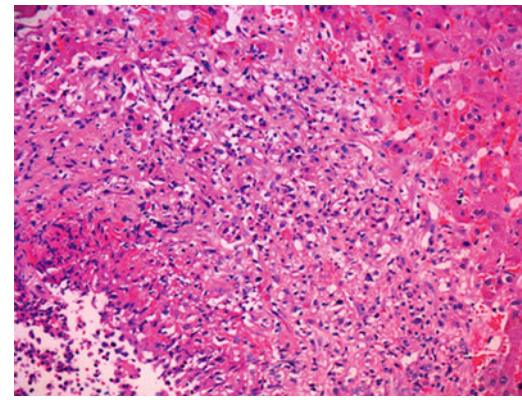

Fig. 1 Candidoma of the liver. A central necrosis with neutrophil reaction (*left lower corner*) is demarcated from the liver tissue by granulomas (hematoxylin and eosin stain)

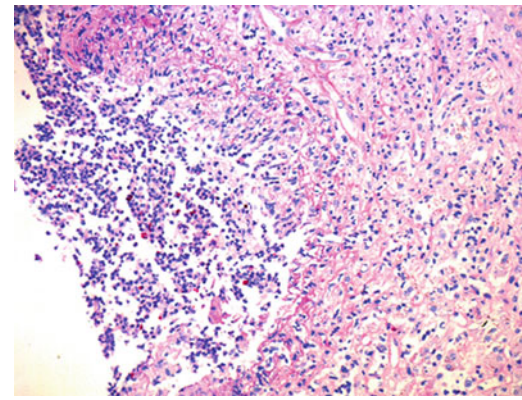

Fig. 2 The exudative center in hepatic candidoma contains PAS-positive *Candida* organisms (PAS stain)

lesions are characterized by small accumulations of neutrophils and macrophages, the latter being more frequent at the periphery of the lesions, where also a few lymphocytes and eosinophils may be seen. The center of lesions may show focal tissue necrosis, but not of the caseifying type. Within the lesions, typical *Candida* elements can be found (Figs. 1 and 2).

Granulomatous Hepatitis

Candida infection of the liver may induce the formation of epithelioid macrophages and the

generation of granulomas, depending on the immune status of the host and macrophage reactivity. *Candida*-induced granulomatous hepatitis was observed in patients with hematologic malignancies (Jones 1981), The granulomas may contain *Candida* elements or may not show any microorganisms.

Candidal Liver Abscesses

Most of liver abscesses caused by *Candida* species occur in patients with hematologic malignancies and are a manifestation of disseminated candidiasis (Lewis et al. 1982; Haron et al. 1987). The clinical features of these sometimes large lesions have been described in detail. Apart from disseminated candidiasis, candidal liver abscesses can also develop subsequent to fungemia from the portal vein or an ascending retrograde infection from the biliary tract (McGuire et al. 1992; Annunziata et al. 1997). Candidal liver abscess may rarely develop in immunocompetent and nondiabetic hosts, e.g., following severe calculous cholecystitis (Lima et al. 2010), in primary sclerosing cholangitis (Melero et al. 2008), and in neonates (Filippi et al. 2009). Candidal liver abscesses are solitary or multiple lesions, whereby the latter seem to be more common. These lesions produce a characteristic imaging picture. In the active phase of disease, hepatomegaly is found together with the "wheel-in-wheel" phenomenon, the "wagon wheel" appearance, and/or the "bull's eye" lesions, whereas later phases show hypoechoic parenchymal defects (Bartley et al. 1982; Ho et al. 1982; Schmidt et al. 1986; Grunebaum et al. 1991; Rudolph et al. 2004). Histopathologically, the morphologic presentation of candidal abscesses deviates somewhat from that of bacterial abscesses. Pus is present in the center of most lesions, but the delimitating wall of granulation tissue more often displays activated macrophages and epithelioid cells, sometimes with a granulomatous reaction. This feature can be recognized in needle or wedge liver biopsies (Johnson et al. 1988). The suppurative exudate that may contain significant components of necrotic debris is tissue sludge, and fungal elements are often visible in H&E-stained preparations already.

Selected References Finkelstein et al. (1985), Friedman et al. (1987), Maxwell and Mamtora (1988), Filice et al. (1989), Ishii et al. (1990), Singh et al. (1992), Miyata et al. (1995), Lipsett et al. (1997), Lai et al. (2005), Tsai et al. (2006), Melero et al. (2008), Lima et al. (2010), and Yellapu et al. (2010).

Focal Hepatic Candidiasis ("Candidomas")

Focal hepatic candidiasis is a distinct clinical variant of candidiasis occurring mainly in immunocompromised patients. Although affected patients may exhibit previous evidence of extrahepatic candidiasis, disease manifestations are localized to the liver at the time point of diagnosis (Tashjian et al. 1984; Abella et al. 1990; Tsui and Liang 1991). Clinically, patients with focal hepatic candidiasis have fever unresponsive to antibacterial therapy, marked abdominal symptoms, elevated serum alkaline phosphatase, and hepatic defects on abdominal CT. Peritoneoscopy may reveal studding of the liver surface with white plaques, which may later be followed by perihepatic adhesions (Gordon et al. 1990).

Histologically, the focal lesions consist of parenchymal necrosis colonized by variable numbers of *Candida* elements, mainly hyphal forms. Some of the focal lesions have an infarctoid aspect, so that vascular oburation (e.g., due to fungal vasculitis) may be assumed. The damaging effects of neutrophil granulocytes may play an important pathogenic role. This is underlined by the observation that focal hepatic lesions may become invisible during neutropenia (Pestalozzi et al. 1997). Some lesions contain large amounts of fibrin-rich exudate intermingled with necrotic debris. It has been suggested that this exudative reaction is responsible for the "sonographic snowstorm" seen in some cases of focal hepatic fungal infection (Keane et al. 1995).

Candidal Cholangitis (Mycotic Biliary Obstruction, *Candida* Bile Duct Obstruction, Biliary Fungus Balls)

Infections of the biliary tract with *Candida* species are rare disorders but have increasingly been seen in the past years. Symptomatic biliary tract candidiasis (candidal cholangitis) can involve the bile duct system as a component of a systemic infection or as an isolated affliction, the former being uncommon. In most cases, the presence of *Candida* in the lumina of bile ducts does not seem to be of clinical significance. In a series of 123 consecutive patients undergoing ERCP, 54 patients showed *Candida* species in bile samples. The yeasts were mainly *C. albicans* and *C. glabrata* and rarely *C. parapsilosis* (Lenz et al. 2009). *Candida* species have also been found as a biofilm on biliary stents, e.g., *C. glabrata* in microbial community with *Mycoplasma salivarium* (Henrich et al. 2010). However, in a subset of infected patients, and mainly those with immunosuppression, candidal cholangitis (symptomatic biliary tract candidiasis) develops, eventually associated with biliary obstruction (Uflacker et al. 1982; Gupta et al. 1985; Chen et al. 1986; Irani and Truong 1986; Morris et al. 1990; Radin and Johnson 1992; Potoczek and Kuliczkowski 1994; Diebel et al. 1996; Wig et al. 1998; Alvarez et al. 2000; Reeves et al. 2000; Domagk et al. 2001; Zhao et al. 2005; Kulaksiz et al. 2006; Rodriguez et al. 2007). In cholangitic patients, endoscopy can reveal the typical signs of inflammatory change with stenosis and mycelia in the bile duct system (Domagk et al. 2006). *Candida* may be the sole identified organism, but patients may also show mixed fungal and bacterial infections of the bile ducts (so-called polymicrobial cholangitis; Diebel et al. 1996; Alvarez et al. 2000). Candidiasis of the common bile duct may cause high-degree stenosis with prestenotic dilatation, followed by chronic secondary sclerosing cholangitis with a bead-like deformation of the bile ducts (Domagk et al. 2001). Cholangiography showed dominant or multiple stenosis and irregular contour of the bile duct mucosa, and one or more intraluminal filling defects represent fungus balls. In a subset of patients with biliary candidiasis, large amounts of *Candida* organisms proliferate in superficial parts of, and in exudate on, the mucosa. In case this layer of fungal mycelia intermingled with the exudate and the bile detaches from the bile duct surface, large fungal masses may develop, termed fungal balls. These structures may cause biliary obstruction (Marcucci et al. 1978; Magnussen et al. 1979; Uflacker et al. 1982; Carstensen et al. 1986; Irani and Truong 1986; Ho et al. 1988; Cheema 1995).

Pathologically, the bile duct in biliary candidiasis shows varying degrees of mucosal inflammation, sometimes with erosions and ulcerations. The inflamed mucosa and the mucosal defects are covered with bile-containing exudate, in which the typical *Candida* elements are seen, often forming a dense population of organisms. *Candida* fungi may invade the epithelium and cause necrosis and apoptosis. In one patient, a long tubular filamentous structure with several branches could be extracted from the common bile duct, representing a *Candida* conglomerate (Domagk et al. 2001).

Promotion of Liver Metastases by *Candida*

Systemic candidiasis favors the development of hepatic metastases. *Candida* contains peptide components that enhance melanoma cell adhesion to endothelial cells (Ramirez-Garcia et al. 2011).

Hepatobiliary Cryptococcosis

Introduction

Cryptococcosis or cryptococcal disease is a common and potentially fatal fungal infection caused by species of *Cryptococcus* (the name meaning "hidden sphere"), mainly *Cryptococcus neoformans*. This infectious disease is also termed the Buschke disease or Busse-Buschke disease (Buschke 1895; Busse 1894). *Cryptococcus* is a basidiomycete fungus genus that is found worldwide and causes disease (cryptococcosis) in humans and diverse vertebrate animal species

(review: Casadevall and Perfect 1998). The classification of one of the most important pathogenic yeast genera in medicine, *Cryptococcus*, is complex because *Cryptococcus* is not monophyletic and forms a species complex (Lin and Heitman 2006). Cryptococci belong to the class *Hymenomycetes*, but there are cryptococci in the orders *Cystofilobasidiales*, *Trichosporonales*, *Filobasidiales*, and *Tremellales*. The genus *Cryptococcus* includes more than 50 species, but *C. neoformans* (including its variant grubii), *C. gattii*, *C. albidus*, *C. uniguttulatus*, *C. laurentii*, and *C. uzbekistanensis* are the only species that are pathogenic for humans.

Clinical Features

Cryptococcosis presents with a distinct spectrum of manifestations (Lewis and Rabinovich 1972). Clinically, three principal types of infection are recognized, viz., wound or cutaneous cryptococcosis, pulmonary cryptococcosis, and cryptococcal meningitis/meningoencephalitis (CNS cryptococcosis). Less common clinical entities comprise bone cryptococcosis (chiefly osteolytic lesions), chorioretinitis, myocarditis, cellulitis, and focal cryptococcal lesions of internal organs. In part of the patients, cryptococcosis presents as an asymptomatic pulmonary infection followed by the development of meningitis/meningoencephalitis, while disseminated cryptococcosis is a rare disease occurring in immunocompromised patients, chiefly AIDS patients but also organ transplant recipients. This is due to the important role played by the T-lymphocyte system in anti-*Cryptococcus* defense (Lewis and Rabinovich 1972).

Liver Involvement in Cryptococcosis

Involvement of the liver is a recognized feature, however, with several presentation patterns. The overall prevalence of liver disease in cryptococcosis is only partially known. Among 171 liver specimens from patients with AIDS (155 autopsies and 16 biopsies), eight patients (5 %) showed hepatic cryptococcosis (Lanjewar et al. 2004).

Table 2 Forms of hepatobiliary cryptococcosis

Miliary cryptococcosis of the liver
Hepatic cryptococcal abscess
Hepatic cryptococcoma
Cryptococcal hepatitis
Cryptococcal cholangitis
Cryptococcal inflammatory pseudotumors
Fungal peritonitis

Overall, several studies report rates of hepatic cryptococcosis ranging from 1 % to 13 % of AIDS patients, as determined by biopsy or by autopsy. In contrast, cryptococcal liver infection is rare in non-HIV-infected patients. In review of 13 patients performed by Liu et al. (2009), two patients had hepatic failure, three had hepatitis, two showed miliary hepatic cryptococcosis, four had cholestatic jaundice, one suffered from cirrhosis, and one had acute abdominal pain.

Pathologically, hepatobiliary cryptococcosis can present in the form of several phenotypes (Table 2).

The essential histologic features of cryptococcosis in immunocompromised patients consist of fungal accumulations with a typical morphology, necrosis, and a macrophage response, but only minor lymphocytic and neutrophilic components (Staib 1986; Shibuya et al. 2001). The fungi present as globose to ovoid yeast cells (depending on the variety; see above) that have a capsule, producing neither well-developed pseudohyphae nor true hyphae. *Cryptococcus* differs from *Candida* by not forming pseudohyphae. Macrophages containing *Cryptococcus* may show a faint cytoplasmic PAS positivity. This phenomenon may be due to the fact that cryptococci located within macrophages are associated with permeabilization of phagosomes and the accumulation of polysaccharide-containing vesicles in the cytoplasm (Tucker and Casadevall 2002).

Miliary Cryptococcosis

In patients with laboratory signs of *Cryptococcus*-induced liver damage, the involvement may be microscopic only, with typical fungi located in dilated hepatic sinusoids (Fig. 3; Utili et al. 2004;

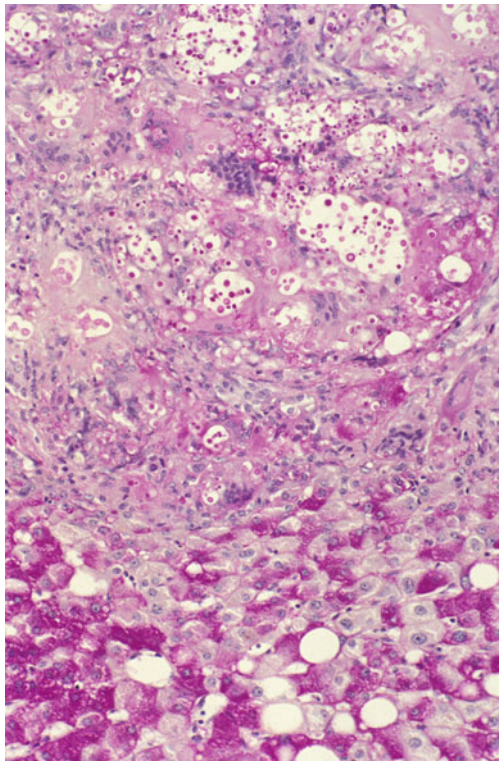

Fig. 3 Cryptococcosis of the liver. The numerous organisms present as clusters of encapsulated spherical fungi (PAS stain)

Lu et al. 2009). The spread of fungi to several organs may induce the formation of miliary lesions resembling tuberculosis (Pomar et al. 2005).

Hepatic Cryptococcal Abscess

Rarely, disseminated cryptococcosis is associated with hepatic abscesses visualized as low-attenuated liver lesions (Liu et al. 2009). These forms of abscesses deviate in their histologic presentation from bacterial abscesses, in that a macrophage component is prominent.

Cryptococcomas

Cryptococcomas are tumor-like lesions consisting of tissue necrosis, massive accumulation of fungi, and masses of phagocytes, in particular macrophages. Cryptococcomas are known from the central nervous system, but have also been observed in other tissues, including the breast (Collins et al. 1971) and the liver. In the liver, these lesions may grow to a size of several centimeters and present as low-attenuated lesions at CT, similar to abscesses. Due to their mass effect, cryptococcomas may stenose bile ducts and cause obstructive jaundice (Nara et al. 2008). Hepatobiliary cryptococcomas may develop within the lumen of bile ducts (Kim et al. 1994). Mass-forming cryptococcal lesions similar to cryptococcomas of humans have experimentally been induced in mice (Price and Bulmer 1972). Histologically, cryptococcomas are characterized by a focal parenchymal necrosis with a relatively minor cellular reactions and accumulation of numerous capsulated fungal organisms.

Cryptococcal Hepatitis

Cryptococcal hepatitis is a very uncommon manifestation of cryptococcosis (Procknow et al. 1965; Wright and Harman 1983). It may cause hepatic failure (Sabesin et al. 1963); in fact, severe hepatobiliary dysfunction may be the initial manifestation of disseminated cryptococcosis, parenchymal failure being caused by extensive hepatic necrosis (Lin et al. 1999). Necrotizing cryptococcal hepatitis can cause intrahepatic cholestasis (Mendez-Sanchez et al. 2006). Cryptococcal hepatitis can induce biliary obstruction and subsequent cirrhosis (Goenka et al. 1995).

Cryptococcal Cholangitis

A further form of hepatobiliary cryptococcosis is characterized by a distinct cholangitis resembling primary sclerosing cholangitis (Lefton et al. 1974; Bucuvalas et al. 1985).

Cryptococcal Inflammatory Pseudotumors

Cryptococcal infection may induce mass lesions that are rich in plump spindle cells arranged in a

storiform pattern. These lesions are termed cryptococcal inflammatory pseudotumors and may mimic malignancy (Sing and Ramdial 2007). Hepatobiliary cryptococcosis has been shown to sometimes have a presentation resembling Klatskin's tumor with obstructive jaundice (Kothari and Kothari 2004).

Fungal Infections in Tissue Adjacent to or Surrounding the Liver

Cryptococcosis may develop in structures adjacent to the liver. Spontaneous fungal peritonitis caused by *Cryptococcus* in immunosuppressed or non-immunosuppressed patients with liver cirrhosis is a rare disorder (Mabee et al. 1995; Stiefel et al. 1999; Sungkanuparph et al. 2002; Albert-Braun et al. 2005; Singh et al. 2010). Patients with liver cirrhosis and cryptococcosis may develop cryptococcal ascites (Franca et al. 2005; Sikorski and Marcinowska-Suchowierska 2007).

Hepatic Mucormycosis (Zygomycosis)

Introduction

Zygomycosis (formerly termed mucormycosis) is an important emerging fungal infection caused by several fungal taxa of the *Zygomycetes*. Zygomycosis in a debilitated patients is a highly aggressive and often fulminating disease with high morbidity and mortality. Zygomycosis typically involves the rhino-facial-cranial area, lungs, gastrointestinal tract, skin, and less often other organ systems (reviews: Ribes et al. 2000; Prabhu and Patel 2004; Brown 2005; Roden et al. 2005; Naggie and Perfect 2009; Skiada et al. 2011). The term, *Zygomycetes*, is an older designation of the group and traditionally existed in two orders of organisms that produce human disease, the *Mucorales* and the *Entomophthorales* (Kwon-Chung 2012). Most human zygomycoses are caused by members of the *Mucorales*; this is the main reason why many infections are termed mucormycosis, but this would require the proof (via culture or, now more commonly, molecular biology methods) that the genus *Mucor* is in fact involved. The *Mucorales* are commonly associated with angioinvasive fungal disease, often leading to thrombosis, necrosis, or infarction of the involved tissues and organs and tissue destruction mediated by a number of fungal proteases, lipases, and mycotoxins (review: Ribes et al. 2000).

Epidemiology and Clinical Features

Zygomycosis or, specifically, mucormycosis is a rare opportunistic fungal infection with increased frequency in immunosuppressed individuals (including graft recipients), patients with hematologic neoplastic disease, and during chemotherapy-induced neutropenia (Fisher et al. 1980; Singh et al. 1995; Pagano et al. 1997; Spellberg et al. 2005). *Zygomycetes* are known for their great ability to infect a broader, more heterogeneous population of human hosts than other opportunistic molds. *Mucor* infection provokes several clinical entities, namely, rhinocerebral, pulmonary (these two are the most common), cutaneous, gastrointestinal, and disseminated diseases (Mantadakis and Samonis 2009). The gastrointestinal form (including the liver) is uncommon, accounting for about 2 % of the cases only (Singh et al. 1995).

Liver Involvement in Zygomycosis

Liver involvement has been recognized under several circumstances, but mostly occurs in patients with disseminated zygomycosis (Chailly and Couturier 1976; McGinnis et al. 1982; ter Borg et al. 1990; Al-Asiri et al. 1996; Erdem et al. 1996; Oliver et al. 1996; Schipper et al. 1996; Suh et al. 2000; Tsaousis et al. 2000; Yamauchi et al. 2002; Mekeel et al. 2005; Padmanabhan et al. 2007; Skiada et al. 2009; Lüer et al. 2009; Busca et al. 2010; Itoh et al. 2012). The radiologic presentation of *Mucor*-induced lesions has been described. Abdominal CT demonstrates few to multiple hypodense lesions with distinct margins (Hagspiel et al. 1995; Suh et al. 2000; Singh 2002; Busca et al. 2010). Zygomycosis of the

Table 3 Hepatic lesions in zygomycosis

Mycotic aneurysms

liver can result in hepatic failure (Erdem et al. 1996). In zygomycosis, several types of parenchymal lesions of the liver can develop (Table 3).

Macroscopically, the fungus-induced lesions are either small and ill-defined necroses or, less commonly, larger infarct-like lesions. These large lesions are called eumycetomas (Sedlacek et al. 2009). As zygomycosis is markedly angioinvasive, the formation of mural vascular thrombi that harbor masses of fungal hyphae is a hallmark. *Mucor*-induced thrombosis of the major hepatic veins associated with Budd-Chiari syndrome has been observed (Vallaeys et al. 1989). In grafted livers, *Mucor* infection can compromise the liver artery anastomosis via induction of thrombosis (Marco del Pont et al. 2000; Brandao et al. 2003). Infection of the hepatic artery can lead to artery rupture (Zhan et al. 2008).

Miliary Necroses/Microabscesses

Histologically, liver lesions are necrotic foci of variable size. Typically, the morphology of the necrosis is that of the so-called coagulative necrosis, with nuclear debris (karyorrhexis) and signs of karyopyknosis. The necroses may, at their periphery, be demarcated by an epithelioid macrophage reaction, and multinucleate giant cells with phagocytosed hyphae may be in evidence (McGinnis et al. 1982). The inflammatory response in zygomycosis is predominantly neutrophilic in about half of the cases, whereas less common presentations are pyogranulomatous or granulomatous. Fungal angioinvasion and perineural invasion are seen in practically all cases (Frater et al. 2001). In tissue sections, the hyphae in zygomycosis are irregularly shaped filaments with focal bulbous dilatations ("ballooning"), a "twisted ribbon" appearance, and infrequent septations (Fig. 4). In contrast to *Aspergillus*, branching is blunt, i.e., with angles more than 45°. The organisms are readily recognized in PAS, silver methenamine, and Grocott stains. As primitive coenocytic hyphae, the filaments are delicate and may be rapidly damaged by processing, rendering diagnosis difficult in some cases.

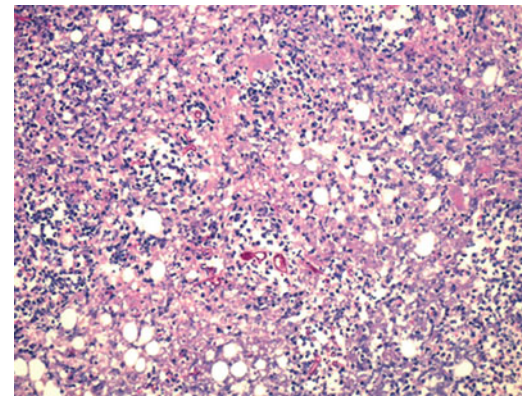

Fig. 4 Hepatic zygomycosis (mucormycosis). A densely infiltrated tissue area in a steatotic liver contains irregularly shaped fungal organisms (PAS stain)

Mycotic Macroabscess

Some zygomycotic infections can induce liver masses that correspond to classical pyogenic liver abscess, e.g., *Rhizopus oryzae* (Dalgic et al. 2011).

Hepatic Hilar Zygomycotic Pseudotumor

Zygomycosis caused by *Mucor* species can mimic hilar cholangiocarcinoma. In a 36-year-old man with jaundice, abdominal CT and MR revealed a mass lesion occupying the porta hepatis and partial left lateral liver lobe. MR cholangiopancreatography demonstrated an abrupt stenosis of the

bile duct confluence with symmetric upstream dilatation of the intrahepatic bile ducts. The resection specimen showed inflammatory tissue with fungal hyphae typical for *Mucor* (Li et al. 2010).

Mycotic Venous Thrombosis

Infection with *Mucor* can cause thrombosis of hepatic veins and Budd-Chiari syndrome (Chailly and Couturier 1976; Vallaeys et al. 1989).

Mycotic Arterial Thrombosis

Infection of the wall of the hepatic artery by *Mucor* species can cause thrombosis of this vessels. This severe complication has also been found in a liver graft (Marco de Pont et al. 2000).

Mycotic Aneurysms

Zygomycosis can result in the development of mycotic artery aneurysms and pseudoaneurysms, including the aorta, pulmonary arteries, and also visceral arteries, e.g., the splenic artery (Nevitt et al. 2001). The involved hepatic artery can undergo rupture (Zhan et al. 2008).

Hepatobiliary Aspergillosis

Introduction

Aspergillus species are opportunistic pathogens that cause the human infectious disease, aspergillosis (review: Latge 1999). Aspergillosis is the term employed to denote any animal or human disease caused by any member of the *Aspergillus* genus on a living host. *Aspergillus fumigatus* causes 90 % of invasive aspergillosis, a devastating disease with a still very high mortality rate. Besides this acute invasive aspergillosis, a chronic form of this infection may be encountered as chronic necrotizing pulmonary aspergillosis or chronic invasive sinusitis. The fungal genus *Aspergillus* already received its name in 1729. In viewing the conidia-bearing fungus in the microscope, Micheli was reminded of the sprinkling device used in Roman Catholic ritual, the asperges. The defining feature of the genus *Aspergillus* is the aspergillum-like conidia-bearing structure. End cells or foot cells of hyphae develop a specialized structure called conidiophore perpendicular to the long axis of the hyphal cell. The conidiophore enlarges at its apex and forms a club-shaped vesicle. The fertile domain of the vesicle procures a layer of cells called phialides (synonym: stigmata). The phialides generate long chains of mitotic spores called conidiospores or conidia. The conidia have distinct colors in different *Aspergillus* species (green in *A. fumigatus*, black in *A. niger*). *Aspergillus* has at least 250 defined species.

Epidemiology

The incidence of aspergillosis is increasing in parallel with the number of immunosuppressed individuals, but it is also a well-recognized disease in critically ill but non-immunocompromised patients. Among patients with solid organ transplantation, lung and liver transplant recipients are at the highest risk of developing acute invasive aspergillosis (Rubio et al. 2011). After liver transplantation, aspergillosis has been found in 19/408 (4.6 %) recipients by the use of routine and molecular methods (Badiee et al. 2010). Other associated conditions include influenza, nonfungal pneumonia, chronic obstructive lung disease, immaturity, sepsis, alcoholism, acute and chronic liver failure, and surgery (Falcone et al. 2011; Stevens and Melikian 2011).

Clinical Manifestations of Aspergillosis

Aspergillosis presents in the form of several disease phenotypes which differ between patients with or without immunosuppression, generalized infections being more common in the latter. The most important clinical form of this fungal infection is pulmonary aspergillosis. It manifests as noninvasive aspergillosis characterized by

aspergilloma (fungus balls, often in the setting of tuberculosis or silicosis), acute invasive pulmonary aspergillosis (mainly in neutropenic patients), chronic narcotizing aspergillosis (a slowly progressive, semi-invasive form mainly seen in mildly immunosuppressed individuals), and allergic aspergillosis (ranging from extrinsic asthma to hypersensitivity pneumonitis). Noninvasive aspergilloma may develop following repeated exposure to inhaled conidia and usually target preexisting lung cavities such as bronchiectases or healed tuberculous caverns. Allergic bronchopulmonary aspergillosis is found in individuals with altered lung function such as asthma and cystic fibrosis. A second important form is a group of localized aspergillosis, mainly of the paranasal sinuses and the skin. Thirdly, there is disseminated aspergillosis, caused by hematogenous dissemination to several visceral and other organs.

Hepatobiliary Aspergillosis

It has been found that 11 % of patients who die of or with aspergillosis have liver involvement (Young et al. 1970). The clinical pattern of hepatic aspergillosis varies and depends on the extent of invasion and the anatomic site of the liver involved. In few instances, primary hepatic aspergillosis has been observed in adult patients with no evident immunological impairment (Carosi et al. 1985). Preexisting liver disease can be followed by aspergillus infection, e.g., biloma (Ioannidis et al. 1995).

Aspergillosis of the liver presents in eight major forms (Table 4), i.e., septic foci with miliary to submiliary lesions, liver abscesses, aspergilloma, fungus-containing liver necroses, *Aspergillus* cholangitis, angioinvasive aspergillosis with invasion of large hepatic veins, hepatic artery aspergillosis, and disseminated aspergillosis with a presentation resembling veno-occlusive disease.

Table 4 Major forms of hepatobiliary aspergillosis

Submiliary/miliary aspergillosis of the liver
Aspergillotic liver abscess
Aspergilloma of the liver
Aspergillotic inflammatory pseudotumor of the liver
Aspergillus cholangitis
Angioinvasive aspergillosis with invasion of large hepatic veins
Hepatic artery aspergillosis
Disseminated aspergillosis mimicking veno-occlusive disease

Submiliary/Miliary Hepatic Aspergillosis

In part of the patients with disseminated aspergillosis, multiple liver lesions mimicking those seen in hepatosplenic candidiasis may develop, chiefly during neutropenic phases following an induction chemotherapy (Callister et al. 2004; Potenza et al. 2008). The lesions consist of small foci of parenchymal necrosis containing *Aspergillus*, but only a minor cellular infiltrate, owing to the neutropenic status of the patients (Figs. 5 and 6). In most situations, one notes a tiny focus of parenchymal necrosis, sometimes, with apoptotic bodies, admixed with a fibrinous exudate. Within this background of slightly eosinophilic granular debris, typical *Aspergillus* hyphae are in evidence. As the hyphae are sometimes pale, they may be overlooked in the necrosis background, but they are clearly visualized in PAS and silver methenamine stains. *Aspergillus* hyphae are septated and typically branched with a bifurcation angle of

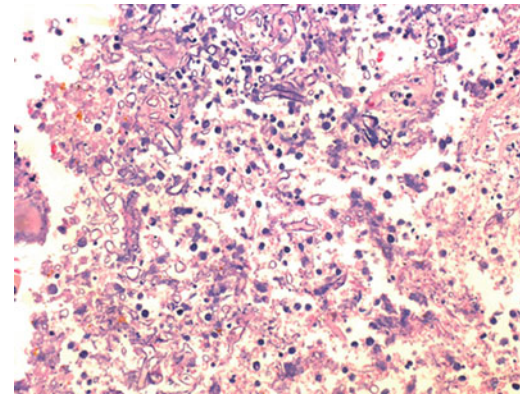

Fig. 5 Aspergillus abscess of the liver. The lesion contains numerous filamentous fungi that show bifurcation (hematoxylin and eosin stain)

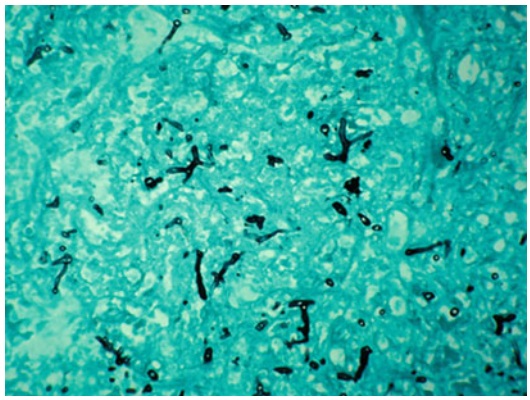

Fig. 6 Hepatic aspergillosis. The fungal filaments bifurcate with an angle smaller than 90° (silver methenamine stain)

about 45°. The reticulin network may still be preserved. At the periphery of the lesions, few neutrophils and lymphocytes are noted, and there may be signs of Kupffer cell activation in the vicinity. The fungal hyphae may invade small vascular channels, in particular sinusoids of adjacent liver parenchyma, with sinusoidal thrombosis.

Aspergillotic Liver Abscess

The development of true and large hepatic abscesses by *Aspergillus* infection is rare and has predominantly been found in patients with acute leukemia and other hematologic malignancies (Trachana et al. 2001; Lee et al. 2003; Marotta et al. 2005; Yamada et al. 2010, Yeon et al. 2010). *Aspergillus* liver abscesses are also found in immunodeficient children, e.g., caused by *Aspergillus terreus* in common variable immunodeficiency (Trachana et al. 2001). Hepatic aspergillus abscesses can be diagnosed by the use of fine needle aspiration cytology. It has been reported that puncture yielded a clear milky fluid that was positive for *Aspergillus* fungi (Vairani et al. 1990). Liver abscesses in aspergillosis may show a diameter of several centimeters and mimic neoplastic tumors. Histologically, the abscesses exhibit a central part which consists of necrotic tissues, a leukocyte accumulation, and a fibrinous exudative reaction. The leukocyte population varies markedly from one lesion to the other and is poor in neutrophils in neutropenic patients. In the latter, the abscess is atypical in that necrosis and exudate predominate over the classical pus expected in true abscesses. The periphery of the abscess shows an infiltrate that contains lymphocytes, macrophages, and few plasma cells. An epithelioid cell reaction may be encountered, but a true granulomatous response is usually not in evidence.

Aspergilloma of the Liver

It is, above all, hepatic aspergilloma which may clinically and radiologically mimic liver malignancy. The imaging features of aspergilloma in the liver have been outlined (Ow et al. 1991). Aspergillomas are large lesions that result from confluence of smaller abscesses and/or necroses caused by parenchymal *Aspergillus* infections. Most of the masses are usually accounted for by necrotic tissue admixed with exudate. The lesions are demarcated by a rim of granulation tissue.

Aspergillotic Inflammatory Pseudotumor of the Liver

In rare instances, a marked inflammatory response ensues, resulting in hepatic mass chiefly consisting of cellular infiltrates replacing necrosis, granulation tissue, and fibroblastic proliferations with deposition of extracellular matrix (Tamsei et al. 2004). It may be difficult to detect viable *Aspergillus* organisms within this tissue.

Aspergillus Cholangitis

The gallbladder and gallbladder stones form a niche where several species of fungi can exist, including *Aspergillus*, often without clinically manifest fungal infection (Gupta et al. 1993). Aspergillosis of the biliary tract with inflammatory changes in duct walls (cholangitis) is observed in

patients with relevant immunosuppression, e.g., after liver transplantation. In biliary duct biopsies, an exudative inflammation is seen, the exudate and the adjacent tissue being colonized by *Aspergillus* hyphae (Yuchong et al. 2010).

Angioinvasive Aspergillosis with Invasion of Hepatic Veins

Hepatic aspergillosis with invasion of hepatic veins causes a disorder resembling Budd-Chiari syndrome (Young 1969). Following liver transplantation, *Aspergillus* invasion of the portal vein system, associated with thrombosis of these vessels, has been observed (Gavilan et al. 1998).

Hepatic Artery Aspergillosis

Aspergillus invasion of the hepatic artery was observed following liver transplantation (Gavilan et al. 1998). Mixed *Aspergillus* and *Mucor* hepatic artery infection after liver transplantation led to artery rupture in one patient following combined liver and kidney transplantation (Zhan et al. 2008).

Disseminated Aspergillosis Mimicking Hepatic Veno-occlusive Disease

Disseminated aspergillosis mimicking hepatic veno-occlusive disease is very uncommon and is caused by invasion of hepatic sinusoids by fungal hyphae (Daikos et al. 2005).

Differential Diagnosis

In regard to etiology, aspergillosis may be confounded with other fungal infections characterized by growing hyphae, in particular *Mucor* infections. Both *Aspergillus* and *Mucor* have septated hyphae. In PAS- or silver methenamine-stained sections, the branching mode of the hyphae is a decisive diagnostic discriminator, as hyphae in *Aspergillus* consistently show acute branching angles, while branching angles in *Mucor* are blunt and exceed 90°.

Histoplasmosis

Introduction

Histoplasmosis is a fungal infection caused by the onygenalean fungi *Histoplasma* (*H.*) *capsulatum* and *H. duboisii* (reviews: Cano and Hajjeh 2001; Nosanchuk and Gacser 2008; Kauffman 2007, 2009). The fungal infection is also known under the terms Cave disease, Darling's disease (in honor of the scientist who found the fungus), Spelunker's lung, and Caver's disease. Infections with *H. capsulatum* reveal certain endemic features; e.g., histoplasmosis caused by this agent is endemic to the Midwestern and east central states in the United States near the Mississippi and the Ohio River valleys ("Ohio River valley fever"), Mexico, and Rio de Janeiro state in southeastern Brazil. Endemic areas in Europe have also been detected (Ashbee et al. 2008). One species of *Histoplasma*, *H. duboisii*, is common in caves of southern and East Africa. It is estimated that *H. capsulatum* is the most common cause of invasive fungal pulmonary disease worldwide and that about 500,000 infections occur in the United States each year.

Hepatobiliary Involvement in Histoplasmosis

Gastrointestinal and hepatic involvement are common in disseminated histoplasmosis caused by *H. capsulatum*, both in immunocompetent and immunosuppressed subjects (Goodwin et al. 1980; Escher et al. 2012). In African histoplasmosis caused by *H. duboisii*, gastrointestinal involvement has been estimated to be 26 % (Pichard et al. 1987). The liver has been estimated to be involved in up to 90 % of cases with disseminated *H. capsulatum* disease (Goodwin et al. 1980), but this figure may be too high. In HIV-infected patients having hepatobiliary disease and treated with non-highly active antiviral therapy, liver biopsies revealed *Histoplasma* infection in 20 % (Lizardi-Cervera et al. 2005).

Clinically, hepatomegaly was detected in about two-thirds of patients with disseminated histoplasmosis by the use of CT (Radin 1991).

In histoplasmosis, several types of liver lesions can develop (Table 5).

In the liver, the most common findings are hepatic granulomas (granulomatous hepatitis, both within the parenchyma and in portal tracts; Jariwalla et al. 1977; Lazo 1977; Lizardi-Cervera et al. 2005; Kibria et al. 2009) and portal tract lymphohistiocytic inflammation. Granulomatous hepatitis in histoplasmosis is less common than nonspecific hepatitis and seen in less than 20 % of involved livers in one study of 52 patients (Lamps et al. 2000). Rarely, hepatic histoplasmosis is manifest as acute granulomatous hepatitis (Lanza et al. 1970). In disseminated histoplasmosis, a diffuse accumulation of macrophages containing the fungi may occur (Escher et al. 2012). This is the diffuse hepatic macrophageal disease (DHMD). Increased numbers of fungus-containing macrophages are noted in the distended sinusoids, and these macrophages apparently cause sinusoidal congestion.

Large accumulations of parasitized macrophages may coalesce to form nodular lesions that are visualized at gross examination (the nodular form of hepatic histoplasmosis). Among 36 autopsied patients with liver involvement, grossly enlarged livers were found in 47 %, and 39 % had mottled or markedly congested livers. 17 % had discrete, grossly apparent hepatic lesions, forming nodules ranging from 0.2 cm to more than 1.0 cm in greatest dimension. These nodules were parenchymal and capsular in location (Lamps et al. 2000). In advanced disease, necrosis resembling caseous necrosis can develop (Darling 1909; Chen and Lin 1990). In the cases analyzed by Darling (1909), the areas of necrosis were grayish yellow in color, the larger ones often being arborescent in shape. These arborescent necroses involved the portal radicals which they followed, and these arborescent twigs had four to six limbs, reflecting to angioarchitecture and hence suggesting a vascular damage pathway. The necrobiotic changes associated with inflammation can resemble tuberculous lesions ("pseudotubercles"), all the more so as they can cause hepatic calcification (Okudaira et al. 1961). Histologically, the necroses resemble coagulation necrosis with shadow cells and nuclear debris. These areas often contain large cells, probably macrophages, that are distended by parasites (Fig. 7; Darling 1909). Few multinucleated giant cells of the Langhans type are noted. In smears of fresh lesions, the yeast form of *H. capsulatum* is round or oval in outline and measures 1–4 μm

Table 5 Types of liver involvement in histoplasmosis

Nodular hepatic histoplasmosis
Giant cell-rich lesions in African histoplasmosis
Histoplasmotic pseudotumor

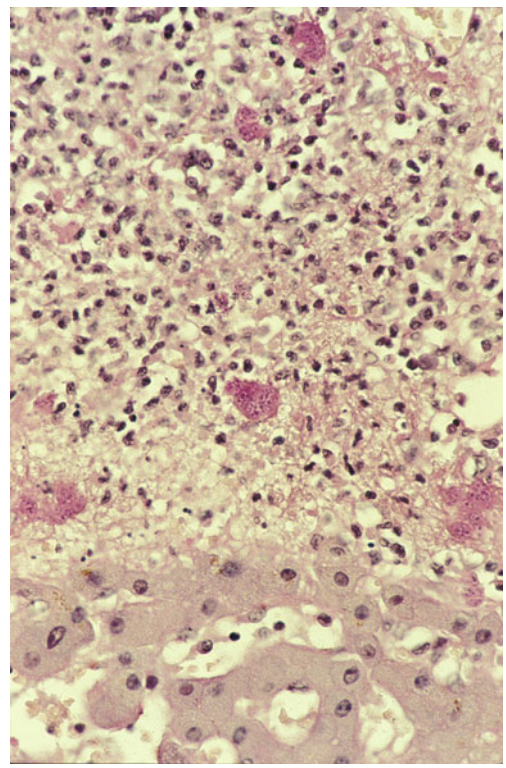

Fig. 7 Histoplasmosis of the liver. Enlarged macrophages contain numerous small spherical fungal organisms (PAS stain)

through its greatest diameter. In Leishman's or Hastings' stains, the inner part of the fungal cell contains variably shaped chromatoid bodies. The latter occupy the periphery of the fungal cell, while they are more centrally placed in yeasts located within macrophages. The yeast is typically surrounded by a refractile capsule, one-sixth of the diameter of the fungus in width, which does usually not stain. *Histoplasma* is seen within macrophages as numerous small and spheroid organisms, already visualized in H&E-stained sections, but more evident in PAS and Gomori methenamine stains.

The liver may be involved in African histoplasmosis (Williams et al. 1971; Valmary et al. 1984; Delclaux et al. 1992). The pathological presentation of African histoplasmosis is distinct from that of classical histoplasmosis caused by *H. capsulatum*. In a necropsy study of 45 cases of African histoplasmosis observed in Nigeria (Williams et al. 1971), the liver was usually enlarged to about 1.5 times its normal size. The capsule was studded with tiny yellowish discrete nodules, and miliary lesions of yellow to whitish color were also noted in the parenchyma. Most of these lesions did not exceed 3 mm in diameter; they may coalesce, the resultant confluent nodules then becoming much larger, causing a tumor-like space-occupying mass with satellite nodules (Williams et al. 1971). Similar miliary lesions were sometimes found on the peritoneal surface of the gallbladder. Histologically, a typical *H. duboisii* lesion is a granuloma that may be rich in multinucleated giant cells of the Langhans type. Some of the foci almost exclusively consist of these giant cells. The lesions contain numerous yeast cells that are larger (8–15 μm in diameter) and thicker walled than those of *H. capsulatum*. These yeast cells may occur in chains of four to five cells (review: Gugnani and Muotoe-Okafor 1997).

Involvement of Extrahepatic Bile Ducts

In disseminated histoplasmosis, involvement of the extrahepatic bile ducts may occur. It has been observed in pediatric patients in the absence of HIV infection, i.e., in one child with lymphoblastic leukemia and histoplasmotic cystic duct obstruction (Patrick et al. 1992) and in another child without any signs of immunosuppression and common bile duct obstruction (Rescorla et al. 1994). Extrahepatic bile duct involvement has also been found in adults with and without HIV infection, sometimes causing biliary obstruction (Kahi et al. 2005; Abu al Rub et al. 2009; Kapelusznik et al. 2011). In two of these cases, distal common bile duct obstruction was associated with duodenal and in part ulcerative inflammation (Abu al Rub et al. 2009; Kapelusznik et al. 2011).

Basidiobolomycosis

Introduction

Basidiobolomycosis is a newly emerging fungal infection of the zygomycosis type caused by *Basidiobolus ranarum* (Kian Joe et al. 1956; Symmers 1960; review: Gugnani 1999). It is chiefly a cutaneous and subcutaneous infection, but part of the patients have gastrointestinal disease (gastrointestinal basidiobolomycosis, GIB) that causes substantial morbidity and mortality (Khan et al. 2001; Lyon et al. 2001).

Epidemiology

Kian Joe and coworkers (1956) seem to be the first who have identified *B. ranarum* with certainty as the cause of human infection, based on extensive subcutaneous granulomas found in an Indonesian child (Kian Joe et al. 1956). These authors cited to other reports in which infection had been attributed to *B. ranarum*, one concerning a horse from the East Indies (van Overeem 1925) and the other concerning an infected gastric ulcer from a man of Istria (Casagrandi 1931). Basidiobolomycosis is mainly a disease of children and young adolescents, being less common in older adolescents and adults. Females are more often affected. Most

cases of basidiobolomycosis have been identified in warm or tropical countries.

Clinical Features

The cutaneous-subcutaneous form of basidiobolomycosis (subcutaneous zygomycosis) is clinically characterized fluctuant firm and non-tender swellings on trunk and extremities. Gastrointestinal basidiobolomycosis (gastrointestinal zygomycosis) has a nonspecific presentation and most often involves the colon (Khan et al. 2001; van den Berk et al. 2006; Hussein et al. 2007; El-Shabrawi and Kamal 2011; Vikram et al. 2012). It presents with fever, abdominal pain, signs of the so-called acute abdomen, abdominal mass, and high blood eosinophilia. In children, intestinal basidiobolomycosis can resemble fistulating Crohn's disease (Saadah et al. 2012). Colonic basidiobolomycosis can cause colonic masses closely mimicking malignancy. Basidiobolomycosis can also manifest as pulmonary disease, retroperitoneal infection, or a disseminated fungal disease, the latter form having a high mortality and developing in both immunocompetent and immunocompromised individuals.

Hepatobiliary Basidiobolomycosis

In part of the patients with gastrointestinal basidiobolomycosis, the infection involves the liver and produces pseudotumoral masses mimicking a hepatic malignancy (van den Berk et al. 2006). Among 44 patients with gastrointestinal basidiobolomycosis, liver or gallbladder involvement was detected in 13 patients (30 %) (Vikram et al. 2012). In a 61-year-old male with stenosing colonic basidiobolomycosis, abdominal CT revealed a hepatic mass of 6 cm diameter, first thought to be an amoebic abscess. Under therapy, the lesion grew to a diameter of 9 cm, and biopsy revealed basidiobolomycosis (van den Berk et al. 2006).

Histopathology is characterized by a marked granulomatous reaction with giant cells and formation of palisading granulomas around fungal elements. In tissue sections, the fungus is visualized as unusually large, thin-walled, aseptate or rarely septate broad hyphae or hyphal fragments with an eosinophilic sheath (Williams 1969). The latter can present as typical Splendore-Hoeppli phenomenon (Williams et al. 1969). The fungus is often localized within macrophages and multinucleated giant cells derived thereof. An eosinophilic infiltrate is a characteristic feature.

Pneumocystosis: An Unusual Fungal Infection of the Hepatobiliary Tract

Introduction

Pneumocystis as an opportunistic pathogen causes a severe and frequently fatal pneumonia when the host immune system fails, e.g., in AIDS and during cancer chemotherapy (review: Wazir and Ansari 2004). In individuals with HIV infection leading to AIDS, *P. carinii* pneumonia has been a major cause of death prior to the advent of HAART. Usually, *Pneumocystis* maintain an extracellular existence in pulmonary alveoli, but in severe infections, extrapulmonary manifestations can occur, including the hepatobiliary system.

The organism now termed *Pneumocystis carinii* was first reported in the early twentieth century (Chagas 1909; Carini 1910). Carlos Justiniano Ribeiro Chagas was born in 1878 and was the later director of the renowned Instituto Oswaldo Cruz in Brazil. Both authors thought that the organisms were novel species of *Trypanosoma*. Chagas discovered the organism in experimental animals and confused it with part of the life cycle of *Trypanosoma cruzi* (the causal agent of Chagas disease) and later called both organisms *Schizotrypanum cruzi*, a form of trypanosome infecting humans. The genus was again discovered in 1912 by Delanoe and Delanoe (Delanoe and Delanoe 1912) at the Pasteur Institute in Paris. These authors proposed the genus name and termed the species, *carinii*, in honor of Dr. Carini who had described the cysts in 1910 ("the cysts of Carini" in the title of the French publication). The fungus was redescribed as a human pathogen in 1942 (Van der Meer and

Brug 1942). Originally classified as a protozoan, members of the genus *Pneumocystis* are now allocated to the fungal kingdom, based on phylogenetic analyses of several parasite genes (Haase 1997).

Hepatobiliary *Pneumocystis carinii* Infection

Hepatobiliary pneumocystosis occurs in the setting of generalized extrapulmonary *Pneumocystis* infection associated or not associated with AIDS, and usually organs other than the liver are also involved, in particular the spleen, the bone marrow, lymph nodes, and the CNS (Jarnum et al. 1968; Rahimi 1974; Unger et al. 1988; Cote et al. 1990). Extrapulmonary infection with this agent in AIDS patients is regarded as uncommon. Hepatic pneumocystosis is an uncommon disease presenting in the form of various manifestations (Table 6).

Pneumocystis Hepatitis

Hepatic involvement can present in the form of hepatitis with or without cholestasis, sometimes with progressive elevation of liver enzymes in serum (Jarnum et al. 1968; Awen and Baltzan 1971; Rahimi 1974; Grimes et al. 1987; Pilon et al. 1987; Steigman et al. 1987; Hagopian and Huseby 1989; Poblete et al. 1989; Sachs et al. 1991; Wilkins et al. 1991; Merkel et al. 1992; Mendez-Sanchez et al. 2006; Levitt et al. 2012). In the case reported by Hagopian and Huseby, liver biopsy showed acellular nodules of necrosis with a foamy eosinophil appearance, in a periportal distribution. Methenamine silver stain revealed the presence of typical cup-shaped *Pneumocystis* structures within necrosis (Hagopian and Haseby 1989). In some situations, hepatic sinusoids were expanded by foamy eosinophilic material associated with diffuse Kupffer cell necrosis and focal hepatocellular necrosis, these lesions containing *P. carinii*. The organisms were mainly found in sinusoidal spaces, in intimate association with the location of Kupffer cells. Immunohistochemically, trophic forms were found lining the hepatocytes, similar to what is seen in pulmonary alveoli (Cote et al. 1990). *Pneumocystis* organisms in hepatitis lesions were described in a subsequent report (Levitt et al. 2012). Granulomatous hepatitis with presence of *Pneumocystis* within granulomas has been documented by the use of electron microscopy (Guan et al. 2001).

Table 6 Classification of hepatobiliary pneumocystosis

Pneumocystis hepatitis
Granulomatous *Pneumocystis* hepatitis
Multiple focal necroses
Pseudotumoral hepatobiliary pneumocystosis
Hepatic calcifications
Biliary obstruction by extrinsic compression

Multiple Focal Necroses

In other cases, infection of the liver by *P. carinii* presented in multiple focal necrotic liver lesions (Davey et al. 1989; Hardy et al. 1989; Dembinski et al. 1991; Trojan et al. 1998). In one patient with AIDS, autopsy revealed multiple well-circumscribed white nodules (1–5 mm diameter) in the liver, histologically composed of a foamy acellular eosinophilic material without an accompanying host inflammatory response. Central calcification was present in some of the lesions. In these foci, *P. carinii* was detectable in silver stains and immunohistochemically (Dembinski et al. 1991). In one patient of a necropsy series of 227 patients with HIV infection, the liver exhibited multiple lentil-sized whitish foci containing a granular material incrustated by calcium salts, these lesions being positive for *Pneumocystis* cysts (Trojan et al. 1998).

Pseudotumoral Hepatobiliary Pneumocystosis

Involvement of hepatic hilar structures can produce a mass and bile duct stenosis with intrahepatic duct

dilatation. In one patient with these changes, endoscopic biopsy of the common hepatic duct revealed cholangiocytes and associated foamy material containing *P. carinii* (Mustafa et al. 2002). *P. carinii infection* of the common bile duct has been found to rarely cause an intraluminal mass consisting of an exuberant vascular proliferation associated with a multinucleated giant cell reaction, the giant cells being attached to the branching blood vessels. This abnormal tissue contained numerous *Pneumocystis* cysts in the Grocott methenamine silver stain (Yang 2000).

Hepatic Calcifications

In some patients, hepatobiliary pneumocystosis presents in the form of calcifications in the liver substance. These calcifications may be multiple punctate lesions on imaging (Feuerstein et al. 1990; Fishman et al. 1990; Lubat et al. 1990; Radin et al. 1990; Dembinski et al. 1991; Valdè et al. 1994). In one patient with punctate lesions, fine needle aspiration of the liver was positive for *P. carinii* (Lubat et al. 1990), and *P. carinii* was detectable by immunohistochemistry in calcified liver lesions in another patient postmortem (Valdès et al. 1994). Calcifications may also involve extrapulmonary blood vessels (Wakabayashi et al. 1992). It is likely that vascular calcifications are causally related to hypercalcemia associated with *P. carinii* infections and in particular *P. carinii* pneumonia (Ahmed and Jaspan 1993; Mills et al. 1999; Aguirre et al. 2007). It is thought that the marked macrophage/epithelioid cell reaction in this infection may be involved in the pathogenesis of hypercalcemia, because monocyte-derived cells can convert vitamin D3 into its active metabolite via expression of D3 bioactivating CYP27A1 (Gottfried et al. 2006).

Biliary Obstruction by Extrinsic Compression

Biliary obstruction in pneumocystosis can emerge caused by lymphonodal involvement at the porta hepatis (Hassan et al. 1992).

Life Cycle

In regard to the organism's morphology, four morphotypes are identified, i.e., trophozoites, cysts, precysts, and sporozoites (review: Wazir and Ansari 2004). Trophozoites are pleomorphic and measure 2–4 mm. They are unicellular structures that may contain two or more nuclei. The cyst is the cytologically/histopathologically diagnostic form and steins with Giemsa, Papanicolaou, and Grocott methenamine silver nitrate stains and also immunohistochemically. In the light microscope, the cysts embedded in a characteristic foam-like background appear as a spherical, cup-shaped, or crescent-shaped object measuring 4–8 mm in diameter. Part of these cysts seem empty and collapsed, while others contain dark bodies or dots representing focal thickenings of the cyst wall. Cysts contain up to eight sporozoites. Sporozoite-containing cysts have a pellicle consisting of three layers, i.e., the inner plasmalemma, an electron-lucent middle layer, and an electron-dense outer layer. Referring to the life cycle of this organism (review: Cushion et al. 1997; Cushion 1998), the terminology so far follows zoological terms rather than mycological terms, reflecting the initial misinterpretation of *Pneumocystis* as a protozoan parasite. An asexual mode of replication through binary fission of the trophic form and a sexual mode mediated by mating of trophic forms and resulting in the formation of an ascus (cyst) containing eight ascospores have been distinguished. The cysts or asci often collapse forming crescent-shaped bodies clearly visible in stained sections. Apart from the ascus and the trophic forms, several intermediate forms have been identified that are thought to represent the progression from zygote through meiosis, the additional mitotic step to generate eight nuclei, and the subsequent separation into ascospores.

The natural reservoirs are not well known, because no environmental form or life cycle has so far been identified. Infection of the human host is initiated by attachment of inhaled *Pneumocystis* trophs to alveolar type I pneumocytes. Once in the alveolar space, clusters of organisms proliferate from the trophic forms anchored to pneumocytes and start to fill the alveolar space, ending up with

the characteristic "foamy" material that is seen in the microscope.

Tumor-Like Protozoal Infections of the Hepatobiliary Tract

132

Contents

Abstract

Amebiasis is a common infection worldwide and is still a major cause of death. Infections with *Entamoeba histololytica* induce a highly characteristic type of liver abscess or an abscess-like ass-forming lesion with an aggressive biology. This form of hepatic lesion is more prevalent in males and persons with suppressed cell-mediated immunity. The process is usually localized to the right liver lobe. Through coalescence of smaller parenchymal necroses, larger lesions develop that contain a thick liquid of reddish-brown color. Histologically, the term "abscess" is a misnomer, as a purulent reaction is not the feature of amoebic liver lesions. The process can involve the biliary tract and may extend beyond the organ boundaries. Invasive hepatic amebiasis can penetrate and perforate the diaphragm to produce hepatothoracic fistulas. Pathogenetically, *Entamoeba* trophozoites reach the liver through the portal venous system and are translocated to the sinusoidal channels. Within hepatic sinusoids, endothelial cells are induced by trophozoites to undergo apoptosis, allowing trophozoite contact with hepatocytes which are destroyed leading to an immune reaction and inflammation.

Amebiasis

Introduction

Amebiasis belongs to the top three causes of death from parasitic disease worldwide. It is estimated that amebiasis is responsible for up to 100,000 deaths worldwide each year (Petri 1996, 2002; Stanley 2003; Ali et al. 2008; Raston and Petri 2011). Amoeba infections (but not disease) are caused by one of three species – *Entamoeba histolytica*, *E. dispar*, and *E. moshkovskii* – whereas classical invasive amebiasis is only caused by *E. histolytica*. *E. histolytica* colonizes the human intestine causing amoebic colitis and disseminates through the vascular route to form liver abscesses. Morbidity and mortality due to amebiasis have remained high, also owing to the hepatic and other complications caused by this parasite. The main hepatic manifestation of amebiasis is the amoebic liver abscess, which is different from pyogenic liver abscess in many respects. These sometime very large inflammatory lesions show an invasive phenotype and may mimic primary or secondary hepatic malignancy.

The classification of amoebae is a complex task due to the fact that many members of the group lack morphologically reliable features. A thorough understanding of the taxonomy of amoebae therefore requires genetic data such as rRNA and DNA sequencing (Stothard et al. 1998). Traditionally, amoebae have been classified as the protozoan taxon Sarcodina, with a taxonomic structure that separated species with supported pseudopodia from those with unsupported pseudopodia and those with skeletal elements from those without (Corliss 1984; Cavalier-Smith 1993; Patterson 1999; Tree of Life Web Project, http://tolweb.org). Three species of *Entamoeba* are capable to infect the human organism, i.e., *E. histolytica* (the only species that can cause invasive amebiasis), *E. dispar*, and *E. moshkovskii*. In the environment, amoeba exists in a distinct microhabitat. Hydrophobic organic matter accumulates at the water-air interface of all natural water bodies to establish the surface microlayers. These form a dynamic environment where bacteria, protists, and aquatic molds are enriched compared to their numbers in the bulk liquid phase; this is also the case for amoebae (Preston 2003). The recent sequencing of the *E. histolytica* genome has opened the way to large-scale approaches to the biology and biochemistry of this organism. *Entamoeba histolytica* is an amitochondriate protozoan with numerous bacterium-like fermentation enzymes. The development of disease following contact with *Entamoeba histolytica* involves a complex pathogenic cascade (review, Petri 2002). During colonization of the gut, transcriptome analysis has shown that diverse *Entamoeba histolytica* genes are activated.

Amoebic Liver Abscess

Amoebic liver abscess is more prevalent in persons with suppressed cell-mediated immunity, in men, and in younger people (Hughes and Petri 2000; Kurland and Brann 2004; Lodhi et al. 2004). A higher prevalence in young men is in contrast to pyogenic liver abscesses, which are more commonly found in persons older than 50 years and are typically associated with a history of diabetes and jaundice. In a retrospective study on 75 patients with confirmed disease, mean patient age at presentation was 35.5 years, and 80 % were male (Hoffner et al. 1999). The abscess usually develops in the right liver lobe; 10 % or less of the lesions are found in the left lobe and are usually a solitary lesion, at least initially. Liver abscesses caused by *E. histolytica* are invasive lesions that, similar to malignant neoplasms, tend to destroy the liver substance and to form pathological communications between the abscess and perihepatic organs and tissues. Patients present with fever, right-upper quadrant discomfort or pain, hepatomegaly, and sometimes jaundice (see below). Among 75 patients, the most common complaint was fever, (77 %), followed by abdominal pain (72 %), cough (16 %), and chest pain (19 %), and the majority of patients had symptoms for less than 13 days (Hoffner et al. 1999). Both in adults and in

children, these lesions can sometimes follow a fulminant course, with recurrence of multiple abscesses and pleuropulmonary complications (Genel et al. 2004). Mainly large abscess can extend beyond the limits of the liver and invade and perforate the diaphragm; communicate with pleural space, bronchi, and/or pericardial cavity (Salles et al. 2003); rupture into the peritoneal cavity (Bukhari 2003); form a hepatogastric fistula (Chang et al. 2002); open into the vena cava (Guevara-Gonzalez and Mendez-Sanchez 2002); or invade the hepatic artery, sometimes followed by formation of an aneurysm (Yanagisawa et al. 2002) or a pseudoaneurysm (Khan et al. 2011). Clinically, amoebic liver abscess may produce a mass effect similar to hepatic tumors. The lesion can imitate metastatic carcinoma (Ritchie et al. 2005).

Pathology of Amoebic Liver Abscess

Through coalescence of small parenchymal necroses, larger lesions result that contain a homogeneous thick liquid of reddish-brown to yellow or chocolate-like color, similar to "anchovy paste" (Figs. 1 and 2). Based on this morphology, the term "abscess" is a misnomer, because an abscess is per definition an accumulation of pus in non-preexisting tissue space, while amebiasis of the liver is characterized by a massive necrosis with accumulation of blood and blood products, in the absence of grossly visible pus. Through liquefaction of the necrosis, large cysts can develop which lead to massive hepatomegaly (Kaur et al. 2001). In case of intrahepatic bile duct invasion, bile enters the abscess fluid and causes a yellowish-greenish discoloration of the fluid. In the central fluid, fragments of necrotic tissue or coagulated blood are floating.

Histology mainly shows a massive necrosis of liver substance, with parts exhibiting coagulation necrosis with hepatic shadow cells and parts showing a hemorrhagic proteinaceous fluid containing intact or lysed erythrocytes and erythrocyte fragments. At the border of the lesion, a thick layer of granulation tissue is found, containing numerous macrophages. In the transition zone between necrosis and granulation tissue, amoebae can be found, especially by the use of a PAS stain (Fig. 3). In peripheral parts of the abscess, but particularly in the atrophic liver tissue surrounding the lesion, variable infiltrates of lymphocytes, macrophages, neutrophils, and plasma cells are found. It has been shown that abscess-associated lymphocytes exert a high amebicidal activity (Vohra et al. 2003).

Amoebic Involvement of the Biliary Tract

Bile duct involvement in amebiasis has mainly been observed in situations of amoebic liver

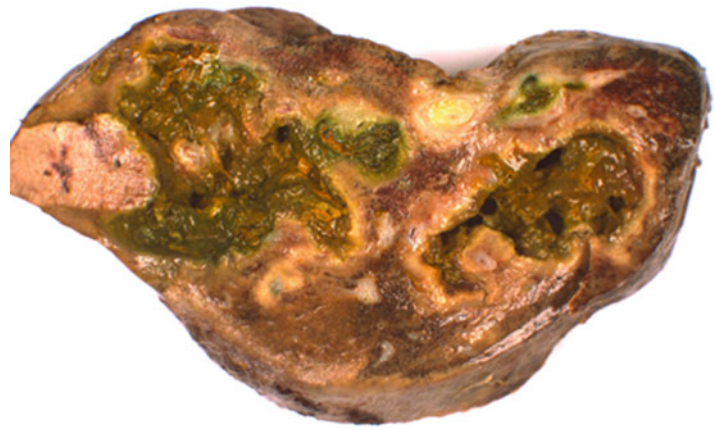

Fig. 1 Amebiasis of the liver (so-called amoebic abscess). Large cavities with necrotic walls are a salient feature

Fig. 2 Amoebic liver abscesses can contain a chocolate-brown mass derived from blood decay in long-standing hemorrhage

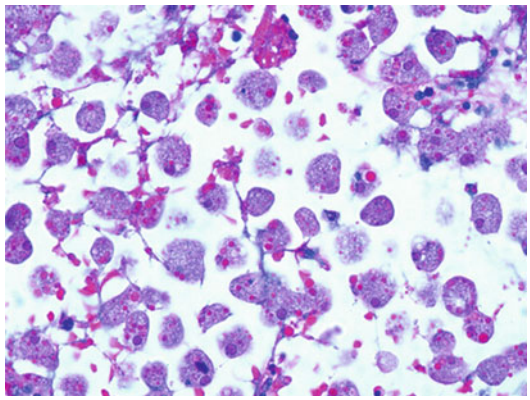

Fig. 3 Amebiasis of the liver. *Entamoeba histolytica* organisms with signs of erythrocytophagocytosis (PAS stain)

abscesses communicating with intrahepatic bile ducts (fistula) or with intrabiliary rupture (Boquien and Lenne 1962; Viana 1966; Shrimali and Choudhary 1969; Brondum Nielsen and Hegedüs 1975; Griffin et al. 1983; Ibrarullah et al. 1994; Agarwal et al. 1995; Kumar et al. 1995; Misra et al. 1997; Sonsuz et al. 1998). In comparison with other perforation sites, intraductal drainage of amoebic liver abscess is uncommon; among 100 patients with such an abscess, perforation into pleuropulmonary structures was found in 72 %, the subphrenic space in 14 %, and the peritoneal cavity in 10 %, while bile duct perforation was only seen in a few cases (Meng and Wu 1994). Fistulation of an amoebic abscess can cause hemobilia (Moine et al. 1965). In a systematic study on 525 patients from India with hepatic abscesses, there were 20 patients who developed a demonstrable communication between liver abscess and intrahepatic ducts (mainly the right hepatic dust), and out of these, 16 were amoebic abscesses (Sharma et al. 2006). In 33 consecutive patients with amoebic liver abscess, abscess-biliary communication was found in 27 %, and patients with such a communication presented more frequently with jaundice (67 % vs. 0 %) and with a longer duration of illness and had larger lesions (median 600 ml vs. 320 ml), requiring a longer period of drainage (Agarwal et al. 1995).

