Abstract

In contrast to hepatic blood vessel tumors, tumors and tumor-like lesions of hepatic lymph vessels are very rare conditions. Primary lymph vessel tumors of the liver present as multifocal or solitary tumorous lesions. A multifocal process is lymphangiomatosis, a disorder occurring both in children and adults. Predilection sites include lungs, skeletal muscle, and bone, whereas visceral organs are rarely involved. In the liver, lesions form large and in part confluent masses that consist of densely packed lymphatic channels and cystic structures. The process can rapidly progress and recur after resection. Solitary and localized hepatic lymph vessel tumors comprise cystic lymphangioma, non-cystic lymphangioma, capillary lymphangioma, and the very rare lymphangioma of bile ducts. Tumor-like lymphatic vessel lesions of the liver include hepatic lymphangiectasis, hepatic lymphocele, and primary lymphatic dysplasia of the liver.

Introduction

A broad array of clinical disorders of lymphangiogenesis are currently known (review: Witte et al. 2001), and some of them can manifest in the liver. In contrast to the morphogenesis of blood vessels, still less is known about mechanisms involved in normal, dysplastic, and neoplastic lymphangiogenesis, but similar pathways employing an analogous biochemical machinery may be operational (Witte et al. 2001). Overall, lymph vessel tumors of the liver are rare and unusual lesions. They comprise lymphangiomatosis, lymphangiomas, which are traditionally divided into three groups (capillary, cavernous, and cystic forms), lymphangiomyomatosis, and few other lesions characterized by an increase of abnormal lymph vessels, but of doubtful neoplastic character. Lymphangiomyomatosis is discussed in the context of tumors of the perivascular epithelioid cell system. Are clinically benign lymph vessel tumors neoplastic disorders? According the modern concepts, part of the lesions are now classified as lymphatic malformations, sometimes with a progressive character (Salazard et al. 2006; Perkins et al. 2010), and their pathogenesis has been reviewed in detail (Wiegand et al. 2008).

Lymphangiomatosis

Lymphangiomatosis is a rare disorder occurring in children and adults without gender predilection, characterized by the multifocal occurrence of lymphangiomas, and in some way reflecting the counterpart of angiomatosis (Ozeki et al. 2007). This unique lesion mostly manifests in children and is rare after age 20, but even though congenitality is suggested in systemic forms, the diagnosis is usually not common at birth, the tumor requiring a latent developmental period until it will be detectable. In the systemic variant, predilection sites are the lungs, soft tissues (particularly skeletal muscle), and bone, multiple bone lesions being observed in more than three-fourth of the patients, whereas visceral manifestations are less frequent (Jain et al. 2007; Kim et al. 2010). Apart from the extent of disease, the main localization bears an impact on prognosis, liver, spleen, lung, and thoracic duct involvement usually being associated with a poorer outcome. Lymphangiomatosis exceptionally develops in the liver, either as a manifestation of a systemic disorder or as an isolated, nonsystemic organ manifestation This process, which has alternatively been termed lymphangioendothelioma (Peters et al. 1989), is characterized by a pathologic proliferation of lymphatic channels involving soft tissues, bone, and solid organs. The abnormal growth of lymphatics can present as capillary-like/cavernous, cavernous, or cystic phenotypes. The cystic variant is also called cavernous lymphangiomatosis and may clinically and radiologically mimic polycystic liver disease (O'Sullivan et al. 1998). Diffuse hepatic lymphangiomatosis can undergo massive progression after liver resection (Datz et al. 2001) and recur after orthotopic liver transplantation

(Ra et al. 2007). Some of the cases involve infants and small children, suggesting that at least part of lymphangiomatoses are congenital malformations rather than a bona fide neoplastic process.

Macroscopy

In the liver, the lesions can grow to large and in part confluent, grayish-white masses causing sometimes massive hepatomegaly (Schmid et al. 1991; Ra et al. 2007). From the outside, the liver can show a nodular surface with several to numerous blue-dome cysts having a diameter ranging from few mm to more than 2 cm. The capsule between these cystic structures is either gray or mottled brown to dark red. In cut surfaces, clusters of cystic spaces with a clear to turbid fluid are seen, and in advanced cases, the hepatic parenchyma is mostly replaced by a network of cystic spaces with zones of fibrosis. Large areas of fibrosis developing in cystic areas can form stellate scars similar to those seen in focal nodular hyperplasia (Schmid et al. 1991).

Histopathology

Histologically, abnormal and sometimes densely packed lymphatic channels may predominate in the portal tracts and around bile ducts and ductules. Cystic lymphatic spaces are often noted, filled with an eosinophilic proteinaceous fluid and showing a flat endothelial lining. At the border of the cyst lumen, a rim of vacuoles similar to those seen in thyroid gland follicles can be seen, sometimes with confluence to form a halo (Asch et al. 1974). In later phases, the lymph vessel proliferation is accompanied by associated fibrotic changes resulting in septal structures which may reach the capsular surface and produce externally visible stellate capsular scars. The 3D network of fibrous septa or scars (Schmid et al. 1991) can lead to the separation of the liver substance into rather large nodule-like masses and to hepatocyte hyperplasia, visualized at gross examination and at imaging and not to be confounded with liver cirrhosis or regenerative nodular hyperplasia. In some cases, sinusoids of preserved hepatic lobules are dilated, and particularly in the periportal zone 1, it may be difficult to distinguish these structures from adjacent lymph vessels. By the use of silver impregnation, it has been observed that the lymph-draining perisinusoidal space of Disse is dilated, and it has been suggested that, in hepatic lymphangiomatosis, some of these spaces may be directly connected with lymph vessels in the portal tracts (Haratake et al. 1992).

Immunohistochemistry

Immunohistochemically, the cells lining the abnormal lymphatic channels are reactive, to variable degrees, for Ulex Europaeus agglutinin 1, von Willebrand factor (factor VIII-related antigen), and CD31 (Schmid et al. 1991; Haratake et al. 1992; Ramani and Shah 1993), whereas one group was unable to detect CD31 and CD34 in the abnormal endothelial cells (Datz et al. 2001). The cystic variant is characterized by large and apparently communicating cystic spaces identifiable at imaging (Cutillo et al. 1989) and which may under rare circumstances be extremely abundant, thus mimicking polycystic liver disease (O'Sullivan et al. 1998). Even though the growth of the abnormal lymphatic channels appears to be a benign or non-neoplastic process, the sometimes rapid and massive increase of lymphatic mass, in few cases

almost entirely replacing the liver substance (Peters et al. 1989), can cause severe morbidity, organ failure, and even death, in particular when the lungs are diffusely involved. Isolated manifestations in the liver may be clinically silent and incidentally detected, or they may rarely result in massive growth (massive hepatic lymphangiomatosis) requiring surgery or, in case of liver failure, even liver transplantation (Miller et al. 1988; Tepetes et al. 1995; Datz et al. 2001). Owing to the observation of acute and chronic pericholangiolitis in association with pediatric multifocal hepatic lymphangiomatosis, it has been suggested that some of these lesions may represent a reactive, pseudoneoplastic dilatation of liver lymphatics subsequent to an inflammatory response (Sathyavagiswaran and Sherwin 1989). Hepatic cystic lymphangiectasis has been reported to occur within a syndromatic setting, e.g., with the VACTERL association (vertebral anomalies, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or segmental atresia, reno-urinary anomalies, and limb defects; Distefano et al. 1998).

Cystic Lymphangioma of the Liver

ICD-O code 9170/0

Introduction

In situations where small lymphatic channels are lacking or are not readily detectable, hepatic lymphangiomatous lesions with a predominantly cystic component pose a differential diagnostic problem. In some reports, such tumors have been classified as variants of lymphangiomatosis (Singh et al. 1971; Rumpf and Mannfeld 1972). However, *cystic lymphangiomas* (synonym: cystic hygroma) morphologically very similar or indistinguishable from respective tumors at other sites occur in the liver as well, both in children and adults, albeit as an uncommon condition. Based on a series of 139 patients, only about 9 % of pediatric lymphangiomas have been reported to occur in the intra-abdominal compartment (Hancock and Dickens 1992), whereas in another study, intra-abdominal lymphangiomas accounted for less than 5 % of cases (Kosir and Sannino 1991). Lymphangioma of the liver usually presents as an isolated lesion not associated with other disorders, but the hepatic tumor can develop together with splenic lymphangioma (Dupuy et al. 1984), and a patient with intra-abdominal and hepatic lymphangiomas associated with diffuse venous hemangiomas of the skin and visceral organs has been described (Canataroglu et al. 2003). Cystic lymphangioma can rarely develop in the hepatic ligaments, e.g., the ligamentum teres (Zaev 1989).

Macroscopy

Cystic lymphangiomas of the liver are usually solitary lesions with a diameter of few cm, but giant tumors have also been described (Symmers and Ward-McQuaid 1950; Zeidan and Delarue 2008; Stunell et al. 2009; Huang et al. 2010). In the 1.5 year-old-boy described by Rumpf and Mannfeld (1972), a cystic tumor measuring more than 15 cm in diameter was attached to the right liver lobe through a stalk. Similar to the respective soft tissue tumors, hepatic cystic lymphangiomas consist of cystic spaces, sometimes interconnected, which contain a serous, serosanguinous, or chylous fluid. The clustering

of cysts with intervening fibrous septa often results in a lobulated morphology of the tumors. The cyst walls may contain calcifications, sometimes extensive. The lining of the cysts is smooth, and the cyst walls are usually thin. The lesions can grow as multilocular and pedunculated masses extending beyond the liver surface (Koh and Sheu 2000), and the tumors can also develop within the hepatic ligaments (Zaev 1989).

Histopathology

Histologically, the cysts contain an eosinophilic, proteinaceous fluid with marginal vacuoles and are lined by a flat endothelium of the lymphatic type, and the wall of the channels or cysts may contain lymphoid tissue, smooth muscle cells, and foam cells (Enzinger and Weiss 1995; De Perrot and Rostan 1998¸ Figs. 1, 2, 3, and 4). Outside the liver, regression of lymphangiomas has been reported to occur spontaneously (Hancock and Dickens 1992), but progressive growth may also ensue (Saiji and Munro 1975; Hancock and Dickens 1992). Lymphangiomas may show focally dense lymphocytic infiltrations (mainly T lymphocytes) and sometimes abundant tissue mast cell infiltrates, the latter being much less evident in lymphangiomatosis. Some lymphangiomas exhibit hemorrhage between the vascular

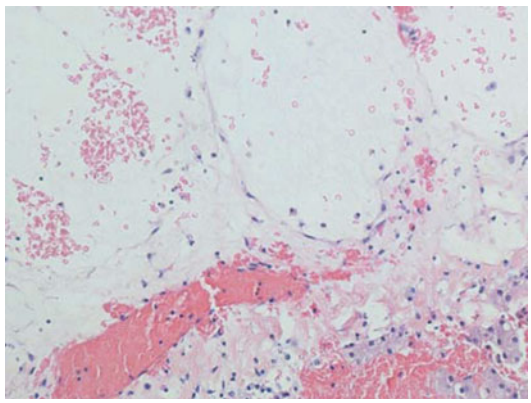

Fig. 2 Markedly dilated lymphatic channels in cystic lymphangioma of the liver (hematoxylin and eosin stain)

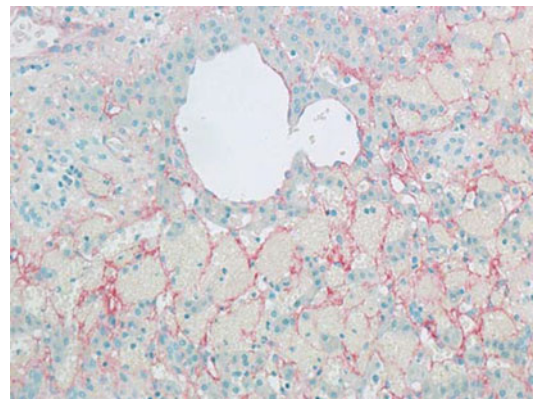

Fig. 4 Lymphangioma of the liver with a meshwork of abnormal lymphatic channels (D2-40 immunostain)

channels and even blood within the vascular spaces, but whether this qualifies such changes to employ the term hemangiolymphangioma is doubtful, even though this term has been used for tumors with these features, also in the liver (Damascelli et al. 1984).

Differential Diagnosis

Cystic lymphangiomas might be confounded, at imaging, with lymphoceles. Lymph cysts, e.g., in topographical association with bile ducts (Nishino et al. 1988), may emerge without foregoing trauma. Finally, cystic hamartomas of the hepatic pedicle can contain dilated lymph vessels and may be confounded with cystic lymphangiomas (Bugnon et al. 1987).

Non-cystic Lymphangioma of the Liver

Hepatic non-cystic lymphangiomas not related to congenital lymphangiomatosis have also been observed, including cavernous variants (Serio and Marini 1965; Delamarre et al. 1990 (with a literature review); Stavropoulos et al. 1994; Nikhinson 1994; Bartelheimer et al. 2001). A lymphangiomatous component can also emerge within the manifestations of systemic angiomatosis, e.g., in pregnancy (Bardeguez et al. 1990).

Capillary Lymphangioma of the Liver

Capillary lymphangioma, i.e., non-cystic lymphangioma of the liver, is a very unusual condition, and we are aware of only few published cases, observed in neonatal and adult patients (Van Steenbergen et al. 1985; Peters et al. 1989). In the neonate reported by Peters et al. (1989), the tumor almost entirely replaced the liver substance; no other organs were involved. The adult patient described by Van Steenbergen and coworkers (1985) showed an unusual, diffuse lymphangiomatous infiltration of the liver, whereby the numerous lesions were not distinguishable from necrotic metastases by the use of ultrasonography and CT.

Lymphangioma of the Bile Ducts

Introduction

Lymphangiomas are very rare tumor lesions of the biliary tract and are considered to either be neoplasms or tumor-like lymph vessel malformations. So far, the majority of lymphangiomas were located to the ampullary region and Vater's papilla (Artaza et al. 1995; Friedrich et al. 1985; Sriram et al. 2000; Targarona Modena et al. 2005). Lymphangioma of Vater's papilla results in stenosis, sometimes followed by obstructive jaundice (Friedrich et al. 1985) or acute pancreatitis (Sriram et al. 2000).

Pathology

Lymphangiomas are usually cystic and circumscribed nodular lesions with thin-walled cystic spaces. Following dissection, a clear fluid escapes from the cysts, sometimes with signs of previous hemorrhage. Lymphangioma cysts are lined by a flat complete or incomplete lymphatic endothelium. The septa between the cystic spaces consist of hypocellular connective tissue with focal lymphocytic infiltration. Cysts contain an eosinophilic, lymph-like fluid rich in proteins, sometimes containing clusters of lymphocytes and monocytoid cells. At the border of the cysts, vacuoles may be seen in the proteinaceous material.

Differential Diagnosis

Apart from true lymphangioma, para-bile duct lymphatic cysts have been described (Nishino et al. 1988). Retroperitoneal multiple lymphangioma can grow toward the extrahepatic

bile ducts and cause stenosis with biliary dilatation (Adachi et al. 2001).

Multifocal Lymphangioendotheliomatosis with Thrombocytopenia

Introduction

Multifocal lymphangioendotheliomatosis with thrombocytopenia (MFLAM) is a rare form of congenital vascular anomaly involving the skin and the gastrointestinal tract. MFLAM is characterized by numerous angiomatous skin lesions, gastrointestinal tract (GIT) lesions, GIT hemorrhage, and thrombocytopenia. In the original report, the three patients presented with hundreds of congenital red-brown to violaceous skin plaques (macules and papules) as large as a few centimeters, with similar lesions throughout the gastrointestinal tract with severe GI tract bleeding. One patient had synovial involvement. All had significant refractory thrombocytopenia. Histology of the skin lesions showed thin-walled vessels in the dermis and subcutis lined by hobnailed, proliferative endothelial cells co-expressing the hyaluronan receptor LYVE-1 and CD31, most vessels displaying intraluminal papillary, hypercellular, and sometimes glomeruloid projections. The lesions were similar to benign lymphangioendothelioma (North et al. 2004). Other reports confirmed the uniqueness of this entity (Piggott et al. 2006; Yeung et al. 2006; Maronn et al. 2009; Campbell et al. 2010; Noel et al. 2012; Zegpi et al. 2012). The skin lesions progressively grow in size and number. The sometimes indurated skin papules may show central pallor and others central scar-like areas. GIT hemorrhage may be present since birth up to the first 2–3 years of age. The pathogenesis of refractory thrombocytopenia in MFLAM is not clarified, but consumptive loss of thrombocytes in the abnormal vascular channels, associated with coagulopathy, has been suggested. Thrombocytosis in MFLAM worsens with transfusions (Piggott et al. 2006; Maronn et al. 2009). A disorder similar to MFLAM was described in a later report, based on ten children (Prasad et al. 2005).

Hepatic Manifestations of MFLAM

Few reports have documented multiple lymphangioendotheliomatic lesions in the liver in the setting of generalized MFLAM (Prasad et al. 2005; Maronn et al. 2009).

Differential Diagnosis

The presentation of MFLAM in some respects resembles that of kaposiform hemangioendothelioma (K-HE), first described in 1993 as a vascular neoplasm with local aggressiveness (Zukerberg et al. 1993). K-HE mainly involves the skin and retroperitoneal space and, in contrast to MFLAM, also develops deep nodules and papules with telangiectasias. Gastrointestinal involvement has so far only been observed as an exceptional finding (Burgos et al. 2009).

Lymphangiectases of the Liver

Hepatic lymphangiectases have been identified at autopsy in an infant with congenital pulmonary lymphangiectasis. The markedly dilated lymph vessels spaces were localized to the portal tracts (Hirano et al. 2004). The latter disorder is a rare disease characterized by dilatation of the pulmonary lymphatic vessels and exists as congenital and acquired (secondary) form (Laurence 1955). The congenital form may present as a familial disorder (Scott-Emuakpor et al. 1981; OMIM 265300).

Hepatic Lymphocele

A lymphocele (chylous lymphocele) is a circumscribed and sometimes cystic accumulation of lymph following inflammation or

traumatic injury and subsequential to lymph vessel traumatism, e.g., post-surgery. Lymphocele is a rare condition in the liver and occurs at the hepatic hilum, within the liver substance proper, in a perihepatic compartment, or in a subcapsular position (Jahne et al. 1988; Bauer and McLeod 1998; Rao et al. 2000). It has been observed as a subcapsular extension of pelvic lymphocele after pelvic surgery (Bauer and Mcleod 1998).

Primary Lymphatic Dysplasia of the Liver

Primary lymphatic dysplasia (PLD) is a rare disorder which can present with lymphedema, chylothorax, and chylous ascites and is sometimes manifest in the newborn period already (Hanssler et al. 1990). Together with other causes, primary lymphangiectatic or lymphatic dysplastic disorders may therefore clinically be classified as so-called primary chylous disorders (PCDs; Noel et al. 2001).

Primary lymphangiectasia of the gastrointestinal tract does not appear to directly involve the liver, but the intestinal form has been observed to occur together with congenital liver fibrosis, eventually representing a novel syndrome (Chagnon et al. 1982; Pelletier et al. 1986).

Cellular and Tissual Origins of Hepatic Lymphatic Tumors

It is a current view that hepatic lymph vessel tumors take their origin from pre-existing lymphatic vessels and lymphatic channels of the liver. However, an origin from lymphatogenic mesenchymal stem cells giving rise to lymphatic endothelial cells has also to be considered. Small lymph vessels are present in portal tracts of the liver and show a distinct spatial relationship to blood vessels (Clain and McNulty 1968). Hepatic lymphatics can easily be visualized by means of podoplanin immunostaining (Yokomori et al. 2010). In situations with significant hepatic outflow obstruction, liver lymphatics become more prominent (Rajaram and Subramanian 1978).

The Identification of Lymph Vessel Endothelia

The identification of tumor cells as lymphatic endothelia is difficult and in some way still enigmatic, owing to a considerable overlap between blood and lymph vessel endothelial phenotypes, differences being related to quantitative aspects rather than qualitative ones, and the fact that levels of gene expression in these cell lineages are markedly influenced by physiologic and pathologic conditions (Sleeman et al. 2001). Ultrastructurally, endothelial cells of lymphatics can be identified owing to their lack of Weibel-Palade bodies (Ghadially 1988), but electron microscopy will not be available in the majority of cases analyzed. Although some of the factors expressed in lymph vessel endothelia briefly discussed below have been claimed to be "specific," we still are in a situation where a combined approach may result in reliable cell identification, but in some circumstances, the cells of interest will so far remain indistinguishable at histologic and immunohistochemical examination (also in tumors), until novel and truly specific cellular components will be identified. Molecules analyzed so far include factor VIII-related antigen, CD31, CD34, PECAM, desmoplakin, podoplanin, LYVE-1 (a homologue of the hyaluronan receptor, CD44), basement membrane proteins (laminin and type IV collagen), and certain enzymes (alkaline phosphatase and 5′ endonuclease), results obtained differing from one study to the other.

Conventional Markers

Employing immunoelectron microscopy, an expression of CD31, CD34, and type IV collagen has been demonstrated in lymphangiomas (Sauter et al. 1998), but CD34 is not always detectable using light microscopic immunohistochemistry

(Paal et al. 1998). Lymphangiomas can also express cytokeratins, including K7 and K18 (Miettinen and Fetsch 2000). In a recent study on lymphangiomas (LA) and congenital pulmonary lymphangiomatosis (CPL), which make part of a spectrum of lymphatic disorders, there was evidence that LA and CPL shared a similar immunohistochemical profile for vimentin, factor VIII-related protein/von Willebrand factor, CD31, CD34, and, to a lesser extent, CD45RO (Brown et al. 1999). However, these are features which are also expressed in other vascular tumors thus not being useful for distinguishing lymphatic from other lesions. LYVE-1, a CD44 analogue, has been proposed to be restricted to endothelia of lymph vessels (Banerji et al. 1999; Jackson et al. 2001), but has recently been shown to be expressed in endothelia of normal liver blood sinusoids in mice and humans (Mouta Carreira et al. 2001). Promising results for lymph vessel tumor identification may be expected via assessment of the expression of Prox-1, a homeobox transcription factor expressed in lymphangioblasts and lymphatic endothelium (see above; Wigle and Oliver 1999; Rodriguez-Niedenfuhr et al. 2001).

Podoplanin

A further useful marker is podoplanin, a 43- or 38-kDa membrane protein controlling the shape of glomerular podocytes (Matsui et al. 1999) and staining lymphatic but not blood vessel endothelial cells, together with VEGFR-3. Podoplanin is present in small but not in large lymphatics (Breiteneder-Geleff et al. 1999). Podoplanin has also been shown to be expressed in endothelia of benign lymphatic tumorous lesions (Breiteneder-Geleff et al. 1999). It has been shown that the beta-chemokine receptor D6 is expressed by the lymphatic endothelium in a subset of vessels of the skin, intestine, and lymphoid tissues, but not in others (Nibbs et al. 2001), suggesting a heterogeneity of the lymph vessel system in the body.

Vascular Endothelial Growth Factors and Their Receptors

Furthermore, the identification of distinct vascular growth factors may, in the future, have a larger impact on the definition of cells in tumors suspected to be of lymph vessel origin, including those developing in the liver. VEGFR-3 is expressed in lymphatic endothelial cells, but it is also expressed in a subset of fenestrated blood vessels in humans (Partanen et al. 2000). VEGFR-3 mRNA has been localized to human lymphangioma (Kaipainen et al. 1995), and both VEGFR-2 and VEGFR-3 have been detected in a mouse model of lymphangioma (Mancardi et al. 1999). In a study on 29 cases of lymphangioma, employing RNA in situ hybridization, endothelial cells of these tumors co-expressed transcripts of VEGF-C and its receptors, VEGFR-3 (Flt4) and VEGFR-2 (Flk1), whereas there was little or no expression of VEGF-C and the two receptors in endothelial cells of hemangiomas or angiosarcomas (Huang et al. 2001), suggesting that VEGF-C and its receptors may have a role in lymphatic tumor growth via autocrine or paracrine regulation. VEGF-C expression was detected in 36 % of adult cystic hygromas, while VEGFR-3 expression was found in 72 % of cavernous lymphangiomas and 71 % of cystic hygromas (Itakura et al. 2009).

Other Lymphatic Endothelial Markers

D6 is detectable in a subset of vascular tumors with a lymphatic endothelial cell lineage (Nibbs et al. 2001). Prox-1, which plays a decisive role in lymphangiogenesis, can be detected in lymphatics, but it is also expressed in non-endothelial cells such as the heart, liver, and pancreas. By the use of phage-displayed peptide libraries and phage-screening procedures, a peptide (LyP-1) was recently identified and shown to co-localize with three other markers to lymphatic vessel cells, suggesting that LyP-1 is a novel marker for this cell lineage (Laakkonen et al. 2002).

Solitary Fibrous Tumor and Tumors with a Hemangiopericytoma-Like Pattern

Solitary Fibrous Tumor/ Hemangiopericytoma of the Liver

61

Contents

Abstract

Solitary fibrous tumors form a complex spectrum of neoplasms, at least part of which were previously related to perivascular cells and thus termed hemangiopericytomas. The classical solitary fibrous tumor, occurring in the form of several variants, typically develops in the pleuropulmonary compartment, but also exists in certain visceral organs, including the liver. Rare variants are those which contain components with hemangiopericytoma-like features. In addition to these lesions, there still exist so-called true hemangiopericytomas, neoplasms that typically occur in the meninges and the sinonasal space. In the liver, primary solitary fibrous presents as well-circumscribed and expanding lesions with fibroma-like features. Histologically, the neoplasms are cellular tumors composed of spindle cells looking different from fibroblasts and myofibroblasts. These cells are arranged in a storiform pattern or form dense sheaths surrounding slit-like vascular channels. The origin of the cells is not yet elucidated. Solitary fibrous tumors show recurrent breakpoints in 12q13, associated with frequent deletions affecting STAT6, caused by somatic fusions of two genes, NAB2 and STAT6.

ICD-O codes:

Solitary fibrous tumor	8815/1
Hemangiopericytoma including lipomatous hemangiopericytoma	9150/1

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_61

Introduction

This group of tumors was previously thought to be derived from specialized cells supporting blood vessels, i.e., pericytes and glomus cells, leading to the term hemangiopericytoma. The lesion was first described in 1942 as a vascular tumor featuring Zimmermann's pericytes (Stout and Murray 1942). In 2002, the WHO tumor classification system reclassified soft tissue tumors known so far as hemangiopericytomas as a variant of solitary fibrous tumor. In particular, cellular solitary fibrous tumor is regarded as a synonym of hemangiopericytoma (Park and Araujo 2009). Solitary fibrous tumors represent a heterogeneous group of spindle cell neoplasms with a biological behavior varying between benign and low-grade malignant phenotypes. The term, solitary fibrous tumor (SFT), is now preferred to the former term, hemangiopericytoma, all the more so because the cell of origin is still disputed (Penel et al. 2012). In the WHO classification, solitary fibrous tumor is listed in the intermediate (rarely metastasizing) category, characterizing neoplasms that are often locally aggressive but may have the capability to give rise to distant metastases in some patients, the risk of such a metastatic phenotype being less than 2 % and not predictable from the histologic presentation. Solitary fibrous tumor has several subgroups, comprising fibrous, cellular, fat cell-containing, and giant cell variants. The cellular variant, showing a hypercellular component exceeding 90 % of the tumor, covers most of the "classical" hemangiopericytomas (Knösel et al. 2010). The fat cell-containing variant was previously termed lipomatous hemangiopericytoma, and the variant rich in giant cells is equivalent to giant cell angiofibroma.

Currently, a small spectrum of tumors with a hemangiopericytoma-like pattern may be considered (Table 1). However, recent molecular genetic findings suggest that the entire spectrum of lesions may be separated into two major groups, i.e., classic pleuropulmonary SFT showing the most common NAB2-STAT6 fusion variant, mainly occurring in older patients and having a more favorable course, and deep-seated hemangiopericytomas showing the second most common NAB2-STAT6 fusion variant, occurring in much younger patients, and having a more aggressive phenotype (Barthelmess et al. 2014).

Table 1 Tumors with a hemangiopericytoma-like pattern

Solitary fibrous tumor (classical pleuropulmonary SFT and several variants, in part in other visceral organs)
True hemangiopericytomas (meningeal hemangiopericytoma, deep-seated hemangiopericytomas, myopericytoma, glomangiopericytoma, and the sinonasal hemangiopericytoma group)
Tumors with occasional hemangiopericytoma-like features

Hemangiopericytoma was described in 1942 as a relatively uncommon distinctive vascular tumor thought to be derived from Zimmermann's pericapillary pericytes (Stout and Murray 1942). Pericytes, identified in 1873 already (Rouget 1873) and analyzed in detail in 1923 (Zimmermann 1923), are dendritic or arborizing cells with multilineage features, arranged along capillaries and venules. In addition to their cases, Stout and Murray cite one or possibly two cases of hemangiopericytoma in a group of vascular tumors described in 1937 (Schmidt 1937) which this author, following the suggestion of Orsos (1934), termed gemmangiomata (gemmangiomas). The features of this neoplasm were characterized in more detail in the following years (Stout 1949; 1956; McMaster et al. 1975; Enzinger and Smith 1976; Mentzel et al. 1994; Nappi et al. 1995; Spitz et al. 1998), also in context with related tumors and the question as to the true entity of hemangiopericytoma (Gengler and Guillou 2006; Park and Araujo 2009). Pericytes can differentiate along fibroblastoid, myoid, osseous, and adipocyte lineages, what is of importance for the understanding of tumors derived thereof, because some pericytomas can develop a myoid component or produce neoplastic adipocytes (lipomatous hemangiopericytomas) (fat-forming solitary fibrous tumors; Lee and Fletcher 2011). Related tumors comprise myofibromatosis and the so-called infantile hemangiopericytoma, glomangiopericytoma, myopericytoma, and perivascular myoma. As most of the hepatic primary manifestations of this tumor category were

described under the term hemangiopericytoma, this label will sometimes be used in addition to solitary fibrous tumor in the following paragraphs.

Epidemiology

Solitary fibrous tumor typically presents in adult individuals. Among 106 cases analyzed, the mean age at presentation was 45 years. The tumors were usually deep-seated lesions (Enzinger and Smith 1976). The tumors occupy clinically and biologically characteristic anatomical locations, including meningeal, cerebral, orbital, sinunasal, osseous, pulmonary, pleural, soft tissue, and visceral tumors. The tumors also occur in the pediatric age group (Fernandez-Pineda et al. 2011), including the entity of multicentric infantile hemangiopericytoma (Sulit et al. 2011). For hepatic SFT, the tumors develop more frequently in females, and the mean age at diagnosis was 55.8 years (Vennarecci et al. 2005). In an earlier study of nine patients, seven patients were female and two male, with an age range at presentation of 32–83 years (mean, 57.5 years; Moran et al. 1998). A recent review of 38 published cases listed 26 female and 12 male patients (Liu et al. 2013). In one investigation, hepatic hemangiopericytoma was associated with occupational exposure to vinyl chloride monomer (Hozo et al. 2000). Most reports concerning primary hepatic SFT described single cases or very small series of this neoplasm.

Hemangiopericytoma/Solitary Fibrous Tumor of the Liver

Clinical Features

Primary SFTs exhibit a clinical presentation that is non-characteristic in most patients, but particularly in the case of large tumors, abdominal distension, right upper quadrant or periumbilical pain, nausea, weight loss, and abnormal liver tests may occur. Hepatic SFT is a rare lesion, and metastatic disease may be difficult to exclude in a given patient owing to the peculiar biology of these neoplasms (Balouet and Destombes 1967; Bergnach 1967; Weitzner 1970; Klein et al. 1971; Wyrick and Wren 1975; Roesler et al. 1985; Thapa et al. 1986; Sano et al. 1991; Zornig et al. 1992; Maeda and Nakaba 1995; Noda et al. 1995; Flores-Stadler et al. 1997; Campion et al. 1999; Hozo et al. 2000; Kruskal and Kane 2002; Ghiur et al. 2003; Plikat et al. 2003; Caruso et al. 2009; Bokshan et al. 2012). In one series, tumor size ranged from 2 to 32 cm in diameter, and the largest weight of a published tumor was 4725 g (Vennarecci et al. 2005). The tumors can grow to such a large size that resection is not feasible, even in the absence of remote disease (Bergnach 1967). Primary hepatic SFT/hemangiopericytoma can present as a multicentric tumor with cystic cavernoma-like areas (Klein et al. 1971).

Part of the hepatic lesions have been reported to show an aggressive course (malignant hemangiopericytoma; Thapa et al. 1986; Sano et al. 1991; Yilmaz et al. 2000; Ghiur et al. 2003; Plikat et al. 2003; Chan et al. 2007; Seijas et al. 2009; Peng et al. 2011; Jakob et al. 2013). These lesions exhibit an invasive phenotype, can traverse the liver capsule, infiltrate the abdominal wall, and give rise to metastasis either in the liver

or in extrahepatic sites. Frankly malignant variants may present with abdominal hemorrhage due to tumor rupture. In one patient SFT of the liver exhibited local recurrence 6 years after resection, and histologic examination of the recurrent tumor displayed features of an aggressive form of SFT (Brochard et al. 2010). In a given case, it is difficult to judge what the biologic course will probably be, although hypercellular parts with increased nuclear atypia and elevated proliferative activity have been observed, suggesting low-grade malignant transformation (Fuksbrumer et al. 2000).

Several observations document an association between SFT/hemangiopericytomas and sometimes severe hypoglycemia, a syndrome called non-islet cell tumor hypoglycemia (NICTH), tumor-associated hypoglycemia (TAH), and the Doege-Potter syndrome (Paullada et al. 1968; Wegmann et al. 1994; Adams et al. 1999), a phenomenon also known for primary SFT/hemangiopericytoma of the liver (Weitzner 1970; Guglielmi et al. 1998; Campion et al. 1999; Kruskal and Kane 2002; Plikat et al. 2003; Bokshan et al. 2012), related to the production of insulin-like growth factor II (ILGF-II) and caused by loss of imprinting of the respective gene (Sohda and Yun 1996; Grunenberger et al. 1999), or by ILGF-II- and ILGF-binding protein 6 (Hoekman et al. 1999), by these neoplasms. Tumor-associated hypoglycemia has also been detected in a patient with hepatic fibrosarcoma (Immerman et al. 1982).

Imaging Features

Hepatic solitary fibrous tumors/hemangiopericytomas are usually solitary lesions, but multicentricity has also been reported (Klein et al. 1971). Sonographically, a complex mass with hyper-isoechoic solid components and hypoechoic cystic areas was described (Caruso et al. 2009). Speckled calcifications may be found. Administration of contrast media in CT and MR imaging reflects the high vascularization of the lesions, showing early, intense, and prolonged enhancement (Caruso et al. 2009). Scintigraphically, large cold nodules in the liver have been reported in a patient with multifocal tumor (Klein et al. 1971). In MR pictures, solid tumor masses prevail, sometimes with a large central necrosis (Plikat et al. 2003).