There are few informations relating to the occurrence of amoeba in the biliary tract in the absence of an amoebic liver abscess (Steinitz and Talis 1964). Amoebic liver abscess can cause obstructive jaundice. Although mild jaundice is not an infrequent finding in amoebic liver abscess, severe obstructive jaundice is, however, a rare complication (Haider et al. 1975; Ramachandran et al. 1976; Nigam et al. 1985; Sharma and Sarin 1987; Khan et al. 1990). In a review of 70 cases of amoebic liver abscess, clinical jaundice was present in up to 33 % of all cases, but moderate to severe jaundice was found in only 7 % (Sharma and Sarin 1987). In a another study analyzing 137 patients with amoebic liver abscess, clinical

jaundice was noted in 8 %, but only two patients had a serum bilirubin concentration exceeding 5 mg/100 ml (Ramachandran et al. 1976). The patients presenting with jaundice are usually reported to have an acute onset of the disease, occurring especially in males with a history of excessive alcohol intake. Moreover, jaundice is more common in patients with multiple abscesses (43 %) than in those with a solitary abscess (33 %) and seems to be proportional to the size of the abscess. This may suggest that a pressure effect in the biliary tract may be involved. In fact, exterior compression of bile ducts by a large amoebic liver abscess causing obstructive jaundice has been observed (Sarda et al. 1998).

Pathogenic Pathways of Hepatic Amebiasis

E. histolytica entering the liver interacts with several hepatic cell types. Trophozoites reach the liver through the portal venous system, the parasites being transported to the sinusoidal channel network. Within sinusoids, endothelial cells respond to interaction with *E. histolytica* by retraction and apoptotic cell death, through effects of the amoeba on cell cycle gene expression and integrin-mediated adhesion signaling (Faust et al. 2011). In the early phase of infection, trophozoites are found close to undamaged hepatocytes. As a consequence of these interactions, hepatocytes are destroyed, leading to host immune cell activation, characterized by an infiltrate containing CD8+ T lymphocytes, CD68+ macrophages, and neutrophils (Ventura-Juarez et al. 2003). In the pathway leading to hepatocyte destruction, Kupffer cells play an important role via their induced secretion of TNF-alpha (Helk et al. 2013).

Hepatobiliary Leishmaniasis

Introduction

Leishmaniasis is a widespread and serious infection prevalent in Europe, Africa, Asia, and the Americas, debilitating millions and killing thousands of people each year. An estimated two million new cases are reported annually, and it appears that around 350 million people are at risk worldwide. At least 20 *Leishmania* species infect humans. Leishmaniasis in the human host is classified as follows: (a) visceral leishmaniasis, the most dangerous form, characterized by the spread of the parasite from the entry site to several visceral organs and tissues, including the liver, spleen, and bone marrow; (b) cutaneous leishmaniasis, in which the parasites remain at the site of entry and cause a chronic ulcerating skin disease (review, Akilov et al. 2007); and (c) mucocutaneous leishmaniasis, a chronic inflammation of mucosal tissues that develops from cutaneous leishmaniasis in less than 5 % of affected persons.

Cutaneous leishmaniasis is caused by the *Leishmania* species, *L. major*, *L. tropica*, *L. aethiopica*, *L. infantum*, and *L. archibaldi* in Eurasia and Africa and by *L. mexicana*, *L. venezuelensis*, *L. amazonensis*, *L. braziliensis*, *L. panamensis*, *L. chagasi*, *L. guyanensis*, and *L. peruviana* in the Americas (review, Akilov et al. 2007). Visceral leishmaniasis is commonly caused by *L. donovani* (anthroponotic cycle) and by *L. infantum* (zoonotic cycle). Old World leishmaniasis is transmitted by sandflies of the genus *Phlebotomus*. There is a striking association between certain Old World species complexes of *Leishmania* and particular subgenera of *Phlebotomus*, suggesting features of coevolution (review, Ready 2000). In the Americas, leishmaniasis is transmitted by sandflies of the genus *Lutzomyia*.

Hepatobiliary Leishmaniasis

Liver disease in leishmaniasis is found in all forms of visceral leishmaniasis, the susceptibility to which is modulated by genetic factors of the host, virulence factors of the parasite, and environmental factors (El-Safi et al. 2006). Several types of manifestations are recognized (Table 1). These various types of manifestations are in part linked to the immune status of the host (reactivity or areactivity of the immune system). In a pediatric group of patients ($N = 367$) with kala-azar,

Table 1 Classification of hepatic leishmaniasis

Macronodular (pseudotumoral) form of hepatic leishmaniasis
Necrotizing hepatic leishmaniasis

liver function tests were deranged in two thirds of the patients (Rahim and Ashkan 2007), but hepatomegaly is commonly less pronounced than splenomegaly in this age group (Bhattacharya et al. 2006). Among nine autopsies of AIDS patients infected with *L. infantum*, liver involvement associated with generalized parasitic disease was observed in four patients (Hofman et al. 2000). Visceral leishmaniasis is rarely associated with the hemophagocytic syndrome (Marom et al. 2001; Pahwa et al. 2004; Agarwal et al. 2006) and may exceptionally result in acute liver failure (Sagnelli et al. 2012). Imaging findings in hepatic leishmanial involvement are variable but include multiple hypodense, nodular liver lesions (sometimes forming conglomerates several cm in diameter) that may pose diagnostic difficulties (Bütke et al. 2004).

Diffuse Leishmaniasis of the Hepatic Macrophage System

Hepatic involvement in visceral leishmaniasis is common and is mainly dominated by sometimes massive accumulation of amastigotes in hepatic macrophages and by parenchymal cell damage (Koshy et al. 2001; Artan et al. 2006; Gangneux et al. 2006). The intracellular amastigotes are usually clusters of round to ovoid intracytoplasmic bodies, 2–5 μm in diameter. They are amphophilic in the hematoxylin-eosin stain and slightly more basophilic in the H&E safran stain and dark blue in the Giemsa stain. Already in H&E stains, a tiny dot can be recognized in an eccentric location of the amastigotes, representing the kinetoplast (Fig. 4). In the Giemsa preparation, this structure is stained in purple or red. Extracellular parasites may rarely be seen, but it is difficult to judge whether they entered the extracellular space

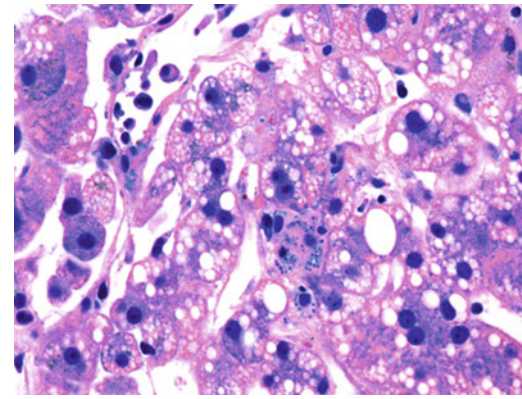

Fig. 4 Leishmaniasis of the liver. Hepatic macrophages (center of figure) contain very small and spherical, strongly basophilic microorganisms (Giemsa stain).

owing to cell decay. Macrophages containing amastigotes are found in portal tracts or in hepatic macrophages/Kupffer cells located to the sinusoidal space. A variable lymphocytic infiltration of portal tracts may be seen. In a series of 18 patients with visceral leishmaniasis, a specimen before treatment showed Kupffer cells/hepatic macrophages colonized by amastigotes in 40 % of the cases (El Hag et al. 1994). Large accumulations of parasite-laden macrophages, with or without a granulomatous reaction, may form large nodular lesions that are low-attenuated in CT (Bütke et al. 2004). Apart from macrophages, electron microscopic investigations have shown that also hepatocytes may harbor amastigotes, eventually entering this cell population by endocytosis (Duarte et al. 1989).

Granulomatous Form of Hepatic Leishmaniasis

A granulomatous hepatic reaction has been observed in liver leishmaniasis (El Hag et al. 1994; Geramizadeh et al. 2011), developing as a function of the immune response of the host. Granulomas are also recognized in experimental murine hepatic leishmaniasis (Gutierrez et al. 1984). The prevalence of *Leishmania*-induced granulomas in livers varies considerably. In a series of patients with visceral leishmaniasis

undergoing liver biopsy, no granulomas were detected (El Hag et al. 1994). Apart from epithelioid granulomas, fibrin-ring granulomas may occur in hepatic leishmaniasis (Moreno et al. 1988; Marazuela et al. 1991).

Macronodular (Pseudotumoral) Hepatic Leishmaniasis

These granulomas may grow to large size (macronodular hepatic granulomas, "leishmaniomas") and may thus be confounded with neoplastic lesions. In one reported observation, ultrasound examination of the liver showed two solid lesions with peripheral hypoechoic halo, 3 cm and 1.5 cm in diameter. Needle aspiration of the larger nodule revealed a granulomatous reaction associated with numerous amastigotes in macrophages (Canalias et al. 1997).

Necrotizing Hepatic Leishmaniasis (Areactive Leishmaniasis)

In immunodeficient individuals, viscerotropic *Leishmania infantum* infection of the liver can rarely induce scattered and in part large necroses of the liver substance, thought to depend on the immune reaction status of the host (Angarano et al. 1998).

Associated Alterations of the Liver

Associated parenchymal alterations include hepatocyte ballooning, hepatocyte apoptosis, lobular infiltrates, perisinusoidal fibrosis, portal tract infiltrates (sometimes with interface lesions), portal tract fibrosis, and fibrosis of the hepatic terminal venules (El Hag et al. 1994). In few cases, the lobular fibrosis is diffuse (Duarte and Corbett 1987). Fibrotic changes, in particular pericellular fibrosis and portal tract fibrosis, appear to increase in frequency after treatment of visceral leishmaniasis (El Hag et al. 1994), but regression of diffuse intralobular fibrosis has also been reported (Corbett et al. 1993). Diffuse fibrosis of the liver with signs of remodeling (interpreted as "cirrhosis") occurring in conjunction with leishmaniasis had already been described in India in 1908 (Rogers 1908), but the pathogenic relationships are difficult to judge based on such observations. Rare instances of hepatic leishmaniasis are characterized by marked cytolysis and cholestasis, eventually leading to liver failure (Khaldi et al. 1990) or to fulminant hepatitis (Singh et al. 1995). Diffuse nodular regenerative hyperplasia has been seen in an HIV-infected patient with visceral leishmaniasis and suggested to be caused by deranged sinusoidal blood flow caused by enlarged infected macrophages (Fernandez-Miranda et al. 1993).

Tumor-Like Parasitic Lesions of the Hepatobiliary Tract: Liver Flukes and Other Trematodes

133

Contents

Abstract

Tumor-like parasitic lesions and hepatobiliary cancers can be induced by several species of liver flukes. Fascioliasis is an infestation of the biliary tract by the common liver fluke, *Fasciola hepatica*, and by *Fasciola gigantica*. Liver flukes are an important cause of ruminant disease in Europe, Africa, and Latin America. *Fasciola* has a complex life cycle involving a distinct developmental stage in aquatic snails. Metacercariae released from snails are ingested by ruminants and humans who eat uncooked aquatic food such as watercress. Infestation of the human biliary tract by *Fasciola* results in a chronic, often severe and fibrosing cholangitis, sometimes ending up in hepatic inflammatory pseudotumor. Rarely, fascioliasis results in the formation of huge and multilocular lesions, mimicking hydatid disease. Clonorchiasis denotes an infestation with the oriental liver fluke, *Clonorchis sinensis*. Infestation rate is high in certain regions of East Asia and is associated with increased risk for cholangiocarcinoma. Species of the trematode genus *Opisthorchis* cause the zoonotic parasitic disease, opisthorchiasis, mainly involving *O. viverrini* and *O. felineus*. Similar to clonorchiasis, this parasitosis causes chronic bile duct inflammation, abnormal hyperregeneration of epithelia, and association with cholangiocarcinoma.

Fascioliasis

Introduction

Fascioliasis (fasciolosis) is the infestation of the biliary tract by the common liver fluke, *Fasciola hepatica* (Linnaeus 1758), and by *Fasciola gigantica* (reviews: Chen and Mott 1990; Saba et al. 2004; Lim et al. 2008; Marcos et al. 2008). *F. hepatica* is a parasitic digenean flatworm of the family Fasciolidae. Liver flukes are an important cause of ruminant (cattle and sheep) disease mainly in Europe, Africa, and Latin America. *F. hepatica* expanded from its European origin due to the exportation of European livestock to colonize five continents, where it has adapted to other indigenous mammal species, such as camelids in Africa, aukenids in South America, and marsupials in Australia. Strikingly, the parasite is capable to adapt to new host species rather rapidly and along wide taxonomic mammal ranges. A second factor of importance in worldwide spread dynamics is the expansion of the intermediate vector, i.e., pond snails of the genera *Galba* and *Pseudosuccinea*.

F. gigantica is the main fasciolid species in Egypt and is also widely distributed in other parts of Africa. Intermediate/hybrid/introgressed forms between *F. hepatica* and *F. gigantica* have been described (Periago et al. 2008). Sequence analysis of rDNA supports the existence of the intermediate *Fasciola* between *F. hepatica* and *F. gigantica* in mainland China (Lin et al. 2007). The wide distribution of *F. hepatica* is related to climatic factors such as the availability of humid habitats subject to flooding offering niches for the intermediate vector, pond snails. Successful spread of fascioliasis is also related to the capacity of the parasite to adapt to highly various environments, including high altitude.

Human fascioliasis is a very old disease and has been detected (via coprolith analysis) down to Stone and Bronze Ages. It is at present emerging and reemerging in many countries, and as a distinct vector-borne infestation, it presents the widest known latitudinal, longitudinal, and altitudinal distribution. The most important health problems caused by fascioliasis are found in western Europe, the Caspian area (Iran and neighboring countries), Andean South America, the Caribbean (specifically Cuba), and northern Africa. The highest prevalences and intensities have been found in the Northern Bolivian Altiplano. Similar hyperendemic areas are Peru and Egypt. Interestingly, a global analysis of the distribution of human cases has shown that the expected correlation between animal and human fascioliasis only appears at the basic level and that other epidemiological patterns, e.g., high infestation intensities in females and children, have to be taken into account (reviews: Mas-Coma et al. 1999; Mas-Coma 2005).

The Parasite

Fasciola species are highly specialized members of digenean flatworms that, during evolution, probably migrated from Africa to Eurasia, with secondary colonization of Africa (Lotfy et al. 2008). The living adult liver fluke is a flat, roughly lancet-shaped worm of brownish-gray color, 18–50 mm long and with a width of 7–14 mm. The cone-shaped head region (the apical conus) is separated from the body by a shoulder. The oral sucker is situated at the top of the apical cone and the abdominal sucker at the cone's base. The body of the fluke displays markedly arborizing inner organs, mainly gonads and the uterus.

Parasitic Life Cycle

Fasciola hepatica has a complex life cycle, as it requires a distinct developmental stage in an aquatic snail. Embryonated eggs produced by the parasite in the host's bile ducts are passed in the feces. A fluke can produce up to 20,000 eggs per day, and it is estimated that a sheep with numerous flukes will deposit half a million eggs onto pasture per day. Part of the eggs can be stored for 8–16 weeks in the gallbladder of the mammalian host. Upon contact with sufficiently oxygenated water in the environment, the egg's operculum opens at temperatures more than

10 centigrades, and a larva is liberated which will develop into a mature miracidium. A miracidium is a free-living multicellular and ciliated larva which can actively swim. This larva searches its first host in the cycle, aquatic snails (pond snails). During this search, the miracidium does not feed, and in case it does to reach its host, it will not survive much beyond 24 h. The first hosts are snails of the genus *Galba*, *Pseudosuccinea*, and *Lymnaea*, most commonly *Galba truncatula* and *Pseudosuccinea columella*, and in Latin America *Lymnaea cubensis*, *L. viatrix*, and *L. neotropica* (family Lymnaeidae, pond snails). The miracidium enters the snail by use of a pair of large penetration glands which open near the apical papilla. Within the snail host, the parasite undergoes a complex cycle comprising sporocysts and rediae. After penetration of the snail host, the miracidium reaches the snail's digestive gland and develops, within about 14 days, into the second larval stage, the sporocyst larva. Rediae are highly active and motile larvae which feed on the snail's body fluid and cells. Rediae migrate to the digestive glands of the snail. Important for the further propagation of the parasite is the production of another swimming larva termed cercaria, looking like a tiny tadpole. It is produces by germ balls of daughter rediae in the winter period. Cercariae leave the mother or rediae through their birth pores. From the germ balls of each redia, 14–20 cercariae are produced. From the digestive glands of the host snails, cercariae pass into the pulmonary sac and then escape into the surrounding water. They actively swim through water bodies in pasture, capable of swimming 5 min to 1 h in summer. They attach on nearby vegetation, e.g., water plants at the borders of ponds, the tail is cast off, and the cercaria encysts to become a metacercaria. Together with plants, metacercariae are ingested by ruminants or by humans who eat uncooked food such as infested watercress. The low pH in the stomach of the final host prepares excystment, which then takes place in the duodenum, where the liberated juvenile parasites burrow through the intestinal wall into the peritoneal cavity. The juvenile parasite then finds contact with the liver surface, where it starts feeding on hepatic parenchyma (the hepatic phase or hepatic stage). The juvenile parasites browse on liver tissue for up to 5–6 weeks and then find their way to the lumina of bile ducts, where final maturation to flukes takes place (the biliary phase or biliary stage). Cross-fertilization between two mature flukes takes place in the bile duct lumen. Embryonated eggs are released through the gonopores and are transported by the bile into the intestinal tract and from there into the environment.

Clinical Features

The clinical presentation of fascioliasis is characterized by abdominal pain, fever, chills, weakness, pruritus, weight loss, and eventually muscle pain (Aksoy et al. 2006). The definitive diagnosis of fascioliasis is based on the presence of *Fasciola* eggs in a stool or gallbladder sample or on a positive serological test plus imaging findings indicating this parasitosis. In accordance with the evolution of disease, human fascioliasis is classified as acute and chronic disease. Acute disease is present if the duration of symptoms is less than 4 months and there are no motile echogenic images on the gallbladder at admission. Chronic disease is present if signs and symptoms persist for more than 4 months or there are motile echogenic images in the gallbladder (Saba et al. 2004). *F. hepatica* can localize to the lumen of the common bile duct (Kim et al. 2006) and may cause common bile duct obstruction (Dobrucali et al. 2004; Gulsen et al. 2006; Caprino et al. 2007), sometimes mimicking cholangiocarcinoma (Yalay et al. 2012). Biliary fascioliasis rarely causes hemobilia (Wong et al. 1985; Bahcecioglu et al. 2007). This complication may be due to bleeding bile duct ulcers induced by the parasite (Acuna-Soto and Braun-Roth 1987). Exceptionally, fascioliasis is associated with generalizer vasculitis (Llanos et al. 2006).

Hepatobiliary Alterations

Imaging findings are different in the hepatic stage vs. the biliary tract stage. During the hepatic stage,

flukes migrate through the liver substance and digest and consume hepatocytes and other liver cells, and they thus dig tunnels and caves where they stay for months. These alterations are mainly seen in peripheral, subcapsular parts of the liver, because this is the region where metacercariae penetrate the organ (Kabaalioglu et al. 2000; Maeda et al. 2008). Clusters of microabscesses arranged in tract-like fashion develop (burrow tracts; Han et al. 1993). These lesions are nodular or tubular hypodense foci. In contrast to pyogenic abscesses, necrotic cavitated lesions caused by *F. hepatica* do not coalesce to form large abscesses; rather, small necrotic lesions (so-called microabscesses; they are not true abscesses with accumulation of pus) are arranged in a serpentine fashion, the lesions starting at or close to the liver surface (the entry site), reflecting the complex feeding tract of the parasite within the liver (Lim et al. 2008; Figs. 1, 2, 3, and 4).

The tract-like hepatic tissue necrosis elicits granulation tissue and scarring, the reason why at imaging these tracts are seen for months or even years. Following necrosis of infested and inflamed bile ducts, well-demarcated cystic masses mimicking a necrotic cystic tumor may develop, containing greenish-yellow, bile-containing necrotic material and surrounded by dense fibrous tissue. These lesions can contain mummified adult worms and eggs (Kim et al. 1999a). On CT images, the entire migration and necrosis path may be visualized, accompanied by clustered small necrotic cavities seen as caves (Kim et al. 1999a; Lim et al. 2008). In a study of ten patients, CT revealed tubular branching lesions in five patients and nodular lesions, suggesting small abscesses in four (Aksoy et al. 2006). On MR images, three types of lesions have been identified, arranged in a tract-like fashion. The outermost area presents as an iso-signal area in T1-weighted images, with slightly higher signal intensity in T2-weighted images and diffuse enhancement after i.v. contrast. The second type is a well-defined low signal area in T1WI, not enhanced, and also shows low signal intensity in T2WI. The third type has low signal intensity in T1WI, not enhanced, and has high signal intensity in T2WI, similar to a fluid-containing lesion such as an abscess (Han et al. 1996). Rarely, the necrotic lesions at the parasite entry site at the liver surface may induce fistulization, with subsequent formation of subcapsular or perihepatic abscess.

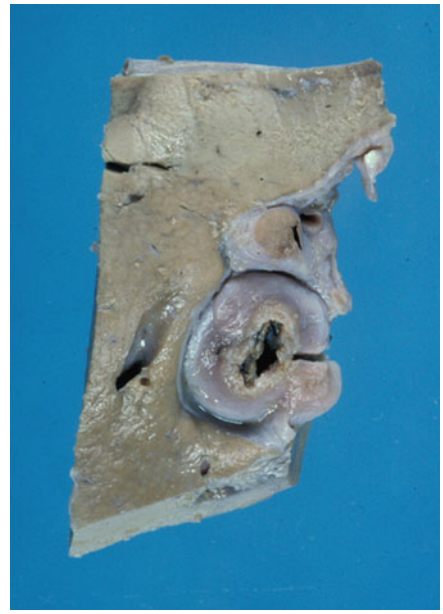

Fig. 1 Fascioliasis of the liver (*Fasciola hepatica* infestation). An inflamed bile duct with a thickened wall contains a thin and flat structure in the lumen, a liver fluke

Fig. 2 Cross-sectioned inflamed and fibrosed bile duct at higher magnification. The intraluminal leaflet-like parasite is well recognizable

Fig. 3 Cross-sectioned *Fasciola hepatica*

Fig. 4 Hepatic fascioliasis. In this long-standing *Fasciola hepatica* infestation, the involved bile duct shows a marked ulcerating and fibrosing inflammation (fixed necropsy specimen)

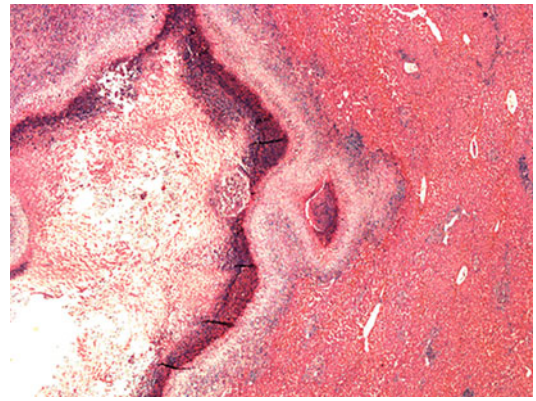

Fig. 5 Fascioliasis of the liver. *Fasciola* infestation can elicit bile duct destruction followed by abscess formation, often with a strong eosinophilic infiltration and epithelioid cell reaction (hematoxylin and eosin stain)

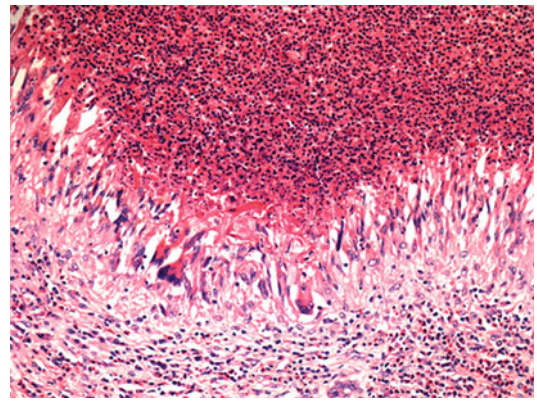

Fig. 6 Fascioliasis of the liver. The purulent exudate of this abscess is dominated by eosinophils ("eosinophil pus," eosinophilic abscess). The abscess is demarcated by epithelioid cells and giant cells. Increased numbers of eosinophils are also present in adjacent tissue (hematoxylin and eosin stain)

In the biliary stage, the parasites find their way to the lumina of the intrahepatic bile ducts, and later they may advance into the extrahepatic ducts and the gallbladder. Adult liver flukes are demonstrated on sonography, CT, or MR cholangiography as small intraductal profiles and sometimes as floating objects on sonography (Lim et al. 2007, 2008; Aminian et al. 2012). The parasites can be identified during ERCP (Dias et al. 1996), which also allows endoscopic extraction of living flukes (Ozer et al. 2003). Adult flukes promote hyperplastic and hypertrophic bile duct wall changes, resulting in a thickening of the walls detectable by sonography or CT (Bassily et al. 1989).

F. hepatica can induce an inflammatory reaction, ending up in hepatic pseudotumor and eosinophilic abscesses (Figs. 5 and 6; Cabanillas et al. 1989). Intrahepatic multiple ill-defined hypoattenuating lesions and filling defects of the lesion lumens may mimic intrahepatic cholangiocarcinoma (Adachi et al. 2005; Kim et al. 2005; Yalay et al. 2012). Rarely, *F. hepatica* infestation results in the formation of huge and multilocular lesions, mimicking hydatid disease (Maeda et al. 2008).

Clonorchiasis: A Parasitosis Highly Associated with Cholangiocarcinoma

Introduction

Clonorchiasis denotes infestation with the Chinese or oriental liver fluke, *Clonorchis sinensis*. Clonorchiasis is of major socioeconomic importance in parts of Asia, including China, Taiwan, Japan, Korea, and Vietnam (reviews: Lun et al. 2005; Rim 2005; Rana et al. 2007; Petney et al. 2013).

Epidemiology

Clonorchiasis is widely distributed in southern Korea, mainland China and Taiwan, Japan, northern Vietnam, and the easternmost part of Russia. Owing to increased migrations, clonorchiasis is also known in areas where Asian immigrants from endemic areas have settled. It has been estimated in a report of 1994 that about 17 million people were infested with oriental liver flukes, 9 million with *Opisthorchis viverrini*, 7 million with *Clonorchis sinensis*, and 1.5 million with *Opisthorchis felineus* (IARC 1994). In certain East Asian regions, the infestation rate with *C. sinensis* is still high. Among 3,080 consecutive Korean patients admitted with gastrointestinal disease, 12.9 % had clonorchiasis (Kim et al. 2009).

The Parasite

C. sinensis (Looss 1907) is a trematodan flatworm of the family Opisthorchiidae. The life cycle of *C. sinensis* has been well studied. Definitive hosts of this fluke comprise humans, dogs, cats, hogs, martens, badgers, weasels, mink, and rats. Egg discharge in the human feces is high in infested subjects, the average number of eggs per gram feces in one Chinese study being 3,055 (Liang et al. 2008). Embryonated eggs pass via feces into water bodies of the environment, where they are ingested by water snails of the genera *Parafossarulus* (China, Korea, Japan, eastern Russia), *Bithynia (*China), *Melanoides* (China), *Assiminea* (China), *Semisulcospira* (China), and *Tarebia* (China). Inside the snail, miracidia hatch from the ingested eggs. The miracidium develops into a sporocyst, inside which several asexual generations of rediae emerge. The rediae are the source of several rounds of cercariae, one miracidium therefore producing a large number of cercariae. The cercariae are free-swimming larvae which seek and penetrate the second intermediate host, freshwater fish of the cyprinid group, including the genera *Pseudorasbora*, *Gnathopogon*, *Pseudogobio*, *Pungtungia*, *Acheilognathus*, *Hemibarbus*, and *Sarcocheilichthys*. Inside fish muscle, the cercariae produce a protective metacercarial cyst, thus encapsulating the parasite body. When uncooked cyprinid fish are ingested by humans, acid-resistant metacercariae pass the stomach undigested to reach the small intestine. From here, metacercariae (or juveniles; "adolescariae") actively reach the orifice of the common bile duct and ascend the biliary tract. Experimental infestations in rodents have shown that the common bile duct is the only natural route taken by *C. sinensis* (Sun et al. 1968). Alternative ways seem to be possible, based on animal experiments with common bile duct ligation (Wykoff and Lepe 1957). In the bile duct lumina, the hermaphrodite worms mate and start producing eggs, eggs being delivered every 1–30 s.

Clinical Features

Clonorchiasis may be symptomatic or asymptomatic. Among 2,175 Chinese individuals having *C. sinensis* in their stools, 57.2 % showed symptomatic infestation (Liang et al. 2008). The spectrum of lesions induced by this fluke is complex and has been clinically summarized under the term oriental cholangiohepatitis, often with recurrent pyogenic cholangitis (Stunnell et al. 2006). The course of the disease often goes on for many years, owing to the longevity of the parasites, their lifetimes sometimes exceeding 20 years (Sun 1984). There is a clear relationship between parasite burden and the pattern of clinical

manifestations. Clinically, signs and symptoms may be mild and nonspecific, mainly in patients with small worm burdens (fewer than 100 flukes). Up to 40 % of the patients experience peripheral eosinophilia. Patients with greater parasite numbers (several hundred up to 1,000) often display malaise, diarrhea, fatigue, weight loss, fever, and chills. In contrast to Fascioliasis, *Clonorchis sinensis* is a fluke that chiefly inhabits the medium-sized and small intrahepatic bile ducts, often in a diffuse pattern and sometimes with formation of worm conglomerates. This constellation will determine the characteristic pattern of liver disease. The flukes induce bouts of intrahepatic cholangitis followed by typically multifocal periductal fibrosis and eventually liver atrophy. The inflammatory process induced by *C. sinensis* can induce reactive common bile duct masses (Oh and Kim 2010) or extend into the ampullary region and cause papillitis with obstructive jaundice (Lim et al. 2011). Patients with severe parasitosis may harbor up to 20,000 or more flukes and show attacks of severe cholangitis and obstructive jaundice. Cholangitis may end up with the formation of a hepatic parasitic abscess, mimicking intrahepatic cholangiocarcinoma (Jang et al. 2007). The flukes can also induce focal intrahepatic duct dilatation, mimicking intrahepatic cholangiocarcinoma (Kim et al. 2011). In the late stage, hepatosplenomegaly, portal hypertension, ascites, and biliary cancer may ensue. Clonorchis is also well known to cause pancreatitis (Balthazar and Lamb 1993; Kim 1999a) and cholecystitis/cholecystolithiasis (Qiao et al. 2012). *C. sinensis* has been shown to cause eosinophilic cholecystitis (Kim 1999b). Imaging is useful for diagnosis, but serology will be the decisive diagnostic step. Serodiagnosis is accomplished by assessing excretory-secretory antigen by ELISA (Choi et al. 2003) and a trematode-nematode pan-specific antigen expressed by *C. sinensis* (Chen et al. 2011). Other antigens which may serve in serodiagnosis comprise an excretory-secretory lysophosphatidic acid phosphatase homolog (Hu et al. 2007) and MYND-type tegumental zinc finger protein (Wang et al. 2010).

Pathology of Hepatobiliary Inflammatory and Hyperplastic Changes Associated with Clonorchiasis

C. sinensis causes, mostly at the level of small and intermediate intrahepatic bile ducts, chronic fibrosing inflammation associated with epithelial (cholangiocyte) hyperplasia, metaplastic changes, and epithelial dysplasia (Hou 1955; Sun 1984), also documented in experimental infestation in rodents (Lee et al. 1978; Hong et al. 1990) and the cat (Hou 1965). In the human host, macroscopic alterations in severe chronic infestation present as dilated intrahepatic bile ducts visible through the liver capsule already and being prominent on cut surface. Histology of these bile ducts reveals a lymphohistiocytic infiltration in the duct walls and surrounding the ducts, with or without prominent eosinophilia. Cholangiocyte epithelial hyperplasia is a hallmark of clonorchiasis, as is periductal fibrosis. Metaplasia of the cholangiocyte lining into mucin-producing cells occurs already early in infestation. These mucin-secreting cells may form glandular-like structures and may involve peribiliary glands, causing mucin-rich and sometimes viscid bile (Chou and Gibson 1970). Infestation of bile ducts may be associated with gallstone disease. Gallbladder stones in clonorchiasis can contain parasite eggs, this phenomenon being helpful in diagnostic procedures (Qiao et al. 2013).

Cholangiocarcinoma in Clonorchiasis

C. sinensis infestation is associated with cholangiocarcinoma, although the link is less strong than that for infestation with *Opisthorchis*. This relation has been recognized early in the literature, in fact as early as 1900 (Katsurada 1900; Watson-Wemyss 1919; Nauck and Liang 1928), and has since been confirmed in numerous observations and studies (Hou 1956; Belamaric 1973; Purtilo 1976; Chow and Allen 1978; Flavell 1981; Schwartz 1980, 1986; Chan and Lam 1987; IARC monograph 1994; Watanapa and Watanapa 2002). In 2009, infestation with *Clonorchis*

sinensis was classified as carcinogenic to humans (group 1 carcinogen) based on its involvement in the etiology of cholangiocarcinoma by the International Agency for Research on Cancer. Studies in Korea have shown that known areas of *C. sinensis* endemicity revealed high incidence rates of cholangiocarcinoma. From a meta-analysis, the summary odds ratio for cholangiocarcinoma due to *C. sinensis* infestation was 4.7, and overall about 10 % of cholangiocarcinomas in Korea were caused by chronic *C. sinensis* infestation (Shin et al. 2010). *C. sinensis* promotes the induction of cholangiocarcinoma during a two-step carcinogenesis (Lee et al. 1994). In carcinogenic pathways, products of the excretory-secretory system seem to cooperate with known environmental carcinogens such as dimethylnitrosamine (Pairojkul et al. 1991). For the elucidation of genes and gene products involved in carcinogenesis, the transcriptome of *C. sinensis* is currently studied in detail by the use of high-throughput sequencing (Young et al. 2010).

Infestation with *C. sinensis* induces characteristic alterations of the biliary tract mucosa, including cholangiocellular hyperplasia (Hou 1955; Sun 1984), sometimes of the papillary type (Kim et al. 1999b). Experimentally, it has been shown that cholangiocyte turnover is increased in clonorchiasis (Hong et al. 1993). It is thought that these hyperplastic alterations shift into dysplasia and from there to cholangiocarcinoma, which is significantly associated with clonorchiasis (Kim 1984a; Choi et al. 2004). Cholangiocarcinomas associated with clonorchiasis comprise almost the entire histological spectrum known for this tumor group, including mucinous cholangiocarcinoma (Shim et al. 2004), forms of intrahepatic/peripheral cholangiocarcinoma (Belamaric 1973; Ona and Dytoc 1991), hilar cholangiocarcinoma (Sher et al. 1989), and cholangiocarcinoma of the extrahepatic ducts (mostly located in the proximal third; Kim 2003a). Intraductal papillary neoplasms of the bile ducts have been found in clonorchiasis (Kim et al. 1989; Suh et al. 2000; Jang et al. 2008). These tumors of patients with clonorchiasis differ in their MUC expression from those of noninfested patients (Jang et al. 2008).

Gallbladder carcinoma has been observed in conjunction with clonorchiasis (Drinka and Sheeny 1985; Kim 2003b). Rarely, hepatocellular carcinoma has been detected in patients with clonorchiasis (Nakashima et al. 1977).

Pseudotumoral Hepatic Lesions Associated with *C. sinensis*

C. sinensis was found to be associated with solitary necrotic nodule of the liver (Tsui et al. 1992).

Opisthorchis viverrini

Introduction

Species of the trematode genus *Opisthorchis* cause the zoonotic parasitic disease, opisthorchiasis (reviews: Sripa 2003; Upatham and Vivanant 2003), one of the common forms of fish-borne zoonotic trematodiasis (review: Hung et al. 2013). The taxonomy of *Opisthorchis* species was first in state of some confusion (review: Kaewkes 2003). In 1908, Verdun and Bruyant noted that *Opisthorchis felineus* was found in Indochina. In 1911, worms were described, collected from the autopsy of two prisoners in Chiang Mai (Northern Thailand) as *O. viverrini* (Leiper 1911), whereas a later report (Kerr 1916) identified parasites in male Chiang Mai prisoners as *O. felineus*. In 1927, Prommas reported a single case of *O. felineus* from a human autopsy in Northern Thailand. In 1929, Bedier and Chesneau reported that *O. viverrini* was present in 23 % of 1,231 examinees in Thakhek and in 15 % of 523 persons in Vientiane, two Laotian cities. Today, it is settled that all cases of opisthorchiasis in Thailand, Laos, and Cambodia are caused by *O. viverrini*, while *O. felineus* is a parasite occurring in the more western parts of Asia and in Eastern Europe.

Epidemiology

O. viverrini infestation is predominantly found in Thailand, Laos, and Cambodia, whereas *O. felineus* is endemic in Western Siberia, Kazakhstan, Ukraine, parts of Eastern Europe, and Germany. *O. viverrini* exhibits a very heterogeneous distribution pattern in the target areas: it is, e.g., widely distributed in Northern Thailand, while it has a lower prevalence in Central Thailand, and opisthorchiasis as a disease does not seem to occur in Southern Thailand. It was estimated that 3.5 million persons in Thailand harbor *O. viverrini* (review: Smout et al. 2011a). The infestation begins at a very early age, with prevalence rapidly rising as a function of age, this rise being related to the increasing consumption of dishes prepared with raw fish. Owing to the longevity of the parasite (years to decades), infestation remains relatively constant through older host ages. Epidemiology of human infestation reveals marked seasonal differences. The largest number of human infestations occurs during the last portion of the rainy season and the first third of the dry season, when pond snails producing cercariae and cyprinids harboring the fluke metacercariae are very abundant. The construction of dams, ponds, irrigation systems, and roads has an impact on parasite-harboring water bodies (Sithithaworn et al. 2012b).

Opisthorchiasis shows a very high reinfection rate after successful therapy. In one study, 88.7 % of subjects having negative stools following praziquantel therapy were again positive within 1 year of treatment. Interestingly, moderate disease instead of low-level disease was more prevalent in reinfected subjects in comparison with the pretreatment situation (Upatham et al. 1988).

The Parasite

O. viverrini (synonym: *Distoma viverrini*) is a trematodan flatworm of the family Opisthorchiidae, which is paraphyletic to Heterophyidae. Recent molecular studies suggest that *O. viverrini* consists of two cryptic species with genetic microheterogeneity or even forms a species complex (Saijuntha et al. 2007; Sithithaworn et al. 2012a). Similar to *Fasciola* and *Clonorchis*, the adult worm has two main body parts, i.e., a headlike region and the body which is dominated by the genital organs. Overall, adult worms are flat and leaf shaped and almost transparent, however, with a slightly bile-like reddish color. The leaflike and flabby worms have a size range from 8.0 to 15.0 mm long by up to 4 mm wide. The size of worms collected from the human host is slightly larger than that from dogs or cats. The parasites have an impressive longevity, surviving up to 20 years or even more.

The life cycle of *O. viverrini* is similar to that of *Clonorchis sinensis*. It involves a snail as the first intermediate host, where asexual expansion of larval stages takes place, following by liberation of invasive cercariae which invade cyprinid fish as second intermediary hosts. For *O. viverrini*, 3 subspecies of *Bithynia siamensis* and 18 species of cyprinid fish are susceptible first and second intermediate hosts, respectively (Wykoff et al. 1965; Kaewkes 2003). *Bithynia siamensis* is only known snail species to be parasitized by *O. viverrini*. This snail ingests embryonated eggs released into water bodies, and within the snail, miracidia hatch which will then develop into a sporocyst, followed by asexual production of rediae and cercariae. Free-swimming and invasive cercariae infest cyprinid fish, where they locate in fins, skin, and muscles. Cyprinid genera known to act as second intermediary hosts comprise *Puntius*, *Puntioplites*, *Hampala*, *Labiobarbus*, *Cyclocheilichthys*, *Esomus*, *Mystacoleucus*, *Onychostoma*, *Osteochilus*, *Hypsibarbus*, and *Barbodes*. In Thailand, the most important intermediate fish hosts are *Puntius orphoides*, *Hampala dispar*, and *Cyclocheilichthys siaja*. These cyprinids inhabit numerous standing or flowing water bodies (including rice paddies, draining trenches, irrigation channels, and ponds) in Thailand and Laos and are caught in large quantities for food, dishes often prepared of raw or semi-fermented fish, vegetables, and spices, e.g., koi pla, a highly appreciated dish in rural parts of Thailand. The infested fish contain the encapsulated metacercariae of the

parasite, which upon ingestion are freed in the intestine of the definitive hosts. The natural definitive host for *O. viverrini* is *Prionailurus bengalensis* (a small fish-eating feline called leopard cat); other hosts include man, dogs, and domestic cats. Hatched metacercariae enter the papilla of Vater to ascend into the biliary tract. Adult worms live long (in the range of decades) and produce up to 200 eggs per day.

Clinical Features

The pattern of clinical presentation markedly resembles that of clonorchiasis (Wykoff et al. 1966; review: Mairiang and Mairiang 2003). It is estimated that about 80 % of infested individuals are asymptomatic, at least for extended time periods, but peripheral eosinophilia is commonly found. A typical acute stage as in *O. felineus* infestation does not occur with *O. viverrini*. Again, similar to clonorchiasis, the clinical features are linked to parasite burden. In asymptomatic weak infestation, 1,000 eggs or less are present in 1 g of feces. Heavy infestation is characterized by general malaise, epigastric and right upper quadrant pain, anorexia, diarrhea, weight loss, mild fever and eventually jaundice. In long-lasting infestations and with heavy parasite burdens, the gallbladder shows obstructive hydrops and is excluded (Sripa et al. 2003). As in clonorchiasis, flukes cause chronic and recurrent cholangitis followed by periductal fibrosis and biliary-type cirrhosis with ascites and eventually biliary tract cancer. In experimental hamster infestation, periductal fibrosis is correlated with TGF-beta activity and upregulation of matrix metalloproteinases and their inhibitor, TIMP (Prakobwong et al. 2009). Advanced periductal fibrosis correlates with elevated levels of interleukin-6 (Sripa et al. 2009). The source of interleukin-6 and interleukin-8 are the cholangiocytes, via upregulation of toll-like receptor 4 by excretory/secretory products of the fluke (Ninlawan et al. 2010). Apart from the clinical presentation and imaging findings, serology testing of antibodies directed against fluke or fluke larval-associated antigens is a decisive diagnostic procedure (reviews: Akai et al. 1994; Upatham and Vivanant 2003; Wongratanacheewin et al. 2003). *O. viverrini* also produces distinct metabolic products, the excretory-secretory antigens. One component (89 kDa) is copiously passed via feces, this antigen component being detectable by Mab-ELISA (Sirisinha et al. 1995).

Pathology

The pathology of hepatic *O. viverrini* infestation has been reviewed in detail (Sripa 2003). The livers of markedly infested livers are enlarged, sometimes more than double the normal. A dilatation of peripheral and in part subcapsular intrahepatic bile ducts is in evidence, these ducts usually showing a fibrotically thickened wall (Hitanant et al. 1987; Riganti et al. 1989). In early-stage intrahepatic bile duct disease, the histologic changes are discrete or even lacking. In significant chronic disease, epithelial hyperplasia ensues, often with formation of glandular/acinar structures (Riganti et al. 1989). There is a periductal infiltration of lymphocytes, macrophages, eosinophils, and some plasma cells. In this stage, progressive periductal fibrosis (PDF) develops, first with a loose and hypercellular connective tissue rich in glycosaminoglycans, followed by a dense and hypocellular fibrous tissue. Parasite-induced PDF can be identified by ultrasound examinations (Chamadol et al. 2014). In case parasite eggs are transferred to the hepatic parenchyma, a foreign body reaction is seen (Viranuvatti and Stitnimankarn 1972; Riganti et al. 1989). In addition to intrahepatic ducts, adult parasites may also be found in the gallbladder, extrahepatic ducts, and the pancreatic duct, the numbers of flukes found in the gallbladder ranging from few to more than 100 (Pungpak et al. 1985; Sithithaworn et al. 1991; Sripa et al. 2003). The gallbladder changes, characterized by hydrops, thickening of the wall owing to inflammation and fibrosis, and bile sludge are evident at imaging and sonography (Haswell-Elkins et al. 1991; Mairiang et al. 1992). Cholelithiasis is not frequent in *O. viverrini* infestation. In sludge and gallstones, parasite fragments and fluke eggs have been detected (Riganti et al. 1988).

Cholangiocarcinoma

O. viverrini is classified as a class I carcinogen due to the association between chronic *O. viverrini* infestation and cholangiocarcinoma (reviews: Kaewpitoon et al. 2008; Sripa et al. 2012), also analyzed in experimental animal models (Songserm et al. 2009). Numerous cases of cholangiocarcinoma associated with *O. viverrini* infestation have been reported (Elkins et al. 1990; Akai et al. 1994; Watanapa and Watanapa 2002). According to the 1994 report of the World Health Organization and the International Agency for Research on Cancer (IARC), an estimated 9 million persons were infested with *O. viverrini* and 1.7 million with *O. felineus*, and of these infested patients, a part will develop cholangiocarcinoma. These patients often present with jaundice (60 % in a Northeastern Thailand study), and this jaundice may be of the pure obstructive type, febrile obstructive jaundice, or jaundice associated with signs of acute cholangitis with fever. In one study from Thailand, more than two-thirds of the patients were male, and the mean age at diagnosis of cholangiocarcinoma was 48.8 years in males and 48.1 years in females (Bunyaratvej et al. 1981). A study published in 1988 showed that the incidence of cholangiocarcinoma was almost twice that of hepatocellular carcinoma in endemic areas of *O. viverrini* in Northeastern Thailand (Srivatanakul et al. 1988). As in clonorchiasis, several types of cholangiocarcinoma have been observed in opisthorchiasis, including peripheral cholangiocarcinoma, hilar/perihilar carcinomas, and carcinomas of the extrahepatic duct system. Genetic and environmental determinants of risk for *O. viverrini*-associated cholangiocarcinoma in Thailand have been analyzed (Honjo et al. 2005).

The molecular pathways leading from chronic fluke infestation of bile ducts to carcinogenic pathways are complex and involve mutagenic substances delivered from inflammatory cells (including reactive oxygen species), continuously augmented cholangiocyte regeneration associated with increased mutagenicity, and preneoplastic factors (parasite proteome) secreted by the parasite (Laha et al. 2007; Wongratanacheewin et al. 2003; Mulvenna et al. 2010). Exome sequencing of *O. viverrini*-associated cholangiocarcinoma revealed mutations of TP53 in 44.4 % of cases, KRAS in 16.7 %, SMAD4 in 16.7 %, and several newly implicated genes in 3.7–14.8 % of cases. The latter included inactivating mutations in MLL3, ROBO2, RNF4, and PEG3 and activating mutations in the GNAS oncogene (Ong et al. 2012). Exome sequencing identified distinct mutational patterns in liver fluke-related and fluke-non-related cholangiocarcinomas, indicating that different causative factors may induce distinct somatic changes (Chan-On et al. 2013). One of the proteases of *O. viverrini*, cathepsin F, has been suggested to be a factor for cholangiocarcinogenesis (Pinlaor et al. 2009). Ov-GRN-1, a granulin-like growth factor from *O. viverrini*, causes proliferation of mammalian host cells (Smout et al. 2009, 2011b). In vitro, components of the excretory-secretory product of *O. viverrini* increased cell proliferation of mouse fibroblasts (Thuwajit et al. 2004). Secreted *O. viverrini* glutathione S-transferase regulates cell proliferation through AKT and ERK pathways in cholangiocarcinoma cells (Daorueang et al. 2012). Several oxysterols have been identified in bile in the context of biliary tract infection, and there is evidence that these compounds play a role in biliary tract carcinogenesis (Kuver 2012). In extracts of *O. viverrini*, novel oxysterol derivatives have been detected, part of them having an estrogen core (Vale et al. 2013).

Opisthorchis felineus

Epidemiology

It is currently estimated that worldwide around 1.2 million persons are infested with *O. felineus* (WHO 1995). High prevalences are known in Belarus, Russia, and the Ukraine and in certain regions of Europe, specifically Germany and Greece (Bernhard 1985; Sänger et al. 1991; Hering-Hagenbeck and Schuster 1996; Tselepatiotis et al. 2003). Infestation with *O. felineus* has also been observed in Italy, from fish of two lakes, including the Lake Trasimeno

(Crotti et al. 2007), the patients having ingested raw tench filets (*Tinca tinca*) (Armignacco et al. 2008, 2013; Pozio et al. 2013).

The Parasite

O. felineus (Rivolta 1884) is a trematodan flatworm of the family Opisthorchiidae, discovered in 1884 by Sebastiano Rivolta in the liver of a cat. Five years later, the parasite was detected in the human host by Vongradov, who termed this parasite Siberian liver fluke. The life cycle of *O. felineus* was specified in 1934 (Vogel 1934). Embryonated eggs in water infest water snails of the genus *Bithynia* as first intermediate hosts (*Bithynia inflate*, *B. troschelii*, and *B. leachii*). Here, miracidia emerge which transform into sporocyst to produce rediae and cercariae, as specified in the paragraph on *O. viverrini*. It is estimated that 2 weeks are required between entry of the parasite into the human body and homing into the bile ducts.

Clinical Presentation

In contrast to *O. viverrini* infestation, *O. felineus* may cause an acute disease stage occurring 2–4 weeks after ingestion of raw fish, characterized by fever, malaise, arthralgia, lymphadenopathy, and skin rash (Brodov 1968; Belov 1971). Subacute and chronic disease is dominated by (recurrent) pyogenic cholangitis (Brazhnikova 1989) and liver abscesses (Kirilenko 1979). *O. felineus* can be identified by the use of PCR (Pauly et al. 2003).

Paragonimiasis of the Liver

Introduction

Paragonimiasis is an infestation caused by lung flukes of the genus *Paragonimus* (*P.*), mainly *P. westermani* which is endemic to Asia. Clinical manifestations of paragonimiasis, characterized by abdominal pain, fever, and diarrhea, are caused by the host's immune and inflammatory reactions toward the migrating parasites (Yokogawa 1969). Apart from the lung, other tissue and organ "terminals" are known, such as the CNS and the liver (extrapulmonary paragonimiasis).

The Parasite and Its Life Cycle

Paragonimus species belong to the platyhelminthic family, Troglotrematidae, and class Trematoda. The definitive hosts of *Paragonimus* species are mammals, and the life cycle requires two intermediate hosts, an aquatic snail and a crustacean. Humans attract the parasite by eating undercooked crustaceans containing infective metacercariae. Ingested metacercariae leave the intestine and move to the abdomen and then to lungs, where they transform into a cyst containing fertile adults. These are flukes with a size of 15 mm length and 8 mm width. In cysts, adult flukes cross-fertilize with one another. The cyst will rupture in the lung and liberated eggs are swallowed and transferred to the environment. In water bodies, eggs hatch and become ciliated miracidia which infect the first intermediate host, aquatic snails. The relevant gastropod taxa belong to the two superfamilies, Cerithoidea and Rissooidea (Davis et al. 1994). The second intermediate host, a crustacean, becomes infected by feeding on infected snails. *P. westermani* was the first human lung fluke described (in 1878 by Kerbert; Kim 1984b). Apart from *P. westermani*, several other species have been identified in the human host in Asia, including *P. skrjabini*, *P. heterotremus*, *P. compactus*, *P. hueit'ungensis*, *P. miyazakii*, *P. miyazakii manipurinus*, *P. cenocopiosis*, *siamensis*, and *P. pseudoheterotremus* (Wang et al. 2011; Intapan et al. 2012; Singh et al. 2012). In North America, *P. kellicotti* is an important species (North American paragonimiasis; Procop 2009; Lane et al. 2012).

Liver Involvement

Paragonimus larvae, starting their migration track in the intestinal wall, may get access to the liver and there produce parasitic mass lesions. These lesions, most of which consist of a marked inflammatory response, are macroscopic and spherical, mimicking malignancy at imaging (Lee et al. 1985, 1987; Singcharoen et al. 1988; Kim et al. 1991, 2002, 2004; Nabeshima et al. 1991; Takemasa et al. 2002; Cheng et al. 2010; Li et al. 2012). On CT images, the lesions usually present as clusters of small cysts with rim enhancement in peripheral parts of the liver (Kim et al. 2004). In one patient, a cystic lesion with internal septation and a peripheral thick capsule was found in the left liver lobe (Rha et al. 1999). Hepatic lesions are occasionally elongated form of tubular low-attenuated lesions of up to 2 cm in length. Laparoscopically, such lesions appear as a white, slightly elevated patch (Lee et al. 2005). In case of multifocal hepatic infestation, multiple low-density areas on CT can develop (Takemasa et al. 2002). In *P. skrjabini* infestation, large chronic eosinophilic liver abscesses with Charcot-Leyden crystalloids were found at autopsy (Hu et al. 1982). The parasite larvae sometimes stop their migration track on the liver surface, causing active hepatic capsulitis (Sasaki et al. 2002). In the setting of peritoneal parasite spread, multiple perihepatic adhesions can develop (Hu et al. 1982).

Tumor-Like Parasitic Lesions of the Hepatobiliary Tract: Echinococcosis and Cysticercosis

134

Contents

Abstract

Echinococcosis is a widespread infestation with mainly two species of *Echinococcus* (*E.*), *E. alveolaris* (the cause of alveolar echinococcosis), and *E. hydatidosus*/*granulosus* (the cause of hydatid disease). Adult *E.* tapeworms inhabit the intestinal tract of various canids, including domesticated dogs and foxes. In both forms of echinococcosis, man is infested by the ingestion of embryonated eggs that hatch into larvae. These transmigrate from the intestinal tract into various tissues and form complex colonies of larvae. Alveolar echinococcosis of the liver is a severe and sometimes life-threatening condition characterized by invasively growing parasite colonies that produce large masses that may extend beyond the organ boundaries. The process can clinically mimic hepatic cancer. In contrast, cystic echinococcosis or hydatid disease is characterized by solitary or multiple cystic structures lined by chitin lamellae and a cambium of embryonal parasite cells that give rise to daughter organisms. In contrast to alveolar echinococcosis, the daughter cysts of hydatid disease contain larvae equipped with a scolex bearing hooklets, an important diagnostic feature. In rare instances, human livers are infested with larvae of the pork tapeworm, *Taenia solium*, a condition termed cysticercosis.

Echinococcosis

Introduction

Echinococcosis, caused by several tapeworm species of the genus *Echinococcus*, is a dangerous and potentially fatal helminthic zoonosis in wildlife animals, livestock, and humans. Echinococcosis occurs in four forms, i.e., cystic echinococcosis (CE; hydatid disease) caused by *Echinococcus* (*E.*) *granulosus*, alveolar echinococcosis (AE) caused by *E. multilocularis*, and the uncommon polycystic echinococcosis (PCE) caused by *E. vogeli* and unicystic echinococcosis (UCE) caused by *E. oligarthra*. CE has a worldwide distribution, whereas hepatic AE is endemic in the Northern Hemisphere (Palearctic and Nearctic distribution), while PCE and UCE originated in the neotropics (reviews: Vuitton 1997; Eckert et al. 2001; McManus and Thompson 2003; Eckert and Deplazes 2004).

CE is a parasitosis that is known since antiquity (review: Cox 2002). Hippocrates, Galen, and Aretaeus mentioned large cysts of the liver filled with water. First and more exact descriptions of hydatids date from the sixteenth and seventeenth centuries (e.g., by Felix Plater). Well-described cases of CE are found in the work "Sepulchretum" (Bonetus/Bonet 1679), a text on anatomy and pathology based on numerous necropsies. Until the seventeenth century, the cysts were regarded as cystic enlargements of lymphatic vessels. It was Francesco Redi in the seventeenth century who first appreciated the parasitic nature of the cysts (Redi 1684). Redi, a physician and naturalist interested in entomology and parasitology, was struck by his observation that living macroorganisms can dwell inside another living organism. The German clinician and naturalist Pierre Simon Pallas demonstrated, in 1766, that cysts are the larval stages of tapeworms (Pallas 1766). The causative parasite of CE was first designated as *Hydatigera granulosa* by Batsch in 1786. The genus, *Echinococcus*, was coined in 1801 by Karl Asmund Rudolphi from Greifswald (1771–1832). The first detailed scientific descriptions of *Echinococcus* in the human body dates from 1819, by the physician and parasitologist Johann Gottfried Bremser (1767–1827), who had created a famous helminthologic collection in Vienna. He published excellent documentations on tapeworms in his book, entitled *Living Worms in the Living Human* (*Über lebende Würmer im lebenden Menschen*; Bremser 1819). In 1855, Virchow published his findings on *E. multilocularis* and hence was the first to recognize this disease as caused by a distinct *Echinococcus* species (Virchow 1855; review: Tappe and Frosch 2007). Frans Buhl had described the lesion before and had termed it "alveolar colloid," but he interpreted it as a form of gelatinous cancer (Buhl 1852, 1854). A third case was reported by Zeller (1854). By careful examination of his case, including necropsy findings, Virchow recognized vesicles suggesting *Echinococcus* elements, and he finally detected protoscolices, being very rare in human AE. Furthermore, he uncovered the infiltrative aspect of this parasite, a highly characteristic feature of AE. In the title of his work, he termed the disorder, "echinococcal tumor/Echinokokkengeschwulst" (Virchow 1855). Aspects of hepatic echinococcosis were summarized in 1856 by Luschka (1856). A detailed compilation of facts regarding several types of helminth parasites in man, including hydatid disease, appeared as a book (*On Human Entozoa*) in 1863 (Smith 1863), and hepatic echinococcosis was again summarized in book form in 1869 (Lindner 1869). The species *E. alveolaris*/*multilocularis* was described in 1863 by Leuckart. Experimental evidence for the complex life cycles was obtained by von Siebold (1853) who found that *Echinococcus* cysts from sheep produced adult tapeworms when ingested by dogs and by Naunyn (1863), who observed adult tapeworms in dogs fed with hydatid cysts from a human.

The Parasites

The tapeworm genus *Echinococcus* belongs to the Cestoda family Taeniidae and contains nine valid species (Nakao et al. 2013a,b; Table 1). In two of them (*E. granulosus* and *E. multilocularis*), the complete genomes have been analyzed (Tsai et al. 2013).

Table 1 Species of *Echinococcus* (*E.*)

Species	Disease
E. multilocularis (syn.: *E. alveolaris*)	Alveolar echinococcosis
E. granulosus sensu stricto (syn.: *E. hydatidosus*)	Cystic echinococcosis
E. equinus	
E. ortleppi	
E. canadensis	Cystic echinococcosis
E. shiquicus	
E. vogeli	Polycystic echinococcosis
E. oligarthrus (*E. oligarthra*)	Unicystic echinococcosis

Alveolar Echinococcosis: General Aspects

AE is the most serious form of echinococcosis, with a high morbidity and mortality rate (Clerc 1912; Weinberg 1947). In contrast to CE, AE has a distribution involving the Northern Hemisphere, including northern areas of Asia, Europe, and North America (Palearctic and Nearctic distribution). Regions with a high incidence of AE are Russia (including Siberia), China, northern Japan, southern Germany, Switzerland, France, and Alaska. Since the late 1980s, a number of hot spots were found in continental Asia, mostly in China and Central Asia, with discrete patches of endemicity. This phenomenon particularly relates to south Gansu, at the eastern border of the Tibetan plateau, south Ningxia, and the western Tian Shan. Within these hot spots, distinct transmission ecologies involving small mammal "flagship" species were found (Giraudoux et al. 2013). While CE seems to decrease in frequency, the prevalence and distribution of AE in red foxes in Europe increased significantly in the last 10–15 years, with a majority of cases identified in France, Germany, and Switzerland (Craig 2003).

Alveolar Echinococcosis: Macroscopic Pathology

The pathology of AE has been summarized in detail (Daujat 1912; Posselt 1931). At gross examination, AE lesions are characterized by ill-defined or polycyclic masses with a granulovesicular cut surface, from which usually no fluid emerges, in contrast to CE (Figs. 1 and 2). AE usually presents in the form of a solitary pseudotumor, while diffusely infiltrating variants are very rare. Most lesions occupy central or core parts of the liver, and the liver margins are usually spared. Similar to malignancies, the right liver lobe is more often affected. The size ranges from few cm to masses exceeding the size of a human head. The shape of the masses is ovoid, wedge-shaped, or irregular, sometimes with complex arborizations or tunnellike or mine-like extensions. Small satellite lesions may occur. The cut surface is whitish gray, but may also have reddish-

Fig. 1 Alveolar echinococcosis of the liver. An invasive tumor-like mass consisting of necrotic tissue and numerous small parasites has destroyed part of the liver substance

Fig. 2 Invasion of the hepatic pedicle in alveolar echinococcosis

brown areas or may be yellow (bile stained) in case of bile duct invasion. The masses can resemble a neoplastic process with invasive features. In fact, some patients show gross invasion of bile ducts and/or large hepatic veins, or the inferior vena cava. In contrast to primary liver cancer or metastases, AE lesions reaching the liver capsule do not result in umbilication or production of surface furrows. However, superficial masses may bulge from the surface and can even produce grape-like masses protruding from the liver surface. AE lesions can extend to the porta hepatis, or may primarily develop in this region. The masses may penetrate the liver capsule, or invade the gallbladder. The vesicles or alveolar structures typical of AE are small (2 mm diameter or less), but part of them may be visualized with the naked eye, the largest vesicles attaining pea size or even the size of a cherry (cited in Posselt 1931). There are AE lesions that almost exclusively consist of very small vesicles, not discernible at gross examinations. Such lesions may easily be confounded with a malignant neoplastic process.

AE lesions can undergo several secondary alterations. Large lesions can develop a central cavity caused by necrosis. There is evidence that bile, which can enter the parasite mass following bile duct invasion, promotes severe parasite damage and necrosis (bile infarction of parasite; Melnikow-Raswedenkow 1901). In large central necroses, putrefaction occurs, with discharge of a sanious, fetid, or ichorous fluid (in the German literature, "Verjauchung"; Posselt 1931). Cystic necroses may perforate the liver capsule and penetrate into the peritoneal cavity. Necrosis and/or infection of the parasite mass can elicit ulcerations of central cystic spaces (Mangold 1892). The fluid in cystically altered necrotic foci can contain blood, hemoglobin, and hematoidin (Posselt 1931). Cystic necrosis can result in sequestration of parts of the parasite and/or the involved liver substance (Kränzle 1880). The sequesters appear as ill-defined gray to whitish of bile-stained, friable tissue areas sometimes separated from the remaining liver and parasite by a slit-like space. In contrast to CE, gas formation almost never occurs in AE (Posselt 1931).