Macroscopic Pathology

Similar to tumors in other locations, the neoplasms form well-circumscribed and expanding lesions and usually form solid masses of gray to reddish or tan color. The tissue is firm, similar to that of fibromas. The tumors often exhibit partial or apparently complete encapsulation, sometimes with a typically shiny capsule, or formation of a pseudocapsule with perifocal liver atrophy. The cut surface is lobulated. Part of the tumors exhibit whorled and fasciculated cut surface (Korkolis et al. 2008). Hemorrhages may occur, while gross necrosis is unusual, at least in primary tumors. However, very large tumors have shown extensive geographic and sometimes infarctoid central necrosis (Moran et al. 1998). Both gross necrosis and hemorrhage have been encountered (Guglielmi et al. 1998). Some primary hepatic tumors grow to large or huge size (Kottke-Marchant et al. 1989; Guglielmi et al. 1998; Fuksbrumer et al. 2000), and masses up to 22 cm in diameter have been seen (Weitzner 1970), with a weight exceeding 4 kg (Chan et al. 2007). Central cystic cavities have been reported (Barnoud et al. 1996), and the hepatic lesions rarely present as a cyst containing a hemorrhagic fluid and mural tumor nodules of varying size (Klein et al. 1971). SFT with a multiloculated cystic appearance has also been described (Güray Durak et al. 2013). An expanding growth mode prevails, with the adjacent liver showing marked compression atrophy and signs of vascular engorgement. Secondary vascular and/or bile duct compression is sometimes found, and local invasive growth can be encountered, including invasion of intrahepatic veins (Fuksbrumer et al. 2000). Rarely, a pedunculated growth pattern has been seen (Moran

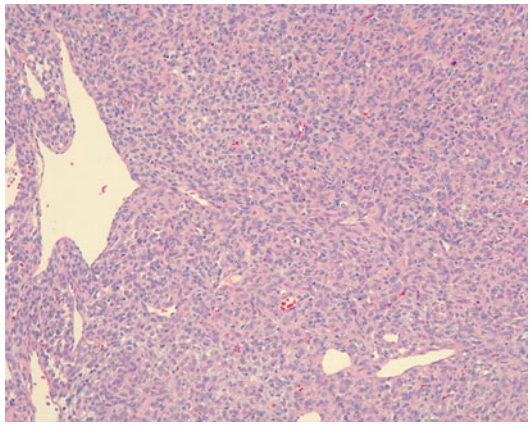

Fig. 1 Primary solitary fibrous tumor of the liver. Part of the tumor cells are associated with vascular spaces (hemangiopericytoma-like pattern; hematoxylin and eosin stain)

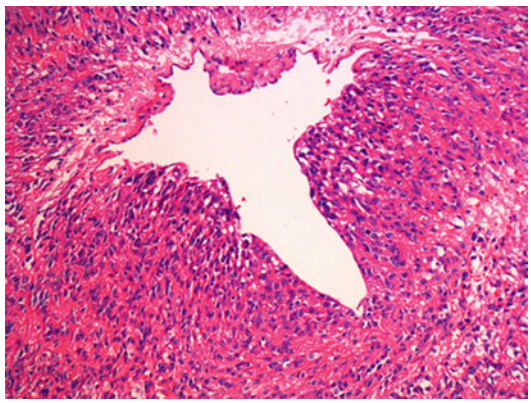

Fig. 2 Solitary fibrous tumor of the liver. The perivascular cellular cuff results in a pericytomatous pattern (hematoxylin and eosin stain)

et al. 1998; Park et al. 2011). Hepatic SFT belongs to the category of liver neoplasm causing capsular retraction (Blachar et al. 2009).

Histopathology

SFTs are often cellular tumors composed of spindle cells with a rather poorly developed and only slightly eosinophilic cytoplasm. These cells, which look different from both fibroblasts and myofibroblasts, either form a short storiform

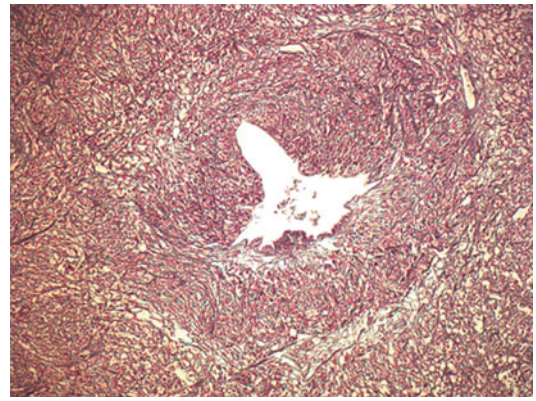

Fig. 3 Solitary fibrous tumor of the liver with a dense network of reticulin fibers (Gomori silver stain)

(so-called patternless) pattern or dense sheaths surrounding slit-like vascular channels (Figs. 1, 2, and 3). The latter pattern previously raised the suspicion that the cells might represent a pericyte or a pericyte-like cell. In most cells, the cytoplasm is not well delineated, and the nuclei are hyperchromatic and either spindled in shape or plump. Mitotic figures are usually rare, but one may find areas with 5–10 mitoses per ten high-power fields. The cellular lesions are traversed by a characteristic vascular ramifying tree showing a "staghorn" pattern. In silver stains, the tumor displays a very dense network of reticulin fibers, which encircle groups of spindle cells or even single cells, and is usually more dense in proximity of blood vessels (the pericapillary reticulin sheath; Stout 1949). In part of cases, an inflammatory response with lymphocytes and mast cells may be encountered. Focal myxoid change may occur (Korkolis et al. 2008), an alteration that can dominate SFT presentation in extrahepatic tumors (myxoid SFT; Lau et al. 2009).

Electron Microscopy

Electron microscopically, the tumor cells are closely apposed, but show poor development of cell-to-cell junctions. The organelle content of cells is highly variable and non-characteristic. Flocculent basement membrane material is

deposited linearly along the surface of many tumor cells (Flores-Stadler et al. 1997).

Immunohistochemistry

Immunohistochemically, the majority of the tumor cells are markedly reactive for vimentin, and staining for BCL-2, CD99, and alpha-1 antitrypsin is at least focally present (Patra et al. 2012; Liu et al. 2013). Endothelia of the intervening vessels and part of the spindle cells are CD34 positive (Fig. 4; Hanau and Miettinen 1995; Barnoud et al. 1996; Kwak et al. 2007; Korkolis et al. 2008; Peng et al. 2011). CD34 reactivity is considered characteristic for SFT (Brunnemann et al. 1999). Part of hepatic SFT expressed VEGF in a pattern resembling that of proliferating hemangiomas, and some of the cells were reactive for factor XIIIa, similar to the interstitial cells of cellular hemangiomas of infancy (Flores-Stadler et al. 1997). A subpopulation of factor XIIIa-positive cells was identified, similar to the "interstitial cells" of cellular hemangiomas of infancy (Flores-Stadler et al. 1997). At least part of the tumors exhibit nuclear reactivity for STAT6 (Doyle et al. 2013; Schweizer et al. 2013; Barthelmess et al. 2014), linked to NAB2-STAT6 fusion (see below). Immunoreactivity for cytokeratins, epithelial membrane antigen (EMA), desmosomal proteins, S-100 protein, smooth muscle actin, and desmin is usually lacking, although keratin positivity has been reported in one instance (Kim and Damjanov 1983).

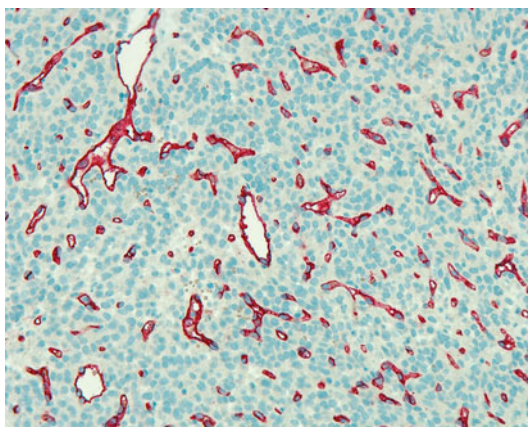

Fig. 4 Solitary fibrous tumor of the liver. The highly cellular neoplastic tissue is strongly vascularized (CD34 immunostain)

Solitary Fibrous Tumor/ Hemangiopericytoma of Hepatic Ligaments

Hemangiopericytoma/SFT rarely develops in the ligamentum teres of the liver (Majnarich and Stout 1960) and in the falciform ligament (Gidwani et al. 2004).

Differential Diagnosis

SFTs/hemangiopericytomas primary to diverse locations can extensively metastasize to the liver (van Assendelft et al. 1984; Chakravarty et al. 1991; Nakamura et al. 2005; Alberti et al. 2006; Balaji et al. 2008; Cheng et al. 2008; Zalinski et al. 2009; Balibrea et al. 2013). Among these neoplasms, meningeal hemangiopericytoma is particularly prone to metastasize to the liver (Buccauw et al. 2011). The metastases can cause paraneoplastic non-islet cell hypoglycemia due to production of IGF-II (Bell and Buist 1981; Sohda and Yun 1996; Lawson et al. 2009). Intra-abdominal SFT/hemangiopericytoma located close to the liver and/or extensively spreading may mimic hepatic localizations of this tumor, e.g., peritoneal spread (Prakash et al. 2009; Reicks and Wilkinson 2011).

Molecular Genetic Alterations

In SFT, chromosome banding and FSH showed recurrent breakpoints in 12q13, associated with frequent deletions affecting STAT6. This feature is associated with somatic fusions of the two genes, NGFI-A-binding protein 2 (NAB2) and STAT6, and nuclear expression of the C-terminal part of STAT6 (Chmielecki et al. 2013; Mohajeri et al. 2013; Robinson et al. 2013; Schweizer et al. 2013; Barthelmess et al. 2014; Koelsche

et al. 2014). In a series of 52 cases of SFT, 12 different NAB2-STAT6 fusion variants were detected in 92 % of cases. Immunohistochemically, all tumors showed strong and diffuse nuclear reactivity for STAT6 (Barthelmess et al. 2014). The NAB2-STAT6 fusion was also found in meningeal hemangiopericytomas (Schweizer et al. 2013). NAB2 is the transcriptional regulator NGFI-A-binding protein 2, a protein which functions in the nucleus to activate or repress transcription, in part through interaction with nucleosome remodeling and deacetylase complexes. NAB2 regulates and modulates the expression levels of the tumor necrosis factor (TNF) family member TNF-related apoptosis inducing ligand/TRAIL (Balzarolo et al. 2013). SFT also strongly expresses the GRIA2 gene (Vivero et al. 2014), encoding a protein of the ionotropic AMPA glutamate receptor.

Putative Cellular Origins

The cell of origin and the histogenesis of solitary fibrous tumors have not been elucidated so far, but putative mesothelial or primitive mesenchymal cells have been suggested. What is the evidence for the involvement of a mesenchymal progenitor cell? One argument is based on the finding of several lines of differentiation in solitary fibrous tumors: (1) fibrous variant, (2) cellular variant (more than 90 % cellularity), (3) adipocyte-forming variant (fat-forming SFT; lipomatous hemangiopericytoma), (4) giant cell-rich variant (giant cell angiofibroma with floret cells, including the vascular variant), (5) myxoid SFT, (6) synchronous pleuro-renal and renal solitary tumor, and (7) malignant solitary fibrous tumors. Based on electron microscopic investigations showing a mixture of mesenchymal cells and cells with features of mesothelia, a submesothelial origin of the tumor has been proposed (Kottke-Marchant et al. 1989; Barnoud et al. 1996). However, the convincing demonstration of SFTs at extrapleural sites strongly argues against its mesothelial or submesothelial origin. Parts of the cells are reactive for CD99 and CD34, and ultrastructurally the dominant cell population exhibits some degree of myofibroblastic differentiation, focal smooth muscle features, and undifferentiated cells in a perivascular location (Ide et al. 2005; Rodriguez-Gil et al. 2009). The involvement of a perivascular cell is also supported by the fact that solitary fibrous tumors may show transition to hemangiopericytomas (the hemangiopericytoma/solitary fibrous spectrum; Park and Araujo 2009). In fact, soft tissue with hemangiopericytoma-like growth patterns can now be divided into three categories, as summarized in the Table, and one of these categories is the solitary fibrous tumor group (Knösel et al. 2010). Therefore, a CD34-reactive fibroblastoid and vessel-associated progenitor cell may histogenetically be involved, but such a putative mesenchymal stem cell has not yet been identified in the normal liver. A common or characteristic cytogenetic anomaly has not been detected so far (Torabi et al. 2008; Torres-Olivera et al. 2009).

DOI 10.1007/978-3-319-26956-6_62

Abstract

Primary neoplasms of the liver originating from fibroblasts and myofibroblasts are very rare lesions. Few cases of hepatic fibroma have been reported in the literature, but part of them may have been solitary fibrous tumors. True fibromas of the liver can grow to a very large size and had weight exceeding 4 kg. The tumors consist of a fibroblastoid tissue similar to that in extrahepatic fibromas. Very few fibromas were observed in the biliary tract. Fibrosarcoma is defined as a malignant mesenchymal tumor composed of neoplastic fibroblasts. The neoplasm can occur as a primary lesion in the liver, but part of older published cases would now be classified as other sarcomas or metastatic disease. Hepatic fibrosarcoma may be associated with paraneoplastic hypoglycemia. The neoplasms are usually solitary lesions of high cellularity. Very rarely, congenital and infantile fibrosarcoma manifests in the liver. Generalized infantile hepatic myofibromatosis can involve the hepatobiliary tract. Other primary hepatic neoplasms containing fibroblastoid cells include desmoid tumors, tumors with myxoid features, and tumors derived from stellate cells.

Fibroma of the Liver

These are unusual tumors which, owing to their rarity, have so far not been analyzed in detail by use of modern methods (Fig. 1). The first case may have been described by Chiari (1877), and only few cases have since been reported (Yokota 1944; Ishak 1976; Craig et al. 1989; Craig 1994; Tameda and Shiraki 1995). In Chiari's patient, an egg-shaped tumor was detected in the right liver lobe, microscopically consisting of a hypocellular fibrous tissue. Bona fide fibromas should be distinguished from solitary fibrous tumors, which occur in the liver (see below), but make part of the group of mesothelial neoplasms. As more specific immunohistochemistry was not available in previously described cases, it is difficult to judge which examples in fact correspond to

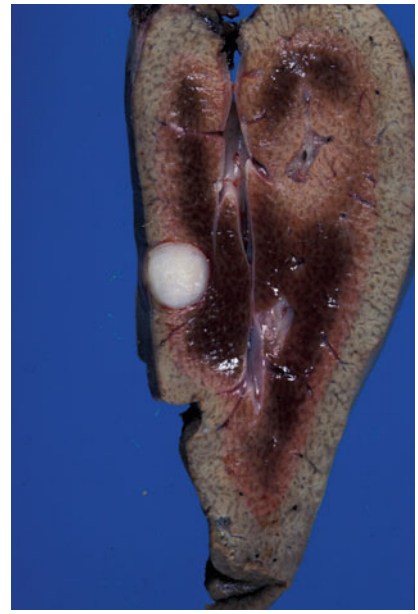

Fig. 1 Fibroma of the liver. The tumor appears as a well-delineated, white, and firm nodule in a non-cirrhotic liver

fibroma or to solitary fibrous tumor. As far as can be judged with the few examples, hepatic fibromas occur both in younger and older individuals. The cases reported in the AFIP atlas (Craig et al. 1989) are striking by their size, the maximum diameter observed being 27 cm and the weights ranging from 860 to 4,500 g. Hepatic fibromas are either expanding or pedunculated lesions and exhibit a polycyclic contour, the cut surface showing a whitish color, a nodular structure, and a fibrous texture with whorls and fibrous septa separating the nodules (Craig et al. 1989). Central necroses and cysts may occur. The histologic presentation is variable, ranging from hypocellular and bland-looking fibrous tissue to more cellular parts. The typical cell is spindle shaped and fibroblast- or myofibroblast-like, and these cells are embedded in a matrix consisting of collagen fibers. Mitotic figures may be encountered.

A unique case was reported from Japan (Yokota 1944). A 33-year-old male patient presenting with a history of upper abdominal pain showed on abdominal X ray a tree-like "stony" shadow in the gallbladder region. Under the preoperative diagnosis of gallstone disease,

laparotomy was performed. Exploration revealed a tumor mass in the right liver lobe, close to the anterior margin, adherent to gallbladder, transverse colon, and omentum. The lesion was resected and left a concave depression in the liver substance. Grossly, the tumor measured up to 6 cm in diameter and had a weight of 41 g. Strikingly, the nodular mass was as hard as a stone. Histologically, the tumor consisted of partly hyalinized bundles of connective tissue cells with associated matrix, focally with necrosis. The overall cellularity and vascularity were low. Extensive mineralization was noted, sometimes with heterotopic ossification, the bony tissue being devoid of osteoblasts. The diagnosis was fibroma ossificans (ossifying fibroma; "osteofibroma").

Fibroma of the Biliary Tract

Only few reports document primary fibroma of the biliary tract (Albers 1862; Holzinger 1901; Chu 1950; Taute et al. 1988; Shiga 1996). Fibroma may arise anywhere along the extrahepatic bile ducts, including the common bile duct (Albers 1862), the common hepatic duct (Chu 1950), and the hepatic ducts (Holzinger 1901). Pedunculated fibroma of the common hepatic duct can cause biliary obstruction (Taute et al. 1988). The lesion described by these authors measures about 6 mm and was associated with a massively dilated gallbladder. Histology showed a tumor consisting of fibroblastoid cells somewhat resembling a neurofibroma, and focal sclerohyalinosis was noted.

Fibromas of the bile ducts are mass-forming lesions that may lead to duct stenosis. In the case reported by Chu (1950), a 45-year-old male patient was examined due to progressive jaundice and clay-colored stools. The patient deceased and necropsy showed a tumor 2.5 cm proximal to the junction of the cystic and common hepatic ducts, presenting a firm ovular nodule, measuring up to 1 cm in diameter and located to the lateral wall of the common hepatic duct, causing compression of the lumen. The nodular lesion described by Holzinger (1901) was very similar to the case of Chu and also had led to massive biliary obstruction, including marked hydrops of the gallbladder. Pedicled (pedunculated) fibroma of the extrahepatic bile duct causing obstructive jaundice has been reported (Taute et al. 1988). In the latter case (female patient of 33 years of age), laparotomy showed, in the opened common hepatic duct, a cherry-sized pedunculated tumor which had obturated the lumen completely.

The morphologic features of biliary fibroma are those of fibromas located elsewhere, although relatively few descriptions are available. In the case of Chu (1950), the lesion situated in the wall of the common hepatic duct showed a circumscribed mass of closely arranged, elongated, thin, spindle-shaped cells suggesting fibroblasts/fibrocytes. They were disposed in interlacing bundles and were of regular size, shape, and staining. No mitotic figures were evident. The mucosa of the duct overlying the nodule exhibited necrosis and atrophy. Their muscular layer was not apparent, and a thin, compressed fibrous capsule surrounded the nodule. In the case of the pedunculated fibroma described by Taute et al. (1988), histology showed a lesion composed of fibroblastoid cells arranged in the form of interlacing bundles, sometimes with a wave-like pattern. The nuclei were elongated, but palisading was not noted, although the neoplasm somewhat resembled a neurogenic tumor.

Fibrosarcoma of the Liver

ICD-O Code 8810/3

Introduction

Fibrosarcoma is defined as a malignant mesenchymal tumor composed of neoplastic fibroblasts and fibrocytes, with variable amount of connective tissue fibers. Primary fibrosarcoma of the liver is, apart from malignant fibrous histiocytoma, one of the more frequent hepatic sarcomas in adult patients. In early reports, however, it is difficult to judge whether the sarcoma was in fact primary to the liver, and whether the

lesion was bona fide fibrosarcoma, because of the frequently used term, spindle cell sarcoma. A compilation of numerous cases published in 1909 listed 113 cases (Costantini 1909), but it is likely that only about 40 of these were primary hepatic sarcomas. Herxheimer analyzed these and other cases and published the results in 1930 (Herxheimer 1930). In his table, a subset of hepatic sarcomas was identified as spindle cell sarcoma, and at least part of them may represent fibrosarcomas primary to the liver (Orth 1885; Windrath 1885; Podrouzek 1888; Bramwell and Leith 1897; Cesaris-Demel 1900; Scheidemandel 1903; Marx 1904; Pater 1905; Bertelli 1908; Dominici and Merle 1909; Costantini 1909; Saltykov 1914; Dubs 1916; Goldstein 1921; Jaffe 1924). Several cases from the older literature, however difficult to classify from the respective reports, are cited by Thöhle is his, in those days, seminal book on the surgery of liver tumors (Thöhle 1913). From the second half of the twentieth century onwards, more detailed and/or reliable reports of true hepatic fibrosarcoma are available. In part of the cases, the primary localization to the liver has been confirmed at autopsy (Bodker and Boiesen 1981; Nakahama et al. 1989; Ito et al. 1990). In very few instances, primary hepatic fibrosarcoma occurred in combination with carcinoma in the liver (Dominici and Merle 1909; Saltykov 1914; Jaffe 1924). A subset of hepatic fibrosarcomas have been observed in cirrhotic livers (Dominici and Merle 1909; Jaffe 1924; Steiner 1960; Alrenga 1975).

Similar to other mesenchymal tumors, some hepatic fibrosarcomas were associated with (sometimes severe) hypoglycemia (Snapper et al. 1964; Gen et al. 1983; Kameya et al. 1985; Kotani et al. 1993). This form of tumor-associated hypoglycemia is termed syndrome of extrapancreatic tumor hypoglycemia (EPTH) or non-islet-cell tumor hypoglycemia (NICTH), and is caused by the paraneoplastic secretion of insulin-like growth factor II (Fukuda et al. 2006). In one case of hepatic fibrosarcoma with hypoglycemia, production of insulin-like growth factor II (IGF-II) was proposed to have induced hypoglycemia, based on the detection of IGF-II reactivity in the Golgi area of the neoplastic cells (Kotani et al. 1993).

Selected References Shallow and Wagner 1947; Simpson et al. 1955; Steiner 1960; Ojima et al. 1964; Snapper et al. 1964; Totzke and Hutcheson 1965; Balouet and Destombes 1967; Cavallo et al. 1968; Smith and Rele 1972; Walter et al. 1972; Chudacek 1973; Alrenga 1975; Papazian et al. 1978; Bodker and Boiesen 1981; Gen et al. 1983; Kameya et al. 1985; Bremondy et al. 1989; Nakahama et al. 1989; Ito et al. 1990; Kotani et al. 1993; Tameda and Shiraki 1995; Kelle et al. 2005; Ali et al. 2008; Zhao et al. 2008.

Pathology

Macroscopy

At gross examination, the mostly solitary tumors may grow to a size exceeding 15 cm diameter (Bramwell and Leith 1897; Dubs 1916; Jaffe 1924; Alrenga 1975; Nakahama et al. 1989). The size of the large or very large hepatic sarcomas was not always specified; sometimes only descriptions such as "enormous primary sarcoma" are found in the reports (Bramwell and Leith 1897). Saltykov (1914) reported on a 62-year-old male with liver cirrhosis, where necropsy revealed two primary liver tumors: the larger tumor, measuring 20 by 16 by 9 cm, was a hepatic spindle cell sarcoma, while the smaller tumor (3 cm) was hepatocellular carcinoma. A similar situation was reported by Jaffe (1924), who described a double synchronous liver tumor observed in a 64-year-old man who had liver cirrhosis. One tumor was located in the right lobe, measured 17 by 12 by 14 cm, and was spindle cell sarcoma; the other tumor was much smaller, was located to the left lobe, and was hepatocellular carcinoma. Dubs (1916) reported on a spindle cell sarcoma measuring 30 by 30 by 25 cm diagnosed in a 26-year-old female. Exceptionally, the tumors involve both liver lobes and

form conglomerates of firm nodules (Ali et al. 2008). The tumor appearance varies from firm and gray to white masses to myxoid lesions and those with hemorrhagic necroses, sometimes with marked central softening (Ito et al. 1990). The tumors are grossly well-delineated from the surrounding liver substance and usually form more or less spherical masses with or without satellite nodules. Lobulated morphologies are also known (sometimes termed "sarcoma phyllodes" in the older literature, in analogy to the respective breast tumor; Thöhle 1913). Macroscopic invasion of the portal vein has been noted (Alrenga 1975).

Histopathology

Histologically, the neoplasms are composed of interlacing bundles of fibroblastoid spindle cells. The nuclei are elongated, with pointed ends, and show minor pleomorphism and hyperchromasia. Mitotic figures are found, albeit usually in rather low numbers. A moderate amount of stainable collagen is seen between the neoplastic cells.

Immunohistochemistry

As in other locations, hepatic fibrosarcoma is markedly vimentin positive (Nakahama et al. 1989; Ito et al. 1990; Kelle et al. 2005). A subset of the tumor cells may be reactive for alpha-SMA. By use of podoplanin immunostaining, fibrosarcomas lack typical lymph vessels, a finding which is consistent with the infrequent occurrence of sarcoma metastasis to lymph nodes (Mahendra et al. 2008).

Differential Diagnosis

The main differential diagnosis is fibrosarcoma metastatic to the liver (Franseen and McCort 1948; Hall and Amin 1981; Yamaguchi et al. 1989; Isobe et al. 1997). Tumor-induced hypoglycemia was also detected in metastatic fibrosarcoma of the liver (Bousvaros 1960).

Sclerosing Epithelioid Fibrosarcoma

Introduction

Sclerosing epithelioid fibrosarcoma (SEF) is a variant of fibrosarcoma that had been first described in 1995 (Meis-Kindblom et al. 1995). This rare tumor is characterized by epithelioid neoplastic cells arranged in cords, sheets, strands, or nests embedded within a sclerotic collagenous matrix, whereby a picture resembling carcinoma may result.

There is some histologic overlap between SEF and low-grade fibromyxoid sarcoma/LGFMS. SEF is a low-grade sarcoma, but about 50 % of patients are estimated to develop local recurrence and/or metastases (review: Ossendorf et al. 2008). SEF involves the soft tissues of upper and lower extremities, limb girdles, head and neck area and trunk (mainly the chest), and rarely deep-seated organs and structures. Part of SEF cases have shown rearrangement of the FUS locus by FISH (Rekhi et al 2011; Wang et al. 2012). FUS rearrangements are typical for low-grade fibromyxoid sarcoma (Patel et al. 2011), further discussed in the respective chapter. MUC4, which was identified as a sensitive and specific marker for LGFMS, was also expressed in 78 % of cases of SEF, and FUS rearrangement was detected in 38 % of MUC4-positive SEF cases, showing that MUC4 reactivity is more common in SEF than FUS rearrangement. MUC4-positive SEFs with FUS rearrangement are likely closely related to LGFMS (Doyle et al. 2012).

Primary Sclerosing Epithelioid Fibrosarcoma of the Liver

SEF primary to the liver was observed in a 39-year-old male patient presenting with general fatigue and abdominal discomfort (Tomimaru

et al. 2009). CT and MRI revealed a large liver tumor measuring about 7 cm in diameter located in segment 1. Invasion of the inferior vena cava was noted, and extended left hepatectomy with resection of caudate lobe, diaphragm, right lower lung lobe, and pericardium was performed. In the resection specimen, the tumor measured up 68 mm in diameter and presented as a lobulated neoplasm that had also caused a tumor thrombus in the left portal vein. Histologically, the tumor showed round or polygonal, vimentin- and CD99-positive, cytokeratin-negative cells with a morphology typical for SEF. The cells were negative for EMA, desmin, alpha-SMA, and HMB45, and t (X;18), often found in synovial sarcoma, was not observed. The neoplastic ells were embedded in an abundant collagenous and partially hyalinized matrix (a sclerosing tumor). Peripheral part of the neoplasm showed spindle cells in a fascicular arrangement. The mitotic rate was low.

Congenital and Infantile Fibrosarcoma

Introduction

Congenital or infantile fibrosarcoma (CFS) was identified as a distinct entity by Stout in 1962 (Stout 1962). The majority of CSF affects patients younger than 5 years, and about 90 % are diagnosed in infants. The congenital variant proper is defined as a fibrosarcoma occurring within 3 months after birth (Kempson et al. 2001). CSF has a much less aggressive behavior than fibrosarcoma in adults, and it rarely metastasizes (Soule and Pritchard 1977; Coffin et al. 1994). The tumors mostly occur in several soft tissue compartments, but may rarely develop in visceral organs, e.g., the colon (Buccoliero et al. 2008).

Liver Involvement

Metastasis of a paraspinal CFS to the liver was observed in a fetus of 26 weeks of gestation (Nonaka and Sun 2004). At necropsy, the liver was congested and exhibited multiple, well-circumscribed, small, tan metastatic tumor nodules of up to 4 mm diameter, histologically showing the same fascicular pattern with herringbone appearance and marked mitotic activity as the primary tumor. At the periphery of the nodules, the tumor tissue interdigitated with liver parenchyma. The cellular variant of congenital mesoblastic nephroma, having the same chromosomal translocation as CFS, has also been found to rarely metastasize to the liver (Patel et al. 2003).

Etiology and Pathogenesis

The cell of origin of CFS is not known so far (Coffin et al. 1994). It is assumed to be a primitive mesenchymal cell which may give rise to several differentiation lineages, including vascular cells. CFS can come as a hemangiopericytomatous hypervascular tumor which, with time, may regress to hemangiomatous remnant (Miura et al. 2002). It has been shown that CFS has a characteristic cytogenetic alteration, i.e., t(12;15)(p13;q25), causing the fusion ETV6-NTRK3 (ETS variant gene 6 in band 12p13; neurotrophic tyrosine kinase receptor type 3 in band 15p15; Knezevich et al. 1998; Wai et al. 2000), detectable by PCR (Argani et al. 2000; Sheng et al. 2001) and fluorescence in situ hybridization (Adem et al. 2001) and identical to that found in the cellular variant of congenital mesoblastic nephroma (Sandberg and Bridge 2002). The same chromosomal translocation has been detected in secretory breast carcinoma (Lambros et al. 2009). A different translocation may also occur in bland-looking variants of CFS, i.e., 3-way t(12;15;19) translocations involving chromosome bands 12p13.2, 15q25.3, and 19p13.1, associated with trisomies 8, 11, and 20 (Mariño-Enriquez et al. 2008).

The ETS (E-twenty-six) family member ETV6/TEL is a phosphoprotein and transcriptional repressor active in the nucleus that can inhibit Ras-dependent cell growth and induce cellular aggregation of Ras-transformed cells. ETV6/TEL is, however, also actively exported from the nucleus. This exit from the nucleus is accomplished by posttranslational modification by sumoylation at lysin 99 in a highly conserved

ETV6 domain, a regulating mechanism assumed to play a role in cellular growth control (Wood et al. 2003). ETV6/TEL possesses several putative mitogen-activated protein (MAP) kinase phosphorylation sites; it becomes phosphorylated by p38 activated by cellular stress, but not by JNK1 (Arai et al. 2002; Hanson et al. 2008). Neurotrophins and their receptors have a central role in development, growth, and differentiation (Bernd 2008). The ETV6-NTRK3 fusion gene encodes the sterile alpha motif oligomerization domain of the ETV6 (TEL) transcription factor linked to the protein tyrosine kinase domain of the neurotrophin receptor 3. The resulting chimeric oncoprotein links to multiple signaling cascades including Ras-MAP kinase and PI3K-AKT through the insulin-like growth factor 1 receptor (IRS-I) adaptor protein and seems to act on several cell lineages (Lannon and Sorensen 2005). ETV6 is a fusion partner of more than 20 partner and is involved in leukemogenesis (Bohlander 2005).

Infantile Hepatic Myofibromatosis

Introduction

Infantile myofibromatosis (IM) is a rare mesenchymal tumor involving musculoskeletal, subcutaneous, and visceral fibrous tissues (Stout 1954; Chung and Enzinger 1981; Roggli et al. 1980; Wiswell et al. 1988; Jones et al. 2007; literature review: Ang et al. 2004; historic perspective: Matthews and Cockerell 2006; recent review of literature: Hausbrandt et al. 2010). This type of tumor was previously diagnosed as hamartomas, mesenchymal hamartomatosis, multiple vascular leiomyomas of the newborn, or hemangiopericytomas. Stout first described this entity (Stout 1954). Based on a review of 61 pathologic specimens, the term, IM, was then coined in 1981 (Chung and Enzinger 1981), as the cells involved have features of both differentiated fibroblasts and smooth muscle cells or myofibroblasts. IM represents the most common type of fibrous tumor in infancy, may be congenital or familial, and is sometimes associated with congenital anomalies (Inamadar et al. 2005). IM is more common in girls, is manifest at birth or in early infancy, and almost 90 % of the cases present by age two (Coffin and Dehner 1991), but few cases in older children have been reported (Franzese and Carron 2005). Multicentric IM may cause fetal death (Pelluard-Nehmé et al. 2007).

IM occurs in several variants, solitary myofibromatosis and congenital multicentric (multiple) myofibromatosis, the latter with or without involvement of visceral organs (Chung and Enzinger 1981; Coffin et al. 1995). Fewer than 25 % of all patients with IM have visceral involvement, including the intestine, colon, the spleen, and the lungs, but for those patients the mortality may be elevated (Wiswell et al. 1988; Jones et al. 2007; Dhall et al. 2008; Muraoka et al. 2008; Short et al. 2008). Solitary and multiple variants and apparently also generalized lesions may show the phenomenon of spontaneous regression or self-healing (self-healing IM), in that after the proliferative phase during the first months of life, spontaneous regression of the nodules occurs (Schaffzin et al. 1972; Chung and Enzinger 1981 Zeller et al. 1997; Hatzidaki et al. 2001; Martin et al. 2008), probably via apoptosis (Fukasawa et al. 1994). Although in principle non-malignant, the generalized lesion is unique in presentation by its pressure effects on different visceral organs and thus carries a high mortality rate (approaching 75 %, Wiswell et al. 1988). Furthermore, IM may involve blood vessels and be associated with generalized fibromuscular dysplasia of arteries, lesions that may add to poor outcome (Wright et al. 2004). Systemic complications usually arise during the proliferative phase of the disease. Apart from sporadic cases, hereditary IM is now well recognized (OMIM 228550). In some families, an autosomal dominant trait has been identified (Jennings et al. 1984; Ikediobi et al. 2003; Zand et al. 2004), while other families revealed autosomal recessive inheritance (Salamah et al. 1988; Narchi 2001). The gene(s) and gene product (s) involved have not been identified. IM has rarely been observed in patients with constitutional mismatch-repair deficiency (CMMR-D) syndrome (Lynch syndrome), caused by germline mutations in the mismatch-repair genes MLH1,

MSH2, MSH6, or PMS2 (Kruger et al. 2008; Wimmer and Etzler 2008).

Both vimentin-positive tumor cells and endothelial cells express connective tissue growth factor (CTGF) in IM (Kasaragod et al. 2001). The ETV6-NTRK3 gene fusion recognized in congenital fibrosarcoma has not been detectable in IM (Bourgeois et al. 2000), although there is histologic overlap between the two lesion types (Alaggio et al. 2008). In contrast to deep fibromatoses, nuclear beta-catenin expression has not been observed in IM (Bhattacharya et al. 2005; Thway et al. 2008).

Hepatobiliary Involvement

Involvement of the liver occurs almost exclusively in the generalized variant of IM and has been documented several times, sometimes with multiple liver lesions (Coffin et al. 1995; Leaute-Labreze et al. 2001; Day et al. 2002; Spadola et al. 2002; Gandhi et al. 2003). In an autopsy case of an infant with congenital generalized IM, nodules around the common bile duct were observed in addition to hepatic nodules (Coffin et al. 1995). Solitary hepatic IM has been described only twice (Hastier et al. 1998). The first case reported involved an 11-year-old girl with obstructive jaundice and dilated intrahepatic bile ducts. Exploratory laparotomy revealed the presence of a fibrous mass histologically compatible with IM behind the hilum, extending into the right and left liver lobes (Bosc et al. 1987). In a second case, a solitary hepatic myofibromatosis was diagnosed in a 16-year-old girl presenting with cholestatic jaundice. The tumor was localized at the hilum and measured 3–4 cm in diameter. The potential local invasiveness of the neoplasm was evidenced by the destruction of the bile ducts (Hastier et al. 1998). In a neonate with congenital generalized IM with marked visceral involvement (albeit not in the liver), the process was associated with neonatal hemochromatosis (Aksoy et al. 2000). Solitary IM (termed infantile myofibroma by the authors) was detected as a large mass contiguous with the liver in a female infant of 37-week gestational age (Schurr and Moulsdale 2008).

Pathology

Macroscopy

The hepatic manifestations either occur in the form of multiple small nodules reminiscent of metastatic disease, or present as rather large and circumscribed nodes with a pushing border and a low-density mass in CT (Sty et al. 1996). Macroscopically, IM lesions are described as spherical, non-mobile, firm, rubbery, flesh to purple-colored nodules. In a fetus with multicentric IM, manifestations have been found at the hepatic portal (Pelluard-Nehmé et al. 2007).

Histopathology

Histology is characterized by whorled nodules of eosinophilic, biphasic, and plump spindle cells embedded in a more or less collagenous ECM. The lesion generally has a zonal architectural pattern with more immature-looking cells in the center of the lesions and spindle cells with a more myoid appearance at the periphery of the nodules, but a monophasic cellular variant has also been recognized (Zelger et al. 1995). In regard to cells involved, there is a broad spectrum of morphologies ranging from immature-looking spindle cells via myofibroblast-like cells to a hemangiopericytoma-like vascular pattern, suggesting that IM and so-called infantile hemangiopericytomas represent different stages of maturation of the same entity (Mentzel et al. 1994). The complex pattern of the lesions is already in evidence at low magnification, with areas showing the characteristic staghorn pattern of vascular channels typical for the hemangiopericytoma-like component, and other areas exhibiting fascicles of elongated spindle cells, with an overall moderate to high cellularity.