The liver areas harboring AE lesions can undergo atrophy with or without associated fibrosis and nodular hyperplasia, sometimes with a cirrhosis-like change in the liver substance surrounding the parasite (review: Posselt 1931).

Alveolar Echinococcosis: Histopathology

The histologic hallmark of AE is the presence of a complex, sievelike system of vesicular structures ("alveoles"; hence the name alveolar echinococcosis) surrounded by an eosinophilic, PAS-positive lamina, the parasite elements being embedded in a fibrous matrix with inflammatory infiltrates (Figs. 3 and 4). Three-dimensional digital reconstruction of *E. alveolaris* larval structures from hepatic tissues demonstrated a rootlike network of interconnected vesicles and tubules extending into the periphery of the lesion (Tappe et al. 2010). There is evidence that new vesicles and microcysts first devoid of a laminated covering arise from mother vesicles as bleb-like cellular sprouts and grow into tissue in the form of rootlets resembling those of plant-penetrating soil. Larger vesicles and growing cysts then start to add a laminated cover (Vogel 1978; Mehlhorn et al. 1983). In contrast to

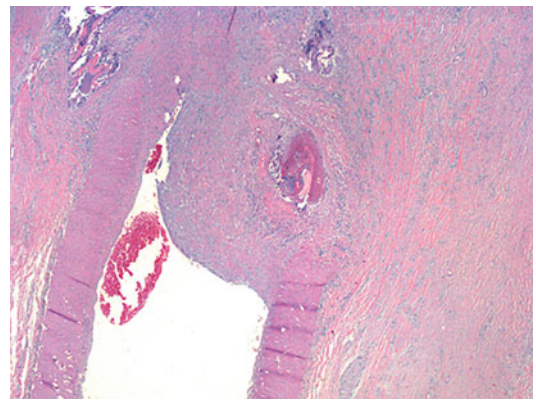

Fig. 3 Hepatic alveolar echinococcosis with arterial invasion. The wall of the artery is interrupted by an inflammatory lesion that contains a focus of parasite lamellae without cysts or hooklets (hematoxylin and eosin stain)

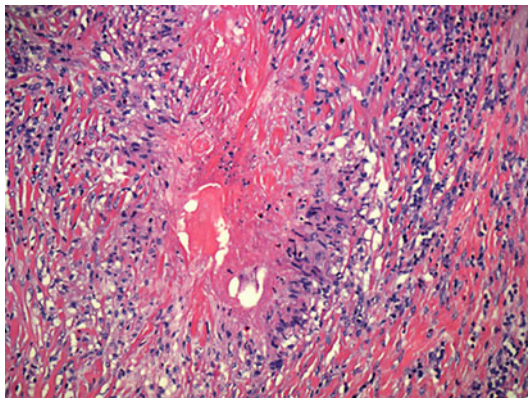

Fig. 4 Echinococcal granuloma in hepatic alveolar echinococcosis (hematoxylin and eosin stain)

CE, AE in the human host hardly ever shows fully developed protoscolices (Mehlhorn 2001), although Virchow detected them in his classical investigation leading to the recognition of AE as an echinococcal disease (Virchow 1855). In rodents harboring *E. multilocularis* metacestodes, protoscolices are regularly found, suggesting that the asexual production of protoscolices strongly depends on the intermediate host involved. Echinococcal differentiation processes directed toward the protoscolex stage involve an echinococcal gene encoding an epidermal growth factor receptor orthologue (Spiliotis et al. 2003) and a gene encoding a member of the insulin receptor family (Konrad et al. 2003), genes that may be differentially expressed in various hosts. Histologically, the invasive features of the parasite seen at macroscopy are confirmed. Clusters of vesicles accompanied by PAS-positive lamellae of varying thickness grow into the tissue of liver in an infiltrative fashion, similar to invasive cancer, and may penetrate into bile ducts and the walls of the portal vein, hepatic veins, and inferior vena cava. Similar to a carcinoma, the parasite is associated with a fibrous, stroma-like tissue.

Similar to cancers, the invasive cascade of AE involves several types of peptidases and proteases, including a cathepsin L-like peptidase (Sako et al. 2007) and a cathepsin B-like peptidase (Sako et al. 2011). A cysteine protease produced by *E. multilocularis* metacestodes digests eotaxin, a CC pro-inflammatory chemokine (Mejri and Gottstein 2009). On the other hand, the parasite also secretes proteins that inhibit proteases, such as a serpin active on trypsin, neutrophil elastase, and a trypsin-like plasmin (Merckelbach and Ruppel 2007).

Antigens of *E. multilocularis* elicit of vigorous local immune reaction mediated by lymphocytes and macrophages (Bresson-Hadni et al. 2008; Brehm 2010). The parasite contains and expresses several antigens, e.g., a laminated layer-associated protein (Ingold et al. 1998), a T24-like tetraspanin located to the germinal layer (Dang et al. 2009), and the B antigen complex (Mamuti et al. 2004). Metacestodes of *E. multilocularis* modulate cellular cytokine and chemokine release by mononuclear cells. This modulation leads to differential up- and downregulations of certain cytokines, in particular Th1 and Th2 cytokines and chemokines, thus generating a pro-inflammatory immune response (Hübner et al. 2006). Secretory products of *E. multilocularis* metacestodes induce tolerogenic properties and apoptosis in dendritic cells in vitro (Nono et al. 2012). Infestation with *E. multilocularis* results in a fibrotic reaction surrounding the parasite cysts. In the pericystic hepatic tissue, increased expression of the fibrokine, TGF-beta, and an activated TGF-beta/Smad signaling pathway have been identified (Wang et al. 2013). *E. multilocularis* can elicit a granulomatous reaction in the liver (Gaultier et al. 2009), sometimes with giant cells (Caesar 1901). The formation of epithelioid cells and macrophages is probably linked to specific interactions between components of the parasite, specifically its protoscolices, and Kupffer cells/macrophages (Walbaum et al. 1994). On the other hand, clustering of cases within families and a link to certain MHC polymorphisms suggest that *E. multilocularis* may modulate immune reactions to escape host defense (Vuitton et al. 2006; Gottstein and Hemphill 2008). The complex interaction between *E. multilocularis* and its hosts is regulated by the parasite's distinct proteome, which will also be used for diagnostic typing of strains (Cui et al. 2013).

Cystic Echinococcosis (CE; Hydatid Disease): General Aspects

Cystic echinococcosis (CE; hydatid disease) is in most instances caused by *E. granulosus* (hydatidosus), but infestations with *E. canadensis* strain G7 (pig strain) are increasing in Central Europe (Schneider et al. 2010). CE is known in human medicine for a long time and has, e.g., been described in 1840 under the name *Echinococcus hominis*, as a "rare species of hydatid" found in the human liver (Curling 1840). CE is a widespread parasitosis with a worldwide distribution and represents a global problem of increasing importance (Matossian et al. 1977; McManus and Thompson 2003). It was a rather common parasitosis in former times, but the worldwide incidence and prevalence of CE have fallen significantly over the past decades (Grosso et al. 2012). The impressive differences in incidence from one country or region to the other are, apart from control programs, mainly due to different distributions and numbers of intermediate hosts (goat flocks, seminomadic and nomadic sheep) and canines as final hosts, with the common sheep G1 strain being the predominant strain (Grosso et al. 2012). In most instances, hydatid involves adults, but pediatric cases of CE are also well known (Young 1923).

Hepatobiliary CE is characterized by the development of the larvae of *E. granulosus* causing liver cysts. Early hepatic hydatid disease is usually asymptomatic for long time periods, but as the parasitic cysts slowly grow and enlarge over years, they can exert a mass effect sometimes resembling a hepatic neoplasm (Barrier 1840; Frerichs 1860/1861; Duclaux 1875; Scherer et al. 1978; WHO Informal Working Group 2003; Nunnari et al. 2012). Solitary cysts or cysts with satellite lesions produce space-occupying masses that may, in slender individuals, seen as bulging tumors, or are palpable as fluctuant lesions. Hepatomegaly is sometimes important, with marked displacement of the liver by the parasite cysts.

These large cystic or multicystic lesions have distinct physical properties linked to the presence of fluid-filled spheres with a membrane and a pericyst which are under a certain tension. These cysts that are distended by fluid have remarkable elasticity, so that a shock is transmitted through the whole mass as a prolonged trembling motion (Smith 1863). This may rarely lead to a unique auscultatory and percussion phenomenon termed "son hydatique" (Piorry 1828) in French, translated as "hydatid sound" or "hydatid fremitus" (Markham 1856; Little 1857). Pierre Adolphe Piorry (1794–1879) was an outstanding clinician and pioneer of percussion and pleximetry. He was struck by the peculiar vibrations at auscultation and found that the vibrant feature may also be obtained through percussion. Markam (1856) described that a hydatid projecting from the liver, "when percussed, communicates to the finger which is struck a most peculiar sensation, resembling very exactly that which arises from the vibrations of a loosely hung steel spring." Apart from right upper abdominal discomfort or pain, the cysts may give rise to complications, such as cyst infection, cyst rupture, or compression of bile ducts. Rarely, CE was associated with, or caused, Budd-Chiari syndrome (Parker 1959; Raciti 1972; Agarwal and Kumar 2009). This complication is due to the fact that *E. granulosus* cysts can invade veins and the heart cavities and can even cause pulmonary embolism.

Cystic Echinococcosis: Macroscopic Pathology

In his 1840 article on liver hydatid associated with *Echinococcus hominis*, Curling gave a pertinent macroscopic description of the cystic parasite, which clearly illustrates the typical features of this disease. He noted, "a cyst of fibro-cartilaginous structure, lined by a soft loose albuminous membrane enclosing a large number of separate hydatid cysts of various sizes from that of a pea to that of a large cherry, surrounded by and floating in a transparent fluid. Upon opening a cyst, there escaped a large number of small white particles, some of which were found floating in the fluid within, while others were in contact with the inner surface of the membrane composing it. The latter appeared like grains of white sand thickly studded over the interior of the

cyst. On examination in the microscope, these little bodies were ascertained to be the vermiculi of the *Echinococcus*" (Curling 1840). These "vermiculi" ("small worms") represent the protoscolices of the present nomenclature, and the "sand" (in German, "Hydatidensand") is a mixture of viable and dead protoscolices and parasite debris. Curling (1840) identified the crown of hooklets and the suckers and also found that part of the hooklets had detached and were floating in the cyst fluid or were stuck within protein masses.

Solitary cysts or mother cysts in case of a conglomerate of cysts range in size from 5 mm to more than the size of an orange (Figs. 5 and 6).

Fig. 5 Cystic echinococcosis (hydatid disease) of the liver. The large parasitic cyst contains a partially detached milky-white parasitic lamella lining the cyst. The yellow discoloration is due to leakage of bile from damaged bile ducts

The cyst walls are generally of uniform thickness, roughly proportional to the size of the cyst. The interior cyst wall surface is either colorless and transparent or of opaque tint in fresh specimens, while it turns to a milky or turbid color upon formalin fixation. In has been compared to the appearance of a boiled egg. In case of bile duct rupture or hemorrhage, the wall is yellow or reddish brown, respectively. The cavity of the cysts contains a more or less abundant liquid, which is serous or limpid, and sometimes viscid. Large hydatid cysts (the parent hydatid or mother cyst) may enclose several smaller daughter cysts, which are connected with the wall of the mother cyst or are freely floating. The internal surface of young cysts is smooth, while it becomes rough in older cysts, sometimes covered with a thick exsudation.

Part of hepatic cysts in CE display daughter cysts that are located exterior to the fibrous pericyst of the largest mother cyst ("extracapsular cysts"). In one study, this phenomenon was found in 16 % of cases (Kalovidouris et al. 1992), whereas the real incidence of these cysts in operative specimens was as high as 29.5 % (Voros et al. 1999). The germinal layer and recently produced material of the laminated layer may detach from the older cyst layer and float within the cyst. Old cysts often show internal septations and daughter cysts. As cysts become older, the intracystic fluid, which is usually limpid, diminishes in quantity and thickens, with a more viscid consistency, finally assuming the appearance of painter's putty or chalk (Smith 1863). In other

Fig. 6 Cystic echinococcosis (hydatid disease) of the liver. In this case, the cyst is filled with necrotic parasitic matter following therapy, mimicking a necrotic malignancy

cases, the cyst content assumes a color and consistency strikingly similar to that of tuberculous calcification or resembles that of an atheroma/epidermoid cyst. In large cysts, the pericyst frequently undergoes calcification, and in part of the lesions, the entire cyst wall may be replaced by a thick calcified shell with a bony consistence. In case of bile duct invasion or rupture into bile ducts, bile can flow into the parasite cysts, staining them yellow. Hydatid cyst may be infected, followed by supportive inflammation and eventually formation of a cyst empyema. In case of infection with anaerobic bacteria, gas formation can occur (Garnier 1907; Adnet 1910; Fiessinger 1924). In the presence of large cysts, the involved liver part can undergo atrophy.

Cystic Echinococcosis: Histopathology

Active, viable cysts are lined by a layer of small parasite cells, the germinal layer. This germinal layer is the site from where secondary larval colonies arise, first forming small bud-like structures that grow out into macroscopic, milky-white and coral-like and cauliflower-like structures containing numerous so-called brood capsules (Figs. 7, 8, and 9). These structures are lined with a germinal cell layer morphologically similar or identical to that in larger mother cysts. At many places, the metacestodic larval cell system of the brood capsule generates protoscolices having the complete set of hooks. The cell systems of the germinal layer are in contact with tegument cells which in turn line the multilayered, PAS-positive lamina, which is produced by tegument cells. Hooks (or hooklets) which either form a crown in protoscolices or are free structures embedded in parasite or host tissue, or are floating in the cyst fluid, are small in *E. granulosus* and *E. multilocularis* (17–49 μm in length) and have a much larger size in neotropical *Echinococcus* species (43–60 μm).

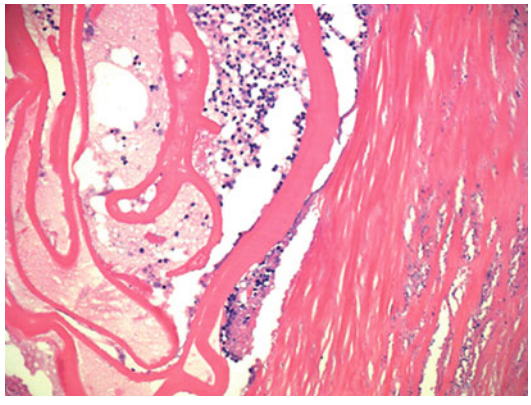

Fig. 7 Cystic echinococcosis (hydatid disease) of the liver. Parasitic cysts are lined by a layered eosinophilic lamella or membrane. Viable embryonal parasite cells which line these membranes are not seen in the present case (hematoxylin and eosin stain)

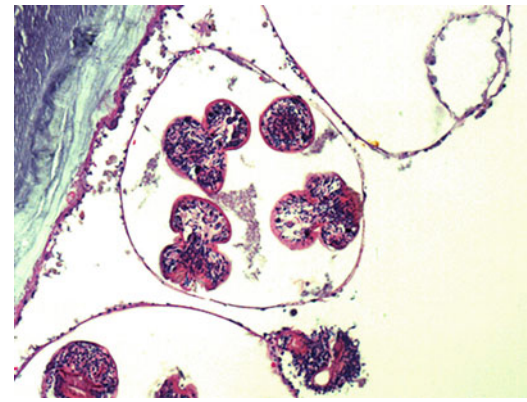

Fig. 8 In contrast to alveolar echinococcosis, cystic echinococcosis contains hydatid cysts with parasite embryos (Masson's trichrome stain)

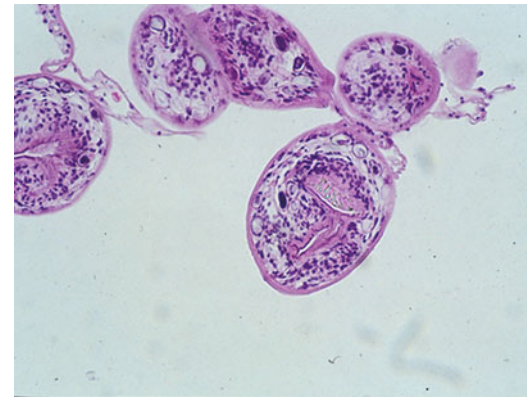

Fig. 9 Cystic echinococcosis of the liver. Parasite embryos show a ring or collar of hooklets that is also found in the adult parasite (hematoxylin and eosin stain)

Old cysts may undergo atrophy of the parasite, or the epithelial component of the parasite may completely vanish in dead *Echinococcus*, and the hooklets of the protoscolices will furnish the only indication of the previous existence of CE (Smith 1863). The hooklets are transparent objects and may this be missed, but they stain pink or red in the Ziehl-Neelsen stain. The laminated membrane of old or dead cysts shows accumulation of fat droplets, crystalloids, and signs of rupture of laminae seen in the PAS stain. The entire membrane may become ruffled and can finally collapse due to loss of stability and failure of fluid production by the dead parasite, with subsequent effacement of the cyst cavity. In PAS stains, collapsed cysts show contracted membranes folded together, with an appearance like "petals of a poppy enclosed within the calyx" (Smith 1863). Even after complete atrophy of a cyst, both the membrane and the hooklets resist degradation for long time periods, and even after years one my detect hooklets and/or membraneous shreds.

Infestation with *E. granulosus* elicits a vigorous immune reaction driven by parasite antigens (Delunardo et al. 2010). Immune reactions induced by *Echinococcus* are thought to serve as a protection of the host against the parasite, but the parasite itself may also profit from a complex immunologic interplay (review: Vuitton 2003). Antigen B (EgAgB) is a major metacestodic protein antigen belonging to a gene family composed of at least ten unique genes which are differentially expressed in different life cycle stages of *E. granulosus* and play a role in modulating immune responses of the host (Zhang et al. 2010). Expression and secretion of interleukin-17A by immunologic effector cells results in immunoprotection against the parasite (Mezioug and Touil-Boukoffa 2012). The local generation of cytokines and fibrokines results of the generation of a fibrous zone surrounding the parasite cyst (the so-called pericyst), associated with a cellular infiltrate.

The pericyst surrounding the parasite cyst consists of collagen fibers, fibroblasts/myofibroblasts, and a cellular infiltrate of variable density. This infiltrate contains eosinophilic granulocytes, lymphocytes (both T-and B-cells), macrophages, and plasma cells. The density of this infiltrate is usually greater in early hydatid disease, while it is often sparse in old fibrotic and/or calcified lesions. In case of rupture of a parasitic cyst into the bile duct system, entry of parasite material and in particular the cyst fluid containing brood capsules and necrotic parasite elicits a vigorous immune and inflammatory reaction, with formation of ductocentric epithelioid cell granulomas, granulomas protruding in the duct lumen, and a periductal inflammatory infiltrate with numerous eosinophils. Fragments of the PAS-positive lamella, entire viable or dead protoscolices, or hooklets may "heal" into these granulomatous areas, promoting the formation of foreign body-type giant cells. Following albendazole therapy, germinal layer cells and protoscolices revealed degenerative changes and a loss of viability (Stankovic et al. 2005).

Morphology of Echinococcal Parasites

Echinococcal parasites have a complex internal structure. In *E. multilocularis* (alveolaris), the small interconnecting cysts are surrounded by an acellular laminated layer containing glycoproteins and chitin, therefore being strongly PAS positive. The interconnecting cysts are filled with fluid, and the larval cell system forms a thin layer (germinal layer, germinal membrane) juxtaposed to the laminar layer. The germinal membrane consists of asexually proliferating cells. Several metacestodic cell types are identified including tegumental cells forming a syncytium underneath the laminated layer and synthesizing the layer substance, glycogen storage cells, muscle cells, calcareous corpuscle cells, excretory duct cells, and stem cells. Furthermore, *E. alveolaris*/*multilocularis* possesses a larval nervous system with nerve cells (Koziol et al. 2013). Within the labyrinth of PAS-positive interconnecting cysts, the metacestode larvae are not always easily detectable, because the parasite tissue is fragile and often damaged by tissue processing. Invaginations of the cyst walls result in so-called brood capsules which may contain protoscolices. The protoscolices, which have a structure similar to

that of the scolex of an adult tapeworm, is invaginated within a small posterior body (Koziol et al. 2013). The germinal layer cells of *E. multilocularis* have been cultured, and these cells can be used to produce metacestodes in experimental animal models (Yamashita et al. 1997; Brehm and Spiliotis 2008). As in other species of *Echinococcus*, germinal cells can give rise to small structures exhibiting a central body, a small number of concentric layers and calcified matter, the so-called calcareous corpuscles. These bodies can also arise from brood capsule cells (Ohnishi and Kutsumi 1991). The generation of new metacestodes is thought to mainly originate from germinal cells situated on the inner surfaces of brood capsules, but there are also cell accumulations on the outer brood capsule surface, suggesting that brood capsule itself may have the potential to produce new brood capsules (Ohnishi and Kutsumi 1995). A germinal cell layer lining the cyst wall is also found in *E. granulosus*, the parasite causing CE. Although cysts in CE tend to grow slowly, germinal cells in culture are capable for rapid proliferation, with an estimated population doubling time of 48 h (Albani et al. 2010, 2013). It has been shown that, in the course of scolicogenesis, the protoscolex surface displays five cellular territories, and three of these territories are surrounded by a basal lamina. These cellular territories correlate with the expression of specific genes and the regionalization of DNA synthesis in protoscolices (Galindo et al. 2008).

Life Cycles and Pathways of Infestation

The life cycles of *Echinococcus* species are closely linked with a predator-prey association involving two obligate mammalian hosts. Definitive hosts of the adult tapeworms are carnivores, mainly canids. Intermediate hosts harboring the metacestode larvae are herbivore preys, such as ungulates, lagomorphs, and rodents. Humans form an accidental host for metacestode infestation. In the human host, the metacestode larvae usually develop in the liver, but other parenteral sites can also be infested.

Infestations of *E. multilocularis* proceed along a sylvatic cycle, wild canids – in particular red fox and arctic fox – being the definitive hosts. A second life cycle in *E. multilocularis* infestation is the synanthropic cycle, in which domestic dogs and cats are definitive hosts. Intermediate hosts in AE are small microtine and arvicoline rodents. These infested rodents harbor metacestodes which, when ingested by predators, give rise to adult tapeworms which deliver embryonated eggs in the feces of definitive hosts. Humans are infested via contact with material contaminated with excrements of foxes, such as forest berries and mushrooms, on which embryonated eggs can survive for a while. It follows that infestation with eggs strongly depends on behavioral and occupational factors, berry and mushroom pickers, hunters, and trappers being at higher risk. Domestic dogs are well-known sources of human infestation, but the role of domestic cats is less clear. In humans, ingested embryonated eggs become oncospheres migrating to organs (specifically the liver), where they develop into metacestodes.

In CE, the definitive hosts are primarily dogs and other canids, mainly the domestic dog, while the intermediate hosts are primarily ungulates, marsupials, and primates. Gravid proglottids of the tapeworms pass in the feces and rupture, releasing eggs that are ingested by the intermediate hosts. These are many mammals, but sheep predominate. The ingested eggs hatch in the intestine of intermediate hosts, giving rise to oncospheres that penetrate the intestinal mucosa, enter the bloodstream, and develop into metacestodes and hydatid cysts in several organs and tissues. The life cycle is completed when the metacestode cyst is ingested by a definitive host.

E. vogeli has the bush dog (*Speothos venaticus*) as its final host. The bush dog (called cachorro-vinagre, "vinegar dog," in Brazil) is a canid inhabiting Central and South America. It is the closest living relative of the South American mane wolf. The main prey of bush is the large caviomorph rodent, the paca (*Cuniculus paca*), which is the intermediate host of *E. vogeli* and harbors the metacestodes (the cycle in neotropical forests; D'Alessandro and Rausch 2008). Humans are thought to be infested via ingestion of

embryonated eggs attracted from infested dogs that had fed on pacas (the domiciliary transmission). After ingestion of embryonated eggs, the oncospheres released in the intestine are transferred to the liver, where the oncosphere produces a primary lacuna, and then the development of the metacestode is initiated. In nonnatural intermediate host such as humans, an initial vesicle is formed, from which new vesicles sprout through asexual proliferation (D'Alessandro and Rausch 2008). *E. oligarthrus*/*oligarthra* metacestodes were identified in opossums, agoutis, spiny rats, pacas, and rabbits. The most common final host of *E. oligarthrus*/*oligarthra* is the cougar (*Puma concolor*), but it is expected that this parasite can also parasitize other felids.

Cysticercosis of the Liver

Introduction

Cysticercosis is the infestation of the human host with larvae (*Cysticercus cellulosae*) of the pork tapeworm, *Taenia solium*, following ingestion of embryonated *Taenia* eggs. Infestation takes place via intake of contaminated food or water, external feces, or, in case the human host itself harbors a pork tapeworm, the person's own feces being the source of the eggs. The infestation of humans with cysticerci is a "dead end" for the parasite, as no further transmission takes place. In contrast, intestinal infestation of humans by the pork tapeworm, *Taenia solium*, requires the ingestion of viable cysticercal larvae through ingestion of undercooked or uncooked pork and pork products.

After ingestion of *T. solium* eggs, these eggs hatch in the intestinal tract and give rise to migrating and invasive larvae, the *Cysticercus cellulosae*. These larvae are semitransparent, opalescent white organisms of an oval to elongated shape and have a body length of up to 1.8 cm. Cysticerci have a scolex with four large suckers and a rostellum armed with double row of large and small hooklets, numbering 22–32 (review: Sparks et al. 1976). The cysticerci penetrate the intestinal wall, enter the bloodstream, and start to spread in the human body, to settle at few predominant sites. At these sites, the larvae form a cystic space containing protoscolices. Typical sites are the brain and spinal cord (neurocysticercosis; including the development of cysts in the ventricles), ophthalmic cysticercosis, muscle cysticercosis, and cutaneous/subcutaneous cysticercosis. Neurocysticercosis and ophthalmic cysticercosis together account for more than 85 % of cases. In muscle and soft tissues, the cysticerci can encapsulate and may survive for many years. Rare localizations comprise the heart, peritoneum, lung, and other visceral organs, such as the liver.

Cysticercosis of the Liver

Hepatic cysticercosis is a rare disorder, of which only few cases have been reported. Hepatic involvement is usually diagnosed in the setting of disseminated cysticercosis (Cocchi 1953; Hrusovsky et al. 1989; Vianna et al. 1991; Sickel et al. 1995; Figurnov et al. 2002; Vijayaraghavan 2004; Sathyanarayanan et al. 2011; Singh et al. 2012; Chaudhary et al. 2014). Among 25 autopsies of patients with cysticercosis, liver involvement was detected in 4 % (Vianna et al. 1991). Solitary cystic or nodular hepatic lesions caused by cysticercosis usually remain asymptomatic, while multicystic lesions may cause signs and symptoms resembling hepatitis or a neoplastic process. The hepatic cysticercus reported by Sickel et al. (1995) was a symptomatic lesion found in a 62-year-old male patient. In the patient with cysticercosis described by Vijayaraghavan (2004), multiple elliptical millet seed-shaped calcifications were seen in the liver, mesentery, and retroperitoneal adipose tissue. Multiple small cysticercus foci are well known in intermediate animal hosts. The 25-year-old male patients described by Sathyanarayanan et al. (2011) presented with hepatomegaly and peripheral eosinophilia. Abdominal ultrasound revealed multiple cystic lesions in the liver with scolices inside the cysts. IgG of cysticercosis detected by ELISA was strongly positive.

The cysts consist of a wall that exhibits, away from scolices, a thickness of 100–200 μ. The

interior cyst surface often contains projections that are 10–25 μ in diameter (Sparks et al. 1976). The main constituent of the cyst wall is the tegument, which is a thin lamella of less than 5 μ of thickness, covered by microvilli at its outer surface. The tegument is surrounded by a layer containing two rows of smooth muscle cells and a layer of tegumental cells. In the region of the scolex, the tegument is thicker, up to 20 μ. The scolex has four suckers and a double row of hooklets on its rostellum. The entire cyst is embedded in a tissue infiltrated with lymphocytes, macrophages, plasma cells and eosinophils, and a fibrous zone surrounding the cyst develops in older lesions.

Tumor-Like Parasitic Lesions of the Hepatobiliary Tract: Round Worm Infestations

135

Contents

Abstract

Several species of round worms (nematodes) can induce circumscribed and in part tumor-like lesions in the liver. Pinworms of the genus *Enterobius* can, during their oviposition at the anal outlet, migrate into the genitourinary tract to invade the peritoneal cavity. From here they may enter the liver and produce parasite granulomas. The liver can also be involved in capillariasis. This is an infestation syndrome caused by in humans by several species of the genera *Calodium*, *Capillaria*, *Eucoleus*, and *Pearsonema*. In the liver, capillarids can induce mass lesions consisting of necrosis, granulomas with eosinophils, granulation tissue, and finally fibrosis. Toxocariasis denotes an infestation with larvae of nematode parasites of the genus *Toxocara*. Men acquire toxocariasis through the ingestion of embryonated eggs attached to hair and soil contaminated by the natural hosts, cats, and dogs. In the human liver, *Toxocara* induces eosinophilic granulomas, eosinophilic abscesses, pseudotumors, and focal calcifications.

Hepatic Enterobiasis (Hepatic Pinworm Granuloma)

Introduction

Pinworms (*Enterobius*; threadworms; seatworms) are common intestinal nematode parasites that chiefly infest children in a worldwide distribution. Pinworms belong to the genus *Enterobius* (family Oxyuridae of the phylum Nematoda). Humans are hosts only to one of two *Enterobius* species, *Enterobius vermicularis* (formerly *Oxyuris vermicularis*) and *E. anthropopitheci*, parasitizing the chimpanzee. The infestation is called enterobiasis or oxyuriasis, the latter term being now obsolete. In Western countries, the pinworm is the most common parasitic worm infestation. In United States, the Center for Disease Control reported an overall incidence of 11.4 % among people of all ages, and in England the infestation rate in the childhood age group was 50 %.

The Parasite

The pinworm is a small and thin nematode, with females having a length of 8–13 mm and males 2–5 mm. The entire parasite life cycle takes place within the intestinal tract of a single human host. Eggs contaminate a wide spectrum of objects, including the hands and fingernails, bed linen, cushions, night clothing, water, food, furniture, toys, bathroom and toilet objects, and house pets. After ingestion of embryonated eggs, the eggs hatch in the duodenal lumen. The hatched larvae rapidly grow and migrate through the intestine to the colon, with two molts underway to reach the mature stage. Pinworms mate in the ileum. Egg laying starts about 5 weeks post ingestion of eggs. In the course of egg laying, the female migrates through the colon (12–14 cm/h) to reach the rectum and the anal canal. The female emerges from the anus and stays on the anal skin in order to obtain oxygen required for egg maturation.

Hepatic Enterobiasis

During their oviposition at the anal outlet, pinworms can migrate into the genitourinary tract and may ascend the uterine cavity and the uterine tubes and enter the peritoneal cavity. In the abdominal cavity, *Enterobius* is known to cause parasite granulomas in several organs and tissues, including the liver. Few cases of hepatic enterobiasis (oxyuriasis) have been reported. Hepatic manifestations are of certain interest insofar as the liver nodules induced by the parasite can be misinterpreted as malignancies, in particular metastases. The first case may have been reported in 1973 (Little et al. 1973). In a later report, oxyural granuloma of the liver was observed in a 62-year-old female with a history of recurrent surgery for colorectal cancer (Daly and Baker 1984). So-called threadworm or pinworm granuloma was reported by other authors (Slais 1962/1963; Ng et al. 2004). In a 74-year-old male patient, a nodule was incidentally seen at the liver surface during left colectomy. Histology revealed a granuloma containing numerous *Enterobius* eggs and a cross section of a mature nematode (Mondou and Gnepp 1989). Several reports document the tumor-like presentations of hepatic oxyuriasis (Arkoulis et al. 2012; Roberts et al. 2012). In one patient, a solitary liver nodule was diagnosed as a liver metastasis following rectal cancer. The resection specimen showed a necrotic nodule containing *E. vermicularis* (Roberts et al. 2012).

Capillariasis

Introduction

Capillariasis is an infestation syndrome caused by several species of the nematode family Capillariidae, containing 17 genera and more than 300 species (Okulewicz and Zalesny 2005). Humans are infested by four species of capillarids, viz., *Calodium hepaticum*, *Capillaria philippinensis*, *Eucoleus aerophilus*, and

Pearsonema plica (formerly *Capillaria plica*) (-Moravec 2001). *Calodium hepaticum* (synonyms: *Capillaria hepatica*; *Hepaticola hepatica*, Bancroft 1893) is the main parasite causing the zoonosis, capillariasis, and is a nematode parasite of wild rodents and other mammals, including primates and humans. Human capillariasis (visceral larva migrans; Lee et al. 1976) is an infestation that was first reported in 1924 (McArthur 1924). The clinical presentation is variable, sometimes rather bland, with nonspecific upper abdominal discomfort. Hepatomegaly (sometimes persistent febrile hepatomegaly) and peripheral eosinophilia are well-known features.

Hepatic Capillariasis

Several reports have described hepatic capillariasis, which may produce mass lesions (McArthur 1924; Berger et al. 1990; Pannenbecker et al. 1990; Choe et al. 1993; Tesana et al. 2007; Fuehrer et al. 2011). In the liver, *C. hepaticum* induces necrosis, granulomas with variable eosinophil infiltration and Charcot-Leyden crystalloids, granulation tissue, and finally fibrosis. Multinucleated giant cells may be noted (Attah et al. 1983; Kaplan et al. 2001). Within this inflamed area, barrel-shaped bioperculated eggs are seen, showing polar plugs and a thick trilaminar capsule with striation of the outer layer. The parasite is a known cause of solitary necrotic nodule of the liver (Koea and Smith 2008). In part of the cases, the chronic inflammatory process can induce septal fibrosis of the liver (Ferreira and Andrade 1993), a phenomenon which has also been observed in hepatic capillariasis of the rat (Santos et al. 2001, 2007). Hepatic capillariasis may cause a hepatic mass associated with locoregional lymphadenopathy, suggesting a neoplastic process (Kohatsu et al. 1995; Klenzak et al. 2005). In a 54-year-old man with such a mass lesion, the segmental resection specimen showed a 2.5 cm, irregular serpiginous mass of necrotizing granulomatous inflammation with marked eosinophilia and several small degenerating roundworms exhibiting the banded esophageal stichosome typical for *Calodium hepaticum* (Klenzak et al. 2005).

Toxocariasis

Introduction

Toxocariasis denotes the infestation with larvae of nematode parasites of the genus *Toxocara*. In the human host, two *Toxocara* species are recognized as parasites, *T. canis* and less often *T. cati*. Wilder in 1950 was the first to described toxocariasis in humans, based on the observations of ocular granulomas in patients thought to have retinoblastoma, and disease was then described in more detail in 1952 (Beaver et al. 1952). It is currently assumed that toxocariasis is the most common human parasitic worm infestation in the United States, affecting millions of Americans living in poverty. Toxocariasis is also highly prevalent in many developing countries, owing to a very high infestation rate of dogs (Hotez and Wilkins 2009). In North America, the prevalence of *Toxocara* infestation is about 20 % for adult dogs and 80 % for puppies, while in Mexico the prevalence is 28–42 % for cats. The mature *T. canis* living in the intestine of canines is an ascariform roundworm.

In the human host, toxocariasis is acquired via ingestion of infective embryonated eggs from hair and soil contaminated with the feces of the natural hosts, dogs and cats, this mode of acquisition being typical for preschool children, but toxocariasis is also a food-borne disorder in societies where the consumption of raw meat is prevalent. Infestation by ingestion of raw meat, specifically uncooked liver from paratenic hosts (mainly pig and poultry viscera), is becoming more frequent. Also the ingestion of raw cow liver is a pathway of infestation. When humans ingest embryonated eggs, larvae hatch in the intestine, whereas in the case of ingestion of infested raw meat, arrested larvae are present. In both

situations, larvae invade the intestinal wall and get access to the portal venous blood stream. The larvae settle in the liver, lungs, and other organs, where their development is arrested in the human host. In the liver, the larvae are 0.5 mm in length. During their slow migration in hepatic parenchyma, they induce an immune reaction with epithelioid macrophages, giant cells, and eosinophilia, the lesions slowly growing to sizes exceeding 1 cm.

Hepatic Toxocariasis

Toxocara invading the liver produces distinct focal lesions that may closely mimic metastatic disease (Park et al. 2012). Densely packed lesions in severe hepatic infestation (Hartleb and Januszewski 2001) may coalesce to form tumor-like masses that may require hepatic resection (Takacs et al. 2004; Chang et al. 2006). As parasites are not easy to identify as such, serological tests are crucial for the establishment of diagnosis (rapid screening ELISA, quantitative ELISA, immunodiffusion tests) using *Toxocara* excretory-secretory antigens.

Toxocariasis of the liver is characterized by several types of focal lesions, part of which may mimic a neoplastic process (Table 1).

In the liver, the migrating *Toxocara* larvae induce a granulomatous reaction accompanied by variable and sometimes marked eosinophilia (parasitic eosinophilic granuloma and eosinophilic abscess; Rayes et al. 1999; Kaplan et al. 2001; Leone et al. 2006; Jung et al. 2007; Lee and Shin 2011; Treska et al. 2011; Mukund et al. 2013). This reaction is driven by excretory-secretory antigens produced by the larvae (Kayes 1997). The center of the lesions is often occupied by a granular eosinophilic material probably consisting of necrotic and apoptotic cells and parasitic proteins. This part is surrounded by a rim of epithelioid macrophages sometimes forming round granulomas with or without multinucleated giant cells. The granulomatous reaction is surrounded by an eosinophilic infiltrate of variable density, sometimes with typical Charcot-Leyden crystalloids. Eosinophilic parasite granulomas may coalesce to form large conglomerated masses, mimicking a neoplastic process (parasitic eosinophilic hepatic pseudotumors; Chang et al. 2006; Kantarcioglu et al. 2009; Jackson et al. 2010; Pilsczek 2010). Numerous large nodules can resemble hepatic metastatic disease (Ota et al. 2009). In the center of the lesions, more or less intact components of the PAS-positive larvae can be seen. Mainly in peripheral parts of the lesion, a lymphocytic infiltration is observed, the cells also being intermingled with the epithelioid macrophages. *T. canis* elicits both T helper (Th)1 and Th2 responses with Th2 predominance, the latter being important for eosinophilia and IgE production. A subset of lymphocytes belong to the $CD25^{+}CD4^{+}$ regulatory T cell population (Fehérvari and Sakaguchi 2004). The lymphocyte populations surrounding the lesions' cores have been shown to contain Foxp3-expressing regulatory cells (Othman et al. 2011; Fan et al. 2013), cells that have been shown to be important for the homeostasis of the immune system and to play a distinctive role in the regulation of parasite-induced immune reactions. In experimental toxocariasis, the density of these cells increased as a function of the lesions' evolution, and the cells were also detected in adjacent portal tracts (Othman et al. 2011). De novo Foxp3 expression in T cells is stimulated by parasitic antigens, in particular excretory-secretory antigens, through the TGF-beta pathway (Grainger et al. 2010).

Tumor-Like Parasitic Lesions of the Hepatobiliary Tract: Pentastomiasis

136

Contents

Abstract

Pentastomiasis (so-called tongue worm infestation) is an infestation by members of the *Pentastomida*, a group of taxons related to crustacean arthropods. Species that infest humans belong to pentastomid families *Linguatulidae*, *Armilliferidae*, and *Porocephalidae*. More than 90 % of human cases are caused by larvae or nymphs of *Linguatula serrata* and *Armillifer armillatus*. Adult reproducing pentastomids inhabit the respiratory tract of reptiles and amphibians, in particular snakes. Man can become infested through contact with infested snakes and their food, i.e., rodents, or contaminated environment. The human host can only harbor larvae. In humans, visceral pentastomiasis, including the hepatic form, is caused by larval stages that migrate to the liver and form solitary or multiple, tumor-like nodules. These mainly consist of necrotic tissue, but may contain larval remnants.

Introduction

Human pentastomiasis (tongue worm infestation) is an infestation by members of the *Pentastomida Diesing*, 1836. This is an ancient parasitic zoonosis that has been described in the eighteenth and early nineteenth centuries (Frölich 1789; Rudolphi 1819; Diesing 1835) and in more detail by Pruner in 1847, the parasite (or one of them)

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_136

then being scientifically described by Wyman in 1848 (reviews Sambon 1922; Cannon 1942; Self and Kuntz 1967; Self 1969; Drabick 1987; Tappe and Büttner 2009).

Pentastomids or tongue worms form a group of parasitic invertebrates that are not "worms" but are phylogenetically related to arthropods (see below) and are composed of numerous taxons that have recently been revised (Poore 2012; Christoffersen and De Assis 2013). Many taxons of vertebrates are parasitized by pentastomids, including man. The human host is infested by the larval stages (nymphs) of only a few species of pentastomids (*Linguatula serrata*, *Armillifer armillatus*, *Armillifer moniliformis*, *Armillifer grandis*, *Porocephalus crotali*, and *Porocephalus taiwana*). Infestations with *Linguatula serrata* are termed linguatuliasis, those with *Porocephalus* species, porocephalosis. The phylogenetic positioning of pentastomids among metazoans has a complex history. Originally placed in a separate phylum of wormlike animals, the parasites are currently defined as arthropods (based on molecular studies) and assigned to a separate subclass of the crustacean class *Maxillopoda*, related to fish lice/*Branchiura*. The taxonomical term, *Ichthyostraca*, has been proposed for a clade comprising *Branchiura* + *Pentastomida*. The anterior end of the parasite is equipped with four clawed retractile leg-like structures and an armed mouth constructed for blood sucking. These five structures evoking the impression of five mouths have led to the organisms' name, pentastomids ("those with five mouths"). The life cycle includes a main host and an intermediate host. Pentastomids are bloodsucking endoparasites that normally inhabit the lung and other parts of the respiratory tract of reptiles and amphibians, especially snakes (Riley and Henderson 1999). It is estimated that around 70 % of the definitive hosts are snakes, followed by crocodiles, lizards, amphibians, and turtles. Few species occur in marine birds, and one (*Linguatula serrata*) occurs in the nasopharynx of canines. Embryonated eggs laid by the parasites are discharged by the nasal and fecal discharges of the animal hosts and contaminate soil, vegetation, and several types of water bodies. Intermediate hosts comprise mammals (mainly rodents and small herbivores such as goats and sheep), reptiles, amphibians, and insects. Rodents as important intermediate hosts acquire the embryonated eggs via ingestion of contaminated environmental components (mainly plants). The eggs hatch in the intestine, and the larvae burrow their way into the visceral cavity and into more remote organs, where they encyst within a variety of tissue sites (often abdominal fat bodies, liver, lymph nodes, and lungs), causing the development of granulomas with eosinophil infiltration and a mast cell reaction (McHardy et al. 1993). When snakes predate on these infested rodents, the life cycle is completed. Through contact with contaminated environmental components and infested snakes or rodents, carnivores, herbivores, and man can become infested, the pathway being thought to be same as in rodents (see above). Man can be infested by direct handling of infested snakes, utilizing snakes or other edible reptiles as food (Magnino et al. 2009), via contact with oral slime, or through contact with fecal droppings. A special situation occurs when raw or incompletely cooked offal of infested herbivores or carnivores harboring large numbers of parasites is consumed, causing infestation of the human or animal nasopharynx (a disorder called halzoun or halazoun, or Marrara syndrome; Kirk 1958; Khalil and Schacher 1965; Schacher et al. 1969; Yagi et al. 1996; Morsy et al. 1999). In halzoun, worm-shaped parasites are released in the nasal discharge, e.g., during coughing and sneezing.

Epidemiology

Species that infest humans belong to the pentastomid families *Linguatulidae*, *Armilliferidae*, and *Porocephalidae*. More than 90 % of human cases are caused by the larvae/nymphs of *Linguatula serrata* and *Armillifer armillatus*. Most human cases of pentastomiasis have been reported from Africa, Southeast Asia, and the Middle East, less often from East Asia and Latin America. The disorder is rare in North America and Europe (Tappe and Büttner 2009). The highest prevalences are known from necropsy records in Malaysia (45.4 %; with a large

proportion of aborigines; Prathap et al. 1969) and Central Africa (22.5 %; Meyers et al. 1976). In Europe and North America, most cases seem to refer to persons having emigrated from endemic areas.

Hepatic Pentastomiasis

Visceral pentastomiasis in humans is caused by larval stages (nymphs) of pentastomids. The liver is frequently involved (Gast-Galvis 1960; Gardiner et al. 1984; Baird et al. 1988; Guardia et al. 1991; Ma et al. 2002; Dakubo et al. 2008; Yao et al. 2008). Part of patients, specifically those having widespread liver involvement, become symptomatic, with abdominal pain, abdominal tension, fever, diarrhea, weight loss, and anemia (Lai et al. 2010; Wang et al. 2013). The parasite larvae elicit a distinct type of hepatic necrosis associated with an inflammatory response, forming usually spherical lesions. In patients with disseminated liver involvement, severe parenchymal damage and hepatic encephalopathy may develop. In one of these patients, the entire liver was studded with numerous calcified parasite nodules, which were also detected in the bowel, rectum, mesentery, and urinary bladder (Adeyekun et al. 2011).

Multifocal hepatic pentastomiasis presents as numerous small, pearly, cystic, and friable nodules 3–10 mm in diameter ("*Linguatula* nodules"; Symmers and Valteris 1950; Guardia et al. 1991; Ma et al. 2002; Latif et al. 2011). Larger lesions may resemble hepatic abscess (Latrive et al. 1980) or may cause infarct-like mass lesions mimicking a hepatic tumor (Machado et al. 2006). In the case reported by Machado and coworkers (2006), a liver mass had been detected during routine abdominal ultrasound examination, visualized as a 3 cm tumor in segment VI on CT images. The resection specimen revealed a white, soft, well-defined rounded lesion with peripheral endurance and a cystic central area. During the opening of the specimen, a white tubular wormlike organism measuring 2 cm in length was noted inside. In some cases of hepatic pentastomiasis, a miliary pattern of the lesions has also been described

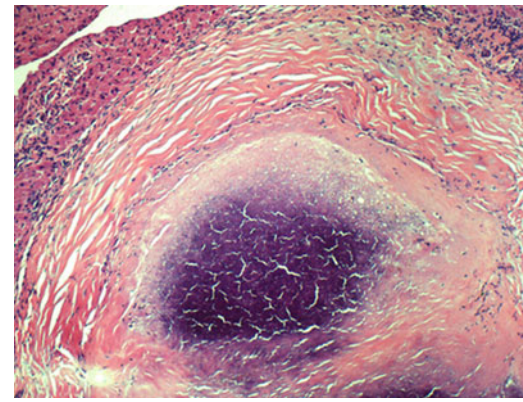

Fig. 1 Pentastomiasis (tongue worm infestation) of the liver. The spherical lesion is characterized by central necrosis with dystrophic calcifications, surrounded by a fibrous zone. Parasite remnants are often not detectable (hematoxylin and eosin stain)

(Yao et al. 2008), probably representing granuloma formation. The larva and the associated tissue reaction may be seen in the form of typically pearly and sometimes protruding foci on the surface of the liver (Ma et al. 2002; Dakubo et al. 2008). A free larva stuck in an intrahepatic portal vein radicle was observed (Dakubo et al. 2008). In some of the fresh resection specimens, coiled nymphs can be found and isolated.

Histologically, the lesions are characterized by three types of patterns. The first pattern is that with a preserved (viable) parasite, described below. The second and most common pattern is characterized by a focus of necrosis developing after death of the parasite, with or without detectable nymph, often surrounded by a thin rim of epithelioid macrophages and a collagenous capsule-like zone (Fig. 1). The necrotic foci resemble caseification and may show calcification (in particular, calcified parasite remnants), these changes tending to be concentric and targetoid in appearance (Ma et al. 2002). Outside the fibrous zone, one notes dense infiltrates of lymphocytes, macrophages, plasma cells, eosinophils, and sometimes multinucleated giant cells, as dead pentastomids release large amounts of parasite antigens (Tappe and Büttner 2009). Pentastomiasis of the liver can elicit a marked and florid granulomatous reaction surrounding the necrotic center of the lesions (Gardiner

et al. 1984; Baird et al. 1988), but in older lesions this reaction tends to be replaced by fibrosis/scarring. The third lesion pattern is seen after the dead parasite has been resolved and the immune reaction has been downregulated, leaving a central calcified necrosis within a hyalinized scar surrounded by minor round cell infiltrates.

In a considerable number of cases, no conclusive parasitic remnants are seen in the necrotic masses, except some cuticular fragments (Ali-Kahn and Bowner 1972; Self 1972; Self et al. 1972). In these situations, the parasitological diagnosis is difficult or impossible. However, some of the lesions may show better preserved parasites or parts thereof, in the form of a worm-like organism arranged in a flat C-shaped spiral and located in a cystic space. After several molts within the focus, the nymphs resemble adult pentastomes in shape, albeit they are smaller/shorter. The living parasite is surrounded by a thin rim of secreted eosinophilic material. Lesions harboring viable parasites usually show less inflammatory reaction, because less antigenic material is shedded (Tappe and Büttner 2009). Remnants of dead parasites are visualized as more or less complete necrotic shadows of the parasite with the oral and circumoral apparatus, as two pairs of circumoral hook-like structures, or scissors-like structures indicating a longitudinal section of a hook (Ma et al. 2002). Mouth parts with arciform fulcra may be found, with largest transverse diameter of 90–100 μm, consistent with the measurement of the mouth region of the *L. serrata* nymph (Ma et al. 2002).

Tumor-Like Necroses of the Liver: Liver Infarct and Hepatic Pseudo-infarct (Zahn's Infarct)

137

Contents

Abstract

Liver infarcts are macroscopic parenchymal alterations that may mimic, through their mass effect, neoplastic processes. An anemic infarct or infarction of the liver is defined as an ischemic necrosis that is usually caused by hepatic artery occlusion, thrombosis of the celiac artery, portal vein occlusion, or mixed hepatic vascular occlusions. Although hepatic artery circulation is crucial for the biliary tract, acute occlusion of this artery can also cause hepatic ischemic necrosis. Anemic liver infarcts are well-demarcated pale areas of sometimes more than 10 cm diameter, often wedge shaped and located both peripherally and deep in the liver substance. These lesions can undergo secondary changes, including abscess formation following infection, hemorrhage, liquefaction, calcification, bile accumulation, and fibrosis/scarring. Large infarcts may be separated from preserved liver parenchyma, a process termed sequestration. In contrast to true infarct, hepatic pseudo-infarct or Zahn's infarct is a well-demarcated zone of hepatic congestion leading to parenchymal atrophy.

Introduction

Infarct (anemic infarction) of the liver is defined as an ischemic necrosis that results in a macroscopically visible area or mass that may be confounded with a neoplastic process. In contrast,

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_137

pseudo-infarct of the liver (Zahn's infarct) represents a hepatic area of marked congestion associated with atrophy of the parenchyma, but without coagulation necrosis. True anemic liver infarct can, due to the altered features of tissue and tissue swelling, produce a mass that can closely mimic a hepatic tumor (Bohn et al. 2010).

Epidemiology

True anemic infarction of the liver is rare, but has already been described in the nineteenth century (Rattone 1888; Ogle 1895; Baldwin 1902; Rudczynski 1905; Kretz 1916; Wiessner 1917; Pass 1935; Woolling et al. 1953; Parker 1955; Kanter 1965; Seeley et al. 1972; Soni and Persaud 1972; Chen et al. 1976). The rarity of this lesion has been attributed to the protection of the liver from ischemic events and complications provided by the double arterial and portal venous blood supply. However, this proposed explanation does not hold true, because if the arterial blood supply alone is arrested, an intact portal venous blood supply cannot protect the liver from infarction in many cases (Nakata and Kanbe 1966; review: Carroll 1963). Winternitz (1911) did not encounter a single case among 3,500 autopsies performed at Johns Hopkins Hospital. In an investigation of 5,420 consecutive autopsy cases, 20 hepatic infarction cases could be selected in Japan (Saegusa et al. 1993). Anemic liver infarction is a disorder mainly occurring in adults, but it also exists in the pediatric age group (Kochin et al. 2011).

Etiology of True Hepatic Infarction

Numerous types of vascular lesions can cause anemic liver infarction, but most of the reported cases are due to occlusion of the hepatic artery related to various pathologies. The main vascular lesions causing, or associated with, liver infarction are listed in Table 1. It has once again to be emphasized that an intact portal vein blood flow cannot protect the liver substance from infarction when the hepatic arterial blood flow is arrested. In addition to distinct occlusive events of hepatic blood vessels, systemic circulation failure can significantly contribute to the development of hepatic infarction, even in the absence of complete vascular occlusion. In the autopsy study of Saegusa and coworkers (1993), 85 % of the infarct cases were clinically associated with systemic circulatory insufficiency. In fact, the pathogenesis of hepatic infarction often requires an association of several factors synchronously compromising compensatory blood flow mechanisms in the liver.

Table 1 Vascular lesions causing anemic infarction of the liver

Hepatic artery occlusion
Spontaneous thrombosis of the hepatic artery
Hepatic artery thrombosis in hepatic cancer
Hepatic artery thromboembolism
Embolized vegetations in bacterial endocarditis
Polyarteritis nodosa and other types of arteritis/vasculitis
Hepatic artery aneurysms and pseudoaneurysms
Dissecting aortic aneurysm
Coagulopathies
Accidental artery ligation
Thrombosis of the celiac artery
Portal vein (PV) occlusion
PV occlusion in liver cirrhosis
PV occlusion in hematologic diseases and coagulation disorders
PV occlusion in infectious disease/pylephlebitis
PV occlusion in malignant hepatic disease
Mixed hepatic vascular occlusions
Thrombosis of both the hepatic artery and portal vein
Thrombosis of the portal vein combined with hepatic arterial vasospasm
Mixed thrombosis of the hepatic artery and portal vein (e.g., in polycythemia vera)

Hepatic Artery Occlusion

Although hepatic parenchyma strongly depends on portal vein blood flow, the hepatic artery plays a critical role in blood supply of the liver and specifically for the biliary tract (review: Rappaport and Schneiderman 1976). There are documented events of spontaneous hepatic artery thrombosis followed by anemic liver infarction (Carroll 1963; OConnor et al. 1976).

Thrombosis of the hepatic artery causing infarction was found in patients with primary hepatic cancer or hepatic metastatic disease (Carroll 1963). A further cause of hepatic artery occlusion is an entire spectrum of abdominal interventional procedures, including angiography, therapeutic transcatheter arterial chemoembolization/TACE, radiofrequency ablation, and ethanol injection (Trojanowski et al. 1980; Holbert et al. 1996; Fujiwara et al. 2004; Akahane et al. 2005; Dai et al. 2007; Kim et al. 2007; Chiu et al. 2009; Guiu et al. 2012; Ladra Gonzalez et al. 2013; Dolak et al. 2014), and disorders leading to hemoconcentration, such as nephrotic syndrome (Vea et al. 1990). The hepatic artery can also be occluded by a thromboembolus originating from the left heart (e.g., subsequent to atrial fibrillation or mural ventricle thrombus after myocardial infarction) or from atherosclerotic plaques of the aorta or celiac trunk. Embolic occlusion of the hepatic artery can be followed by secondary thrombosis proximal to the embolus. A second source of embolism is detached vegetations in bacterial endocarditis (Henrich et al. 1975; Carroll 1963). Hepatic infarction caused by hepatic vascular accidents is a well-established complication of preeclampsia and eclampsia (Kronthal et al. 1990; Miyakoshi et al. 2004; Cholongitas and Burroughs 2008).

True liver infarction is a well-documented complication of polyarteritis nodosa involving the celiac plexus and the hepatic artery (Pass 1935; Price and Flanagan 1953; Haratake et al. 1988, Bohn et al. 2010). Other types of vasculitis causing hepatic artery stenosis or occlusion and hepatic infarction include Churg-Strauss syndrome (Otani et al. 2003), chronic periaortitis (Salvarani et al. 2011), vasculitis in systemic lupus erythematosus/SLE (Matsumoto et al. 1992a), vasculitis in the antiphospholipid syndrome (Millan-Mon et al. 1993), and radiation aortitis (Cox and Millar 1993). The hepatic artery can also undergo occlusion in the setting of artery aneurysms and pseudoaneurysm followed by liver infarction (Ross and Osler 1877–1878; Chuang et al. 2005) or dissecting aneurysm of the aorta (Myrtue et al. 1994). Anemic liver infarct was also observed following therapeutic or accidental hepatic artery ligation, e.g., in the setting of cholecystectomy (Kehr 1903; Kerr 1933; Graham and Cannell 1932–1933). Similar to thrombosis of the hepatic artery proper, thrombotic occlusion of the celiac trunk can also cause anemic hepatic infarction (MacDonald and Holt 1966).

Occlusion of the Portal Vein

In comparison with hepatic artery occlusion, thrombotic occlusion of the portal vein alone only rarely gives rise to hepatic anemic infarction, although most of the parenchyma is supplied by portal venous blood (Versé 1907; Yamashita et al. 1997). Hepatic infarction due to portal vein thrombosis was found in patients with liver cancer, cirrhosis, or chronic pancreatitis (Kim et al. 2002).

Mixed Hepatic Vascular Occlusions

Anemic liver infarction resulting from mixed hepatic and portal vein thrombosis was observed following blunt abdominal trauma (Francque et al. 2004), liver transplantation (Haque et al. 2009), transcatheter arterial embolization/TAE (Takakuwa et al. 1993), or polycythemia vera rubra (Ghandur-Mnaymneh 1976). Hepatic infarct can also develop in patients with HELLP syndrome and factor V Leiden having portal vein thrombosis plus arterial vasospasm (Seige et al. 1998).

Complex Mechanisms Affecting Several Vascular Systems

Very rarely, hepatic infarction was caused by torsion of an accessory liver lobe, inducing complex patterns of vascular occlusion and also primarily involving the microvascular system (Lotte and Madier 1960). Hepatic infarction was also observed in the setting of S-A hemoglobin (Mengel et al. 1963).

Hepatic Infarction in the Absence of Vascular Occlusion

Exceptionally, hepatic infarction was observed in the absence of radiologically detectable vascular occlusions (so-called nonocclusive hepatic infarction; Sundaram et al. 1978).

Clinical and Imaging Features

The clinical signs and symptoms of anemic hepatic infarction are largely nonspecific and include upper abdominal pain or discomfort, vomiting, and signs of acute abdomen or upper abdominal peritonitis. At imaging, hepatic infarcts appear as wedge-shaped, rounded or oval, or irregularly shaped low-attenuation lesions usually paralleling bile ducts, whereby wedge-shaped infarcts are peripherally located (Adler et al. 1984; Lev-Toaff et al. 1987; Holbert et al. 1996; Cook and Crofton 1997; Smith et al. 1998).

Macroscopic Pathology

Macroscopically, anemic liver infarcts are well-demarcated pale areas of sometimes more than 10 cm diameter that are wedge shaped and located either deep in the liver substance or to peripheral parts of the organ (Figs. 1 and 2).

Fig. 1 Peripheral anemic infarction in a cholestatic liver

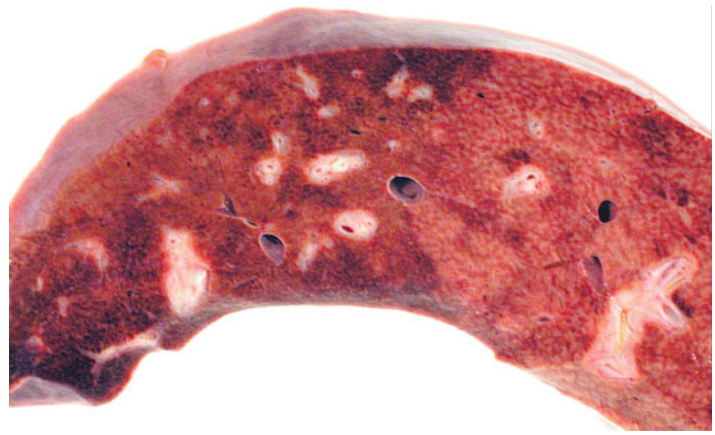

Fig. 2 Anemic infarction of the liver in hepatic arteritis

Fig. 3 Large sequestered infarct of the liver. The necrotic tissue has detached from the intact adjacent liver substance

Peripheral infarcts are typically separated from the liver capsule by a thin rim of preserved liver parenchyma, as this tissue is supplied by a different vascular system. Subcapsular infarcts were also observed following liver transplantation (Abecassis et al. 1991). In rare cases, an infarct can occupy almost an entire liver lobe (Carroll 1963). The pale area of ischemic necrosis can show a red rim at the edge caused by hyperemia (congestion) and hemorrhage from damaged microvessels. In infarcts caused by hepatic artery thrombosis, the arterial thrombus often or always extends up to the infarct in the liver substance (Carroll 1963).

Liver infarcts can undergo several types of secondary changes, including liver abscess due to superinfection, hemorrhage, liquefaction of necrotic tissue, calcification, and fibrosis/scarring. In case the infarction involves larger intrahepatic bile ducts, bile leakage ensues, resulting in bile accumulation in the infarcted tissue (bile lakes; Peterson and Neumann 1984). Large necrotic areas may become separated from preserved (vital) hepatic parenchyma, resulting in infarct sequestration (Fig. 3).

Pass (1935) reported that hepatic infarcts caused by polyarteritis nodosa of the hepatic artery frequently convert into large abscesses that may be difficult to distinguish from genuine pyogenic abscesses. Large postinfarction abscesses of the liver may be associated with collapse of the right lower lobe of the lung (Davson et al. 1948).

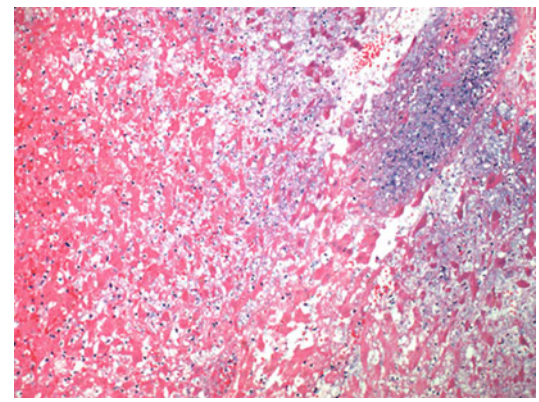

Fig. 4 Anemic infarction of the liver. The traces of the previous hepatic parenchyma are visible in the form of "shadow liver plates/trabecules." Note the numerous nuclear debris (hematoxylin and eosin stain)

Histopathology

Macroinfarcts typically show distinct zones, similar to those described in renal ischemia (Figs. 4, 5, and 6; Sheehan and Davis 1958) and animal experiments (Beresnegowski 1908). A central area of variable diameter shows eosinophilic cells with a granular cytoplasm, a vague circumference, and fading or faded nuclei (karyolysis). Nuclear debris are found (karyorrhexis). Remnants of sinusoids are noted, devoid of red cells and Kupffer cells, and usually without endothelial nuclei or then only nuclei with signs of karyopyknosis. Remnants of blood vessels can contain an affine web of fibrin (Carroll 1963), but no fresh thrombi and no fibrinoid thrombi. In

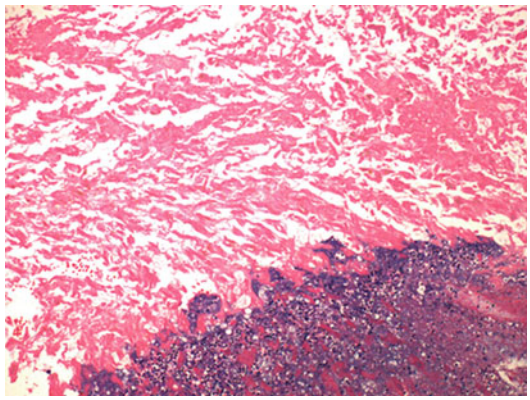

Fig. 5 In advanced hepatic infarction, compacted areas of coagulative necrosis, nuclear debris, chromatin fragments, and strongly basophilic "DNA powder" may ensue (hematoxylin and eosin stain)

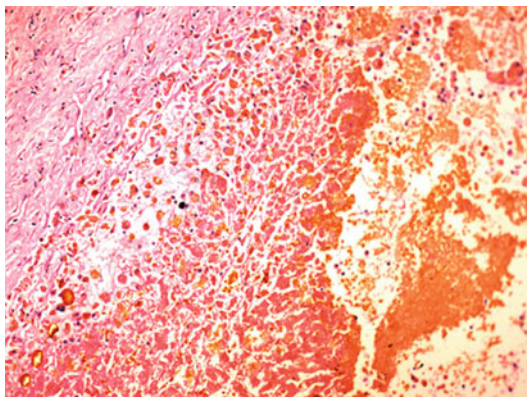

Fig. 6 Anemic infarction of the liver with bile duct destruction and leakage of bile (hematoxylin and eosin stain)

central parts, neutrophils are lacking, as they cannot be transported to this area excluded from circulation. In hepatic infarction caused by portal vein thrombosis, the borders between infarcted parenchymal areas and preserved parenchyma are usually located around central veins, corresponding to the periphery of the portal venous blood flow system (Saegusa et al. 1993). After few days, the centrally located area of coagulation necrosis is surrounded with a zone showing an infiltrate of neutrophils and few macrophages. Here, the hepatocytes appear shrunken, with a strongly eosinophilic cytoplasm and karyopyknotic nuclei. In this zone, sinusoids contain erythrocytes and Kupffer cells. After about 10 days, ductular proliferations containing progenitor cells start to appear. These proliferations originate from portal tracts and later invade the damaged lobular parenchyma. The tissue surrounding the infarct shows signs of hepatocyte regeneration, with an increase of hepatocyte mitotic figures. The necrotic process can also involve portal tracts, where interlobular bile ducts display severe ischemic damage or are absent, mainly in cases with hepatic artery occlusion (ischemic cholangiopathy). Involvement of larger bile ducts can result in bile leakage (Fig. 6) and the formation of bile duct cysts (Doppman et al. 1979). Infarcted liver parenchyma elicits an inflammatory reaction in the surrounding hepatic tissue, followed by granulation tissue, scarring, atrophy, and tissue contraction.

Differential Diagnosis

Anemic liver infarct clinically and radiologically resembles pyogenic liver abscess, in particular when infarcts undergo secondary suppurative changes, amebic liver abscess, and cancer. A difficult differential diagnostic situation may occur when ascending infection through the portal vein causes pylephlebitis followed by liver abscess (Brown et al. 2003). In patients with preeclampsia or eclampsia, hepatic hepatoma occurs (Sherbahn 1996) that may mimic infarction.

Hepatic Pseudo-infarct (Zahn's Infarct)

A rare differential diagnosis of liver infarct is the pseudo-infarct of the liver or Zahn's infarct (also termed infarct-like cyanotic atrophy). In contrast to true ischemic infarction, Zahn's infarct is a more or less, usually well-demarcated zone of hepatic congestion leading to parenchymal atrophy. Zahn's infarct is named after Friedrich Wilhelm Zahn (1845–1904), a German pathologist who studied under von Recklinghausen and received his M.D. in 1870 based on a work he performed in Bern, Switzerland, under Edwin

Klebs (review: Benaroyo 1991). After having served as a military physician during the war of 1870, he became professor of pathologic anatomy in Geneva, where he organized the new institute. Zahn is well known for contributions to the understanding and definition of thrombus. He was the first to put emphasis on the distinction of red and white thrombi and offered detailed descriptions of the process of thrombus corrugation (Zahn 1872, 1875, 1891: reviews: Bräunig and Doerr 1991, 1994). Zahn described the hepatic lesion named after him in 1897 under the term "atrophische rothe Leberinfarcte" (atrophic red hepatic infarcts), although he noted that there was no evidence of hepatocyte necrosis, but rather liver cell atrophy, "infarct" therefore being a misnomer. This has later led to the term "pseudo-infarction." As a pathogenic pathway, Zahn considered the combination of occlusion of a branch of the hepatic artery and an elevated pressure in the inferior vena cava and the hepatic veins caused by right-sided heart failure. However, part of these cases had portal vein thrombosis. Zahn's infarct has been observed in the setting of various vascular processes, including occlusive phlebitis in portal vein radicles (Matsumoto et al. 1992b), portal vein thrombosis (Funatsu et al. 1994), portal vein thromboembolism (Symmers 1951), and tumor-induced stenosis of intrahepatic vessels (Tsuuchi et al. 1990). Macroscopically, Zahn's pseudo-infarcts appear as more or less circumscribed dark red areas. Due to congestion and decrease of oxygenation, the lesions may turn bluish red, leading to the term "cyanotic atrophy." In contrast to true anemic infarction, Zahn's infarct mostly shows severe centrilobular congestion (passive hyperemia) associated with hepatocyte plate atrophy, but no coagulation necrosis, or then only a minor centrilobular hepatocyte necrosis. Sinusoids are usually dilated and packed with red cells, this change increasing in severity toward the center of lobules. In pericentral areas with incipient or established hepatocyte necrosis, neutrophils accumulate, reflecting that sinusoidal circulation is not interrupted, in contrast to true anemic infarction (Horrocks and Tapp 1966). The pathogenesis of centrilobular necrosis following congestion, including Zahn's pseudo-infarct, is complex and not yet fully understood (review: Shibayama et al. 1993).

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_138

Abstract

The liver can develop several types of reactive cystic lesions that can resemble cystic hepatobiliary neoplasms, in particular mucinous cystic neoplasms. A large cyst can exert a mass effect. The most common nonparasitic liver cysts are simple cysts related to congenital maldevelopment of certain parts of the biliary system. These cysts have an estimated incidence of 0.1–2.5 % in the general population and are usually asymptomatic lesions. The detection rate increases as a function of age. The cysts usually do not communicate with the biliary tract and are lined by a normal-looking biliary epithelium. A second, but less common type of hepatic cyst is ciliated foregut cyst, lined by a ciliated epithelium. This type of cysts also occurs in the gallbladder. Hepatic cysts can undergo secondary changes, including hemorrhage and infection.

Nonparasitic Liver Cysts: Simple Cysts and Ciliated Foregut Cyst

Introduction

Several types of nonparasitic cysts of the liver can grow to a large size and produce a mass effect, thus resulting in tumor-like lesions. The cysts may also mimic cystic hepatic neoplasms, in particular cystadenomas and related lesions. The main types of nonparasitic liver cysts comprise simple (biliary) cyst and ciliated foregut cyst.

Simple Hepatic Nonparasitic Cysts

Introduction

Simple liver cysts (non-hereditary developmental cysts) are common hepatic lesions that rarely cause significant morbidity or mortality. These cysts are related to congenital maldevelopment of certain parts of the biliary system, but are non-hereditary lesions. Large symptomatic cysts can have a mass effect and mimic malignant disease.

Nomenclature

Simple cysts are benign hepatic cystic lesions that can be classified by etiology into congenital and acquired cysts. To distinguish simple cysts from hydatid cysts, they are termed nonparasitic cysts. These cysts are congenital and are divided into parenchymal and biliary cysts, whereby parenchymal cysts can be isolated/solitary, multiple, or polycystic. As polycystic liver disease is a hereditary disorder with distinct mutations of critical proteins, liver polycystosis does not make part of the spectrum of simple nonparasitic liver cysts sensu stricto, although these cysts can be multiple. Complicated cysts are simple nonparasitic cysts that have undergone certain "complications," including hemorrhage and infection, or malignant transformation (see below).

Epidemiology

Simple cysts constitute the most common form of liver cysts in adults, with an estimated prevalence between 0.1 % and 2.5 % in the general population. In a study performed at the Mayo Clinic, it was estimated that the incidence of hepatic cystic disease is 17 per 10,000 abdominal explorations (Sanfelippo et al. 1974). However, the incidence is probably higher, as small cysts may be missed at conventional imaging. In autopsies, the incidence ranged from 14 to 53 per 10,000 (Eliason and Smith 1944). A study from Taiwan documents an overall prevalence of 3.6 %. An increasing prevalence with age was demonstrated, ranging from 0.83 % from below age of 40 up to 7.81 % of patients over 60 years old (Huang et al. 1995). Simple congenital cysts are also diagnosed in children and adolescents, where they rarely induce symptoms (Rogers et al. 2007; Bryce et al. 2008). Most antenatally detected liver cysts appear to be simple (Charlesworth et al. 2007). In a study testing patients with spiral CT in situations unrelated to hepatic pathology,

the prevalence of simple cysts was 18 % (Carrim and Murchison 2003). In an analysis of 78 patients with large (> or =4 cm) hepatic cysts, 57 of the lesions were simple cysts (Regev et al. 2001). These lesions were much more common in females (F:M, 49:8). Large cysts are preferentially found in women. Most of congenital cysts manifest in the fifth to seventh decades, with a mean patient age of 59 years (Sanfelippo et al. 1974).

Clinical Features

Most simple hepatic cysts are asymptomatic. Symptoms and signs arise when cysts become large (typically larger than 4 cm) and start to exert pressure on critical intrahepatic or extrahepatic structures (review: Tonolini et al. 2014). Large cysts can compress the biliary tree or, in very large lesions, adjacent organs such as the stomach. Cyst-induced compression of bile ducts can promote obstructive jaundice (Cappell 1988; Terada et al. 1993). Compression of the portal vein can promote gastric varices in the absence of liver cirrhosis (Kinjo et al. 2013). Rarely, simple liver cysts cause complications, such as bleeding, rupture, and cyst infection (Ishikawa et al. 2002; Agrawal et al. 2012; Macutkiewicz et al. 2012). As large hemorrhagic cysts can show an unevenly thickened wall and high-density strips at imaging, they sometimes resemble hepatobiliary cystadenoma (Zhang et al. 2009b). Upon cyst rupture, fluid can be retained under the liver capsule (Ueda et al. 2010). Infection can result in purulent change of cysts, cyst empyema, or abscess formation (Plenk 1910; Chatzipetrou et al. 2008). In infection, cysts can rapidly enlarge due to accumulation of intracystic exudate. Such growing cysts can compress the inferior vena cava and induce Budd-Chiari syndrome (Long et al. 2014). Large cysts can induce thrombosis of the inferior cava (Musielak et al. 2014). Cyst sclerosis may cause biliary stenosis mimicking malignancy (Muñoz-Bellvis et al. 2012). Huge cysts can encroach upon the atrium and eventually cause arrhythmia/atrial premature beats (Ker 2010).

Pathology

Macroscopy

Most simple hepatic cysts are small lesions. In a Taiwanese investigation, 53 % of cysts had a diameter of 1–3 cm, and only 7 % were larger than 5 cm (Huang et al. 1995). Cysts are classified as large when they have a diameter of =>4 cm. In rare instances, simple cysts become huge lesions that occupy a large part of the upper abdominal cavity and may reach down into the pelvis in case they show extrahepatic extension. Müller described a cyst containing 6 l of hemorrhagic fluid (Müller 1893). In the female patient reported by Plenk, the fluctuating and massively infected cyst (*Streptococcus* infection) filled with purulent exudate had a diameter of about 20 cm and had markedly displaced the stomach (Plenk 1910). With few exceptions (see below), simple cysts have no biliary communication (Harris et al. 1986). The cysts show a fibrous wall of usually uniform thickness and contain a watery, clear, and nonviscous (serous) fluid that is not bile stained, but may be yellowish following hemorrhage (Winckler 1891; Leppmann 1900; Figs. 1 and 2). In case of bleeding, the cyst content is reddish brown or may look like frank blood. The inner surface of uncomplicated cysts is smooth and glistening, in the majority of cases without trabecula or septa, while fibrous strands or plaques are found in complicated cysts after infection or following sclerotherapy. Subsequent to hemorrhage, the cyst wall shows a brownish or yellow, patchy discoloration due to deposition of hemosiderin and bilirubin (hematoidin). Part of the cysts are located beneath the hepatic capsule and

Fig. 1 Simple nonparasitic cyst in a cirrhotic liver

Fig. 2 Simple nonparasitic cyst of the liver. In this cyst deroofing specimen, secondary alterations of the cyst wall are present, including plaque-like fibrosis/scarring after bouts of inflammation

are visualized as slightly bulging cysts covered by a thinned capsule. Depending on the cyst content, the color of subcapsular cysts ranges from grayish greenish (serous fluid) to red blue (hemorrhagic fluid). Large subcapsular cysts may show a thickened fibrotic wall (the "cyst roof"), in case of recurrent inflammation with fibrous strands and/or adhesions. Some large simple cysts protrude from the liver as pedunculated cysts, relatively often close to the gallbladder, forming a sac with a thin fibrous wall containing macroscopical blood vessels. Pedunculated cysts can become huge and extend into the pelvic region, sometimes being confounded with cystic tumors of the ovaries. Some of these cysts exhibit a vascular pedicle and may undergo torsion followed by hemorrhage and necrosis/infarction. Extrahepatic cysts may adhere to the gallbladder. Rare forms of simple cysts show septal structures, a feature that may suggest cystadenoma (Sato et al. 2013). Liver lobes occupied by large cysts undergo perifocal atrophy, sometimes massive, with compensatory hypertrophy of the contralateral lobe (atrophy-hypertrophy complex).

Histopathology

The epithelial lining of simple cysts consists of a single layer of columnar, cuboidal, or flat epithelial cells with a biliary phenotype (Fig. 3). The cells typically lack cilia. Similar to epithelial cells

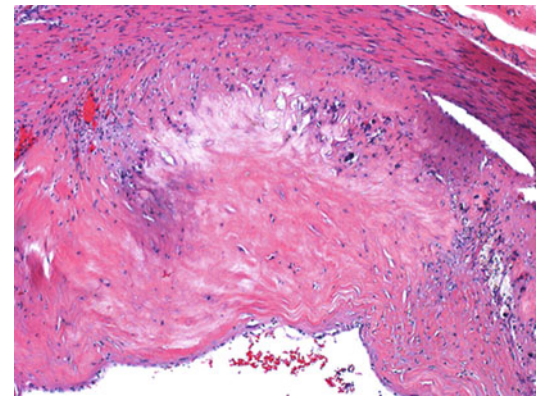

Fig. 3 Simple nonparasitic cyst of the liver. The epithelial lining of this cyst is lost, and the cyst wall is thickened due to fibrosis and scarring (hematoxylin and eosin stain)

of polycystic liver disease, the epithelial lining of simple cysts has little mucin (Terada et al. 1991). The cells express biliary-type cytokeratins, but with variable intensity. High epithelial cells are usually found in small or young cysts, while flat cells predominate in large cysts (epithelial atrophy). Large cysts or those with complications often show extended areas lacking any epithelial lining. This is also a finding frequently encountered in deroofing preparations. The subepithelial tissue consists of vascularized collagenous connective tissue with rare elastic fibers. With few exceptions, smooth muscle cells are uncommon. Hemorrhage into cysts is followed by granulation tissue formation, accumulation of macrophages, and hemosiderosis. Sclerotherapy is followed by

the formation of hypocellular fibrous tissue within the collapsed cyst wall.

Hepatic Cysts with a Biliary Communication

The large majority of simple hepatic cysts have no communication with the biliary tree, in contrast to cystic lesions in Caroli's disease. There is, however, a very small subset of cysts showing biliary communication (Ravindra et al. 1999; Yamada et al. 2009). The communication can be identified through cystography (Yamada et al. 2009). The communication may also be detected during deroofing as bile leakage from a small orifice in the cyst cavity (Chiba and Obata 2002; Masatsugu et al. 2003).

Hilar Cysts

A heterogeneous subset of cysts is located to the liver hilus and sometimes accompanies larger bile ducts (Ozeki and Miura 1994; Fujioka et al. 1997; Yuasa et al. 1997; Colina et al. 1998). Some of these cysts appear as multiple lesions closely following bile ducts (Yuasa et al. 1997). The spectrum of hilar cysts is complex, as part of these lesions are solitary or multiple peribiliary cysts and not congenital parenchymal cysts (Johnson et al. 2007).

Malignancy Arising in Simple Nonparasitic Liver Cysts

These cysts can be complicated by cholangiocarcinoma and squamous cell carcinoma (discussed in separate chapters). Very rarely, other malignancies develop in cysts, e.g., biliary carcinosarcoma (Terada et al. 1994).

Differential Diagnosis

Simple nonparasitic cysts have to be distinguished from hydatid cyst, ciliated foregut cyst, hepatobiliary cystadenoma, cystic malignant tumors (including cystic metastases), and cystic GIST metastasis following imatinib mesylate therapy. On the other hand, biliary cystadenoma with a thin wall can mimic a simple hepatic cyst (Matsumoto et al. 1997).

Pathogenic Pathways

Although thought to be congenital lesions, the cause of simple hepatic cysts is not yet known. A derangement of bile duct/ductal plate development or dilatation of biliary microhamartomas have been discussed. An origin from aberrant bile ducts has been proposed (Cesaris-Demel 1905; Plenk 1910).

Ciliated Foregut Cyst

Introduction

Ciliated hepatic foregut cyst (CHFC) is a rare, usually solitary and unilocular cyst in the liver. A solitary nonparasitic hepatic cyst with a ciliated epithelium has first been described by Friedreich in 1857 (Friedreich 1857), followed by a short report in 1866 (Eberth 1866). Few cases followed in the nineteenth century (von Recklinghausen 1881; Zahn 1896). Friedreich proposed that this type of cyst is a congenital lesion and compared the lining with that of the ciliated bile ducts occurring in some mammals. The cyst has later been termed ciliated hepatic foregut cyst, in 1984 (Wheeler and Edmondson 1984), and interpreted to derive from the embryonic foregut already then. The designation is based on the hypothesis that the epithelial phenotype of this cyst reflects the primitive foregut which is the origin of the tracheobronchial tree, the esophagus, and part of the liver, explaining the presence of ciliated columnar cells, mucin-producing cells, and stratified squamous epithelial cells. This pathogenic view is supported by the fact that there are other ciliated cysts in foregut derivatives, including the respiratory tract, mediastinum, stomach, pancreas, upper

intestinal tract, and ciliated cysts in Brunner gland hamartomas (Chatelain et al. 2002). Ciliated cells that may have derived from foregut endoderm are normally found in normal murine intrahepatic bile ducts (Grisham 1963). Less than 100 cases of CHFC have been reported.

(1999a), Bogner and Hegedüs (2002), Balducci et al. (2003), Horii et al. (2003), Cai et al. (2004), Jakowski et al. (2004), Kang et al. (2006), Straus and Osipov (2006), Stringer et al. (2006), Sharma et al. (2008), Shaw et al. (2008), Goodman et al. (2009), and Oida et al. (2009), at least 24 in Japan until 2008 (Mannami et al. 2008).

Epidemiology

The mean age at diagnosis, based on 96 published cases, was 48 ± 12 years (Sharma et al. 2008), and there is a slight male predilection (Vick et al. 1999a). CHFC has also been diagnosed in the pediatric age group, including neonates and infants (Carnicer et al. 1996; Kim et al. 2005; Stringer et al. 2006; Rogers et al. 2007; Young et al. 2007; Betalli et al. 2008; Guérin et al. 2010; Zaydfudim et al. 2010).

Clinical Presentation

CHFC is thought to be small in children but will then slowly grow during life to reach a diameter that may cause symptoms. In a review of the published cases, the average cyst diameter was 3.6 cm at diagnosis (range: 1.1–13 cm). It is commonly a benign and asymptomatic cystic lesion incidentally found on imaging. In the review of Sharma et al. (2008), 62 % of the patients were asymptomatic at the time of diagnosis; others complained of upper abdominal pain. Pain occurring even in case of small cysts may be related to the cysts' location close to the liver capsule, causing stretching of the Glissonian, innervated capsule. Part of the patients have symptoms and signs, e.g., portal hypertension by hepatic vein compression (Harty et al. 1998) or obstructive jaundice by hepatic duct compression (Dardik et al. 1964). Rarely, stones can develop within a CHFC (Ozeki 1995). In exceptional situations, CHFC is not located to the liver substance proper, but to the subhepatic area (Idress et al. 2005).

Imaging Features

On ultrasonography, CHFC is characterized by a commonly unilocular hypoechoic cyst (Mukai et al. 1988; Shoenut et al. 1994). Among the numerous cases reviewed by Sharma et al. (2008), 71 % of the cysts were hypoechoic, 7 % hyperechoic, and 1.8 % anechoic. Complex cystic spaces with echogenic material in the lumen may also occur, overall found in 32 % of the cases (Kadoya et al. 1990; Vick et al. 1999a). Unenhanced CT usually shows hypodense lesions in most patients (Kadoya et al. 1990; Sato 1990; Kanzaki 1992; Shoenut et al. 1994; Benlolo et al. 1996). MRI using T1-weighted images showed a mixed picture with cysts presenting with variable densities. Conversely, T2-weighted images are commonly bright and hyperdense in nature (Fang et al. 2005). CHFC may have a solid tumor appearance on CT (Kimura et al. 1990; Sasaki et al. 1991; Abe et al. 1994) and mimic hepatic malignancy (Wu et al. 1998). CHFC may also be confounded with hydatid cyst (Geramizadeh et al. 2008).

Macroscopic Pathology

CHFC are usually unilocular lesions. Most cysts are unilocular, only 7/96 being multilocular in one report (Sharma et al. 2008). However, one of the first reports (Eberth 1866) already described a multilocular variant. In the review of Sharma et al. (2008), 7/96 cases were multilocular. CHFC is mostly located to the left liver lobe, with a strong predilection for segment IV (44/96

patients; Sharma et al. 2008), but it is also described for the right liver lobe (26/96 patients). In children, the cyst may be in communication with the intrahepatic bile ducts, a phenomenon which may cause rapid cyst growth owing to bile accumulation in the cyst lumen. In most cases, the cysts contain a viscous or mucoid fluid, while bile-stained fluid was detected in only very few patients (three in the study of Sharma et al. 2008), illustrating the fact that most cysts are not connected to the bile duct system. The three cases with bile-stained cyst fluid were those with such a communication, and all referred to pediatric patients (Stringer et al. 2006; Rogers et al. 2007; Young et al. 2007). The case of Eberth was described as a subcapsular cyst, the size of a hazelnut, with several chambers filled with gray-yellow, mucoid fluid, histologically lined by a ciliated epithelium. The inner surface of the cyst is usually smooth, but in situations of inflammation, patches of sticky exudate may be attached to the cyst wall. After cyst hemorrhage, coagulated fresh or old blood may adhere to the wall. The cyst content is either watery and clear or viscous/mucinous.

Histopathology

CHFC has a characteristic four-layered wall. The innermost layer consists of a single or pseudostratified cuboid to columnar epithelium with or without mucin production. At least part of cells possess typical cilia, and the ciliated phenotype may in some cases involve the entire cyst lining (Fig. 4). Goblet cells positive for PAS, alkaline alcian blue, mucicarmine, and high-iron diamine are found (Vick et al. 1999a). The second layer is the subepithelial connective tissue layer which shows arcades of thin-walled blood vessels and capillaries, followed by the third layer, smooth muscle bundles. There are very rare examples of CHFC lacking any smooth muscle cells in the wall (Sato et al. 2006; variant CHFC). The outermost layer consists of dense collagenous fibrous tissue (Wheeler and Edmondson 1984; Terada et al. 1990; Vick et al. 1999a; Chatelain et al. 2000; Bogner and Hegedüs 2002; Horii et al. 2003). In contrast to bronchogenic cysts, CHFC never contains hyaline cartilage. Owing to the presence of ciliated epithelial cells in the aspiration material, CHFC can be diagnosed by cytology (Zaman et al. 1995; De et al. 2006; Kaplan et al. 2007a; Young et al. 2007). This examination has a predictive value of 76 % (Sharma et al. 2008). The diagnostic feature is the presence of ciliated pseudostratified tall columnar cells suspended in a mucoid background. In case of inflammation, granulocytes and macrophages may be seen, admixed with erythrocytes. The only differential diagnosis of a cyst having ciliated cells would be bronchogenic cyst, but this type of cyst apparently does not exist within the liver. Ultrastructurally, the cilia display the characteristic 9 + 2 pattern of microtubules (Vick et al. 1999a).

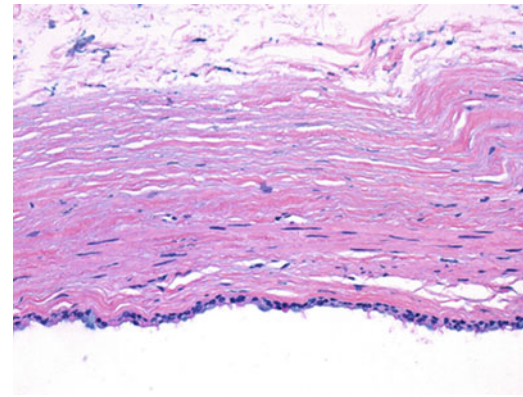

Fig. 4 Ciliated foregut cyst of the liver (hematoxylin and eosin stain)

Immunohistochemistry

The cells lining CHFC are immunoreactive for cytokeratins (AE1/AE3 and CAM5.2), epithelial membrane antigen (EMA), and CEA (Terada et al. 1990; Vick et al. 1999a). Some of the cells within the epithelial lining of CHFC are immunoreactive for CC10, where CC10 is a secretory protein which is specific for bronchiolar Clara cells (Chatelain et al. 2000). The lining

also contains relatively few endocrine cells reactive for chromogranin A, synaptophysin, calcitonin, and bombesin (Chatelain et al. 2000). The smooth muscle layer stains for alpha-SMA, and the epithelial basement membrane and outer connective tissue layer stain positively for type IV collagen and laminin (Vick et al. 1999a). The histologic and immunohistochemical features of CHFC are similar to those of bronchi (Terada et al. 1990), but also of bronchioles of the lower respiratory tract; this has led to the assumption that this hepatic cyst may represent an intrahepatic bronchiolar cyst (Chatelain et al. 2000).

Secondary Changes in CHFC

Hemorrhage and Inflammatory Changes

CHFC can undergo hemorrhage, sometimes with massive intracystic bleeding. Accumulation of blood in the cyst lumina is associated with atrophy or loss of cyst epithelium. Later, hemosiderin may be deposited in the cyst wall, and a loose infiltrate of lymphocytes and macrophages may develop, sometimes with a slight degree of fibrosis. Cholesterol crystals and cholesterol granulomas may be found in few cases. Few cysts underwent purulent or mucopurulent inflammation (Momin et al. 2004). Exceptionally, cyst empyema can develop, with or without a hemorrhagic component.

Metaplastic Changes

Similar to other epithelial surfaces having ciliated columnar cells, squamous cell metaplasia (sometimes extensive) is known to occur in CHFC, however much less commonly than, e.g., in the bronchial tree or in bronchogenic cysts (de Lajarte-Thirouard et al. 2002; Furlanetto and Paolo Dei Tos 2002; Ben Mena et al. 2006; Zhang et al. 2009a). The squamous epithelium can undergo keratinization. The squamous cell expresses cytokeratins 5 and 6, and the superficial squamous cell is CK7 positive (Ben Mena et al. 2006).

Malignant Neoplasms Arising in Ciliated Foregut Cyst of the Liver

CHFC can be complicated by secondary malignancy. Squamous cell carcinoma arising in bona fide CHFC has been observed at least three times (Vick et al. 1999b; de Lajarte-Thirouard et al. 2002; Furlanetto and Paolo Dei Tos 2002; Zhang et al. 2009a) and is associated with squamous metaplasia and high-grade dysplasia of the cyst epithelium (Furlanetto and Dei Tos. 2002; Zhang et al. 2009a). In the case of Zhang and coworkers (2009a), the hepatic resection specimen disclosed an irregular, smooth tumor mass measuring $7 \times 6 \times 5$ cm. The cut surface showed a partially encapsulated gray-white and solid tumor with multiple cystic areas. Histology revealed squamous cell carcinoma within a cyst that still showed a lining of ciliated cells. There were areas with squamous metaplasia and high-grade dysplasia, from which the bulky carcinoma had arisen. In a fourth report, squamous carcinoma had developed in a right-sided hepatic cyst classified as epidermoid intestinal cyst; however, a photomicrograph of this report depicted a cyst wall with ciliated epithelium in addition to squamous metaplasia (Caratozzolo et al. 2001).

Ciliated Foregut Cyst of the Gallbladder

CHFC is observed in the gallbladder (Kakitsubata et al. 1995; Benlolo et al. 1996; Vick et al. 1999a; Chatelain et al. 2000; Nam et al. 2000; Hirono et al. 2002; Muraoka et al. 2003). The case by Kakitsubata et al. (1995) referred to a 71-year-old man with a gallbladder cyst measuring 1.1 cm in diameter, with a thin wall composed of a fibromuscular layer and lining of ciliated columnar cells. These authors suggested that this cyst may have originated in Luschka's duct. However, Luschka's duct does not have a ciliated epithelium. Benlolo et al. (1996) described a ciliated gallbladder cyst they found in a 75-year-old female. The cyst measured 3 cm in diameter. In the case reported by Nam et al. (2000), the cyst measured 1.5 cm in diameter, was unilocular, without communication to the lumen. Similar to

the hepatic counterpart, the cyst showed an underlying smooth muscle cell layer. Where specified in the literature, the cysts were located in the gallbladder fundus (Kakitsubata et al. 1995; Benlolo et al. 1996; Nam et al. 2000). A rare case of a hepatic CHFC communicating with the gallbladder has been reported (Koletsa et al. 2005).

Hepatic Pseudocyst in Pancreatitis (Intrahepatic Pancreatic Pseudocysts)

Introduction

Pseudocysts are one of the best known sequelae and complications in patients suffering from pancreatitis. They are defined as a collection of pancreatic juice admixed with inflammatory exudate, enclosed by a wall of nonepithelialized granulation tissue or fibrous tissue. The incidence of pseudocysts is 5–16 % following acute pancreatitis and 20–40 % in chronic pancreatitis (Ahgdassi et al. 2008). Twenty percent of pancreatic pseudocysts are extrapancreatic, with the most common sites being the spleen, pelvis, pleura, and mediastinum and rarely other organs such as the kidney and liver. After acute or chronic pancreatitis, the development of a pseudocyst located to the liver is an exceptional event. A published literature search as of 2009 documented 22 reported cases, 17 men and 6 women, with a mean age at presentation of 51 years. 17/22 patients suffered from acute pancreatitis, and the pseudocyst(s) were in the left liver lobe in 12, in the right lobe in 6, and in both lobes in 5 cases (Guesmi et al. 2009). Intrahepatic pseudocysts mostly develop in the context of acute pancreatitis and are mainly located in the left liver lobe. Intrahepatic pseudocysts subsequent to chronic pancreatic are more seldom seen (Les et al. 2006).

Selected References Julien et al. (1965), Gautier-Benoit et al. (1974), Gould et al. (1979), Epstein et al. (1982), Hospitel et al. (1983), Atienza et al. (1987), Lantink et al. (1989), Okuda et al. (1991), Hamm and Franzen (1993), Wang et al. (1993), Scappaticci and Markowitz (1995), Lederman et al. (1997), Mehler et al. (1998), Mofredj et al. (2000), Shibasaki et al. (2002), Bhasin et al. (2005), Yi et al. (2008), Al-Ani et al. (2009), and Atia et al. (2009).

Clinical and Imaging Features

Clinically, patients with intrahepatic pancreatic pseudocysts can present with recurrent pain attacks following pancreatitis or suffer from continuous epigastric pain (Mofredj et al. 2000). Physical examination may reveal a palpable abdominal mass, hepatomegaly, or sometimes jaundice (Gautier-Benoit et al. 1974; Hospitel et al. 1983; Atienza et al. 1987; Aiza et al. 1993; Wang 1993; Lederman et al. 1997). Intrahepatic pseudocysts may be stable in size, slowly grow, or regress (with obliteration of the cavity and fibrosis/scarring) (Les et al. 2006).

CT scans of the abdomen characteristically reveal round to oval often well-delineated intrahepatic areas of decreased attenuation. In case of accumulation of blood and/debris, areas of high attenuation may develop (Epstein et al. 1982; Lantink et al. 1989; Hamm and Franzen 1993; Mehler et al. 1998). In the context of acute pancreatitis, contrast-enhanced CT of intrahepatic pseudocysts has shown dilated, low-attenuation tubular structures in the porta hepatis that branched into the liver substance following the geometry of the biliary tract (Scappaticci and Markowitz 1995). MRI with gadolinium for endovenous contrast showed well-delimitated cystic lesions without enhancement after gadolinium administration (Les et al. 2006).

Pathology

Macroscopy shows a rather broad spectrum of presentations, ranging from thin-walled cystic lesions containing a considerable amount of juice to lesions filled with debris and exudate and only a small collection of juice. Cysts filled with necrotic masses and viscous exudate also occur. The pancreatic origin of the pseudocysts

can be documented by the detection of amylase and/or lipase activity in the fluid collections (Balzan et al. 2005; Yi et al. 2008; Atia et al. 2009). An amylase level <479 U/L had a 73 % sensitivity and 98 % specificity for diagnosing pancreatic pseudocyst (Ryu et al. 2004). Pseudocysts in the right liver lobe are even much less common (Mofredj et al. 2000; Ancel et al. 2005; Balzan et al. 2005). Intrahepatic pseudocyst has also been identified in the caudate liver lobe (Wang et al. 1993) and may involve both liver lobes (Aiza et al. 1993; Atia et al. 2009). Pancreatic pseudocyst can also produce fistula to the common bile duct, but this complication is not associated with intrahepatic pseudocyst (Hauptmann et al. 1992). Puncture of intrahepatic pseudocysts may drain a fluid with a reddish-yellow or slightly green color, with floating exudate or debris particles; typically, this fluid does not grow bacteria. Most intrahepatic pseudocysts are solitary lesions, but multiple cysts have also been described (Slim et al. 1992; Casado et al. 2007). In the case reported by Casado et al. (2007), three soft cystic tumors were located in the left lobe of the liver with a very dense and necrotic content on exploration with intraoperative ultrasonography. The pseudocysts were full of debris with only a small amount of juice. Histologically, the cyst contains either an eosinophilic, protein-rich fluid with suspended debris and exudate cells or an accumulation of necrotic eosinophilic matter with shadow cells and more or less preserved leukocytes. The peripheral wall consists of granulation tissue rich in macrophages, followed at the periphery by fibrous tissue. An epithelial lining is typically lacking. The adjacent liver tissue shows some atrophy, ductular proliferations, and an inflammatory infiltrate of lymphocytes, macrophages, and few plasma cells.

Pathogenic Pathways

Hypothetically, the location of the "mother" pseudocyst in the pancreas may have an impact on the location of the intrahepatic pseudocyst, because it is thought that leaking pancreatic juice with active enzymes plays an important pathogenic role. A first pathway between the inflamed pancreas and the liver suggests the release of pancreatic juice from the posterior part or tail of the pancreas toward the lesser sac and from there toward the left liver lobe along the lesser omentum or the gastrohepatic ligament, where the juice will get into contact with the liver surface and invade the liver substance by its enzymes. A second pathway includes a propagation of pancreatic juice from the pancreatic head via the hepatoduodenal ligament to the porta hepatis; the latter mechanism would also explain the development of right-sided lesions or even bilobar lesions (Scappaticci and Markowitz 1995; Shibasaki et al. 2002; review: Casado et al. 2007). The presence of pancreatic enzymes in the intrahepatic pseudocyst fluid is an argument for the role of pancreatic juice invading the liver, although the production of amylase by cholangiocytes and effects of liver cell transdifferentiation have also been proposed (Atia et al. 2009).

Cerebrospinal Fluid Pseudocyst

Introduction

Intrahepatic collections of cerebrospinal fluid can occur as a complication of ventriculoperitoneal (VP) shunts. VP shunting of cerebrospinal fluid (CSF) is a standard therapy for the management of hydrocephalus. Even after the introduction of silastic catheters, abdominal complications still occur, including pseudocysts (review: Bryant et al. 1988). Intra-abdominal CSF pseudocysts are a rare but important complication of VP shunting; since 1954, more than 100 cases of pediatric CSF pseudocysts have been reported. In one study, the incidence of pseudocyst formation was 4.5 % (Rainov et al. 1994). A relation between pseudocyst formation and abdominal procedures after the initial insertion of the shunt has been suggested (Fischer and Schilito 1969; Gotierrez and Raimondi 1976; Goldfinc et al. 1978). Important predisposing factors comprise multiple shunt revisions and infections. The

most common presentation is with symptoms of elevated intracranial pressure and abdominal pain.

Hepatic CSF Pseudocysts

Intrahepatic CSF pseudocysts are among the rarest forms of CSF pseudocysts (Rana et al. 1985; Wang and Miller 1989; Banka et al. 2007; Kaplan et al. 2007b; Kolic et al. 2010; Faraj et al. 2011; Dabdoub et al. 2013). They have been classified as intra-and extra-axially growing cysts (Kaplan et al. 2007b). Intrahepatic CSF cysts can present as a tumor-like hepatic mass (Wang and Miller 1989), may mimic hydatid disease (Faraj et al. 2011), and can form large fluid collections reaching to the porta hepatis and causing elevated liver enzymes (Rana et al. 1985). Intrahepatic CSF pseudocyst can be caused by perforation of the intraperitoneal catheter through the liver capsule, followed by dissection of the liver substance by the CSF and a fluid accumulation that can induce hepatomegaly (Wang and Miller 1989). Misplaced ventriculoperitoneal shunt can also cause a pseudocyst of Glisson's capsule (Peltier et al. 2011).

Macroscopically, one notes thin-walled pseudocysts that contain a clear or only slightly turbid watery fluid, the cystic space having a smooth, glistening surface. Histologically, the pseudocyst cyst wall consists of compressed liver tissue with a proteinaceous layer with our without leukocytes or, in late stages, of a hypocellular fibrous tissue, with accumulation of macrophages and lymphocytes in the innermost part of the wall (Rainov et al. 1994).

Other Hepatobiliary Cysts That May Mimic Hepatic Cystic Neoplasms

Hepatic Epidermoid Cyst

Epidermoid cysts located within the liver substance or related to bile ducts are very rare alterations of unknown etiology. A developmental error has been considered, with endodermal cells fated to an aberrant cell lineage, or keratinocytes derived from an accessory foregut bud. On the other hand, squamous metaplasia of biliary cysts followed by epidermization may be another explanation (Fernandez-Castroagudin et al. 2001; Chiu et al. 2005). The lesions were also observed in children (Schullinger et al. 1983). Epidermoid cysts of the liver usually present as solitary cystic lesions, but multiloculated forms are also known (Sando et al. 1996). They can grow to a large size and eventually mimic hydatid disease (Fernandez-Castroagudin et al. 2001). Epidermoid cysts of the liver can be complicated by intrahepatic squamous cell carcinoma (Lombardo et al. 1995; Odemis et al. 2006).

Hepatic Bronchogenic Cyst

Bronchogenic cyst, which shares a ciliated epithelium with ciliated foregut cyst, can occur, apart from its well-known mediastinal sites, in the diaphragm but is the rarest hepatic nonparasitic cyst (Cerwenka et al. 2000).

Intramural Bile Duct Cysts

Intramural bile duct cysts are very rare lesions that may derive from dilated peribiliary glands, secondary obliterated diverticula, or may represent small choledochoceles or circumscribed, incomplete ductal duplications (Scotiniotis and Kochman 2001; Garcia-Cano et al. 2005).

DOI 10.1007/978-3-319-26956-6_139

Abstract

The granulomatous hepatobiliary reactions that characterized sarcoidosis (Morbus Boeck) induce a wide array of secondary alterations, part of which resemble neoplastic conditions. Liver involvement in sarcoidosis amounts to 10 % or more than 80 % of cases, depending on criteria used. The main features of hepatic sarcoidosis comprise granulomatous hepatitis, chronic cholestasis, portal hypertension, Budd-Chiari syndrome, and liver cirrhosis. Cholestasis in sarcoidosis can clinically mimic primary biliary cirrhosis or primary sclerosing cholangitis. Granulomatous hepatitis is a very common manifestation of hepatic sarcoidosis. Typically, sarcoid granulomas lack central necrosis but may contain Schaumann bodies and asteroid bodies. Hepatic granulomas can coalesce to form larger nodular and tumor-like lesions. Such masses may grow to large size to form pseudotumors or so-called sarcoidomas. The granulomatous inflammation can involve bile ducts and cause biliary obstruction with typical secondary liver changes. Also, small bile duct involvement is known, resulting in vanishing bile duct syndrome.

Sarcoidosis of the Liver

Introduction

Sarcoidosis (Boeck's disease; Morbus Boeck; Morbus Boeck-Besnier-Schaumann) is a chronic granulomatous disorder of unknown etiology and characterized by a highly variable presentation spectrum and course, although pulmonary and lymph node involvements are predominant features (review: Morgenthau and Iannuzzi 2011). Abdominal sarcoidosis is diagnosed by imaging modalities in 5–15 % of the patients (Warshauer et al. 1994a,b), and the most common CT findings in abdominal sarcoidosis are hepatosplenomegaly and lymphadenopathy (Britt et al. 1991; Foltz et al. 1995).

Epidemiology

How frequent are manifestations of sarcoidosis in the liver? Among a total of 736 sarcoidosis patients enrolled in the ACCESS study (A Case Control Etiologic Study of Sarcoidosis), 85 patients or 11.5 % had liver involvement (Baughman et al. 2001). In a study of 1,436 patients with presumed sarcoidosis, 340 patients had abnormalities in liver tests, and 40 with confirmed sarcoidosis underwent a liver biopsy. Among these, 50 % had bile duct depletion and 26 % had bridging fibrosis or cirrhosis. Male gender, hepatomegaly, splenomegaly, and normal chest radiograph were associated with hepatic sarcoidosis (Kahi et al. 2006). Exclusive liver involvement without lung disease in patients with systemic sarcoidosis is uncommon and only found in 13 % of patients (Kennedy et al. 2006). Severe chronic liver diseases, i.e., cirrhosis and/or portal hypertension, are only observed in 1 % of patients with sarcoidosis.

Clinical Features of Hepatic Sarcoidosis

The main features of hepatic sarcoidosis comprise granulomatous hepatitis, chronic cholestasis, portal hypertension, Budd-Chiari syndrome, and biliary cirrhosis. In part of patients, hepatic sarcoidosis is associated with splenic involvement (hepatosplenic sarcoidosis; Sekine et al. 2012). Chronic cholestasis is a typical albeit uncommon hepatic manifestation of sarcoidosis. Most cases are caused by progressive destruction of small intrahepatic bile ducts (vanishing bile duct syndrome), discussed in more detail below.

and Edoute (2004), Ayyala and Padilla (2006), Kahi et al. (2006), Karagiannidis et al. (2006), Deniz et al. (2008), Ebert et al. (2008), Rose et al. (2008), Aravinthan et al. (2012), Bakker et al. (2012), Elloumi et al. (2012), Buxbaum et al. (2013), and Hashash et al. (2013).

Cholestasis in sarcoidosis can mimic primary biliary cirrhosis (PBC) (Rudzki et al. 1975; Thomas and Micci 1977; Bass et al. 1982; Hughes et al. 1983) or primary sclerosing cholangitis (PSC) (Alam et al. 1997; Maambo et al. 2007), two autoimmune disorders which are also characterized by a granulomatous reaction in the liver. On the other hand, there is evidence that sarcoidosis may in fact be combined with autoimmune disorders such as PBC and PSC. Cutaneous sarcoidosis has been observed to occur in conjunction with AMA-positive PBC (Karlish et al. 1969; Stanley et al. 1972; Byrne et al. 1977; Keefe 1987; Xerri et al. 1989; Leff et al. 1990; Hughes and McGavin 1997; Kishor et al. 2008). Late-onset sarcoidosis has been observed in a patient after liver transplantation for primary biliary cirrhosis (Gur et al. 2007). Sarcoidosis has been found in conjunction with PSC (Keller et al. 1997), and hepatic sarcoidosis can be associated with an elevated serum level of immunoglobulin IgG4 (Inoue et al. 2012). Cholestasis in sarcoidosis can also be caused by granulomatous and fibrosing cholangitis of the large bile ducts (Bloom et al. 1978; Kusielewicz et al. 1988; Albu et al. 1995; Rezeig and Fashir 1997) and compression of the extrahepatic bile ducts by enlarged lymph nodes showing granulomatous lymphadenitis (Bloom et al. 1978; Baughman 1988). Liver-associated lymph nodes may develop large sizes in sarcoidosis (Inoue et al. 1995). Sarcoid stenosis of bile ducts may mimic cholangiocarcinoma (Rezeig and Fashir 1997).

Hepatic sarcoidosis can seldom recur after liver transplantation, with biopsy-proven hepatic granulomas (Fidler et al. 1997; Cengiz et al. 2005), in one case manifesting with severe hypercalcemia (Cengiz et al. 2005). On the other hand, three post-transplant patients having died from non-sarcoidosis-related causes did not show liver granulomas at necropsy (Casavilla et al. 1993). Generalized sarcoidosis can be complicated by subsequent malignant non-Hodgkin's lymphoma, the sarcoidosis-lymphoma syndrome (Goljan-Geremek et al. 2013), which may be expected to potentially involve the hepatobiliary tract.

Macroscopic Pathology

Whitish and well-defined nodules of variable size without a hyperemic margin are noted (Giovinale et al. 2009). Many of these nodules are visualized by sonography (Sartori et al. 2002) and as low-density areas on CT and have bioptically been shown to represent conglomerated masses of non-caseating and fibrosing granulomas (Nakata et al. 1989; Kim et al. 1992; Hoeffel et al. 1996; Scott et al. 1997; Thanos et al. 2002), but there are also focal hepatic lesions that are not detectable by CT or MRI (Sakai et al. 1995). Nodular hepatic lesions may be isolated or occur together with similar lesions in the spleen. In a review of images of 20 cases, isolated splenic involvement was seen in seven, isolated hepatic involvement in four, and simultaneous hepatic and splenic involvement in nine patients (Scott et al. 1997). Large confluent sarcoid lesions may present as tumorous nodules and hence mimic disseminated hepatic malignancy (Oketani et al. 1992). In stage IV disease (biliary cirrhosis), the organ is coarsely nodular and shows irregularly or garland-shaped regenerative nodules on the cut surface, with dense and broad fibrous septa and with or without signs of cholestasis. In fibrosing sarcoidosis of the hilar region, hilar cholangiocarcinoma can be mimicked (Suzuki et al. 2011).

Histopathology

Granulomatous Hepatitis

Liver biopsies performed owing to clinical evidence of liver disease show sarcoid granulomas in

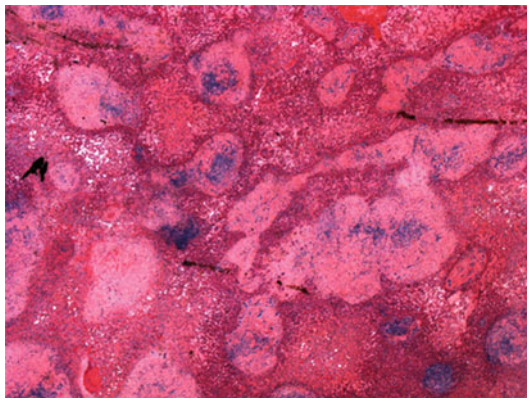

Fig. 1 Sarcoidosis of the liver. Numerous, in part confluent, non-caseating granulomas are seen (hematoxylin and eosin stain)

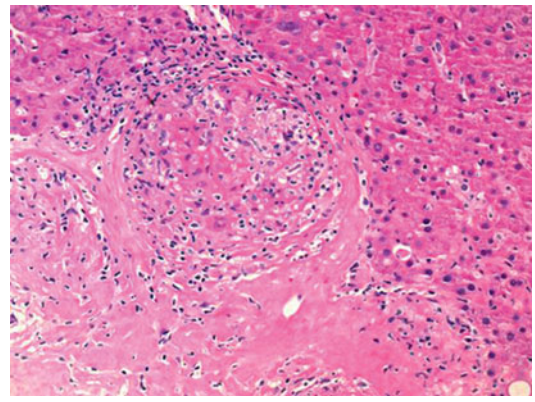

Fig. 3 Sarcoidosis of the liver. In sarcoidosis, granulomas tend to undergo fibrosclerosis which may compromise the structure of involved bile ducts and blood vessels (hematoxylin and eosin stain)

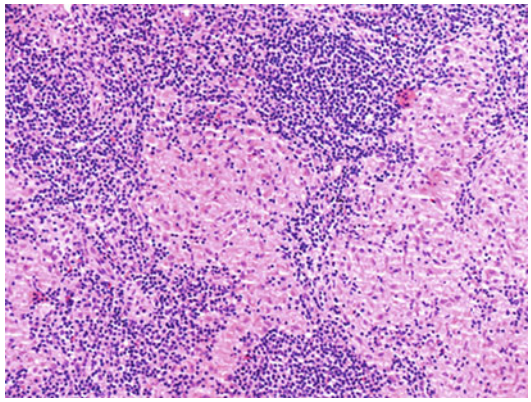

Fig. 2 Sarcoidosis of the liver. Epithelioid cell granulomas without necrosis (hematoxylin and eosin stain)

a large proportion of cases (Figs. 1, 2, and 3; Klatskin and Yesner 1950; Hercules and Bethlem 1984; Devaney et al. 1993; Trenn et al. 1999; Bilir et al. 2000; Aravinthan et al. 2012; Aga et al. 2013). Reported prevalences of hepatic granulomas in sarcoidosis range, however, from 11 % to more than 80 % (Branson and Park 1954; Maddrey et al. 1970; Bilir et al. 2000; Ayyala and Padilla 2006; Harder et al. 2007), these differences probably being related to varying immune reactions, individual interpretation of biopsies (small epithelioid cell clusters vs. giant cell-containing, well-developed granulomas), and sampling effects. How many cases of granulomatous hepatitis in general are caused by sarcoidosis ? In a retrospective study of 442 cases with biopsy-proven hepatic granulomas found in a series of 12,161 liver biopsies of a single center, 37 cases (8.37 %) were caused by sarcoidosis, while 215 cases or 48.64 % were caused by primary biliary cirrhosis (Drebber et al. 2008). In other studies with smaller number of cases, the prevalence of sarcoidosis among cases of granulomatous hepatitis was 7.5 % (Dourakis et al. 2007) and 11.1 % (Gaya et al. 2003). The granulomas are more often located to portal tracts than to the lobular parenchyma (Elloumi et al. 2012). In a minority of cases, granulomas in sarcoidosis may show central necrosis but not of the caseification type (Bilir et al. 2000). Giant cells of the Langhans type are often present in sarcoid granulomas and develop via cell fusion of epithelioid macrophages (van Maarsseveen et al. 2009). The characteristic inclusions of giant cells, i.e., Schaumann bodies and asteroid bodies, are regarded as typical for senescent granulomas in sarcoidosis and have been found in hepatic granulomatous lesions (Bilir et al. 2000) but are not seen in all cases (Ishak 1998). Schaumann bodies (Metchnikoff-Schaumann bodies) are strongly basophilic ("blue"), concentrically laminated ovoid structures. When fully developed, Schaumann bodies look like raspberries. The bodies contain calcium and iron, and calcium oxalate monohydrate is detectable

in them (Kirkpatrick et al. 1988; Reid and Andersen 1988; Symmans et al. 1995). Schaumann bodies are often found within giant cells, but in case they are very large or numerous, they can be extruded into the extracellular space. Small birefringent calcific particles and particles of dolomite found in epithelioid cells may be precursors of Schaumann bodies (Reid and Andersen 1988). Asteroid bodies are stellate inclusions of giant cells with numerous rays radiating from a central core. Asteroid bodies are thought to be derivatives of the cytosphere. The body and arms of the star-like structure consist of longitudinally oriented microfilaments with accompanying microtubules (Cain and Kraus 1977). Asteroid body morphogenesis seems to involve unusual microtubule dynamics in monocyte-derived epithelioid cells (Gadde and Moscovic 1994). Granulomas may heal without leaving a trace, but confluent granulomas often induce a fibrosing reaction, probably via production of fibrokines by the immunologic effector cells, causing scarring and the formation of supramiliary nodules.

Nodular Lesions

In part of the patients, coalescent clusters of granulomas with or without fibrosis/sclerosis can form tumor-like nodular lesions (Kim et al. 1992; Warshauer et al. 1995). The nodules are usually small (Warshauer et al. 1995) but may reach a diameter of up to 1.5 cm. Sarcoidosis with nodular lesions is associated with hepatomegaly and adenopathy (Warshauer et al. 1995). Large nodules consisting of scarred confluent granulomas may mimic cholangiocarcinoma (Menias et al. 2008).

Pseudotumoral Hepatic Sarcoidosis (Sarcoidomas)

Rare cases of nodular hepatic sarcoidosis characterized by large nodules having a diameter of 1.5 cm or more (Warshauer et al. 1994b), or conglomerates reaching several cm in diameter, have been called pseudotumoral hepatic sarcoidosis or "sarcoidomas" (Devaney et al. 1993). The lesions may reach a size of 6 cm or even more and may mimic malignancy (Stephan et al. 1965; Jung et al. 2004). In case such large lesions are located to the bile duct or hilar compartments, obstructive jaundice can develop (Albu et al. 1995). Healing conglomerated lesions may end up in rather large irregular scars that are sometimes difficult to interpret.

Granulomatous and Fibrosing Cholangitis

In a subset of patients with hepatobiliary sarcoidosis, a special form of granulomatous cholangitis develops, with a tendency for fibrosis (Bloom et al. 1978; Kusielewicz et al. 1988; Rezeig and Fashir 1997; Buxbaum et al. 2013). In the fibrosing/scarring phase, the bile duct changes may radiologically and histologically resemble primary sclerosing cholangitis (PSC) (Tombazzi et al. 2008). Specifically, the fibrosing process can cause multiple bile duct strictures that radiologically closely resemble those in PSC (Alam et al. 1997). The ductocentric fibrosclerosing process in certain patients with sarcoidosis may mimic cholangiocarcinoma (Nehls et al. 2006), in particular Klatskin's tumor (Pungpapong et al. 2006).

Small Bile Duct Disease

Hepatobiliary sarcoidosis can be associated with distinct patterns of small bile duct disease. The most important is vanishing bile duct syndrome, which has been documented in the literature several times (Nakanuma et al. 1979, 1983, 2001; Pereira-Lima and Schaffner 1987; Sherlock 1987; Ludwig et al. 1988; Desmet 1990; Murphy et al. 1990; Devaney et al. 1993; Reau and Jensen 2008; Farouj et al. 2011). In a study of 100 patients with sarcoidosis, 19 patients displayed bile duct lesions similar to primary biliary cirrhosis, and in 37 patients with chronic cholestasis, a decrease in the number of the small bile ducts (ductopenia) was noted (Devaney et al. 1993). Bile duct disease

in sarcoidosis is associated with hepatic cholestasis and histochemically detectable copper deposition in hepatocytes (Mounajjed et al. 2013).

Phlebitis

The inflammatory reaction of the small intrahepatic bile ducts is often accompanied by alterations of the small portal vein branches. These comprise florid phlebitis, adventitial granuloma formation, and phlebosclerosis with luminal narrowing (Moreno-Merlo et al. 1997; Nakanuma et al. 2001; Chawla and Dhiman 2008). This stenosing phlebopathy is probably causing parenchymal ischemia and may contribute to chronic fibrosing hepatopathy in sarcoidosis.

Fibrosis and Cirrhosis

The chronic granulomatous inflammation in the portal tract spaces causes fibrosis which may develop along extensions of portal tracts, ending up with septal fibrosis and cirrhosis, which is visualized on postcontrast CT images (Tsukada et al. 1993). Almost half of the cases are characterized by large central regenerative nodules associated with wedge-shaped areas of peripheral parenchymal atrophy (Ferreira et al. 2013). This progression has histologically been proven (Yoshiji et al. 2011). Histologically, portal tract and septal fibrosis are of the type seen in many forms of chronic biliary obstruction, with ductular proliferations and so-called biliary piecemeal necroses (Nakanuma et al. 2001). Mostly due to chronic biliary obstruction with bile duct loss but also in the course of progressive fibrosis of granulomatous inflammation, secondary biliary cirrhosis can develop (Thomas and Micci 1977; Hughes et al. 1983; Kitamura et al. 1998; Khan and Irfan 2001; Gavilan et al. 2003; Gupta et al. 2008). True liver cirrhosis in sarcoidosis has been observed in the setting of HFE-associated hemochromatosis (Barton et al. 2009). The fibrosing hepatic remodeling in sarcoidosis can cause portal hypertension (Mino et al. 1949; Cheitlin et al. 1960; Bruix et al. 1980; Windler et al. 1983; Tekeste et al. 1984; Yoshiji et al. 2011; Ivonye et al. 2012; Tan et al. 2012).

Budd-Chiari Syndrome

Hepatic venous thrombosis as a complication of hepatic sarcoidosis has been reported only few times. As in other situation of this syndrome, the main clinical manifestations were ascites, jaundice, and hepatomegaly (Natalino et al. 1978; Russi et al. 1986; Deniz et al. 2008; Delfosse et al. 2009; Maamouri et al. 2009; Van Brusselen et al. 2012).

Alterations in Liver-Associated Locoregional Lymph Nodes

Locoregional lymph nodes of the hepatobiliary tract can participate in sarcoidosis of the liver and show alterations known from other anatomical sites. The hallmark of lymph node sarcoidosis is the presence of non-caseating epithelioid cell granulomas with multinucleated giant cells of the Langhans type (granulomatous lymphadenitis). In early-stage disease, microgranulomas are mainly found in the subcapsular area of nodes, a phenomenon which rose suspicion of an infectious process reaching the lymph node by the lymph. Enlarging granulomas may then coalesce, ending up with an almost complete or complete effacement of the lymph node architecture. This progressive granulomatous reaction can be associated with fibrosis. In the centers of large granulomas, epithelioid macrophages may undergo atrophy or decay, and even small eosinophilic necroses may ensue, but the granular eosinophilic coagulation necrosis characterizing caseification in tuberculosis is absent. In and around granulomas, Schaumann bodies and/or asteroid bodies can be found. In sarcoidosis, Schaumann bodies are found in up to 88 % of lymph nodes, but asteroid bodies are much less common, occurring in 2–9 % of sarcoidotic

lymph nodes. Small yellow-brown, ovoid, or spindled bodies consisting of a ceroid-like substance and resembling budding fungal organisms may be observed. These structures are termed Hamazaki-Wesenberg bodies (synonyms: yellow-brown/Y-B bodies, Hamazaki corpuscles). The bodies stain with predigested PAS and are acid-fast in the long Ziehl-Neelsen acid fast stain but not in ordinary Ziehl-Neelsen stains. They are located in the cytoplasm of epithelioid cells and Langhans giant cells, sometimes in large numbers, but can also be extruded into the extracellular space and into sinusoids. The bodies were first described by Hamazaki in 1938 in mesenteric lymph nodes (Hamazaki 1938) and were later redescribed by Menne, again in mesenteric lymph nodes (Menne 1952). Apart from sarcoidosis, Hamazaki-Wesenberg bodies also occur in lymph nodes draining cirrhotic livers, appendicitis, colorectal cancer, and lymphoid neoplasms (Sieracki and Fisher 1973; Ro et al. 1987; Winters et al. 2007). The bodies are altered giant lysosomes, and the yellow-brown material may represent a distinct form of ceroid resulting from lipid oxidation in decaying macrophages/epithelioid cells.

Sarcoidosis of the Gallbladder

Granulomatous inflammation in sarcoidosis can rarely involve the gallbladder (Lloyd-Davies and Forbes 1965; Mert et al. 2004)

Hepatic Sarcoidosis and Malignancy

Sarcoidosis seems to be associated with an increased incidence of malignancy (Romer et al. 1998; Askling et al. 1999). Hepatic sarcoidosis was found to be complicated by hepatocellular carcinoma (Wong et al. 1999; Chalasani et al. 2005; Ogata et al. 2010). In a patient with ulcerative colitis, primary sclerosing cholangitis, and generalized sarcoidosis, bile duct carcinoma had developed (Van Steenbergen et al. 1987).

Differential Diagnosis

The key feature of hepatic pathology in sarcoidosis, i.e., granulomas, is typically also found in the portal tracts of primary biliary cirrhosis, overlap syndrome, and primary sclerosing cholangitis (Ludwig et al. 1995). Sarcoid-type granulomas have been found in locoregional lymph nodes draining hilar cholangiocarcinoma (Onitsuka et al. 2003). A disorder related to sarcoidosis is necrotizing sarcoid granulomatosis (NSG). NSG is predominantly a pulmonary disorder with features in between those of sarcoidosis and Wegener's granulomatosis (Popper et al. 2003; Lazzarini et al. 2008; Yeboah et al. 2012). NSG can rarely involve extrapulmonary organs and tissues, e.g., the central nervous system (Strickland-Marmol et al. 2000) and the gastrointestinal tract (Le Gall et al. 1996; Ahmed et al. 2010).

Etiology and Pathogenic Pathways

The etiology and pathogenesis of sarcoidosis have not been clarified (review: Müller-Quernheim et al. 2012). Sarcoidosis development has a genetic background (Rybicki et al. 2007; Smith et al. 2008). Genetic associations of American sarcoidosis susceptibility implicate MHC class II allele, DRB1*1101. Patients with sarcoidosis reveal oligoclonal populations of alphabeta CD4+ T cells, consistent with an MHC-restricted antigen-driven process (review: Oswald-Richter et al. 2010). Recent molecular, genetic, and immunologic studies suggest the association of sarcoidosis with infectious agent antigens (review: Saidha et al. 2012). Currently, strong candidates comprise antigens of *Propionibacterium* and *Mycobacterium* species (Song et al. 2005; Drake et al. 2007; Dubaniewicz et al. 2007). A Th-1 immune response to mycobacterial protein antigens has been detected within sarcoidosis samples, proteins that are actively secreted by the mycobacterial SecA 2 secretion system (review: Oswald-Richter and Drake 2010). In sarcoidosis, cellular responses directed against the mycobacterial virulence factors, ESAT-6 and katG, occur (Drake et al. 2007). Recognition of the

mycobacterial ESAT-6 peptide by CD4+ T cells presented by antigen-presenting cells depends on the expression of MHC class II DRB1*1101 (Oswald-Richter et al. 2010).

Pathogenetically, sarcoidosis is related to the function of inflammasomes and NOD proteins forming nodosomes (reviews: Tattoli et al. 2007; Dagenais et al. 2010; Khare et al. 2010). In the cytoplasm, NOD1 and NOD2 proteins are chiefly expressed by antigen-presenting cells (dendritic cells and macrophages) and epithelial cells (NOD1 in most epithelia, NOD2 in Paneth cells). NODs recognize distinctive muropeptide structures derived from bacterial cell wall peptidoglycans and released by growing bacteria. Specifically, NOD1 detects meso-diaminopimelic acid, a component which is mainly found in Gram-negative bacteria. NOD2 recognizes and senses muramyl dipeptide, a component present in both Gram-positive and Gram-negative bacteria. NOD1 is upregulated by interferon-gamma, NOD2 by both interferon-gamma and TNF-alpha. The signaling pathways of NOD sensors are further discussed in the paragraph on Blau syndrome.

Autoinflammatory Granulomatous Diseases: Blau Syndrome and Early-Onset Sarcoidosis

Introduction

Blau syndrome (juvenile sarcoidosis; OMIM 186580), described in 1985, and its counterpart, early-onset sarcoidosis (EOS), share a phenotype characterized by skin rash, arthritis, and uveitis, with a distinct granulomatous reaction (Raphael et al. 1993; Becker and Rose 2005; Shetty and Gedalia 2008; Sfriso et al. 2012). Blau syndrome makes part of a complex group of monogenic autoinflammatory syndromes (MAIS; Caso et al. 2013; Tripathi and Leslie 2013; Caso et al. 2014, 2015).

Blau Syndrome

Blau syndrome (OMIM 186580; familial juvenile systemic granulomatosis; Jabs syndrome) is caused by mutations in the NOD2/CARD15 gene (see below) and is clinically characterized by erythematous and papular skin rash, arthritis (in part polyarthritis), uveitis/iridocyclitis, often with a granulomatous inflammatory reaction, and granulomatous hepatitis. The symptoms and signs timely occur in this sequence, but the presentation is variable, mainly in regard of ocular manifestations, and part of the patients may have fever is the sole sign (Kurokawa et al. 2003; Arostegui et al. 2007; Rose et al. 2011). In comparison with sarcoidosis, patients with Blau syndrome have elevated serum angiotensin-converting enzyme, but they have a negative Kveim-Sitzbach test and lack pulmonary involvement (James 1994). The disorder is caused by mutations in the CARD15/NOD2 gene (Pillai and Sobrin 2013). Many mutations are detectable in the centrally located NOD region and are associated with ligand-independent NFkappaB activation (Priori et al. 2004; Okafuji et al. 2009). The phenotype of Blau syndrome is influenced by the type of NOD2 mutations involved, in that certain mutations are associated with arteritis of the Takayasu type (Khubchandani et al. 2012; Inoue et al. 2013). Recently, Blau syndrome has been associated with *Mycobacterium avium* subspecies paratuberculosis (MAP), the cause of an inflammatory enteric disease predominantly in ruminant animals and termed Johne's disease. It has been suggested that MAP induces autoimmune disorders in human through triggering of autoimmune antibodies via its heat shock proteins (Dow 2012).