Focal necrosis is commonly seen. Immunohistochemically, reactivity for alpha-SMA chiefly involves the spindled myofibroblasts, while the cells situated between the dilated vascular channels in the hemangiopericytoma-like parts are usually not SMA-positive, rendering the origin of this cell type difficult. However, the vascular channels in these parts show a thin rim of SMA-positive cells between the endothelium and the perivascular neoplastic cells. There is no reactivity for desmin, but this stain may help to identify invasion of adjacent muscular tissue structures. In the CD34 immunostain, the neoplastic cells are negative, but the dense vascular network is visualized. Interestingly the vascular lining of the pericytoma-like areas stains much less for CD34 than the vessels in the myofibroblastic parts. In the Ki-67 stain, the marked proliferative activity is obvious. In regressing lesions, fatty change of spindle cells has been found (Iijima et al. 1999). Further characteristic features comprise necrosis and mineralizations/calcifications, chiefly in central parts of the lesions. A typical cellular component is a myofibroblast-like cell reactive for vimentin and alpha-SMA, but negative for desmin (Fisher 1996). In one report, congenital generalized IM (not involving the liver) was associated with neonatal hemochromatosis (Aksoy et al. 2000).

Hepatic Desmoid Tumor

Intrahepatic Desmoid Tumor in Association with Familial Adenomatous Polyposis

Desmoid tumors (desmoids; aggressive fibromatosis) are fibrous proliferations that occur sporadically or in association with familial adenomatous polyposis (FAP) and Gardner syndrome (see below; Kotiligam et al. 2008). Patients with FAP have a thousand-fold risk of developing a desmoid tumor, usually in an intra-abdominal location (Gurbuz et al. 1994). Desmoids may behave aggressively, but do not metastasize. One case of hepatic manifestation has been described in a patient with familial adenomatous polyposis (Middleton et al. 2000): a 14-year-old female patient with a strong family history of desmoid disease in the context of FAP. During abdominal surgery, she was found to have at least four intra-abdominal desmoids, one of which was contained entirely in the substance of the liver. The tumor in the liver presented, in CT, as a roundish well-delineated mass of more than 10 cm size, and a core biopsy confirmed desmoid tumor (Middleton et al. 2000).

"Angiofibroma" of the Liver

Very few cases of so-called angiofibroma have been observed in the liver (Gmunder and Schmid 1972) or hepatic ligaments (Spay et al. 1973). In one of these mesenchymal lesions interpreted to be an angiofibroma, hypoglycemia was noted (Gmunder and Schmid 1972). It is likely that these rare lesions would be classified in a different manner today. Part of the tumors may have been solitary fibrous tumors. The lesion should not be confounded with cellular angiofibroma (angiomyofibroblastoma-like tumor), a neoplasm originally described to almost exclusively occur in the vulva, perineum, and pelvis of women (review: Iwasa and Fletcher 2004; Koo et al. 2009; Tardio 2009).

Myxoid Mesenchymal Tumors of the Liver (Myxoma, Myxosarcoma, Myxofibrosarcoma, Fibromyxoid Sarcoma, and Other Myxoid Mesenchymal Neoplasms)

Myxoma and Myxosarcoma

Myxomas and myxosarcomas (the latter probably an obsolete term) are not single entities, but rather form a heterogeneous group of complex lesions that, at least in part, await precise definitions. Myxoid neoplasms or lesions are classified as

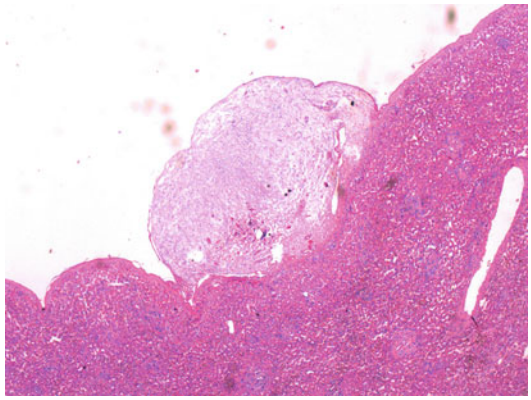

Fig. 2 Capsular myxofibroma of the liver (hematoxylin and eosin stain)

myxomas of soft tissues, myxomas located outside soft tissues, inadequately substantiated myxomas, myxoid soft tissue tumors not regarded as true myxomas, myxoid fatty conditions, other soft tissue lesions and neoplasms that are markedly myxoid, other soft tissue tumors having myxoid components, and non-neoplastic myxoid mesenchymal lesions (review: Allen 2000). Distinct and more common types of soft tissue myxomas consist of intramuscular myxoma, juxta-articular myxoma, superficial angiomyxoma (cutaneous myxoma), aggressive (deep) angiomyxoma, and myxoid neurothekeoma/myxoma of nerve sheaths. The WHO classification includes distinct categories of malignant soft tissue tumors with a myxoid component, such as myxoinflammatory fibroblastic sarcoma (ICD-O 8811/3), myxofibrosarcoma (ICD-O 8811/3), low-grade fibromyxoid sarcoma (ICD-O 8811/3), and malignant ossifying fibromyxoid tumor (ICD-O 8842/3). Well-recognized visceral myxomas include sino-orbital myxoma, renal myxoma, and myxoma of the small intestine. Few fibroblastoid neoplastic lesions occurring in the liver contain a marked myxoid component (Fig. 2).

Apparently, "true" myxoma has not been observed in the liver or biliary tract. Very few cases of so-called myxosarcoma primary to the liver have been reported. One case has been observed in childhood (Sarra and Bertolini 1968).

Involvement of the Liver in Cardiac Myxoma

Cardiac myxoma is the most common primary cardiac tumor, constituting about 50 % of all benign heart tumors in adults. Three-fourths of these lesions are located to the left atrium. Although benign lesions, cardiac myxomas can cause sudden death owing to coronary or systemic tumor embolism or to obstruction of blood flow at the mitral or tricuspid valve. Right atria myxoma can cause chronic congestion associated with dysfunction of the liver (Kluge et al. 1971), or hepatomegaly, jaundice and liver failure (Campisi et al. 1981). Myxoma of the right atrium can block the atrioventricular ostium or prolapse into the inferior vena cava, eventually followed by Budd-Chiari syndrome (Cujec et al. 1987; Anagnostopoulos et al. 2004). Right atrial myxoma can also induce portal and splenic vein thrombosis (Onan et al. 2011). Giant right atrial myxoma may radiologically mimic hepatic cirrhosis (Tok et al. 2007). Left atrial myxoma can embolize to the arterial tree, cerebral emboli being a severe and sometimes lethal complication. Embolization of myxoma was also found in the hepatic artery tree (Matsuoka et al. 1992). Embolization to the liver might cause metastatic disease. In one patient, two highly echogenic liver masses were detected 2 years after cardiac myxoma resection, suggestive of hepatic metastasis (Silaruks et al. 1999).

Differential Diagnosis

The differential diagnosis comprises few other hepatic mesenchymal tumors that have a myxoid tissue component, including primary hepatic myxoid leiomyosarcoma (Tsiatis et al. 2008), primary myxoid leiomyoma (Choi et al. 2014), and primary myxoid liposarcoma (Binesh et al. 2012). Right atrial metastasis of hepatocellular carcinoma can mimic atrial myxoma (Chua et al. 1986; Anwar et al. 2010).

Tumors with a Hepatic Stellate Cell Lineage (Spongiotic Pericytoma and Other Putative Hepatic Perisinusoidal Stellate Cell Tumors)

Introduction

Hepatic stellate cells (HSC; Ito cells) form an important perisinusoidal cell system in the liver. Activated HSCs differentiate into smooth muscle actin-positive myofibroblasts and play a central role in hepatic remodeling and fibrogenesis. The cell of origin of HSCs is not yet known. Although hepatic stellate cells (HSCs) have originally been described within the pericyte concept (Zimmermann 1923), their lineage appears to be more complex, with a purported derivation from the neural crest. It has also been suggested that HSCs are derived from mesothelial cells via mesothelial-mesenchymal transition in liver injury (Li et al. 2013). Notwithstanding the fact, that the liver contains a significant fraction of HSC, these cells do not seem to give rise to neoplastic lesions frequently.

Pure Hepatic Stellate Cell Tumors of the Liver (Spongiotic Pericytoma)

An interesting hepatic tumor apparently derived from hepatic stellate (perisinusoidal) cells and termed spongiotic pericytoma has been observed in the liver of N-nitrosomorpholine-treated rats (Stroebel et al. 1995). Ten years later, a similar lesion has been reported in a human. A 35-year-old woman showed a polycyclic liver tumor containing multiple nodular cell aggregates. The tumor cells were fusiform, with extensive cytoplasmic processes, a prominent Golgi apparatus, and fat droplets. Immunohistochemically, the cells were reactive for vimentin, CD34, CD105, CD99, CD56, and smooth muscle actin. This phenotype was interpreted as a neoplasm of hepatic stellate cells, i.e., a spongiotic pericytoma (Kaiserling and Müller 2005).

Hepatic Tumors Thought to Contain Hepatic Stellate Cells (HSCs) or HSC-Like Cells

Based on the expression of CD56, alpha-SMA and adipophilin in neoplastic cells of an undifferentiated embryonal sarcoma (UES) of the liver, it was suggested that UES may perhaps derive from HSCs or differentiating HSCs (Tanaka et al. 2012). HSCs or HSC-like cells have also been detected in cases of mesenchymal hamartoma of the liver (von Schweinitz et al. 1999). In one tumor, there were spindle cells positive for vimentin, alpha-smooth muscle actin, tenascin, alpha-crystallin, and desmin, a phenotype suggesting activated HSC (Shintaku and Watanabe 2010).

Abstract

Leiomyoma, composed of smooth muscle cells, is a rare primary tumor of the liver. Part of these lesions develop in immunosuppressed patients, in particular HIV-infected individuals and following organ transplantation, and there is an association with Epstein-Barr virus infection. Hepatic leiomyomas are solitary or multiple lesions that can grow to large size with cystic change. Leiomyoma can develop in the biliary tract and large veins of the liver. The malignant counterpart, leiomyosarcoma, is a very uncommon primary hepatic malignancy. These are usually solitary nodular masses, sometimes exceeding 20 cm in diameter, with a tendency for necrosis and hemorrhage. In contrast to high-grade sarcomas, the mitotic activity may be low, but undergoes significant increase as a function tumor progression and intrahepatic metastasis. One variant of hepatic leiomyosarcoma is characterized by a myxoid component.

Hepatic Leiomyoma

Introduction and Epidemiology

Leiomyoma is a benign neoplasm derived from and composed of smooth muscle cells. Primary leiomyoma of the liver is rare, with only relatively few cases having been reported in immunocompetent hosts.

Selected References Demel 1926; Rios-Dalenz 1965; Ishak 1976; Hawkins et al. 1980; Stark 1988; Rummeny et al. 1989; Hollands et al. 1989; Herzberg et al. 1990; Iwatsuki et al. 1990; Bartoli et al. 1991; Reinertson et al. 1992; Shiraki and Tameda 1995; Yoon et al. 1998; Mesenas et al. 2000; Belli et al. 2001; Kanazawa et al. 2002; Beuzen et al. 2004; Clarke et al. 2004; Imasato et al. 2005; Urizono et al. 2006; Kalil et al. 2009.

A more significant fraction of hepatic smooth muscle tumors (both benign and malignant) has recently been encountered in immunosuppressed

patients, in particular HIV-infected individuals (Wachsberg et al. 1994; Prévot et al. 1994; McClain et al. 1995; Wang et al. 2000), and following organ transplantation (Doyle et al. 1991; Ha et al. 1993; Le Bail et al. 1996; Brichard et al. 2001; Sclabas et al. 2002) HIV-infected immunocompromised hosts include both children (Ross et al. 1992; Mueller et al. 1992; Levin et al. 1994) and adults (Prévot et al. 1994; Wachsberg et al. 1994; Wang et al. 2000), although generally children seem to be more frequently involved (Prévot et al. 1994).

Of specific biologic interest is the now well-documented association between hepatic leiomyomatous tumors and Epstein-Barr virus (EBV) infection in immunosuppressed subjects. Prevot and coworkers reported the first case of EBV in hepatic smooth muscle neoplastic cells in an HIV-infected adult patient in 1994 (Prévot et al. 1994). Views concerning the possible causal relationship between immunosuppression, EBV infection, and the emergence of smooth muscle cell growths in several organs, including the liver, are briefly discussed below.

Clinical and Imaging Features

Clinically, some of the patients do not show symptoms, and the lesions are detected by imaging performed for other purposes, whereas other patients disclose upper abdominal pain or a palpable mass. Most cases reported so far were solitary tumors, sometimes more than 10 cm in diameter, large lesions resulting in compression of adjacent tissues or organs. In ultrasonography, hepatic leiomyoma presents as a low echoic mass with a clearly defined boundary, and contrast-enhanced CT is characterized by a hypovascular, sharply delineated nodule with peripheral enhancement during the equilibrium phase (Mueller et al. 1992; Wachsberg et al. 1994; Mesenas et al. 2000; Kanazawa et al. 2002; Sclabas et al. 2002). On MR imaging, the lesion has been shown to be hypointense by T1-weighted imaging and isointense with central hyperintensity by T2-weighted imaging (Sclabas et al. 2002; Kanazawa et al. 2002).

Macroscopic Pathology

At gross examination, hepatic leiomyomas are usually solitary lesions, but multiplicity has also been described (Wachsberg et al. 1994; Sclabas et al. 2002). Some solitary lesions may grow to very large size (giant leiomyoma of the liver; in one case with a diameter of 30 cm, Belli et al. 2001). The tumors exhibit an expanding growth pattern, with formation of a liver compression/atrophy zone at their periphery resulting in a sharply demarcated and roughly spherical lesion. On the cut surface, the usually firm neoplasms exhibit a whitish to gray color and may show a fibrous texture, similar to uterine leiomyomas (Fig. 1). Large tumors can develop cystic changes (Yoon et al. 1998; Sclabas et al. 2002), but gross necrosis or hemorrhage is usually lacking.

Histopathology

Histologically, the pattern is similar to leiomyomas occurring in other locations, although the cellularity may vary considerably. The key cell is a spindled leiomyocyte with elongated nuclei and a slightly eosinophilic cytoplasm (Fig. 2). The neoplastic cells are arranged in the form of fascicles, sometimes with a crisscross pattern. In most cases, nuclear atypia is slight,

Fig. 1 Primary leiomyoma of the liver. Note the fasciculated structure of the lesion, similar to uterine leiomyoma. There is peritumoral atrophy of the liver, caused by expanding growth of the tumor

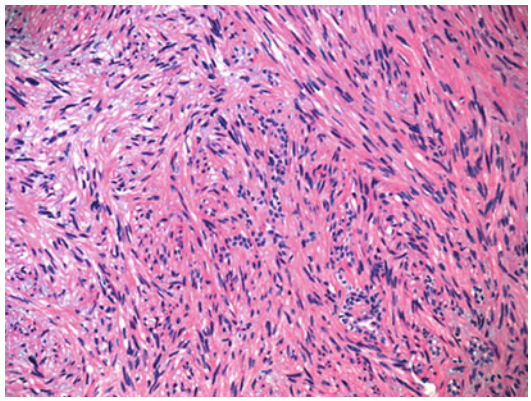

Fig. 2 Primary leiomyoma of the liver. Eosinophilic neoplastic smooth muscle cells with characteristic nuclei-form interlacing bundles (hematoxylin and eosin stain)

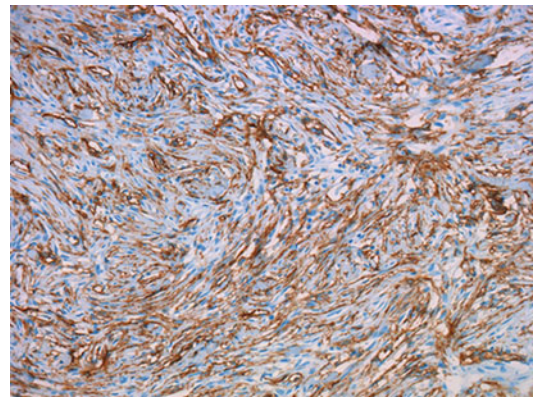

Fig. 3 Leiomyoma of the liver with strong reactivity of tumor cells for smooth muscle actin (alpha-SMA immunostain)

and only few mitotic figures are discernible (less than 1 per 20 HPFs). Some visceral leiomyomas, including those of the liver, occurring in immunosuppressed individuals may show a rather high cellularity and/or nuclear atypia, resulting in terms such as "cellular leiomyoma" or "atypical leiomyoma." In fact, it may sometimes be difficult to decide, by use of histology alone, whether the tumor in question is bona fide benign or malignant. In case of doubt, the neutral term, smooth muscle tumor of unknown dignity, may be preferable. In between the cells, a rich network of reticulin fibers is found, whereas a band of collagen fibers may be seen at the periphery of the lesion, indicating expansive growth, however without formation of a fibrous capsule. At the tumor-liver interface, a narrow zone of fibrovascular tissue is observed, containing an increased density of vessels running from the periphery to inner parts, probably illustrating the vascular pattern suggesting tumor angiogenesis seen at imaging (Kanazawa et al. 2002; see above). Immunohistochemically, there is marked reactivity for alpha-SMA (Fig. 3) and less for vimentin, whereas desmin is slightly expressed or lacking. In typical leiomyoma, there is no reactivity for CD34, S-100 protein, and HMB 45. In the tumors reported by us, the proliferative activity as based on Ki-67 immunostaining was low, i.e., less than 5 % (Sclabas et al. 2002).

Myxoid Leiomyoma of the Liver

In a minority of primary hepatic leiomyomas, neoplastic myocytes are embedded in a myxoid matrix. Such neoplasms are termed myxoid leiomyoma of the liver (Yoon et al. 1998; Choi et al. 2014). The neoplasms are uniformly hypocellular and consist of scattered, spindled smooth muscle cells with blunt-ended, cigar-shaped nuclei. The background tissue appears edematous, but is characterized by myxoid features with abundant intercellular substance.

Hepatic Leiomyoma and Epstein-Barr Virus Infection

An interesting feature of hepatic leiomyomas is their association with Epstein-Barr virus (EBV) infection. In EBV infection ensuing in immunocompromised hosts and transplanted patients in particular (Collins et al. 2001), benign and malignant smooth muscle tumors have now been detected, apart from the liver, in several organs (EBV-associated smooth muscle tumors, EBV-SMT; reviews: Deyrup 2008; Moore Dalal et al. 2008). The phenomenon of an association between EBV infection and the emergence of smooth muscle tumors (EBV-SMT) has now been documented also for the liver several times.

The tumors have in part be designated as leiomyoma (Prévot et al. 1994; Lee et al. 1995; Le Bail et al. 1996; Davidoff et al. 1996; Wang et al. 2000; Cheuk et al. 2002; Sclabas et al. 2002), whereas other studies employed the term leiomyosarcoma (McClain et al. 1995; Rogatsch et al. 2000; Brichard et al. 2001; Monforte-Munoz et al. 2003; Nur et al. 2007). Based on the distinctive clinicopathologic and biologic features, it is now proposed to term these lesions, EBV-associated smooth muscle tumors, also for those arising in the liver (Le Bail et al. 1996; Sadahira et al. 1996; Cheuk et al. 2002; Salamanca and Massa 2009). In several reports, more than one or even multiple synchronous hepatic lesions were detected (Lee et al. 1995; Sadahira et al. 1996; Rogatsch et al. 2000; Brichard et al. 2001; Sclabas et al. 2002; Gallien et al. 2008), and also EBV-associated multifocal leiomyosarcoma can present with multiple liver nodules (Nur et al. 2007). Morphologically, there seems to be a difference between EBV-associated hepatic smooth muscle tumors and those which do not exhibit such an association. EBV-SMT are typically well-differentiated smooth muscle tumors with little atypia and usually a low level of mitotic activity. They are consistently alpha-SMA positive, but less often positive for desmin. The tumors may contain primitive round cell areas and prominent intratumoral T lymphocyte infiltrations (Deyrup et al. 2006).

What is striking is the marked expression of EBV early antigen (EBER) in the nuclei of numerous tumor cells, already documented in the first reports by use of in situ hybridization/ISH (leiomyoma:Prévot et al. 1994; leiomyosarcoma: McClain et al. 1995). Nuclear EBER-ISH signals have subsequently been described in these hepatic lesions (Sadahira et al. 1996; Le Bail et al. 1996; Cheuk et al. 2002; Sclabas et al. 2002), and also viral DNA was demonstrated in the tumors by use of Southern blot analysis (Le Bail et al. 1996). We have seen two hepatic leiomyomas in a renal transplant recipient where EBV-LMP was not detectable, similar to a previous study (Lee et al. 1995), whereas there were marked ISH signals for EBV early antigen (EBER) (Sclabas et al. 2002). In patients with AIDS developing EBV-associated leiomyosarcomas (including hepatic tumors), the human EBV receptor (CD21) was expressed on tumor cells, more so on cells from HIV-infected individuals than on cells from HIV-negative individuals, suggesting that immunodeficiency may result in upregulation of CD21, which may be a prerequisite for EBV infection of smooth muscle cells (McClain et al. 1995). In the same study, quantitative PCR demonstrated high levels of EBV in tumor tissues, with as many as 4.3 genome copies per cell (McClain et al. 1995). In the three patients described by Lee and coworkers (1995), one of which had a hepatic lesion; molecular genetic analysis showed the EBV genome to be clonal in all three. Thus, hepatic EBV-associated smooth muscle tumors exhibit, with respect to EBV expression, molecular biologic features similar to the tumors that have been detected elsewhere, and the results obtained so far suggest that EBV can infect smooth muscle cells and may contribute to the pathogenic pathway of leiomyomas and leiomyosarcomas in immunocompromised hosts.

Leiomyoma of Bile Ducts

Introduction

Biliary leiomyomas mostly occur in the extrahepatic bile ducts, including the junction/bifurcation area (Mandeville and Stawski 1991), the common bile duct (Archambault and Archambault 1952; Kune and Polgar 1976; Lagun et al. 1993; Saito 1996), the distal common bile duct (Yamaoka et al. 1993; Goo et al. 2006; Kalaitzakis and Sturgess 2011), and, somewhat more commonly, the ampullo-papillary region (Nemsmann und Schroder 1984; Octavio de Toledo et al. 1991; Tseng et al. 2003).

Clinical Features

Lesions in the common bile duct almost always cause obstruction with intermittent jaundice,

prestenotic duct dilatation, and obstruction-induced secondary sclerosing cholangitis (Archambault and Archambault 1952; Kune and Polgar 1976; Lagun et al. 1993; Yamaoka et al. 1993; Goo et al. 2006). Biliary obstruction is also documented for leiomyomas located to the ampullo-papillary compartment (Tseng et al. 2003).

Pathology

Leiomyomas of the most proximal parts of the extrahepatic bile ducts, and particularly of the bifurcation area, may grossly and clinically mimic Klatskin tumor (Mandeville and Stawski 1991). In a case with pancreatoduodenectomy, the resected specimen showed a small hard tumor about 4 mm in diameter projecting into the lumen from the wall of the intrapancreatic portion of the common bile duct (Yamaoka et al. 1993).

Histology showed the features known for leiomyomas situated elsewhere (Yamaoka et al. 1993). The nodules are composed of interlacing bundles of bland looking, slightly eosinophilic spindle cells with elongated nuclei lacking atypia (Fig. 4). Mitotic figures are absent. The tumor cells are markedly reactive for vimentin and alpha-smooth muscle actin.

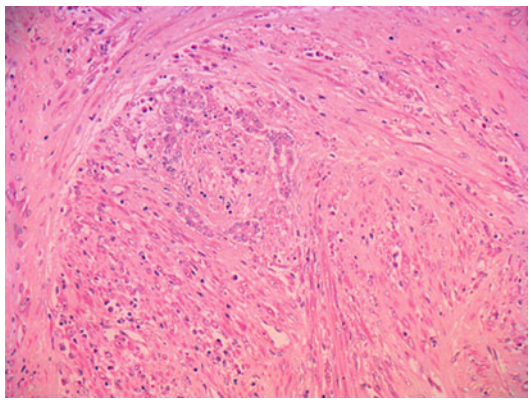

Fig. 4 Leiomyoma developing in a bile duct (hematoxylin and eosin stain)

Angioleiomyoma of the Bile Duct

Angioleiomyoma of the common bile duct has been observed in an 80-year-old woman presenting with obstructive jaundice (Ponka et al. 1983).

Pathogenic Pathways

It is assumed that the rare bile duct leiomyomas take their origin from preexisting smooth muscle cells located in the duct wall. The equipment of extrahepatic bile ducts with myocytes has been analyzed in detail since the first comprehensive study of bile duct anatomy by Kiernan (1833). It has been reported several times that the subepithelial connective tissue layer of the common duct may contain scant smooth muscle cells (Jordan 1952; Gray 1959; Bloom and Fawcett 1962; Arey 1963; Hess 1965); however, the different texts reveal some paucity of accurate information on the presence or absence of muscle cells in the different segments of the ducts. Conversely, few systematic studies provided more detailed informations, albeit with controversial results what may in part be related to methodological constraints and limitations. In a study of 24 normal common bile ducts, the authors reported complete absence of muscle cells, based on the dynamics of bile flow (Myers et al. 1962). In contrast, other reports documented the histologically proven presence of myocytes in the wall of the common bile duct (Hendrickson 1898; Burden 1925; Daniels et al. 1961; Burnett et al. 1964; Ludwick 1966; Watts and Dunphy 1966; Karski 1974a). It was observed that myocytes of the duodenal muscularis are in connection with myocyte bundles of the terminal segment of the common bile duct (Karski 1974b). In a systematic analysis of 100 common bile ducts obtained at necropsy of individuals with a normal hepatobiliary system, covering an age range of 13 years to 94 years, 88 % had no smooth muscle fibers whatsoever in the duct wall when studied in H&E, van Gieson's, and Masson trichrome stains, while 12 % of the

specimens had smooth muscle clearly demonstrated in the wall of the duct (Mahour et al. 1967). The quantity of smooth muscle cells varied among specimens, but, except for one specimen, such cells were always seen in sections from both the distal and the proximal segments. The myocytes were scattered in the fibroelastic tissue of the wall, in both circular and longitudinal directions, but in no instance did they form layers or muscular sheaths around the duct. There was no relationship between the age of the subject and the presence or absence of smooth muscle in the ducts. In another necropsy study (20 subjects), well-defined layers of smooth muscle did not exist in the common bile duct, but there were clusters of myocytes. In the upper third of the duct, there were only sparse longitudinally oriented cells, while in the midportion of the duct, the myocytes became more prominent, the cells then becoming a longitudinal layer toward the sphincter of Oddi (Ludwick 1966). A longitudinal orientation of myocytes was found to vary in man according to age, a more irregular arrangement of the cells being prevalent at higher age (Kialian and Aznaurian 1995).

The presence of intramural smooth myocytes in the supraduodenal portion of the common bile duct has been confirmed by use of immunohistochemistry (anti-actin), and the immunoreactive cells were predominantly oriented in a longitudinal direction (Walsh and Akoglu 1979). In a systematic study of 101 consecutive Whipple-type pancreatoduodenectomies and 21 autopsy specimens, extrahepatic bile ducts were analyzed immunohistochemically (desmin stain) in regard to the presence of smooth muscle cells. The pattern of smooth muscle distribution was categorized as continuous, interrupted, scattered, or lacking. The predominant patterns of the lower third of the common bile duct were interrupted (49 %) and continuous (43 %), those of the middle third were scattered (63 %) and interrupted (23 %), and those of the upper third have no muscle cells (58 %) and were scattered (39 %), suggesting a typical gradient of duct musculature both with respect to cell density and distribution. Because scattered muscle fibers or no muscle fibers were the main features of the upper third of the duct, understanding of this pattern may also be helpful for the assessment of the depth of invasion of bile duct cancer (Hong et al. 2000).

Other Hepatic Tumors with a Smooth Muscle Cell Lineage

Apart from leiomyomas evolving in the hepatic substance, this tumor can also develop in large liver veins, including the portal vein and the hepatic vein. Portal vein leiomyoma is exceedingly rare, one report documenting an increased proliferative activity of the tumor suggesting "semimalignancy" (Kremer et al. 1976). In one instance, an atypical leiomyoma of the hepatic vein occurring in a 14-year-old boy extended in the inferior vena cava and the right atrium and induced Budd-Chiari syndrome, suggesting the sometimes complex growth pattern of vascular leiomyomas (Dunlap and Udjus 1990; Lee et al. 1990). A similar situation of hepatic venous outflow tract obstruction has been observed in primary smooth muscle tumor of the inferior caval vein (Lintner et al. 1978).

A smooth muscle cell lineage is rarely involved in vascular tumors of the liver (see above), and one such lesions has been termed hepatic angiomyoma (Beissert et al. 2002). In an autopsy case, multiple hepatic benign smooth muscle cell tumors had been observed together with lesions representing cavernous hemangioma, and these composite tumors have been termed leiomyomatous hemangiomas of the liver (Key and Rao 1986). It may be surmised that a vascular progenitor cell of leiomyocytes may be involved in such an unusual situation. Hepatic angiomyolipomas, which are described in the respective chapter on perivascular cell tumors, may predominantly be composed of smooth muscle cells, which can then result in a difficult differential diagnosis (Nonomura et al. 1998).

Interestingly, neoplastic smooth muscle components may arise in hepatic tumors with a

non-mesenchymal cell lineage, including hepatoblastomas (see the respective chapter) and other epithelial neoplasms. Of particular theoretical interest is the observation of a primary smooth muscle tumor of the liver encasing a hepatobiliary cystadenoma without mesenchymal stroma (Yanase et al. 1999). In this tumor detected in a 59-year-old female, a solid and hypervascular mass consisting of neoplastic smooth muscle cells may have developed from cells involved in the mesenchymal component of hepatobiliary cystadenoma.

Leiomyomas of Large Liver-Associated Veins

The literature documents few cases of vascular tumors interpreted as leiomyomas. Most of these lesions were described in a time when modern diagnostic methods and criteria for smooth muscle cell tumor malignancy were not yet elaborated. Therefore, it is difficult to judge whether all of these neoplasm were bona fide leiomyomas of rather low-grade malignancy leiomyosarcomas. The majority of tumors interpreted as primary venous leiomyomas originated from the inferior vena cava (Abdullaeva 1951; Macek 1960; Hachisuka et al. 1963; Hoffmann 1963; Salaquarda 1964; Mandelbaum et al. 1974). Rarely, leiomyoma of the inferior vena cava was of the symplastic type (symplastic leiomyoma; Kahveci et al. 2012). Symplastic or atypical leiomyoma is characterized by moderate to severe cellular atypia in the absence of necrosis and a mitotic count of less than ten mitotic figures per ten HPFs. There is a single report on a leiomyoma of the portal vein (Kremer et al. 1976). The authors described a 34-year-old female patient who showed, at cholecystectomy, well-delineated tumor of 16 cm diameter at the pancreatic head. At surgery, this tumor was seen arise from the anterior portal vein wall. Histology showed a cellular leiomyoma. The postoperative follow-up revealed no evidence of disease at 12 months. An atypical leiomyoma, with a histology intermediate between benign and malignant features, was diagnosed in the hepatic vein of a 14-year-old male patient. The tumor extended into the right atrium and had caused Budd-Chiari syndrome (Lee et al. 1990).

Vascular Leiomyoblastoma of the Liver

Introduction

Leiomyoblastomas are epithelioid smooth muscle tumors that consist of a cell lineage with immature smooth muscle differentiation. The tumors chiefly occur in the uterus and the neoplastic cells mimic smooth muscle cells of the fetal uterus (Modafferi 2002; Watanabe et al. 2003). A morphologically somewhat similar but genetically different type of uterine tumor is plexiform leiomyoma, characterized by a neoplasm with ribbons and nests of smooth muscle cells that have an epithelioid shape and are entrapped in an abundant extracellular matrix (Hodge et al. 2008).

Leiomyoblastoma has been reported to occur in the stomach (rare tumors different from gastrointestinal stromal tumors; Huang et al. 2004, with review), the greater omentum (Tsurumi et al. 1991), the lesser omentum (Pizzimbono et al. 1973), the tongue (Sancho Alvarez et al. 2001), and the urethra (Sakai et al. 2000). Histologically, these tumors are composed of epithelioid, rhabdoid, and large vacuolated cells intermingled with spindle-shaped cells. Prominent nuclear atypia is usually lacking. Immunohistochemically, the tumor cells are intensively positive for desmin and alpha-smooth muscle actin (SMA) and sometimes for non-muscle myosin heavy chain, whereas positivity for heavy molecular weight caldesmon is restricted. Ultrastructurally, some of the cells contain dense aggregates of intermediate filaments as typically seen in rhabdoid cells (Watanabe et al. 2003). It seems that smooth muscle cells in some leiomyomatous tumors have the ability to transform in a rhabdoid or rhabdoid-like cell lineage (Parker et al. 2005). A subset of epithelioid smooth muscle tumors have a relation to blood vessels and are termed vascular leimyoblastoma. Based on the distinct distribution of epithelioid cells around blood vessels, the lesions may mimic PEComas (Zamecnik and Michal 2001) or glomangiomyomas (Sakai 2007).

Vascular Leiomyoblastoma of the Liver

This rare lesion has been observed in the liver of a 57-year-old male patient with a mass in the upper abdomen. Ultrasonography revealed a tumor of 8 cm diameter in the left liver lobe. The tumor was noteworthy for the associated paroxysmal pain attacks. Liver resection revealed an encapsulated tumor in the peripheral part of the left hepatic lobe and being in contact with the gastric wall. Histologically, the neoplasm consisted of globoid or epithelioid cells associated with a rich vasculature. These cells were positive for actin (Bianchi and Comino 1989).

Intravascular Leiomyomatosis

Introduction

Intravascular leiomyomatosis (IVL; intravenous leiomyoma) is a principally benign smooth muscle tumor (leiomyoma), usually originating from the myometrium and characterized by intrusive growth in uterine, ovarian, and other pelvic veins, sometimes causing worm-like plugs of tumor within uterine veins and macroscopically visible nodules in extrauterine vessels involved (Norris and Parmley 1975; Mulvany et al. 1994). IVL recurs in about 10 % of the patients and must be distinguished from low-grade endometrial stromal sarcoma and leiomyosarcoma with vascular invasion. IVL may be associated with so-called benign metastasizing leiomyoma, a lesion complex thought to be caused by embolic dislodgment of IVL leiomyomatous tissue to remote organs, mainly the lung (Arif et al. 2006; Garcia Rinaldi et al. 2007; Lee et al. 2008).

Involvement of the Hepatic Venous Outflow Tract

Involvement of the venous outflow tract of the liver may be expected in those cases where IVL extends from uterine and/or pelvic veins to the cavoatrial system, with extension of the tumors into the heart cavities, which is a well-known complication of this tumor and may cause cardiac failure and death via valvular obstruction (Mandelbaum et al. 1974; Saitoh et al. 2004; Vallejo et al. 2005; Demirkiran et al. 2013; Xu et al. 2013). The tumor may show extensive intracaval attachment in these situations (Nam et al. 2003) and the sometimes large tumor plug may obturate hepatic vein entry in the caval vein (Vallejo et al. 2005). Direct involvement of the hepatic veins has been described in a 66-year-old woman (Bahary et al. 1982) and in a patient who had developed Budd-Chiari syndrome (Kuenen et al. 1996). In rare instances, an equivalent oncological situation is produced by uterine leiomyosarcoma invading the large abdominal veins and extending along the inferior vena cava to the atrium (intravenous uterine leiomyosarcomatosis; Moorjani et al. 2005). Caval extension has also been found in a variant of IVL, intravascular lipoleiomyomatosis (Brescia et al. 1989). Exceptionally, leiomyomatosis peritonealis disseminata can also show intravascular extension (Haberal et al. 2007).

Pathology

Histology displays richly vascularized leiomyomatous tissue with typically constructed bundles of slender myocytes and very low mitotic activity (Bertrand et al. 1998). It has been reported that IVL occurs in several morphotypes, including cellular IVL, epithelioid IVL, IVL with bizarre nuclei, myxoid IVL, IVL with endometrial component, and intravascular lipoleiomyomatosis (Clement et al. 1988).

Pathogenesis

IVL is characterized by chromosomal aberrations, such as der(14)t(12;14)(q15;q24), suggesting that IVL arises from uterine leiomyoma with the same aberration (Quade et al. 2002; Dal Cin et al. 2003). Skewed X chromosome inactivation was observed in tumor samples, but not in myometrium, and in each tumor sample, the lower molecular weight allele of HUMARA was

nonrandomly inactivated, a finding most consistent with origin of IVL from a single transformation event (Quade et al. 2002). In contrast to preexisting vessel wall components, the intravascular leiomyomatous tumor tissue expresses estrogen and progesteron receptors, supporting intravascular tumor transport rather than novel tumorigenesis in situ (Kir et al. 2004).