Blau syndrome is histologically characterized by the presence of non-caseating granulomas in the involved tissue. The granulomas are in principle of the type found in adult sarcoidosis (De Chadarévian et al. 1993), however with certain special features. In contrast to granulomas found in sarcoidosis and NOD2-associated Crohn's disease, Blau syndrome biopsy specimens typically showed polycyclic granulomas with large lymphocyte coronas, extensive emperipolesis of lymphocytes within multinucleated giant cells, giant cell death, fibrinoid necrosis, and fibrosis (Janssen et al. 2012). Liver granulomas have

been observed in both Blau syndrome and the related disorder early-onset sarcoidosis (EOS) (Saini and Rose 1996).

Classification

Blau syndrome and related disorders belong to the monogenic autoinflammatory syndromes (MAIS; Table 1). MAIS are characterized by amplified danger sensing and cytokine dysregulation (Sanchez et al. 2013) involving numerous complex sensing and signaling platforms and interactomes (see below).

An especially important group of hereditary autoimmune disorders is the periodic fever syndromes. Familial Mediterranean fever (FMF; OMIM 249100; also termed recurrent polyserositis, periodic peritonitis, Reimann's syndrome, and Wolff periodic disease) is an autosomal-recessive condition characterized by recurrent and self-limited attacks of fever,

Table 1 Monogenic autoinflammatory syndromes (MAIS; review: Caso et al. 2013)

***Hereditary recurrent fevers* (*periodic fever syndromes*)**
Familial Mediterranean fever (FMF)
FMF-related neutrophilic lobular panniculitis
Tumor necrosis factor receptor-associated periodic syndrome (TRAPS)
Mevalonate kinase deficiency (hyperimmunoglobulinemia D syndrome)
Periodic fever, aphthous stomatitis, pharyngitis, and adenitis syndrome (PAPA)
PAPA-hidradenitis suppurativa (PAPASH)
***Cryopyrin-associated periodic syndromes* (*CAPS*; *inflammasomopathies*)**
Cryopyrin-associated periodic syndrome
Neonatal-onset multisystem inflammatory disease (NOMID)
Muckle-Wells syndrome
Familial cold autoinflammatory syndrome (FCAS)
Pyogenic disorders
CRMO syndrome
Majeed syndrome
Deficiency of the interleukin-1 receptor antagonist
Immune-mediated granulomatous diseases
Blau syndrome
Early-onset sarcoidosis
Crohn's disease
Monogenic immune-dysregulatory disorders
Monogenic systemic-onset juvenile idiopathic arthritis caused by mutations in LACC1
Inflammasome disorder caused by NLRP3 mutations
Inflammasome disorder caused by NLRP4 mutations
Immune-dysregulatory syndromes with chronic type I interferon signature caused by mutations in TMEM173/STING IFIH1/MDA5 and DDX58/RIG-I
Immune-dysregulatory syndromes caused by mutations in ADA2, TRNT1, and COPA, AP1S3, and TFNRSF11A
Immune-dysregulatory syndromes caused by mutations in PRKDC, STAT3, CTLA4, and PIK3R1
Idiopathic febrile syndromes
PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, adenitis)
Behçet syndrome
Proteasomal autoinflammatory syndromes
CANDLE syndrome/Nakajo-Nishimura syndrome
Other disorders
NLRP12-associated autoinflammatory disorder

polyserositis, synovitis, and pain. The episodes typically last 1–3 days. Amyloidosis is a well-known late complication (review: Portincasa et al. 2013). It is caused by mutations in MEFV, a gene encoding the protein pyrin. An autosomal-dominant form caused by heterozygous MEFV mutations is also known (Stoffels et al. 2014). Neutrophilic lobular panniculitis may belong to the widened spectrum of FMF. Periodic fever occurs in mevalonate kinase deficiency (OMIM 610377), an autosomal-recessive disorder characterized by hyperimmunoglobulin D syndrome and mevalonic aciduria, presenting with recurrent fever episodes often starting in infancy. Tumor necrosis factor receptor-associated periodic syndrome or TRAPS (familial Hibernian fever, OMIM 142680) is an uncommon autosomal-dominant disorder characterized by recurrent episodes of long-lasting fever and inflammatory changes in skin, muscles, skeletal system, serosal membranes, eye, and gastrointestinal tract. TRAPS is caused by mutations in the TNFRSF1A gene (TNF receptor superfamily 1A gene). In TRAPS, distinct circulating microRNAs were found, expression of microRNA-92b being inversely correlated with the number of fever attacks per year (Lucherini et al. 2013). PAPA syndrome (pyogenic sterile arthritis, pyoderma gangrenosum, and acne) is a further rare autoinflammatory disorder characterized by periodic fever, being caused by mutations in the PSTPIP1 gene (Demidowich et al. 2012). A variant of this PSTPIP1-associated condition has, in addition, hidradenitis suppurativa (PAPASH; Marzano et al. 2013).

The group of cryopyrin-associated periodic syndromes (CAPS) include several autosomal-dominant disorders, namely, CAPS proper, familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome, and neonatal-onset multisystem inflammatory disease (CINCA/NOMID). These disorders share a defect in the CIAS1 or NALP3/NLRP3 gene on chromosome 1, encoding the protein cryopyrin (review: Chang 2013). NALP3/NLRP3 is a component of the multiprotein complex called inflammasome, and CAPS are therefore a distinct group of inflammasomopathies. CAPS is the typical periodic fever syndrome associated with a cryopyrin anomaly. CINCA/NOMID is a complex disorder manifesting in neonates, with cutaneous, neurological, and osteoarticular signs and outbreaks of fever (Aksentijevich et al. 2002). CINCA is the abbreviation for chronic infantile neurological, cutaneous, and articular syndrome, and patients with this condition show recurrent fever, chronic meningitis, uveitis, sensineural hearing loss, urticarial skin rash, and a typical deforming arthropathy. CINCA syndrome (OMIM 607115) is caused by distinct CIAS1 mutations. Muckle-Wells syndrome is characterized by recurrent inflammatory attacks associated with chronic recurrent urticaria, sensineural deafness, periodic arthritis, and sometimes secondary amyloidosis. Familial cold autoinflammatory syndrome (FCAS) displays a phenotype that is less severe than patients with Muckle-Wells syndrome and has to be distinguished from acquired cold urticarial and familial atypical cold urticaria (FACU).

Autoimmune pyogenic disorders mainly comprise chronic non-bacterial osteomyelitis in children (CRMO; OMIM 259680), a chronic recurrent non-suppurative inflammation involving multiple skeletal sites and radiologically mimicking infectious osteomyelitis. Two genetic syndromes have CRMO as the dominant phenotype, i.e., Majeed syndrome and deficiency of the interleukin-1 receptor antagonist, suggesting a pathogenic role of interleukin-1. Majeed syndrome (OMIM 609628) is characterized by CRMO, congenital dyserythropoietic anemia, neutrophilic dermatosis (Sweet syndrome), and hepatosplenomegaly. The disorder was found to be caused by homozygous mutations in the LPIN2 gene. Interleukin-1-receptor antagonist deficiency (DIRA; OMIM 612852) is an autosomal-recessive disorder caused by mutations in the IL1RN gene, leading to a truncated protein that is not secreted, rendering immune cells hyperresponsive to interleukin-1beta stimulation. The patients suffer from osteitis with hyperostosis, periostitis, and pustulosis with subcorneal pustular dermatitis. A disorder mimicking CRMO is SAPHO syndrome, a rare condition that mainly affects bone and skin, with synovitis, acne, pustulosis, hyperostosis, and osteitis. LPIN2 or NOD2 variants were not detected in this syndrome.

Immune-mediated granulomatous diseases comprise Blau syndrome (see below), early-onset sarcoidosis, and NOD2-associated Crohn's disease. Early-onset sarcoidosis (OMIM 609464) is similar in its presentation to Blau syndrome and is also caused by mutations of NOD2.

Idiopathic febrile syndromes form a complex group of autoimmune conditions. Systemic-onset juvenile idiopathic arthritis is also termed juvenile or adolescent-onset Still's disease. It is a systemic inflammatory disorder within the spectrum of juvenile idiopathic arthritis, characterized by a chronic and often severe course and visceral involvement, including hepatosplenomegaly, lymphadenopathy, and anemia. The disorder can be complicated by macrophage activation syndrome or AA amyloidosis. A polymorphism in macrophage migration inhibitory factor has been implicated in this disorder. PFAPA stands for periodic fever, aphthous stomatitis, pharyngitis, and adenitis syndrome. PFAPA usually starts in patients less than 5 years of age, has less than 20 episodes, and is not associated with significant long-term sequelae. SPAG7 is a candidate gene for PFAPA, encoding a protein expressed in tissues affected by the disorder and being functionally linked to inflammatory and antiviral responses. Behçet syndrome (OMIM 109650) is a systemic inflammatory condition involving both innate and adaptive immunity. It is an immune-mediated systemic small-vessel vasculitis that often presents with mucosal ulcerations, genital ulcers, and ocular disease, mainly uveitis. There is evidence that mutations in the NLRP3/cryopyrin inflammasome are pathogenically involved.

Autoinflammatory syndromes can also be caused by proteasomal disorders. Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE syndrome; OMIM 256040) is caused by mutations in proteasome subunit beta type 8 (review: Gomes 2013), a gene reported to cause the JMP syndrome (joint contractures, muscle atrophy, microcytic anemia, and panniculitis-induced childhood-onset lipodystrophy) in adults. In Japan, the disorder is known as Nakajo-Nishimura syndrome.

Microbial Sensing Proteins and Pattern Recognition Molecules: NLRs, NOD Proteins, Nodosomes, TLRs, and RIGs

NOD proteins are involved in innate immunity, the most ancestral and ubiquitous system of defense against microbial infection. The innate immune system employs different molecules that sense microbial pathogen-associated molecular patterns (PAMPs and PAMP-sensing proteins). These include Toll-like receptors, involved in the detection of microbes in the extracellular compartment, and a large group of molecules that detect intracellular microbes and their products, including RIG-1-like receptors, NOD-like receptors, and CARD components of inflammasomes (reviews: Inohara et al. 2002; Inohara and Nunez 2003; Kufer et al. 2006; Kanneganti et al. 2007; Le Bourhis et al. 2007; Rietdijk et al. 2008; Philpott and Girardin 2010; Bauernfeind and Hornung 2013). NOD proteins or Nod-like receptors are now members of the nucleotide-binding and oligomerization domain-like receptors (NLRs) containing family (review: Lamkanfi et al. 2007; Mathews et al. 2008). The NLR family contains more than 20 members, and these are grouped into molecules that contain either a CARD motif (see below) or a Pyrin motif. NLRs currently include the two major subfamilies, NLRC (the NODs) and NLRP (formerly called NALPs), and also comprise the MHC Class II transactivator (CIITA) and NAIP. NLR proteins are characterized by three structural domains: a C-terminal leucine-rich repeat domain able to sense a microbial motif, an intermediary nucleotide-binding site essential for the oligomerization of the molecule that is necessary for the signal transduction induced by different N-terminal effector motifs, such as a pyrin domain, a caspase-activating and recruitment domain (CARD), or a baculovirus inhibitor of apoptosis protein repeat (BIR) domain (review: Chamaillard et al. 2003).

NODs (newly termed NLRC) act as scaffolding proteins that assemble signaling platforms that trigger nuclear factor kappaB (NFkappaB) and mitogen-activated protein kinase signaling

pathways, while Pyrin molecules such as NALP3 regulate Il-1beta and IL-18 production (reviews: Mathews et al. 2008; Reitdijk et al. 2008; Franchi et al. 2009). Together with Toll-like receptors, NOD1 and NOD2 are cytoplasmic microbial sensors that trigger immune defense in response to bacterial peptidoglycans (Viala et al. 2004; Jiang et al. 2013; Keestra and Bäumler 2014). They act in a complex signaling cascade and induce, via muramyl dipeptide-induced activation of NRkappaB and RIP2 (Strober et al. 2006), antimicrobial effectors, such as nitric oxide and antimicrobial peptides. However, an isoform of NOD2, NOD2-C2, is capable of activating NFkappaB in the absence of muramyl dipeptide (Kramer et al. 2010). Activation of NFkappaB is a central functional platform of this pathway, and the activity status of NFkappaB is also regulated by factors that terminate its activation, e.g., the ubiquitin-editing enzyme A20/TNFAIP3 (Coomaert et al. 2009; Vereecke et al. 2009). This inhibiting action of AP20 is in turn modulated by a member of the ABIN family of proteins, ABIN3 (LIND), which binds to AP20 and is a lipopolysaccharide-inducible inhibitor of NFkappaB activation (Wullaert et al. 2007). NOD2 can also activate antiviral innate immune responses involving IRF3-dependent interferon-beta production after viral ssRNA recognition through a RIP2-independent mechanism requiring the mitochondrial adaptor protein MAVS (review: Lecat et al. 2010). Together, they form a cooperative system that is called the nodosome (Tattoli et al. 2007). NOD signaling also results in the activation of protein kinases and the production of chemokines. Hepatocytes express functional NOD1 and NOD2 receptors, and ligand-induced activation of hepatocyte NOD1 leads to activation of MAP kinases and expression of chemokines CCL5 (RANTES) and CXCL1 as part of the hepatic innate immune system (Scott et al. 2010). The chaperone (Hsp90; heat shock protein 90)-mediated function of NLR receptors in innate immunity depends on the co-chaperone Sgt1 and CHORD (cysteine- and histidine-rich)-containing protein 1 (Wu et al. 2008). CHORD domains are associated with CS domains, either with the same protein, as in the mammalian melusin and Chp1, or in separate but interacting proteins, and both CHORD and CS domains are independently capable of interacting with the chaperone Hsp90 (Zhang et al. 2010). NOD proteins undergo negative regulation via the splice variant of NOD2, NOD2-S (which inhibits NOD2/receptor-interacting protein kinase 2-induced signaling pathways; Rosenstiel et al. 2006), the ubiquitin-editing enzyme A20, pyrin domain-only proteins, and CARD proteins which all have a negative effect on NOD2 or NRLP3 signaling (review: Coll and O'Neill 2010). Also, olfactomedin 4, a glycoprotein upregulated in inflammatory bowel disease and *Helicobacter pylori* infection, exerts a negative feedback effect on NFkappaB through a direct association with NOD1 and NOD2 (Liu et al. 2010).

The function of NOD proteins is linked to autophagy, in that NOD2 recruits the critical autophagy protein, ATG16L1, to the plasma membrane during bacterial invasion and hence augments autophagy (Travassos et al. 2010). This is an important mechanism insofar as there is a critical link between autophagy and effective innate immunity. On the other hand, NLR-containing immunoamphisomes in dendritic cells regulate, via NOD2, the function of Toll-like receptors in that they amplify Toll-like receptor 7 (TLR7) signaling (Blanchet and Piguet 2010).

NLRPs

These caspase 1-activating receptors were previously termed, NALPs (Chamaillard et al. 2003). Like NODs, they contain a C-terminal leucine-rich repeat, which may be involved in the recognition of microbial pathogens, and a nucleotide-binding site for nucleoside triphosphates. The interaction with other proteins, e.g., ASC, is mediated via N-terminal pyrin domain. The family comprises in human 14 members (NLRP1-14).

Proteins with a CARD Domain

NOD proteins belong to a group of proteins which contain a homotypic interaction motif called the caspase recruitment domain (CARD; Le and

Harton 2013). Proteins possessing CARD are involved in the regulation of apoptosis or adaptive or innate immunity. Apart from NOD1 (CARD4) and Nod2 (CARD15), the group comprises NAC (NLRP1/NALP1/DEFCAP/CARD7), TUKAN (CARD8/Cardinal /NDPP/Dakar), CARD6 (which modulates NFkappaB activation by Nod1 and Cardiak; Stehlik et al. 2003a), caspase-9 and Apaf1 (involved in the intrinsic death pathway), Bcl10 and CARD11 (which mediate antigen receptor-induced NFkappaB activation), and Cardiak/Rip2/Rick (receptor-interacting protein (RIP)-like interacting caspase-like apoptosis regulatory protein kinase, which activates NFkappaB). Bcl10 is a signaling adaptor able to interact with Carma1, an interaction that is required for signaling from the T cell receptor to NFkappaB. Carma1 regulation of regulatory T cell development involves modulation of interleukin-2 receptor signaling (Lee et al. 2010). The association of Bcl10 with Carma1 is modulated by the calcium sensor, calmodulin, the interaction being localized to the CARD domain of Bcl10 (Edin et al. 2010). One CARD member, CARD6, has a domain structure different from other CARD proteins and is related to the superfamily of interferon-inducible GTPases. CARD6 interacts with receptor-interacting protein (RIP)-like interacting caspase-like apoptosis regulatory protein kinase (RICK) (Dufner and Mak 2006). CARD8 physically interacts with NOD2 and inhibits nodosome assembly and subsequent signaling upon muramyl-dipeptide stimulation, and CARD8 inhibits the direct bactericidal effect of NOD2 against intracellular infection with *Listeria monocytogenes* (Von Kampen et al. 2010). All inflammasomes require ASC (adaptor protein apoptosis-associated speck-like protein containing a CARD) for the activation of caspase-1 (Stutz et al. 2013), CARD playing a critical role in ASC foci formation and inflammasome signaling (Proell et al. 2013).

Toll-Like Receptors (TLRs)

Toll-like receptors (TLRs) have been established to play an essential role in the activation of innate immunity by recognizing specific patterns of microbial components. TLR signaling pathways arise from intracytoplasmic TIR domains which are conserved among all TLRs, and TLR signaling is modulated by other TIR-containing adaptors, such as MyD88, TIRAP, and TRIF. MyD88 is involved in the function of all TLRs, while TIRAP is specifically involved in the MyD88-dependent pathway via TLR2 and TLR4, and TRIF is implicated in the TRL3- and TLR4-mediated MyD88-independent pathway (review: Takeda and Akira 2004). The negative regulation of TLR signaling includes posttranscriptional regulation by miRNAs, posttranslational regulation by ubiquitination, and regulation by splice variants such as MyD88s, TRAM adaptor with GOLD domain, and IRAK2 isoforms (review: Coll and O'Neill 2010). Another negative regulation loop involves NOD2, which inhibits proapoptotic TLR4 signaling in enterocytes but not in macrophages (Richardson et al. 2010).

Virus-Sensing Proteins

Virus infection of mammalian cells elicits a variety of defense responses that are initiated by signals from virus-sensing receptors expressed by the host. The most important of these receptors are the ubiquitously expressed RIG-I-like receptor (RLR; retinoic acid-inducible gene-I-like receptors) family of DExDH/boxRNA helicases, which are potent RNA sensors (reviews: Nakhaei et al. 2009; Yoneyama and Fujita 2009; Zou et al. 2009; Rehwinkel and Reis e Sousa 2010). RIG-I detects invading viral RNA by recognition of 5′-triphosphate-containing viral RNA and activates the transcription factors NFkappaB and IRF3 through the mitochondrial protein MAVS. RNA bearing 5′-triphosphate strongly activates the RIG-I-IRF3 cascade, requiring polyubiquitin chains, and induces type I interferon-mediated antiviral immune responses. RIG-I binds specifically to K63-polyubiquitin chains through its tandem CARD domains in a manner that depends on

RNA and ATP. CARD domains therefore act as an ubiquitin sensor, and unanchored K63-polyubiquitin chains are signaling molecules in antiviral innate immunity (Zeng et al. 2010). A second intracellular viral sensor is MDA-5, which is also a DExDH/box RNA helicase.

NACHT-Containing Proteins

A further group of intracellular pathogen sensors are the NACHT (NAIP [neuronal apoptosis inhibitory protein], CIITA [MHC class II transcription activator], HET-E [incompatibility locus protein from *Podospora anserina*], and TP1 [telomerase-associated protein]) family proteins. CLAN (CARD, LRR [leucine-rich repeat], and NACHT domain-containing protein) (synonyms: CARD12, NLRc4, IPAF), an NACHT-containing molecule originally demonstrated to bind and activate pro-caspase-1, is also capable of influencing the functions of other members of the NACHT family, in that it associated with NALP1 [NACHT, LRR, and Pyrin protein 1]/NAC (nucleotide-binding domain and CARD-containing protein). The NACHT domain of CLAN binds all NACHT domains of CLAN itself, NOD1, NOD2, cryopyrin, NAC/NALP1, PAN2 (PAAD [pyrin, AIM (absent in melanoma), ASC (apoptosis-associated speck-like protein containing a CARD), and death domain-like and NACHT-containing protein), and NAIP. NAIP1 (neuronal apoptosis inhibitory protein 1) is involved in the recognition of distinct bacterial components, specifically the bacterial type III secretion needle protein (Yang et al. 2013). Interaction of CLAN with NOD1 and NOD2 inhibits NOD-induced NFkappaB activation (Damiano et al. 2004a). CLAN modulates endogenous caspase-1 activation and subsequent IL-1beta secretion from macrophages after exposure to lipopolysaccharides, peptidoglycan, and pathogenic bacteria (Damiano et al. 2004b). It is also a potent flagellin sensor but can also activate caspase-1 independent of bacterial flagellin and can restrict bacterial infection independently of caspase-1 (Abdelaziz et al. 2010).

The DNA Damage Sensor PARP1

PARP1 (poly[ADP-ribose] polymerase 1) is a DNA damage sensor that is cleaved by caspase in apoptosis. It is also cleaved in pyroptosis via the action of the NLRP3 and NLRC4 inflammasomes (Malireddi et al. 2010).

PAAD Proteins

Proteins containing PAAD and DD domains are a group of proteins that have a structure similar to that of NODs, and like NODs, they are involved in innate immunity and cause NFkappaB and caspase-1 activation. PAAD stands for [pyrin, AIM (absent in melanoma), ASC (apoptosis-associated speck-like protein containing a CARD)], and DD stands for (death domain-like). Several of these proteins utilize the adaptor protein ASC. For example, the PAAD-only protein-1 (POP1/ASC2) on chromosome 16 associates with ASC via PAAD-PAAD interactions and modulates NFkappaB and procaspase-1 regulation by this adaptor protein (Stehlik et al. 2003b).

NODs in Human Disease

NOD-like receptors play an important role in numerous human diseases (review: Zhong et al. 2013). NOD1 plays an important role in host defense and recognizes the minimal components of bacterial cell wall peptidoglycans, meso-diaminopimelic acid and meso-lanthionine (Takada and Uehara 2006; Uehara et al. 2006). NOD1 is expressed within the eye and its activation results in uveitis in an IL-1beta-dependent mechanism (Rosenzweig et al. 2009). NOD2 (CARD15) is composed of two N-terminal CARDs, a nucleotide-binding domain, and multiple C-terminal leucine-rich repeats. It is predominantly present in the monocyte/macrophage system and is a receptor for the ligand muramyl dipeptide (Grimes et al. 2012; Mo et al. 2012). Binding of this ligand to the NOD2 receptor activates NFkappaB (Ogura et al. 2001). This pathway activates primary FOXP3+ T lymphocytes.

This activation is functionally relevant to cell survival, as muramyl dipeptide-stimulated human FOXP3+ T cells are protected from death receptor Fas-mediated apoptosis (Rahman et al. 2010). Activated NOD2 ordinarily downregulates responses to Toll-like receptor stimulation, and thus cells lacking NOD2 are expected to mount increased responses to such stimulation. NOD2 is notable that variants in the ligand recognition domain are associated with Crohn's disease and other disorders such as Blau syndrome (reviews: Strober et al. 2008; Tigno-Aranjuez and Abbott 2012). Gene-wide analyses of single nucleotide polymorphisms in inflammatory bowel diseases have uncovered consistent variants and mutations in the NOD2, CARD15, interleukin-23 receptor, and autophagy-related 16-like 1 (ATG16L1) genes (reviews: Grant et al. 2008; Yao 2013). In Crohn's disease, the disease-associated NOD2 polymorphism causes failure of apoptosis protection in muramyl dipeptide-stimulated FOXP3+ T cells (Rahman et al. 2010). NOD2 activates autophagy in a manner requiring ATG16L1, another Crohn's disease susceptibility gene. NOD2 autophagy induction is required for bacterial handling and MHC class II antigen presentation in dendritic cells. Dendritic cells from Crohn's disease patients having the NOD2 or ATG16L1 variant display reduced autophagy induction after NOD2 triggering resulting in impaired bacterial clearance (Brain et al. 2010). ATG16L1 and NOD2 interact in an autophagy-dependent antibacterial pathway, and this pathway is impaired in the presence of Crohn's disease-associated NOD2 variants (Homer et al. 2010).

Inflammasomes

Several members of the NLR family of sensors (see above) can form multiprotein complexes called inflammasomes that trigger the activation of the cysteine protease caspase-1. Inflammasomes are components of the innate immune system (reviews: Sutterwala et al. 2007; Brodsky and Monack 2009; Pedra et al. 2009; Lamkanfi and Dixit 2009; Schroeder and Tschopp 2010). The caspase-1 inflammasome has a central role in pathway mediating innate immunity (Yu and Finlay 2008). Cell death mediated by inflammasomes is called pyroptosis (Bortoluci and Medzhitov 2010). Autoproteolytic maturation of caspase-1 zymogens within these inflammasomes leads to maturation and secretion of the pro-inflammatory cytokines interleukin-1beta and interleukin-18. The NLR proteins ICE protease-activating factor (IPAF/CLAN/NLRC4; detecting bacterial flagellins), ASC, NLRP1b, NLRP3/cryopyrin, NLRP4, and AIM2 (absent in melanoma) assemble caspase-1-activating inflammasomes in a stimulus-dependent manner (Lamkanfi and Dixit 2009; Broz et al. 2010). Based on these components of the inflammasome supramolecular complex, several types of inflammasomes have been proposed, viz., ASC inflammasome, AIM2 inflammasome, NLRP inflammasomes, and the Ipaf/CLAN12/NLRC4 inflammasome.

The ASC inflammasome contains ASC (apoptosis-associated speck-like protein containing a CARD) which is an important adaptor protein of inflammasomes, but ASC can also prime T cells in an inflammasome-independent manner (Ippagunta et al. 2010). ASC has a bipartite structure, consisting of an N-terminal pyrin domain and a C-terminal caspase recruitment domain (CARD). The pyrin domain of ASC is known to interact with various pyrin domain-containing intracellular danger signal sensors and pyrin domain-only proteins, such as POP-1 (Srimathi et al. 2008). ASC bridges activated NLRs with caspase-1. It translocates from the nucleus to the cytosol in response to inflammatory stimulation in order to promote an inflammasome response. Several isoforms of ASC exert an important influence on inflammasome structure and dynamics. Full-length ASC and the isoform ASC-b co-localize with NLRP3 and caspase-1, while the isoform inhibiting inflammasome assembly, ASC-c, co-localizes only with caspase-1 but not with NLRP3 (Bryan et al. 2010).

The AIM2 inflammasome is mainly characterized by the action of AIM2 which can bind DNA and engages the caspase-1-activating adaptor protein ASC to form a caspase 1-activating inflammasome. In response to double-stranded

viral and bacterial DNA, AIM2 regulates caspase 1-dependent maturation of IL-1beta and IL-18, as well as pyroptosis (Rathinam et al. 2010). The NLRP1 (NALP1) inflammasome is characterized by the presence of NLRP1 and recruits ASC as well as capsase-1 and caspase-5. NLRP1 is directly activated by muramyl dipeptide. The NLRP1 inflammasome is widely expressed in many cell types but is highly expressed in immune cells, particularly T cells and Langerhans cells. The NLRP3 (NALP3/cryopyrin) inflammasome is comprised of NLRP3, ASC, caspase-1, CARDINAL, and pyrin protein (which contains a pyrin domain). NLRP3 is an intracellular adaptor of the caspase-1 inflammasome (Mariathasan 2007) and mediates caspase-1 activation in response to a wide variety of bacterial ligands, dsRNA, and the endogenous danger signal uric acid (Lamkanfi et al. 2007). The *Mycobacterium tuberculosis* protein, ESAT-6, is a potent activator of an infection-inducible inflammasome consisting of NLRP3, ASC, and caspase-1, promoting the secretion of IL-1 beta (Mishra et al. 2010). The NLRP3 inflammasome also functions as a negative regulator of tumorigenesis during colitis-associated cancer (Allen et al. 2010). Mutations in NLRP genes cause several clinical syndromes. Mutations of the NLRP1 locus is associated with vitiligo-associated autoimmune disease. CIITA mutations cause the bare lymphocyte syndrome, and NLRP7 mutations may induce hydatidiform moles. Most important are mutations of NLRP3 which have been associated with a group of autoinflammatory disorders termed the cryopyrin-associated periodic syndromes (CAPS, cryopyrinopathies). CAPS include familial cold autoinflammatory syndrome of Muckle-Wells syndrome and chronic infantile neurologic, cutaneous, and articular syndrome (CINCA/neonatal-onset multisystem inflammatory disease, NOMID). CINCA/NOMID and Muckle-Wells syndrome exhibit constitutive increases in the secretion of IL-1beta and IL-18. Mutations in other components of the NLRP3 inflammasome platform include pyrin (encoded by the MEFV gene), mutated in autosomal-recessive familial Mediterranean fever. Both the NRLP3 and MEFV genes were also associated with psoriatic juvenile idiopathic arthritis.

The Ipaf inflammasome contains Ipaf (CARD12 or CLAN; new designation: NLRC4; Sutterwala and Flavell 2009), which is homologous to NLRP1 and NLRP3. It forms an inflammasome in response to flagellin stimulation and activates caspase-1. The recognition of flagellin by Ipaf is a specific process in that a second flagellin sensor, TLR5, responds more generally to flagellated bacteria, whereas Ipaf responds to bacteria that express both flagellin and distinct virulence factors, such as the *Salmonella* virulence factor transport systems (SPI1 type III secretion system and the Dot/lcm type IV secretion system) (Miao et al. 2007; Miao and Warren 2010). The Ipaf inflammasome contains a CARD domain, a central NACHT domain, and a C-terminal LRR, and activation of this complex induces the combined activation of the TLR and NLR pathways.

Pyroptosis (Pro-inflammatory Programmed Cell Death) and the Pyroptosome

Pyroptosis is a distinct form of programmed cell death that occurs by the action of inflammasomes. The term pyroptosis has been proposed from the Greek roots pyro, relating to fire or fever, and ptosis, denoting falling (Cookson and Brennan 2001; reviews: Fink and Cookson 2005; Bortoluci and Medzhitov 2010; Kepp et al. 2010). The mechanism and its components are packed in a subtype of the inflammasome termed pyroptosome. In contrast to apoptosis, pyroptosis requires the function of caspase-1, which is activated during pyroptosis by a large supramolecular complex termed the pyroptosome. Only one large pyroptosome is formed in each macrophage within minutes after infection, mainly with *Salmonella* and *Shigella*.

Hepatobiliary Manifestations of Chronic Granulomatous Diseases of Childhood

140

Contents

Abstract

The recurrent bacterial and fungal infections that complicate chronic granulomatous disease (CGD) can involve the hepatobiliary tract and induce abscesses and obstructing lesions. CGD is a heterogeneous group of primary immunodeficiency diseases, whereby phagocytes fail to kill certain bacteria and fungi after phagocytosis. CGD is a hereditary defect characterized by deficient production of reactive oxygen metabolites required to destroy intracellular microorganisms. This failure is related to several defects in NADPH oxidase. Pediatric patients with CGD frequently show hepatomegaly and bacterial liver abscesses, which are a clinical hallmark of CGD. The frequent and complex infections can also induce hepatobiliary granulomas and their secondary effects. Venopathy of portal vein branches is common in CGD and is associated with portal hypertension and splenomegaly.

Chronic Granulomatous Disease

Introduction

Chronic granulomatous disease (CGD; Bridges-Good syndrome; Quie syndrome; chronic granulomatous disorder; OMIM 306400; ICD-9: 288.1, ICD-10: D71) is a heterogeneous group of primary immunodeficiency diseases. In CGD, phagocytes fail to kill certain bacteria and fungi

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_140

after phagocytosis caused by a genetically defective respiratory burst (Berendes et al. 1957; Landing and Shirkey 1957; Bridges et al. 1959). Patients with CGD typically suffer from recurrent bacterial and fungal infections involving lungs, lymph nodes, soft tissue, bones, and liver (reviews: Segal et al. 2000; Heyworth et al. 2003; Loffredo 2011; Song et al. 2011).

Epidemiology

Based on a US registry, the minimum estimate of incidence was 1/200,000–1/250,000 live births, with about 20 new cases diagnosed each year (Winkelstein et al. 2000; Heyworth et al. 2003).

Clinical Manifestations

The clinical presentation of CGD is dominated by recurrent bacterial and fungal infections, excessive inflammation, and the sequelae of granuloma formation, related to phagocyte failure (Rosenzweig and Holland 2004; Khanna et al. 2005; Antachopoulos et al. 2007). Patients with CGD are particularly susceptible to catalase-positive microorganisms and certain Gram-negative bacteria (Ben-Ari et al. 2012) and often develop pneumonia, lymphadenitis, liver abscess, osteomyelitis, purulent dermatitis, and cellulitis.

The leading bacteria in CGD infections are *Staphylococcus aureus*, *Serratia marcescens*, *Streptococcus*, *Salmonella* species, *Klebsiella* species, *Pseudomonas* (*Burkholderia*) *cepacia*, *Psychrobacter immobilis*, and *Nocardia*, while the most important fungi include *Aspergillus fumigatus* and *Candida albicans* (Ben-Ari et al. 2012; Falcone et al. 2012; Sriaroon et al. 2014). In a large study, pneumonia was the most prevalent infectious disease (79 %), with *Aspergillus* being the most common infectious agent identified, followed by suppurative lymphadenitis (53 %, *Staphylococcus* the most prevalent cause), subcutaneous abscesses (42 %, mostly caused by *Staphylococcus*), liver abscess (27 %, again *Staphylococcus* the prevalent cause), and osteomyelitis (25 %, most often caused by *Serratia*) (Winkelstein et al. 2000). CGD can also promote mycobacterial infections, including *Mycobacterium fortuitum* and *M. avium* infections, disseminated *Mycobacterium flavescens* infection, and especially generalized BCGosis/BCGitis (review of the literature: Bustamante et al. 2007), the phagocytic respiratory burst playing an important role in the antimycobacterial defense (Lau et al. 1998). X-linked CGD has been reported to closely mimic juvenile sarcoidosis, with cervical and pulmonary granulomatous lymphadenopathy and high angiotensin-converting enzyme (Brunner et al. 2007). CGD is also characterized by exuberant inflammatory reactions and autoimmune phenomena, attributed to deficient anti-inflammatory signaling. For example, patients with CGD can develop an inflammatory bowel disease resembling Crohn's disease (Marciano et al. 2004; Marks et al. 2009). It has been suggested that impaired apoptotic cell clearance (efferocytosis) in CGD due to macrophage skewing contributes to enhanced inflammation, due to altered IL-4-dependent macrophage programming (Fernandez-Boyanapalli et al. 2009; review: Rieber et al. 2012). In addition, neutrophils from CGD patients only weakly inhibit gamma-delta T cells, while normal neutrophils are known to potently suppress gamma-delta T cell function (Sabbione et al. 2014).

Hepatic Manifestations of Granulomatous Disease

Hepatic Abscesses

Hepatosplenomegaly is present in up to 90 % of patients with CGD. Bacterial liver abscesses are a clinical hallmark of CGD (Chusid 1978; Mulholland et al. 1983; Lublin et al. 2002; Mamishi et al. 2011; Leiding et al. 2012; Székely et al. 2012). A hepatic abscess may be part of the initial presentation of CDG or may develop years after the diagnosis of CGD had been made. CGD can present as recurrent hepatic abscess in adult patients (Al-Khuwaitir et al. 2007). As found in a study on 368 patients, liver abscess was the most common hepatic manifestation of CGD (27 %), mostly caused by *Staphylococcus aureus*

(Winkelstein et al. 2000). In a study of 429 patients with CGD, liver involvement was found in 32 % of the patients (van den Berg et al. 2009). In contrast to sporadic liver abscess, which typically occurs as a single event and shows on CT images a thin enhancing rim with an internal liquefied, non-enhancing material, hepatic abscesses in CGD are often multiple lesions and have the tendency to remain enhancing without liquefaction (Garcia-Eulate et al. 2006). In fact, persistence of hepatic abscesses is a frequent phenomenon in CGD (Lublin et al. 2002). Macroscopically, abscesses often show multiple lobulated gray-to-yellow foci of up to several cm diameter. The lobulated areas have cavities filled with thick, purulent material typical for pus seen in staphylococcal infections, peripherally delimitated by granulation tissue and a fibrous reaction. Histologically, the abscesses show a purulent center with damaged neutrophil granulocytes, necrotic cell debris, fibrin-rich exudate, and macrophages. The periphery exhibits a demarcation zone composed of granulation tissue, an infiltrate of in part foamy macrophages, few epithelioid cells, lymphocytes, and plasma cells. In the vicinity of the abscess, macrophages with a ceroid-like, PAS-positive yellow-brown pigment may be seen.

Hepatic Granulomas in CGD

In a study of seven patients with CGD, with an age range of 5–41 years, hepatic histology was analyzed by biopsy or wedge resection in five and by autopsy in three cases. Histologically, the most consistent finding was the presence of foamy macrophages that contained a finely granular golden brown pigment, predominantly present in the portal tracts but also within the lobules. The presence of pigmented lipid-laden macrophages/histiocytes in the viscera was already noted in one of the first reports of CGD (Landing and Shirkey 1957). Four cases showed palisading granulomas with a giant cell reaction and central necrosis, lesions resembling *Candida* granulomas, and in part of these cases cultures for *Staphylococcus aureus* were positive. One case exhibited hyalinized portal tract and intralobular granulomas (Nakhleh et al. 1992). Among seven liver biopsies obtained from four pediatric patients with CGD, one biopsy showed granulomas and a second numerous classical pigmented macrophages in the sinusoids (Levine et al. 2005). In an analysis of the charts of 194 patients with CGD, liver abscess occurred in 35 %, and bioptic liver histology showed granulomas in 75 % and lobular hepatitis in 90 % of the specimens (Hussain et al. 2007).

Hepatic Vascular Anomalies in CGD

Venopathy of portal vein branches is common in CGD (80 %) and is associated with portal hypertension and splenomegaly. Venopathy of the central vein was also frequent (63 %) and was associated with the number of abscess episodes. Nodular regenerative hyperplasia (NRH) was seen in nine patients (Hussain et al. 2007). Mortality in CGD patients is associated with the development of non-cirrhotic portal hypertension (Feld et al. 2008). As in other disorders, NRH in CGD is likely to be caused by the vascular anomalies.

Differential Diagnosis

Combined immunodeficiency with autoimmune features caused by RAG1 mutations can evolve into a disorder resembling CGD (Reiff et al. 2013).

Molecular Mechanisms of Granulomatous Diseases

CGD is a hereditary defect of leukocyte function (Good et al. 1968) and is caused by the inability of phagocytes (neutrophils, monocytes, macrophages, eosinophils) to generate sufficient amounts of reactive oxygen metabolites required to kill microorganisms subsequent to their phagocytosis. This failure is caused by several defects of NADPH oxidase (Babior 2004), the key enzyme for this sequence of reactions (reviews: Curnutte 1993; Meischl and Roos 1998; Morel 2007). The superoxide-generating respiratory-burst oxidase

(NADPH oxidase) makes part of an enzyme complex that catalyzes the NADPH-dependent reduction of oxygen into the superoxide anion in phagocytic cells. The superoxide anion then generates other antimicrobial reactive oxygen intermediates, including H2O2, hydroxyl anion, and peroxynitrite anion. The activation of NADPH oxidase requires the translocation of the cytosolic enzyme subunits p47phox (phagocyte oxidase), p67phox, and the low molecular weight GTPase Rac to the membrane-bound flavocytochrome b558, a heterodimer consisting of the heavy chain gp91phox and the light chain p22phox (Leusen et al. 1996). The resulting enzyme complex transfers electrons from NADPH on the cytoplasmic side to oxygen on the vacuolar or extracellular side, thereby creating superoxide anions, the gp91phox subunit thought to contain the electron transport machinery of the oxidase as well as the NADPH- and FAD-binding sites (reviews: Segal et al. 2000; Vignais 2002). Phagocytic NADPH oxidase activity is regulated by phosphorylation of gp91phox/NOX2 by protein kinase C, which enhances its diaphorase activity and binding to Rac2, p67phox, and p47phox (Raad et al. 2009). In 1966, Holmes et al. detected an abnormality of phagocyte function in CGD (Holmes et al. 1966), while Quie et al. in 1967 demonstrated defective in vitro killing of bacteria by phagocytes obtained from CGD patients (Quie et al. 1967). Also in 1967, Bahner et al. reported a defective reduction of nitroblue tetrazolium by CGD phagocytes, proposing this phenomenon as a diagnostic test (Baehner et al. 1967). In 1968, a deficiency of reduced nicotinamide-adenine dinucleotide oxidase as a cause of CGD was found (Baehner and Karnovsky 1968). Subsequently, defective superoxide production from phagocytes in CGD was shown (Curnutte et al. 1974). The deficiency of the leukocyte oxidative burst in CGD favors infections above all with Gram-positive bacteria (Kaplan et al. 1968) and fungi (Kim et al. 1969). Defective NADPH oxidase expression in CGD was confirmed in 1975 (Hohn and Lehrer 1975), and the defective gene in X-linked CGD assigned to chromosome Xp21 (Segal 1987). The four components of the NADPH complex implicated in CGD are gp91phox, p22phox, p47phox, and p67phox. The X-linked variant of CGD is by far the most common (70 % of all cases of CGD), resulting in a greater number of affected males, but females with X-linked CGD are also known, attributed to skewed X inactivation. X-linked CGD is caused by alterations in the gp91phox gene (the CYBB gene localized to chromosome Xp21.1). It can involve deletions, frameshift, missense, nonsense, null, splice site, and intronic mutations of the CYBB gene (Noack et al. 2001; Brunner et al. 2007; Lewis et al. 2008; review: Song et al. 2011). Larger X-chromosomal deletions of the critical area cause the so-called contiguous gene syndrome, resulting in associations of the Kell phenotype (McLeod syndrome with X-linked CGD, Duchenne muscular dystrophy, and X-linked retinitis pigmentosa). X-linked CGD portends a worse prognosis with a higher annual mortality compared with the other genotypes.

Autosomal recessive CGD has been found to be caused by mutations of the p91phox (Umei et al. 1987), p22phox gene (Umei et al. 1987), p47phox gene (NCF1; Curnutte et al. 1987), and p67phox gene (Umei et al. 1987; Shamsian et al. 2008; van de Vosse et al. 2009).

Diffuse Hepatic Granulomatous Infiltration Syndrome

Introduction

In rare instances where the liver substance is heavily infiltrated by a granulomatous reaction in the absence of known causes of granulomatous hepatitis, including sarcoidosis, these alterations may be difficult to distinguish from a malignant process replacing the parenchyma.

Granulomatous infiltration of unknown cause with replacement of liver parenchyma has first been described in a 76-year-old man who had presented with fever, weight loss, and abnormal liver function tests (Millson et al. 2007). Ultrasound of the liver showed diffuse hepatomegaly, and MRI demonstrated a diffusely abnormal liver.

Pathology

Liver biopsies exhibited a granulomatous process that diffusely infiltrated and replaced the hepatic parenchyma, leaving portal areas and efferent veins in their original positions. Some granulomas had central necrosis, and most showed a peripheral zone of often large multinucleated pigmented CD68-positive epithelioid macrophages, becoming gradually replaced by loose fibrous tissue toward the center of the lesions. Obliterated efferent veins were found within the lesion, the obliteration being caused by an intimal fibrous thickening. The changes regressed after steroid therapy (Millson et al. 2007). A similar disorder had previously been reported, characterized by widespread granulomatous lesions in the liver and pure intrahepatic granulomatous venulitis, but tuberculosis and sarcoidosis were not formally excluded in this 72-year-old male patient (Nakanuma et al. 1980).

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_141

Abstract

A spectrum of idiopathic tumor-like fibrosclerotic lesions can involve the biliary tract and cause stenotic lesions. Idiopathic retroperitoneal fibrosis denotes a group of still not well-defined disorders that include Albarran-Ormond syndrome, chronic periaortitis, inflammatory aortic aneurysms, sclerosing mesenteritis, sclerosing mediastinitis, orbital pseudotumor, and Riedel's thyroiditis. The mass-producing effect of fibrosing processes taking place in the retroperitoneal space or the mesentery can encroach upon the extrahepatic biliary tree and result in biliary obstruction. A second group of conditions is summarized under the term IgG4-related sclerosing disease, characterized by infiltrations of IgG4-expressing plasma cells associated with a chronic fibrosclerosing process. In the hepatobiliary tract, these disorders mainly present as IgG4-related cholangitis, IgG4-realted pseudotumors, and bile duct alterations secondary to IgG4-related autoimmune pancreatitis.

Hepatobiliary Involvement in Idiopathic Retroperitoneal Fibrosis and Related Disorders

Introduction

Idiopathic retroperitoneal fibrosis (IRPF; Albarran-Ormond syndrome; Gerota syndrome; Ormond's disease; fibrous retroperitonitis) denotes a group of progressive fibrosclerotic disorders now characterized by the development of fibrosis in several tissue compartments, i.e., not only in the retroperitoneal space as was previously thought. The eponyms associated with idiopathic retroperitoneal fibrosis (Albarran-Ormond syndrome and Gerota syndrome or Gerota's fasciitis) are John Kelso Ormond (1886–1978), an American urologist; Joaquin Maria Albarran y Dominguez (1860–1912), a Cuban urologist; and Dimitrie D. Gerota (1867–1939), a Romanian anatomist and surgeon. Dr. Albarran y Dominguez studied histology with Louis-Antoine Ranvier (Ranvier's nodes), and together with Halle, he described the Bacillus pyogenes, later to be named Bacterium coli. In 1906 he became the chairman of the Clinic of Urology at the Paris Necker Hospital and described the periureteric lesions found in the syndrome in 1905 (Albarran 1905). Ormond also published his findings based on the ureteral involvement in the disease in question (Ormond 1948). He summarized the main features of the syndrome in 1965, naming the condition idiopathic retroperitoneal fibrosis (Ormond 1965). Dr. Gerota was, in addition to his function as a professor of surgical anatomy and experimental surgery, also a professor at the Art Academy of Bucharest and teacher to the well-known sculptor Constantin Brancusi. Together, they performed the famous carved muscles study known as The Ecorché (1905). Gerota's fascia is named after him. Since the first descriptions of the condition, it has been recognized that retroperitoneal fibrosis and its variants makes part of a group of what is now called fibroinflammatory disorders, comprising retroperitoneal fibrosis sensu strictiori, chronic periaortitis and part of inflammatory aortic aneurysms, sclerosing mediastinitis, sclerosing mesenteritis, orbital pseudotumor, and Riedel's thyroiditis (reviews: Dehner and Coffin 1998; Alberti 2007). Fibrotic processes in the retroperitoneal space and the aortic/periaortic compartment are now recognized to cover an entire spectrum of lesions (Bulkley 1960; Sethia and Darke 1983; Mitchinson 1984, 1986; Martina et al. 1993; Amiya et al. 2005; Table 1).

Table 1 Idiopathic retroperitoneal fibrosis (IRPF) and the spectrum of fibroinflammatory disorders

Idiopathic retroperitoneal fibrosis sensu strictiori (Albarran-Ormond syndrome)
Chronic periaortitis/perianeurysmal retroperitoneal fibrosis
Inflammatory aortic aneurysms
Sclerosing mesenteritis
Sclerosing mediastinitis
Orbital pseudotumor
Riedel's thyroiditis
Several lesions from the spectrum of systemic IgG4-related sclerosing disease

More recently, chronic periaortitis has been proposed to represent a term under which the several manifestations of the disease may be listed, including idiopathic retroperitoneal fibrosis (the previous Albarran-Ormond or Gerota syndromes), perianeurysmal retroperitoneal fibrosis, and inflammatory abdominal aortic aneurysm (Jois et al. 2004; Vaglio and Buzio 2005; Vaglio et al. 2006a, 2007).

Fibroinflammatory Disorders Are Often Manifestations of Systemic IgG4-Related Sclerosing Disease

The aetiology and pathogenesis of the retroperitoneal fibrosis complex are only partially clarified. It has been reported that asbestos exposure is a risk factor for idiopathic retroperitoneal fibrosis. In addition, an increasing number of studies showed an association between these fibrotic disorders and autoimmune processes (Vaglio et al. 2003, 2006b). At least part of these conditions are pathogenetically related to an entity termed, IgG4-related autoimmune disease (IgG4-associated multifocal systemic fibrosclerosis; IgG4-related sclerosing disease; systemic IgG4-related plasmacytic syndrome, SIPS; Hyper-IgG4 disease; Neild et al. 2006). In this disorder, a moderate to marked infiltration of IgG4-positive plasma cells together with CD4- and/or CD8-positive T lymphocytes is noted in the target tissues, including peripancreatic, retroperitoneal, lung, salivary gland, and large bile duct tissues (-Kamisawa et al. 2003a; Hamed et al. 2007). Retroperitoneal fibrosis and chronic periaortitis develop in conjunction with the IgG4-related autoimmune disease (Yamashita et al. 2008), and a subset of inflammatory abdominal aortic aneurysms has a close relationship to IgG4-related periaortitis (Kasashima et al. 2008; Matsumoto et al. 2008; Sakata et al. 2008).

Pathology

The macroscopic presentation of retroperitoneal fibrosis is most frequently that of a firm or rubbery, unencapsulated fibrous plaque or flat mass of gray to whitish color, this mat with indistinct borders being sometimes several centimeters thick, firmly adherent to the posterior peritoneum and displacing it anteriorly. The main portion of the plaque is commonly at the level of the sacral promontorium, with variable extension upward and to the sides. Typically, the process envelopes the retroperitoneal structures, in particular the large- and medium-sized vessels and the ureters, but it may also involve the extrahepatic bile ducts.

Histologically, the tissue shows a chronic inflammation with lymphocytes, macrophages, and plasma cell infiltrates of variable density associated with fibrosis, which is cellular in early or active phases and later becomes hypocellular and sclerotic. The lymphocytic infiltrates are chiefly located around blood vessels, often with central core of CD20-positive B cells and a peripheral zone of CD3-positive T cells. Generally, T cells predominate in diffuse lymphocyte infiltrates (Corradi et al. 2007). Eosinophil and neutrophil granulocytes are present in variable numbers. In some phase of the disease, macrophages (in part foamy cells) predominate (Hughes and Buckley 1993). In the setting of adipose tissue invasion/replacement by the fibrotic process, lipogranulomas can develop. In cases associated with IgG4-related multifocal fibrosclerosis, many of the plasma cells are IgG4 positive and usually occur together with T lymphocytes, both CD4- and CD8-positive. In regard to mesenchymal cells found in the lesions of the disease spectrum, it has been suggested that myofibroblasts are involved in the development of inflammatory aortic aneurysm (Sakata et al. 2007).

Bile Duct Involvement in Idiopathic Retroperitoneal Fibrosis

The mass-producing process of IRPF can encroach upon the extrahepatic biliary system and sometimes mimic bile duct cancer. In the course of anterior extension of fibrosclerosis, it can involve the tissue of the hepatoduodenal ligament, the peripancreatic tissue, and tissues of the hepatic hilum, thus causing encasement and stenosis of extrahepatic bile ducts and leading to biliary obstruction with jaundice.

Selected References Hardy (1962), Schneider (1964), Renner et al. (1980), Lundström (1983), Wetter et al. (1991), Laitt et al. (1992), Cappell (1994), Chutaputti et al. (1995), Pereira-Lima et al. (1996), Dejaco et al. (1999), Lechiche et al. (2001), Tamura et al. (2003), Zhao et al. (2004), Fukui et al. (2005), Kamisawa et al. (2006a), Matsushita et al. (2009), and Quante et al. (2006).

The necropsy case of Schneider (1964) showed a plaque-like mass which completely surrounded several large retroperitoneal vessels, both ureters, body and head of the pancreas, the retroperitoneal part of the duodenum, and the distal end of the common bile duct. The liver was described as green owing to biliary obstruction. The 46-year-old male patient described by Dejaco et al. (1999) was presented with jaundice, and ultrasonography revealed a solid tumor in the porta hepatis about 2 cm in diameter and dilated intrahepatic bile ducts. Subsequent ERCP demonstrated a stenosis of the common bile duct, and a presumptive diagnosis of Klatskin tumor was made. Resection of the lesion histologically showed a manifestation of Ormond's disease, with chronic inflammatory and fibrotic fatty tissue surrounding a narrowed bile duct. Quante et al. (2006) described involvement of the hepatic ducts by the fibrotic process, causing a duct stricture suggesting malignancy. Extrahepatic bile duct stenosis caused by retroperitoneal fibrosis may thus mimic sclerosing cholangiocarcinoma (Klatskin tumor; Wetter et al. 1991; Dejaco et al. 1999). Apart from large bile ducts, extending retroperitoneal fibrosis may also compromise the venous inflow tract of the liver, causing portal hypertension and hypoplasia (or rather atrophy) of a liver lobe (Hisatomi et al. 2004).

IRPF can involve the pancreas and the peripancreatic tissues and subsequently the distal-most part of the common bile duct, causing biliary obstruction (Cappell 1994). In some cases, IRPF encased the pancreatic head, with formation of firm and grayish-white tissue that compressed the distal bile duct, or with generation of a fibrous pseudotumor (Chutaputti et al. 1995; Zhao et al. 2004). Apart from autoimmune pancreatitis, autoimmune disorders of bile ducts, in part related to IgG4 disease, occur in the setting of IRPF. The process can be associated with primary biliary cirrhosis (Sevenet et al. 1985), primary sclerosing cholangitis (Hellstrom and Perez-Stable 1966; Laitt et al. 1992; De Suray et al. 2009), and hepatobiliary inflammatory pseudotumors (De Suray et al. 2009). Also IRPF with concomitant autoimmune pancreatitis has been found to be associated with sclerosing cholangitis (Alpert and Jindrak 1972; Fukui et al. 2005).

Chronic periaortitis (or perianeurysmal retroperitoneal fibrosis) has been observed to sometimes be complicated by common bile duct obstruction (Quante et al. 1991; Remedios et al. 1991). In the 67-year-old female patient reported by Remedios and coworkers, an inflammatory abdominal aortic aneurysm with surrounding retroperitoneal fibrosis was resected. The patient died of a ruptured perinephric abscess, and autopsy revealed a firm 4 cm mass in the pancreatic head severely constricting the pancreatic duct and infiltrating part of the wall of the common bile duct adjacent to the ampulla. Histology of the mass showed extensive dense fibrosis in the peripancreatic tissue adjacent to the site of the previously resected inflammatory aneurysm (Remedios et al. 1991).

Bile Duct Disease in Sclerosing Mesenteritis

Sclerosing mesenteritis has rarely been found to be associated with an idiopathic form of stenosing bile duct fibrosis closely mimicking hilar/perihilar cholangiocarcinoma (Klatskin tumor; Medina-Franco et al. 2001). In this 64-year-old jaundiced male patient, abdominal ultrasound showed intrahepatic biliary dilatation without extrahepatic dilatation. ERCP demonstrated a hilar stricture compatible with Klatskin tumor. Dynamic contrast-enhanced helical CT scans revealed focal thickening of extrahepatic bile ducts as well as an infiltrative mass measuring 8.4 × 4.6 cm in the root of the mesentery. Laparotomy showed a dense infiltration in the proximal mesentery, extending to the hepatic hilar region. Histologically, the mesenteric lesion was sclerosing

mesenteritis, and the bile duct was extensively encased by this inflamed sclerotic tissue.

What Is Sclerosing Mesenteritis?

Sclerosing mesenteritis (SCM), first described in 1924 (Jura 1924), is known in the literature under several other terms, including retractile mesenteritis, fibrosing mesenteritis, liposclerotic mesenteritis, xanthogranulomatous mesenteritis, mesenteric lipodystrophy, mesenteric lipogranuloma, and mesenteric panniculitis (Panniculitis mesenterialis). Jura (1924) already employed the term, retractile and sclerosing mesenteritis (in the Italian publication: mesenterite retrattile e sclerosante). These different terms have caused considerable confusion, but they are currently thought to reflect different evolution phases and/or severity grades of the same disease process (Durst et al. 1977; Ghosh and Kum 2007). It is a chronic inflammatory process of unknown aetiology, located to the mesenteric adipose tissue (more frequently involving the small bowel meso than the colonic meso; in the small bowel mesenterium chiefly the mesenteric root), with a tendency to progress to extensive lipofibrosis or liposclerosis. The disease rarely involves the peripancreatic tissue, the omentum, or the pelvic adipose tissue. The disease may occur in conjunction with retroperitoneal fibrosis, which in this disease most probably reflects an extension of the disease from the mesenteric root to the retroperitoneal space (Sabaté et al. 1999). Peripancreatic involvement may cause the clinical presentation of pancreatic pseudotumor (Sheikh et al. 1999). That SCM may belong to the spectrum of multiorgan fibrosclerosing disorders is supported by the observation that SCM occurs in conjunction with idiopathic orbital inflammation (Sharma et al. 2006). The incidence of the disorder is not known, but postmortem studies have reported an incidence of up to 1 % (Streuli and Stamm 1994). The peak incidence is in the sixth to seventh decades, and males are more frequently affected than females (2:1). Patients usually present with abdominal discomfort or pain, nausea, weight loss, and, less commonly, fever of unknown origin. Probably caused by remodeling of the mesenteric lymph vessels by the inflammatory process, multiple mesenteric lymphatic cysts (Johnson et al. 1997) and/or chylous ascites may develop (Ehrenpreis et al. 2008). SCM may produce tumor-like mesenteric lesions; a palpable mass has been reported to be found in 50 % of the patients. The etiology and pathogenesis of SCM remain unclear. Potential causes that have been discussed include autoimmune causes, infections, and vascular disorders.

Idiopathic Sclerosing Peritonitis

Idiopathic sclerosing (encapsulating) peritonitis (idiopathic encapsulating peritonitis; abdominal cocoon syndrome) is a rare condition characterized by intraperitoneal fibrosclerosis, mainly reported in young adolescent women as a cause of small bowel obstruction. In this disorder, which can be associated with ascites, the small bowel is encased in an encapsulating fibrous sac or saclike membrane termed abdominal cocoon (Masuda et al. 1993). The firm nacreous fibrotic membrane may wrap the intestine in a concertina-like fashion (Da Luz et al. 2011). Apart from the idiopathic form, secondary sclerosing peritonitis occurs to be caused by intraperitoneal chemotherapy, peritoneal dialysis, practolol therapy, meconium peritonitis, tuberculous peritonitis, or the positioning of a peritoneal-jugular shunt in cirrhotic patients with refractory ascites (reviews: Cleffken et al. 2008; Minutolo et al. 2008). The idiopathic form, which is the main cause of abdominal cocoon, was first described in 1978 based on observation on ten girls with a narrow age range of 13–18 years (Foo et al. 1978). As the fibrous cocoon is associated with extensive adhesions, it may be expected that the structure of the hepatoduodenal ligament can be compromised.

Segmental Pericholangial Fibrosis

This is a rare benign fibrotic disorder observed in a child who underwent surgery to remove a hepatic hilar mass suspected to be malignant. It represents a fibrous disorder of unknown etiology located to the bifurcation of the hepatic duct, where the bile

duct wall and the surrounding tissue were markedly fibrotic. Histologically the resected lesion was characterized by a loose connective tissue containing myofibroblasts and chronic inflammatory cells, while more advanced fibrosis was noted in the adjacent soft tissues (Takabe et al. 1997). The potential relationship of this disorder to the spectrum of IRPF is currently unknown.

Fibrosing Thyroid Disease and Sclerosing Cholangitis

Riedel's thyroiditis, an IgG4-related disorder with or without associated multisystemic sclerosis (Dahlgren et al. 2010), may be combined with sclerosing cholangitis (Bartholomew et al. 1963; Brihaye et al. 2008).

IgG4-Related Disease of the Hepatobiliary Tract

Introduction

IgG4-related disease (synonyms: IgG4-related systemic disease; IgG4 syndrome; IgG4-related sclerosing disease; IgG4-reated systemic sclerosing disease; multifocal fibrosclerosis) is a systemic disorder that is characterized by extensive IgG4-positive plasma cells and T-lymphocyte infiltration of various organs, followed by a variable fibrosing process and obliterative phlebitis of the target tissues (reviews: Bateman and Deheragoda 2009; Cheuk and Chan 2010; Okazaki et al. 2010; Sato et al. 2010; Takahashi et al. 2010; Khosroshahi and Stone 2011a, b; Smyrk 2011; Zen and Nakanuma 2011; Carruthers et al. 2012; Divatia et al. 2012; Stone 2013; Mahajan et al. 2014). The disease was first identified based on the observation that patients with sclerosing pancreatitis (now autoimmune pancreatitis) have high serum IgG4 concentrations (Hamano et al. 2001) and that autoimmune pancreatitis is characterized by the presence of numerous IgG4+ plasma cells (Hamano et al. 2002). Clinical manifestations mainly involve the pancreas, the biliary tract, and the salivary glands, but also the retroperitoneal tissues, kidney, lung, prostate, and numerous other organs and tissues (review: Kamisawa and Okamoto 2008). The disorder has also been termed multifocal idiopathic fibrosclerosis, IgG4-related sclerosing disease, IgG4-related systemic disease, IgG4-related autoimmune disease, IgG4-related syndrome, IgG4-related plasmacytic syndrome (SIPS), and IgG4-related multiorgan lymphoproliferative syndrome. Also the term, hyper-IgG4 disease, has been proposed (Neild et al. 2006). The Japanese Research Committee for Systemic IgG4-related Sclerosing Disease appointed the term, IgG4-related disease, as a minimal consensus to all conditions of the disorder (review: Okazaki et al. 2010). The disorder is usually associated with an elevation of serum IgG4 levels, and the serial measurement of these levels is useful to determine the disease activity (Tabata et al. 2011). IgG4-related disease manifesting in the biliary tract is typically associated with stenosing duct lesions that mimic malignancy. On the other hand, IgG4-related disease of the pancreas and bile ducts cause significant morbidity, organ dysfunction, and malignancy (Huggett et al. 2014). The clinical entities associated with this disease are numerous, and a selection is shown in the Table 2. In all of these disease entities, the presence of IgG4-containing plasma cells in the lesions is a characteristic and diagnostically significant feature (Deheragoda et al. 2007).