Leiomyomatous Hamartomas/ Hamartosis

Introduction

Hamartomas with a leiomyomatous component are lesions well recognized to occur in the breast, albeit an uncommon tumor (myoid hamartoma; Stafyla et al. 2007; Bayar et al. 2010). Such lesions also occur in the lung, mostly in middle-aged women and commonly multiple (diffuse fibro-leiomyomatous hamartosis; multiple pulmonary leiomyomatous hamartomas; Cruickshank and Harrison 1953). The lesions may regress during pregnancy, suggesting hormonal dependency of these growths (Horstmann et al. 1977). Rarer locations of leiomyomatous hamartomas or hamartosis include the oral cavity (Nava-Villalba et al. 2008), the breast (Magro and Bisceglia 1998), and the intestinal tract (e.g., with congenital jejunoileal atresia; Rosenmann et al. 1980).

Myoid Hamartomas of the Liver

In a first report of this rare lesion, the tumor was termed mesenchymal, predominantly leiomyomatous, differentiated hamartoma of the liver (Leipner et al. 1984). In a later observation, a similar tumor was observed in a 17-year-old male patient (Gornicka et al. 2004). This patient had presented with jaundice and light stools and was admitted with suspicion of Klatskin's tumor, irrespective of his young age. Imaging demonstrated a solid lesion about 3 cm in diameter, situated in liver segment IV, associated with widening of the hepatic ducts. Diagnosed with perihilar malignancy, the patient underwent right-sided hemihepatectomy. The resection specimen showed a single, vaguely delineated and unencapsulated solid hilar tumor of cream color, measuring $5 \times 3.5 \times 3$ cm. Histologically, the lesion consisted of elongated spindle-shaped cells with eosinophilic cytoplasm and long, blunt-ended nuclei. The cells were arranged in tight bundles intersecting focally. The nodule contained numerous bile ductules, sometimes associated with arterioles. The border of the lesion was ill defined, with blending into liver parenchyma and perifocal liver atrophy. Immunohistochemically, most of the spindle cells were markedly reactive for alpha-smooth muscle actin, whereas only few cells were CD34 and desmin positive. The proliferation activity, based on Ki67 staining, was less than 5 % (Gornicka et al. 2004).

Leiomyomatous Hemangiomas of the Liver

This unique lesion was described in an autopsy report (Key and Rao 1986). A 74-year-old man died of cardiac arrest secondary to severe coronary artery atherosclerosis. At necropsy, the cut surface of the liver (1530 g) revealed several white, solid tumors in both lobes. These nodules ranged in size from 0.3 to 0.6 cm in diameter and had a firm texture. Histologically, the tumors were well circumscribed and consisted of interlacing bundles of spindle-shaped cells. These cells had the appearance of smooth muscle cells with fusiform nuclei. Small areas of hemorrhage were present in some of the tumors, but there was no necrosis. Bile ducts could be identified within the tumor in some sections. Some of the lesions seemed to arise from smooth muscle of intrahepatic veins, as tumor cells blended with the veins' tunica media. In addition to these myoid tumors, the liver also contained two cavernous hemangiomas. Intramural leiomyomas were found in this patients in parts of the gastrointestinal tract, including the proximal jejunum and the prepyloric region of the stomach (Key and Rao 1986).

Hamartoma-Associated Smooth Muscle Tumors of the Liver

This term is based on the observation of two patients who had hepatic tumors of long duration interpreted as hamartomas in whom, after many years, widespread metastases of malignant smooth muscle cells developed in a pattern of "carcinomatous lymphangiosis" in the lungs. In one patient (59-year-old male), autopsy revealed several firm nodules in the liver, lobulated like hamartomas, composed of a hypocellular matrix that contained collagen, reticulin, and elastin. The lesions were calcified and partially ossified. The nodules containing atypical myoid cells invaded vessels and were of the same morphology as those forming the pulmonary and lymphonodal metastatic deposits. The smooth muscle cell lineage was defined by electron microscopy. This patient also showed hypertrophic pneumatic osteoarthropathy of bones of the ankles and wrists. The second patient (46-year-old female) showed a similar lesion pattern, with a large hamartoma-like tumor in the liver and numerous pulmonary myoid nodules interpreted as leiomyosarcomatosis (Echevarria et al. 1978).

Leiomyosarcoma of the Liver

ICD-O code 8890/3

Introduction

Leiomyosarcomas are an important group of malignant mesenchymal tumors that chiefly occur in the uterus, certain soft tissue regions, and gastrointestinal tract (reviews: Fletcher et al. 2002; Miettinen and Fetsch 2006). Primary hepatic leiomyosarcoma is a very rare tumor of the liver, accounting for less than 1 % of primary liver malignancies. As malignant neoplasms derived from smooth muscle cells, hepatic leiomyosarcoma may arise from intrahepatic vascular structures, bile ducts, or myoid cells located to the hepatic ligaments.

Epidemiology

Following early reports on spindle cell sarcomas observed in the liver, a long series of reports have documented to existence of primary leiomyosarcoma of the liver, although earlier reports could not prove the diagnosis by use of immunohistochemistry. Hepatic leiomyosarcoma is typically a neoplasm of aged patients, most of them being diagnosed in patients older than 60 years. There are very few cases of pediatric hepatic leiomyosarcoma; one tumor was found in an infant (Surendrababu et al. 2006) and few others in children with acquired immunodeficiency syndrome (Ross et al. 1992). One report from Lebanon described three cases of primary hepatic leiomyosarcoma with unusually young age distribution (i.e., 20, 30, and 39 years at presentation; Shamseddine et al. 2010). A 25-year-old male patient with hepatic leiomyosarcoma has been described (Iordanidis et al. 2002). There is no gender preference.

Clinical and Imaging Features

As other primary hepatic sarcomas, leiomyosarcomas of the liver present a clinical dilemma in so far as they are often asymptomatic until they become large, and even then they produce nonspecific symptoms (Gates et al. 1995; Yu et al. 2008). About half of the patients have abdominal pain and/or weight loss. In case of large and very large lesions, vomiting and jaundice may ensue. Most patients have no evidence of hepatitis or liver cirrhosis. Jaffe reported that hepatic neoplasms of mesenchymal origin were associated with cirrhosis in only 29 % of cases (Jaffe 1924). Some patients may show abnormal liver function tests, but serum AFP is consistently normal. Complications include acute bleeding and IVC obstruction (Jeong et al. 2008). Leiomyosarcoma of the liver was reported to mimic hepatic abscess (Gates et al. 1995). The tumor was found in conjunction with other tumors, including gastric lymphoma (Linares Torres et al. 2002) and von Recklinghausen's neurofibromatosis (Maruta et al. 2004). Hepatic leiomyosarcoma was identified together with cholangiocarcinoma in a liver showing thorotrastosis (Shurbaji et al. 1987).

Hepatic leiomyosarcoma has been found to metastasize within the liver (Baur et al. 1993; Tsuji et al. 2000; Kwon et al. 2005). Extrahepatic metastases have also been analyzed during autopsy (Von Ebert 1978) and have been reported for the hepatopancreatic and retroperitoneal locoregional lymph nodes, peritoneal seeding, lungs, pleura, skin, and kidneys. In case the tumor can be completely resected, the course may be favorable, with long-term survival described several times (Pinson et al. 1994; Poggio et al. 2000; Matthaei et al. 2009). As hepatic leiomyosarcoma tends to metastasize within the liver, early resection in low-stage disease is mandatory.

CT findings of primary hepatic leiomyosarcoma have been described as a large, well-defined, heterogeneous hypodensity mass with internal and peripheral enhancement or cystic mass with an enhancing thick wall. Large tumors may show a central markedly hypoattenuating area corresponding to tumor necrosis (Paraskevopoulos et al. 1991; Gandhi et al. 1995; Gates et al. 1995; Soyer et al. 1995; Ferrozzi et al. 1996; Fujita et al. 2002; Yu et al. 2008; Liang et al. 2009). Some tumors may show capsular retraction and internal small punctuate calcifications (Soyer et al. 1995). On contrast-enhanced CT scans, tumor enhancement is predominantly peripheral, but heterogeneous internal and peripheral enhancement and pseudocystic patterns may also occur. On T1-weighted images, the tumors are well defined and slightly heterogeneous, with hypointensity to the adjacent liver substance. T2-weighted images show heterogeneous, hyperintense lesions (Ohtomo et al. 1992; Soyer et al. 1996). In case of large central hemorrhage and necrosis, the presentation may mimic hemorrhagic hepatocarcinoma (Morris and Ghanta 2010). Angiography has revealed that the tumors are fed by vessels originating from the hepatic artery (Paraskevopoulos et al. 1991). Leiomyosarcoma was detected by high F-18 fluorodeoxyglucose positron emission tomographic uptake (Nishiguchi et al. 2001).

Macroscopic Pathology

Hepatic leiomyosarcomas are usually solitary nodular, nonencapsulated masses which are soft and hemorrhagic and may grow to large size, with reported diameters of 20 cm or even more (Fig. 5). The tumors are sharply delineated from the liver, with signs of perifocal liver atrophy. Large tumors may show central necrosis and hemorrhage.

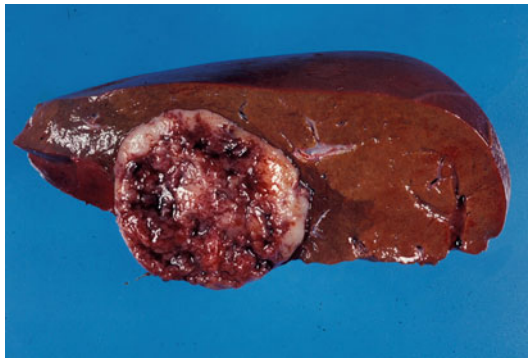

Fig. 5 Primary leiomyosarcoma of the liver. Large and friable tumor with marked hemorrhage and necrosis in a non-cirrhotic liver

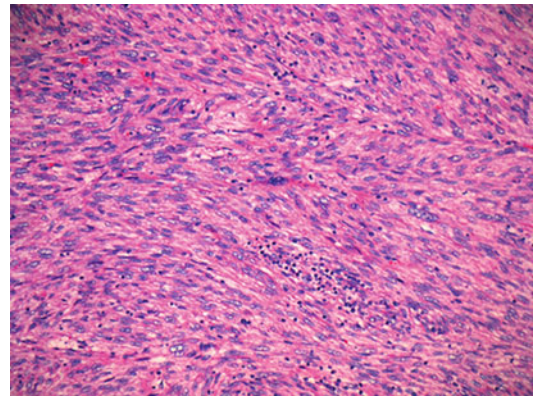

Fig. 6 Primary leiomyosarcoma of the liver (grade 3). The hypercellular tumor consists of abnormal smooth muscle cells with enlarged nuclei and shows focal necrosis with nuclear debris (hematoxylin and eosin stain)

Histopathology

The tumors exhibit a variable cellularity with little fibroblastic tissue and rather inconspicuous blood vessels. The cells are spindle shaped and arranged in fascicles. The cytoplasm is eosinophilic, pale, or clear, and the nuclei are typically blunt ended and elongated (Figs. 6 and 7). Nuclear pleomorphism varies from very slight to marked. The mitotic activity may be low (one per ten HPF), but it may undergo a significant increase in progressing tumors and in intrahepatic metastases (Baur et al. 1993). Apart from cellular and nuclear features, the most important criterion of diagnosing leiomyosarcoma appears to be the presence of mitotic figures, and the presence of one mitosis per two high-power fields is generally a marker for aggressiveness (Lee 1983). Primary hepatic leiomyosarcoma was diagnosed by use of fine-needle aspiration cytology (Smith et al. 1994). Ultrastructurally, the tumor cells contain myofilaments along with cytoplasmic dense bodies and marginal dense plaques, the more distinctive subcellular markers of smooth muscle cells. Mitochondria are sometimes numerous and diffusely distributed in the cell body (Bloustein 1978; Paraskevopoulos et al. 1991).

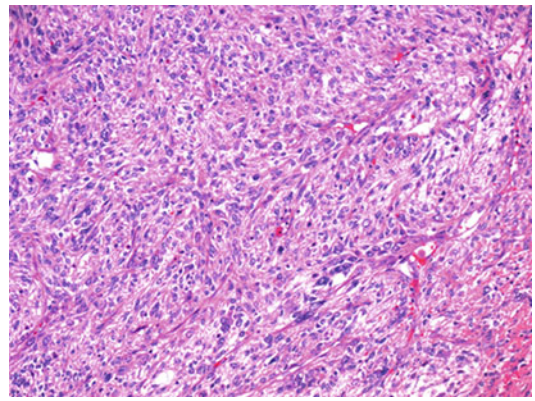

Fig. 7 Primary hepatic leiomyosarcoma (grade 3) with increased pleomorphic and a vague fascicular structure (hematoxylin and eosin stain)

Immunohistochemistry

The tumor cells are reactive for muscle-specific actin, alpha-SMA, desmin, and vimentin (Fig. 8; Watanabe et al. 1991; Saint-Paul et al. 1993; Dominguez Iglesias et al. 1995; Higuchi et al. 1995; Maruta et al. 2004; Sicaja et al. 2006). Smooth muscle tumors also express a unique pattern of gamma-smooth muscle isoactin gene expression (Brittingham et al. 1997). Desmin reactivity is seen in only part of the cases and in heterogeneous distribution in a given tumor, in one study involving only 20 % of the tumor cells (Korbi et al. 1991). The tumors also variably express SM1/SM2 myosin isoforms and non-muscle myosin. SM1/SM2 and

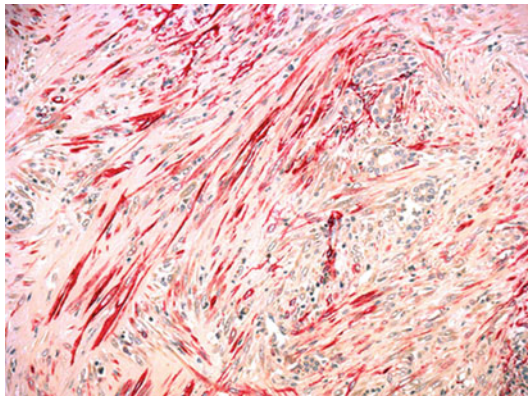

Fig. 8 Primary leiomyosarcoma of the liver. The atypical spindle cells express smooth muscle actin (alpha-SMA immunostain)

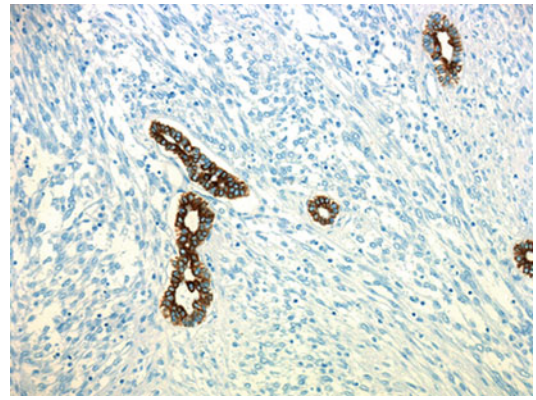

Fig. 9 Strongly invasive leiomyosarcoma of the liver with entrapment of small bile ducts (cytokeratin 19 immunostain)

non-muscle myosin expression pattern are not paralleled by different proliferation or apoptosis levels (Valenti et al. 1998). Smooth muscle cells and tumors derived thereof express h-caldesmon, which is a lineage marker for smooth myocytes (Watanabe et al. 1999, 2000). H-caldesmon is a protein which is combined with actin and tropomyosin and which is involved in contraction and cell motility. A novel marker that characterizes smooth muscle cell differentiation in sarcomas is transgelin (Robin et al. 2013). Leiomyosarcoma cells are markedly positive for p16, a finding which serves to distinguish this tumor from leiomyoma and its variants, where p16 staining is weak or lacking (Gannon et al. 2008; Hakverdi et al. 2011). In contrast to certain other sarcomas, leiomyosarcomas do not show nuclear p63 reactivity (Jo and Fletcher 2011). The highly invasive features of leiomyosarcoma with entrapment of small bile ducts can be visualized by cytokeratin immunostaining (Fig. 9). High-grade leiomyosarcomas exhibit an elevated proliferative activity as seen in MIB1 immunostains (Fig. 10).

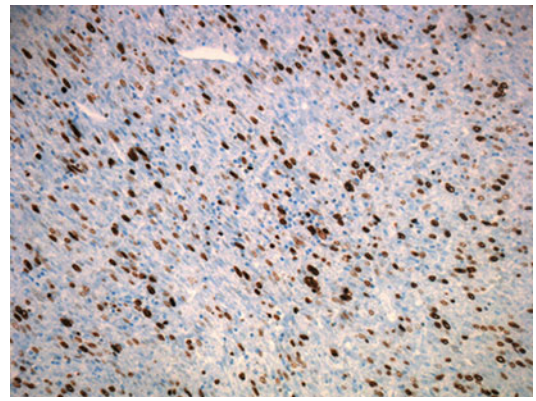

Fig. 10 High proliferative activity in grade 3 leiomyosarcoma of the liver (MIB1 immunostain)

Myxoid Leiomyosarcoma of the Liver

One variant of hepatic leiomyosarcoma is characterized by smooth muscle cells with a clear cytoplasm suspended in a myxoid stroma (hepatic myxoid leiomyosarcoma). Hepatic myxoid leiomyosarcoma was found in normal liver (Lee et al. 2002; Tsiatis et al. 2008) or in cirrhotic liver (Sicaja et al. 2006). Myxoid leiomyosarcoma had originally been described as a distinct subtype in the uterus (King et al. 1982). Subsequently, similar tumors were identified in extrauterine sites, including soft tissues, gastrointestinal tract, and vulva. The tumor diameters in the cases described ranged from 2.9 to 16 cm. Histologically, the spindled myocytes form interlacing bundles embedded in a rich, Alcian blue-positive myxoid matrix. The mitotic activity was reported to be low (one per ten HPFs; Sicaja et al. 2006). The clear aspect of the cytoplasm in one case was due to glycogen accumulation, as seen in electron microscopy (Sicaja et al. 2006). Immunohistochemically, the

tumor cells were positive for alpha-SMA and muscle-specific actin (HHF-35). In one case, strong and diffuse nuclear staining for estrogen receptor-b was observed (Tsiatis et al. 2008).

Epithelioid Leiomyosarcoma of the Liver

Epithelioid leiomyosarcoma is a rare subtype of malignant smooth muscle tumors. It has been reported as multiple primary lesion in the liver (Cioffi et al. 1996). The differentiation pathways of these neoplasms may be complex. For example, an oncocytic variant of primary epithelioid leiomyosarcoma of the liver has been reported (Delecluse et al. 1992).

Lipoleiomyosarcoma of the Liver

Lipoleiomyosarcoma (well-differentiated liposarcoma with leiomyosarcomatous differentiation) is a rare type of sarcoma that chiefly occurs in the retroperitoneal space, the paratesticular-inguinal region, the mediastinum, abdomen, and popliteal fossa. The tumor is histologically characterized by a multifocal, gradual transition of well-differentiated liposarcoma into smooth muscle areas (Folpe and Weiss 2002).

Inflammatory Leiomyosarcoma of the Liver

Inflammatory leiomyosarcoma denotes a leiomyosarcoma with a marked infiltration of lymphocytes, macrophages, and sometimes plasma cells. In one case, it was characterized by specific near-haploid chromosome changes (Dal Ci et al. 1998).

Hamartomatous Leiomyosarcoma of the Liver

This is an unusual lesion which has been described based on two patients (Echevarria et al. 1978). In the livers, lobulated nodules with a mesenchymal hamartoma-like configuration were found, histologically characterized by a hypocellular hyaline matrix with focal calcifications and ossifications. Atypical cells were embedded in the matrix, and at the periphery of the nodules, vascular proliferations and proliferated bile ducts were in evidence. Progression of the process was characterized by metastatic spread in the lungs and mediastinal lymph nodes of a cell lineage ultrastructurally showing the features of smooth muscle cells.

Leiomyosarcoma of the Bile Ducts

Introduction

Primary leiomyosarcomas of the biliary tract are very rare neoplasms that have been observed in the common bile duct (Schuppler 1934; Whitcomb et al. 1967; Jin et al. 1990), the ampullary region (Nitshe and Suckle 1947), and the duodenal papilla (Kefalas et al. 2004).

Pathology

There are few published pathology findings. In a 62-year-old female patient suffering from obstructive jaundice, surgical intervention showed that the proximal portion of the common bile duct was markedly dilated to a diameter of 5 cm and contained a solid green, fleshy, outwardly avascular tumor which extended into the right and left hepatic ducts and was attached to the wall of the common hepatic duct (Whitcomb et al. 1967).

In the case reported by Whitcomb et al. (1967), the tumor showed a well-vascularized tissue characterized by palisading and interlacing bundles of spindle-shaped cells with blunt-ended nuclei, reminiscent of abnormal smooth muscle cells. There was considerable cellular and nuclear polymorphism throughout the tumor, with many bizarre and occasionally multinucleated anaplastic cells. Abnormal mitoses were numerous and varied from two to eight per HPF (Whitcomb et al. 1967).

Differential Diagnosis

The histology of well-differentiated leiomyosarcoma may be confounded with leiomyoma of the bile ducts (Mandeville and Stawski 1991; Yamaoka et al. 1993; Saito 1996). Leiomyosarcoma enters the differential diagnosis of other spindle cell tumors occurring in the biliary tract (Yuan et al. 1995), including rhabdomyosarcoma of the adult (Aldabagh et al. 1986). Visceral leiomyosarcoma may metastasize to the extrahepatic bile ducts (e.g., leiomyosarcoma of the pancreas; Del Gallo et al. 1997). Based on biopsy sampling effects, the spindle cell-myoid component of biliary tract carcinosarcoma (Loud et al. 1997; Yoon and Choi 2004) may be misinterpreted.

Leiomyosarcoma of the Porta Hepatis

This is a rare primary location of this tumor and has been described as a hypervascular tumor (Balthazar 1981).

Leiomyosarcoma of the Hepatic Ligaments

Malignant mesenchymal tumors primary to the hepatic ligaments are very rare tumors. Leiomyosarcoma was observed in both the ligamentum falciforme (Morita et al. 1987) and the ligamentum teres hepatis (Mital and Bazaz-Malik 1971; Adachi et al. 1979; Yamaguchi et al. 1996). In sarcoma originating in the falciform ligament, supply of the tumor by the hepatic falciform artery has been demonstrated (Morita et al. 1987).

Differential Diagnosis

The most important differential diagnosis is certainly liver metastasis of primary extrahepatic leiomyosarcoma (Bowden and Murphy 1955; Kershner 1969; Soyer et al. 1997; Lang et al. 2000). The majority of the tumors have their primary site mostly in the viscera (Chen et al. 1998). In a series of 65 patients with hepatic sarcoma metastases, 61 patients had an intra-abdominal primary site, with 85 % being high-grade leiomyosarcomas (Jacques et al. 1995).

In a study of 34 patients undergoing hepatic resection for metastatic leiomyosarcoma, the site of the primary tumor was the stomach (31 %), small bowel (15 %), vena cava (4 %), kidney (4 %), colon (4 %), upper abdomen (19 %), and retroperitoneum (19 %) (Lang et al. 2000). Among 331 patients who had hepatic resection for sarcoma metastatic to liver, 61 % had gastrointestinal stromal tumors or leiomyosarcomas of the GI tract (DeMatteo et al. 2001). In contrast, metastatic leiomyosarcomas originating in the uterus are much rarer (Rose et al. 1989; Jacques et al. 1995; Soyer et al. 1997; Pawlik et al. 2006; Kuwahara et al. 2011; Lorenzo-Zuniga et al. 2011). In the study of 65 cases reported by Jacques et al. (1995), only one gynecologic primary tumor was found. The primary tumor may be situated close to the liver, e.g., the pancreas (Nobili et al. 2010), greater omentum (Koga et al. 2002), or the inferior vena cava (Hashimoto et al. 2012). Leiomyosarcomas metastatic to the liver differ from primary tumors on CT imaging. They are commonly large and circumscribed so-called cannonball lesions that distort the normal hepatic architecture. The larger metastases are still sharply defined and often show a central necrosis and are accentuated by contrast enhancement of normal surrounding liver. Smaller perfused metastases often become isodense following contrast medium administration (Noon et al. 1980). On MR images, a hemangioma-like pattern was the most common feature on T2-weighted images (Soyer et al. 1997). Leiomyosarcoma of the inferior vena cava, a well-known entity, may invade or metastasize into the liver (Huguet et al. 1992; Thompson et al. 1993; Hashimoto et al. 2012). Also retroperitoneal leiomyosarcoma situated behind the liver has been confounded with a primary liver tumor (Wada et al. 1994). A second group of tumors that enter differential diagnosis are EBV-associated hepatic smooth muscle tumors, which are discussed in another chapter. Leiomyosarcoma

can occur as a primary lesion in the gallbladder (Kumar et al. 1993; Tocchi et al. 1993; Danikas et al. 2001). Primary or secondary GIST of the liver and other non-myoid hepatic spindle cell tumors may be confounded with leiomyosarcoma, correct diagnosis requiring immunohistochemistry. Kit analysis serves to distinguish GIST from other spindle cell tumors. However, up to 5 % of GISTs can be completely negative for Kit on immunohistochemistry. Conversely, leiomyosarcomas may rarely express Kit, but are virtually never associated with an activating Kit mutation (Trent et al. 2007). Rarely, primary carcinosarcomas of the liver may contain a leiomyosarcomatous component, which may dominate the pattern in a needle biopsy.

Leiomyosarcoma of the Inferior Vena Cava and the Hepatic Veins

Introduction

Leiomyosarcoma of the inferior vena cava with or without involvement of associated veins is a rare neoplasm arising from smooth muscle cells of the venous wall; it represents only 0.5 % of all adult soft tissue sarcomas (Hollenbeck et al. 2003). However, the inferior vena cava is the most common site of origin for venous leiomyosarcomas, followed by major veins of the extremities.

Clinical and Imaging Features

The original description of a primary leiomyosarcoma of the inferior vena cava was published in 1871 (Perl 1871). Since then, numerous cases have been reported, either being restricted to distinct segments of the caval vein or concomitantly involving its large associated veins (Hallock et al. 1940; Deutsch et al. 1968; Wray and Dawkins 1971; Parrilla et al. 1992; Hollenbeck et al 2003; Dew et al. 2005; Hardwigsen et al. 2005; Sokolich et al. 2008; Krüger et al. 2010; Laskin et al. 2010; Sessa et al. 2010; Huang et al. 2011; Ulla et al. 2011). Leiomyosarcoma of the inferior vena cava occurs in patients usually older than 40 years; in a study of 25 patients, the age range was 41–79 years, with a median age of 56 years (Hollenbeck et al. 2003). The tumor may involve the hepatic veins and the renal vein confluences, sometimes combined (Lygidakis et al. 2007; Spinelli et al. 2008). Rarely, the process involves the infrarenal or the suprahepatic segments of the caval vein (Dew et al. 2005; Delis et al. 2008; Tameo et al. 2010). But caval leiomyosarcoma is most common in the retrohepatic portion of the inferior vena cava, between the renal and hepatic veins (Kulaylat et al. 1997; Mingoli et al. 1997; Hardwigsen et al. 2005). This is a complex and distinct localization for this malignancy, with a characteristic clinical presentation and biology of disease (Praseedom et al. 2007). Generally, the signs and symptoms are so nonspecific and mainly comprise abdominal pain and sometimes a flank mass (Wray and Dawkins 1971; Hardwigsen et al. 2005), but tumors encroaching upon the liver may mimic a primary hepatic tumor (Sokolich et al. 2008). In markedly symptomatic tumors, the initial presentation is dominated by inferior vena cava syndrome, Budd-Chiari syndrome, and thrombosis (Pollanen et al. 1987; Arraztoa et al. 1994; Mingoli et al. 1997).

Budd-Chiari syndrome, characterized by rapidly evolving hepatomegaly, jaundice and ascites, has a poor prognosis. The first case of leiomyosarcoma of the IVC associated with Budd-Chiari syndrome was reported in 1940 already (Hallock et al. 1940). Since then, there have been many further cases reported in the literature. Tumors in this compartment sometimes exhibit distinct and clinically important growth patterns. Leiomyosarcoma of the retrohepatic portion of the vena cava has been shown to grow through the venous wall and to infiltrate the right liver lobe (Huguet et al. 1992) or extend into the right atrium (Deutsch et al. 1968; Thompson et al. 1993; Fonseca et al. 2002), sometimes with dominant obstruction of the tricuspid valve (Hoffbrand and Lloyd-Thomas 1964). This can cause sudden death from pulmonary tumor embolization (Gowda et al. 2004). Primary embolization of caval leiomyosarcoma into the pulmonary artery has also been reported (Krüger et al. 2010).

In case of expanding growth, the tumor may displace segment I of the liver, mimicking a hepatic tumor (Schwarzbach et al. 1997).

Previously, 44 % of the cases have not been diagnosed until at autopsy and 50 % not until surgery (Chauhan et al. 1981). But recent advances in imaging techniques have enabled a more accurate diagnosis prior to surgical resection (Peh et al. 1993; Sessa et al. 2010; Huang et al. 2011), including direct-MDCT cavography where the injection of contrast agent through both lower limbs achieves maximum enhancement of the inferior vena cava (Ulla et al. 2011).

Apart from acute complications such as those related to Budd-Chiari syndrome, atrial involvement, and embolism, the biology of disease is positively influenced by combined surgical and chemotherapeutic therapies (Mingoli et al. 1997; Hollenbeck et al. 2003; Dew et al. 2005; Reges et al. 2008). As many of the tumors are large or very large at diagnosis, the lesions are often unresectable. The liver and the lungs are most often involved in hematogenous metastatic dissemination (Pollanen et al. 1987; Sokolich et al. 2008). Mingoli and coworkers (1997) reported that, up to August 1994, 218 patients were enrolled into The International Registry of Inferior Vena Cava Leiomyosarcomas. Among 120 patients where radical resection of the IVC tumor was performed, tumor recurrence was observed in 57.3 % at a mean follow-up of 32 ± 4 months, with a 5-year survival rate of 55 % (caval wall resection) and 37 % (caval segmental resection). These findings were largely confirmed in later investigations. In a study of 25 patients, 84 % underwent complete resection of the tumor; local recurrence occurred in 33 % and distant recurrence in 48 % of patients. Patients with complete resection had 3-year and 5-year disease-free specific survival rates of 76 % and 33 %, respectively (Hollenbeck et al. 2003). In a report on the experience with 22 patients, the 3-and 5-year mean actuarial survival rates in patients who underwent resection were 52.0 % and 34.8 %, respectively. Eleven patients died after a mean follow-up period of 43.7 months due to local recurrence and/or distant metastasis in nine cases and complications of chemotherapy in two (Kieffer et al. 2006). In a recent study of 40 patients, the 5-year and 10-year survival rates after resection without documented residual macroscopic disease were 50 % and 22 %, respectively. Suprahepatic vena caval and right atrial involvement by tumor, predominant intraluminal tumor growth, and residual postsurgical macroscopic disease were factors that correlated with death within 2 years. By univariate analysis, intraluminal tumor, compromised liver, and moderate to poor tumor differentiation were associated with increased tumor-related mortality, whereas a compromised liver (liver injury or failure) was the only factor correlated with mortality by multivariate analysis (Laskin et al. 2010).

The biology of leiomyosarcoma of the inferior vena cava is difficult to predict, as some tumors grow slowly within the luminal space of the vein, sometimes with nonspecific signs and symptoms of ten or more years' duration (Rosch et al. 2002). The difficulty in estimating biology of disease was mainly based on the small case series, until many patients could be evaluated in the context of The International Registry of Inferior Vena Cava (IVC) Leiomyosarcomas, established in 1992 (Mingoli et al. 1996). There is evidence that the prognosis after complete resection likely depends on the histologic features of the primary tumor. Factors such as tumor differentiation, mitotic index, and tumor size affect long-term prognosis. In a detailed description of vascular leiomyosarcomas, it was concluded that the mitotic index was the most important pathological feature on which a prognostic evaluation for a vascular leiomyosarcoma could be the bases. Patients with a mitotic index greater than 35/10 HPFs had a poor prognosis (Varela-Duran et al. 1979).

Pathology

Leiomyosarcoma of the inferior vena cava can grow to large size. In a study of 40 cases, the tumors ranged in size from 3.5 to 15.0 cm (median: 8.5 cm), and most involved the middle segment of the vessel and grew extraluminally (Laskin et al. 2010). The nodular masses can

grow into the hepatic vein inlets. In case of Budd-Chiari syndrome, the sometimes necrotic intraluminal tumors are associated with thrombotic material attached to the neoplastic nodules. Retrohepatic tumors can invade the venous wall and infiltrate the posterior part of the liver. In such situations, a primary liver malignancy with secondary involvement of the caval vein may be suspected macroscopically.

The sarcomas show a proliferation of atypical smooth muscle cells with increased grades of nuclear atypia and presence of mitotic figures. In a series of 40 patients, tumor grade was grade I in 11, grade II in 21, and grade III in 5 patients (Laskin et al. 2010). Caval leiomyosarcoma has been diagnosed by intraluminal biopsy (Shimoda et al. 1998), fine-needle aspiration cytology (Al-Rikabi et al. 2007), or endoscopic ultrasound-guided fine-needle aspiration biopsy (Jenssen et al. 2008).

Differential Diagnosis

Metastatic leiomyosarcoma may encroach upon the hepatic veins and induce a Budd-Chiari-like syndrome (Fortner et al. 1977).

Leiomyosarcoma of the Portal Vein and Its Tributaries

Introduction

Leiomyosarcomas originating from a vein wall are rare lesions. In the liver-related venous system, most of these neoplasms arise in the retrohepatic part of the inferior vena cava and the hepatic veins, whereas leiomyosarcoma of the portal venous system is a much more exceptional finding. The reason of this striking difference is currently unknown.

Clinical and Imaging Findings

Leiomyosarcoma primary to the portal vein is a rare cause of portal vein block (Wilson and Hine 1987; Sundaresan et al. 1990; Madariaga et al. 1995). The venous block causes portal hypertension with extensive collateral circulation and congestive splenomegaly (Madariaga et al. 1995). CT imaging shows well-defined heterogeneously enhancing solid masses, sometimes with areas of hypoattenuation representing cystic or necrotic changes. In contrast to benign thrombosis of the portal vein, which is associated with a moderate vessel enlargement at sonography (Van Gansbeke et al. 1985), involvement of the vein by a malignant tumor causes a marked and sometimes tremendous enlargement of the caliber of the vein (Wilson and Hine 1987). The vascular primary tumor may spread to the liver substance, with formation of intrahepatic metastases (Sundaresan et al. 1990). Leiomyosarcoma may also develop in the wall of large veins draining into the portal vein, specifically the superior mesenteric vein (Goldin et al. 2002).

Pathology

Leiomyosarcoma of the portal vein can grow to very large size. In one case, the resected tumor was 30 cm in diameter and weighed 1880 g (Sundaresan et al. 1990). Macroscopically, the tumor is similar to leiomyosarcomas of other locations, with an expanding growth pattern, a bosselated surface, and a cut surface with a whorled appearance. Histologically, the neoplasm consists of interlacing fascicles of eosinophilic spindle cells with elongated, blunt-ended nuclei. Usually, there are marked nuclear pleomorphism and numerous mitotic figures, the mitotic index sometimes exceeding 30/10 HPFs (Sundaresan et al. 1990).

Differential Diagnosis

Among tumor-induced portal vein block, hepatocellular carcinoma is the most common event (Mathieu et al. 1984). Extrahepatic tumorous portal vein obstruction has been shown to be caused by a wide array of malignancies, e.g., gastric and pancreatic carcinomas, Hodgkin's disease, and

malignant non-Hodgkin lymphomas. Gastric leiomyosarcoma can involve and block the extrahepatic portion of the vein (Sharma et al. 1996).

Leiomyosarcomatosis

Multicentric leiomyosarcomatosis is a very rare disorder that may involve both intra-abdominal and extra-abdominal organs (Case et al. 1973; Akata et al. 1999). Diffuse leiomyosarcomatosis has been noted in the gastrointestinal tract, with numerous tumors in the colon, stomach, or the entire GI tract from the stomach to the jejunum or even to the colon (Korman et al. 1997).

The liver may be involved in this complex process. In one reported patient, synchronous leiomyosarcoma nodules not considered to be metastatic deposits were observed in the gastrointestinal tract, liver, lungs, diaphragm, parathyroid gland, bone marrow of the vertebrae, and subcutaneous tissue (Fridie et al. 1992). Tumor manifestations in the ligamentum teres have been found in another patient with widespread organ involvement, again with tumors also in the bones (Akata et al. 1999).

Oncocytic Smooth Muscle Tumors

There are very few reports of malignant epithelioid smooth muscle tumors of the uterus and gastrointestinal tract showing oncocytic cell change (Nance and Reddick 1987; Nguyen et al. 2001). A primary and large hepatic epithelioid leiomyosarcoma treated by liver transplantation showed extensive oncocytic change, this feature having first led to the suspicion of a neuroendocrine tumor (Delecluse et al. 1992).

DOI 10.1007/978-3-319-26956-6_64

Abstract

Rhabdomyosarcomas (RMS) are a group of aggressive malignancies derived from a skeletal muscle cell lineage. These neoplasms occur in several distinct body regions in children and adults. One subset of RMA develops in the hepatobiliary tract, mainly in the pediatric age group, associated with a distinct clinical and radiological syndrome. Hepatobiliary RMS is defined as a mucosal-type RMS arising from the wall of intrahepatic or extrahepatic bile ducts. This neoplasm is the most common biliary tract tumor in children, but is overall rare, accounting for only 0.8 % of all RMS and 1.3 % of malignant liver tumors in childhood. The neoplasm can form polypoid masses that protrude into the bile ducts. Histologically, most hepatobiliary RMS are embryonal RMA, whereas alveolar RMS is a very rare hepatic malignancy. Histologically, embryonal RMA of the liver shows a loose neoplastic tissue with desmin-positive stellate cells and cells resembling rhabdomyoblasts. Frequently, a cellular layer is found underneath the biliary tract epithelium, the so-called cambium. RMS of the hepatobiliary tract can rarely also occur in adults.

Pediatric Hepatobiliary Rhabdomyosarcoma

ICD-O codes:

Embryonal rhabdomyosarcoma	8910/3
Alveolar rhabdomyosarcoma	8920/3
Pleomorphic rhabdomyosarcoma	8901/3

Introduction

Rhabdomyosarcomas (RMS) are a group of aggressive mesenchymal malignancies well known to occur in several distinct body regions of children and histologically characterized by a growth of immature muscle cells with or without detectable cross-striation. Several types of RMS are now recognized, including embryonal RMS, alveolar RMS, pleomorphic RMS, spindle cell RMS, and anaplastic forms (Parham and Barr 2013).

Hepatobiliary rhabdomyosarcoma (HBRMS) is defined as a mucosal-type RMS arising from the wall of the intra- or extrahepatic bile ducts. This RMS is almost always an embryonal RMS. The lesion has first been described in 1875 (Wilks and Moxon 1875) and has later also been described as embryonic tumor with striated muscle (Sheehan 1930), a malignant mixed tumor of the choledochal duct (Goeters 1941), and a cystic liver tumor of the mixed type (Williams 1953). The case of Sheehan (1930), a 6-year-old girl, was described in great detail, and the author already pointed out that this type of tumor may present in the form of intrahepatic cysts representing dilated bile ducts obstructed by the intraluminally growing tumor. The lesion was further specified by Willis (1962).

Malignant muscle tumors have already been identified in the nineteenth century. The first case of RMS may have been described by the famous Viennese pathologist, Karl Freiherr von Rokitansky, who noted a tumor consisting of striated muscle cells in the tunica albuginea of the testis (von Rokitansky 1849). The first pediatric case might have been observed in a 3-year-old child by the Czech physician, Vilém Dusan Lambl, who called the tumor "muscle carcinoma" (Lambl 1860). Lambl is best known for his detection of an intestinal parasite which he called *Cercomonas intestinalis* (however, first observed by Anton van Leeuwenhoek) and which is now termed *Giardia lamblia*, an eponym based on Lambl and the French biologist, Alfred Mathieu Giard (1846–1908). Several classifications of RMS have been proposed (reviews: Parham 2001; Caillaud et al. 2006), and attempts for molecular classification have been undertaken (Davicioni et al. 2009).

Epidemiology

HBRMS is the most common biliary tract tumor in the pediatric age group and is, e.g., clearly more common as pediatric cholangiocarcinoma. But the

tumor is, overall, rare, and it accounts for only 0.8 % of all rhabdomyosarcomas and 1.3 % of all malignant liver tumors in childhood. At the time of diagnosis, 75 % of the children are under 5 years of age, and the tumor most often occurs in children aged 3–4 years. Girls are generally more frequently involved (5:1). However, in a review of 26 patients reported between 1875 and 1981 (Lack et al. 1981), 13 were male, 12 were female, and in 1 patient, the sex was not specified. Rarely, HBRMS occurs in adolescents (Haider et al. 2013).

Clinical Features

Clinical signs and symptoms are rather nonspecific and include upper abdominal pain, abdominal distention, nausea with vomiting, and hepatomegaly The clinical presentation is closely linked to the distinct growth pattern of the tumor, which grows along and within the bile ducts, causing biliary obstruction and cholestatic jaundice. Jaundice with or without associated leukocytosis was found as the presenting sign in 60–80 % of cases and critically depends on the level of bile duct involvement, being common in RMS located to the porta hepatis and obligatory in RMS of the ampullary region. Jaundice is commonly associated with marked hepatomegaly, and this combination may be confused with forms of icteric and cholestatic hepatitis. Obstructive jaundice occurs relatively late in the course of the disease, i.e., when the tumors are adequately large and then obturating the lumina, because bile flow continues between the intraluminal tumor projections. As in other malignancies (Staalman and Umans 1993), HBRMS may be associated with the paraneoplastic syndrome, hypertrophic osteoarthropathy (Geary et al. 2004). Radiologically, HBRMS may mimic choledochal cyst (Zampieri et al. 2006; Rebollo Guelar et al. 2013; Margain-Deslandes et al. 2013).

HBRMS of the Intrahepatic Bile Ducts

The intrahepatic biliary tree is the second most common manifestation of HBRMS, this tumor being more common in the extrahepatic duct system (see below). Sonography, conventional radiology, and CT display rather typical and, sometimes, pathognomonic changes. They comprise intrahepatic masses of heterogeneous structures with cystic areas and septations and bile duct stenosis with prestenotic duct dilatation (Witcombe 1979; Ruymann et al. 1985; Williams and Sheward 1986; Arnaud et al. 1987; Lee et al. 1996; Donnelly et al. 1998). MRI of the lesions show high signal intensity with heterogeneous enhancement in T2-weighted single-shot fast spin-echo axial MR images (Geary et al. 2004).

HBRMS of the Extrahepatic Bile Ducts

HBRMS involvement of the common bile duct is rare, but important pathology of the lower biliary tract in children, and is the most common site of HBRMS. Leriche (1934) reported the first case. The patient was a 4.5-year-old boy who presented with jaundice and a huge abdominal mass. At laparotomy, an enormous cystic dilatation of the common bile duct was seen. RMS of the large bile

duct can mimic a choledochal cyst (Nemade et al. 2007; Ali et al. 2009). The dilated duct contained copious bloody, mucoid fluid and a tumor the size of a child's head (Leriche 1934). Several other cases were reported since.

Selected References Goeters 1941; Willis 1948; Werner 1951; Horn et al. 1955; Farinacci et al. 1956; Bernheim et al. 1962; Delany et al. 1966; Gout et al. 1974; Majmudar and Kumar 1976; Sarrazin et al. 1977; Taura et al. 1977; Phatak and Prabhu 1982; Friedburg et al. 1984; von der Oelsnitz et al. 1991; Verstandig et al. 1991; Sanz et al. 1997; Berghoff et al. 1998; Prasad et al. 2003; Aggarwal et al. 2004; Kirli et al. 2012.

Ultrasonography typically shows biliary dilatation (Friedburg et al. 1984; Arnaud et al. 1987; Geoffray et al. 1987) and a space-occupying process or intraductal mass within the common duct, usually surrounded by fluid which may reflect necrosis (Friedburg et al. 1984; Geoffray et al. 1987). The portal vein may be displaced by large lesions, but portal vein thrombosis has not been noted (Geoffray et al. 1987). Color Doppler imaging has revealed numerous abnormal tumor arteries with low resistive index (Roebuck et al. 1998). CT images disclose low-density irregularly shaped masses within the dilated duct, with hypodense and heterogeneous attenuation patterns (Geoffray et al. 1987). Low attenuation areas within the tumor have been reported (Miller and Greenspan 1985; Caty et al. 1990; Patil et al. 1992; Linstedt-Hilden and Brambs 1994). With contrast enhancement, the tumors show four patterns: strong heterogeneous, incomplete globular, mild, and none (Roebuck et al. 1998). The masses may be surrounded by fluid collections which represent bile fluid between the duct wall and the protruding tumor masses (Roebuck et al. 1998). This pattern is also seen in cholangiograms, showing irregular luminal defects (Friedburg et al. 1984), a large mass in the duct lumen (Sanz et al. 1997), or the replacement of the common duct by a multilocular cystic lesion associated with prestenotic marked bile duct dilatation (Kitagawa and Aida 2007). This lesion pattern has been described as early as 1979 by the use of percutaneous transhepatic cholangiography (Cannon et al. 1979). In the case of RMS located to the hepatic hilum, multilocular cystic lesions are seen in US and CT (Kitagawa and Aida 2007). The characteristic luminal alterations caused by RMS can also be demonstrated by use of endoscopic retrograde cholangiopancreatography (ERCP; Himes et al. 2008). In case of marked bile duct dilatation caused by stenosis, choledochal cyst was a frequent diagnosis before surgery (Ruymann et al. 1985; Caty et al. 1990; von der Oelsnitz et al. 1991; Tireli et al. 2005). It has been reported that coronal CT sections were particularly useful in demonstrating the complex relationship of common bile duct RMS to the porta hepatis, pancreas, and duodenum (Verstandig et al. 1991). In MR images, the tumors show predominantly low signal intensity on T1-weighted images with intense but inhomogeneous contrast enhancement. On T2-weighted images, the tumors are moderately to markedly hyperintense (Roebuck et al. 1998).

Pediatric Rhabdomyosarcoma of the Ampullary Region

Embryonal RMS located to the ampullary region is a very rare variant of hepatobiliary RMS causing biliary obstruction. This pathology was first described in 1968 based on autopsy findings on a 6-year-old child (Isaacson 1978). In another case, a 3-year-old boy, exploratory laparotomy performed for obstructive jaundice and a cystic ampullary mass at imaging showed a cystic tumor within the posterior aspect of the pancreatic head, contiguous with the distal common bile duct. The cystic mass was opened, and botryoid, gelatinous material was spontaneously extruded from the cavity. Histology displayed embryonal RMS. Pancreaticoduodenectomy followed by adjuvant chemotherapy and irradiation resulted in long-term survival (Caty et al. 1990). A third case related to a 20-month-old baby girl who presented with 1-month history of progressive jaundice. Contrast-enhanced CT showed a large heterogeneous mass which appeared to arise from the

ampullary region causing biliary dilatation. Endoscopy revealed a large ulcerated lesion in the second part of the duodenum. In the resection specimen, an exophytically growing tumor of 11 cm diameter centered on the ampulla was found. Histology showed ampullary embryonal RMS with invasion of the distal common bile duct, duodenal wall, and pancreas (Perera et al. 2009).

HBRMS in Choledochal Cyst

Choledochal botryoid RMS was described in a 22-month-old boy who developed obstructive jaundice. Imaging first suggested cystic lymphangioma, but the cystic space was found at surgery to be a choledochal cyst harboring RMS (Sassi et al. 2008). A second reported patient was a 6-year-old girl who presented with recurrent jaundice and loss of weight. A large abdominal mass was palpable, and US and CT revealed a large subhepatic mass with multiple septations. The common bile duct opened directly into the mass, and the mass was continuous with the intrahepatic radicles. The resection specimen showed that the mass was choledochal cyst with secondary RMS (Patil et al. 1992).

Pediatric Rhabdomyosarcoma of the Liver Not Related to the Biliary Tract

Primary intrahepatic rhabdomyosarcoma not related to the biliary tract is extremely rare in children. Pack and Miller (1956) reported on a 14-year-old girl with a large tumor in the right liver lobe. Almost the entire lobe was replaced by a cystic thick-walled mass (up to 15.5 cm diameter) filled with amorphous necrotic brown-stained material and thin blood-tinged fluid. The histology showed embryonal RMS. Scheiden et al. (1988) described a 7-year-old boy who had presented with painful hepatomegaly and huge tumor in the left liver lobe. Surgical resection revealed an 18 cm-sized tumor in the left lobe, with extensive central regressive and cystic change. Histology showed embryonal RMS with immature-looking, desmin-positive tumor cells. The patient of Huang and coworkers (2003) was an 8-year-old boy presenting with abdominal pain, spiking fever, and a rapidly growing abdominal mass. Imaging revealed a large solid tumor in the right liver lobe, and the mass was removed by an extended right hepatectomy. Histology showed pleomorphic RMS. The patient died 2 months after resection due to tumor recurrence and massive internal hemorrhage. A second report described a 10-year-old boy who had a voluminous tumor at the inferior face of the right liver lobe, associated with thrombosis of the retrohepatic part of the inferior caval vein. The histology was embryonal rhabdomyosarcoma (Chat et al. 2007).

Rhabdomyosarcoma of the Hepatic Pedicle

In the pediatric age group, the hepatic pedicle or porta region represents an anatomical compartment where unusual tumors may arise, including liposarcoma and rhabdomyosarcoma. Embryonal RMS was observed in the mesenchyme of the liver pedicle in a 10-year-old child (Ferlicot et al. 1999).

Macroscopic Pathology

Most HBRMS exhibit a growth pattern centered on the intrahepatic bile ducts. Apart from this main pattern, RMS may also show a predominantly invasive growth pattern, with marked infiltration of the liver substance (Linstedt-Hilden and Brambs 1994). The tumor may present in the form of a mass filled with hemorrhagic and necrotic material (Kebudi et al. 2003). In resection specimens, one may note polypoid tumor masses that take their origin in the bile duct wall and protrude into the dilated bile duct lumen, sometimes resulting in the typical grape-like morphology that gave this RMS its name (botryoid meaning, grape-like). Resected polypoid, botryoid growths show a striking resemblance to nasal polyps. This

botryoid pattern may result in voluminous papillary-polypoid growths (Leriche 1934; Davis et al. 1969). Smaller resection specimens may only consist of soft, polypoid, gelatinous, and/or transparent tissue fragments. In RMS mainly showing an intrahepatic growth pattern, the cut surface of resection specimens may show, within the mass, bulging tumor nodules representing the polypoid intraductal lesions (Lack et al. 1981).

Histopathology

The histopathology of HBRMS is, as such, the same for intra- and extrahepatic tumors and is therefore summarized for both paragraphs (Figs. 1, 2, and 3; Bässler and Voth 1962). Non-necrotic tumors have an intact surface toward the biliary lumen. Already Sheehan (1930), in his report of a large intrahepatic HBRMS, emphasized that "the mucous columnar epithelium of the included cysts and the bile ducts remained intact and healthy. Thus in the extension down the common bile-duct the large mass of tumour cells had spread underneath the epithelium which it had raised undamaged on its surface." The intact biliary epithelium (with some degrees of epithelial disarray and/or atrophy) is expectedly positive for cytokeratins 7 and 19 and seems to play a significant role for the botryoid growth pattern. The subepithelial tumor generally shows a low cellularity, except a characteristic subepithelial zone of high cellularity, the so-called cambium layer well known from other mucosal sites of RMS. This layer contains most frequently embryonal rhabdomyoblasts, round cells with a myogenic cytoplasm, and racquet and strap cells. The latter possess large nuclei and dark, clumped chromatin and may show cross-striations. Within the cambium, foamy macrophages laden with lipids are not infrequently found (Davis et al. 1969). Interspersed among these neoplastic cells is a myxoid tissue component which becomes more prominent toward deeper layers of the tumor, where the neoplastic cells are more commonly stellate or spindled. The loose aspect of this tissue component may pose considerable differential diagnostic difficulties, because it may be misinterpreted as reactive edematous tissue in biopsies. This myxoid tissue may grow around septal and interlobular bile duct, producing a characteristic tissue sheath. Small bile ducts are usually surrounded by a hypercellular cambium which is in turn surrounded by a looser myxoid tissue (Davis et al. 1969). This tumor tissue induces stenotic changes with the formation of small bile duct cysts.

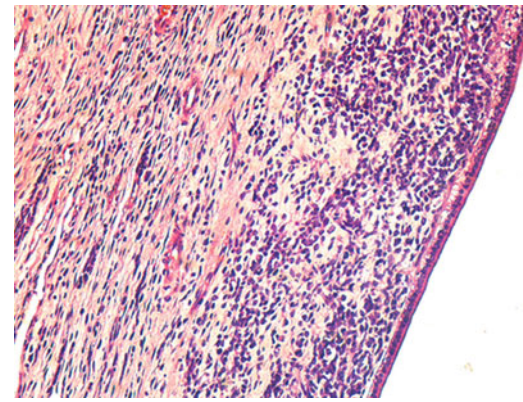

Fig. 1 Hepatobiliary rhabdomyosarcoma, embryonal type. Immature tumor cells form a hypercellular subepithelial layer in a bile duct, the so-called cambium layer (hematoxylin and eosin stain)

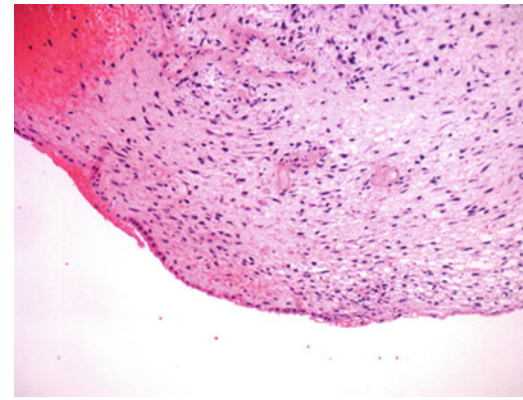

Fig. 2 Hepatobiliary rhabdomyosarcoma, embryonal type. Some of these neoplasms produce polypoid lesions with a loose hypocellular tumor tissue, protruding into bile ducts (botryoid rhabdomyosarcoma; hematoxylin and eosin stain)

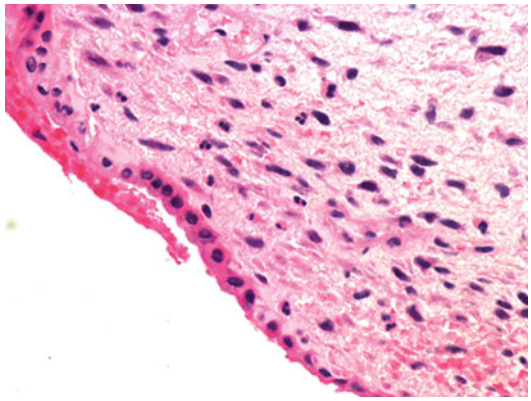

Fig. 3 Botryoid hepatobiliary rhabdomyosarcoma. The embryonal rhabdomyosarcoma consists of slender rhabdomyoblasts. The lesion is covered by damaged biliary epithelium. Botryoid rhabdomyosarcomas may lack a cambium layer (hematoxylin and eosin stain)

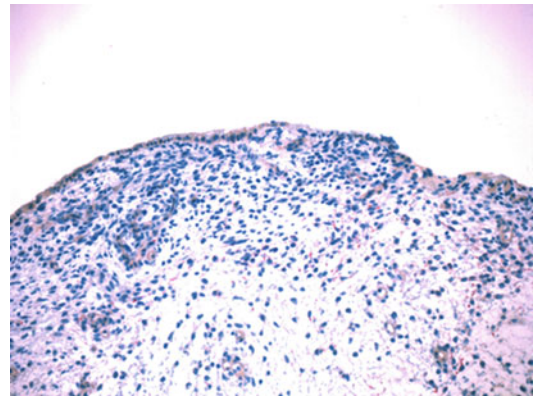

Fig. 4 Hepatobiliary rhabdomyosarcoma, embryonal type. Tumor cells in the cambium layer and stellate cells deeper in the loose tissue are desmin positive (desmin immunostain)

Immunohistochemistry

Immunohistochemistry has been considered to be the decisive diagnostic method in more than 20 % of RMS. RMS cells are consistently reactive for vimentin, and they express the skeletal muscle cell lineage markers, desmin, myogenin, and myogenic regulatory protein D1/MyoD1 (Fig. 4; Dias et al. 1990; Parham et al. 1991; Cessna et al. 2001; Sebire and Malone 2003). In a study of 956 cases (the majority of course being extrahepatic tumors), it was found that myogenin and MyoD1 were equally sensitive (positive for 97 % of RMS cases), with both also showing similar specificity (90 % vs. 91 % of cases), but expression was more consistent in alveolar RMS (ARMS) than embryonal RMS/ERMS (Morotti et al. 2006). In particular, nuclear myogenin expression is more pronounced in ARMS than in ERMS (Morgenstern et al. 2008). In pediatric liver tumors, polyclonal desmin and muscle-specific actin were variably immunoreactive in undifferentiated embryonal sarcoma (UES) and RMS; however, myogenin and MyoD1 were uniformly negative in UES and routinely positive in the majority of hepatobiliary RMS (Nicol et al. 2007). Embryonal RMS did not stain for the paired box transcription factor, PAX5, while 67 % of alveolar RMS were positive (Sullivan et al. 2009). It has been reported that diffuse myogenin expression in soft tissue pediatric RMS is an independent marker of poor survival (Heerema-McKenney et al. 2008). RMS with a component of round cells may be difficult to distinguish from other blue small cell tumors, e.g., neuroblastoma. Peripherin and alpha-internexin are specifically expressed in neuroblastoma but not in RMS. Microtubule-associated protein 1B (MAP1B) is strongly and diffusely expressed in all neuroblastomas but is also detectable in RMS. Nestin is diffusely expressed in RMA but also (multifocally) in a fraction of neuroblastomas (Willoughby et al. 2008). Part of RMS (more commonly ARMS than ERMS) may express anaplastic lymphoma kinase (ALK), most likely independent of the chromosomal fusion status (Corao et al. 2009). The intraluminal polypoid tumor masses in botryoid hepatobiliary RMS are lined by the preexisting cholangiocyte population (Fig. 5).

Ultrastructure

At electron microscopy, cells remote from the biliary mucosal surface are usually separated by a greater amount of loose ground substance containing few scattered collagen fiber bundles. Small aggregates of tumor cells may be partially surrounded by basement membrane. Many tumor

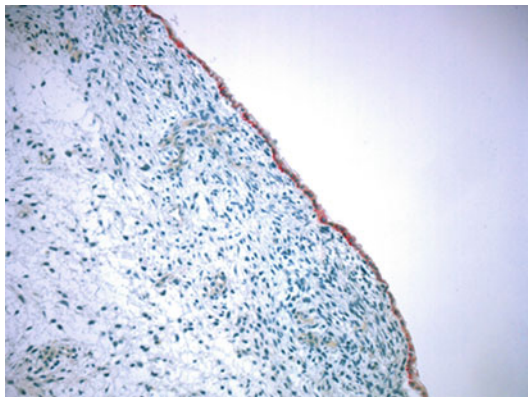

Fig. 5 Hepatobiliary rhabdomyosarcoma, embryonal type. A cytokeratin 19-positive cholangiocyte lining covers the bulging tumor. Note the vague cambium layer and the loose tumor tissue with stellate cells in the deeper part of the duct (CK19 immunostain)

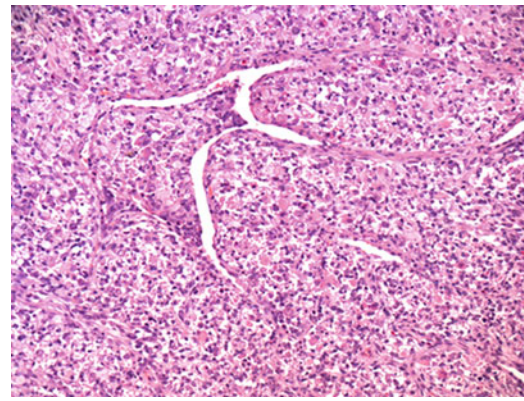

Fig. 6 Alveolar rhabdomyosarcoma of the liver (hematoxylin and eosin stain)

cells are so immature that a proper ultrastructural classification is not possible, but there are also rhabdomyoblasts with variable degrees of differentiation and sometimes well-defined, transversely oriented electron-dense areas and/or incomplete or deformed sarcomeres (Lack et al. 1981). In one electron microscopic study, the neoplasm was shown to consist of three types of cells: polygonal, elongated, and small cells. In contrast to the first two cell types, which revealed moderate to large amounts of myofibrils and occasional A, I, and Z bands, the small cell population was poor in myofibrils, but had dilated ER profiles (Taura et al. 1977).

Biology of Disease

HBRMS is an aggressive lesion that may infiltrate the liver substance and cause local and remote tumor spread, although this type of RMS is more prone to invasion of contiguous structures (Davis et al. 1969; Ruymann et al. 1985). In about 30 % of cases, metastases to the peritoneum, omentum, and locoregional lymph nodes occur. Distant metastases have been found in the lungs, pericardium, and bones of skull and extremities (Davis et al. 1969).

HBRMS remained incurable for a very long time period, until a child was cured by partial surgical resection, radiotherapy, and chemotherapy in 1971 (Akers and Needham 1971). In 1985, the Intergroup Rhabdomyosarcoma Study Group (IRSG) reported ten cases of HBRMS treated on the IRS I and IRS II protocols (Ruymann et al. 1985). Four of these ten patients survived, showing that, at that time, outcome was still poor. Aggressive surgery had been proposed (Martinez et al. 1982; Schweizer et al. 1994), but an analysis of 25 eligible patients with HBRMS enrolled in IRSG studies I through IV from 1972 to 1998 showed that gross total resection is rarely possible despite aggressive surgery and that outcome is good despite residual disease after surgery (Spunt et al. 2000). The signs and sequelae of obstructive jaundice/cholestasis may be relieved by external and internal-external biliary drainage (Roebuck and Stanley 2000). RMS located in soft tissues and classical sites will more and more be stratified for risk, e.g., via immunohistochemical marker expression or gene expression profiling (metagene patterns; Bortoluzzi et al. 2005). This has not yet been accomplished with hepatobiliary RMS, owing to the rarity of these lesions.

Hepatobiliary Alveolar Rhabdomyosarcoma

Hepatobiliary alveolar RMS is a very rare neoplasm (Fig. 6). Only in two reports there is evidence of an alveolar component. In a pediatric

hepatic rhabdomyosarcoma with striated tumor cells and associated with mucin-producing cysts reported in 1930 (Sheehan 1930), one figure of the publication depicts what seem to be alveolar rhabdomyosarcoma. The other patient with an alveolar hepatic RMS was an adult male (68 years) with a tumor in the right liver lobe (Shibata et al. 1987).

Primary Rhabdomyosarcoma of the Bile Ducts in Adults

Primary RMS of the large bile ducts in adults is extremely rare and has been described in the common bile duct (Aldabagh et al. 1986). The 40-year-old female patient presented with jaundice of short duration. A transhepatic percutaneous cholangiogram revealed an obstructive lesion involving the common bile duct with marked dilatation of the biliary system. At laparotomy, the tumor grossly involved the wall of the choledochus and extended into the cystic duct and common hepatic duct. Histologically, one noted an infiltration of the full thickness of the wall and the surrounding fatty tissue by a desmin- and myoglobin-reactive RMS with a distinct cambium layer. Elsewhere, the cells infiltrated in a single-file pattern with a desmoplastic reaction around normal structures (Aldabagh et al. 1986). Rhabdomyosarcoma may also develop in choledochal cysts. Pleomorphic RMS within a choledochal cysts has been described as a cause of obstructive jaundice (Tufail et al. 2006).

Primary Rhabdomyosarcoma of the Liver in Adults Not Clearly Related to the Biliary Tract

Adult-type rhabdomyosarcoma has been classically defined as a pleomorphic sarcoma with desmin expression occurring in the extremities and the trunk of adult patients. Classification of these lesions has been complex until a consensus was found (Palmer, SIOP, NCI, and International Classifications; review: Parham 2001). Histologically, these neoplasms occur in three categories, i.e., spindle cell RMS, pleomorphic RMS, and mixed forms (Stock et al. 2009). Spindle cell RMS seems to be a variant of embryonal RMS, and this tumor also occurs in the form of sclerosing spindle cell RMS (Gavino et al. 2010). Alveolar RMS is a distinct entity different in many aspects from classical adult-type RMS and shows up in a classical form and variants, including the clear cell variant. RMS occurring in the adult liver as a primary tumor seems to have complex features, in that also embryonal-type RMS and variants thereof have been reported.

Selected References Miller and Pack 1956; Mori et al. 1979; Hatanaka et al. 1983; Watanabe et al. 1983; Morimoto et al 1986; McArdle et al. 1989; Cote and Urmacher 1990; Hayakawa et al. 1990; Zornig et al. 1992; Bürrig and Knauer 1994; Hiyama 1995; Tominaga et al. 1995; Meyer-Pannwitt et al. 1996; McRae and Lee 2005.

Two tumors were reported to be alveolar RMS (Shibata et al. 1987; Schoofs et al. 2011). In one of these neoplasms, FISH analysis revealed PAX3/FOXO1A fusion (Schoofs et al. 2011). The hepatic cell of origin for these sarcomas is not known. Hepatic RMS in the adult may coexist with synchronous hepatocellular carcinoma in the same liver (Hatanaka et al. 1983; Morimoto et al. 1986; Hayakawa et al. 1990).

Pathology

Macroscopically, the tumors were described to be mass lesion with a nodular border, whitish to yellowish, and either soft or firm. Sometimes, hemorrhage and necrosis occur (Watanabe et al. 1983). Embryonal RMS classically consists of small, undifferentiated round to spindled or stellate cells that may resemble embryonic skeletal muscle cells. These cells are embedded in a myxoid matrix, causing a typical "loose" aspect of the tissue, with hypocellular and hypercellular areas. Differentiation of the cell lineage presents as an increasing number of cells with eosinophilic cytoplasm ("tadpole cells" and "strap cells"). These cells contain myofibrils, may show cross-

striation, and are rhabdomyoblasts. This phenotype is the classical variant of embryonal RMS. Part of the tumor cells may show distinct angulation of the muscle fibers – the so-called broken straw sign. The spindle cell variant has not been found in the liver so far. Immunohistochemically, more than 95 % of the tumor cells are reactive for desmin (Altmannsberger et al. 1985) and for HHF35, a monoclonal antibody directed against muscle actins (Schmidt et al. 1988). Nuclear positivity for myogenin is also diagnostically very useful (Cessna et al. 2001).

Rhabdomyosarcoma in/of the Inferior Vena Cava

Sarcoma of the inferior vena cava is usually leiomyosarcoma, with or without associated Budd-Chiari syndrome (see the respective chapter). More than 100 cases of this distinct entity have been reported. In contrast, other sarcomas are exceptional findings in this location. In particular, this refers to vascular RMS, which is mainly known from the pulmonary trunk and the pulmonary artery (Watanabe et al. 1985). A 63-year-old male patient had obstruction of the inferior vena cava caused by intraluminal pleomorphic RMS. This tumor was resected, but the patient died of local recurrence. Autopsy revealed RMS extending from the inferior vena cava just above the right renal vein to the right atrium and involving the caudate lobe of the liver. The tumor was associated with Budd-Chiari syndrome. It was difficult to decide whether the tumor took its origin in the vena cava or the liver (Fujita et al. 1993).

Intraperitoneal Involvement in Pediatric Rhabdomyosarcoma

Peritoneal manifestations of pediatric malignancy chiefly relate to desmoplastic small round cell tumors, lymphoma, germ cell tumors, neuroblastoma, Wilms tumor, and secondary seeding of intracranial tumors by ventriculoperitoneal shunts. Intraperitoneal neoplastic involvement in RMS is not common but may get into differential diagnostic considerations in case the lesions develop on the liver surface. It has been reported that approximately 10 % of children with abdominopelvic RMS may have intraperitoneal involvement either at the time of diagnosis or subsequently. The manifestations of intraperitoneal involvement comprise enhancing nodules or masses, a pseudomyxoma peritonei-like appearance, omental caking, and ascites (Chung et al. 1998). Intraperitoneal involvement has been observed in pelvic RMS, with enhanced nodular lesions in CT also located around the liver and in the lesser sac (Oto et al. 2001).

Liver Metastasis in Pediatric and Adult Rhabdomyosarcoma

RMS may metastasize to almost all organs, but there are instances where patients with RMS present with a distinct mode of diffuse metastasis. These cases may be called the leukemic variant of RMS, because the children can have fever, generalized malaise, bone pain due to marrow involvement, and circulating RMS cells in the peripheral blood smear resembling leukemia (Cohen 1992). Hepatic metastases have also been described for sclerosing RMS (Kikuchi et al. 2013).

Hepatic Rhabdomyomatous Tumors

In the pediatric age group, rhabdomyomas typically occur in the heart and here mostly in the context of tuberous sclerosis. In 1862, Friedrich Daniel von Recklinghausen reported pigeon egg-sized myomas found in the heart of a newborn (von Recklinghausen 1862), and these lesions were termed rhabdomyoma by the German physician and pathologist, Friedrich Albert von Zenker (1864). In childhood, rhabdomyomatous tumors may arise in the liver as a late sequela of fetal rhabdomyomatous nephroblastoma. This lesion is considered to be a predominantly monophasic mesenchymal variant of Wilms tumor, sometimes bilateral, which has not been seen in patients older than 4 years. It exhibits a less aggressive biology than standard

Wilms tumor despite its usually much larger size (Wigger 1976; Eble 1983; Joseph et al. 2003). Primary and metastatic lesions of this nephroblastoma variant can undergo maturation (Ishikawa et al. 2001). In a 14-year-old boy, a tumor with the features of a fetal rhabdomyoma arose in the liver 13 years after treatment for fetal rhabdomyomatous nephroblastoma (van der Kwast et al. 1992).

Other Liver Tumors with a Rhabdomyocytic/ Rhabdomyoblastic Differentiation

In the pediatric age group, hepatoblastoma may develop rhabdomyoblastic components within the spectrum of mixed epithelial and mesenchymal hepatoblastoma with teratoid features (Shabanov et al. 1981). However, there are also pediatric liver tumors with a rhabdomyoid component that cannot easily be allocated to mixed hepatoblastomas. Williams (1953) described, in 2-year-old boy, a neoplasm which he termed liver tumor of mixed type. The tumor presented as a cystic mass located in the right liver lobe. At necropsy, the mass consisted of cysts with a diameter ranging from 1 to 3 cm and solid components. The largest cystic mass had a fibrous capsule and contained thin leaves of tissue separated by a glairy mucous substance. Microscopically, the cysts were lined by a mucus-secreting cuboid or flattened epithelium. The cysts were separated by a mesenchyme that showed embryonic features and hypercellular areas, containing round cells, spindle cells, or strap-like cells and focally immature muscle cells with cross-striation. A similar tumor had been described by Sheehan (1930). A 6-year-old girl showed, at necropsy, a liver tumor of 12 cm diameter. This tumor grossly consisted of whitish tissue and was fairly soft, but showed little necrosis and no hemorrhage. It had a well-defined but not encapsulated edge. An extension had spread down the bile duct, with formation of a bulging and bulbous intraluminal mass. Histology in part corresponded to rhabdomyosarcoma, with striated tumor cells. In addition, however, there were clusters of cysts associated with the tumor, measuring up to 2 cm in diameter. The cysts were lined by single layer of columnar epithelium which secreted mucin. There are primary hepatic tumors which co-express features of both, hepatocellular carcinoma and rhabdomyosarcoma (so-called rhabdomyosarco-hematoma; Goldman and Friedman 1969), or features of combined cholangiocarcinoma and rhabdomyosarcoma. These carcinosarcomas are discussed in a separate chapter. Gastrointestinal stromal tumors (GIST) can show, both in the primary tumor and liver metastasis, rhabdomyosarcomatous differentiation after tyrosine kinase inhibitor therapy (Liegl et al. 2009). Schmid and coworkers reported a liver tumor observed in a 36-year-old female patient who had developed intermittent fever and increasing asthenia (Schmid et al. 1979). In a right hepatectomy specimen, they found a spherical, well-circumscribed tumor of 8.5 cm diameter, composed of a whitish-gray, moderately firm tissue with small cystic areas. Histologically, the tumor did not invade the surrounding liver tissue, but rather caused perifocal tissue compression. The interface between the tumor and the liver was characterized by a dense inflammatory infiltration. The neoplasm itself consisted of elongated spindle cells and large and pleomorphic, often multinucleated cells with only rare mitotic figures. Some of the cells displayed a ribbon-shaped appearance like skeletal muscle fibers, however without cross-striation. Also the interior of the tumor showed an inflammatory reaction. These findings suggested a rhabdomyoblastic origin, but ultrastructurally, the tumor cells shared features with hepatocytes. Hence, this neoplasm may represent an example of epithelial-mesenchymal transition.