Chronic rhinosinusitis
Thoracic organs
IgG4-related thyroiditis
IgG4-related esophagitis
Mediastinal fibrosis
Interstitial pneumonia (IgG4-positive pulmonary disease)
Cardiovascular system
Thoracic inflammatory aortic disease
Inflammatory aortic aneurysm
IgG4-related arteritis and periarteritis
IgG4-related pericarditis
Abdominal organs
IgG4-related autoimmune pancreatitis
IgG4-related cholangitis/cholangiopathy
IgG4-related hepatobiliary pseudotumors
Sclerosing mesenteritis
IgG4-related inflammatory bowel disease
Retroperitoneal space
Retroperitoneal fibrosis
Genitourinary tract
Tubulointerstitial nephritis
Ureteral inflammatory pseudotumor
IgG4-related epididymo-orchitis
IgG4-related prostatitis
Skin and associated structures
IgG4-related skin diseases
IgG4-related mastitis
Skeletal-articular system
IgG4-related arthritis
Peripheral nervous system
Perineural IgG4(+) plasma cell infiltration
Lymphoreticular system
IgG4-related lymphadenopathy

comprises primary sclerosing cholangitis (PSC), autoimmune-related SC, and secondary sclerosing cholangitis (SSC) caused by stenosing lesions of the biliary tract. One subset of autoimmune-related SC is associated with or caused by IgG4-related disease, with or without other manifestations of this disorder (IgG4-SC; Hamano et al. 2005; Hamed et al. 2007; Hayashi et al. 2007; Nakanuma and Zen 2007; Cheung and Lo 2008; Erdogan et al. 2008; Alderlieste et al. 2009; Fujita et al. 2010; Mizutani et al. 2012; Naitoh et al. 2012; Nakazawa et al. 2012, 2013; Novotny et al. 2012; Nowatari et al. 2012; Boonstra et al. 2014; Saito et al. 2013; Silveira 2013; Graham et al. 2014; Joshi and Webster 2014; Okazaki et al. 2014). The diagnostic criteria for this distinct type of cholangiopathy have recently been reviewed (Ohara et al. 2012). IgG4-SC typically affects patients 60–80 years old, 80–85 % being male, and usually manifests as obstructive jaundice and organ swelling mimicking cancer (Beuers et al. 2014). This type of SC is mostly found in conjunction with autoimmune pancreatitis (AIP) discussed in the following paragraph and may be associated with other IgG4-related disorders, such as retroperitoneal fibrosis and sclerosing sialadenitis (Hamed et al. 2007). IgG4-related SC without pancreatic manifestations is rare. Even less common are types of autoimmune but non-AIP-related SC without elevation of serum IgG4 (Sawai et al. 2011). IgG4-SC can clinically and radiologically mimic hilar cholangiocarcinoma/Klatskin tumor (Hamano et al. 2005; Cheung and Lo 2008; Nguyen-tat et al. 2012; Tabata et al. 2013) or other cholangiocarcinomas (Lytras et al. 2012; Maeda and Shimada 2012) and, in case of lesions in the distal common bile duct, resemble ampullary cancer (Aomatsu et al. 2012). Intrahepatic IgG4-related SC can result in sepsis caused by secondary suppurative cholangitis and can sometimes result in recurrent liver failure (Clendenon et al. 2011). The disorder is sometimes associated with hepatic inflammatory pseudotumors (Zen et al. 2004). IgG4-SC may show similar manifestations as eosinophilic cholangitis (Iwamuro et al. 2009). The disorder can be associated with other lesions found in IgG4-related sclerosing disease, such as autoimmune pancreatitis/AIP (discussed in the following paragraph), retroperitoneal fibrosis, and sclerosing sialadenitis (Hamed et al. 2007). IgG4-related SC has been observed together with

retroperitoneal fibrosis in the absence of AIP (Miura and Miyachi 2009; Rompa et al. 2010). Similar to type 1 autoimmune pancreatitis, IgG4-SC is associated with significant morbidity and mortality due to malignancy and organ failure involving the liver, kidney, and brain. In one study, malignancy occurred in 11 % shortly before or after the diagnosis of IgG4-related disease, with development of pancreatobiliary cancers (Huggett et al. 2014).

IgG4-SC presents with a characteristic pathology. Similar to PSC, bile ducts show a chronic fibrosclerosing process that results in marked stenosis of the involved parts. In the patients reported by Hamano and coworkers (Hamano et al. 2005), ERCP showed long-segment, smooth narrowing of the common bile duct, and in one case MRI revealed a mass-like lesion around the common bile duct that involved the portal vein. In contrast to PSC, where cellular infiltrates in the florid inflammatory phase are mainly lymphocytes, IgG4-SC shows IgG4-expressing plasma cells at high density, typically >50 IgG4-positive cells per high-powered field. In part of patients, dense infiltrates of IgG4-positive plasma cells were noted in portal tracts and associated with destructive cholangitis, suggesting an overlap between IgG4-SC and primary biliary cirrhosis (Takemoto et al. 2014). The presence of high-density infiltrates of IgG4-positve plasma cells in hilar areas of liver explants from patients with PSC was significantly associated with dominant biliary strictures and need for biliary stenting (Fischer et al. 2014), suggesting a causal relationship between IgG4(+) plasma cells and the pathogenesis of marked fibrosclerosing biliary changes.

IgG4-Related Sclerosing Cholangitis in Autoimmune Pancreatitis (AIP-Associated Sclerosing Cholangitis)

Autoimmune pancreatitis (AIP) is one of the chief manifestations of IgG4-related sclerosing disease (Kamisawa et al. 2003b; Kojima et al. 2007; Blejter et al. 2008; Okazaki et al. 2008; Smyrk 2011). AIP has been reported in 1961 as a peculiar type of pancreatitis associated with hypergammaglobulinemia (Sarles et al. 1961) and described in more detail in 1995 (Yoshida et al. 1995), and consensus diagnostic criteria for AIP have since been worked out (Asian Diagnostic Criteria, Japan-Korea Consensus: Otsuki et al. 2008; Mayo Clinic Diagnostic Criteria/HISORt Criteria: Chari et al. 2006; International Consensus Diagnostic criteria: Shimosegawa et al. 2011). AIP occurs in two histologic variants, i.e., lymphoplasmacytic sclerosing pancreatitis (LPSP; type 1 AIP, associated with elevated serum IgG4) and idiopathic duct-centric pancreatitis (IDCP; type 2 AIP) or granulocytic epithelial lesion-positive pancreatitis (Honolulu Consensus Document; Chari et al. 2011). In contrast to type 1 AIP, type 2 AIP seems to be confined to the pancreas (Deshpande et al. 2011). AIP was localized to the pancreatic head in 94 % of cases, with possible extension into the periphery of the gland and/or into the biliary tract (Esposito et al, 2008). It has later been found that AIP is closely related to the HLA DRB1*0405-DQB1*0401 haplotype (Kawa et al. 2002) and associated with inflammatory infiltrates rich in IgG4-containing plasma cells and that it is accompanied by elevated serum IgG4 levels (Hamano et al. 2001; Sadler et al. 2011). Immunohistochemically, deposition of IgG4 together with IgG and complement C3s has been detected at the basement membrane of pancreatic ducts and acini in AIP (Detlefsen et al. 2010). AIP can cause plasma cell-rich sclerosing mass lesions (pseudotumors) that may closely mimic pancreatic malignancy (Kajiwara et al. 2008).

AIP has been observed in association with several forms of IgG4-related sclerosing disease (reviews: Hirano et al. 2004; Kamisawa et al. 2010; Zhang and Smyrk 2010) and in particular with bile duct lesions mimicking primary sclerosing cholangitis (IgG4-associated cholangitis, see above; review: Björnsson et al. 2007), primary biliary cirrhosis, and Sjögren syndrome (Takuma et al. 2011). In 1963, two cases of PSC with pancreatic involvement seen at the Mayo Clinic were reported, and these cases may represent the first published examples of SC associated with AIP (Bartholomew et al. 1963). Sclerosing cholangitis can in fact develop subsequent to chronic

pancreatitis associated with Sjögren syndrome (Montefusco et al. 1984; Versapuech et al. 1986) and with AIP proper (Erkelens et al. 1999; Nakazawa et al. 2001, 2005; Horiuchi et al. 2002; Kuroiwa et al. 2002; Hirano et al. 2003; Pickartz et al. 2004; Prasad et al. 2004; Nishino et al. 2005, 2007; Kawa et al. 2007; Beristain et al. 2008; Esposito et al. 2008; Ong et al. 2011). In patients with this constellation, serum IgG4 levels are significantly higher than those in patients with primary sclerosing cholangitis (Hirano et al. 2006; Nishino et al. 2007; Hochwald et al. 2008), and the disease in these patients does not show an association with inflammatory bowel disease (Nakazawa et al. 2005). In one study, intra- and/or extrahepatic biliary tract involvement in AIH was 64 % (Esposito et al. 2008), and in another investigation on 16 patients with AIP, stricture of the extrahepatic bile duct was detected in 88 % and duct wall thickening in 94 % of the patients (Nishino et al. 2005). The overall rate of extrahepatic bile duct involvement in AIP is around 70 % (Zhang and Smyrk 2010). Sclerosing cholangitis associated with AIP seems to be a distinct disease that differs from classical primary sclerosing cholangitis (PSC), although there is some overlap (Webster et al. 2009). This has led to the concept of "AIP-associated sclerosing cholangitis" (AIP-SC; Uehara et al. 2005). The mean age at presentation was significantly higher in AIP associated with bile duct disease than in PSC (Kim et al. 2006). Radiologically, the extrahepatic duct was involved in AIP-SC, while both extrahepatic and intrahepatic bile ducts were involved in PSC. Cholangiography can discriminate PSC from AIP-SC, in that band-like stricture, beaded or pruned-tree appearance and diverticulum-like formation were significantly more frequent in PSC, and segmental stricture, long stricture with prestenotic dilatation, and stricture of the distal common bile duct were more common in AIP-SC (Nakazawa et al. 2004). These authors therefore classified cholangiograms of IgG4-related SC into four types. Stenosis with type 1 is located only in the lower part of the common bile duct; stenosis type 2 is diffusely distributed throughout the intrahepatic and extrahepatic bile ducts; type 3 stenosis occurs in both the hilar hepatic region and the lower part of the common bile duct; and type 4 stenosis is detected only in the hilar region.

The clinical, radiological, and pathological features of IgG4-related SC and PSC are different (Zen et al. 2004; Nakanuma and Zen 2007; Deshpande et al. 2009; Cheuk and Chan 2010; Smyrk 2011). IgG4-related sclerosing cholangitis has a more marked male preponderance, involves middle-aged to elderly individuals (PSC: more commonly young adults), and often presents with obstructive jaundice. IgG4 cholangiopathy is histologically characterized by an inflammation with infiltrates showing a transmural and homogeneous distribution within the bile duct wall, whereas inflammatory changes in PSC tend to involve the inner parts of the duct wall. In contrast to PSC, erosive or ulcerous lesions, and onion-skin-type concentric periductal fibrosis, and/or xanthomatous changes are not features of AIP-SC. The diffuse transmural lymphoplasmacytic infiltration in AIP-SC is associated with marked interstitial fibrosis with a focal storiform pattern (similar to that seen in AIP) and occasional obliterative phlebitis. The biliary epithelium is usually spared of injury. Immunohistochemically, IgG4-containing plasma cells are frequent in the infiltrates of AIP-SC (Nishino et al. 2005; Nakanuma and Zen 2007; Ghazale et al. 2008; Naitoh et al. 2009) and can be assessed in biopsies from Vater's ampulla and the common bile duct (Kawakami et al. 2010), and the IgG4-positive plasma cell/mononuclear cell ratio was significantly higher in AIP-SC than in PSC (Uehara et al. 2005). Patients with AIP-SC have significantly higher numbers of IgG4+ plasma cells in ampullary biopsies than patients with PSC and pancreatobiliary carcinomas. In one study, 18 out of 27 patients (67 %) with AIP had more than 10 IgG4+ plasma cells in their ampullary biopsies (Kubota et al. 2008). PSC occurs in younger and AIP-SC in older patients, obstructive jaundice is more often found in AIP-SC, and whereas PSC is associated with inflammatory bowel disease, AIP-SC is associated with extrapancreatic manifestations of AIP (Kawa et al. 2007). AIP-SC may cause stenosing lesions closing mimicking hilar sclerosing carcinoma/Klatskin tumor (Cheung and Lo 2008). Sclerosing cholangitis may

develop in patients having developed a AIP-related pancreatic pseudotumor (Toosi and Heathcote 2004). Rarely, IgG4-negative sclerosing cholangitis is associated with AIP (Sewkani et al. 2005).

Primary Sclerosing Cholangitis Mimicking IgG4-Related Disease

Zen and coworkers described two patients of PSC associated with ulcerative colitis and typical bile duct histology, including duct erosion and xanthogranulomatous reaction, having undergone liver transplantation. The explants showed marked infiltration of IgG4-positive plasma cells, mainly in duct-associated xanthogranulomatous tissue, in the absence of typical features of IgG4-related SC (Zen et al. 2011).

Small Bile Duct Involvement in IgG4-Related Sclerosing Cholangitis

This disorder has been defined as damage of small intrahepatic bile ducts associated with infiltration of >/= 10 IgG4+ plasma cells per HPF and has been observed in 5 out of 22 (26 %) patients with IgG4-related disease. Patients with small duct involvement showed a higher incidence of intrahepatic bile duct strictures on cholangiography. Conversely, 57 % of patients with intrahepatic bile duct strictures on cholangiography had histologically evident small duct involvement. The number of IgG4+ plasma cells was correlated with the site of the most proximal stricture (Naitoh et al. 2011).

IgG4 Hepatopathy and IgG4-Related Hepatitis

IgG4 hepatopathy is a recently described disorder which presents with five histologic patterns: (1) evident portal tract inflammation with or without interface hepatitis, (2) large bile duct obstructive features, (3) portal sclerosis, (4) lobular hepatitis, and (5) canalicular cholestasis (Umemura et al. 2007). A subset of patients with interface hepatitis showing the features of autoimmune hepatitis (AIH) reveal high densities of IgG4+ plasma cells in the cellular infiltrates (IgG4-associated autoimmune hepatitis). This type of AIH was identified in 2007 (Umemura et al. 2007) in one patient showing an International Autoimmune Hepatitis Group (IAIHG) score of 18 and a high serum IgG4 concentration and was later confirmed in other patients (Chung et al. 2010; Castillo-Rama et al al. 2013; Yada et al. 2013) and found in over 3 % of Japanese patients with type 1 AIH (Umemura et al. 2011).

Hepatobiliary Pseudotumors in IgG4-Related Sclerosing Disease

Inflammatory pseudotumors developing in association with IgG4-related disease usually show histologic features that resemble those of ALK rearrangement-positive inflammatory myofibroblastic tumors (IMTs). Inflammatory pseudotumors occurring in patients with IgG4-related disease contain numerous IgG4-positive plasma cells, albeit there is considerable histologic overlap between these two lesion groups. It has been demonstrated that a subset of IMT exhibits an IgG4/IgG ratio that is within the range for IgG4-related sclerosing disease, a feature that is useful for the distinction of two types of IMT (Saab et al. 2011).

Hepatobiliary pseudotumors with high IgG4 plasmocyte cellularity have been observed by several authors, sometimes, but not always, in association with autoimmune pancreatitis/AIP (Sato et al. 2004; Kanno et al. 2005; Sasahira et al. 2005; Martin Malagon et al. 2006; Uchida et al. 2007; de Suray et al. 2009; Kim et al. 2011; Ahn et al. 2012; Hastir et al. 2014). In the case reported by Martin Malagon et al. (2006), a lesion of the inflammatory myofibroblastic tumor type was located in the distal common bile duct of a 51-year-old female patient suffering from lymphoplasmacytic sclerosing pancreatitis. In AIP, pseudotumoral masses have been observed synchronously in the pancreas and the gallbladder (Gumbs et al. 2005). In

another patient with AIP, multiple inflammatory pseudotumors were detected in the liver, associated with peripheral eosinophilia (Sasahira et al. 2005). Hepatic inflammatory pseudotumor may, apart from AIP, synchronously occur with other manifestations, including sclerosing cholangitis, retroperitoneal fibrosis, and sialadenitis (de Suray et al. 2009). Intrahepatic IgG4-related pseudotumor can clinically and radiologically mimic hepatocellular carcinoma (Hastir et al. 2014). Zen and coworkers (Zen et al. 2007) defined two types of hepatic inflammatory pseudotumors, fibrohistiocytic and lymphoplasmacytic. The lymphoplasmacytic type is histologically characterized by diffuse inflammatory cell infiltration, mainly by lymphocytes and plasma cells. The inflammatory cells may infiltrate perineural spaces. Parts of these pseudotumors reveal a significant eosinophil infiltration. Obliterative phlebitis with or without recanalization may be present. IgG4+ plasma cells were significantly more frequent in the lymphoplasmacytic variant. Some areas of pseudotumors display entrapped small bile ducts.

IgG4-Associated Ampullitis

In rare cases, ampullitis is characterized by an infiltrate showing numerous IgG4-positive plasma cells. This disorder was also observed in patients with inflammatory bowel disease, including Crohn's disease (Navaneethan et al. 2011). On the other hand, plasma cells can be increased in ampullary tissue due to extension of IgG4-related autoimmune pancreatitis into the ampullary region (Kawakami and Zen 2010).

Sclerosing Cholecystitis in Autoimmune Pancreatitis

Sclerosing cholecystitis is now well recognized to occur in association with IgG4-related disease (IgG4-related cholecystitis; Abraham et al. 2003; Fukui et al. 2005; Nishino et al. 2005; Kamisawa et al. 2006c; Wang et al. 2009; Leise et al. 2011; Lee et al. 2013; Feely et al. 2014). Thickening of the gallbladder wall was detected on ultrasonography and/or CT in 32 % of AIP patients (Kamisawa and Okamoto 2008) and in another study in 56 % (Nishino et al. 2005). In a study of gallbladders obtained from patients with lymphoplasmacytic sclerosing pancreatitis, 60 % of the gallbladders contained moderate or marked inflammatory infiltrates and lymphoid nodules, and gallbladders from these pancreatitis patients received the highest scores for deep inflammation of all groups compared (Abraham et al. 2003). IgG4-related sclerosing cholecystitis is most common in patients having AIP with extensive bile duct disease and where stenosis of the extrahepatic bile duct is frequent (Kamisawa et al. 2006c). Histologically, fibrosis/sclerosis is associated with a mucosal or transmural lymphoplasmacytic infiltration, the plasma cells containing IgG4 (Kamisawa et al. 2006c). In case of diffuse and marked plasmacytic inflammatory infiltration of the gallbladder wall, the lesion can mimic gallbladder cancer (Lee et al. 2013; Shin et al. 2013).

Locoregional Lymphadenopathy in IgG4-Associated Sclerosing Disease of the Hepatobiliary Tract (IgG4 Lymphadenopathy)

Lymph nodes draining IgG4-associated sclerosing cholangitis and pancreatitis are often enlarged, because the immune reaction driving the disease causes a marked expansion of the nodal cell populations involved and particularly lymphoblasts and IgG4-expressing plasma cells. In such lymph nodes, three histological patterns have been identified, i.e., interfollicular expansion by immunoblasts and plasma cells, follicular and germinal center hyperplasia, and Castleman-like alterations (Cheuk et al. 2008; Shimizu et al. 2010). Some patients with IgG4-related disease may develop generalized lymphadenopathy, sometimes with a histology mimicking multicentric Castleman's disease (Kamisawa et al. 2006a; Sato et al. 2009; Takenaka et al. 2011; review: Sato et al. 2010).

Malignancy Associated with IgG4-Related Sclerosing Disease

Generally, the incidence of total malignancies in patients with IgG4-related disease seems to not be different from control populations (Hirano et al. 2014), but certain neoplasms have been found in association with this disorder. Mucosa-associated lymphoid tissue lymphoma may arise from ocular adnexal IgG4-related disease and IgG4-producing lymphomas exist (review: Sato et al. 2010). In a study on 111 patients with IgG4-related disease with or without AIP and 331 patient-years of observation, 3 patients developed non-Hodgkin lymphoma 3–5 years after the diagnosis of IgG4-related disease. One of the patients showed lymphoma involvement of the liver (Takahashi et al. 2009). Peripheral T-cell lymphoma has been reported in a patient with IgG4-related disease (Kanda et al. 2011). Marginal zone lymphoma involving the meningeal dura has been observed in IgG4-related disease (Venkataraman et al. 2011). Several cases of ductal adenocarcinoma of the pancreas have been reported in association with IgG4-related AIP, and IgG4-related disease can rarely be complicated by cholangiocarcinoma (Douhara et al. 2013).

Differential Diagnosis

It has to be emphasized that IgG4-containing plasma cells may be observed in a wide array of immune reactions and inflammatory responses, in the absence of other features of IgG4-related disease (Strehl et al. 2011). IgG4-positive plasma cells were also found in peritumoral tissue of patients with hilar cholangiocarcinoma, other cholangiocarcinomas, and gallbladder carcinoma (Resheq et al. 2013; Harada and Nakanuma 2014), suggesting that cholangiocarcinoma cells in their function as nonprofessional antigen-presenting cells may indirectly induce an IgG4 reaction via an Il-10-mediated pathway (Harada and Nakanuma 2014). Interestingly, IgG4-positive plasma cells are also encountered in inflammatory myofibroblastic tumor, a rare mesenchymal neoplasm having an anaplastic lymphoma kinase (ALK) rearrangement in the majority of cases and histologically resembling IgG4-related reactive inflammatory pseudotumor (Saab et al. 2011), eventually suggesting a pathogenic link. Increased numbers of IgG4(+) plasma cells were observed in a subset of Rosai-Dorfman disease cases (Menon et al. 2014). There is one report describing an inflammatory angiomyolipoma of the liver showing dense infiltrates of IgG4-positive plasma cells (Agaimy and Märkl 2013).

Pathogenic Pathways

IgG4 has distinct functional properties (review: Nirula et al. 2011). IgG4 is known to be capable to undergo what is called half-antibody exchange in vivo and what causes the generation of recombined antibodies composed of two different binding specificities. The regulation of IgG4 synthesis in plasma cells is not fully understood but seems to depend on an aberrant acquired immunity based on T2-dominated immune responses. IgG4 production is partially driven by T helper 2 cytokines mediating allergic responses and IgE synthesis. In tissues affected by IgG4-related disease, mast cells are a source of T helper 2 and regulatory T-cell cytokines and are therefore suggested to play a role in pathogenic pathways of this disease (Takeuchi et al. 2014). Increased T-helper 2 cytokines produced in IgG4-related cholangitis disrupted the tight-junction-associated biliary epithelial cell barrier, the subsequent biliary leaks considered to contribute to the pathogenesis of chronic bile duct inflammation (Müller et al. 2013). It has been found that interleukin-13 is a T cell-derived cytokine that efficiently directs naïve human B cells to switch to IgG4 and IgE production (Punnonen et al. 1993). Observations in polyclonal IgG4 hypergammaglobulinemia have, however, shown that stimulation of IgG4 synthesis by plasmacytoid cells may be mediated by soluble T cell factors other than IL-13 (Boulanger et al. 2006). In IgG4-related sclerosing cholangitis, there is evidence that the chemotactic factor/receptor system CCl1-CCR8 is involved in the recruitment of lymphocytes (Zen et al. 2013).

DOI 10.1007/978-3-319-26956-6_142

Abstract

Several inflammatory conditions of the biliary tract can mimic biliary cancer, resulting in biliary obstruction and jaundice. Following ulcerating cholangitis, granulation tissue formation can result in inflammatory polyps that may grow to rather large size to obstruct bile duct lumen. In part of cases, foreign bodies such as suture material induces granulation tissue polyps. Mass-forming lesions are also produced by various types of granulomatous cholangitis, including sarcoidosis, Crohn's disease, and tuberculosis. Duct stenosis may be caused by numerous mucosal lymph follicles (follicular cholangitis). A distinct form of recurrent cholangitis that may result in bile duct scarring and associated with stone casts is oriental cholangitis. Similar to the gallbladder, large bile ducts can undergo xanthogranulomatous inflammation. A rare condition is cholesterolosis of bile ducts, which can produce cholesterol polyps.

Inflammatory Polyps of the Bile Ducts

Introduction

Inflammatory polyps are defined as exophytically growing reactive lesions that develop in the context of deranged wound healing on epithelial surfaces and consist of granulation tissue. Inflammatory polyps ("granuloma of the biliary tract"; pyogenic granuloma of bile ducts; postsurgical granuloma) have been reported for all portions of the extrahepatic biliary tract, including the hepatic ducts (Hussain and Ahmed 2003), the bifurcation area (Nagayama et al. 1992), the common bile duct (Ro 1975; Stamatakis et al. 1979; Ezaki et al. 1994; Lee et al. 2007), the gallbladder (Sun et al. 2004), and the ampullary region (Shtamler et al. 1973; Norton et al. 2002). The lesions are mostly solitary, but multiple polyps of the choledochus have been observed (Adachi et al. 1991). Such polyps can grow to rather large size and may then cause biliary obstruction, e.g., reported for the hepatic duct, common bile duct (Ro 1975; Nagayama et al. 1992), and ampullary region. In cholangiograms, inflammatory polyps may mimic stones ("pseudocalculus"; Lautatzis et al. 1988).

Most biliary inflammatory polyps seem to be postsurgical lesions or develop in areas of ulceration caused by stone disease. A postsurgical etiology is suggested by the observation that inflammatory polyps occur in the vicinity of the cystic stump after cholecystectomy (Farkas et al. 1980) or in conjunction with choledochoduodenostomy (Lee et al. 2007).

Pathology

Macroscopically, the lesions appear as small (usually <1 cm) polypoid formations of reddish or grayish color, with either a glistening or finely granulated surface, the granulation being caused by the characteristic surface structure of granulation tissue. The polyps may be covered by a fibrinopurulent exudate or by bile-stained material.

Published histopathologic examinations of inflammatory bile duct polyp are very limited (Figs. 1, 2, 3, 4, 5, 6, and 7). In one study, the polypoid lesions in AIDS-related polypoid cholangitis were demonstrated to consist of granulation tissue (Collins et al. 1993).

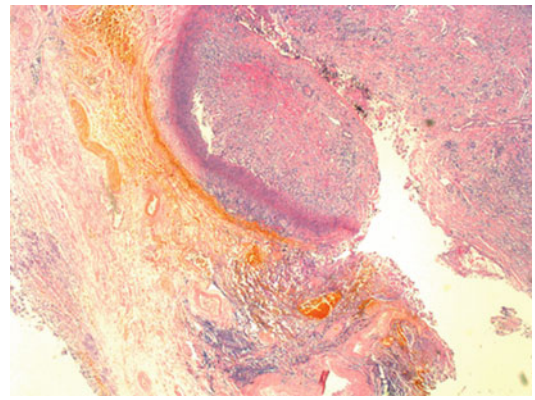

Fig. 1 Inflammatory polyp (granulation tissue polyp) in an ulcerated bile duct. The polyp is partly covered with fibrinoleukocytic exudate (hematoxylin and eosin stain)

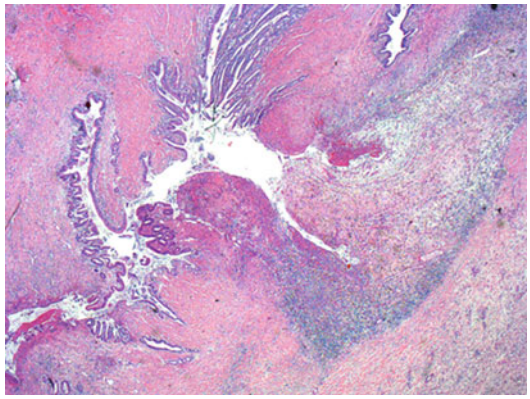

Fig. 2 Inflammatory polyps of the bile duct. The polyps have developed as granulation tissue overgrowths arising from the bottom of non-healing bile duct ulcers. The mucosa adjacent to the polyp in the center exhibits metaplastic epithelial changes (hematoxylin and eosin stain)

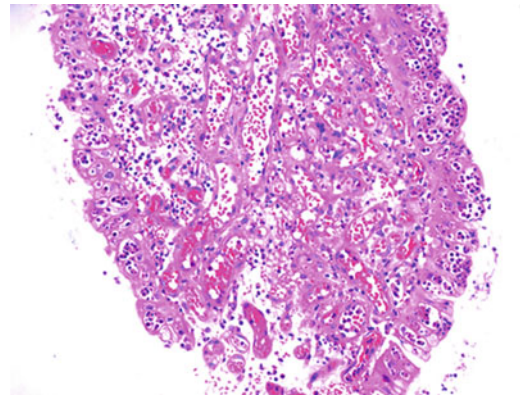

Fig. 4 Inflammatory bile duct polyp in the stage of granulation tissue formation. The highly vascularized tissue is covered by regenerating biliary epithelium. The latter is invaded by numerous neutrophils (hematoxylin and eosin stain)

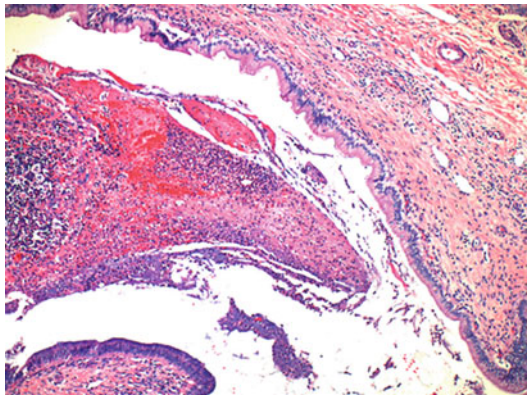

Fig. 3 Apical parts of inflammatory polyps of bile ducts may predominantly consist of fibrin- and leukocyte-rich exudate, as in the present case (hematoxylin and eosin stain)

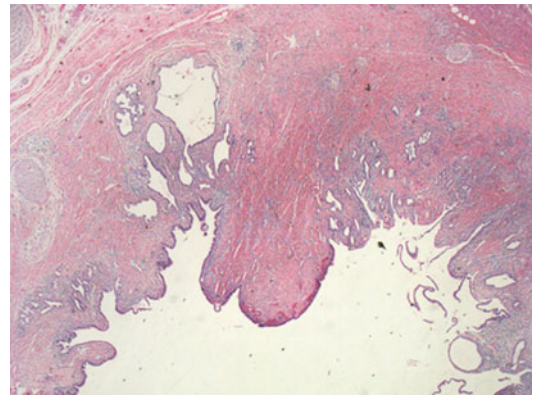

Fig. 5 Fibrous polyp of the bile duct (hematoxylin and eosin stain)

Other Types of Bile Duct Polyps Related to Inflammation and Hyperplasia

AIDS-Related Polypoid Cholangitis

A distinct situation is the occurrence of inflammatory bile duct polyps in patients with AIDS-related sclerosing cholangitis (ARSC; Forbes et al. 1993; Ducreux et al. 1995). Among 31 patients with this disorder, intraluminal polypoidal defects within the common bile duct and larger intrahepatic ducts were detected in eight cases (26 %), and it was proposed to term this condition AIDS-related polypoid cholangitis (Collins et al. 1993).

Suture Granuloma of Bile Ducts

Part of inflammatory lesions with a polypoid or nodular shape consist of a granulating inflammation centered on suture material. Such lesions have been termed suture granulomas. The lesions consist of a fibrosing granulation tissue with numerous macrophages and foreign body-type giant cells. The latter may contain suture thread fragments in their cytoplasm (Brauner et al. 1988). In case such

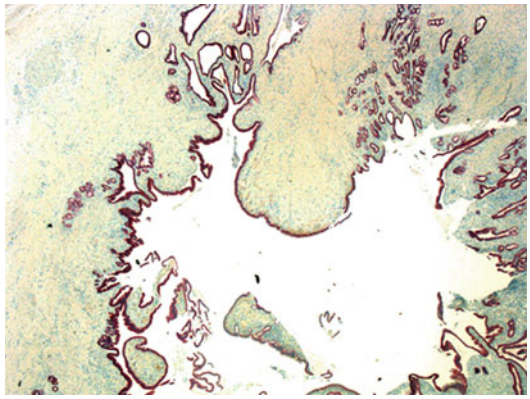

Fig. 6 Fibrous polyp of the bile duct. In contrast to adjacent bile duct mucosa, the cholangiocyte lining of the polyp is still immature and flat (cytokeratin 19 immunostain)

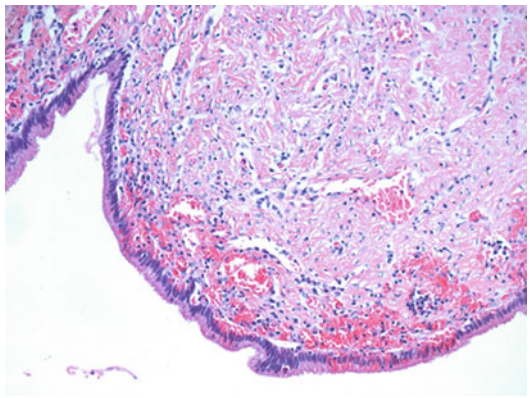

Fig. 7 Fibrous polyp of the bile duct. In the subepithelial area, remnants of granulation tissue are found, while deeper parts are fibrosed/scarred (hematoxylin and eosin stain)

"granulomas" grow to larger size, they may mimic cholangiocarcinoma (Gleeson and McMullin 1987; Murphy et al. 1990).

Mucosal Bile Duct Hyperplasia

There are rare instances where bile duct stenosis is caused by hyperplastic mucosal changes in the biliary tract. In a 71-year-old patient, a tumorous stenosing lesion of the distal bile duct was found. Abdominal ultrasonography revealed dilatation of the intra- and extrahepatic bile ducts and the pancreatic duct. Endoscopic examinations showed swelling and redness of the papilla of Vater with an irregular surface, and a biopsy displayed adenoma at this place. Cholangiography showed disruption of the common bile duct due to a polypoid lesion of its distal part, with occasional prolapse of the lesion into the duodenum. This lesion also compressed the orifice of the pancreatic duct. Histology of the sessile lesion disclosed nodular mucosal hyperplasia, with papillary superficial growths and hyperplasia of mucus gland cells (Kubota et al. 1996). It was suggested that this type of lesion may belong to the group of "adenomatous" or "adenofibromyomatous" hyperplasias occurring in the most distal part of the common bile duct and in the papillo-ampullary region (Zubov and Zubkov 1983; Hirota et al. 1989).

Granulomatous Cholangitis

Granulomatous Cholangitis in Sarcoidosis

In sarcoidosis, epithelioid cell granulomas with or without multinucleated giant cells of the Langhans type are often present in multiple organs, including the liver (Devaney et al. 1993; review: Ishak 1998). Granulomas may heal with leaving a trace, but numerous and in particular confluent granulomas form fibrosing/scarring conglomerates that produce a mass effect. Stenosing lesions cause obstructive jaundice (Bloom et al. 1978; Kusielewicz et al. 1988) and may mimic cholangiocarcinoma, e.g., Klatskin tumor (Pungpapong et al. 2006). On the other hand, granulomatous hepatitis in sarcoidosis was reported to cause biliary tract obstruction (Rezeig and Fashir 1997). Bile duct sarcoidosis may also resemble primary sclerosing cholangitis (Tombazzi et al. 2008). Granulomatous sarcoidotic cholangitis can lead to ductopenia, the underlying pathogenetic mechanism of the chronic cholestatic syndrome of sarcoidosis, discussed in a separate chapter.

Granulomatous Cholangitis in Tuberculosis

Scarring of tuberculous granulomas of the bile duct may be followed by biliary stricture and obstructive jaundice. Fibrous stricture is, however, nowadays a rare complication of biliary tract tuberculosis. It predominates in the common hepatic duct and in proximal and distal parts of the common bile duct (Fan et al. 1989; Kenneth et al. 1999; Kok and Yapp 1999; Prasad and Pandey 2001). This type of benign stricture may mimic bile duct malignancy/cholangiocarcinoma (Behera et al. 1997; Inal et al. 2000).

Crohn's Disease of the Bile Ducts

Crohn's disease and ulcerative colitis are considered as systemic diseases as they are associated with clinical and pathological manifestations involving organs outside the gastrointestinal tract (Rothfuss et al. 2006; Agrawal et al. 2007). Inflammatory lesions histologically compatible with Crohn's disease may develop in the wall of the bile ducts, albeit very rarely. Histologically proven Crohn's lesions of the common bile duct and the ampullary region have been reported to cause obstructive jaundice and acute pancreatitis. Biopsies of the papilla of Vater and common bile duct showed non-necrotizing expanding granulomas (Rivas et al. 2009). Ampullary stenosis with biliary obstruction has been reported in duodenal Crohn's disease (Foutch and Ferguson 1984; Spiess et al. 1992; Yung et al. 2005). Crohn's disease is also associated with a bile duct pathology resembling, or identical with, sclerosing cholangitis (Silbermintz et al. 2006).

Follicular Cholangitis

Segmental stricture/stenosis of the bile ducts found in patients with no history of biliary tract disease raise the suspicion of bile duct cancer (Maeda et al. 1998). Among inflammatory disorders clinically and radiologically mimicking cholangiocarcinoma, follicular cholangitis is a rare but rather typical example. Sclerosing and non-sclerosing forms are distinguished, but it is not known whether this reflects different evolution phases of the same process.

Follicular Lymphoplasmacytic Sclerosing Cholangitis

Among five patients with benign sclerosing cholangitis masquerading biliary tract carcinoma, two had cholangitis with prominent lymph follicle formation (Fujita et al. 2009). Follicular cholangitis can cause a wall thickening of extrahepatic ducts resulting in segmental stenosis and causing obstructive jaundice (Ajisaka et al. 2002). Radiological examinations in a 57-year-old female with a biliary stricture disclosed granular elevated lesions in the common hepatic duct and severe stenosis at the hepatic hilum. Under the tentative diagnosis of hepatic hilar bile duct cancer, the patient underwent extended right hepatectomy with bile duct resection. Histology showed a benign stricture of the bile duct associated with marked formation of lymph follicles with germinal centers (Aoki et al. 2003). In a 62-year-old male patient, this configuration led to the preoperative diagnosis of hilar cholangiocarcinoma and to subsequent resection of the extrahepatic bile duct and part of the right intrahepatic duct. The mucosa of the extrahepatic bile duct showed a coarse granulation and its wall was concentrically thickened to 0.5–0.7 cm. Histologically, the mucosal granulations were caused by prominent lymph follicles. The submucosa of the bile duct exhibited smooth muscle cells hyperplasia, diffuse neural hypertrophy, and diffuse lymph follicle formation (Lee et al. 2005). Among patients who had undergone surgery of the proximal extrahepatic bile duct from 1993 to 2008 on suspicion of proximal bile cancer, two were diagnosed with sclerosing follicular cholangitis, masquerading as hilar cholangiocarcinoma (Fujita et al. 2010).

Follicular Lymphoplasmacytic Non-sclerosing Cholangitis

The presence of lymph follicles, in part with germinal centers, is sometimes an incidental finding obtained during the workup of resected bile ducts (Fig. 8). The accumulation of lymphoid cells and plasmacytoid cells in the common bile duct associated with numerous lymph follicles may be massive, rising suspicion of a neoplastic lymphoproliferative process (Suzuki et al. 2004).

Follicular Cholangitis and Pancreatitis (Follicular Cholangiopancreatitis)

This is a distinct form of cholangiopancreatitis originally observed in five patients (Zen et al. 2012). Three of the patients presented with predominantly hilar bile duct stricture and two with a bulky pancreatic head. Four patients were treated surgically for suspected malignancy and one patient underwent liver transplantation with a clinical diagnosis of primary sclerosing cholangitis. Resected bile duct specimens showed a localized bile duct wall thickening in large hilar or perihilar bile ducts, associated with marked intrahepatic bile duct dilatation and liver atrophy (biliary-type atrophy). Whipple resection specimens of the two patients with pancreatic masses showed an ill-defined mass in the pancreatic head.

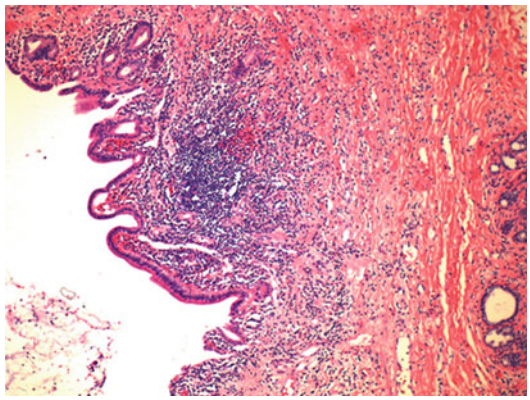

Fig. 8 Follicular cholangitis. The mucosa of the bile duct shows a well-developed lymph follicle without germinal center (hematoxylin and eosin stain)

Histologically, the biliary and pancreatic lesions showed similar features. There was a duct-centered lymphoplasmacytic infiltration with numerous lymph follicles, in part with germinal centers, associated with collagenous fibrous tissue deposition. The collagen-rich fibrosis differed from the storiform fibrosis typically seen in IgG4-related disease, and veno-obliterative lesions were not detected. Many plasma cells and occasional eosinophils were seen between the follicles. Immunohistochemically, only occasional IgG4-positive plasma cells were noted. The pathogenesis of this entity, which may clinically and radiologically be confounded with malignancy, is not yet known.

Pathogenesis

The pathogenesis of follicular cholangitis has not been clarified, but it is likely that it results from marked local immunostimulation driven by so far unknown antigens.

Differential Diagnosis

The histologic differential diagnosis of follicular cholangitis mainly comprises primary bile duct lymphoma (Kosuge et al. 1991; Joo et al. 2004).

Oriental Cholangitis

Introduction

Oriental cholangitis (synonyms: oriental cholangiohepatitis, recurrent cholangitis, recurrent pyogenic cholangitis, oriental infestational cholangitis, Hong Kong disease, intrahepatic pigment stone disease) is a progressive and potentially life-threatening hepatobiliary disease that is endemic in Asian countries and is characterized by episodic biliary obstruction, abdominal pain, and sepsis.

The cause of oriental cholangitis is unknown, but it is probably multifactorial, with parasites (e.g., *Clonorchis*) and bacterial infection thought

to play a role, including *Escherichia coli* and *Salmonella typhi* (reviews: Ong 1962; Stock and Fung 1962; Stock 1968; Seel and Park 1983; Reynolds et al. 1994). The disorder was first described in 1930 in a publication entitled "Common Duct Stones of Liver Origin" (Digby 1930). The author drew attention to the occurrence among the Chinese in Hong Kong of a syndrome to which Cook and coworkers gave the name "recurrent pyogenic cholangitis" in 1954 (Cook et al. 1954). Sporadic cases have been reported from outside of Asia, e.g., the United States (Kirby et al. 1995; Wilson et al. 1996; Honda et al. 2007). Such cases may be seen with increasing frequency because of the influx of immigrants from southeast Asia (Turner and Cramer 1983; Carmona et al. 1984; Sperling et al. 1997).

Clinical and Imaging Features

Oriental cholangitis is typically a disease of adults but also occurs in the pediatric age group (Bergman and Harris 1986). Patients typically present with symptoms and signs of recurrent cholangitis, namely, attacks of fever, chills, abdominal pain, and jaundice. Laboratory findings including leukocytosis and increased levels of bilirubin and alkaline phosphatase reflect the clinical features. Most patients have bile cultures positive for *Escherichia coli* (Ho and Wesson 1974), but there are also patients who are intrahepatic typhoid carriers (McFadzean and Ong 1966). The disorder is further characterized by the formation of pigmented, calcium bilirubinate stones that have a claylike consistency (the earthy stones of Aschoff) (Aschoff 1924) and often fill the ducts with casts (Federle et al. 1982).

Owing to obstruction, the gallbladder may be readily palpable for it is grossly distended (Stock 1968). During acute attacks, the gallbladder may perforate leading to biliary peritonitis. If jaundice is unrelieved, hepatic failure may ensue. Once established, there are periods of exacerbation and remission. During the former, obstruction of the larger ducts into which the infected segment drains occurs, and this results in back-flow infection of hitherto unaffected ducts. After recurrent attacks, biliary strictures develop behind which stones collect, associated with multiple honeycombed abscesses occur. Ultimately, the common bile duct is involved, and obstruction thereto is produced either by spasm of the sphincter or by stones (McFadzean and Ong 1966). Occasionally, a cholangiocarcinoma develops in the damaged ducts.

Imaging shows intrahepatic and extrahepatic bile duct strictures, often associated with primary bile duct stones and biliary obstruction (Scheible and Davis 1981; Sperling et al. 1997). Abdominal ultrasonography may reveal dilated common bile duct and common hepatic ducts, and numerous focal echogenicities with intense shadowing can be seen in the intrahepatic ducts, representing the multiple stones (Lim et al. 1990). However, some stones are isoechoic relative to the liver, lack acoustic shadowing, and may produce a cast in the dilated duct that can be missed at sonography (Chau et al. 1987). Sonography delineates bile duct dilatation in virtually all patients with oriental cholangitis, but the extrahepatic ducts are less often dilated than the intrahepatic ducts (66–79 % vs. 85–100 %; Chau et al. 1987; Lim et al. 1990). The stones detected with sonography may be either in the extrahepatic, the intrahepatic ducts, or both. In some patients, stones are located only in the segmental ducts. The detectability of stones with sonography depends on the stones' size, echogenicity, acoustic shadowing features, and location (Lee et al. 1986; Lim et al. 1990). Usually, intrahepatic stones are echogenic and shadowing, whereas some extrahepatic stones (around 25 %) do not cast shadow. Biliary mud/sludge or isoechoic bile duct stones filling the biliary tree as a cast may be missed as they sometimes appear as soft tissue masses and obscure visualization of intrahepatic ductal dilatation. CT demonstrates ductal dilatations, hyperattenuated stones or sludge, pneumobilia, intrahepatic stones forming casts, and parenchymal abnormalities such as biliary atrophy, the latter accompanied by intrahepatic bile duct crowding (Federle et al. 1982; Chan et al. 1989). Atrophy of the liver in oriental cholangitis is related to portal vein occlusion caused by the recurrent inflammatory process (Kusano

et al. 1992). The lateral segment of the left liver lobe is the most common and most early site of intrahepatic stones and intrahepatic ductal dilatation, and the posterior segment of the right liver lobe is the second most common site (Federle et al. 1982; Chan et al. 1989; Lim et al. 1990). Typically, ductal dilatation involves the first and second divisions of the intrahepatic ducts (Chan et al. 1989). This may be related to the more acute angulation of these ducts, resulting in less efficient drainage on this side of the biliary system (Ong 1962; Chan et al. 1989). Intrahepatic duct dilatation is often associated with strictures and impacted stones (Lim 1991), but strictures are rare in the extrahepatic ducts (Ong 1962), and the dilatation of the extrahepatic ducts generally is not related to the location of stones (Lim et al. 1990). Cholangiography typically shows a beaded appearance of the bile ducts, caused by alternating areas of strictures and dilatation (Chau et al. 1987; Kirby et al. 1995).

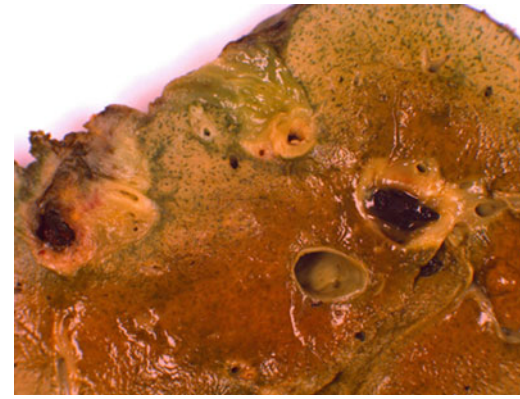

Fig. 9 Purulent intrahepatic cholangitis and pericholangitis

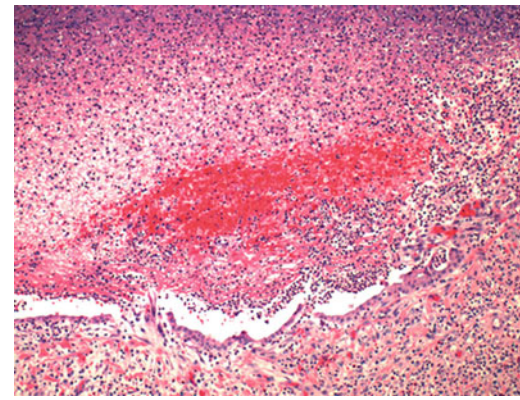

Fig. 10 Purulent and ulcerating cholangitis. The damaged and partially ulcerated mucosa exhibits a covering layer of fibrinopurulent and hemorrhagic exudate (hematoxylin and eosin stain)

Pathology

The main gross findings comprise dilated intrahepatic bile ducts with claylike stones that sometimes form large casts, bile duct scarring with strictures alternating with dilatations, biliary atrophy of the segments involved, and sometimes hepatic honey-combed abscesses located close to the altered bile ducts (Fig. 9). The common bile duct is grossly thickened and dilated, often to 2 cm or more in diameter, packed with soft and rather friable stones of all sizes and sometimes containing pus. The claylike stones may form a solid but friable cast of the entire common bile duct and its hepatic tributaries (Stock 1968; Chou and Chan 1980; Chan et al. 1989; Lim 1991). In some cases, parenchymal atrophy is associated with portal vein obstruction subsequent to pylephlebitis. The gallbladder is usually found to be grossly dilated, thin-walled, hardly inflamed, and rarely containing stones. The papilla of Vater is usually hypertrophied (Ong 1962), fibrosed, and rigid but patent, allowing passage of a large dilator without difficulty. In some cases, there is periampullary stricture due to fibrosis and passage of stones. It is thought that repeated passage of small pieces of stones or small stones through the sphincter of Oddi into the duodenum results in these ampullary changes (Ong 1962).

Histologically, the intrahepatic bile ducts show a purulent and ulcerating inflammation in early phases (Figs. 10 and 11). Later, they often show dilatation and fibrous strictures associated with a periductal lymphohistiocytic and often plasmacellular infiltration. In the lumina, one notes friable stony material stained with bile and sometimes containing purulent exudate in the stone clefts. In case of clonorchiasis, the stones

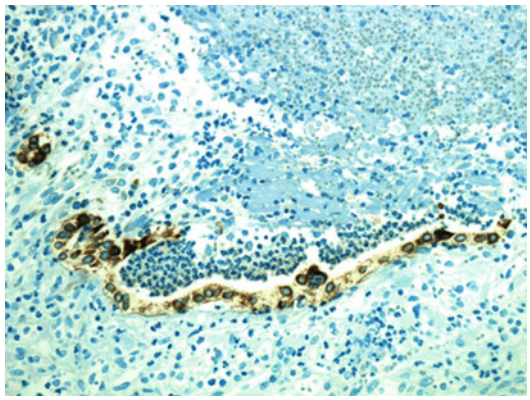

Fig. 11 Purulent ulcerating cholangitis. The injured epithelium detaches from the lamina propria, in part caused by the damaging action of neutrophils in the exudate (hematoxylin and eosin stain)

may contain *Clonorchis* eggs (Lim 1991). In the duct lumina, there are also pigmented mud, debris, and shed epithelial cells and frank pus. Fibrous tissue proliferates in the portal tracts, where also marked ductular proliferations are in evidence, associated with granulocytic ductulitis/periductulitis.

Cholangitis Glandularis Proliferans

Cholangitis grandularis proliferans (CGP; synonym: proliferative cholangitis) is defined as a histologic variant of primary sclerosing cholangitis (PSC). CGP is restricted to the extrahepatic bile ducts and typically presents as painless jaundice. In contrast to PSC, CGP mainly occurs in females and in the absence of inflammatory bowel disease. CGP may be associated with cholangiocarcinoma of the extrahepatic bile ducts (Richardson et al. 1993). However, whether CGP is a premalignant condition is not yet established.

Histopathologically, CGP is characterized by florid intramural proliferations of glandular elements in the extrahepatic bile ducts (Le Quesne and Ranger 1957; Krukowski et al. 1983; Graham et al. 1988). The main histologic differential diagnosis are situations with reactive proliferations of peribiliary glands.

Adenomyosis of the Bile Ducts

Whereas as adenomyosis (adenomyomatosis) is well known and common change in the gallbladder, adenomyosis primary to the extrahepatic bile ducts is a rare lesion. It mostly occurs in the common bile duct, where it can cause obstruction with jaundice (Lin 1983; Diel et al. 1989; Iwaki et al. 2008; Krutsay 2010). Adenomyosis has more often been found in the ampullary region (Huang et al. 1993; Treitschke et al. 2000; Kayahara et al. 2001). Histologically, regular cholangiocytes form invaginations of varying size, depth, and shape, with a sheath of smooth muscle cells. The glandular structures may develop hyperplastic changes (adenomyomatous hyperplasia; Iwaki et al. 2008; Numata et al. 2011). Circumscribed and tumor-like lesions are called adenomyoma and are discussed in a separate chapter. Adenomyosis of the bile duct has to be distinguished from cystically dilated peribiliary glands (Terada and Nakanuma 1990; Nakanuma et al. 1994; Fusai et al. 2005). Whether there is a pathogenic relationship between cystic peribiliary glands and adenomyosis is not known. But cystic peribiliary glands are not usually surrounded by smooth muscle bundles. Adenomyosis of the gallbladder has been found to be associated with benign stenosis of the terminal part of the common bile duct (Pera et al. 1971).

Fibroinflammatory Biliary Stricture

In older reports, non-traumatic benign inflammatory strictures of the extrahepatic bile ducts have been described, with a histology different from that of primary sclerosing cholangitis (Krukowski and Matheson 1989; Standfield et al. 1989). It has been found that benign fibrosing lesions and benign tumors cause 8–13.4 % of all biliary strictures (Hadjis et al. 1985; Corvera et al. 2005), and part of them form a masquerade of hilar cholangiocarcinoma. Later, it has been recognized that at least part of these disorders represent a distinct variant of cholangitis causing benign strictures that can clinically imitate a stenosing

neoplastic process. Fibroinflammatory stricture (FIBS) is a rare benign ductocentric myofibroblastic and inflammatory process that may mimic extrahepatic bile duct malignancy. In a study of 11 patients with FIBS, all presented with obstructive jaundice, and six patients had coexisting autoimmune disease. Radiographic features of bile duct cancer were seen in patients. Four patients had a definable mass associated with the extrapancreatic bile duct, while four patients had soft tissue infiltrating the porta hepatis. The preoperative CT scans showed residual biliary ductal dilatation following stenting in eight patients. ERC revealed a dominant stricture of the extrahepatic bile duct in all patients. Histologically, the bile ducts showed inflammatory and fibrosing changes, with a lymphoplasmacytic component in 45 %. All lesions except one expressed smooth muscle actin in the spindle cells of the fibrosed areas, hence representing myofibroblasts. In five cases, IgG4-positive plasma cells were found in the infiltrate, all of which had ductocentric lymphoplasmacytic inflammation (FIBS+IgG4) (Gamblin et al. 2009). The histopathologic and immunohistochemical findings, in particular the presence of IgG4-positive plasma cells, suggest that FIBS belongs to the growing group of IgG4-related sclerosing diseases. Other fibrosclerosing disorders of the large bile ducts have been found to contain IgG4-positive plasma cells, including IgG4-associated cholangitis (Webster et al. 2009) and lymphoplasmacytic sclerosing cholangitis (Kram et al. 2002; Takuma et al. 2011), which may mimic infiltrating hilar cholangiocarcinoma (Hamano et al. 2005).

Xanthogranulomatous Cholangitis (Xanthogranulomatous Cholangiopathy)

Introduction

Apart from xanthogranulomatous cholecystitis, inflammatory lesions characterized by the presence of numerous lipid-laden macrophages, rendering the involved tissue macroscopically yellow, xanthogranulomatous inflammations can also develop in the gastrointestinal tract, including stomach, pancreas, and colon (Oh et al. 2005; Kubosawa et al. 2007; Shima et al. 2008; Nishimura et al. 2011), and part of or the entire extrahepatic bile duct system, leading to mass lesions and stenosing alterations mimicking malignancy.

Involvement of Extrahepatic Bile Ducts in Xanthogranulomatous Cholecystitis

A xanthogranulomatous inflammation is well recognized in the gallbladder (Reed et al. 1994; Dixit et al. 1998; Guzman-Valdivia 2004). Xanthogranulomatous cholecystitis may rarely cause bile duct stenosis due to its extension into extrahepatic bile ducts (Kawana et al. 1990). The latter report refers to a female infant with obstructive jaundice who had a narrowing of the common bile duct due to surrounding xanthogranulomatous tissue. The biliary obstruction was released by cholecystectomy, resection of the choledochus, and hepaticojejunostomy.

Xanthogranulomatous Cholangitis

Xanthomatous choledochitis is a very rare stenosing bile duct disorder of unknown etiology. It is histologically characterized by the development of usually transmural inflammation rich in lipid-laden macrophages, similar to the histology of xanthogranulomatous cholecystitis, with marked thickening of the duct wall. One observation described a 9-month-old infant presenting with obstructive jaundice caused by a circumscribed xanthogranulomatous lesion located to the distal common bile duct (Prasil et al. 1999). The xanthogranulomatous inflammation may be restricted to the distal common bile duct, a lesion termed xanthogranulomatous choledochitis (Goldar-Najafi and Khettry 2003; Pantanowitz et al. 2004; Krishna et al. 2008; Ma et al. 2013). In the detailed report of Ma and coworkers (2013), the inflammatory process of the distal common bile duct presented in the form

gray-yellow protrusive lesions measuring up to 1.5 cm. Histologically, the fibroinflammatory process contained numerous foamy macrophages and multinucleated giant cells. Xanthogranulomatous cholangitis produces a type of stenosis of the common bile duct that may mimic cholangiocarcinoma (Pantanowitz et al. 2004; Kawate et al. 2006; Menias et al. 2008). Xanthogranulomatous cholangitis may involve the distal-most part of the common duct, extending into the ampullary tissue and mimicking ampullary cancer (Pottakkat et al. 2006). The xanthogranulomatous process may also develop in the pancreatic head itself and cause ampullary stenosis (xanthogranulomatous pancreatitis; Iyer et al. 2004). In few cases, the process involves the entire extrahepatic duct system. In a 34-year-old female patient, the xanthogranulomatous lesion reached from the hepatic ducts to the common bile duct, in the absence of gallstones (Kawate et al. 2006).

Xanthogranulomatous Changes in Primary Sclerosing Cholangitis

A subgroup of patients with primary sclerosing cholangitis (PSC) undergoing liver transplantation exhibited varying degrees of xanthogranulomatous cholangiopathy at the native liver hilum (Khettry et al. 2003; Keaveny et al. 2004). The presence of this alteration in the native liver hilum was associated with a higher rate of early posttransplant mortality or retransplantation (Keaveny et al. 2004). Histology of the lesions was characterized by an inflammatory reaction involving the hilar bile ducts with or without extension into the adjacent hilar soft tissues. The infiltrate contained foam cells, lymphocytes, plasma cells, and neutrophils.

Cholesterolosis of the Bile Ducts

Introduction

Biliary tract cholesterolosis is chiefly recognized for the gallbladder, where it consists in an accumulation of cholesteryl esters and triglycerides in macrophages at the level of the mucosa. This distinct alteration of the gallbladder mucosa has been described by Virchow in 1857 (Virchow 1857) and given the name of cholesterosis by Mentzer in 1925 (Mentzer 1925). Cholesterosis of the gallbladder has been categorized as one of the lesions representing so-called hyperplastic cholecystosis, referring to gallbladder adenoma, adenomyomatosis, and cholesterolosis (Govoni 1981; Berk et al. 1983; Csendes et al. 1998; 2003; Liu and Wang 2006). A prevalence of 4–8 % has been reported for gallbladder cholesterolosis, particularly in males. Apart from a diffuse involvement of the mucosa, resulting in the "strawberry gallbladder," cholesterolosis of the gallbladder may also be manifest in the form of cholesterol polyps with a size ranging from 2 to 10 mm (Sandri et al. 2003).

Cholesterolosis of the Extrahepatic Bile Ducts

In addition to the gallbladder, cholesterolosis also occurs in the extrahepatic bile ducts. The first report dates from 1958 (Fock 1958). This author described the findings obtained at choledochotomy in a 61-year-old woman who had had cholecystectomy but suffered from recurrent stone disease in the extrahepatic ducts. As soon as the common bile duct was opened, bright granular spots were noticed on its inner surface extending over the whole visible section of it. A biopsy revealed typical cholesterolosis. Extrahepatic bile duct cholesterolosis has preferentially been observed in the mucosa of the common bile duct (Fock 1958). Bile duct cholesterolosis has been observed in conjunction with bile duct carcinoma (Kin et al. 1994). The alteration occurs in the cystic duct (Gilloteaux et al. 1997) but has also been noted in the area of Vater's papilla (Peypoch 1971). Similar to the gallbladder, cholesterolosis of the common bile duct can present as endoluminal polypoid lesions, the so-called cholesterol polyps (Ikoma et al. 1995).

Selected References Grosse 1964; Fassati et al. 1967; Bontempini 1980; Okanobu

et al. 1985; Kamiya et al. 1986; Tokumura et al. 1991; Onodera et al. 1993; Ikoma et al. 1995; Arimoto et al. 1998; Akahori et al. 2002; Horaguchi et al. 2007; Fukatsu et al. 2008.

Gross Pathology

In the patient reported by Bontempini (1980), the resected common bile duct showed a typical "strawberry mucosa" ("coledoco al fragola" in the original Italian report), characterized by numerous miliary-sized lesions of yellowish-white color on a pink mucosal background. Similar to the gallbladder, common bile duct cholesterolosis can present as a cholesterol polyp. In the 73-year-old male patient reported by Ikoma and coworkers (1995), endoscopic retrograde cholangiography revealed a filling defect in the common bile duct 3 cm below the confluence of the cystic duct, and abdominal ultrasonography disclosed a small polypoid lesion at this site. Intraoperative cholangioscopy revealed two yellow polypoid tumors. Macroscopically, the excised specimen showed two flat polypoid lesions of 6 and 5 mm size, respectively, with a yellow and granular surface (Ikoma et al. 1995).

Histopathology

Except cholesterol polyps, cholesterolotic deposits of the common bile duct are usually rather small, but they closely resemble those seen in the gallbladder, i.e., characterized by the superficial mucosal accumulation of nests of foamy macrophages. The histology of cholesterol polyps of the extrahepatic bile ducts is characterized by clustered foamy macrophages that occupy the lamina propria and, by their expansion, cause the polypoid deformation of the mucosa (Ikoma et al. 1995). In two patients with bile duct cancer, foamy cell clusters representing a cholesterolosis phenotype have been described to be located in the stromal components of papillary cholangiocarcinoma, forming cholesterol polyps covered by malignant epithelium. These lesions were grossly visible as small yellow spots (Kin et al. 1994). In cholesterolosis of the cystic duct, electron microscopic examinations revealed that mucous secretory granules appeared dilated, and peculiar intracellular cholesterol deposits were detected in the apical and subapical regions of the cells and around condensed mitochondria (Gilloteaux et al. 1997). Similar ultrastructural changes have been observed in cholesterolosis of the gallbladder (Satoh and Koga 1997).

Differential Diagnosis

The differential diagnosis of ductal cholesterol polyp mainly includes gallbladder cholesterol polyps that may detach and be translocated to the common bile duct, eventually followed by polyp impaction and biliary obstruction (Takii et al. 1994).

Reactive Bile Duct Alterations Mimicking Biliary Cancer: Eosinophilic Cholangitis/Cholangiopathy and Other Eosinophilic Disorders

143

Contents

Abstract

A distinct spectrum of disorders causing biliary obstruction is characterized by eosinophilic infiltration. Eosinophilic cholangiopathy denotes an alteration characterized by an increased infiltration of bile duct walls with eosinophils, associated with stenosing bile duct fibrosis. The disorder may be combined with eosinophilic cholecystitis. In part of cases, bile duct fibrosis is severe, mimicking sclerosing cholangitis. Rare forms show additional granuloma formation that also involves liver tissue (eosinophilic granulomatous cholangiohepatitis). In forms that extend into the liver substance, eosinophilic abscesses may develop. These intraparenchymal lesions can develop a vigorous inflammatory reaction followed by inflammatory fibrosis, ending up in mass lesions mimicking liver tumors (eosinophilic pseudotumors).

Eosinophilic Cholangiopathy and Eosinophilic Cholangitis

Introduction

Eosinophilic cholangiopathy (synonym: eosinophilic cholangitis) denotes an alteration characterized by an increased infiltration of bile duct walls with eosinophils (review: Nashed et al. 2010). A similar change can occur in the gallbladder (eosinophilic cholecystitis; Fox and Mainwaring 1972;

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_143

Kerstein et al. 1976; Leegard 1980), and in case both bile ducts and gallbladder are involved, the term eosinophilic cholangiopathy is applied. First reports on this spectrum of disorders related to eosinophilic infiltrations of the gallbladder (Albot et al. 1949; Fox and Mainwaring 1972), and Kerstein and coworkers described what is still called eosinophilic cholecystitis (Kerstein et al. 1976). Since then, several further examples of biliary tract eosinophilia have been reported, under variable situations of eosinophilia. Eosinophilic cholangitis can be combined with eosinophilic cholecystitis (Leegard 1980). Eosinophilic cholangiopathy also occurs in the pediatric age group (Murray and Woods 1981; Waguet et al. 2000).