Abstract

In the liver several adipocytic tumors and fatty lesions mimicking these neoplasms can develop. Primary lipomas of the liver are rare lesions that are either incidental findings or may produce mass effects, because these tumors can grow to very large size. Histologically, they consist of mature adipocytes. Hepatic lipoma has to be distinguished from adipocyte-rich angiomyolipoma, a tumor of the PEComa group, and from pseudolipoma of Glisson's capsule. Other benign hepatic tumors with an adipocyte or adipocyte-like component include myelolipoma and hibernoma. The malignant counterpart of lipoma, liposarcoma, is an exceedingly rare primary hepatic malignancy. Most liposarcomas found in the liver are in fact metastases. Primary hepatic liposarcomas are often large lesions. Histologically, the diverse patterns known for soft tissue liposarcomas are also observed in the respective liver tumors. Adipocytic neoplasms of the liver can be mimicked by other fat-rich lesions, including focal fatty change and focal fatty sparing of the liver.

Lipoma of the Liver

Introduction

Hepatic lipomas are unusual lesions, which previously have been found as incidental findings at autopsy, but have been detected in recent times more frequently in vivo, chiefly owing to refined imaging techniques. Descriptions date from as early as 1938 (Afekowna 1938) and are difficult to judge with respect to the true nature of the lesion, but more cases have been reported from about 1950 onwards. Most hepatic lipomas have been reported individually, four cases were reviewed in 1976 (Ishak 1976), and a larger series of 12 lesions was published in 1984 (Goodman and Ishak 1984). Since 1951, more than 30 cases have been reported.

Selected references: (Dirschmid and Kiester 1979; Hoeffel et al. 1977; Hübener and Hippeli 1980; Kampmann and Allmendinger 1983; Ramchand et al. 1970; Young 1951; Pounder 1983a; Bugovics 1988; Fulcheri 1987; Garant and Reinhold 1996; Liessi 1987; Mathieu et al. 1997; Pham et al. 1986; Prayer et al. 1992; Scapati et al. 1994; Shima et al. 1986; Souz 1984; Takagi et al. 1994; Takayasu 1987; Tarasiuk et al. 1991; Horton et al. 1999; Delis et al. 2008; Martin-Benitez et al. 2012; Nakamura et al. 2009; Petri et al. 2003; Puljiz et al. 2012; Szentpali et al. 2000).

Clinical Features

Clinically, hepatic lipomas are usually incidental findings at imaging or at autopsy, but large lesions may produce hepatic mass effects. The age range of these tumors is large, and there is no sex predilection, as far as can be judged from the cases reported so far. The clinical course is benign; in particular there is no evidence that hepatic lipomas have changed into a malignant tumor. Hepatic lipomas are usually not associated with preexisting liver disease, with the exception of hepatic steatosis. In a study of 92 benign hepatic lesions analyzed with MR imaging, a statistically significant relationship between hepatic lipomas and liver steatosis was found, a relationship suggested to be related to a common insulin resistance mechanism (Martin-Benitez et al. 2012).

Pathology of Hepatic Lipoma

Macroscopy

Hepatic lipomas occur as a usually solitary mass that grossly presents as circumscribed but not completely encapsulated tumors typically with a diameter of few mm to few cm (Figs. 1 and 2), but they can grow to considerable size (giant hepatic lipoma; 15 cm, (Bornstein-Quevedo et al. 2000); 21 cm, (Sonsuz et al. 1994). Multiple hepatic lipomas are exceptional findings (Delis et al. 2008). Most lipomas exhibit a more or less spherical shape and are situated deeply within the organ, but pedunculated variants have also been observed. Hepatic lipoma may occur together

Fig. 1 Primary lipoma of the liver. A *yellow* lobulated tumor displays an expanding growth pattern

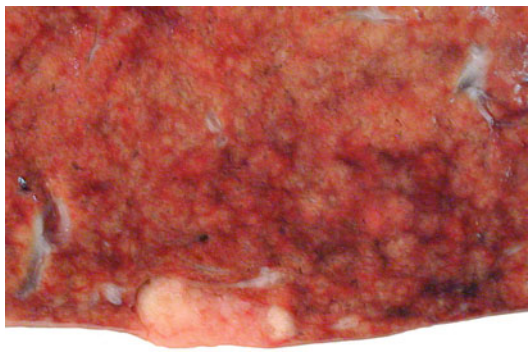

Fig. 2 Small subcapsular lipoma of the liver

with other liver tumors, such as hepatocellular carcinoma (Jover et al. 2001), but this may rather be a coincidental finding than a causal relationship.

Histopathology

Histologically, hepatic lipomas chiefly consist of mature-looking adipocytes, similar to lipomas in other locations. In large lesions one may note small regression foci with accumulation of foamy macrophages. At the border between the tumor and the adjacent liver substance, there is usually not a complete pseudocapsule, and adipocytes are mostly in direct contact to parenchyma, with relatively few cells interdigitating with the lobular tissue. However, there are instances where an incomplete fibrous interface had been observed (Szentpali et al. 2000). Particularly in case of large lesions, there is perifocal atrophy of adjacent liver tissue. Diagnosis of hepatic lipoma can be achieved by aspiration cytology (Langsteger et al. 1990).

Hepatic Lipomas vs. Fat-Rich Angiomyolipoma

A distinct situation are hepatic adipose tissue tumors developing in the context of tuberous sclerosis (Hirasaki et al. 1999; Schneider-Monteiro et al. 2003). It is difficult to judge whether the lesions classified as hepatic lipoma were in fact true lipomas or rather fat-rich hepatic angiomyolipomas. However, in one case a liver tumor was removed, histologically shown to be lipoma and being HMB-45 negative, in contrast to renal angiomyolipoma found in the same patient (Schneider-Monteiro et al. 2003). In a 30-year-old female patient with renal angiomyolipoma associated with tuberous sclerosis, abdominal sonography revealed multiple high echoic round tumors with acoustic shadows in the liver. Subsequent dynamic CT showed that these multiple lesions had contrast enhancement suggesting that these tumors were more likely angiomyolipoma than lipoma. A liver biopsy specimen appeared to have only adipose tissue, resulting in the diagnosis of hepatic lipomatous tumor (Hirasaki et al. 1999). However, it cannot be excluded that these lesions were adipose-predominant angiomyolipomas (see the chapter on these tumors).

Differential Diagnosis

The clinicopathologic differential diagnosis of hepatic lipoma includes fat-rich hepatic angiomyolipoma, hepatic pseudolipoma, the exceedingly rare lipoma of Glisson's capsule, and lipomas located close to the liver, e.g., lipoma of the inferior vena cava (Chou et al. 2001; Grassi et al. 2002; Ubrig-von Barany et al. 2002). The latter is a controversial lesion, because "lipoma" of the inferior vena cava, particularly in its intrahepatic portion, may in at least part of the

cases represent a pericaval and probably normal adipose tissue accumulation rather than a neoplasm. In fact, several cases of a fat mass-like lesion adjacent to and/or projecting into the inferior vena cava, superior vena cava, brachiocephalic vein, and femoral vein have been described, based on diverse imaging procedures, first in 1992 based on 11 cases (Gibo et al. 2001; Han et al. 1997; Hines et al. 1999; Katz and Goffner 2002; McClure et al. 2001; Miyake et al. 1992; Pan et al. 1995; Perry et al. 1994; Raju and Austin 2001; Sheafor et al. 1998; Thorogood and Maskell 1996; Tobias and Berkowitz 1992; Trabut et al. 1999; Vinnicombe et al. 1994). Between 1992 and 1999, more than 30 cases of such lesions spatially related to the subdiaphragmatic portion of the intrahepatic segment of the inferior vena cava have been reported, and some have termed these benign fat tissue structures as intravascular lipoma (McClure et al. 2001; Pan et al. 1995; Perry et al. 1994). A localized fat collection adjacent to the subdiaphragmatic inferior vena cava may mimic intracaval fat on axial CT scans owing to acute angulation of the IVC, probably as a result of anatomic variation (Han et al. 1997).

Lipoma of the Bile Ducts

Benign and malignant lipomatous tumors represent one of the most uncommon neoplastic lesion groups in the biliary tract. In a review on benign tumors of the extrahepatic bile ducts reported in the literature over 100 years, only four lipomatous lesions were identified (reviewed in Chu 1950). Three cases cited as lipomatous tumors that had developed in the extrahepatic bile ducts were associated with biliary retention and jaundice. However, none of these lesions was confirmed by histologic studies (Bouisson 1843; Ehrmann 1843); Dieckman as cited by Devic and Gallavardin 1901). The fourth reported case referred to a girl 3 years of age who clinically manifested progressive jaundice, clay-colored stools, and dark saffron urine characteristic of biliary obstruction. The child deceased and postmortem examination revealed a small "fatty growth" at the junction of the cystic and common bile ducts which was of the size of a large "horsebean." It was described to be a yellowish white, homogeneous, nonvascular growth "which gave a greasy stain to paper." The introduction of a probe showed the cystic and common ducts to be obstructed. The gallbladder "was small and flaccid and contained some grayish seromucoid secretion, which was very unlike its ordinary contents" (Wardell 1869).

Apart from lipoma, liposarcoma of the extrahepatic bile ducts has also been described (Fukusato and Machinami 1996). Lipomas located to the most distal compartment of the large bile duct, or specifically the juxtapapillary region (juxtapapillary lipoma), have been reported somewhat more frequently (Butters 1998; Koninger et al. 1994). The differential diagnosis would include an increase of mural adipose tissue of extrahepatic ducts seen in general obesity and an expansion of the adipose tissue around ducts (peribiliary fat; Shaub et al. 1975). It should be kept in mind that a distinct compartment of adipose tissue is physiologically present at the hepatic hilus (the hilar fat pad; Belloir et al. 1982). Hilar adipose tissue undergoes changes subsequent to corticosteroid therapy (Dietrich et al. 1997).

Lipoma (True Lipoma) of Glisson's Capsule

The first case of apparently true lipoma occurring in Glisson's capsule was reported in 1990 (Sossai and Barbazza 1990). In this 75-year-old female patient with fatal stroke and pneumonia, autopsy showed, on the anterior border of the left liver lobe and incorporated within Glisson's capsule, a yellow mass measuring 3.3 cm in maximum diameter. Histologically, this nodule had a distinct multilobular pattern consisting throughout of mature fat cells, showing only slight variation in size and shape. The lesion was divided by thin trabeculae of fibrous tissue and had a clear vascular network. Importantly for the differential diagnosis with pseudolipoma of Glisson's capsule (see below), the adjacent liver capsule was

populated by small clusters of mature adipocytes.

Pseudolipoma of the Hepatic (Glisson's) Capsule

Introduction

Pseudolipomas of the hepatic capsule, first described in 1929 (Rolleston and McNee 1929), are nonneoplastic solitary lesions consisting of damaged adipose tissue, localized to the hepatic capsule and usually not exceeding 2 cm in diameter (mean diameter for 18 cases reported in the literature, 1.14 cm) (Sasaki et al. 1994). Pseudolipomas were mostly observed as incidental findings in elderly or old individuals. In a review on 18 cases, age at diagnosis ranged from 33 to 86 years (mean, 57 years), and 16 were in male patients (Sasaki et al. 1994). Their significance lies in the risk of being confounded with other fat-containing mass lesions at imaging, in particular true lipoma, hence the terms, pseudolipoma of Glisson's capsule or hepatic pseudolipoma (Fievez and Courtoy 1978; Persaud 1969; Dirschmid and Kiesler 1979; Pounder 1983b; Benbow and Reid 1986; Karhunen 1985; Bruneton et al. 1987; Inoue et al. 1989; Redondo Martinez and Rey Lopez 1990; Quinn and Guzman-Hartman 2003; Sasaki et al. 1994; Shin et al. 2010). Until 1983, only nine cases had been reported (Pounder 1983b), but the prevalence of pseudolipoma was given as 0.2 % in a series of 1,300 consecutive autopsies (Karhunen 1985). Hepatic pseudolipoma has been reported to be missed in sonography, CT being required for detection (Bruneton et al. 1987). CT demonstrates a subcapsular low-density nodule with or without a high-density spot (Sasaki et al. 1994).

Pathology

Macroscopically, the lesions present as polypoid, white to yellowish, encapsulated masses situated on the liver capsule, the nodule being separated from the capsular surface by a more or less prominent peritoneal cleft (Fig. 3; Quinn and Guzman-Hartman 2003), but sometimes they manifest as rather flat lesions, intraoperatively being confounded with metastatic disease. A frozen section will bring the correct diagnosis in such situations. The center of the lesions may consist of friable, slightly granular, or flocculent masses demarcated by a thick capsule-like structure. Histologically, one notes a hypovascular fibrous capsule-like structure surrounding adipose tissue lobules of varying size, frequently with fat necrosis with "shadow adipocytes" (sometimes producing a honeycomb pattern on section), inflammatory reaction (lipophages), calcifications or even ossification, and scarring. Calcium deposits may also occur in the capsule of the lesion. Among 18 reported cases, calcifications within the substance of the nodule were detected in eight and ossification in two, and a central calcification may produce, in CT, a high-density spot resembling a bull's eye within the low-density nodule (Sasaki et al. 1994).

Fig. 3 Pseudolipoma of Glisson's capsule

Pathogenesis

Pathogenically it has been suggested that necrotic or inflamed epiploic appendices or other intraabdominal adipose structures may, via an exudative reaction, adhere to the hepatic capsular surface, subsequently being vascularized by capsular blood vessels (eventually via the induction of an inflammatory granulation tissue) and the

surviving portion then forming an encapsulated adipose tissue nodule. Fat necrosis, e.g., subsequent to strangulation, may induce a repair reaction with formation of a granulation tissue envelope, providing the feeding vessels for the nodule, later changing into a fibrous capsule (circumferential scar). Such a mechanism is supported by the observation that pseudolipomas are more frequently encountered on the anterior aspect of the hepatic capsule, a localization to the posteroinferior aspect being rare (Sasaki et al. 1994). Reattachment and vascularization of amputated fat tissue (migrating loose bodies) may also play a role (Karhunen 1985), but in this study, there was no correlation with previous abdominal surgery or obesity.

It has also been theorized that coelomic mesenchyme originally fated to become omentum or mesentery may ectopically develop in the hepatic capsule to then form what has therefore been termed *coelomic fat ectopia* (Wheeler and Edmondson 1985). Whether this pedunculated lesion, which consisted of mature adipose tissue, was contained in a mesothelial-lined sac, and exhibited numerous bundles of smooth muscle cells, is related to pseudolipoma or represents a different type of lesion is not clear.

Accumulation of Adipose Tissue in Hepatic Fissures and in the Region of the Liver Hilus (the Fat Pad of the Hepatic Hilus)

Fat tissue can develop within hepatic fissures, producing imaging signs of a pseudotumor (Halber and Daffner 1979). Physiologically, adipose tissue is located to the hepatic hilar compartment and here encircles blood and lymph vessels, lymph nodes, and bile ducts. Perihilar fat makes part of the hilar plate, bounded above by segment S4a (the inferior part of the medial segment), on the right by the Rouvière sulcus (a landmark demarcating the division between S6 and S5) and the cystic plate, and on the left is continuous with the umbilical plate (Gadzijev 2002; Kawarada et al. 2000). The adipose tissue located to the hepatic hilus may sometimes grow to larger nodular lesions, in particular in obese individuals. They consist of mature adipocytes and radiologically present as a pseudotumor. These lesions, termed fat pad of the hilus, are usually situated close to the gallbladder infundibulum and have been shown to regress after weight loss of the patient (Belloir et al. 1982). An echo-poor band of fat is seen between the anterior surface of the left lobe of the liver and the anterior abdominal wall in 25 % of patients undergoing an abdominal scan (Vijayaraghavan 1989). Obese patients may show subphrenic adipose tissue causing an increased distance between the diaphragm and the liver (Lindenbraten 1979; Villari et al. 1985). A hepatic/perihepatic adipose tissue pseudotumor can be produced by anteriorly displaced retroperitoneal fat, e.g., in association with pedunculated hepatic hemangioma (Ellis et al. 1985).

Hepatic Hibernoma

Introduction

Hibernomas are rare, benign, and slow-growing neoplasms consisting of brown adipose tissue (Brines and Johnson 1949; Merkel 1906). Typical sites include the thigh, the neck compartment, the scapular region, and soft tissues of the extremities and mediastinal and retroperitoneal spaces. The occurrence of multiple hibernomas has been reported (Baskurt et al. 2004). The classical diagnosis of hibernoma is made by histopathologic examination and finding of characteristic brown fat cells with granular and multivacuolated cytoplasm. However, the percentage of multivacuolated adipocyte-like cells (MVA) varies from one lesion to the other, and this phenomenon has led to the definition of two histologic hibernoma subgroups (Furlong et al. 2001; Ritchie et al. 2006), i.e., lipoma-like hibernoma (<70 % MVA) and non-lipoma-like hibernoma (>70 % MVA). It has been reported that lipoma-like lesions tend to be larger and are well defined, whereas non-lipoma-like lesions tended to be smaller and were unencapsulated (Ritchie et al. 2006).

Primary Hepatic Hibernoma

We are aware of only one reported observation describing a hibernoma component in a primary lipomatous tumor of the liver (Ishak 1976; morphology also reproduced in Craig et al. 1989, Fig. 114). In this situation, two hepatic lipomatous tumors were detected in a 39-year-old female patient. A pedunculated and encapsulated large (8 cm) angiolipoma, grossly presenting as a gritty mass, contained large and granular cells typical for brown adipose tissue, together with focal calcifications. The hibernoma component exhibited apparent transitions from granular cells to large vacuolated adipocytes.

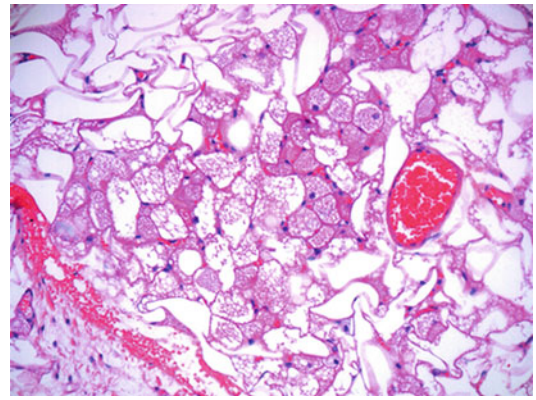

Fig. 4 Hibernoma. The large tumor cells exhibit a foamy, microvesicular cytoplasm (hematoxylin and eosin stain)

General Pathologic Features of Hibernomas

At gross examination, hibernomas vary in their color from brown or tan to yellow, depending on the amounts of granular cells vs. mature adipocytes. Histologically, the tumors exhibit a lobular texture and consist of three principal cell types, i.e., granular eosinophilic, polygonal multivacuolated, and univacuolated cells, and their transition forms (Fig. 4; Gaffney et al. 1983). This has led, as outlined above, to the recognition of two main variants of hibernoma, i.e., lipoma-like and non-lipoma-like forms (Ritchie et al. 2006). A myxoid variant of (Chirieac et al. 2006; Furlong et al. 2001) and a spindle cell variant of hibernoma (Furlong et al. 2001) have been described. Ultrastructurally, there is an inverse relationship between lipid droplet size and the spatial density of mitochondria; the cells exhibit the morphologic signs of marked micropinocytosis, and overall the ultrastructure of normal brown adipose tissue is very similar to that of hibernomas (Gaffney et al. 1983). Immunohistochemically, 85 % of the lesions are positive for S-100 protein (Furlong et al. 2001), and hibernomas express a protein unique to brown adipocyte mitochondria, the uncoupling protein (UCP, see below; Zancanaro et al. 1994). In addition, normal and neoplastic cells of brown adipose tissue express the adhesion molecule, CD31 (platelet-endothelial cell adhesion molecule-1), a member of the immunoglobulin superfamily commonly expressed in endothelial cells and involved in angiogenesis (Rosso and Lucioni 2006).

Hepatic Myelolipoma

Introduction

Myelolipoma is defined as a benign lipomatous tumor that contains variable amounts of normal-looking hematopoietic tissue. Myelolipoma is an unusual neoplasm which mostly occurs in the adrenal gland (review of the literature: Patel et al. 2006), but extra-adrenal sites (extra-adrenal myelolipoma, EAML) are known, including the retroperitoneal space, pelvic region, renal hilum or sinus, parietal pleura, lung, mediastinum, thoracic spine, stomach, and liver, and even generalized variants have been reported (Arzanian et al. 2006; Sawhney et al. 2006). EAML occurs more frequently in females (M:F = 1:2), with a median age at diagnosis of 66.5 years. A strong association of EAML with underlying inflammatory disorders, diabetes mellitus, and cardiovascular disease has been described, similar to that seen with adrenal myelolipomas. Adrenal myelolipoma (in particular the bilateral form) may be associated with endocrine dysfunction (Oliva et al. 1988), specifically adrenogenital syndrome (Miyazaki et al. 1990; Sakaki et al. 2006; Treska et al. 2006), e.g., congenital adrenal hyperplasia

due to 21-hydroxylase deficiency (Umpierrez et al. 1997) and combined 17-alpha-hydroxylase/17,20-lyase deficiency (Patocs et al. 2005). In contrast to the adrenal tumors, extra-adrenal myelolipomas are more frequently associated with hematopoietic disorders of various types. A clonal origin of myelolipoma components has been suggested based on the finding of nonrandom X chromosome inactivation in the hemopoietic elements (Bishop et al. 2006). On the other hand, hemopoietic tissue may accumulate in a tumorous mesenchymal compartment owing to marrow deficiency, as EAML can occur in conjunction with a markedly hypocellular bone marrow (Sawhney et al. 2006). The hemopoietic tissue may be the site of homing for lymphohematologic neoplasms, e.g., Hodgkin's lymphoma (Hagspiel 2005).

Hepatic Myelolipoma

Myelolipoma can occur in the liver as a primary neoplasm originating from an unknown cell type.

Selected references: (Grosdidier et al. 1973; Kaurich et al. 1988; Le Neel et al. 1984; Mali et al. 1986; Nishizaki et al. 1989; Rubin et al. 1984); Moreno Gonzales et al. 1991; (Fauchery et al. 1998; Imaoka et al. 1995; Orlandi et al. 1994; Pavon et al. 2009; Radhi 2010; Savoye-Collet et al. 2000; Takizawa et al. 1995).

As far as can be judged from the few reports, hepatic myelolipomas mostly occur in older individuals, and may be more frequent in females. In a review of six cases, five tumors occurred in females (Nishizaki et al. 1989). In this series, the tumor diameters ranged from 2 to 15 cm. In one report, hepatic myelolipoma developed in a hepatocellular carcinoma, with formation of a central nodule of 1.4 cm diameter in an HCC of 12 cm size (Van Hoe et al. 1994), and bone marrow was also once detected in a liver cell adenoma (Renaldi et al. 1993).

Hepatic myelolipoma was detected incidentally by the use of echography performed after the onset of a nonspecific painful symptomatology (Orlandi et al. 1994). CT examination revealed characteristic features of a fat-enriched mass (Nishizaki et al. 1989). In one case, abdominal MR showed heterogeneous low signal intensity on T1-weighted images, and the mass was initially hypointense after administration of a gadolinium bolus, and on the delayed-phase images, peripheral enhancement was observed (Savoye-Collet et al. 2000). Selective hepatic arteriography depicts myelolipoma as a hypervascular mass with a less vascular center, and unenhanced computed tomograms show a mass of low attenuation due to accumulation of fat (Nishizaki et al. 1989; Rubin et al. 1984).

The tumors may grow to impressive size, diameters of up to 17 cm and a weight of 880 g having been reported (Savoye-Collet et al. 2000). Macroscopically, myelolipomas are circumscribed and lobulated but usually nonencapsulated masses and are typically yellow to tan, the color range being dependent on the relative amounts of adipose tissue vs. hemopoietic tissue (Fig. 5). Large areas of myeloid tissue produce dark-red or purple foci on

Fig. 5 Myelolipoma of the liver. The bulging, well-delineated yellow tumor developed in a liver with secondary biliary fibrosis/cirrhosis

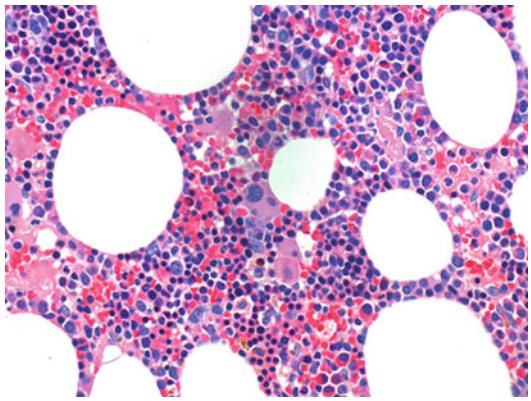

Fig. 6 Myelolipoma of the liver. Hematopoietic tissue intermingled with large adipocytes is the salient histologic feature (hematoxylin and eosin stain)

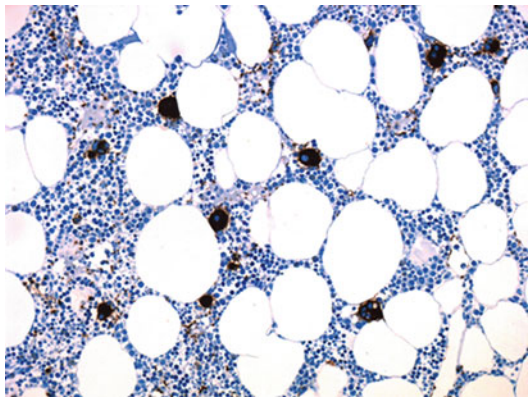

Fig. 7 In myelolipoma, megakaryocytes are typical component (CD61 immunostain)

a yellow background. Histologically, the hepatic tumors exhibit the same pattern as the adrenal ones, including the presence of megakaryocytes in the hemopoietic islands (Figs. 6 and 7; Rubin et al. 1984). The adipose component may be fibrotic, and in the hemopoietic tissue, lipid-laden macrophages may be present, suggesting lipid pinocytosis after decay of adipocytes. In one report, lipoblasts have been observed in the adipose component (Orlandi et al. 1994). The adjacent liver substance shows some atrophy owing to the expansive growth of the lesion, but hyperplastic hepatocyte changes in the tumor's vicinity have also been recognized (Orlandi et al. 1994). Exceptionally, myelolipoma was inside another hepatic mass, e.g., focal nodular hyperplasia (Suarez-Peñaranda et al. 2014).

Hepatobiliary Liposarcoma

Introduction

Liposarcoma primary to the liver is an exceedingly rare tumor. Wolloch and coworkers were apparently the first to describe such a lesion (Wolloch et al. 1973). In this study, the index patient with myxoid liposarcoma of the liver underwent a right hemihepatectomy and survived for 46 days only after surgery. Only a few bona fide cases were subsequently reported.

Selected references: (Aribal and Berberoglu 1993; Chen et al. 1988; Enterlaine et al. 1960; Golebiowski and Abycht 1987; Kim and Reyes 1985; Kim et al. 1987, 2007; Soares et al. 1989; Wolloch et al. 1973; Wright et al. 1993; Khan et al. 2001; Binesh et al. 2012; Gajda et al. 2007; Kuo et al. 2006; Lee et al. 2008; Naik et al. 2013; Nelson et al. 2001; Yu et al. 2002, 2008).

Classification

The WHO classification of liposarcomas is summarized in Table 1.

Epidemiology

In the light of the rarity of this hepatic malignancy, the known epidemiologic features are still fragmentary. Most patients were older than 30 years at the time point of diagnosis, but the tumor also occurs in infants and children, in this age group restricted to the hepatic hilar region (Chen et al. 1988; Soares et al. 1989; Wright et al. 1993).

Table 1 Classification of liposarcomas

	ICD-O code
Intermediate (*locally aggressive*)	
Well-differentiated liposarcoma	8851/3
Malignant	
Dedifferentiated liposarcoma	8858/3
Myxoid liposarcoma	8852/3
Round cell liposarcoma	8853/3
Pleomorphic liposarcoma	8854/3
Mixed-type liposarcoma	8855/3
Liposarcoma, not otherwise specified (NOS)	8850/3

Clinical and Imaging Features

Clinically, patients may present with upper abdominal pain, nausea, fever, and eventually jaundice. Radiological and sonographic examinations disclose a usually large hepatic mass, however with variable patterns at imaging. The masses can be located to the parenchyma of the liver or to the hilar area. In one case, sonography showed a poorly defined, lobulated, infiltrating echogenic lesion with shadowing, with hyperechogenic and hypoechogenic parts representing hemorrhage and necrosis (Khan et al. 2001), and similar observations have been reported for other tumors (Aribal and Berberoglu 1993; Kim et al. 1987), whereas CT has demonstrated low-attenuation masses of fat density (Khan et al. 2001; Kim et al. 2007) or a cystic mass (Kuo et al. 2006).

Pathology

Gross Pathology

Macroscopy reveals a usually large and more or less circumscribed mass. In one case, the tumor diameter was 27 cm (Nelson et al. 2001). The lesions may be pedunculated or exophytically growing in some instances. The cut surface is typically lobular and shows myxoid or tan to gray to yellowish tissue, sometimes with marked necrosis and hemorrhage. In fresh state, the tumor tissue may protrude from the cut surface. Hepatic liposarcomas may present as a huge cystic mass with multiple septa (Kuo et al. 2006).

Histopathology

As in liposarcomas located elsewhere, several patterns of differentiation have been described, including well-differentiated, myxoid, and pleomorphic types. Myxoid liposarcoma can present in the form of a multicentric neoplasm that also involves the liver (Cho et al. 2010).

Liposarcoma of the Biliary Tract

Primary liposarcoma has been observed in the extrahepatic bile ducts (Fukusato and Machinami 1996) and in the gallbladder (Hamada et al. 2006) and may be confounded with liposarcoma primary to the liver. Other primary locations around the liver compartment can result in differential diagnostic difficulties, including liposarcomas in the omentum (McAvoy et al. 1978; Ohi et al. 1992).

Differential Diagnosis

Differential diagnosis of primary hepatic liposarcoma comprises metastasis of this tumor to the liver. The primary tumors have been identified in peripheral soft tissues, the retroperitoneal space, breast, and visceral organs other than the liver.

Selected references: (Brasfield and Das Gupta 1970; Elwood et al. 2007; Ferrari et al. 2007; Garces et al. 2008; Huang et al. 2005; Maluccio et al. 2006; Merimsky et al. 1999; Mohandas et al. 1972; Prakash et al. 2008; Sheah et al. 2008; Teas et al. 1978; Wada et al. 2012).

However, visceral and retroperitoneal liposarcomas are those which most often cause liver metastasis, as it is uncommon for extremity soft tissue sarcomas to spread to the liver (less than 0.5 %; Estourgie et al. 2002; Jaques et al. 1995). Among metastasizing myxoid

liposarcoma, the liver was involved in 33 % of patients (Sheah et al. 2008). Also fat-rich, well-differentiated liposarcomas are known to metastasize to the liver, causing multiple fat-rich hepatic lesions (Prakash et al. 2008). Large retroperitoneal liposarcomas can grow toward the liver, push it aside, or invade it, resulting in a hepatic space-occupying lesion (Teng et al. 2012).

Pathogenic Pathways

The etiology and pathogenesis of hepatic liposarcomas are only partially known. It has been suggested that these neoplasms may originate from immature malignantly transformed mesenchymal cells via differentiated along an adipoblast lineage or from mesenchymal stem cells primed to become preadipoblasts/preadipocytes.

Part of liposarcomas show characteristic cytogenetic and molecular alterations (Table 2; review: Conyers et al. 2011).

There is evidence that certain molecular alterations in liposarcoma directly or indirectly affect features of growth, invasion, and spread. For example, the FUS-CHOP fusion protein interacts with the matrix metalloproteinase-2/MMP-2 promoter and can, via this pathway, facilitate metastasis through transcriptional activation of proteases (Patil et al. 2014).

Table 2 Molecular genetic features of liposarcomas

WDLPS and DDLPS	Supernumerary ring and/or giant rod chromosomes, with amplified segments from the 12q13-15 region; often MDM2 amplification (negative regulator of p53)
MLPS	FUS-CHOP/DDIT3 gene fusion in more than 95 %, through translocation t(12;16)(q13;p11)
PLPS	Complex arrangements of several chromosomes including gains and losses; often deletion of 13q14.2-q14.3; some with amplification of mitotic arrest deficient, MAD2

WDLPS well-differentiated liposarcoma, *DDLPS* dedifferentiated liposarcoma, *MLPS* myxoid liposarcoma, *PLPS* pleomorphic liposarcoma

Hilar Liposarcoma in Infancy and Childhood

Liposarcoma is a very rare tumor in the pediatric age group (Bouche-Pillon et al. 1989; Castleberry et al. 1984; Shmookler and Enzinger 1983). A review of previously published cases revealed that the peak incidence is during infancy and early adolescence, the extremities to be the most common site of origin (51 %), a predominance of myxoid histology (76 %), and a lower overall recurrence rate when compared with adult cases (37 % vs. 72 %, respectively) (Castleberry et al. 1984).

Only a few cases of primary hepatic liposarcoma developing in childhood are known, but interestingly part of them emerged in the region of the porta hepatis, where a distinct situation with respect to mesenchyme is present. An obstructive hilar tumor was first reported in 1989 in a 2-year and 4-month-old Caucasian male child presenting with fever and jaundice and resulting in death. The diagnosis of liposarcoma was confirmed at autopsy (Soares et al. 1989). A second case was a myxoid liposarcoma arising at the porta hepatis of a 3-year-old boy, with initially favorable response to surgery combined with radio- and chemotherapy, but with fatal recurrence about 12 years later, i.e., at age 15 years (Wright et al. 1993). A further case of pediatric hepatic liposarcoma was reported in a series of 55 malignant tumors of the liver studied in Taiwan (Chen et al. 1988).

Distinct Patterns of Hepatic Fatty Change Mimicking Tumor Masses: Focal Fatty Change and Focal Fatty Sparing of the Liver

Focal Fatty Change of the Liver

Introduction

Hepatic steatosis is a well-defined entity which is associated with a variety of disorders. Diagnosis and characterization of fat in the liver is a diagnostic challenge in daily practice, owing to the

rather broad differential diagnosis. It has long been known that fatty change of the liver may assume a nonuniform distribution (Mulhern et al. 1979; Scott et al. 1980). Focal fatty change (FFC; synonyms: focal fatty infiltration of the liver, focal hepatic fatty metamorphosis, focal fatty pseudotumor, geographic steatosis) makes part of a whole spectrum of fatty infiltration (FIL) of the liver, first described in 1934 (Simon 1934). According to the radiologic classification of Jain and McGahan (1993), focal hepatic changes related to fat include FFC, where gross areas with marked steatosis arise in an otherwise non-steatotic liver but also skip lesions defined as non-steatotic areas occurring in a diffuse fatty liver (see above Becher et al. 1988; Marchal et al. 1986). It has to be kept in mind that certain regions of the liver are commonly involved by fatty infiltration, such as the medial segment of the left lobe adjacent to the falciform ligament (Yoshikawa et al. 1987). FFC can be associated with a variety of conditions, including obesity, starvation, parenteral nutrition, diabetes mellitus, alcohol toxicity, disorders of blood supply, and drugs (specifically, cancer chemotherapy). It has to be emphasized that alcohol toxicity is not always associated with diffuse hepatic steatosis, but may present as FFC (Tang-Barton et al. 1985). FFC is mostly a disorder found in adults but may also occur in children (Brawer et al. 1980; Igarashi et al. 1994; Yoon et al. 1987). Pathogenetically, several observations suggest that a local disorder of hepatic blood circulation can result in a deranged hepatocytic triglyceride metabolism ending up in neutral fat storage.

Imaging Findings

There is a wealth of informations regarding the imaging features of FFC, related to the fact that FCC can closely mimic malignancy, in particular metastatic disease, and that FCC can produce a significant mass effect (Bashir 1990; Chong and Fan 1994; Gariballa et al. 1997; Martinez Alvarez et al. 1998; Yates and Streight 1986). FFC may be manifest with various appearances on ultrasonography, CT, MRI, and at gross examination (Basaran et al. 2005; Brawer et al. 1980; Kudo et al. 1989; Paulson et al. 1993; Prasad et al. 2005; Shah and Bellon 1986; Yoshikawa et al. 1987). On CT, FFC is identified as a low-density, usually nonspherical lesion usually lacking a mass effect (Halvorsen et al. 1982); however, FFC lesions with an important mass effect have also been reported (Verhille et al. 1994).