Selected References: Leegard 1980; Butler et al. 1985; Tazawa 1996; Tenner et al. 1997; Rodgers et al. 2001; Abdalla and Vauthey 2002; Herrerias-Gutierrez 2003; Vauthey et al. 2003; Duseja et al. 2005; Reyes et al. 2005; Jeyaman et al. 2007; Matsumoto et al. 2007; Chen et al. 2009; Iwamuro et al. 2009; Dubay et al. 2010; Nashed et al. 2010.

Eosinophilic cholangitis is associated with eosinophilic gastroenteritis (Murray and Woods 1981; Schoonbroodt et al. 1995; Kuniyoshi et al. 1998; Jimenez-Saenz et al. 2003), supposed allergic reactions (Matsumoto et al. 2007), idiopathic hypereosinophilic syndrome (Sussman et al. 2008), and other forms of peripheral eosinophilia of unknown cause (Butler et al. 1985). Eosinophilic cholangitis has also been found in association with other and much rarer instances of eosinophilic organ inflammation, e.g., eosinophilic ureteritis (Platt et al. 1990). In one patient, eosinophilic cholangitis was associated with IgG4-related cholangitis (Iwamuro et al. 2009).

Eosinophilic gastroenteritis, in which probably most cases of eosinophilic cholangitis and cholecystitis have been noted, is a disorder of still unknown etiology and pathogenesis. Clinical features of eosinophilic gastroenteritis depend on which location of the gastrointestinal tract and on which tissue compartments are involved. In a clinical review of 220 cases, the stomach and the proximal small bowel were the single most common sites of involvement, while one third of patients were found to have two or more sites of disease, including the biliary tract. Peripheral eosinophilia is found in 20–90 % of cases (Naylor 1990). Mucosal involvement is the most commonly reported, whereas involvement of the subserosal/serosal compartment has been documented in less than 50 cases (Leveque et al. 1998). Eosinophilic cholangitis can also develop in conjunction with eosinophilic cholecystitis (Leegard 1980). In this situation it has been observed that the eosinophilic infiltration may extend into the tissue of the hepatic hilum and produce signs of biliary obstruction (Rosengart et al. 1990).

Clinical Features

As eosinophilic cholangitis can cause bile duct fibrosis, this disorder may induce extrahepatic biliary obstruction, but biliary obstruction has also been found due to dense eosinophilic duct infiltration alone, i.e., in the absence of relevant fibrosis (Murray and Woods 1981; Butler et al. 1985; Platt et al. 1990; Rosengart et al. 1990; Todd et al. 1990; Grauer et al. 1993; Tenner et al. 1997; Matsumoto et al. 2007; Chen et al. 2009; Nashed et al. 2010). Particularly critical stenosis in eosinophilic cholangitis involved the extrahepatic bifurcation (Rosengart et al. 1990) and the common bile duct (Platt et al. 1990; Grauer et al. 1993). These stenoses or strictures often masquerade common bile duct carcinoma (Rodgers et al. 2001; Chen et al. 2009) or hilar carcinoma (Rodgers et al. 2001). The stenosis is sometimes associated with marked dilatation of the extrahepatic and/or intrahepatic bile ducts (Butler et al. 1985; Platt et al. 1990).

Pathology

The information on macroscopic features of eosinophilic cholangitis is exceedingly sparse. In one resection specimen, the common bile duct showed an encasement by a thick fibroinflammatory mass causing stenosis and a partial

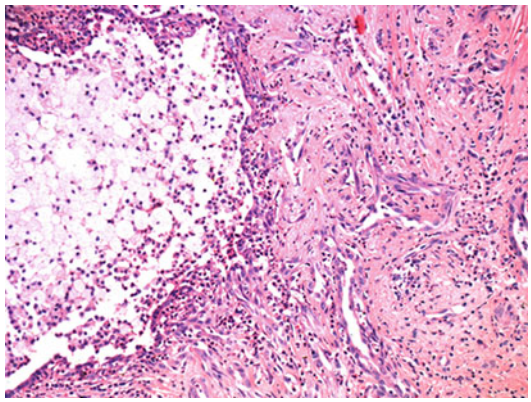

Fig. 1 Eosinophilic cholangitis. The lumen contains a loose exudate with eosinophils and foam cells. Eosinophils also infiltrate the lamina propria (hematoxylin and eosin stain)

effacement of the duct wall layers (Shanti et al. 2001).

The duct walls show a mixed cellular infiltration dominated by eosinophils, commonly with some admixture of lymphocytes, plasma cells, and macrophages (Fig. 1). Eosinophils are found to accumulate in small blood vessels, sometimes with typical eosinophil rolling and attachment to the endothelium. The eosinophils tend to be more frequent in inner and middle layers than in the subserosal compartment. In the case of dense infiltrations, Charcot-Leyden crystals may be seen. The eosinophils also invade the surface epithelium, similar to what is seen in eosinophilic gastroenteritis and with signs of cholangiocyte damage, and there may be infiltration by eosinophils of the peribiliary glands. In the case of dense accumulation of eosinophils in the duct wall, small eosinophilic abscesses may form (Song et al. 1997). The eosinophilic infiltration is sometimes associated with mural fibrosis (Song et al. 1997), even in the absence of clinical signs of sclerosing cholangitis (see below).

Eosinophilic Sclerosing Cholangitis

Eosinophilic cholangitis is known to cause fibrous thickening of the bile ducts walls (Song et al. 1997), but in some patients, there occurs a phenotype where duct sclerosis is a main feature. In fact, a subset of patients with eosinophilic cholangiopathy has been shown to develop all imaging signs of sclerosing cholangitis (Scheurlen et al. 1992; Grauer et al. 1993; Shimomura et al. 1996; Pometta et al. 2000; Miura et al. 2009), also in the pediatric age group (Ichikawa et al. 1997). As this disorder may be seen in association with hypereosinophilic syndrome ("hypereosinophilic sclerosing cholangitis"; Al-Abdulla et al. 2000), it has been suggested that sclerosing cholangitis develops secondary to eosinophilic infiltration of the bile ducts (Grauer et al. 1993; Ichikawa et al. 1997). In fact, marked eosinophilia can be the first manifestation of sclerosing cholangitis (Horiuchi et al. 2009). It has, however, to be added that eosinophilia accompanies PSC in a fraction of the patients (Mir-Madjlessi et al. 1986; in Japanese reports up to 40 %) and that PSC is also known to be associated with eosinophilic infiltration of the liver (Watanabe et al. 1995; Hartleb et al. 1998). Secondary sclerosing cholangitis with dilatation of both the intrahepatic and extrahepatic bile ducts has been described in eosinophilic cholecystitis (Miura et al. 2009).

Eosinophilic Granulomatous Cholangiohepatitis

Hepatic giant cell granulomas with surrounding eosinophilic infiltration (eosinophilic granulomas) have been observed in the context of eosinophilic gastroenteritis (Everett and Mitros 1980).

Eosinophilic Abscess

A mass-producing variant of eosinophilic cholangitis has been reported in a 33-year-old male patient presenting with jaundice and abdominal pain. ERCP showed strictures of the right and left hepatic ducts, and MRI disclosed a 4 cm-sized mass engulfing the junction of the hepatic ducts. Laparotomy showed a multilobulated mass involving the porta hepatis and the fundus of the gallbladder. Histologically, the nodules consisted of sheets

of eosinophils surrounded by a fibro-inflammatory reaction, the eosinophils undermining the surface epithelium. At some places, the tissue was necrotic and densely occupied by eosinophils, thus forming an eosinophilic abscess. The authors observed a similar pseudotumor in a 57-year-old female patient, again in the porta hepatis (Shanti et al. 2001). Eosinophilic liver abscesses occurring in the context of various disorders have been reviewed (Han and Kim 2003; Kang et al. 2004; Jin 2005). Eosinophilic liver abscess may produce nodular mass lesions and thus mimic intrahepatic malignancy (Byun et al. 2006; Kim et al. 2009; Shin 2010). Specifically, eosinophilic liver abscess exhibits contrast-enhancing features on CT and MR images during the hepatic arterial phase, closely mimicking hepatocellular carcinoma (Byun et al. 2006). The differential diagnostic of malignancy is even more important in patients in whom eosinophilic liver abscess was associated with GIT cancer, e.g., gastric carcinoma (Hong et al. 1993).

Eosinophilic Pseudotumor of the Liver and Biliary Tract

Eosinophilic pseudotumors of the liver are mass lesions that resemble eosinophilic hepatic abscesses in morphology, but that show less perifocal inflammatory changes. These lesions are most commonly caused by parasites, chiefly by *Toxocara canis*/visceral larva migrans, most cases being reported from Korea (Hartleb and Januszewski 2001; Jung et al. 2007; Jackson et al. 2010; Lee and Shin 2011), and less commonly by *Ascaris* (Kim et al. 2002). Histologically, a very dense accumulation of eosinophils with signs of eosinophil decay (apoptosis, necroptosis, necrosis) is found, associated with sometimes numerous Charcot-Leyden crystals and eventually remnants of parasites. Clinically, the mass lesions may closely mimic hepatic neoplasia (Jackson et al. 2010) or metastatic disease (Park et al. 2012). Eosinophilic pseudotumor can develop in the ampullary region and cause bile duct obstruction (O'Toole et al. 2003).

Biliary Obstruction Caused by Eosinophilic Inflammation of the Duodeno-ampullary Region

Biliary obstruction may be caused by eosinophilic infiltrates located to the ampullary region, duodenum, or small intestine in the context of eosinophilic gastroenteritis (Rumans and Lieberman 1987; Farahvash et al. 1990; Mohandas et al. 1990; Christopher et al. 2002; Madhotra et al. 2002; Polyak et al. 2002), by an eosinophilic papillary pseudotumor (O'Toole et al. 2003) or by a mass effect of eosinophilic pancreatitis (Eugene et al. 1984; Barthet et al. 1998; Euscher et al. 2000; Sheth et al. 2006).

Eosinophilic Inflammatory Fibroid Polyp of the Biliary Tract

Inflammatory fibroid polyps (synonym: granuloma with eosinophils) are rare lesions of the gastrointestinal tract, histologically often characterized by marked tissue eosinophilia. These polyps predominantly develop in the esophagus (Costa et al. 2000) and the stomach (Rigler et al. 1956; Johnstone and Morson 1978; Battin-Bertho et al. 1987; Hasegawa et al. 1997). The evolution of these polypous lesions has been proposed to follow four stages, viz., a nodular stage with small (<1 cm) lesions composed of spindle cells in a myxoid background, a fibrovascular stage (lesions around 1.5 cm of size) with endothelial proliferation and eosinophilia, and edematous and sclerotic stages, the lesion now being several centimeters in diameter (Kim and Kim 1988). At least part of gastrointestinal inflammatory polyps harbor spindle cells that are reactive for C34 (Hasegawa et al. 1997; Kim et al. 2000; Pantanowitz et al. 2004), but kit negative (Kim et al. 2000). As these distinct mesenchymal elements of polyps also express fascin, calponin, and CD35, a dendritic cell origin of these elements was proposed (Pantanowitz et al. 2004). Inflammatory polyps are very rare in the extrahepatic biliary tract (Ro 1975; Shepherd et al. 1986; Adachi et al. 1991; Adachi and Fukumoto 1996; Moulis 1996; Watananbe et al. 2002; Hussain and

Ahmed 2003). In some of these biliary tract polyps, a marked eosinophilic infiltration is noted, similar to that in the GIT counterparts. Eosinophils are more often seen in basal parts of the polyp than in its most luminal parts, and eosinophils are also noted in the duct wall immediately facing the stalk of the polyp.

Eosinophilic Ascites in Hepatobiliary Eosinophilic Inflammation

Eosinophilic ascites, sometimes massive, has been found in eosinophilic gastroenteritis evolving in conjunction with idiopathic hypereosinophilic syndrome (McNabb et al. 1979; Vandewiele et al. 1991) and also in the subserous/serosal form of eosinophilic gastroenteritis (Sanchez-Fayos et al. 1992; Fortman et al. 1993).

Hepatobiliary Eosinophilic Vascular Disorders

The extrahepatic bile ducts are very rarely involved by allergic granulomatous arteritis of the Churg-Strauss type. The inflamed mural vessels exhibit segmental fibroid necrosis, these foci being surrounded by epithelioid cells and numerous eosinophils. Allergic granulomatous angiitis can cause hepatic artery aneurysms that may rupture into the bile duct system (Nakamura et al. 1991). The disorder is also known to involve the gallbladder (Suzuki et al. 2005). Churg-Strauss syndrome is characterized by marked accumulation of circulating eosinophils in peripheral blood and affected tissues, associated with a distinct type of granulomatous vasculitis (reviews: Abril 2011; Vaglio et al. 2012). In contrast to eotaxin-1 and eotaxin-2, eotaxin-3 was markedly elevated in serum of Churg-Strauss syndrome patients, and the levels were significantly correlated with the peripheral eosinophil count. Immunohistochemically, there was a strong expression of eotaxin-3 in endothelial cells and inflammatory cells of affected tissues (Polzer et al. 2008). The biliary tract may be involved in eosinophilic mesenteric vasculitis (Abdulwahab et al. 2007).

Hypereosinophilic multiple thrombosis (HEMT) is a distinct syndrome characterized by the combination of chronic mature eosinophilia and multiple thrombus formation in several organs (Ishii et al. 1977, 1978). Hypereosinophilia also induces thrombophlebitis (Kanno et al. 2005; Terrier et al. 2006) and thrombotic microangiopathy (Liapis et al. 2005). Large thrombi have been observed in the heart (Kocaturk and Yilmaz 2005; Janoskuti et al. 2006), the CNS sinuses (Sakuta et al. 2007), the portal vein (Kikuchi et al. 2002; Monterrubio Villar et al. 2006), and the hepatic veins, with subsequent Budd-Chiari syndrome (Elouaer-Blanc et al. 1985; Vargas et al. 1993; Zylberberg et al. 1996; Becker et al. 2006).

Parasitic Eosinophilic Cholangitis and Cholecystitis

Hepatobiliary ascariasis is a well-recognized pathology: in a study of 500 Indian patients with this infestation, acute cholangitis was observed in 121 patients (Khuroo et al. 1990). Eosinophilic cholecystitis and cholangitis (sometimes obstructive) are known to occur due to *Clonorchis sinensis*, *Opisthorchis viverrini* and *O. felineus*, *Dicrocoelium dendriticum*, and *Fasciola hepatica* and *F. gigantica* (Sullivan and Koep 1980; Dias et al. 1996; Rim 2005; Lai et al. 2007; Rana et al. 2007). Severe eosinophilic cholangitis with parenchymal destruction has been observed due to hydatid disease. In such situation, small bile ducts may be replaced by epithelioid cell granulomas surrounded by an eosinophilic infiltrate (Raptou et al. 2009).

Bile Duct Rupture and Peripheral Eosinophilia

Rupture of extrahepatic bile ducts may be associated with subsequent peripheral eosinophilia. This phenomenon was, e.g., observed in an infant having spontaneous rupture of the common bile duct and leakage of bile into the abdominal cavity.

Blood eosinophilia raised to 16 % within 5 days after the bile duct event (Imanieh et al. 2006).

Abstract

Various mechanical and anatomical alterations can induce obstruction of the bile duct system, sometimes mimicking biliary cancer. Protruding tissue masses including biliary tumor thrombi and icteric-type hepatocellular carcinoma can massively obstruct bile ducts. A similar effect is produced by periductal tumor growths or compression by periductal enlarged lymph nodes occupied by metastatic disease (external compression). Intraductal blood clots may result in biliary obstruction. Other ductal and intraductal factors causing stenosis include bile duct webs and diaphragms, bile duct angulation, congenital and acquired bile duct diverticula, and bile duct intussusception and volvulus. The peripancreatic inflammatory and necrotic changes that occur in the setting of pancreatitis can cause stricture of extrahepatic bile ducts. A distinct form of derangement of intraductal flow is biliary sludge.

Bile Duct Obstruction Due To Protruding Tissue Masses

So-Called Biliary Tumor Thrombi

The term thrombus to denote the presence of tumor tissue within a ductal lumen is a misnomer, because thrombus is reserved for a distinct product of intravascular blood clotting. The phenomenon is characterized by ingrowth of a malignant tumor into a large bile duct, followed by detachment of a tumor fragment that may either float, obturate the lumen, or be transported in a distal direction. In the proper sense of the term, tumor "thrombus" denotes a free intraluminal tumor fragment rather than a pedunculated intraluminal polyp that is still fixed to the duct wall, e.g., with a vascular stalk.

Icteric-Type Hepatocellular Carcinoma

Intraluminal tumor masses of tumor fragments can cause biliary obstruction and jaundice, mostly reported for hepatocellular carcinoma (HCC) in the context of the distinct oncologic situation, *icteric hepatoma* or *icteric-type hepatocellular carcinoma* (defined by Lin et al. 1975). Since Mallory et al. (1947) first described a case of HCC accompanied with obstructive jaundice secondary to biliary hemorrhage from a tumor invading the cystic duct, several situations have been connected with the term, icteric hepatoma, and we here classify them into five types (Table 1).

Table 1 Types of icteric hepatoma (icteric-type hepatocellular carcinoma)

Type 1
Obstructive jaundice caused by direct invasion and stenosis of bile duct
Type 2
Obstructive jaundice caused by intraductal floating and distally migrating tumor debris
Type 3
Obstructive jaundice caused by tumor-induced intraductal blood clot/hemobilia
Type 4
Obstructive jaundice caused by extrinsic duct compression by tumor and/or nodal metastases and/or tumorous portal vein thrombosis
Type 5
Ectopic hepatocellular carcinoma (hilar or in the extrahepatic ducts)

First, the term is mostly used for those HCCs that cause obstructive jaundice by floating tumor debris in the common bile duct, as outlined below (Chen 2002). Other situations include direct invasion of ducts by HCC (Afroudakis et al. 1978), sometimes with polypoid intraluminal growth (Nonomura et al. 1983), hemorrhagic obturating clot formation (Creed and Fisher 1956), and hemobilia (Johns and Zimmerman 1961). A distinct situation is characterized by usually stenosing HCC apparently arising outside the liver substance proper. Whether all of these tumors are in fact ectopic HCC, or instances where the primary intrahepatic neoplasm has been missed, is sometimes difficult to judge (Badve et al. 1991; Buckmaster et al. 1994; Murakami et al. 2003; Tsushimi et al. 2005; Makino et al. 2006).

In most cases, invasion by HCC of the biliary tract system at some place must have taken place,

and, in fact, bile duct infiltration by HCC followed by intraluminal growth has been documented several times. Even small tumors can then, owing to intraluminal polypoid growth, cause biliary obstruction (Terada et al. 1989). A second mechanism is sometimes reported to consist of HCC rupture into large bile ducts (Chen et al. 1994), but as to how such a ruptured tumor gets access to duct lumina is not really known. In HCCs complicated by bile duct invasion, the levels of serum bilirubin and carbohydrate antigen 19-9 were significantly higher in the bile duct invasion group in comparison with patients with HCC who had no bile duct involvement. Macroscopically, confluent multinodular type and infiltrative HCC types were predominant in the bile duct invasion group, as were tumor with portal vein invasion and intrahepatic metastasis (Ikenaga et al. 2009b). In some HCCs with bile duct invasion, a fragment or fragments of the intracavitary growth may detach and be situated (frequently together with clotted blood) as a floating mass or tumor debris in the lumen (the "tumor thrombus"), and subsequently be dislocated to other places of the biliary tract (e.g., the ampullary region), analogous to an embolus ("tumor embolus").

(2007), Kobayashi et al. (2008), Long et al. (2010, and Wang et al. (2010).

On MRI images, HCC tumor thrombi present as cord-like or columnar masses in the bile duct with proximal cholangiectasis. The tumor thrombi are slightly hypointense on T1-weighted and slightly hyperintense on T2-weighted images. On MRI-cholangiopancreatograms, the majority of the lesions present as filling defect in the bile duct, abrupt obstruction of the bile duct, and duct dilatation above the obstruction (Liu et al. 2010).

In few instances, the migration track from the primary ductal invasion site to the subsequent obturation site ("embolus") could be followed in detail, e.g., from the right hepatic duct to the common bile duct (Wind and Futterman 1977; Tsuzuki et al. 1979). Among 18 with intracommon bile duct manifestations of HCC, choledochoscopy revealed that the site of hepatoma rupture was from the right intrahepatic duct in nine patients, from the left hepatic duct in seven patients, and from the hepatic hilum in two patients (Jan and Chen 1999). Distal migration of intraluminal tumor fragments has also been observed in fibrolamellar carcinoma of the liver (Albaugh et al. 1984; Eckstein et al. 1988). In some instances, distal duct stenosis is not caused by tumor tissue as such, but rather by dislocated clots and/or blood associated with the more proximally located, invasive, and destructive tumor growth (hemobilia; van Sonnenberg und Ferrucci 1979; Fraser et al. 1989; Rhoe et al. 1989; Vagianos et al. 1993). Sandblom first introduced the term hemobilia, and this author already stated that hemobilia can cause biliary obstruction (Sandblom 1948).

How frequent are HCCs complicated by cancer thrombi in bile ducts? In a series of 140 necropsied patients with hepatocellular carcinoma, tumorous invasion of bile ducts was detected in 2.1 % (Carella et al. 1981). Among 238 autopsy and 21 surgical cases of HCC, 24 cases with prominent intrabile duct tumor growth were identified. Progressive obstructive jaundice had occurred during the course of most cases and was the presenting sign in nine patients. The average survival time of the cases was significantly shorter than that of HCC patients without intraductal tumor growth (Kojiro et al. 1982). In a study of 549 cases of HCC in Korea, the authors experienced ten cases with gross evidence of tumor thrombi in the bile duct system (Wang et al. 1999). In another study (from Taiwan),

intraductal HCC fragments were found in nine patients out of 3,921 patients with HCC (Huang et al. 1998). In a Japanese investigation, nine (1.66 %) out of 542 cases of HCC treated surgically disclosed macroscopic bile duct thrombi (Ueda et al. 1994). A retrospective study was undertaken to review 20 patients with obstructive jaundice secondary to ruptured HCC into common bile duct during a 12-year period. All these patients on initial examination had recurrent episodic jaundice and cholangitis, and 75 % showed liver cirrhosis (Chen et al. 1994). In China, where an estimated 300,000 new cases of HCC are diagnosed annually, it is estimated that 1–2 % (Ueda et al. 1994) or 2.3–9.2 % (cited in Xiangji et al. 2009) of HCC cases have coincident bile duct tumor thrombi, which represents 7,000–27,000 new cases of biliary tumor thrombi each year. In a study of 12,114 patients with HCC, 184 patients had tumors complicated by bile duct thrombi (1.84 %; Xiangji et al. 2009).

Other Tumors Causing Biliary Tumor Thrombi

Apart from HCC, other tumors have been reported to produce intraductal obstructive growths, including gallbladder carcinoma (Midorikawa et al. 2000; Rau et al. 2004), carcinoma of the cystic duct (Shibata and Toyoda 1995), cystic duct remnant carcinoma (Gabata et al. 2003), metastatic breast carcinoma (Papo et al. 1996), metastatic renal cell carcinoma (Ueda et al. 2002), and in particular manifestations of colorectal carcinoma. Liver metastases from colorectal cancer easily invade the Glisson's triads and may show prominent intrabiliary polypoid tumor growth (Riopel et al. 1997; Povoski et al. 2000; Takamatsu et al. 2004), sometimes with minimal invasion of the liver substance (Uehara et al. 2004). In a study of 149 patients with liver metastasis from colorectal cancer, 12 % had macroscopic intrabiliary growth, the size of the ingrowths ranging from 4 to 42 mm (Okano et al. 1999). In this study, two thirds of the tumors with macroscopic bile duct invasion were well-differentiated adenocarcinomas with a tendency for less vascular invasion. In another study of 217 patients who underwent hepatic resection for colorectal cancer metastasis, microscopic bile duct invasion was found in 89 patients (40.6 %) and of these, 23 patients (10.6 %) had macroscopic biliary extension. This subset of macroscopic biliary involvement exhibited less aggressive features (Kubo et al. 2002). A smaller percentage of macroscopic bile duct involvement, i.e., 5.8 %, was found in recent study of 103 patients (Sugiura et al. 2006).

Intraductal Tumor Tissue Prolapse

Prolapsed tumor tissue can cause intermittent jaundice, e.g., reported for prolapsed gastric tumor occluding the common bile duct (Rukstinat et al. 1970).

Biliary Obstruction Caused by Postoperative Intraductal Blood Clots

Obstructive jaundice has been seen to be caused by choledochal clots after cholecystectomy (Aguilar Lugue et al. 1983).

Prolapsed Masses and Gastroduodenal Intussusception Causing Ampullary Obstruction

The ampullary orifice can be blocked or stenosed by prolapse of polypoid malignant gastric tumors (Karl et al. 2004) or intussusception of gastric polyps, e.g., polyps in Gardner's syndrome (Herman et al. 1992).

Bile Duct Stenosis Due To Extrinsic Compression

Introduction

Apart from tumors and tumor-like lesions developing in the bile duct walls and causing stenosis/obstruction, the bile duct system can also undergo

stenosis by external compression by a large number of lesions.

Tumors

Several types of neoplasms, but mainly malignant ones, can exert extrinsic compression on large bile ducts and thus induce biliary obstruction. These lesions, e.g., comprise hepatocellular carcinoma (Joehl and Abt 1984; Thomsen et al. 1998; Murata et al.,2003; Camci et al. 2007), fibrolamellar carcinoma (Albaugh et al. 1984), cholangiocarcinomas, hepatobiliary cystadenoma (Erdogan et al. 2006), metastases (Liratzopoulos et al. 2006), non-Hodgkin's lymphoma (Jho et al. 2007), and Hodgkin's lymphoma (Di Sena et al. 2005). Similarly, malignancies of the pancreatic head can compress the distal-most part of the common bile duct.

Compression by Hepatic Cysts

Large nonparasitic liver cysts and cyst in polycystic disease can exert compression mainly on intrahepatic bile ducts (Salam and Keeffe 1989; Ishikawa et al. 2002; Lapeyre et al. 2002). Sudden duct compression can occur upon bleeding into such a cyst (von Woellwarth et al. 2000). Similarly, hemorrhage into cysts in hepatic polycystic disease can cause bile duct stenosis (Rosenfeld et al. 2001). Peribiliary cysts can rarely compress the bile duct and lead to obstructive jaundice (Ikenaga et al. 2009a).

Infectious and Parasitic Causes of Bile Duct Compression

Tuberculosis of bile duct-associated lymph nodes situated in the hepatoduodenal ligament can cause duct compression (Amarapurkar and Agrawal 2006), and periportal tuberculous lymphadenitis may encroach upon the extrahepatic duct system (Stanely et al. 1984). Echinococcus cysts caused by *E. granulosus* exhibit expanding growth and can displace and compress bile ducts (Colle et al. 2002), sometimes with effacement of the bile duct confluence (Martin Molinero et al. 1989).

Vascular Compression

Pulsatile vascular compression of the common bile duct is a rare cause of biliary obstruction. The extrahepatic bile duct system may be compressed by several arteries and their branches, including the right hepatic artery, gastroduodenal artery, cystic artery, proper hepatic artery, and variable branches of the common hepatic artery. Important in this context is the considerable variation of artery anatomy in this vascular compartment (Hiatt et al. 1994; Koops et al. 2004). The relations of these arteries to the biliary ducts have been studied in detail (Michels 1951). Jaundice due to common bile duct obstruction by an aberrant celiac artery was first reported in 1961 (Luttwak and Schwartz 1961).

The right hepatic artery can cause compressive jaundice (right hepatic artery syndrome; Taboga et al. 1969; Tsuchiya et al. 1984; Chung et al. 1994; Miyashita et al. 2005) and may promote the development of lithiasis (Kim et al. 1992b; Ju et al. 2000). A right hepatic artery originating from the gastroduodenal artery has also been shown to induce obstructive jaundice (Baek et al. 2008). Compression of the common bile duct can occur secondary to vascular rings (Goldberg and Doman 1988). Aneurysms of visceral arteries can cause bile duct compression and jaundice, including aneurysms of the abdominal aorta (Smith et al. 2002), hepatic artery (Lewis et al. 1982; Mazziotti et al. 2003), and gastroduodenal artery (Konstantakos et al. 2000; Sipahioglu et al. 2005). Common bile duct compression occurs secondary to visceral venous aneurysms, which most often develop in the portal vein (Sfyroeras et al. 2009). Cavernous transformation of the portal vein is known to compress the extrahepatic biliary tract (portal biliopathy; portal hypertensive biliopathy; Takehara et al. 1993; Chandra et al. 2001; Rosenthal et al. 2008). Enlarged collateral veins occurring in portal hypertension can compress the common bile

duct (Hunt 1965). These alterations are further discussed in a separate chapter.

Bile Duct Webs

Introduction

Bile duct webs (biliary webs; biliary septa; biliary diaphragms) are rare causes of biliary obstruction, likely to be congenital in nature, but presenting in later life due to the initial patency of these webs in allowing bile drainage (review: Margolis and Schein 2001). However, cases in the pediatric age group have been reported as well (Chapoy et al. 1981; Shih et al. 1992), including congenital septate biliary tree (Frexes et al. 1986). The webs present as septum-like folds usually located to the extrahepatic bile ducts. On imaging, webs typically appear as thin radiolucent rings with or without proximal duct dilatation. Webs are predominantly located in the common hepatic duct (Fisher et al. 1968; Furukawa et al. 1992; Kato et al. 1994), the right or left hepatic duct (Goldenberg et al. 1981), the hepatic duct junction (Devanesan et al. 1978), and the common bile duct (Ornet et al. 1966; Pinter et al. 1975; Chari and Harrison 1998; Baek et al. 2005; Shera and Shah 2008).

Congenital webs are extremely rare malformations of the extrahepatic bile ducts, with little more than 20 cases reported in the literature. A congenital origin in at least part of the cases is suggested by an association with congenital anomalies elsewhere in the biliary tract. Webs may be associated with choledochal cysts (Ando et al. 1995; Sharma et al. 1995; Dong et al. 2006). Septum of the common hepatic duct was reported to be associated with an anomalous junction of the biliopancreatic ductal system (Kato et al. 1994) or with complex hepatobiliary pancreatic anomalies characterized by dominant dorsal duct syndrome, with the dorsal pancreatic duct representing the only drainage system (Shera and Shah 2008). On the other hand, there may be instances where webs or septum-like formations develop subsequent to inflammatory changes of ducts. For example, biliary web has been noted in association with cholelithiasis (de Celis et al. 1985; Papaziogas et al. 2002; Baek et al. 2005), but gallstones may also develop as a complication of web-induced bile duct stenosis. Furthermore, webs are a cholangiographic feature in a subset of patients with primary sclerosing cholangitis (PSC; Gulliver et al. 1991).

Macroscopically, the diaphragms or septa are crescent shaped, bridge-like, or shaped like a swallow's nest (aortic valve-like), or they present as ringlike webs (perforated diaphragms). At choledochoscopy, the web may show a micropapillary texture and erosions (Baek et al. 2005).

In the few situations where histologic examination of resected webs or septa had been performed, these structures disclosed a fibrous stroma covered by ductal mucosa (Ando et al. 1995), sometimes with atrophy of the overlying mucosa (Furukawa et al. 1992) or, conversely, with signs of epithelial proliferation (Baek et al. 2005). The resected web in one patient with biliopancreatic maljunction showed a normal histology of the adjacent parts of the common hepatic duct (Kato et al. 1994).

Bile Duct Angulation

Angulation of the large bile duct is an anatomical variant of the duct's course between the confluens and the duodenal entry. These changes gained some actuality owing to the fact that they may produce ERCP difficulties (Affronti 2007) and that they may be involved in stone recurrence. It may occur as congenital anomaly in extrahepatic bile duct angulation; the common bile is seen as deviating to the right as it descends toward the duodenum (Warren 1987). Angulation is measured as the sharpest angle along the common bile duct from 1 cm below the bifurcation to 1 cm above the papilla. Angulation of the large duct is thought to dispose to bile stasis, and angulation of the common bile duct has earlier been found to associate with choledocholithiasis (Warren 1987) and to predispose to recurrent symptomatic bile duct stones (Keizman et al. 2006). In a recent systematic study on 232 consecutive

patients who had undergone endoscopic retrograde cholangiopancreatography for bile duct stones, symptomatic bile duct stones recurred in 16 %, and among these patients, angulation of the common bile duct (145° or less) was an independent risk factor (Keizman et al. 2006). Angulation may also occur as a secondary event, e.g., in association with extrahepatic portal venous obstruction (Khuroo et al. 1993), ampullary or pancreatic tumors (Reibscheid et al. 1973), or induced by T-tube (the elbow sign; Lee and Burhenne 1991).

Diverticula of Bile Ducts

Congenital Diverticula of the Biliary Tract

Congenital diverticula of the biliary tract are rare lesions classified according to the Alonso-Lej system and the Todani systems as being type II choledochal cysts. Alonso-Lej et al. first classified choledochal cysts into three types (Alonso-Lej et al. 1959). Due to the recognition of intrahepatic involvement, Todani and coworkers modified their classification into six types (Todani et al. 1977), later revised and refined (Todani et al. 1984, 2003; Todani 1997).

In an analysis of 878 patients, Yamaguchi found the frequency of type II lesions to be 1.4 % among all types of anomalies (Yamaguchi 1980). Mixed types I and II choledochal cysts with a fusiform common bile duct with a diverticulum originating from the midportion of the common bile duct have also been described (Kaneyama et al. 2005b). Congenital diverticula and ectasias of the biliary tract can develop in inborn disorders of connective tissue metabolism, e.g., multiple hollow organ dysplasia in Ehlers-Danlos syndrome (Kahn et al. 1988; Schippers and Dittler 1989) and Marfan syndrome (Merza and Raiser 1987). Congenital diverticula of the large bile ducts can, depending on their position, size, and geometry, cause inflammation and subsequent stenosis and can also contain gallstones (Kune 1965). Congenital diverticula of the common bile duct are a well-recognized entity.

Selected References Longo (1950), Alden and Sterner (1957), Kune (1965), Luchtman et al. (1971), Sapounov (1972), Pujol-Soler et al. (1975), Camelot et al. (1976), Koytcha et al. (1976), Kostiainen et al. (1983), Shamberger et al. (1985), Ehmke (1987), Mouroux et al. (1987), Solovel et al. (1987), Bastid and Sahel (1989), Bona et al. (1991), Mai et al. (1991), Gelmi et al. (1994), Sato et al. (2002), and Kaneyama et al. 2005b).

They may occur as an isolated lesion or in combination with other rare anomalies of the biliary tract, such as an accessory choledochus (Gelmi et al. 1994). A more common subset of choledochal diverticula develop in the intraduodenal part of the duct (low choledochal diverticula; Pujol-Soler et al. 1975; Kostiainen et al. 1983; Shamberger et al. 1985; Solovel et al. 1987; Bastid and Sahel 1989; Bona et al. 1991). The development of choledochal diverticula is sometimes associated with abnormalities of mucosal cell differentiation, e.g., gastric ectopic mucosa of the pyloric type (Mai et al. 1991).

Diverticulum of the common bile duct may undergo spontaneous rupture with formation of retroperitoneal biloma (Takahashi et al. 2005). Diverticula have rarely been observed in the hepatic duct (Eisen et al. 1963; Jackson and Maxwell 1964; Maxwell et al. 1967; Napoli 1970; Down 1974; Meyers et al. 1976; Schey et al. 1977; Farkas et al. 1980; Flowers and Ho 1998; Kaneyama et al. 2005a; Hashimoto et al. 2007; Fernandes et al. 2010). Hepatic duct diverticulum may occur in the common hepatic duct (hepatodochal diverticulum) or in the left or right hepatic duct and is considered to be a developmental anomaly. It is a rare disorder with the lowest incidence among congenital conditions that cause dilatation of the bile duct (Maxwell et al. 1967; Farkas et al. 1980). Common hepatic duct diverticulum has been shown to cause fatal obstructive cholangitis and sepsis (Flowers and Ho 1998). Diverticula can also develop in the cystic duct (Grassberger and Seyss 1967). Intrahepatic duct diverticula are rare and may occur as solitary or multiple lesions. This type of

diverticulum may be observed in association with pancreaticobiliary maljunction (Ikematsu et al. 1994).

Acquired Diverticula of the Biliary Tract

Acquired biliary tract diverticula and diverticulum-like lesions are known to occur in the context of primary sclerosing cholangitis (PSC). Such diverticula and/or bile duct webs have been considered by several authors to be highly typical cholangiographic features of PSC, although seen in only about a third of the cases (MacCarty et al. 1983), but in contrast to earlier reports (e.g., Rohrmann et al. 1978), these alterations are not specific for this disease (Gulliver et al. 1991; Tibble et al. 2003).

Cholangiographically, the spectrum of lesions ranges from the "beaded" cholangiographic appearance of ducts characteristic for PSC to usually small diverticular outpouchings (MacCarty et al. 1983). Biliary tract diverticula in PSC can occur together with webs or biliary septum formation (Gulliver et al. 1991), but septa also occur in conjunction with biliary tract malformations (Kato et al. 1994). Other conditions sometimes associated with acquired diverticula include common duct stones, postoperative structures, bile duct stent, and choledochoduodenostomy (Gulliver et al. 1991).

Duodenal Diverticula Associated with Common Bile Duct Disease and Biliary Obstruction

Periampullary duodenal diverticula which are common lesions, mainly in older patients, have been classified into three types, according to the position of the major duodenal papilla (Boix et al. 2006): type I, papilla inside the diverticulum; type II, papilla at the margin of the diverticulum; and type III, papilla near the diverticulum. From their critical position in regard to the choledochal entry, duodenal diverticula can cause biliary obstruction (Gudjonsson et al. 1988; Yoneyama et al. 2004). The distinct anatomic relations between the insertion of the choledochal duct into duodenal diverticula have been analyzed in detail based on 96 postmortem specimens. In every instance, the common bile duct either emptied into or immediately adjacent to the diverticulum (Wolfson and Miller 1978). Tissual anomalies associated with duodenal diverticula, such as the so-called mucosal rosette (a periampullary pseudotumor; Bellamy 1993; Price et al. 1993), may contribute to the pathogenesis of deranged flow. One pathogenic factor may be related to the fact that periampullary diverticula lead to pancreatobiliary reflux (Sugiyama and Atomi 2001). Sometimes, food impaction in a duodenal diverticulum induces biliary obstruction (Van der Linde et al. 1997). Intraduodenal diverticulum has been reported to be associated with double common bile duct causing cholangitis (Martins et al. 2007).

Bile Duct Intussusception and Volvulus

Intussusception

Spontaneous intussusception is known for the cystic duct; this event can cause common bile duct obstruction (Aseem and Cohn 1975). Invagination of the common bile duct into the jejunum has been observed in conjunction with choledochjejunostomy (Zografos and Androulakis 1998). It may also be caused by tumors located to the ampullary region (Van Kemmel and L'hermine 1973).

Volvulus

Volvulus is well known for the gallbladder, where it was described in 1898 already (Wendel 1898). It occurs in all age groups, with the highest incidence in elderly women, and a female-to-male ratio of 3:1 (review of literature: Shaikh et al. 2005). In contrast, volvulus is an exceptional event in the extrahepatic bile ducts. The choledochal duct may be dislodged, together with torsion, in case of large diaphragmatic

hernias, ending up with choledochal semivolvulus (Caldeiro et al. 2001).

Bile Duct Stenosis in Pancreatitis

The fibrotic process characterizing chronic pancreatitis often extends into the tissue surrounding the intrapancreatic part of the common bile duct, causing distal bile duct stenosis. In fact, chronic pancreatitis is one of the most frequent causes of biliary stricture/stenosis (McCollum and Jordan 1975; Warshaw et al. 1976; Schulte et al. 1977; Scott et al. 1977; Sarles and Sahel 1978; Yadegar et al. 1980; Wislooff et al. 1982; Eckhauser et al. 1983; Newton et al. 1983; Aranha et al. 1984; Stabile et al. 1987; Abdullah et al. 2007). In a study on 79 patients with moderate or advanced chronic pancreatitis, 46 % had ERCP evidence of distal common bile duct stenosis (Wislooff et al. 1982). In a retrospective analysis of 814 cases of chronic pancreatitis in Korea, biliary stricture was detected in 13.9 % (Ryu et al. 2005). In an Indian nationwide study on 1,086 patients with chronic pancreatitis of diverse etiology, biliary obstruction was found in 8.2 % (Balakrishnan et al. 2008). Distal bile duct stenosis can occur in any form of chronic pancreatitis, including groove pancreatitis (Castell-Monsalve et al. 2008) and autoimmune pancreatitis (Matsubara et al. 2005). Pancreatic pseudocysts developing in the context of chronic pancreatitis may compress the distal common bile duct and induce biliary obstruction (Gonzalez et al. 1965; Christensen et al. 1975; Falko et al. 1975; Chawla et al. 1977; Warshaw and Rattner 1980; Skellenger et al. 1983; Magyar et al. 1994; Noda et al. 1994; Cho et al. 2000; Yeh et al. 2003; Okabe et al. 2006). Persistent biliary obstruction caused by chronic pancreatitis can lead to secondary biliary cirrhosis (Warshaw et al. 1976; Abdullah et al. 2007). Bile duct obstruction also occurs in patients with acute gallstone pancreatitis (Petrosyan et al. 2009). Chronic fibrosing pancreatitis can be associated with pancreatolithiasis. Pancreatic stones may dislodge into the common channel of the pancreatobiliary ducts and cause obstruction and/or cholangitis (Kinoshita et al. 1996; Jain et al. 2005; Naitoh et al. 2008).

Biliary Obstruction Due To Biliary Sludge

Introduction

Sludge is the more or less solid material which results from slow settling of particles and gels dispersed in a viscid, mucin-rich liquid medium (Angelico et al. 1990; Lee 1990). The material of biliary sludge is a mixture of thickened bile with insoluble salts and sometimes collective collagen tissue from damaged bile duct walls. In more detail, the most common precipitates in gallbladder bile are cholesterol monohydrate crystals, calcium bilirubinate granules, calcium phosphate and calcium carbonate crystals, and calcium salts of fatty acids (Filly et al. 1980; Allen et al. 1981; Lee and Nicholls 1986; Jüngst et al. 1996; Keulemans et al. 1998).

By use of immunofluorescence, it was shown that sludge sediment appears as a mixture of vesicular aggregates and pigment particles which are linked by a gel matrix of mucin containing cholesterol monohydrate crystals, in part coated by IgA (de la Porte et al. 2000). Mucin in bile is supposed to accelerate the crystallization of cholesterol monohydrate (Levy et al. 1984; Smith 1987; Wilhelmi et al. 2004). In fact, hepatic bile is modified during residence in the gallbladder, contributing to eventual sludge formation (Ko et al. 2005b). A portion of biliary sludge contains comparatively large particles (1–3 mm) called microliths, the formation of which is an obligatory intermediate step in the development of gallstones. As a consequence of the sedimentation of sludge, the biliary tract (but particularly the gallbladder) may contain layered bile, with the lowest layer showing low-amplitude echogenicity on ultrasound (Jüngst et al. 2006). The components of sludge can be analyzed by use of bile microscopy (Delchier et al. 1986; Ros et al. 1986; Ko et al. 1999), including polarized light microscopy (Gogna et al. 1989).

Clinical Features of Sludge

Although the ultrasonic detection of gallbladder sludge is relatively frequent, the clinical importance remains unclear (Shaffer 2001). Sludge and microliths can cause deranged bile flow followed by colicky pain, cholecystitis, cholangitis, and acute pancreatitis and has thus been suggested to be of clinical relevance (Ohara and Schaefer 1990; Shaffer 2001; Pazzi et al. 2003; Jain 2004). However, only a fraction of patients with biliary sludge may develop clinical manifestations, because sludge spontaneously disappears in many patients (Lee et al. 1988). In a series of 286 patients with sludge, gallbladder sludge disappeared within a relatively short time in 71.4 % of patients, but gallbladder sludge was considered an important phenomenon because gallbladder stones or complications such as acute cholecystitis occurred in 19.6 % of patients (Janowitz et al. 1994). In the early phase of acute pancreatitis of suspected biliary origin, bile duct crystals were found in most cases (Kohut et al. 2001). In contrast, the relationship of bile duct crystals to sphincter of Oddi dysfunction is not clear (Rhee and Elta 2003). In some patients, sludge in the gallbladder or the common bile duct causes pseudotumorous masses, the so-called tumefactive sludge (Ando and Ito 1986; Kelly et al. 1993).

Imaging criteria of biliary sludge are filling defects or plug-like obstruction seen on cholangiograms or material filling the bile ducts seen on sonograms or CT scans (Barton et al. 1995; Gomez et al. 1998; Metrewell et al. 2004). Transabdominal ultrasound examination permits the visualization of sludge particles in bile, usually those of >2–3 mm in diameter. These represent the larger components of biliary sludge and consist of aggregated crystals or microliths suspended in the mucin-rich liquid phase.

What Are Typical Situations Where Biliary Sludge Develops ?

Biliary sludge is known to develop during pregnancy and the postpartum (usually reversible; Maringhini et al. 1988, 1993; Gilat and Konikoff 2000; increasing in frequency from the second trimester [5.1 %] to the postpartum [10.2 %]; Ko et al. 2005a; Bolukbas et al. 2006), in total parenteral nutrition (Messing et al. 1983; Murray and Hawkey 1992), in morbidly obese patients after rapid weight loss (Shiffman et al. 1991), during fasting after gastrointestinal tract surgery (Bolondi et al. 1985), in critically ill trauma patients (Toursarkissian et al. 1995), after choledochoduodenostomy (chronic biliary sludge or "sump syndrome"; Ell et al. 2006), in gastric and duodenal ulcer disease (Maev et al. 2006), in sickle cell disease (Walker and Serjeant 1996; Al-Salem and Qaisruddin 1998; Walker et al. 2000), and in beta-thalassemia major (Portincasa et al. 2004). Gallbladder sludge develops in approximately 70 % of patients after bone marrow transplantation, and sludge often develops in these patients without known predisposing factors (Teefey et al. 1994). This sludge mainly consists of calcium bilirubinate, while cholesterol crystals are almost absent (Ko et al. 1996). Biliary sludge is known to occur after liver transplantation (found by imaging in 13 % in a series of 400 transplanted livers; Barton et al. 1995). However, the development of this complication, in the absence of anastomotic obstruction in the common bile duct, has now become very rare, owing to improved techniques of biliary reconstruction and routine biliary flushing prior to cold preservation. The pathogenesis of sludge post-OLT is likely to be multifactorial, but cold ischemic damage to the bile duct wall may play a significant role (Chen et al. 1988).

Bile Plug Syndrome and Inspissated Bile Syndrome

The two disorders may be different, in that bile plug syndrome (synonym: gall plug syndrome) is commonly reserved for manifestations in large bile ducts, including the ampullary part (Bernstein et al. 1969; Lévy et al. 1979; Mahr et al. 1988), whereas inspissated bile syndrome mainly involves the intrahepatic tract (Hickey and Power 1956; Breunung and Mitschke 1968;

Lukacs et al. 1972). However, the two terms are frequently used synonymously in the literature. Inspissated bile syndrome has been observed in congenital hematological disorders, including hereditary spherocytosis (Kibel 1961), and in association with choledochal cyst (Lai et al. 1998). Bile plug syndrome can resolve spontaneously (Lang and Pinckney 1991), and the inspissated bile has also been shown to be dissolvable by use of mucolytic agents (Brown 1990). Bile plugs are visualized by means of several imaging techniques (Pfeiffer et al. 1986; Sty et al. 1987; Metrewell et al. 2004). Cystic fibrosis (CF) is associated with an inspissated bile syndrome, producing cholestasis secondary to plugging of macroscopically normal bile ducts by the viscid bile (Lindblad et al. 1992; Greenholz et al. 1997). In extreme neonatal forms of CF, with early profound cholestasis, the process can be associated with a marked decrease in bile ductal diameter, varying from hypoplasia (or atrophy?) to atresia. The involved ducts show a ductocentric fibrosis, and the disorder may require a Kasai-type portoenterostomy (Greenholz et al. 1997).

Inspissated Bile in Subacute Nonsuppurative Cholangitis (Cholangitis Lenta)

Subacute nonsuppurative cholangitis (cholangitis lenta) is an uncommon yet important histological finding in liver biopsies from pediatric liver transplant recipients. Apart from ductular proliferation in the absence of an acute inflammatory infiltrate, inspissated bile in ductules is a diagnostic feature (Lin et al. 2007).

Protein Plugs

Protein plugs manifest as filling defects occur in pancreaticobiliary maljunction associated with choledochal cysts. In one study, this phenomenon was found in 22 out of 55 (40 %) patients (Kaneko et al. 1997) and 34.1 % in another series of 126 pediatric patients (Ando et al. 1998).

Drug-Induced Pseudolithiasis

Reversible biliary sludge and/or lithiasis, named as pseudolithiasis, have been reported in patients treated with ceftriaxone, a widely used antimicrobial agent in pediatrics (Schaad et al. 1988; Kim et al. 1992a; Bor et al. 2004; Miloh et al. 2009). This type of sludge can cause acute cholecystitis and acute pancreatitis (Famularo et al. 1999). In a prospective study of 44 children, 11 patients developed pseudolithiasis 2–9 days after initiation of ceftriaxone therapy, and six children (54.5 %) developed this complication within the first 3 days. Pseudolithiasis resolved in all these children (Papadopoulou et al. 1999). It has been suggested that high ambient temperature may lead to easier pseudolithiasis owing to loss of fluid (Araz et al. 2007). The sludge associated with ceftriaxone contains calcium-ceftriaxone salt as a major component (Park et al. 1991).

Obstructive Mucobilia

Introduction

Mucobilia is defined as a condition in which mucin produced by nonneoplastic or neoplastic biliary cells accumulates within the bile duct lumina, admixed with variable proportions of bile, debris, and/or inflammatory exudates. Mucobilia can, due to the viscous character of mucins, interfere with bile flow and thus cause jaundice of the obstructive type (Hadjis et al. 1987; Chen 1998; Tu et al. 2003; Brown et al. 2010). Typical causes of mucobilia are listed in Table 2 (Chamberlain and Blumgart 2000; Kim

Table 2 Causes of mucobilia

Intraductal papillary mucinous neoplasms of the bile duct
Mucin-producing cholangiocarcinoma
Intrahepatic cholangiocarcinoma, intraductal papillary type
Metastatic colorectal carcinoma
Biliary cystadenocarcinoma
Cholangitis with mucus hypersecretion

et al. 2000; Yeh et al. 2004; Kuo et al. 2005; Koea 2012).

Some biliary tract neoplasms, and in particular intraductal papillary mucinous neoplasms, secrete copious mucin into the bile ducts, a change termed mucobilia. Mucin has a greater impact than the neoplasm itself on the cholangiogram and the clinical presentation. The tumor-bearing ducts show a disproportionate or aneurysmal dilatation caused by the accumulation and failing drainage of mucus (Tsou et al. 2008). Mucin as such is usually not detected by imaging examinations such as ultrasonography, CT, or MRI, because of the signal intensity of mucin being the same as that of water (Yeh et al. 2005). Viscid mucobilia can be found in cystic fibrosis. A large series found a high (96 %) incidence of common bile duct stenosis in patients with CF and liver disease (Gaskin et al. 1988). Apart from ductocentric fibrosis (sometimes resembling sclerosing cholangitis; Gaskin et al. 1988) and stenosis caused by pancreatic fibrosis (Lambert et al. 1981), the accumulation of viscid bile in the duct lumina plays a significant role. The mucostasis also involves the peribiliary glands, which are dilated and apparently increased in number (Bilton et al. 1990). In CF, the inspissated bile may show calcification/mineralization (inspissated calcified secretions; Bilton et al. 1990). Mucus plugs have been observed in congenital stenosis of the common bile duct (Vedantham et al. 1992).

In marked mucobilia, endoscopic retrograde cholangiography may show a disproportionate or aneurysmal dilatation of the tumor-bearing bile duct, but the neoplasm may be hidden in the mucin masses (Tsou et al. 2008). Copious mucus/mucin produced and secreted by biliary tract tumors may be discharged through a dilated ampullary orifice. However, this mechanism may also operate in pancreatic intraductal papillary mucinous tumors, where massive mucus discharge through the papilla can block the distal bile duct (Ito et al. 1977; Smith and Matzen 1985; Patel et al. 2005). In some instances, obstructive jaundice due to impaction of thick mucus produced by such tumors is caused by protrusion of mucus through a spontaneous biliopancreatic fistula (Kurihara et al. 2000).

Pathology

In cases with neoplastic mucobilia, the pathology presentation is determined by the type of underlying neoplasm. In intraductal tumors with a papillary growth pattern, the secreted mucus may engulf the tips of the papillae, and the displaced mucus masses contain detached tumor cells, apoptotic cells, debris, and exudate cells, mainly neutrophil granulocytes. Ulceration of the dilated and damaged bile duct wall can lead to extrusion of mucus into the periductal connective tissue, where it elicits a foreign body-type reaction, with accumulation of mucophages (so-called mucus granulomas). Mucobilia developing in the setting of cholangitis shows hypersecretion of epithelial mucin by hypertrophic and hyperplastic biliary and peribiliary gland cells.

Hemoduct and Hemocholecyst (Hemobilia)

Diverse causes, including trauma, infection, and malignant tumors, can lead to accumulation of fresh or coagulated blood in the biliary tract (hemobilia). Coagulated intraluminal blood can obstruct the biliary struct and mimic neoplastic obstructive disease (Seok et al. 2013). Malignant neoplasms and liver abscesses can invade the bile duct system and cause intraductal hemorrhage (Al-Qahtani 2014). Hemobilia can occur after bioptic trauma, including percutaneous liver biopsy, and may cause acute pancreatitis (Van Os and Petersen 1996; Jornod et al. 1999; Kim et al. 1999; Machicao et al. 2002; Sood et al. 2002; Li et al. 2009) or acute cholecystitis (Albuquerque et al. 2005; Edden et al. 2006). Biopsy-induced symptomatic hemobilia can develop as a delayed complication (Lichtenstein et al. 1992; Rossi et al. 2002). Hemobilia can also result from rupture of hepatic artery pseudoaneurysms (Rencuzogullari et al. 2014). Deep mucosal ulcerations may erode arteries and cause luminal

hemorrhage, e.g., cystic artery bleeding in the gallbladder (Contini et al. 2009). Hemobilia has been observed as a complication of photodynamic therapy for unresectable cholangiocarcinoma (Killeen et al. 2009).

145 Bile Duct Compression and Stenosis Due to Anomalies and Acquired Disorders of the Splanchnic Arterial Tree and the Portal Venous System

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_145

Abstract

Large bile ducts can be compressed and stenosed by various anomalies and acquired disorders of the splanchnic arterial tree and the portal venous system. Overall, compression of the extrahepatic biliary tract by arteries is a very uncommon condition. Compression may occur by the right hepatic artery resulting in the so-called hepatic duct compression syndrome. Aneurysms of the hepatic artery can cause intrabiliary stenosis and clot formation. Most of aneurysms inducing bile duct stenosis are extrahepatic alterations. Also dissecting aneurysms of the hepatic artery tree may rarely cause obstructive jaundice. Biliary obstruction can also be caused by pseudoaneurysms, cavitated arteriocentric hematomas without endothelial lining. Hepatic artery thrombosis, severe atherosclerosis, chemotherapy-associated vascular damage, and necrotizing arteritis, including periarteritis nodosa, are sometimes followed by bile duct necrosis and duct stenosis. A further cause of vascular obstruction of the biliary tree is portal biliopathy with cavernous transformation of the portal vein.

Bile Duct Compression Caused by Distinct Anatomical Features of Arteries

In the upper abdomen, compressions of hollow organs by arterial blood vessels mainly include the well-known stricture of the duodenum by the superior mesenteric artery, causing the so-called gas minus ileus. In contrast, compression of the extrahepatic biliary tract by arteries is an exceptional event. The bile duct can be compressed by the right hepatic artery at the hilus of the liver, resulting in what is called the hepatic duct compression syndrome or the right hepatic artery syndrome.

The hepatic artery has a rather complex anatomy, with several known and clinically sometimes relevant anomalies. The right hepatic artery has a variable point of origin, but in about 75 % of cases arises from the common hepatic artery and crosses the common hepatic duct posteriorly. Michels, in an autopsy series of 200 cases, defined the basic anatomic variations in hepatic artery, found variant pattern in 45 %, and specified ten major types (Michels 1966; Table 1). Michels also described the relations of the biliary ducts to the hepatic and cystic arteries

Table 1 Classifications of the hepatic artery tree anatomy

Michels classification (1966)		
Type 1	Normal	55 %
Type 2	Replaced LHA from LGA	
Type 3	Replaced RHA from SMA	
Type 4	Replaced RHA + LHA	
Type 5	Accessory LHA	
Type 6	Accessory RHA	
Type 7	Accessory RHA + LHA	
Type 8	Replaced RHA + accessory LHA or replaced LHA + accessory RHA	
Type 9	CHA from SMA	
Type 10	CHA from LGA	
Hiatt classification (1994)		
Type 1	Normal	75.7 %
Type 2	Replaced or accessory LHA	
Type 3	Replaced or accessory RHA	
Type 4	Replaced or accessory RHA + replaced or accessory LHA	
Type 5	CHA from SMA	
Type 6	CHA from aorta	

LHA left hepatic artery, *RHA* right hepatic artery, *CHA* common hepatic artery, *LGA* left gastric artery, *SMA* superior mesenteric artery

(Michels 1951). In a detailed anatomical study of 1,000 cases, 757 cases were of the normal type 1, with the common hepatic artery arising from the celiac axis to form the gastroduodenal and proper hepatic arteries and the proper hepatic dividing distally into right and left branches. One hundred six cases were of type 3, with a replaced or accessory right hepatic artery originating from the superior mesenteric artery. Ninety seven cases were of type 2, with a replaced or accessory left hepatic artery arising from the left gastric artery. Only 23 cases were of type 4, with both right and left hepatic arteries arising from the superior mesenteric and left gastric arteries, respectively. Fifteen cases showed type 5, with the entire common hepatic artery arising as a branch of the superior mesenteric artery, and two cases were of type 6, with the common hepatic artery originating directly from the aorta (Hiatt et al. 1994; Table 1).

The relationships between the hilar and intrahepatic parts of the hepatic artery and the portal vein also reveal variations. Based on a CT-arterial portography (CTAP) and CT-angiography (CTA) study in 147 patients, the combined anatomy of right anterior hepatic artery and portal vein with regard to segmentation was classified as dorsoventral (26.5 %), dorsoventral and inferior (10.9 %), multiple (18.4 %), and superior and inferior segments (1.4 %) (Ibukuro et al. 2012).

These anatomic arrangements may predispose to impingement, but this effect is extremely rare (Taboga et al. 1969; Doi et al. 1979; Kumada et al. 1981; Watanabe et al. 1982; Tsuchiya et al. 1984; Kim et al. 1992; Kondo et al. 1999; Izuishi et al. 2005; Miyashita et al. 2005; Gottlieb and Brophy 2007). Duplication of the hepatic artery may occur (Tokunaga et al. 2007). When biliary obstruction with jaundice is present, the compression of the duct is more frequently associated with a hepatic artery aneurysm or an aberrant anatomy. In the lateral type of right hepatic artery compression, the bile duct is compressed by the artery lateral to it, while in the transverse type, the bile duct is compressed by the artery crossing it. In the latter situation, intrahepatic stones may be caught at the involved level (Watanabe et al. 1982; Tsuchiya et al. 1984; Kim et al. 1992). A right hepatic artery anteriorly overriding the common hepatic duct has also been shown to cause duct compression and obstructive jaundice (Chung et al. 1994). As an anatomical variation, crossing between the hepatic artery and the common bile duct (arterio-biliary crossing) can occur, causing different grades of biliary obstruction (Manenti et al. 1981). Jaundice due to obstruction of the common duct has been observed to be caused by an aberrant celiac artery (Luttwak and Schwartz 1961). A compression of the common bile duct by the posterosuperior pancreaticoduodenal artery has also been reported (Watanabe et al. 2005). It may be expected that, owing to the variable anatomy of the celiac and hepatic artery system, other situations of bile duct impingement may occur. The types and frequencies of hepatic artery variations differ among larger studies addressing this question, also depending on the methods used. Among 600 patients analyzed by digital subtraction angiography, only 61.3 % had the standard hepatic arterial anatomy. 19.8 % had variant left hepatic arteries, 14.8 % had variant right hepatic arteries, and 4.7 % had a variant involving both left and right hepatic arteries. About 4 % had a variant origin of the common hepatic artery arising from either the superior mesenteric artery or the aorta, and double hepatic arteries were seen in 3.7 % of the patients (Covey et al. 2002).

In a selective celiac and superior mesenteric artery angiography study on 604 patients, normal textbook hepatic artery anatomy was found in 79.1 %, i.e., more frequently than in the former study (Koops et al. 2004). In an analysis of 60 cadaveric livers (minimum age of autopsied patients = 18 years; no liver pathology), 15 % of the livers had a median hepatic artery. A right hepatic artery originating from the superior mesenteric artery was found in 25 %, and a left hepatic artery coming from the left gastric artery in 3.3 %. The right and left hepatic arteries were accessory in 18.3 % and 3.3 % of the cases, respectively (Chaib et al. 2007). The celiomesenteric trunk is a rare but well-recognized anomaly (Petscavage and Maldjian 2007; Tosun et al. 2007). A very uncommon variation of the hepatic artery system is the formation of an arterial ring encircling the

common hepatic duct (Dusanovic et al. 1999). It is known that several non-hepatic arteries can originate from the hepatic arteries. In a systematic study, the most common non-hepatic artery was the right gastric artery, followed by the hepatic falciform artery, an accessory left gastric artery, the posterior superior pancreaticoduodenal artery, and the left phrenic artery. The left hepatic artery was the most frequent origin of non-hepatic arteries (Song et al. 2006). These compression syndromes must be distinguished from pseudo-obstruction of extrahepatic bile ducts from arterial pulsatile compression, resulting in an artifact. The right hepatic artery was found to be the causative vessel in 67 % among 234 patients analyzed (Watanabe et al. 2000).

Arterial Aneurysms

Aneurysms are a rare cause of hemobilia and intrabiliary clot formation sometimes followed by jaundice. The arteries most often involved are branches of the hepatic or gastroduodenal arteries (Fig. 1). Hepatic artery aneurysm comprises a reported incidence of 0.02 % and accounts for about 20 % of all visceral aneurysms. In the literature, the risk of rupture ranges from 14 % to 80 % of all hepatic artery aneurysms (Hashim et al. 2009). Most hepatic artery aneurysms (75–85 %) are extrahepatic, and the parent vessel is most commonly (65 %) the common hepatic artery (Countryman et al. 1983). Location to the right hepatic artery is less frequent, occurring in about 30 % of cases, and location to the left hepatic artery is rare (Boontje 1979; Graham et al. 1980; Shanley et al. 1996). A small part of hepatic artery aneurysms is located intrahepatically (Burns and Slakey 2009). Mycotic aneurysms historically accounted for most hepatic artery aneurysms, but accounted for only 4 % in a more recent review (Shanley et al. 1996). Inflammatory aneurysm of the hepatic artery is a complication of periarteritis nodosa (Park et al. 2006; Parent et al. 2010). Rare causes of hepatic artery aneurysms are inherited connective tissue disorders (see below) and prune belly syndrome, an uncommon disorder thought to be caused by mesodermal delay during ontogenesis (Alhawsawi et al. 2009).

A triad of abdominal pain, hemobilia, and jaundice is seen in less than one-third of the patients. Aneurysm of the hepatic artery may rupture into the biliary tract and cause hemobilia via an arterio-biliary fistula (Gracey 1970; Winchester et al. 1970; Balthazar 1977; Harlaftis and Akin 1977; Petrin et al. 1982; Chen et al. 1983; Casula et al. 1984; Zachary et al. 1986). True aneurysms of the hepatic artery may cause obstructive jaundice (Lal et al. 1989; Chandramohan et al. 2001; Bramis et al. 2002; Mazziotti et al. 2003). In most of these situations, the aneurysms are located in the extrahepatic branches of the hepatic artery, intrahepatic aneurysms as a cause of segmental bile duct stenoses being very uncommon (Salazar et al. 1984). Giant aneurysm of the hepatic artery can cause portal hypertension (Kantarci et al. 2009). Rarely, thrombosis of a hepatic artery aneurysm produces a mass that may be confounded with malignancy (Chhem and Groleau

Fig. 1 Aneurysm of the hepatic artery, producing a mass effect

1989; Elmas et al. 1998). A similar situation has rarely been reported in aneurysms of the gastroduodenal artery (Sipahioglu et al. 2005; Aoufi et al. 2007), the splenic artery (Coulier et al. 2006), and the celiac artery (White et al. 1987). True aneurysm of the cystic artery is rare, but is a known cause of hemobilia (Kirchgatterer et al. 1998).