Pathology

Macroscopy

At gross examination, FFC manifests as sometimes large and usually sharply delimitated areas of clearly yellow tissue on the background of liver substance showing normal features (Figs. 8 and 9). The border of the lesion may be curved or sawtooth-like. In a postmortem study on lesions incidentally detected in ten patients, areas of FFC were measured up to 4 cm in diameter and were predominantly subcapsular in location (Brawer et al. 1980).

As summarized in Table 3, FFC manifests in the form of several morphotypes. Apart from FFC occupying large areas of a segment or lobe as a solitary lesion, there are instances where FFC are multiple or multinodular lesions (Baker and Silverman 1985; Flournoy et al. 1984; Plasencia Martinez and Corral de la Calle 2009; Van Vlierberghe et al. 1998). In case this pattern is

Fig. 8 Focal fatty change of the liver. A *large yellow*, geographic, and sharply delineated lesion occupies the superior aspect of both liver lobes

Hilar/periportal type
Focal steatosis of the gallbladder fossa

diffuse, it closely mimics metastatic disease (diffuse multinodular hepatic steatosis; Amoyal et al. 1989).

Many cases of FFC show a lobar or segmental type of distribution, then mostly presenting with rather large lesions. Part of the FFC may have a nonrandom distribution: in a series of five cases of surgically confirmed FFC, all lesions were located at the anterolateral edge of the medial segment of the liver and were found adjacent to the falciform ligament (Middleton 1989; Yoshikawa et al. 1987). It has been suggested that focal steatosis around the falciform ligament is related to divergence of the portal vein or unusual blood supply (Liu et al. 2008), as outlined in a later paragraph. Apart from the strikingly frequent location near the falciform ligament, FFC were observed at other sites in the frequency sequence, anteromedial portion of segment IV, hilar side of segment IV, anterolateral portion of segment III, and around the hepatic hilum other than segment IV. FFC at the porta hepatis is correlated with aberrant venous drainage (Liu et al. 2008); see below). FFC has also been found in an intrahepatic sequestered segment located to the anterior part of segment IVB, fed by an abnormal transcapsular vascular tract (Battaglia et al. 1995). Foci of FFC may either be wedge shaped (in a subcapsular location) or have multiple lesions that may assume a nodular shape, these nodules sometimes exceeding a diameter of 10 cm (nodular focal fatty change). Further morphotypes of circumscribed fatty infiltration of the liver include periportal FFC (Salmonson et al. 1993), circumscribed steatosis of the gallbladder fossa or adjacent to the falciform ligament (Yoshikawa et al. 1987), and multifocal steatosis (El-Hassan et al. 1992; Sterling et al. 1997; Kemper et al. 2002; Van Vlierberghe et al. 1998). In a study on 1,425 patients, radiological evidence of fatty change of the liver was present in 9.7 %; among these patients, a diffuse fatty change was found in 68 %, FFC in 9 %, and multifocal fatty change in 22 % (El-Hassan et al. 1992).

Histopathology

Histologically, the liver parenchyma occupying the area of FFC preserved a lobular architecture and shows a type of predominantly macrovesicular hepatocyte change which is not distinguishable from that of diffuse fatty change of the liver (Gariballa et al. 1997). The subcapsular variant of FFC appears as a wedge-shaped rim of liver cells with fatty change, with the broad base facing the liver capsule (Glisson's capsule; Brawer et al. 1980). In biopsy, FFC lesions may show Mallory-Denk bodies and leukocytic infiltration, i.e., showing a pattern suggesting steatohepatitis ("focal steatohepatitis"). By the use of fine needle aspiration biopsy, this change may help in the differential diagnostic approach in

those instances, where malignancy is suspected (Layfield 1994; Zeppa et al. 2002). The cytologic features of FFC are characteristic. Aspirates show numerous hepatocytes in a background of blood, and these cells display a single or multiple clear vacuoles (Layfield 1994).

Focal Fatty Change in CARD

A particular distribution of steatosis has been observed in diabetic patients on continuous ambulatory peritoneal dialysis (CARD) treated with intraperitoneal insulin: these patients are known to develop a distinct type of hepatic subcapsular steatosis (Burrows and Jones 1994; Grove et al. 1991; Kallio et al. 2001; Nevalainen et al. 2000; Wanless et al. 1989). Wanless and colleagues were the first to report a postmortem study on 11 diabetic CAPD patients receiving intraperitoneal insulin; ten of these patients exhibited a subcapsular fatty rim measuring 0.05–12 mm in thickness and involving 5–80 % of the surface (Wanless et al. 1989). Grove and coworkers (Grove et al. 1991) observed on the posteroinferior surface of the right lobe a 10 × 8 cm sharply delineated subcapsular area of bright-yellow tissue, 4–6 mm in thickness. In the study of Kallio et al. (2001), subcapsular steatosis was detected in seven out of eight CARD patients receiving intraperitoneal insulin; the steatotic lesions were mostly located at the cranial segments of the liver, and the maximum thickness of the fatty rim ranged from 6.4 to 17.0 mm, visualized as a bright echogenic rim on the liver surface. In some patients there were discontinuous areas of subcapsular steatosis. In two necropsy cases, the gross features were characterized by yellowish subcapsular islands in an otherwise unaltered liver (Kallio et al. 2001). In regard to the possible pathogenic pathways, it has been theorized that insulin as such may play a significant role, the subcapsular location of fatty change in these patients being caused by the locally elevated insulin concentration secondary to its intraperitoneal administration (Wanless et al. 1989).

Focal Fatty Sparing

Introduction

Focal fatty sparing (FFS; skip lesions) denotes the circumscribed lack of detectable fatty change on a background of diffuse hepatic steatosis (Kissin et al. 1986; Marchal et al. 1986; Sauerbrei and Lopez 1986; White et al. 1987; Arai et al. 1988; Becher et al. 1988; Kreft et al. 1995; Yoshioka et al. 1994). It has significance in a clinical-radiologic setting because FFS may be interpreted as a focal tumoral lesion (pseudotumor, pseudolesion, pseudomass) (Fujikawa et al. 2002; Kreft et al. 1995; Vaidyanathan and Horrow 2007; Zezos et al. 2006). FFS is more frequent than focal fatty change (see below) and is typically localized to the liver segments IV and V near the gallbladder fossa, the area adjacent to the falciform ligament, subcapsular liver areas, and to the porta hepatis (Sarti et al. 1993; Chong and Fan 1994; Rubaltelli et al. 1997). The side of the medial segment of the left lobe which is adjacent to the portal vein is commonly spared when the remainder of the liver has significant fatty change (Berland 1986; Sauerbrei and Lopez 1986; White et al. 1987). This area often has decreased portal flow compared to the remainder of the liver (Fernandez and Bernardino 1991). Less commonly, FFS presents as multiple nodular lesions outside the typical locations of FFS (Tom et al. 2004). These lesions may mimic tumors (in particular, adenoma) even more frequently than those in the other locations.

Differential Diagnosis

Tumor metastatic to the liver can mimic sparing in irregular fatty liver (Onaya et al. 1994).

Pathogenesis

Similar to FCC, FFS is thought to be caused by abnormal blood supply to the liver areas involved in part of the cases. This is supported by situations

where abnormal or aberrant venous supply to the liver is associated with FFS in these segments, e.g., in the presence of aberrant gastric veins (Gabata et al. 1997; Terayama et al. 2004; Yoshioka et al. 1994). A focally spared area fatty liver was caused by arterioportal shunt (Arita et al. 1996). Based on biopsy findings it has been suggested that focal sparing is caused by inflammatory changes taking place in the liver area involved (Kreft et al. 1995).

Focal Fatty Sparing Around Liver Tumors

Introduction

Peritumoral sparing of hepatic fatty change is defined as a rim-like zone of liver substance around focal lesions, lacking fat accumulation in contrast to the remaining liver. This phenomenon has been found with several types of liver tumors, both epithelial and mesenchymal, but particularly in tissue surrounding hepatic colorectal cancer metastases and liver hemangiomas.

Clinical Presentation and Imaging Findings

On non-contrast CT scans, one notes a hyperattenuating rim having an attenuation similar to the spleen, a circular or semicircular shape, a width of a few millimeters, a clearly peritumoral localization, and an exhibiting loss of visualization with contrast enhancement. No such rims are seen around hepatic tumors unassociated with fatty infiltration (Itai et al. 1996). It has been reported that opposed-phase gradient-echo MRI is the best method for depicting peritumoral sparing of steatosis (Chung et al. 2003; Gabata et al. 2001; Xu et al. 2000; Chen et al. 2005). Grossholzer and coworkers (Grossholzer et al. 1998) separated focal fatty sparing around tumors into several types. *Peripheral sparing* (fan or wedge shaped) is observed in the liver substance between a peripherally situated nodule (commonly metastasis or HCC) and the overlying liver surface. The latter may be retracted, reflecting both the decrease in volume of the area involved and the increase in volume of the surrounding steatotic liver. *Segmental sparing* is observed when the underlying mass is located near, but not at, the liver hilus. Pathogenetically, it is suggested that the tumor compressed a portal venous branch and hence compromising the dependent parenchyma. *Lobar sparing* is seen when a tumor at the liver hilus causes sparing of an entire lobe by obstructing the left or right main portal vein branch. This alteration may be associated with biliary obstruction, as is, e.g., caused by hilar cholangiocarcinoma (Klatskin tumor).

Peritumoral sparing in hepatic hemangiomas appears as a hypoechoic lesion with or without a geographic hyperechoic rim in sonography (Kim et al. 2008), a hyperattenuating rim on unenhanced CT (Itai et al. 1996), and a hyperintense peritumoral rim on chemical shift MRI (Chen et al. 2005; Xu et al. 2000; Kim et al. 2006). Hepatic hemangiomas are known to have arterioportal shunts (Naganuma et al. 1999; Yu et al. 1998; Kim et al. 2006). Dilution of portal vein blood flow by arterial blood through the arterioportal shunts is considered to be the cause of peritumoral sparing (Kim et al. 2008). In contrast to the high frequency of arterioportal shunts in hepatic hemangioma, the shunt is rare in hepatocellular carcinomas, but a deranged local portal venous flow is thought to cause perilesional sparing in this tumor (Kim et al. 2008).

Pathology

Macroscopically, a pale rim separating a tumorous lesion from the yellowish liver substance is noted. This rim is usually only very thin, but may reach a thickness of 5 mm. Histologically, there is a rather sharp peripheral delimitation between the low-fat parenchymal rim and the surrounding steatotic liver, although some degree of interdigitation may occur (Chung et al. 2003). At the interface between the two areas, some hepatocyte ballooning and/or leukocytic infiltration may be seen

("steatohepatitic interface"). The rim may show some degree of liver atrophy (Chung et al. 2003).

Abstract

Apart from mixed epithelial and mesenchymal hepatoblastomas, which commonly produce osteoid, hepatic neoplasms with osteogenic or chondroid differentiation are very rare lesions. True osteoma of the liver has apparently not been documented. In contrast, primary osteosarcoma of the liver is a well-documented, albeit rare malignancy that is diagnosed in older patients. It presents as pure neoplasms or mixed tumors (carcinosarcomas) with osteoid components. Pure hepatic osteosarcoma forms tumor of very large size, lesions sometimes exceeding a weight of 3000 g. Histology corresponds to that of skeletal osteosarcoma, with variable amounts of calcified tumor osteoid. Part of the neoplasms contain multinucleated tumor giant cells. Primary chondroma of the liver is an exceptional neoplasm, while primary hepatic tumors with a chondrosarcomatous component have more often been described. The differential diagnosis of these lesions mainly consists of metastatic liver disease, both osteosarcomas and chondrosarcomas metastasizing to the liver.

Osteoma of the Liver

Primary osteoma of the liver has apparently not yet been documented in the literature.

Primary Osteosarcoma of the Liver

ICD-O Code 9180/3

Introduction

Relatively few osteosarcomas primary to the liver have been described, the first published observation dating from 1930, and the overall number of cases identifiable in the literature is rather low (Ogawa 1930). The diagnosis of primary osteosarcoma of the liver requires the fulfillment of the criteria for extraosseous osteosarcoma, i.e., the lack of a neoplastic epithelial component, the reliable detection of osteoid with or without mineralization, and of course the exclusion of metastatic disease (Ojima et al. 1964; Maynard and Fone 1969; Allan and Soule 1971; Sumiyoshi and Niho 1971; von Hochstetter et al. 1987; Craig et al. 1989; Liony et al. 1990; Kitayama et al. 1995; Govender and Rughubar 1998; Boldt et al. 1999; Phelip et al. 2007; Nawabi et al. 2009; Park et al. 2009).

Epidemiology

The female/male ratio in these eight tumors was 1/7, and the age range of presentation was 52–75 years. In the majority of cases, the tumor involved the right liver lobe, in three both liver lobes (no information in one case). Several patients had liver cirrhosis, including one patient, where hepatic osteosarcoma developed in cirrhosis associated with hemochromatosis (Maynard and Fone 1969).

Clinical and Imaging Features

The clinical presentation includes abdominal pain, an abdominal mass, signs of intestinal obstruction, or hepatic failure in patients with cirrhosis. CT scans show a rather dense, inhomogeneous mass revealing calcifications (Boldt et al. 1999), and angiography was characterized by a hypervascularized lesion (Liony et al. 1990). The clinical course of hepatic osteosarcoma is highly unfavorable. In four out of seven patients, remote metastatic disease was present at the time-point of diagnosis, and the tumor resulted in death in 7/7, the survival time after diagnosis ranging from 7 days to 4 months. The metastatic spread may involve both blood and lymph vessels. In an autopsy study, lymphatic spread to the hepatoduodenal ligament was observed, but the tumor also spread to the parietal and visceral peritoneum and the subjacent structures (von Hochstetter et al. 1987).

Pathology

Macroscopy

Macroscopically, hepatic osteosarcomas are large to very large lesions (in part more than 3000 g), with a diameter of 10 (Kitayama et al. 1995) to 25 cm (von Hochstetter et al. 1987; Govender and Rughubar 1998). The masses have a whitish to gray color, show a sandsoap consistency (depending on the amount of tumor bone), and may show large necroses.

In the first report on hepatic osteosarcoma, a 66-year-old female patient, the large tumor was located to the right lobe, with metastases to lymph nodes at the hepatic hilum and in the omentum (Ogawa 1930). An early autopsy report (male, 64-year-old) described a tumor of up to 13 cm size in the right lobe of a cirrhotic liver with hemochromatosis. The tumor had a fungating anterior surface and invaded the under surface of the right hemidiaphragm and the adjacent peritoneal surface. The cut surface of the neoplasm had the consistency of sandsoap, was white in color, and had a small area of necrosis (Maynard and Fone 1969). In a further autopsy report of 72-year-old female patient, a non-cirrhotic liver contained a large tumor (3350 g) measuring 25 × 19 × 14 cm and involving both liver lobes. The lesion was gray-white to pale yellow in color and had a gritty consistency on sectioning. There were large areas of necrosis. Tumor thrombi were present in the hepatic veins and hepatic portion of the inferior vena cava, and there was direct extension of tumor

into the porta hepatis. No lymph node or remote metastases were noted (Govender an Rughubar 1998). In a second necropsy of a 52-year-old male patient with liver cirrhosis, a tumor of about 10 cm in diameter bulged from the superior surface of the right lobe. The cut surface of the mass disclosed a yellowish-brown, focally whitish tumor with a partly fibrous capsule. The central area of the neoplasm showed marked necrosis and hemorrhage. In this patient, osteosarcoma was combined with a minute hepatocellular carcinoma (Kitayama et al. 1995). A further autopsy report referred to 75-year-old male patient, again with liver cirrhosis, showing a 6 cm multilobated and firm tumor in the right lobe. The tumor substance was yellowish and revealed hemorrhage and necrosis. Several nodular metastases were detected in the epiploon (Liony et al. 1990). Liver cirrhosis in conjunction with primary hepatic osteosarcoma was also described in an early Japanese report (Sumiyoshi and Niho 1971). In this 52-year-old male, the liver was enlarged (1700 g) and nodular, and the right lobe contained several firm, large, nodular tumor masses bulging from the interior surface. The cut surface disclosed a huge, yellowish-gray, multinodular tumor mass containing a small hemorrhagic or necrotic area. Extensive infiltrating growth into the branches of the portal vein was observed, and the inferior vena cava was completely occluded by a continuous growth of the tumor. A metastatic lesion was found in the septal wall of the right atrium, and few polypoid metastatic foci were present in the mucosa of the small bowel (Sumiyoshi and Niho 1971). On the cut surface, a grayish to red or speckled tissue is in evidence, sometimes with gritty features owing to the presence of calcified components. Gross necrosis may be impressive, and large tumors may contain a cystic cavity caused by tissue breakdown (Craig et al. 1989). The sarcoma has been reported to invade large veins of the hepatic outflow tract and the caval vein (the latter in three out of eight reported cases; Sumiyoshi and Niho 1971; Govender and Rughubar 1998; Boldt et al. 1999), eventually producing a tumor thrombus reaching the right atrium (Boldt et al. 1999).

Histopathology

Histology corresponds to standard osteosarcoma of the skeletal system. Most neoplastic cells are polymorphous or spindle-shaped elements, the latter sometimes arranged in the form of fascicles or whorls. However, predominantly osteoblastic lesions have also been noted (Govender and Rughubar 1998). Osteoid with or without mineralization in a lace-like pattern and a chondroid matrix with atypical chondroblast-like cells are regularly noted, even though the elaboration of osteoid may be heterogeneous or sparse (Fig. 1). In some of the lesions, chondroid differentiation (or chondrosarcoma) was noted (Ogawa 1930; Ojima et al. 1964; Sumiyoshi and Niho 1971; Kitayama et al. 1995; Boldt et al. 1999). One case showed numerous osteoclast-like giant cells, present mainly in the osteoblastic areas (Govender and Rughubar 1998). Some of the neoplasms contain multinucleated tumor giant cells. In part atypical mitotic figures are frequent, amounting to more than five mitoses per 10 HPF at $\times 40$ magnification in one study (Boldt et al. 1999). Expectedly, the neoplastic cells were immunoreactive for vimentin (Kitayama et al. 1995; Govender and Rughubar 1998; Boldt et al. 1999). Ultrastructurally, the neoplastic cells in one case exhibited the features of collagen-producing cells, showing indented nuclei with coarse heterochromatin along the inner membrane of the nuclear envelope, extensive labyrinthine spaces of dilated rough endoplasmic reticulum,

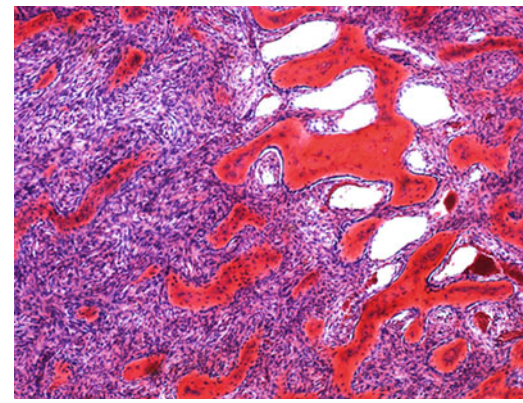

Fig. 1 Primary osteosarcoma of the liver with formation of immature tumor osteoid (hematoxylin and eosin stain)

numerous mitochondria, and small Golgi fields. In the pericellular maze of collagen fibrils, mineralization was detectable in the form of membrane-bound vesicles containing crystalline needles (von Hochstetter et al. 1987).

Differential Diagnosis

Skeletal osteosarcoma is known to metastasize to the liver (Shapiro et al. 1988). Also extraskeletal osteosarcomas can metastasize to the liver, including tumors arising in the mesentery or the omentum majus (Hussain et al. 2011; Tao et al. 2011). Histological difficulties arise in case of metastasis of small cell osteosarcoma to the liver (Ali et al. 2014), because other small cell malignancies may be mimicked. In the absence of evidence for metastatic disease, the main differential diagnosis of primary hepatic osteosarcoma is mixed hepatocellular carcinoma with osteosarcomatous components (hepatic carcinosarcoma with osseous components, Celikbilek et al. 2011; see the respective chapter). Histologically distinguishing these two lesion groups markedly depends on the sampling strategy employed, for this reason, one group of investigators prepared 155 tissue blocks to exclude an epithelial neoplastic component (Kitayama et al. 1995), but, similar to other situations of suspected mixed tumors, no reproducible sampling guidelines have been proposed so far. In addition, other tumors primary to the liver may contain osteoid, including malignant fibrous histiocytoma, malignant mesenchymoma, malignant teratomas, and adult-type hepatoblastoma.

Chondroma of the Liver

Primary cartilaginous tumors (chondromas and chondrosarcomas) of the liver are exceedingly rare, albeit pathogenically very interesting lesions. We are aware of only one report describing a large hepatic chondroma diagnosed in a 44-year-old woman, successfully removed at surgery, and showing the typical morphology of a benign cartilage tumor (Fried et al. 1992). This hepatic mass had been detected incidentally, and she had been followed up for 6 years with serial computed tomograms. Two liver biopsy specimens obtained by laparoscopy 3 and 6 years earlier showed only benign cartilaginous tissue, and the patient remained asymptomatic over this time period. After detection of an increase in mass, a preoperative MRI showed a large hepatic mass occupying the entire right liver lobe and extending into the caudate lobe. The mass contained numerous calcifications and measured approximately 16 cm in maximum diameter. Visceral angiography showed the mass to be hypovascular. Liver resection showed a histologically benign cartilage tumor with a non-aneuploid DNA content at flow cytometry (Fried et al. 1992).

Primary Hepatic Tumors with a Chondrosarcomatous Component

Primary chondrosarcoma of the liver has apparently been published only once so far. In 67-year-old male patient, synchronous occurrence of hepatocellular carcinoma and primary chondrosarcoma at two different places of the liver was observed (Sonoda et al. 1984). Cartilaginous components have been observed in mixed tumors or carcinosarcomas of the liver in adult patients, mostly associated with hepatocellular carcinoma (for more details, see ▶ Chap. 46, "Hepatobiliary Carcinosarcomas and Related Neoplasms"). The neoplastic cartilage component exhibits the features of chondrosarcoma (Imholz and Noltenius 1977; Kishimoto et al. 1984; Kawarada et al. 1985; Ooi et al. 1987; Leger-Ravet et al. 1996; Kinoshita and sakurai 1998; Nomura et al. 2000; Fu et al. 2000). These tumors are discussed in more detail in the respective chapter. Of special interest in the present context is the observation of Sonoda and coworkers, who reported on a 67-year-old male who showed hepatocellular carcinoma and chondrosarcoma arising from different areas of a cirrhotic liver, i.e., presenting as two independent tumors (Sonoda et al. 1984). Primary hepatic chondrosarcoma has been observed in mammals, e.g., the dog (Chikata et al. 2006). In few reports,

chondrosarcoma has been described to be located close to the liver, e.g., between the chest wall and liver (Cao et al. 2011), or in the right inferior aspect of the liver in case of costal chondrosarcoma (Nagata et al. 2012).

Metastases of Chondrosarcoma to the Liver

Rare metastases from skeletal and extraskeletal chondrosarcoma (mostly the myxoid variant) to the liver have been reported (Ryan et al. 2000; Mehanna et al. 2004).

Differential Diagnosis

Apart from metastases of chondrosarcomas (Ryan et al. 2000; Mehanna et al. 2004) and of chondroid salivary gland tumors (Youngs and Scheuer 1973; Chen 1978), the differential diagnosis may comprise chondroma of the diaphragm (Itakura et al. 1990).

Gastrointestinal Stromal Tumors (GISTs) of the Liver

67

Contents

Abstract

Gastrointestinal stromal tumors (GISTs) are mesenchymal tumors with distinct clinical, morphologic, immunohistochemical, and molecular genetic features. GISTs account for 1–3 % of all gastrointestinal tumors, mainly occur in older adults, and are associated with specific KIT and PDGFRA mutations. Most GISTs immunohistochemically express KIT/CD117. GIST can involve the entire gastrointestinal tract, with a predilection for the stomach and the small intestine, whereas the liver is an uncommon primary location. Primary hepatic GISTs are well-circumscribed, firm tumors that may show central necrosis and satellite lesions. The histologic presentation corresponds to that of GISTs in other sites. Much more common than primary hepatic GIST are metastatic lesions, the liver being one of the most common metastatic sites of gastric and intestinal GIST. Liver metastases of GIST can undergo a distinct cystic change upon therapy with imatinib. Radiologically, part of these cysts closely mimic simple nonparasitic liver cysts.

ICD-O code 8936:

Benign GIST, prognostic groups 1, 2, 3a	8936/0
GIST with uncertain malignant potential, prognostic group 4	8936/1
Malignant GIST, prognostic groups 3b, 5, 6a, 6b	8936/3

Introduction

Gastrointestinal stromal tumors (GISTs) form a group of mesenchymal neoplasms with distinct clinical, morphologic, immunohistochemical, and molecular genetic features and a biologic behavior ranging from benign to malignant (reviews: Miettinen et al. 1999; Miettinen and Lasota 2001; Koh et al. 2004; Blay et al. 2005; Miettinen and Lasota 2006a, b; Biasco et al. 2009; Saleem and Ahmed 2009; Steigen and Eide 2009; Laurini and Carter 2010; Liegl-Atzwanger et al. 2010; Corless et al. 2011). They represent the most common primary mesenchymal tumor of the gastrointestinal tract, with roughly 1–3 % of all gastrointestinal tumors, but approximately 2000 cases of GIST are diagnosed annually in the United States.

Owing to some histologic resemblance, GISTs have formerly been mistaken to be smooth muscle tumors of the GI tract. GISTs were first described by Mazur and Clark in 1983 and are now the most common mesenchymal tumors of the human gastrointestinal tract (reviews: Miettinen et al. 2002; Koh et al. 2004). Today, neoplasms previously termed gastrointestinal autonomic nerve tumors (GANT) and gastrointestinal pacemaker cell tumors (GIPACT) are now regarded as belonging to the spectrum of GIST (Lee et al. 2001).

Epidemiology

GIST is typically a tumor of older adults, such neoplasms in young adults, adolescents, and children being very rare and more heterogeneous (Miettinen et al. 2005; Prakash et al. 2005). In the pediatric age group, GISTs mainly affect girls, and the tumors differ from those in adults in several respects. Pediatric GISTs typically arise in the stomach as multifocal tumors with a multinodular growth pattern, epithelioid morphology, lymph node metastases, and absence of KIT or PDGFRA mutations. One subset of adult GISTs present with almost the same pattern and are called “pediatric-type” GISTs in adults (Rege et al. 2011).

GISTs can involve the entire GI tract, but the majority develop in the stomach (60–70 %) and the small intestine (25–35 %), other locations being more uncommon, such as the colorectum (up to 5 %), the duodenum (up to 4 %), and the esophagus (2 %). GIST rarely develops in the periampullary region of the duodenum (Cavallini et al. 2005) or in the papilla Vateri itself (Wellmann et al. 2004). Lesion sites unrelated to the tubular GIT include the omentum, the mesentery, the retroperitoneal space, the pancreas, and the liver. GISTs are usually sporadic tumors, but they rarely occur in the setting of syndromes such as Carney triad (GIST, pulmonary chondroma, paraganglioma) or Carney-Stratakis syndrome (GIST plus paraganglioma). Syndromic GISTs are diagnosed in younger individuals, including children, and are more common in females (Postow and Robson 2012). Multiple GISTs may be associated with a very rare inherited condition, autosomal dominant familial GIST with germ line c-Kit mutations, of which around 20 families have been observed (Kim et al. 2005; Li et al. 2005).

General Histologic Features of GISTs

The histopathologic features characteristic of GIST have been extensively reviewed (Miettinen et al. 2002; Miettinen and Lasota 2006; Foo et al. 2012), and the histologic criteria of GIST have been defined by a consensus conference (Blay et al. 2005). GISTs vary from cellular spindle cell neoplasms to epithelioid or mixed, epithelioid, and spindle cell variants. Apart from the typical cellular and histologic features, few GISTs exhibit aberrant patterns, e.g., pseudopapillary structures in epithelioid variants or the formation of osteoclast-like giant cells (Leung et al. 2002) or the development of rhabdoid features (Richmond et al. 2004). In addition, some GISTs show epithelioid cells characterized by round to oval cells exhibiting a less cohesive pattern of growth and eosinophilic cytoplasm. A subtype of GIST with a myxoid and epithelioid differentiation and mast cell infiltration is associated with mutations of the PDGF receptor alpha gene (Sakurai et al. 2004). PDGFRA-mutated

GISTs were significantly more often epithelioid and had a higher PDGFRA expressed compared to c-Kit mutants (Agaimy et al. 2013). Rarely, GIST can undergo histologic dedifferentiation, e.g., to an anaplastic KIT-negative phenotype (Antonescu et al. 2013). Treatment with tyrosine kinase inhibitor (imatinib) can induce several changes in histology and immunohistochemistry. GISTs treated with imatinib can undergo cystic change (see below). Rhabdomyosarcomatous change has been found (Liegl et al. 2009). Remarkably, the immunophenotype of GIST may change upon treatment with imatinib, in that part of the tumors lose KIT positivity (even in continuing c-Kit mutations), and a subset of these also lose reactivity for CD34 (Pauwels et al. 2005).

Immunohistochemically, most GISTs express Kit (CD117; Sarlomo-Rikala et al. 1998; Hasegawa et al. 2002), although Kit-negative GISTs are known, and part of those have PDGFRA mutations (Debiec-Rychter et al. 2004; Medeiros et al. 2004). Up to 70 % of the lesions are immunoreactive for CD34 (more frequently in gastric tumors; Emile et al. 2004), and there is variable expression of smooth muscle actins (20–30 %), while only very few percent of the cases show desmin positivity. Differential diagnostically important is the low frequency of reactivity for S 100 protein, i.e., 10 % or less (review: Miettinen et al. 2002). cDNA microarray techniques may uncover other markers for GIST. By such an approach, a hypothetical protein termed DOG1 has been found to be expressed by GIST, irrespective of c-Kit or PDGFRA mutations (West et al. 2004).

Primary GIST of the Hepatobiliary Tract

Introduction

Rarely, GISTs are tumors primary to the liver (Hu et al. 2003; Park 2004a; De Chiara et al. 2006; Luo et al. 2009; Ochiai et al. 2009; Terada 2009; Yamamoto et al. 2010; Alecu et al. 2011; Li et al. 2012; Zhou et al. 2014). CT images showed hypoattenuation of the lesion in all three phases, and ultrasound with contrast revealed a hypervascular lesion in the arterial phase and hypoechoic features during portal and late phases (Luo et al. 2009). Malignant GIST rarely develops in the gallbladder (Park et al. 2004b), sometimes with evidence of interstitial cells of Cajal phenotype (Mendoza-Marin et al. 2002). Very rarely, GIST is associated with other hepatic tumors, e.g., inflammatory pseudotumor of the liver (Lo et al. 2004). In one patient with primary hepatic GIST, a PDGFRA gene mutation was found (Yamamoto et al. 2010).

Pathology

Macroscopy

In one patient with a malignant primary hepatic GIST, the mass measured 15 cm in diameter. It was a circumscribed tumor which, on cross section, revealed a firm and homogeneous, brownish-tan mass with large central necrosis, accompanied by three smaller satellite nodules (Hu et al. 2003). In a second patient, the solitary primary hepatic GIST had a diameter of 5 × 4 cm (Alecu et al. 2011).

Histopathology

The histopathology of hepatic GIST reflects that of GISTs located elsewhere, i.e., with predominance of a spindle cell population. However, an epithelioid morphology has also been described (Yamamoto et al. 2010). In few cases which had been immunohistochemically analyzed, the neoplastic tissue was markedly reactive for CD117 and vimentin and focally for CD34 (Hu et al. 2003; Luo et al. 2009; Ochiai et al. 2009). In one patient, metastases showed multinucleated giant cells that were not seen in the primary lesion (Hu et al. 2003). In another patient, a KIT-positive GIST primary to the liver metastasizes to the lung, and it was hypothesized that the liver tumor might be related to extra-GIT cells with a pacemaker cell phenotype (De Chiara et al. 2006).

Immunohistochemistry

Immunohistochemically, most GISTs express Kit (CD117; Sarlomo-Rikala et al. 1998; Hasegawa et al. 2002), although Kit-negative GISTs are known, and part of those have PDGFRA

mutations (Debiec-Rychter et al. 2004; Medeiros et al. 2004). Up to 70 % of the lesions are immunoreactive for CD34 (more frequently in gastric tumors; Emile et al. 2004), and there is variable expression of smooth muscle actins (20–30 %), while only very few percent of the cases show desmin positivity. Differential diagnostically important is the low frequency of reactivity for S 100 protein, i.e., 10 % or less (review: Miettinen et al. 2002). cDNA microarray techniques may uncover other markers for GIST. By such an approach, a hypothetical protein termed DOG1 has been found to be expressed by GIST, irrespective of c-Kit or PDGFRA mutations (West et al. 2004).

Secondary GIST of the Liver (Metastases)

Much more commonly, the liver manifestations of GIST are metastatic (DeMatteo et al. 2000; Sandrasegaran et al. 2005; Cheung et al. 2014). Among 94 patients with GIST metastases, 61 showed liver metastases, 51 of these liver only (DeMatteo et al. 2000). In one study, liver metastases amounted to 32 % (Sandrasegaran et al. 2005). In another study with follow-up, 38/53 patients with metastases had metastases to the liver (Burkill et al. 2003). Liver metastases of GIST may be a delayed phenomenon in some patients, e.g., found after 11 years (Ballarini et al. 1998). The imaging features of hepatic GIST metastases after chemotherapy have been specified (Sandrasegaran et al. 2005; Yang et al. 2005; Patnaik et al. 2012). In patients with recurrence of GIST following complete surgical resection, relapse commonly occurs in the liver (Plumb et al. 2013).

Therapy-Associated Cysts in GIST Metastases

It is important to note that liver metastases of GIST respond to imatinib therapy by rapidly showing cystic change (Fig. 1; Chen et al. 2002), and some of these treated lesions are almost indistinguishable from simple hepatic cysts (Sandrasegaran et al. 2005). This phenomenon is unusual, as imatinib induces not tumor necrosis but tumor cell apoptosis. Cystic degeneration of GIST following imatinib treatment is related to lack of CD34 expression (Koh et al. 2012). There are, however, rare instances of cystic liver metastases of GIST prior to the imatinib treatment era or before any treatment (Zonios et al. 2003; Jain et al. 2009; Colovic et al. 2013). Part of GISTs, mainly those with a high-risk mitotic status, show vasculogenic mimicry, characterized by the formation of fluid-conducting channels by highly invasive and genetically dysregulated tumor cells. GISTs having vasculogenic mimicry are prone to develop liver metastases (Sun et al. 2008). Not much information is available regarding molecular features that might favor liver metastases of GIST. In a recent study, GIST patients with loss of the succinate dehydrogenase subunit A, due to germ line mutations, show a slow course of disease, but have a slightly higher rate of liver metastases (Miettinen et al. 2013).

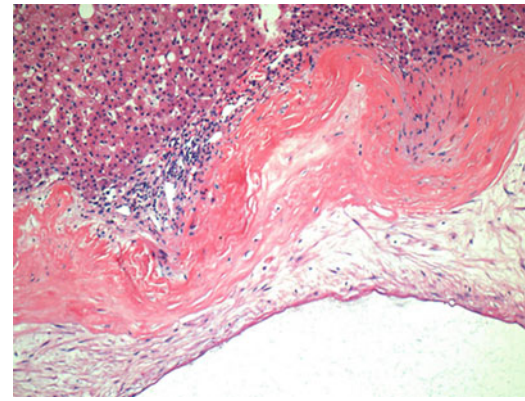

Fig. 1 Hepatic metastasis of gastrointestinal stromal tumor (GIST) post-therapy. Therapy has induced a cystic lesion. The cyst wall has an interior loose, slightly myxoid connective tissue, followed to the periphery by a waved band of collagenous tissue (hematoxylin and eosin stain)

Differential Diagnosis

Differential diagnosis mainly involves other spindle cell tumors primary to the liver or hepatic metastases of spindle cell sarcomas. In the

pre-immunohistochemistry area, many tumors now classified as GIST may have been diagnosed as benign or malignant smooth muscle tumors.