Aneurysms of the celiac artery, first described in 1745, are rare vascular lesions that represent only 3.6–4 % of splanchnic artery aneurysms, with estimated incidence of 0.005–0.01 %. Earlier, this aneurysm was associated with frequent morbidity and mortality; before 1950, more than 90 % of the patients presented with epigastric pain, and up to 87 % died of aneurysmal rupture, the diagnosis most frequently having been made at autopsy. More recently (1985–1995), 69 % of the patients presented with abdominal pain, and just 7 % presented with rupture, 14 % being asymptomatic, and with an overall mortality rate of 14 %. During the first half of the last century, the mean age at diagnosis was 39.7 years, men outnumbered women 9:1, and syphilis was the apparent cause in 31 % of cases. Since that time, the mean age at diagnosis has increased to 53.7 years and women constitute 44 % of those affected, perhaps reflecting a paucity in luetic infections (reviews: Graham et al. 1985; Stone et al. 2002; McMullan et al. 2006). In the patient described by White and coworkers (1987), a massive celiac artery aneurysm caused both biliary and portal obstruction, associated with portal hypertension and extensive retroperitoneal varices. Abdominal aortic aneurysms with or without rupture rarely compress the common bile and cause biliary obstruction (Dorrucci et al. 2001; Smith et al. 2002).

Dissecting Aneurysm of the Hepatic Artery Tree

Primary dissecting hepatic artery aneurysms, unaccompanied by aortic or other dissections, have been reported only few times (Callicot and Hoke 1968; Gurrero 1970; Hill et al. 1974; James 1976; Pinkerton et al. 1976; Larson et al. 1987; Derhy et al. 1988; Roh and LeSher 1989; Muller and Kim 1995; Garcia et al. 1996; Hashimoto et al. 1998; Nakamura et al. 1998; Al Hilli 2001). Dissecting aneurysm of the celiac axis and hepatic artery has been found to be associated with obstructive jaundice (Bret et al. 1987).

Pseudoaneurysms

Pseudoaneurysms are cavitated arteriocentric hematomas that lack an endothelial lining. Extrahepatic artery pseudoaneurysms are caused by several mechanisms, including artery dissection and traumatic vessel damage, but such lesions caused by visceral artery dissection with or without aortic dissection are very rare. Pseudoaneurysm causing fistula, hemobilia, or rupture into the gallbladder is known to occur in the hepatic artery (Natalini et al. 1978; Ahmed et al. 2001; Akatsu et al. 2004). One well-known cause of hepatic artery pseudoaneurysms is liver transplantation, where this complication usually occurs within the first 2 months of grafting, and is characterized with a high mortality rate (Tobben et al. 1988; Adani et al. 2008). Hepatic artery pseudoaneurysm can occur following laparoscopic cholecystectomy (Rivitz et al. 1996). Pseudoaneurysm of the hepatic artery with delayed fatal hemorrhage has been observed few days after percutaneous liver biopsy (Ahmed et al. 2001). Pseudoaneurysm of the cystic artery develops with or without associated cholecystitis and is known to be a rare cause of arterio-biliary fistula and hemobilia (Reddy 1983; Barba et al. 1994; England et al. 1998; Kaman et al. 1998; Maeda et al. 2002; Akatsu et al. 2007; Beuran et al. 2008; Moses et al. 2008). Pseudoaneurysm of the gastroduodenal artery as a cause of obstructive jaundice has been reported (Kossak et al. 2001). Pseudoaneurysm complicating a choledochal cyst was found to cause hematobilia. In this situation, pseudoaneurysm is caused by chronic inflammatory changes in the wall of the choledochal cyst, and the contiguity of the cyst to the hepatic artery could result in chronic pressure erosion, resulting in the pathologic

communication between the artery and the cyst (Eliscu and Weiss 1988). Pseudoaneurysms of visceral arteries can also cause biliary obstruction and may present as an intrahepatic mass, leading to considerable differential diagnostic difficulties (Widjaja et al. 1999).

Biliary Obstruction Associated with Arteritis

Clinical manifestations in the liver are not common in patients with polyarteritis nodosa (PN), although necrotizing arteritis in the liver as an autopsy finding is not infrequent. Hepatic artery aneurysms and hepatic infarction are the most common hepatic complications (Park et al. 2006; Parent et al. 2010). PN involves the hepatobiliary system either in conjunction with systemic vasculitis or as an isolated (organ-specific) involvement of the hepatic and biliary artery tree. The latter situation is best known for apparently isolated PN of the gallbladder. PN involving the bile duct arterial system can cause ductal wall necrosis (infarction) or segmental duct atrophy, followed by rupture and hemobilia (Cho et al. 2011). The lesions are histologically characterized by necrotizing arteritis of the bile duct arteries. The ischemic necroses of bile ducts induce a scarring reaction which may end up with a presentation that is similar to sclerosing cholangitis with duct stenosis (Wold and Baggenstoss 1949; Dillard and Black 1970; Alleman et al. 1986; Barquist et al. 1991; Parangi et al. 1991; Goritsas et al. 1997; Park et al. 2007). Ischemic and inflammatory damage to the duct wall may also be followed by cystic dilatation of the duct, likely through weakness of the duct structures (Doppman et al. 1979; Amir et al. 1984; Chang et al. 2003). Hepatic lobar atrophy has been observed in combined involvement of hepatic artery branches and of the hepatic portal tissue in PN (Nakazawa et al. 1992).

Systemic vasculitis (particularly PN and vasculitis occurring in lupus erythematodes) is associated with an increased risk of aneurysms developing in the visceral arteries, including the hepatic artery and often complicated by rupture and/or hemobilia (Glassman and Skerrett 1960; McCollum et al. 1979; Bookman et al. 1983; Trambert et al. 1989; Choy et al. 1997; Stambo et al. 2004; Yamazaki 2004; Park et al. 2006). PN can cause pseudoaneurysms that may, due to their sometimes considerable size, exert compression of the extrahepatic biliary system and induce obstructive jaundice (Dönmez et al. 2005).

Apart from the more frequent manifestations seen in PN and related disorders, other forms of vasculitis may involve the hepatobiliary arterial system. They include temporal arteritis (polymyalgia rheumatica; polymyalgia arteriitica; Heptinstall et al. 1954; von Knorring and Wasastjerna 1976; Lie 1978; Ogilvie et al. 1981; Rousselet et al. 1989), producing giant cell arteritis in hepatic artery branches and sometimes leading to ischemic cholangiopathy (Rousselet et al. 1989), and Churg-Strauss syndrome (Nishie et al. 2003). Necropsies of patients dying in the acute phase of arteritic polymyalgia are rare, particularly since the establishment of effective therapy. Therefore, the knowledge relating to biliary pathology is rudimentary. A rare arteritis that can cause hepatic artery aneurysms is allergic granulomatous arteritis (Churg-Strauss disease; Nakamura et al. 1991). Vasculitis of the peribiliary vessels causing ischemic necrosis was noted in Schönlein-Henoch purpura (Viola et al. 1999). A vasculitis involving peripheral arteries in portal tracts and associated with acute cholangitis has been observed in Kawasaki disease (Gear et al. 1992).

Biliary Tract Damage in Atherosclerosis and Calcifications of the Hepatic Arteries

Although involved in general atherosclerosis, atherosclerosis of the hepatic artery or the celiac trunk arteries is regarded as rare and difficult to assess clinically. Evident differences in the occurrence of atherosclerosis between hepatic and coronary arteries have systematically been analyzed by histologic investigations on autopsy material. It was found that, in contrast to coronary arteries, hepatic artery intimal thickening was incidental

during the first four decades of life and regular only later on. During all age periods studied, intimal thickness in hepatic arteries was less pronounced than that in coronary arteries. True atherosclerosis was detected during the eighth and ninth decades in the hepatic artery, i.e., about 4 decades later than in coronary arteries (Krus et al. 2000). In a UK-based medical review of the literature, there was no report of hepatic artery atherosclerosis preventing the use of a procured liver for transplantation, but the authors reported one such case for the first time (Maluf et al. 2004). A further case of reported hepatic artery atherosclerosis was observed in conjunction with celiac artery aneurysm (Papadimitriou et al. 2005). In the literature, most reports refer to hepatic artery calcifications which may cause differential diagnostic difficulties in regard to pneumobilia or intrahepatic stones (Desai et al. 1989; White and Wilson 1994; Christensen et al. 1995; Pai and Bude 2002). Atherosclerotic narrowing of the hepatic arteries of intrahepatic arteries was found to be associated with biliary stricture (Sajura et al. 2001), probably caused by postischemic fibrosis/scarring of the duct wall. In another patient, benign biliary stricture was found to be accompanied by fibrous replacement of the media of the accompanying artery (Hashikura et al. 1994). Calcifications of the hepatic artery, with variable stenosis, are well recognized as a complication of chronic renal failure, mainly in the context of chronic hemodialysis (Okuda et al. 2002, 2003), although in dialysis patients, the hepatic artery is less frequently involved than the abdominal aorta and the splenic artery (Okuda et al. 2002).

Hepatic artery calcification is also known in the rare autosomal-recessive disorder, idiopathic infantile arterial calcinosis (IIAC; OMIM; Wax et al. 2001). IIAC is characterized by calcifications in the arterial media and fibroproliferative changes in the intima of larger arteries, sometimes resulting in reduced vascular elasticity and blood flow. In a female neonate, hepatic arterial involvement resulted in reduced blood flow in the narrowed hepatic artery and in fatal progressive liver failure (Whitehall et al. 2003).

Bile Duct Damage in Hepatic Artery Thrombosis

Hepatic artery thrombosis can occur in grafted livers, reported to occur more frequently in children than in adults (Tzakis et al. 1985; Wozney et al. 1986; Bhattacharjya et al. 2001; Silva et al. 2006; Vaidya et al. 2007). In a series of 18 OLT patients with graft loss owing to bile duct necrosis, radiographic vascular studies suggested hepatic arterial thrombosis or stenosis in 11 cases (Krishna et al. 2005). In a study on 4,234 OLTs performed between 1984 and 2007, hepatic artery thrombosis was noted in 203 patients (5 %), associated with reduced graft survival (only 10 % graft salvage; Duffy et al. 2009). A similar figure was found in a systematic review of OLT (overall 4.4 %), the complication being more common children (8.3 %) vs. adults (2.9 %) (Bekker et al. 2009). Hepatic artery thrombosis is sometimes followed by biliary strictures requiring stenting as a late complication (Cook and Crofton 1997). Intrahepatic biliary necrosis has been observed in late post-OLT hepatic artery thrombosis, i.e., occurring after 6 months (Valente et al. 1996; Gunsar et al. 2003).

Biliary Tract Disorders in Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) is well known to involve the hepatobiliary system, with an estimated prevalence ranging from 8 % to 31 % in retrospective studies. HHT causes pathologic changes of the hepatic artery, including arterial tortuosity, arteriovenous malformation, and hepatic artery aneurysm (Graham et al. 1964; Peery 1987; Milot et al. 2007; Miyabe et al. 2007). Anatomically, three different patterns of abnormal vascular communications can occur in the liver: portal vein to hepatic vein (portovenous), hepatic artery to hepatic vein (arteriovenous), and hepatic artery to portal vein (arterioportal). Only 5–8 % of patients with these vascular malformations are symptomatic (Khalid and Garcia-Tsao 2008). Anicteric cholestasis has been

noted in 73 % of a series of patients with HHT (Bernard et al. 1993). In fact, biliary tract manifestations are now well recognized in HHT, and according to shunt type and size, Garcia-Tsao has classified patients into three groups presenting with cardiac failure, biliary disease, or portal hypertension. Type 1 shunts can cause a cardiac and/or biliary-type clinical pattern. Cholestasis is the most frequent marker, indicating bile duct damage (specifically ischemia), even when the clinical evolution is dominated by cardiovascular signs (Garcia-Tsao et al. 2000; Lerut et al. 2006). Arteriovenous malformations, specifically tortuosities of the main hepatic and intrahepatic arteries located close to the bile ducts, may result in external bile duct compression with subsequent bile duct dilatation (Hatzidakis et al. 2002; Hayashi et al. 2008). In a series of 19 patients with HHT, five symptomatic patients had elevated alkaline phosphatase levels and radiographic evidence of bile duct anomalies similar to those of Carolis' disease or those in primary sclerosing cholangitis (Garcia-Tsao et al. 2000). Stenosis and/or dilatations are thought to be causes by ischemic necrosis and atrophy of the bile duct wall, biliary tract necrosis having been observed in HHT (McInroy et al. 1998). In a report on HHT based on the results of the European liver transplant registry, biliary necrosis causing hepatic failure was observed in 12/40 patients (Lerut et al. 2006). In this report, a biliary type of HHT was recognized, and the liver explants with this type of disease showed cholangitis associated with a diffuse and extreme modification of bile duct morphology, cystic bile duct dilatation, intrahepatic biliary sludge and/or stones, bile-stained necrotic areas, and biliary mucosal necrosis (Lerut et al. 2006). HHT may be associated with multiple intrahepatic bile duct stenosis, focal cystic bile duct dilatations along the course of the intrahepatic ducts, and large biliary cysts (Lin and Stall 2007). It has been proposed that arteriovenous shunts may cause hypoperfusion of the peribiliary plexus supplying the biliary tree, promoting bile duct ischemia with subsequent fibrosis and atrophy of the bile ducts, or even bile duct wall necrosis followed by biliary cysts (Garcia-Tsao et al. 2000; Asma et al. 2005). Postischemic bile duct cysts can become infected, with formation of numerous intrahepatic bile duct-derived cystic spaces measuring up to 4 cm (Hillert et al. 2001). It has been suggested that hepatolithiasis occurring in conjunction with HHT may be promoted by biliary stasis (Ball and Duggam 1990). The treatment of HHT-associated arteriovenous malformations by embolization may itself cause biliary complications, e.g., ischemic cholangitis (Chavan et al. 1998) and biliary necrosis (Odorico et al. 1998).

Biliary Obstruction Caused by Chemotherapy-Induced Cholangiopathy

Jaundice can develop in patients with liver cancer (mainly metastases of colorectal carcinoma) during hepatic arterial infusion chemotherapy (HAIC; hepatic artery infusion, HAI), particularly when fluoropyrimidines were used. Apart from hepatotoxic effects (chemical hepatitis), focal biliary obstruction mediated by chemotherapy-induced bile duct strictures (so-called iatrogenic sclerosing cholangitis; toxic biliary sclerosis; chemotherapy-induced sclerosing cholangitis, CISC) plays a significant role. In early phases of duct damage, bile duct infarction can develop, sometimes mimicking multiple liver metastases (Shrikhande et al. 2002; with literature review). Most strictures occur in the proximal parts of the extrahepatic bile duct system and at its bifurcation, and intrahepatic ducts show a variable degree of involvement (Daly et al. 1984; Botet et al. 1985; Hohn et al. 1985; Pien et al. 1985; Anderson et al. 1986; Laughlin 1986; Clark and Gallant 1987). In the study of Anderson and coworkers, the strictures were long, on the average 2–3 cm long, with smooth tapering both proximally and distally, they involved the proximal common bile duct 1–2 cm from its origin from the porta, and there was no evidence of beading as seen in primary sclerosing cholangitis (Anderson et al. 1986).

How frequent is chemotherapy-associated stenosing cholangiopathy? The estimated incidence ranges from 8 % to 26 %. Among 54 patients with liver metastases of colorectal

carcinoma treated with floxuridine HAI, 5 patients (9.2 %) developed biliary toxicity with jaundice and cholangitis/cholangiopathy, and extrahepatic biliary sclerosis was detected in 3 patients (Aldrighetti et al. 2001). The analysis of a randomized trial of the Northern California Oncology Group (NCGOG), comparing intravenous vs. intra-arterial FUDR in patients with hepatic colorectal carcinoma metastases, showed that among the first 25 patients in the intra-arterial higher-dose therapy arm (0.3 mg FUDR/kg/day), ten patients developed radiologically evident biliary strictures, and three developed permanent jaundice (Hohn et al. 1989). In a study of 11 patients with CISC, the mean age at presentation was 59.5 years, and cholangiographic findings revealed a stricture confined to the common hepatic duct in two patients, involving the hepatic hilum in seven patients, involving the right and/or left main hepatic ducts in nine patients, and extending to the intrahepatic radicles in two patients. The grade and extent of biliary strictures did not change in five, improved in one, recurred in two, and progressed in two patients over the follow-up period of 28.2 months (Alazmi et al. 2006). In a study of 17 patients with intra-arterial FUDR-induced cholestasis, all patients studied had segmental involvement at the common hepatic duct bifurcation. The cystic duct and the gallbladder were often involved, but the distal common bile duct was spared. Histologic features of periductal fibrosis were present in specimens obtained from liver biopsies in three patients and autopsy in two patients (Shea et al. 1986).

Pathogenetically, it has been proposed that that bile duct lesions are caused by toxic vascular damage followed by ischemic cholangiopathy (Ludwig et al. 1989; Hasegawa et al. 2000), demonstrating the importance of blood flow from the peribiliary vascular bed for the survival of the biliary mucosa (Clark and Gallant 1987). 5-fluorouracil is toxic to arterial endothelial cells and seems to exert a thrombogenic effect (Cwikiel et al. 1996; Kinhult et al. 2003). In a rat model, both 5-fluorouracil and peplomycin induced endothelial cell apoptosis upon intra-aortic injection, but the incidence of apoptosis was higher with 5-fluorouracil (Sudoh et al. 2004).

Portal Biliopathy and Bile Duct Varices

Introduction

Portal biliopathy is a term describing a spectrum of lesions and functional disturbances occurring in the bile ducts secondary to extrahepatic portal venous obstruction (EHPVO), specifically thrombosis of its extrahepatic portion as a major pathology of this vessel (Janssen et al. 2001; Garcia-Pagan et al. 2008). The conception of portal biliopathy was put forward in 1992 (Sarin et al. 1992), and this disorder was later worked out in more detail (Chandra et al. 2001; Akaki et al. 2002; He and Fan 2002; Condat et al. 2003; Perego et al. 2003; Rangari et al. 2003; Dhiman et al. 2007; Shin et al. 2007). EHPVO is a common cause of portal hypertension and constitutes up to 40 % of all patients with portal hypertension.

Portal biliopathy (synonyms: portal hypertensive biliopathy; cholangiopathy associated with portal hypertension; portal cavernoma-associated cholangiopathy) refers to a clinicopathologic complex comprising all abnormalities of the entire biliary tract (including extra- and intrahepatic bile ducts, cystic duct, and gallbladder) in patients with compromised portal venous circulation. The definition should not exclusively refer to portal hypertension, because some anomalies of the portal vein, such as aneurysm, may induce biliopathy in the absence of portal hypertension. On the other hand, changes similar to portal biliopathy have been recognized in patients with portal hypertension not related to EHPVO, such as cirrhosis of the liver or idiopathic portal hypertension, albeit with lesser frequency (review: Dhiman et al. 2007). Depending on the anatomic manifestations of portal biliopathy, this disorder has been cholangiographically classified in several types and subtypes (Table 2; Chandra et al. 2001). The etiology and pathogenesis of portal biliopathy are incompletely known, but, as outlined in the following paragraphs, mechanical and/or ischemic effects on bile ducts (compression, bulging, protrusion) caused by pathologically structured veins seem to prevail.

Table 2 Classification of cholangiography changes in portal biliopathy (Chandra et al. 2001)

Type I: Involvement of extrahepatic bile duct
Type II: Involvement of intrahepatic ducts only
Type IIIa: Involvement of extrahepatic bile duct and unilateral intrahepatic duct (left or right)
Type IIIb: Involvement of extrahepatic bile duct and bilateral intrahepatic ducts

Cavernous Transformation of the Portal Vein: Morphologic Aspects

Terms frequently employed in the literature referring to portal biliopathy are cavernous transformation of the portal vein and portal vein "cavernoma" (Gibson and Richards 1955). In fact, the terms describe at least two lesions that may occur alone or in combination. Cavernous transformation of the portal vein refers to a condition where, due to collateral blood accumulation/flow in obstruction of the extrahepatic portal vein, marked dilatation of the parabiliary venous plexus takes place (for the definition of parabiliary plexus, see the paragraph below on "Anatomical Substrates of Portal Biliopathy"). Hence, this change does not describe a cavernous change of the portal vein itself, but a complex remodeling of venous vessels associated with the portal vein in case of obstruction of the latter (Figs. 2, 3, and 4).

Morphologic studies have shown that cavernous transformation is not only dilatation of periportal venous collaterals but also neogenesis of vessels. An early study had shown that, on histological examination, cases of cavernous transformation show a combination of chronic recanalized portal vein thrombosis (Koga et al. 1986) and formation of paraportal hepatopetal collaterals (Bechtelsheimer and Conrad 1980). Sections of recanalized portal veins in fact show an endoluminal spongy network of new formed vascular channels, in some way reminiscent of cavernous hemangioma, thus explaining the term "cavernoma." This alteration is commonly associated with portal vein phlebosclerosis, itself caused by high venous pressure load (portal hypertension) and/or intimal

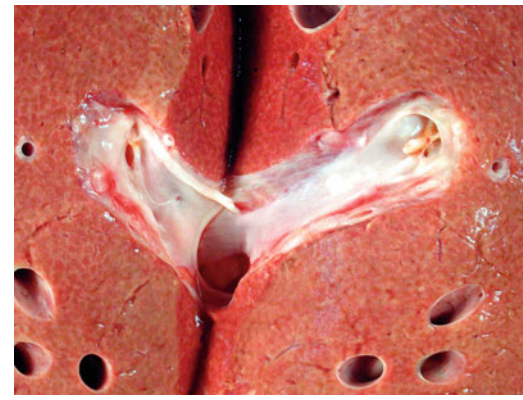

Fig. 2 Cavernous transformation of the portal vein. The portal venous branch is longitudinally opened and shows fibrous intraluminal strands and nets

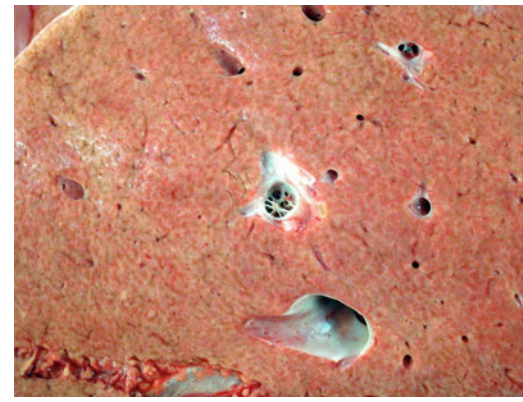

Fig. 3 Cavernous transformation of the portal vein. Net-like intraluminal fibrous strands in an intrahepatic portal vein branch

integration of organized thrombotic material. The network of dilated and sometimes varicose venous vascular channels is mostly caused by expansion of veins of the parabiliary plexus. However, it has also been proposed that formation of collaterals starts with new growth of primitive sinusoidal vessels originating from the portal vein and protruding into the paraportal tissue, later to exhibit increasing venous differentiation up to the point of formation of varices (Bechtelsheimer and Conrad 1980). The grossly visible cavernous vein system commonly produces a sponge-like sheath around the portal vein and the large bile ducts, periductal collaterals being situated in the fibroadipose outer compartment of the hepatoduodenal ligament, but the dilated collateral may also involve the mural parts of the ducts (intramural cavernous transformation; intramural varices; Chow and Jeffrey 1999), sometimes producing a ductal mural cavernoma (Novellas et al. 2004). In the hepatic hilar region, variceal intramural collaterals may, also in conjunction with a fibrogenic/sclerosing reaction, result in an enhancing, vascular mass (Geyer et al. 2005). Even by use of Doppler sonography, the original portal vein may no longer be visualized within the mass of tortuous vessels. In addition, the phlebectatic changes seen in cavernous transformation can extend into the liver, this pattern consisting of numerous thin-walled vessels observed in the medium-sized portal tracts of the liver ("intrahepatic cavernous transformation"; Koga et al. 1986; Terada et al. 1988), a change also noted in situations of tumor-induced venous obstruction (Terada et al. 1990).

Biliopathy in Portal Vein Thrombosis or Cavernous Transformation of the Portal Vein (Cavernoma; Portal Cavernomatosis)

The first patient with symptomatic biliary obstruction due to EHPVO was reported in 1944 (Fraser and Broun 1944), Subsequently, several observations confirmed stenosis of the extrahepatic bile ducts by a thrombosed portal vein (Seez et al. 1980; Khuroo et al. 1993; D'Souza et al. 2009; Htun Oo et al. 2009). Among 17 patients with portal vein cavernoma, symptomatic biliary obstruction was detected in 82 % (Belhadjbrik et al. 2006). Compression of bile ducts with subsequent obstructive jaundice by cavernoma has been observed in children (Ruszinko et al. 2004) and has been shown to reversible upon portal decompression (Gauthier-Villars et al. 2005). The vascular anomalies and the subsequent changes of the bile ducts may mimic cholangiocarcinoma (Kessler et al. 2007).

The thrombosed vessel and/or associated venous (varicose) collaterals exert a compression effect usually on the common bile duct (Lohr et al. 1993), and in some instances, thrombosis of this vessel causing biliary obstruction may mimic a tumor (Nyman et al. 1996; Horie et al. 2005). The dilated, varicose collateral veins developing in EHPVO have been demonstrated to cause smooth indentations of the common bile duct, seen in cholangiography (Vleggaar et al. 1999), and duct stenoses, ductal narrowing, or duct wall irregularities have been found by use of MRI (Chevallier et al. 2006). The distinct changes of large bile ducts may suggest sclerosing cholangitis ("pseudosclerosing cholangitis"; Dilawari and Chawla 1992). Apart from mechanical compression, ischemic pathogenic pathways have been considered, because some biliary changes may persist after shunt surgery (Dhiman et al. 1999). Obstructive extrahepatic portal vein obstruction can be associated with portal vein calcification (calcified cavernous transformation) and can cause obstructive jaundice, the common bile duct being extrinsically compressed by the calcified cavernoma (Mackenzie et al. 1978).

Obstructive Cholestasis Caused by Aneurysms of the Portal Vein

Aneurysm of the extrahepatic portal vein is rare but is the most frequent visceral venous aneurysm, followed by aneurysms of inferior vena cava, superior mesenteric vein, splenic vein, and iliac veins (Barzilai and Kleckner 1956; Calligaro et al. 1995; De Gaetano et al. 2006). Extrahepatic portal vein aneurysms seem to be acquired

lesions, but congenital PV aneurysms have been reported as well (Gomez et al. 2004; Giavroglou et al. 2006), and they have also been observed in conjunction with Abernethy malformation/congenital extrahepatic portosystemic shunt (Kumar et al. 2008). Its clinical manifestations are variable (Lau et al. 2002). Intrahepatic portal vein aneurysms have also been described (Laumonier et al. 2005). There are few reports describing jaundice and/or recurrent cholestasis apparently caused by this venous pathology, biliary obstruction probably caused by the displacement of the biliary tract (Barzilai and Kleckner 1956; Hermann and Shafer 1965; Thomas 1967; Yamane et al. 2006).

In fact, one patient with this clinical constellation showed a markedly bent extrahepatic bile duct caused by the extrinsic pressure exerted by extrahepatic cystic portal vein aneurysm (Yamane et al. 2006). In the patient of Hermann and Shafer, suffering from obstructive cholestasis, laparotomy revealed a large (6 × 4 cm) saccular aneurysm of the extrahepatic portal vein. The portal vein emerged from the posterior and medial side of the aneurysm which lay at the junction of the splenic and superior mesenteric veins under the duodenum and pancreas and directly anterior to the inferior vena cava. On the artist's drawing (Fig. 5 of this publication), the close spatial relationship between the large aneurysm and the bile duct is in evidence (Hermann and Shafer 1965).

The etiology and pathogeneses of portal vein aneurysms have not yet been clarified. Ontogenetically, the PV system takes its origin from the vitelline and umbilical veins draining the splanchnic blood of the embryo. The so-called "congenital theory" of PV aneurysms postulates a failure in the regression of the right primitive vitelline vein, and a diverticular remnant of this vitelline vein may then enlarge to form a saccular aneurysm of the PV in later life. Other authors attribute the development of PV aneurysms to an inherent weakness of the venous wall. The hypothesis of a congenital origin of these aneurysms is supported by the detection of congenital/connatal lesions and the occurrence of this condition in children and young adults without a history of liver disease (review: Lau et al. 2002).

Biliopathy in Portal Vein Varicosis

Varicose deformation and dilatation of the portal vein in portal venous hypertension can compromise the structure and function of large bile ducts in several ways. The varicosities are known to exert external compression of bile ducts with consecutive obstructive jaundice (Varin et al. 2005).

Biliary Varices

Bile duct varices (biliary tract varicosis) usually occur in conjunction with extrahepatic portal venous obstruction (EPVO), in particular portal vein thrombosis and cavernous transformation of the portal vein (Williams et al. 1982; Kim and Chew 1988). Biliary varices are defined as multiple, large, serpiginous, anechogenic vascular channels in and/or surrounding the extrahepatic bile ducts. Bile duct varices can, via their pressure effect on the duct wall, induce reactive fibroinflammatory lesions with wall thickening (Denys et al. 1998) or produce changes mimicking duct involvement by tumor ("pseudocholangiocarcinoma sign"; Bayraktar et al. 1992; Gorgul et al. 1996; Strunk et al. 2001).

In a study of 21 patients with EPVO, CT and endoscopic ultrasonography showed varices in the wall of the common bile duct in 76 %, surrounding the common duct in 52 %, and in the gallbladder in 43 %. Among 34 patients with cavernous transformation of the portal vein studied by use of MRI, 67 % had paracholedochal portoportal collateral vessels, with 64 % showing visible luminal channels. Epicholedochal venous collaterals were observed in 23 % (Schaible et al. 2002). Biliary varices can cause obstructive cholestasis (Hunt 1965; Palazzo et al. 2000). Varices were the cause of obstructive jaundice in 14 %, but only when they were in the wall of the common bile duct (Palazzo et al. 2000). In the study of Schaible and coworkers (2002), 70 % of patients demonstrated biliary abnormalities due to portoportal collaterals, leading to duct stenosis in 23 %. The ductal walls were irregular in 20 % and thickened in 32 %.

Gallbladder and/or cystic vein varices are rather common in patients with EPVO

(Charnsangavej et al. 1984; Saigh et al. 1985; West et al. 1991; Chawla et al. 1994; Safadi et al. 1996; Gabata et al. 1997; Morales Perez et al. 1999; Radhi 2003). Among 50 patients with portal hypertension, gallbladder varices were identified in 12 % (West et al. 1991). The cystic vein can function as a bypass in portal vein thrombosis (Myking and Halvorsen 1971). Varicosis may mimic a tumor via thickening of the gallbladder wall (Saigh et al. 1985) or by producing an irregularly structured and voluminous cystic duct.

Anatomical Substrates of Portal Biliopathy

What Are the Pathways Draining Venous Blood from the Extrahepatic Bile Ducts?

Venous drainage of the extrahepatic ducts is mostly by veins that ascend along their course. They form the epicholedochal venous plexus of Saint (1961) and the paracholedochal venous plexus of Petren (Petren and Karlmark 1932). The former represents a fine reticular venous plexus on the common bile duct and hepatic ducts and is in intimate contact with their outer surface. The veins of this plexus vary in diameter, but normally are not larger than 1 mm. The latter consists of veins that run parallel to the common bile duct and are connected to the gastric veins, pancreaticoduodenal veins, portal vein, and liver directly. In a detailed analysis based on seven normal postmortem livers (Vellar 2001), it turned out that axial duct veins were found closely applied to the lateral margins of the bile duct. These were commonly two in number known as the 9 o'clock and 3 o'clock marginal vessels. A 6 o'clock vessel may also occur (three marginal veins). In the retropancreatic portion of the common bile duct, the two vessels tend to break up to form a plexus. These marginal vessels give branches which enter the liver substance superiorly, i.e., segments IV, V, caudate lobe, and caudate process. Other branches join the hilar venous plexus which then enter the caudate process or join the caudate portal venous branches. Marginal veins emptying into segment IV join portal venous branches supplying segment IV from the Rex recessus, while smaller vessels join small subcapsular vessels. In this study, the cystic veins always joined the 9 o'clock marginal vein, and they never joined the portal vein. A constant branch connects the 3 o'clock marginal vein with the right gastric vein (what is of importance in the light of the pathogenesis of bile duct varices in case of portal hypertension). The 9 o'clock and 3 o'clock marginal veins connect inferiorly, either individually or after anastomosing with each other, with the pancreaticoduodenal venous plexus, which in its turn drains into the superior mesenteric vein via the posterosuperior pancreaticoduodenal vein.

What Is the Anatomical Substrate of Gallbladder and Cystic Vein Varicosis ?

The venous system of the gallbladder is in direct communication with the portal vein system (Gabata et al. 1997). Venous blood from the gallbladder drains into the right portal vein directly or via the parabiliary venous plexus through the cystic vein, which also communicates with the deep cystic vein running directly into the liver and communicating with the right intrahepatic portal vein branches (Halvorsen and Myking 1971; Myking and Halvorsen 1971; Saigh et al. 1985; Couinaud 1988). In fact, the cystic vein is a direct bypass in portal vein obstruction (Myking and Halvorsen 1971). Contrast medium-supported helical CT imaging has shown that cholecystic venous blood most frequently enters peripheral portal venous branches of hepatic segment V (96 %) and segment IV (93 %). In order of decreasing frequency, cholecystic venous blood also drained to segments I, VI, VIII, III, and VII. The venous blood subsequently drained into the middle hepatic vein (75 %) or right hepatic vein (71 %; Yoshimitsu et al. 1997). Part of these venous channels are connected to the parabiliary venous system. This system originates from the pancreaticoduodenal and pyloroduodenal veins, runs along the common bile duct and the hepatic

artery, and divides in the liver hilum into a venous network within the hilar plate. This hilar plexus sends branches to the veins of the liver segments adjacent to the hilum, and, in 46 % of specimens studied, part of the cystic veins were anastomosed with the parabiliary system (Couinaud 1988).

What Is the Significance of the Cystic Vein?

In some texts on the hepatobiliary anatomy, a cystic vein proper is not specified, although cystic veins were known to classical anatomists, but analysis of the local vascular anatomy during laparoscopic cholecystectomy shows the presence of venous twigs that run parallel to the cystic duct and perpendicular to the common bile duct, bridging the gap between cystic artery and cystic duct, not crossing the common hepatic duct (Fine 1997). In regard to the drainage pathways of the cystic vein, the drainage routes had been studied mainly by the use of autopsy specimens or cast models (Sappey quoted by Kreider 1933; Kreider 1933; Zielke 1962; Halvorsen and Myking 1971; Satoh 1989). The description of the gallbladder veins by Sappey, a famous French anatomist, is as follows: The veins fall into two groups: those which originate in the superior (peritoneal) surface of the gallbladder and those which originate in the inferior surface. The former usually give rise to two trunks which, either separately or after uniting, empty into the right branch of the portal vein. The latter, 12 or 15 in number, representing so many small accessory portal veins, leave the gallbladder to ramify in the liver lobules which surround the gallbladder fossa (Sappey 1879). In a detailed analysis employing vascular gelatine injection, Kreider in principle confirmed these findings (Kreider 1933). His results showed that the gallbladder is covered with a plexus of usually paired and sometimes unpaired veins which accompany the branches of the cystic artery. This might, according to Krider, be called "cystic plexus" or "cystic plexus proper." The cystic plexus is drained by a number of unpaired cystic veins which are very irregular in number, size, and course and which arise from the smaller paired veins of the cystic plexus. Some of the cystic veins can be followed into large branches of the portal vein, and the others enter the liver at any point of the gallbladder fossa from its margin to its deepest point (the gallbladder fossa outlet veins according to my nomenclature). It has to be emphasized that, in the study of Vellar (2001; see above), cystic veins never entered the portal vein, but always joined the 9 o'clock marginal vein of bile ducts. The venous plexus of the gallbladder mucosa resembles the plexus of the duodenal mucosa and consists of a rich network of small veins, the interstices of which are filled with a network of extremely small veins. The gallbladder muscularis itself contains small veins, some of which unite the mucosal plexus with the cystic plexus. The gallbladder serosal veins take in general a lateral course toward the sides of the gallbladder. Some of them, and especially those in the middle of the peritoneal surface, communicate with the veins of the cystic plexus. The others run off to one side or the other into the liver (Kreider 1933). Based on a detailed autopsy study (100 randomly selected necropsies; ink injection into the cystic artery), Halvorsen and Myking (1971) largely confirmed the previous findings, although larger cystic veins were detected in only a fraction of cases, anatomically separated in five groups amounting to 8.5 %. The smaller veins of the gallbladder converge into larger veins that run on the sides of the gallbladder into the liver. The same pattern was described by Habighorst and coworkers after injection of X-ray contrast into the portal vein (Habighorst et al. 1965). In line with the conception of gallbladder fossa outlet veins and their drainage pathway, the authors always found ink in one and sometimes several large intrahepatic portal vein branches running under and parallel to the gallbladder fossa from the fundus of the gallbladder to the hilus of the liver. These veins were in most cases located 1–1.5 cm deep in the liver substance. The path of the connecting veins is not yet clearly known, although venous ostia were found in the portal vein probably belonging to cystic veins (Douglass et al. 1950).

In hemodynamic studies it has been found, by use of angio-CT, that all cystic veins drained

into the intrahepatic portal vein branches (cystic-intrahepatic inflow vessels). The cystic veins took either of two routes: one into the liver through the hepatic hilum, taken mainly by the portal branch for subsegment 4a (P4a), the anterior portal branch, and the umbilical portion of the portal branch and the other through the hepatic bed, taken mainly by S4a sinusoid, S5 sinusoid, P4a, and P5 (Sugita et al. 2000). In 70 % of the cases, cystic venous flow perfused either P4 or S5 (Kumaoka et al. 1998).

Postcholecystectomy Changes, Biliary Tract Mineralizations, and Intrabiliary Foreign Bodies

146

Contents

Abstract

Following cholecystectomy, several postcholecystectomy changes can simulate biliary tract cancer. Postsurgery strictures associated with fibrosis or scarring may mimic desmoplastic cancers. Also cystic duct remnants, including cystic duct remnant mucocele and bilomas, can induce alterations that may resemble a neoplastic process. In addition, carcinoma can develop within a cystic duct remnant following cholecystectomy. Thickening of the bile duct walls mimicking a neoplastic process can be caused by duct calcifications. Causes of calcifications include infections, infestations, metabolic diseases, calcification of sludge balls, and limy bile syndrome. Stenosis and obstruction of large bile ducts can be induced by various types of foreign bodes. A distinct form of bile duct obstruction is biliary tract bezoar, including phytobezoar, food bezoar, trichobezoar, and fungal bezoars. Bezoars are mimicked by masses that consist of blood, pus, or necrotic tissue (pseudobezoars).

Postcholecystectomy Changes Simulating Biliary Tract Tumor

Introduction

The most important postcholecystectomy disorder complex is summarized under the term postcholecystectomy syndrome (PCS). PCS refers to the

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_146

persistence of gastrointestinal and hepatobiliary signs and symptoms after cholecystectomy. There are a multitude of biliary and non-biliary causes of PCS (Deziel 1994; Kumar and Pande 2001; Tsoraides et al. 2007; Filip et al. 2009; Girometti et al. 2010; Jaunoo et al. 2010; Schofer 2010). A review of 1.6 million cholecystectomies, from 1992 to 1999, demonstrated a 0.5 % incidence of bile duct injury.

Postcholecystectomy Bile Duct Strictures

Extrahepatic biliary tract strictures caused by fibrosis/scarring are a well-known complication after cholecystectomy-induced bile duct injury (Agarwal et al. 2008; Grönroos 2008; Vitale et al. 2008). In a recent overview (1991–2006) on 292 patients who were referred for postcholecystectomy problems, 199 had cholecystectomy-related injuries, and 93 had other pathologies. Sixty-seven patients had bile duct injuries (Amsterdam Academic Medical Center's classification, types B, C, and D), and 46 patients had bile duct strictures (Vitale et al. 2008). In 15–20 % of patients with postcholecystectomy biliary strictures, portal hypertension occurs (Agarwal et al. 2008). Inflammatory scarring may involve distal parts of the common bile duct and can cause sphincter of Oddi dysfunction. Apart from scar-induced stricture, inflammatory and fibrosing reactions around foreign bodies may cause biliary obstruction with obstructive jaundice; e.g., post-surgical granuloma of the common bile duct (Farkas et al. 1980) and suture material induces foreign body reaction (Das et al. 2010).

Postcholecystectomy Syndrome and Cystic Duct Remnant

There is considerable variability in regard to the junction of the cystic duct with the common bile duct. The cystic duct may insert anywhere along the course of the common bile duct from the porta hepatis to the duodenum, and before the junction, the cystic duct may descend for a considerable distance immediately adjacent and parallel to the right side or posterior to the common hepatic duct (Linder and Green 1964).

In a prospective sonographic study of 139 patients, the average diameter of the normal distal cystic duct was 1.8 mm. In 95 % of the patients, the distal cystic duct was located posterior to the common bile duct and, in 5 % of the patients, anterior to the common bile duct (Parulekar 1989). Postcholecystectomy syndrome (PCS) is a rather common condition in patients with cholecystectomy and presents with a heterogenous set of signs and symptoms, including upper abdominal pain, gastrointestinal disorders, vomiting, and eventually jaundice (Colp 1944; Twiss and Carter 1948; Gants 1953; Cavallaro et al. 2009; Girometti et al. 2010; Perera et al. 2011). PCS may be associated with stone disease, including remnant gallbladder lithiasis (Demetriades et al. 2008; Pernice and Andreoli 2009), remnant cystic duct calculi/lithiasis of long cystic duct remnant, and choledocholithiasis (Bystrovskaia and Orlova 2008).

The Cystic Duct Remnant and the Postcholecystectomy Syndrome

The cystic duct remnant (retained cystic duct stump; Stahl 1962; Mathews and Hiatt 1966) is defined as a residual cystic duct greater than 1 cm in length. In few situations of inadequate surgery, the cystic duct stump may be associated with retained parts of the distal gallbladder (gallbladder remnant; Shaw et al. 2004; Demetriades et al. 2008). In laparoscopic cholecystectomy (ERCP study, $N = 113$), the length of the stump was up to 1 cm, 1–2 cm, 2–3 cm, and more than 3 cm in length in 34.5 %, 36.3 %, 24.8 %, and 4.4 % of the patients, respectively (Keiler et al. 1992).

The remnant is readily identifiable by sonography (Crowley and Hedvall 1985), and it is known to be an etiologic factor for several postcholecystectomy disorders, including stone

development in the remnant (the most frequent complication; Zhou et al. 2003), scarring, intestinal adhesions, and traumatic neuroma (the latter being discussed in a separate chapter). The lesion pattern causes complex disorders known under diverse terms, including the so-called cystic duct syndrome/cystic duct stump syndrome and the postcholecystectomy syndrome (Garlock and Hurwitt 1951; Hangos 1958). The postcholecystectomy syndrome refers to a wide spectrum of conditions that may pose a challenging diagnostic dilemma (Shaw et al. 2004), and only part of the disorders are attributable to remnant duct stones (Palanivelu et al. 2009), others being dysfunction of the sphincter of Oddi and, in developmental countries, biliary ascariasis. The symptoms occurring after cholecystectomy are often attributed to a long residual cystic duct (the long cystic duct stump; Salzer 1962) that may favor the development of secondary changes (Larmi et al. 1975; Hopkins et al. 1979). How frequent is the cystic duct stump, and how frequently does the stump cause biliary symptoms? Among 54 symptomatic patients with previous cholecystectomy, a stump was found by use of ERCP in 56 % of the patients, with a mean length of 23 mm (Aärimaa and Mäkelä 1981). In a randomized study of 80 patients comparing standard cholecystectomy with a technique to remove the entire cystic duct, 37 % versus 85 % of the patients, respectively, were free of biliary symptoms during an 8-year period (Jonson et al. 1991), suggesting a pathogenic role of the stump. Cystic duct remnant causes pain, biliary dyskinesia, and sludge formation (the cystic duct remnant syndrome; Perera et al. 2011; Selvaggi et al. 2011). Cystic duct remnants may undergo cystic dilatation (Perera et al. 2011) and are prone to develop calculi (remnant lithiasis; stump stones; Palanivelu et al. 2009; Sahoo and Kumar 2013). As such, unrecognized lithiasis of the cystic duct may be a relatively common event that leaves its traces in the postcholecystectomy stump. In a study of 143 consecutive cholecystectomies, cystic duct lithiasis was detected in 14.4 % of patients (Sezeur and Akel 2011). The remnant can undergo mucus retention with formation of a mucocele (Chatterjee et al. 2011). The formation of sludge and stones in the cystic duct remnant has been documented by sonography (Parulekar 1989). A rare entity is cystic duct remnant-enteric fistulization. Calculous obstruction of the cystic duct remnant or the common bile duct must be present for fistulization to occur (Woods et al. 1992). A long cystic duct remnant with stone formation can cause Mirizzi syndrome (Wani et al. 2010).

Cystic Duct Remnant Mucocele

A rare cause of biliary obstruction after liver transplantation is a tension mucocele of the remnant of the allograft cystic duct. A blind donor cystic duct remnant undergoes distension with mucus and causes extrinsic compression of the common hepatic duct. At liver transplantation, if the biliary anastomosis is done at the level where the allograft cystic duct is contiguous to the common bile duct, the orifice of the cystic duct may be incorporated into the suture line of the anastomosis. As the donor gallbladder is removed, this procedure may create a closed (blind) cystic duct remnant (Koneru et al. 1989; Zajko et al. 1990). Other pathogenic factors include a compromised mucus outflow from the remnant due to contraction of connective tissue in Calot's triangle, ischemic duct damage, and lack of nervous regulation (Liang et al. 2007). This complication has chiefly been found in adult liver graft recipients (Koneru et al. 1989; Zajko et al. 1990; Abcarian et al. 1994; Liang et al. 2007), but has also been reported for the pediatric age group (Pariente et al. 1991; Ahlavat et al. 2008). Cystic duct remnant mucocele presents both as nonobstructive and obstructive lesion. In regard to the prevalence of the nonobstructive cases, an anechoic ovoidal structure just before the portal vein and in proximity of the main bile duct was found in 2–4.5 % of patients (Caputo et al. 1995, 2000). In a series of eight patients with this type of mucocele, all patients had clinical and/or laboratory evidence of biliary obstruction or cholangitis from 2 weeks to 3.3 years following transplantation (Zajko et al. 1990).

Cystic Duct Leaks and Biloma Formation

A subset of patients with postcholecystectomy syndrome have biliary leaks, the chief locations being the gallbladder bed, subhepatic space, right paracolic gutter, lesser sac, and diffusely peritoneal cavity. Cystic duct leaks (cystic duct stump leaks) appear to complicate laparoscopic cholecystectomy more often than open cholecystectomy (Himal 1996; Barkun et al. 1997). Among 207 consecutive patients with postcholecystectomy bile leak, the leak site was the cystic duct stump in 78 % (Sandha et al. 2004). In one systematic study, the leaks post-laparoscopy presented at a median of 4 days after intervention (Woods et al. 1994). In another study ($N = 64$), biliary obstruction was noted in 31 % of the patients, however, in two thirds associated with stones (Barkun et al. 1997). Bile leakage from the cystic stump may result from clip displacement (Hanazaki et al. 1999; Adjepong 2000). Bile draining from the leak may form bilomas, e.g., in the subphrenic space (Albasini et al. 1995) and sometimes forming a cystic mass up to almost 10 cm in size (Meshikhes et al. 2007). Leakage-induced fluid collections in the gallbladder fossa may with time (after years) be demarcated and may seldom communicate via the cystic duct stump with the common bile duct, producing what has been termed a phantom gallbladder (Xing et al. 2007).

Cystic Duct Fistula

Cystic duct fistula is a rare complication of cholecystectomy (Nelson 1984). The fistula can drain into the subhepatic space (Agrawal et al. 1979) or the gastrointestinal tract (Chandar and Hookman 1980; Woods et al. 1992; Abiad and Sidani 2000).

Cystic Duct Remnant Carcinoma

Carcinoma originating from a cystic duct remnant is a rare complication. These adenocarcinomas invade the bile duct system and extend along the common bile duct and cause biliary obstruction (Phillips and Estrin 1969; Dixon and Christensen 1971; Gabata et al. 2003; Noji et al. 2003; Eum et al. 2008).

Calcinosis and Related Conditions of the Biliary Tract

Bile Duct Calcifications in Infections and Infestations

In hepatobiliary tuberculosis, large "chalky" and nodular calcifications are seen along the extrahepatic ducts, in particular the common bile duct (Maglinte et al. 1988). Bile duct calcification is also known to occur in the context of schistosomiasis/bilharziasis (Radhakrishnan et al. 1988; Fataar et al. 1996), discussed in a separate chapter.

Bile Duct Calcifications in Metabolic Diseases

Calcification/mineralization may also involve the small intrahepatic bile ducts and/or the ductules. Ductular epithelial lining calcification has been observed in uremia and suggested to be a result of elevated serum calcium and phosphate (Kurumaya et al. 1989). Chronic renal failure may, via secondary hyperparathyroidism, also cause hepatic artery calcifications producing hilar calcium signals, but the hepatic artery is far less frequently involved than the abdominal aorta and the splenic artery (Okuda et al. 2002). Calcifications of smaller artery branches accompanying the portal vein or the bile ducts also occur (Okuda et al. 2003). Hepatic artery calcifications may be mistaken for biliary calculi (White and Wilson 1994). Bile duct calcifications have been observed in calcifying primary and secondary amyloidosis (Kennan and Evans 1991; Levine 1994; Jacobs et al. 1997; Korkmaz and Kebapci 2004).

Calcifying Sludge Balls

Bile sludge masses are a substrate for mineral crystal formation, rarely resulting in calcified

roundish masses or sludge balls (Feuerstein et al. 1990).

Limy Bile Syndrome

Limy bile syndrome (synonyms: calcium milk bile, milk of calcium bile) is a rare condition in which a radiopaque gallbladder and/or bile ducts are noted on plain roentgenograms, caused by the accumulation of a thick, paste-like material in the biliary tract. The disorder was first described in 1911 (Churchman 1911; he described the material as "calcium soap"), and in 1926, the term milk of calcium (in German: Kalkmilchgalle) was coined (Volkmann 1926), followed by the term limy bile in 1933 (Knutsson 1933). The syndrome is caused by excessive calcium carbonate precipitation in the bile and is usually associated with distal biliary tract obstruction and sometimes with parenteral nutrition, although the etiology of the precipitation of this calcium salt is not known (Le Genissel et al. 1967; Sudhakar Krishnan and Lim 1983; Lazzari et al. 1985; Fowler et al. 1993; Moreaux and Roux 1994; Ballas et al. 2005). The syndrome also occurs in the pediatric age group, including newborns (review of the literature: Eymeri et al. 1989). Atomic absorption spectrophotometry and crystallographic analysis by the X-ray powder diffraction method and infrared spectrometry have confirmed that calcium carbonate is the major constituent of limy bile, mostly in the form of aragonite, followed by calcite and vaterite (Saito et al. 1986). It has been suggested that gallbladder stasis may play a pathogenic role (Naryshkin et al. 1987). Limy bile syndrome can cause cholecystitis without obstruction at the neck of the gallbladder (limy bile cholecystitis; Churchman 1911; Gya et al. 1990). Apart from the gallbladder, calcium milk bile can accumulate in the extrahepatic bile duct, in particular the common bile duct, and can cause obstructive jaundice (Tsukamoto et al. 2003; Ballas et al. 2005; Sasaki et al. 2010), but most such cases, a double localization (i.e., gallbladder plus bile duct) is observed (Sava et al. 1988).

Differential Diagnosis of Bile Duct Calcifications

Calcification can ensue in cholangiocarcinomas, particularly in mucinous cholangiocellular carcinoma (Nagakura et al. 1999).

Bile Duct Stenosis Associated with Porcelain Gallbladder

Chronic cholecystitis with extensive calcification/mineralization of the gallbladder wall (porcelain gallbladder) may be associated with extensive pericystic fibrosis that can lead to fibrous encasement of stenosis of the extrahepatic bile ducts (Snajdauf et al. 2006).

Foreign Bodies in Bile Ducts

Introduction

Several types of foreign bodies can be dislodged into the bile duct via luminal transport, migrate into bile duct tissues, or be introduced in the setting of surgical procedures (Table 1). Non-inert foreign bodies typically induce an inflammatory foreign body-type reaction, followed by fibrosis and eventually fibrotic bile duct stricture/stenosis, in some patients mimicking malignancy.

Table 1 Types of foreign bodies in the biliary tract

Metal clips
Suture material
Fragments of stents, tubes, catheters, or duct prostheses
Gelfoam
Food components (such as fish bones)
Toothpicks
Bezoars
Textile components
Rubber bands
Combat-related foreign bodies

Metal Clips

Clip migration after a laparoscopic procedure was first reported in 1992 (Hemmi et al. 1992; Matsuura et al. 1992; Onghena et al. 1992), and clips usually migrate to the common bile duct, where they can cause obstruction and jaundice (Hemmi et al. 1992; Raoul et al. 1992; Dias and Dharmaratne 2012), but have been identified at the hepatic duct as well (Ahn et al. 2005). Cystic duct clip migration into the common bile duct was observed following cholecystectomy (Rowe and Nikfarjam 2012). Surgical clip migration into the common bile duct has also been found after orthotopic liver transplantation (Alsulaiman et al. 2006). The mechanism of clip migration is poorly understood and can occur from days to years after laparoscopic cholecystectomy. It may be suggested that, via induction of a foreign body reaction and similar to foreign bodies situated elsewhere, leukocyte- and/or infection-mediated tissue necrosis ensues, followed by liberation of the clip through a tissue gap into the duct lumen. Endoclip migration from the cystic stump to the common bile duct has also been observed for polymer endoclips (Kissmeyer-Nielsen and Kiil 2005).

Metal clips, subsequent to migration or in situ, can serve as a nidus for formation of common bile duct and other duct gallstones (called "clip stones" or "clipoliths"; Mansvelt et al. 1993; Brogdon et al. 1996; Ray and Bhattacharya 2013) after open or laparoscopic cholecystectomy (Walker et al. 1979; Wittenberg et al. 1985; Davis et al. 1988; Martinez et al. 1995; Muehlenberg und Löffler 1995; Alberts et al. 1999; Yoshizumi et al. 2000; Lee et al. 2003; Chong et al. 2004; Mouzas et al. 2005; Steffen et al. 2007), thus being one well-identifiable cause of iatrogenic biliary stone (Chong 2005). In these situations, clips can in fact be found as a constituent of the gallstones (Mansoa et al. 2000).

Suture Material

Suture material can elicit a foreign body reaction in the bile duct. In one case, this granuloma generated a mass of 1.5 cm diameter, mimicking Klatskin tumor (Uzcatequi-Paz and Gonzalez-Paredes 2009). In another patient, a stenosing foreign body granuloma (suture granuloma) developed 18 years after duodenal surgery, mimicking cholangiocarcinoma (Murphy et al. 1990). Common bile duct stones may develop around nonabsorbable suture/ligature threads, either in situ or around sutures that had migrated into the common bile duct, a complication already reported at the end of the nineteenth century (Homans 1897; Sigler and Sahler 1969; Orr 1980; Lewis and Urdaneta 1981; Fink and Budd 1983; Ormann 1989; Son et al. 1999; Fortun et al. 2005; Kim et al. 2007), and part of the migrating sutures took their origin at the cystic stump (Leborgne et al. 1981).

Other Intrabiliary Foreign Bodies

A wide array of foreign bodies not related to surgical maneuvers have been reported. They comprise, among others, stents, fragments of damaged and sometimes migrating stents (the so-called stent cholangitis; Figs. 1 and 2; Johanson et al. 1992; Manouras et al. 2007), T-tubes and catheters, migrating bile duct prostheses (Zapata Morcillo et al. 2006), elastic rubber bands (Ochiai et al. 2012), migrating Gelfoam (Riddle et al. 2008), dislocated/migrating food

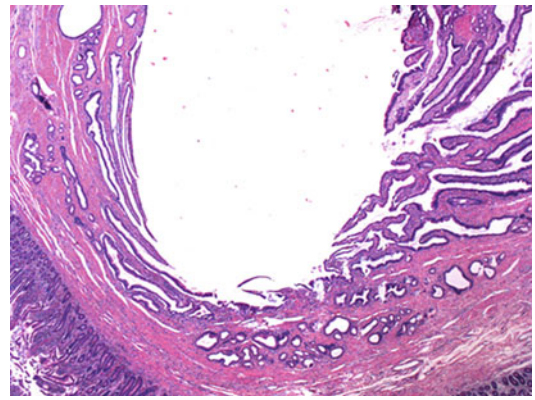

Fig. 1 Stent cholangitis in a biliodigestive anastomosis. Due to compression by the stent, the mucosa is flattened and partially atrophic (hematoxylin and eosin stain)

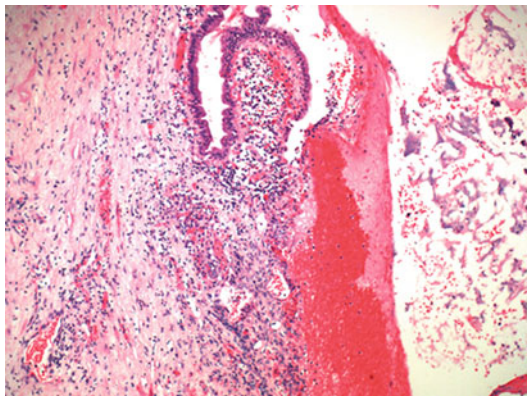

Fig. 2 Stent cholangitis. The stent (now removed) has damaged the bile duct mucosa and induced an ulcerating and fibrosing inflammation, eventually causing stenosis (hematoxylin and eosin stain)

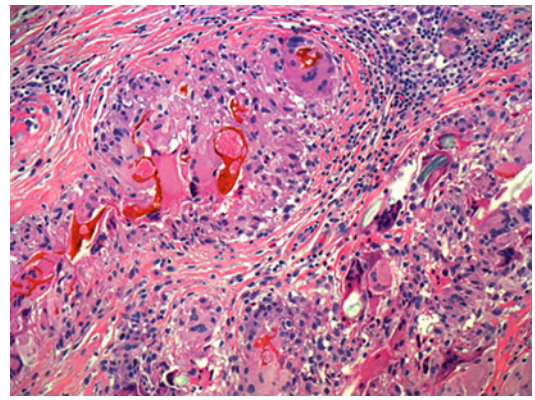

Fig. 4 Foreign body cholangitis. The *upper half* of the figure shows bile granulomas and the lower right corner granulomas with particulate foreign material (hematoxylin and eosin stain)

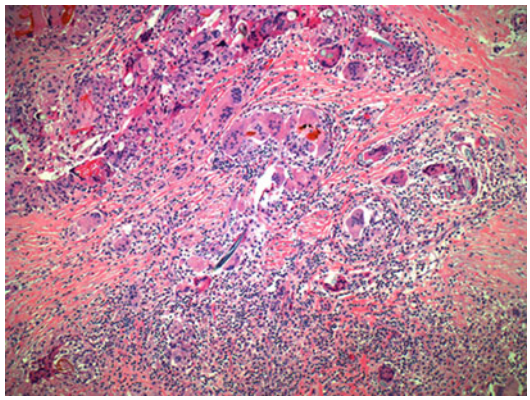

Fig. 3 Foreign body cholangitis. Several foreign body granulomas with multinucleated giant cells have accumulated in the mucosa (hematoxylin and eosin stain)

components (in particular fish bones, which may cause stone formation; Orda et al. 1986; Kaji et al. 2004; Kim et al. 2004; Patel et al. 2006), textile components (including obstructive textilomas; Cimsit et al. 2006), and combat-related foreign bodies, including bullets and shell splinters (Klein et al. 1981; Maheshwari et al. 2003; Kamona et al. 2005). Part of such foreign bodies may form the nidus of a stone, e.g., a T-tube fragment (Hoffman et al. 2008), a plastic biliary stent (Dokas et al. 2009), or a metal stent (Cheon et al. 2002). These foreign bodies can elicit a foreign body reaction (Figs. 3 and 4).

Biliary Tract Bezoars (Biliary Bezoars)

Bezoar (enterolith, gastrolith) is a concretion in the gastrointestinal tract caused by the intake of undigestible material such as plant fibers, hair, or constituents of tablets. The name stems from Arabic bazahr and Persian padzahr, meaning protecting against poison. The "stones" are frequently encountered in the GI tract of ruminants, including goats. Bezoar is then also the name of a goat (*Capra aegagrus*) which is a matriarchal candidate for ancestor of domestic goat (Takada et al. 1997). Bezoars can mineralize to become stonelike structures (bezoar stone, bezoardicum minerale). Such stones still have a certain value in traditional medicine, used as an antidote to poison. This action of bezoar was recorded by the famous French surgeon, Ambroise Paré (1510–1590), who performed a celebrated practical test with a bezoar stone which had been brought from Spain to Charles IX of France. Bezoar as a poison antidote was also used in Asia; Garcias ab Horto, a Portuguese physician of Goa, described a variety of bezoar called lapis malacensis (Malacca stone) found in the liver of a hedgehog and employed as an antidote for poisons in Malacca. A specimen was brought to Rome from Portugal by Cardinal Alexandrinus, and Mercato states that he had seen a test of its virtues as an antidote for poisons.

Table 2 Types of biliary tract bezoars

Phytobezoar (plant components)
Food bezoar
Trichobezoar (hair)
Mycotic bezoars (yeast bezoar, "fungal ball")
Pseudobezoars (hemobezoar; pyobezoar; necrobezoar; bezoars composed of blood clots, pus, or necrotic tissue)

Bile duct bezoars are composed of diverse materials (Table 2)

The formation of bile duct bezoars is a rare event, and these bodies usually occur in the common bile duct, particularly its distal segment. They have been detected in the context of choledochoenteric anastomosis (Siegel 1981), duodenal diverticulum (Armengol-Miro et al. 1977; Seyrig et al. 1989; van der Linde et al. 1997), postcholecystectomy choledochoduodenal fistula (Moghaddam et al. 2006), and clot bezoar after endoscopic sphincterotomy (Groth et al. 2006). Clinical manifestations are obstructive jaundice and cholangitis. In regard to constituents forming bezoars, the terminology and definitions are not consistently respected, in that bezoars should consist of ingested, albeit not necessarily foreign, material (e.g., foreign, phytobezoar; non-foreign, trichobezoar). Hence, "hemobezoars" (Groth et al. 2006) and "pyobezoars" are not true bezoars; otherwise compacted bile sludge and even gallstones would also be bezoars ("pseudobezoars"). The composition of biliary bezoars has been reported to be food components (food bezoar; Zuber-Jerger and Kullmann 2006), plant material (phytobezoar; Vitovec 1975; Malt 1979; Lamotte et al. 1995; Kim et al. 2006, 2013; Garlipp et al. 2012), fibrinoid material with cellular debris (Moghadaam et al. 2006), clumps of yeast (yeast bezoar; Perttala et al. 1975), and coagulated blood (hemobezoar; Groth et al. 2006). Interestingly, part of common bile duct gallstones may develop from bezoars. In a crystallographic investigation, foreign material was identified in part of gallstones, mainly suturing material (postcholecystectomy) and cellulose (Prochazka et al. 1999). Phytobezoar was reported to act as a nidus for gallstone formation (Cetta et al. 1993).

Foreign Material-Containing Gallstones

As already mentioned above, foreign material in the bile ducts can be a cause for cholelithiasis, the gallstone matter being deposited around a foreign body which acts as a nidus. In a study on 54 patients where gallstones were examined qualitatively using crystallographic analysis by X-ray powder diffraction and where foreign material was studied morphologically and by polarization microscopy, foreign material was detected in six patients (11.1 % of the cases), among which four had a history of previous cholecystectomy (Prochazka et al. 1999).