Biology of Disease

In contrast to earlier views, GISTs are to date regarded as non-benign lesions in principle, any such tumor having the potential of malignancy (Fletcher et al. 2002). The frequency of overtly malignant GIST has been estimated as 20–30 % of the frequency of all soft tissue sarcomas, but small, still not overtly malignant tumors are probably much more common (Miettinen et al. 2002). It is estimated that 25 % of gastric GISTs (not counting minimal incidental lesions) are malignant. In the GI tract, the most useful and best analyzed prognostic factors comprise tumor size and mitotic count, the latter expressed as the number of mitotic figures per 50 high-power fields (HPFs), with a total area of 5 mm2. In the TNM classification, grading is based on the mitotic rate. A low mitotic rate is <5 mitoses/50 HPFs; a high mitotic rate is >5 mitoses/50 HPFs. The prognostic groups employed in GIST (groups 1, 2, 3a, 3b, 4, 5, 6a, and 6b) are constructed from the two parameters, tumor size (diameter) and mitotic rate (review: Hou et al. 2009a, b). These prognostic systems have proven to be efficient, mainly in primary GISTs located in the gastrointestinal tube. For tumors located elsewhere, the prediction of malignancy is still difficult. Several informations that have increased our knowledge on the behavior of GIST are here briefly summarized. Prognosis of GIST has been related with tumor size and gender (Hasegawa et al. 2002; Singer et al. 2002; Bai et al. 2005). Among 48 studied patients with GIST, 5-year recurrence-free survival with tumors less than 5 cm, 5–10 cm, and more than 10 cm were 82 %, 45 %, and 27 %, respectively (Singer et al. 2002). In one study, frankly malignant GISTs have been found to be typically large (mean primary tumor size: 13 cm), well-circumscribed (86 %), heterogeneous, centrally necrotic tumors that arise in the wall of the small bowel or stomach, despite their size rarely obstructing the viscera involved (Burkill et al. 2003). An analysis of the predictors of survival in 38 curatively resected GISTs (23 tumors of the stomach 13 tumors of the small bowel and 2 in the color) in the pre-imatinib era showed that the overall 5-year survival rate was 70 % and that the presence of distant metastases, the proliferative index, and deletional mutations of KIT exon 11 correlated significantly with poor outcome, while none of the tumors with a PDGFRA mutant relapsed (Iesalnieks et al. 2005). PDGFRA-mutated GISTs of low or no malignant potential are usually located in the stomach (Lasota et al. 2004).

There is a clear relation between the proliferative activity of GIST and outcome (Hasegawa et al. 2002; Singer et al. 2002; Yokoi et al. 2005), and recent findings confirm that mitotic activity remains the strongest prognostic factor in GIST patients (Demir et al. 2013). The 5-year recurrence-free survival for patients with tumors that had 3 mitoses or fewer per 30 high-power fields, more than 3 but less than 15, and more than 15 mitoses per 30 fields was 89 %, 49 %, and 16 %, respectively (Singer et al. 2002). Pathologically, tumors larger than 5 cm (Yokoi et al. 2005) and/or those that have a mitotic activity count exceeding 5 per 50 high-power fields have a high frequency of intra-abdominal recurrence and liver metastasis. Conversely, tumors smaller than 2 cm and those with mitotic activity counts less than 5 per 50 high-power fields are likely to be benign (review: Miettinen et al. 2002). The histologic phenotype is also a predictor of GIST biology. A spindle cell histology is a favorable feature, while tumors with an epithelioid or mixed histology do worse (Singer et al. 2002), but this furthermore depends on the site of the tumors and their mutational status. There is evidence for a prognostic effect of the mutational status in GIST. Deletions affecting codons 557–558 of the c-Kit gene indicate poor prognosis in patients with completely resected GIST (Martin et al. 2005). In some studies, parameters have been combined in order to assess malignancy in GIST, higher risk being generally related to larger tumor size together with an elevated proliferative activity (Fletcher et al. 2002). In an investigation on 22 patients,

the tumor features were first broken down into the presence or absence of necrosis, each of these groups then further broken down into tumors with 5 cm or less than 5 cm, or more than 5 cm diameter, and finally separated in regard to the proliferation index (< = >3 %). It turned out that malignant GIST either had necrosis and a diameter of 5 or more than 5 cm or had necrosis with a diameter of less than 5 cm but a proliferation index exceeding 3 % (Yokoi et al. 2005).

Progression of GIST is also linked to expression patterns of growth and regulatory factors. Increased KIT signaling with upregulation of cyclin D correlates to accelerated proliferation and shorter disease-free survival in GIST with KIT exon 11 deletions (Haller et al. 2008). The CDKN2A tumor suppressor network (Haller et al. 2005) and the p16 locus are involved consistently in chromosomal losses found in malignant GIST. In fact, p16/INK4a downregulation, partly due to p16 promoter methylation, is implied in GIST progression, and reduced p16 protein immunostaining is associated with clinical malignancy (Ricci et al. 2004; Schmieder et al. 2008). For gastric GIST, CD26/dipeptidyl-peptidase IV seems to be a reliable biomarker of malignancy (Yamaguchi et al. 2008). Overexpression of fascin-1 was found to predict an aggressive behavior, including larger tumor size, higher mitotic counts, and blood vessel invasion (Yamamoto et al. 2013).

Therapy with imatinib has dramatically changed to prognosis of GIST (Croom and Perry 2003; Duffaud and Blay 2003; Chacon et al. 2005; Peshwe et al. 2005; Sanborn and Blanke 2005). Imatinib interferes with cellular availability of key substrates, via interference with glucose transport, glucose oxidation for RNA ribose synthesis in the pentose cycle, and de novo long-chain fatty acid synthesis. Acquired resistance to imatinib is increasing, and development of resistance can be assessed by metabolic profiling (Serkova and Boros 2005). Detailed analyses of the genetic status of GIST having developed resistance to imatinib have demonstrated that changes in the mutational pattern of the c-Kit gene, loss of KIT expression, and secondary PDGFRA mutations play a role (Debiec-Rychter et al. 2005).

Pathogenic Pathways

GISTs seem to be derived from a distinct cell of the GIT, the interstitial cell of Cajal, a cell type that is reactive for the KIT protein and regarded as a pacemaker cell (see below). Central to the tumorigenesis of GIST are activating mutations in the proto-oncogene tyrosine protein kinase c-Kit encoding the KIT protein (Hirota et al. 1998; Kitamura and Hirota 2004; Lasota and Miettinen 2006; review: Barnett et al. 2013), or platelet-derived growth factor receptor alpha (PDGFRA), which are regarded as alternative and mutually exclusive (Duensing et al. 2004a).

KIT Mutations

Generally, tumors with c-Kit mutations tend to develop in the small intestine, while those with PDGFRA mutations originate in the stomach (Penzel et al. 2005). Mutations of the c-Kit oncogene, causing changes in the KIT protein expression, are highly characteristic of GIST and are found in 80–85 % of GIST, while KIT immunoreactivity in the absence of mutations can also be detected in a growing list of other solid tumors, e.g., small cell lung cancer and germ cell tumors (Sihto et al. 2005). c-Kit mutations are also common in incidental GIST 1 cm or less in size, suggesting that activating c-Kit mutations are acquired very early in the GIST development pathway (Corless et al. 2002). GISTs in children with neurofibromatosis 1 (NF1) do not show KIT or PDGFRA mutations. Key mutations of c-Kit gene chiefly occur in exon 11, followed by exons 9, 13, and 17 (Hirota et al. 1998; Corless et al. 2004; Penzel et al. 2005), and such mutations do not occur in smooth muscle tumors of the GIT, with which GIST may be confounded (Lasota et al. 1999). In a subset of so-called wild-type GIST, no mutations of these two genes were found (Corless et al. 2004). There is a connection between mutations of these genes and morphotype, tumor biology, and responsiveness to imatinib. This may be due to distinct gene expression profiles, but there

is also evidence for a complex relationship between differential expression of mutant isoforms in epithelioid and mixed variants of GIST and the tumor site (Wasag et al. 2004). The signal transduction pathways stimulated by activated KIT involve AKT, MAPK, and STATs (Paner et al. 2003; Duensing et al. 2004b). Differentially expressed genes include ezrin, p70S6K, and protein kinases C/PKC, which are known to have important roles in KIT and PDGFRA signaling (Subramanian et al. 2004). However, one PKC species, PKC theta, is a marker of many GISTs, including those that lack c-Kit expression and/or contain PDGFRA mutations (Duensing et al. 2004a).

The correlation between c-Kit mutations and outcome is still controversial. Prognostic associations were found with particular c-Kit mutation types, and patients with missense exon 11 mutations had a higher rate of 5-year recurrence-free survival than those with GIST showing other mutation types. Exon 9 mutations of c-Kit per se did not have prognostic relevance, albeit these mutations are relevant and have direct therapeutic implications (Künstlinger et al. 2013). Moreover, an independent predictor for disease-free survival was the presence of deletion/insertion exon 11 mutations (Singer et al. 2002). In line with these findings is the observation that c-Kit mutations in GIST occur preferentially in the spindle cell rather than in the epithelioid cell variant, the spindle cell variant having a better prognosis (Wardelmann et al. 2002). On the other hand, Exon 11 c-Kit mutations are more common in malignant versus benign GIST (Lasota et al. 1999), and a recent study found that the presence of any c-Kit and PDGFRA mutations and the presence of c-Kit mutations alone were significantly associated with high-risk/malignant GIST (Penzel et al. 2005). It also surfaced that the type of deletional c-Kit mutations affects biology of disease in that they confer worse prognosis (Martin et al. 2005). In contrast, internal tandem duplications in 3′ end of c-Kit juxtamembrane domain occur predominantly in gastric tumors and generally seem to confer a favorable course (Lasota et al. 2003).

PDGFRA Mutations

A subset of GIST (up to 8 %; Corless et al. 2004) contains mutations in the homologous kinase, platelet-derived growth factor receptor alpha (PDGFRA) gene (chiefly exons 18 and 12), and the most common of these mutations is resistant to imatinib in vitro. In more detail, isoforms with a substitution involving codon D842 in exon 18 are resistant to the drug, while other mutations in exon 18 and mutations in exons 12 and 14 confer imatinib sensitivity (Corless et al. 2005). In a study of epithelioid-/mixed-type GIST, activating mutations of c-Kit were found in 50 % (mostly exon 11), while 25 % with no detectable c-Kit mutations demonstrated PDGFRA mutant isoforms. In contrast to other GISTs, neoplasms with PDGFRA mutations had an epithelioid phenotype and had more commonly multinuclear giant cells (Yi et al. 2005; Pauls et al. 2005). Most of the c-Kit mutant epithelioid/mixed tumors originated from non-gastric sites, whereas all GIST with mutant PDGFRA isoforms originated from the stomach (Wasag et al. 2004). That a great majority of GIST with PDGFRA mutations represent gastric tumors (usually with low or no malignant potential) has been found in another study (Lasota et al. 2004). A third situation where GIST develops in the context of a genetic anomaly is neurofibromatosis type 1, where GISTs show CD117 reactivity (even in the absence of c-Kit mutations), whereas nerve sheath tumors do not (Cheng et al. 2004; Andersson et al. 2005). GISTs also make part of Carney's triad characterized by GIST, pulmonary chondromas, and paragangliomas.

Germ Line Mutations of Succinate Dehydrogenase Subunit A or B (SDHA, SDHB)

A subset of about 75–10 % of GISTs reveals loss of succinate dehydrogenase (SDH) subunit B (SDHB), associated with loss of function of this mitochondrial SDH complex. Patients with such losses are wild type in regard to KIT and PDGFRA, and some of the patients have germ line mutations of the SDH subunit genes SDHB, SDHC, or SDHD, known as Carney-Stratakis

syndrome (GIST plus paraganglioma) (Pasini et al. 2008; Lodish et al. 2010; Miettinen et al. 2011; Celestino et al. 2012; Gill 2012). Thirty percent of patients who are SDH function deficient reveal loss of the SDHA unit signaling germ line mutations. SDHA-deficient patients are older than SDHB-mutated individuals and show a slow course of disease in most cases, despite a slightly higher rate of liver metastases (Dwight et al. 2013; Miettinen et al. 2013). SSDH mutations are strongly associated with paraganglioma of the organ of Zuckerkandl (Lodish et al. 2010). SDH-deficient GISTs are characterized by overexpression of insulin-like growth factor receptor 1/IGFR1, due to unknown reasons (Chou et al. 2012; Nannini et al. 2013).

Neurofibromatosis Type 1

Patients affected by neurofibromatosis type 1 (NF1) have an increased risk of developing GIST. NF1-associated GISTs are usually wild type for c-Kit and PDGFRA (Mussi et al. 2008) and can be associated with pheochromocytoma (Ozcinar et al. 2013; Vlenterie et al. 2013).

Abstract

Schwannoma (neurinoma) is a benign nerve sheath tumor composed of neoplastic Schwann cells. These neoplasms have a wide distribution and also occur in the hepatobiliary tract. Primary hepatobiliary schwannomas are mainly diagnosed in older individuals, with equal gender distribution. Hepatic schwannomas take their origin from cells of hepatobiliary nerves which in turn originate from the hepatic plexus, nerves accompanying blood vessels and bile ducts, and nerves of hepatic ligaments. The tumor can grow to large size and may reach a diameter of 20 cm. Large lesions show hemorrhage and necrosis, notwithstanding their benign features, and may undergo cystic change. Histologically, spindle cells form interlacing bundles, sometimes with tapered nuclei and palisading and formation of Verocay bodies. The tumor cells are reactive for S100 protein. A malignant variant, malignant schwannoma, is a well-known soft tissue sarcoma, but is a very rare primary hepatic neoplasm. Also malignant peripheral nerve sheath tumor can occur in the hepatobiliary tract, sometimes in association with neurofibromatosis type 1. Rare benign hepatic tumors of the hepatobiliary tract include neurofibroma and benign hepatic nerve sheath tumor. An important differential diagnosis is amputation neuroma.

Schwannoma of the Liver

Introduction

Schwannoma (synonyms: neurilemmoma; neurinoma) is a benign nerve sheath tumor composed of neoplastic Schwann cells. The neoplasm had first been described by Verocay under the name neurinoma (Verocay 1910). Hepatic schwannomas are thought to take their origin from cells of hepatobiliary nerves, which originate from the hepatic plexus, the largest branch of the celiac plexus, and the nerves accompany the hepatic artery, the portal vein, the bile ducts, and their respective intrahepatic branches. In addition, nerves enter the liver from the ligaments and the peritoneal foldings. Along the nerve network located within the hepatoduodenal ligament, Schwann cell growths occur as well and may cause biliary obstruction.

Epidemiology

Primary hepatic schwannoma has been reported several times, albeit it is a rare lesion (Bialik and Del'tsova 1966; Pereira Filho et al. 1978; Tuder and Moraes 1984; Hytiroglou et al. 1993; Heffron et al. 1993; Yoshida et al. 1994; Nakajima 1995; Wada et al. 1998; Flemming et al. 1998; Kapoor et al. 2005, Lee et al. 2008; Momtahen et al. 2008; Akin et al. 2009; Kim and Park 2010, Ozkan et al. 2010; Hayashi et al. 2012; Ota et al. 2012). Females and males seem to be equally involved. Most of the patients reported so far were old, age at diagnosis ranging from 38 to 74 years, similar to malignant liver schwannomas not associated with neurofibromatosis, whereas malignant liver schwannomas in NF1 usually occur in younger age groups. Hepatic schwannomas can evolve in the context of NF1, but several cases have also been observed in patients without evidence of neurofibromatosis (Heffron et al. 1993; Wada et al. 1998).

Clinical and Imaging Features

Clinically, primary hepatic schwannomas are solitary and expansively growing tumors ranging in size from 4 to 20 cm. Plain CT images show nonhomogeneous masses, with enhanced CT depicting clear margins and an irregularly structured tumor center. Hepatic schwannoma may undergo cystic changes, resulting in a cystic mass mimicking hydatid disease (Flemming et al. 1998). In large tumors, arteries and portal vein branches may be encased, a finding that does not imply malignancy. On MR images, the tumors are hypointense on T1-weighted images and mixed hypo-and hyperintense on T2-weighted images. On serial contrast-enhanced images, the

lesions revealed gradually increasing centrilobular enhancement (Momtahen et al. 2008; Ota et al. 2012).

Pathology

Macroscopy

At gross examination, these are usually firm tumors showing a gray cut surface, which may display geographic necroses and foci of hemorrhage, particularly in large tumors. Hepatic schwannomas may grow to large size (15 cm: Wada et al. 1998; 16 cm: Yoshida et al. 1994). Benign schwannoma of the liver has been reported to undergo extensive cystic change (Hytiroglou et al. 1993; Yoshida et al. 1994), with the risk of being misinterpreted as hydatid disease (Flemming et al. 1998). Sometimes, multiple cystic nodules containing a gelatinous material were noted (Pereira Filho et al. 1978).

Histopathology

Histology is characterized by the phenotype known for schwannomas located in other organs and tissue (Figs. 1 and 2). The leading tumor cell is an elongated spindle cell that forms bundles arranged in an interlacing fashion. The nuclei vary widely in shape and size, but ovoid or elongated forms prevail, with a rather uniform chromatin structure and only mild atypia. The mitotic count is very low, and in many areas mitotic figures are not in evidence. Cellular areas display interwoven fascicles of spindle cells with tapered nuclei and occasional palisading, a feature typical for schwannomas. In tumors with an Antoni A pattern, Verocay bodies are seen. Verocay bodies are nodular or ovoid cellular areas showing prominent palisading of spindle cells at high density, present as a fascicular or turbinate cellular accumulation. Rarely, myxoid areas with or without cystic change are seen.

Electron Microscopy

Tumor cells exhibit long interdigitations surrounded by a discrete basal lamina. Long-spacing collagen (Luse bodies) was not detected (Wada et al. 1998).

Immunohistochemistry

Similar to schwannomas in other locations, the neoplastic cells are markedly reactive for S100 protein (Hayashi et al. 2012).

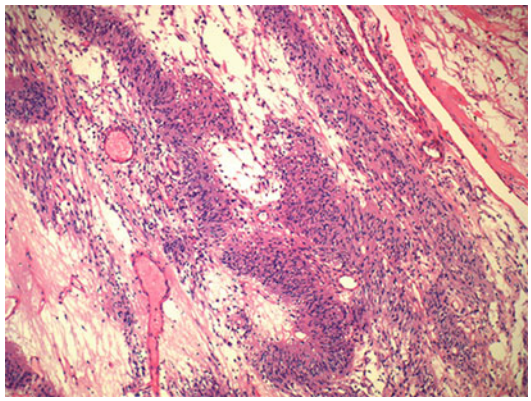

Fig. 1 Primary hepatobiliary schwannoma (neurinoma). Cellular bands with palisading are in evidence. There is focal myxoid change (hematoxylin and eosin stain)

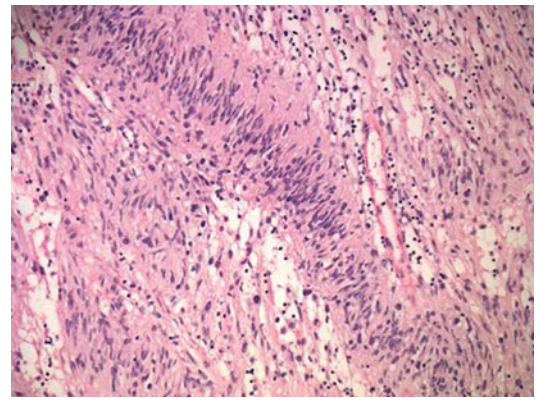

Fig. 2 Primary hepatobiliary schwannoma (neurinoma). Cell palisading at higher magnification (hematoxylin and eosin stain)

Differential Diagnosis

The histologic differential diagnoses mainly include leiomyomatous tumors, stromal tumors, and solitary fibrous tumor, all known to rarely occur in the liver as primary lesions. Schwannoma arising in the diaphragm can clinical mimic a liver tumor (Ikegami et al. 2004).

Primary Schwannoma of the Porta Hepatis

Besides schwannomas located within the liver substance proper, schwannoma arising in the porta hepatis has been described, this tumor apparently taking its origin from tissues of the hepatic artery (Choi et al. 2001; Park et al. 2006; Panait et al. 2011).

Primary Schwannoma of the Bile Ducts

Primary schwannoma can very rarely develop in the intra-and extrahepatic bile ducts (De Sena et al. 2009; Madhusuhan et al. 2009). Schwannomas of the extrahepatic bile ducts are clinically nonspecific. They can become symptomatic as soon as they cause bile duct compression or stenosis owing to intraluminal (polypoid) growth. Painless and progressive obstructive jaundice may ensue (Jakobs et al. 2003; Vyas et al. 2006). Most cases have been identified in the common bile duct (Oden 1955; Dowdy et al. 1962; Ronchetti and Zanniello 1962; Prevot et al. 1999; Honjo et al. 2003; Jakobs et al. 2003; Vyas et al. 2006; Fenoglio et al. 2007; Jung et al. 2007). Schwannoma can develop at the porta hepatis (Park et al. 2006; Kamani et al. 2007) and may clinically and radiologically mimic Klatskin tumor. Schwannoma was also identified in choledochal cyst (Otani et al. 2005).

Bile duct schwannomas show the histology of neurinomas known from other locations, often with Antoni A pattern and palisading of tumor cells (Jakobs et al. 2003; Kamani et al. 2007).

Primary Schwannomas of Hepatic Ligaments

Schwannoma has been observed as a primary tumor in the hepatoduodenal ligament (Pinto et al. 2011).

Primary Schwannoma of Hepatic Blood Vessels

Schwannomas can very rarely take their origin from hepatic blood vessels, e.g., the proper hepatic artery (Huang et al. 2011).

Primary Malignant Hepatic Schwannoma

Whereas malignant schwannoma is one of the most common soft tissue sarcomas in adults, accounting for about 10 % of all such lesions, primary malignant schwannoma of the liver is extremely rare and occurs with or without associated neurofibromatosis (Young 1975; Shmurun and Chibisov 1977; Tuder and Moraes 1984; Lederman et al. 1987; Morikawa et al. 1995; Fiel et al. 1996; Sheikh et al. 1996). In the five cases reviewed by Morikawa et al. (1995), all males, the mean age at the time of diagnosis was 68.7 years for those without associated NF1; the two patients with NF1 were much younger, i.e., 21 and 23 years, respectively. Primary hepatic malignant schwannomas are usually large (diameter of 20 cm, Shmurun and Chibisov 1977; 21 cm, Tuder and Moraes 1984) and solitary lesions, sometimes occupying a whole liver lobe (Morikawa et al. 1995). Among four reported cases, widespread metastasis had been found in two cases. At imaging, typical features include a well-demarcated hypodense mass on CT (Sheikh et al. 1996), and hypovascularity on angiograms, which is rather unusual.

Histology is characterized by a hypercellular neoplasm consisting mainly of spindle and polymorphic cells with hyperchromatic nuclei and numerous mitotic figures. The neoplastic cells are mostly arranged in the form of ill-defined,

sweeping fascicle-like structures. At the tumor-liver interface, the cells clearly invade the parenchyma and may grow into sinusoidal spaces, with atrophy of the adjacent hepatocyte plates. The spindle cells are immunoreactive for S-100 protein and vimentin. Particularly in large tumors, extensive necrosis is in evidence.

Pathogenesis

A critical step for the development of schwannomas is the non-expression of normal schwannomin/merlin by the Schwann cells involved. Merlin is the product of the NF2 gene and is an ezrin-moesin protein that normally localizes underneath the plasma membrane at cell-cell junctions and other cell surfaces sites that are rich in actin and actin-associated proteins and acts as a cytoskeleton organizer (McClatchey and Giovannini 2005; Denisenko et al. 2008). Merlin regulates contact inhibition of proliferation by limiting the delivery of several growth factor receptors at the plasma membrane of Schwann cells (Lallemsand et al. 2009). In mitogen-stimulated cells, p21-activated kinase (Pak) phosphorylates serine 518 in the C-terminal portion of merlin, inactivating the growth suppressive function of the protein (Okada et al. 2007; Roche et al. 2008; Chang and Welling 2009). This phosphorylation process is stimulated by neuregulin and laminin (Thaxton et al. 2008). Merlin/schwannomin phosphorylation requires binding to paxillin and targeting to the plasma membrane. Phosphorylated schwannomin is enriched in the peripheral-most parts of membrane specializations where paxillin, activated Pak, and Cdc42 but not Rac are highly expressed (Thaxton et al. 2007). Merlin was found to be expressed in 98 % of vestibular schwannomas and was inversely correlated with cyclin D1 in regard to intracellular localization. Merlin locates in the cytoplasm during the G0/G1 phase, moves to the nucleus at S phase, and accumulates in the cytoplasm at S phase after phosphorylation on serine 518 (Lü et al. 2008). Point mutation in the NF2 gene in schwannoma cells is associated with the expression of a merlin isoform with attenuated growth suppressive activity (Lepont et al. 2008). Deficiency of merlin, which normally binds to beta1 integrin and focal adhesion kinase, results in pathological adhesion to the extracellular matrix with increased numbers of mature and stable focal contacts, associated with activation of Rac1 (Flaiz et al. 2009). Merlin itself is regulated at the Roc1-cullin4A-DDB1-dependent level, and merlin is recruited to the E3 ligase complex through direct interaction with the WD40-containing adaptor protein VprBP (Huang and Chen 2008). Another protein involved in schwannomagenesis is PRKAR1A which is lost via inactivating mutations in the syndrome, Carney complex. Tissue-specific ablation of Prkar1a in murine neural crest precursor cells (TEC3KO mice) causes schwannomas with nearly 80 % penetrance. This is caused by almost complete loss of both NF proteins (Jones et al. 2008). A subset of patients with schwannomatosis reveal mutations in SMARCB1 (INI1, Hulsebos et al. 2007) or in both SMARCB1 and NF2 (Hadfield et al. 2008). Cell proliferation of differentiated Schwann cells is controlled by several factors and signaling pathways. Schwann cells are derived from neural crest cell precursors which are known to possess considerable plasticity. This is one reason why derivatives of neural crest cells can undergo transdifferentiation. Schwann cells can be transdifferentiated into myofibroblasts by downregulation of Sox10 (Roh et al. 2006).

Malignant Peripheral Nerve Sheath Tumor

ICD-O 9540/3

Introduction

Malignant peripheral nerve sheath tumor (MPNST) is defined as a malignant neoplasm arising from or differentiating toward cells intrinsic to peripheral nerve sheath and probably derived from the neural crest. The tumors often develop in association with neurofibromatosis type 1 (NF1). MPNSTs account for 5–10 % of

soft tissue sarcomas (Stark et al. 2001). Patients with neurofibromatosis type 1 (NF1) carry a 10 % lifetime risk of developing MPNST, this transition thought to be caused by complex genomic alterations (Mantripragada et al. 2009). In patients with NF1 and MPNSTs, survival rates are low and time to death is often less than 2 years (Zhou et al. 2009).

Primary Malignant Peripheral Nerve Sheath Tumors of the Liver and Biliary Tract

MPNST primary to the hepatobiliary tract has been reported several times (Young 1975; Schmurun and Chibisov 1977; Morikawa et al. 1995; Fiel et al. 1996; Iddings et al. 2008; Kobori et al. 2008; Subramaniam et al. 2012). In at least two instances, the tumors were associated with neurofibromatosis (Young 1975; Fiel et al. 1996). Grossly, the tumors resemble those seen in the soft tissues, i.e., firm tumors with central necrosis. The neoplasms may grow to very large size (e.g., diameter of 26 cm, Kobori et al. 2008). The tumor can invade almost entire liver lobes (Morikawa et al. 1995).

Histologically, the tumors are characterized by monomorphic or polymorphic spindle cells with hyperchromatic nuclei and the presence of mitotic figures, the majority of the cells being reactive for vimentin and S100 protein. CD10 is positive in MPNST, in contrast to benign neurofibromas (Cabibi et al. 2009). In the basement membrane component, laminin shows a prominent positivity. This phenomenon is reflected by the ultrastructurally detected presence of amorphous basement membrane-like material in the tumor interstitium (Kobori et al. 2008). Part of the spindle cells may assume a more prominent cytoplasm, causing an epithelioid morphology. Few giant cells may be noted. The mitotic rate varies considerably, ranging from very few mitotic figures to 13–14/10 HPFs (Kobori et al. 2008).

The differential diagnosis includes other primary hepatic spindle cell sarcomas and in particular liver metastasis of extrahepatic MPNST (Tomica et al. 2011; Meng et al. 2013).

Hepatic Schwannomas Undergoing Transformation into MPNST

There are few reports on tumors that seem to have developed from preexisting hepatic schwannomas, with formation of a malignant cell lineage of Schwann cells or perineural cells (Tuder and Moraes 1984; Woodruff et al. 1994).

Combined Hepatic Sarcomas in Neurofibromatosis

Schwannoma with angiosarcomatous change is a rare soft tissue neoplasm that affects older adults and mainly men. The angiosarcomatous component is usually of the epithelioid type and reveals solid or vessel-like cellular structures with CD31 and CD34 positivity (Rückert et al. 2000). In a young man with neurofibromatosis and known hepatic neurofibromas, a combined malignancy developed in the liver, consisting of both malignant schwannoma and angiosarcoma (Lederman et al. 1987).

Malignant Melanotic Schwannoma

A very rare subset of malignant nerve sheath tumors or schwannomas are characterized by the melanin deposition. These highly aggressive neoplasms occur in various organs and can metastasize to the liver (Janzer and Makek 1983), causing differential diagnostic problems with respect to melanoma metastasis. Malignant melanoma can undergo Schwannian differentiation, mimicking malignant melanotic schwannoma. Also this tumor type metastasizes to the liver (Schadendorf et al. 1993).

Malignant Triton Tumors of the Liver and Biliary Tract

Malignant triton tumor forms is a group of malignant tumors with a pluridirectional differentiation. These neoplasms are sometimes classified as subtypes of MPNST. They can express rhabdomyosarcomatous, osteoid, and chondroid components

(Kurtkaya-Yapicier et al. 2003; Ballas et al. 2009), and exceptionally even lipomatous lineages (Suresh et al. 2009).

Pathogenesis

Main molecular alterations include RAS/RAF/MAPK and/or PTEN/PI3K/AKT signaling pathways, PTEN being lost in both murine and human MPNST in NF1 (Gregorian et al. 2009). Eighteen percent of sporadic MPNSTs displayed RAS gene mutations (Perrone et al. 2009). P53 protein is expressed in part of MPNST and is an independent predictor of outcome (Brekke et al. 2009). MPNSTs show expression of PDGFRA, PDGFRB, and epidermal growth factor receptor (EGFR), with higher levels of EGFR expression seen in tumors associated with NF-1 (Holtkamp et al. 2008; Perrone et al. 2009). Overexpression of EGFR was correlated with worse prognostic variables and course. MPNST has a complex cell lineage with features reflecting neural crest/Schwann cell lineage-derived cells or perineural cells, and the tumors reveal deregulated signal cascades involving several pathways (review: Katz et al. 2009). Part of MPNST have typical EMA-positive perineural cells and have been proposed to be termed malignant perineurioma (Rosenberg et al. 2002). The cells express, apart from S100 protein, the erbB kinases mediating neuregulin-1 beta-isoform responses, which promote Schwann cell proliferation and migration during development and tumorigenesis (Stonecypher et al. 2005). The complex lineage pattern of MPNST cells is visualized by a strong reactivity for podoplanin in epithelioid MPNST (Jokinen et al. 2008).

Benign Hepatic Nerve Sheath Tumor

Benign nerve sheath tumor is a very rare neoplasm exceptionally developing in the liver. It was detected in a middle-aged female patient with a progressively enlarging epigastric lump of 8-month duration. CT revealed a 20 cm-sized tumor involving segments 2, 3, and 4 of the liver. The tumor was resected under the diagnosis of liver cell adenoma. The resection specimen disclosed two tumor nodules of 17 cm and 7.5 cm diameter, respectively, soft to firm in consistency. The larger nodule had a central area of necrosis. Histology revealed a spindle cell tumor with cells arranged in whorls and a storiform pattern, surrounded by a fibrous capsule. The cytoplasm of the tumor cells was eosinophilic, with indistinct borders, the nuclei being elongated or irregular. Mitotic figures were absent. The cells were immunoreactive for S100 protein, but were negative for c-kit and alpha-SMA.

Neurofibroma of the Liver

Introduction

Neurofibromatosis (NF; von Recklinghausen's disease) is a hereditary disorder which occurs in two types: type 1 (NF1) and type 2 (NF2). Autosomal dominant NF1 (assigned to chromosome 17q11.2) is primarily a disorder of nerves and astrocytes, with an incidence of about 1: 2000–3000. Conversely, autosomal dominant NF2 (assigned to chromosome 22q11.2) is a disease of the coverings of the central nervous system, intracranial manifestations chiefly including meningiomas and schwannomas, with an incidence of about 1: 50,000. Individuals with NF1 are predisposed to the development of benign and malignant neoplasms that arise primarily in cells derived from the embryonal neural crest (Skuse et al. 1989; Menon et al. 1990; DeClue et al. 1992; Legius et al. 1993; Johnson et al. 1993). The two main peripheral nerve tumors found in patients with NF1 are neurofibromas, a benign tumor, and malignant peripheral nerve sheath tumor (MPNST). The pathology of these lesions in NF1 has recently been reviewed (Woodruff 1999). Apart from nerve tumors, NF1 is associated with a rather broad array of other neoplastic lesions, including gastrointestinal stromal tumors (Giuly et al. 2003), pheochromocytomas, neuroblastomas, and mixed neuroendocrine and neural tumors. Children with NF1 are also predisposed to juvenile myelomonocytic leukemia, and some

heterozygous Nf1 mutant mice develop a similar myeloproliferative disorder. Overall, the risk of malignant myeloid disorders in young children with NF1 is 200–500 times the normal risk. In this chapter, hepatic tumorous manifestations of NF1 are discussed. Schwannomas primary to the liver are reviewed in another chapter.

Hepatic Neurofibromas

Neurofibromas involving the liver are rare and are specifically associated with type 1 neurofibromatosis. The majority of these tumors have been described as plexiform neurofibromas (Ghalib et al. 1995). Plexiform neurofibromas can produce large or even diffuse intrahepatic tumors, e.g., scattered throughout the entire liver around portal radicles. Most tumors have been observed in adults, but pediatric cases are also known. In part of the cases, neurofibromas have involved the compartment of the hepatic hilum, with encasement of vascular branches situated in this region (Poon et al. 2008; Hoshimoto et al. 2009). Plexiform neurofibromas also occur in the large bile ducts and are treated in a separate chapter. Plexiform neurofibroma of the liver may synchronously be associated with other tumors of the hepatobiliary tract, e.g., carcinoid of the ampulla of Vater (Samonakis et al. 2005).

Selected References Tesseraux and Zachmann 1954; Russomanno 1968; Bekker 1982; Meyer et al. 1982; Delacourt et al. 1987; Lederman et al. 1987; Partin et al. 1990; Chen et al. 1992; Hra et al. 1992; Gossios and Guy 1993; Rodriguez et al. 1993; Kakitsubata et al. 1994; Ghalib et al. 1995; Guzman Toro et al. 1995; Nakajima 1995; Andreu et al. 1997; Vilas Ferrol et al. 1998; Gallego et al. 1998; Cardinale et al. 2000; Fenton et al. 2001; Malagari et al. 2001; Imbert et al. 2002; Rui et al. 2002; Samonakis et al. 2005.

Clinical and Imaging Features

The gross presentation of hepatic manifestations of plexiform neurofibroma varies considerably. They produce infiltrative hypoechoic masses at sonography, the tumors being located around the porta hepatis and along the intrahepatic portal branches. On CT images, the masses are usually ill defined and hypoattenuating (Kakitsubata et al. 1994). Hepatic plexiform neurofibromas can grow to impressive size (7 cm; Malagari et al. 2001), and MRI images present them as circumscribed or ill-defined lesions with a multinodular configuration, showing low signal intensity on T1-weighted in- and out-of-phase images and hyperintensity on T2-weighted images (Gallego et al. 1998; Malagari et al. 2001). A periportal distribution of the lesions at imaging may reflect the development of the tumors along preexisting nerve structures located within Glisson's triads. The neurofibromas may grow along the vascular bundles, sometimes resulting in the encasement of the hepatic artery or the portal vein, with an eventual extension to the celiac trunk and into the hepatoduodenal ligament, rendering complete surgical resection difficult in such situations. Large tumors with intratumoral hemorrhage may evolve and have led to death in one young male patient (Lederman et al. 1987). However, in the latter case, neurofibroma lesions were present in portal tracts, and they were associated with malignant schwannoma and angiosarcoma, which is known to occur in the setting of von Recklinghausen's disease (Millstein et al. 1981; Riccardi et al. 1984; Png et al. 1996), even in children (Prasad 1983). A combination of plexiform neurofibromatosis and angiosarcoma of the liver has been described in a further report (Andreu et al. 1997).

Pathology

Macroscopically, hepatic neurofibromas are ill-defined, grayish-white masses that interdigitate with adjacent tissue. Plexiform lesions may show firm, white extensions that follow the intrahepatic portal tract sheaths.

Histology closely reflects the phenotype known for NF1-associated neurofibromas in other organs. Proliferations of all cellular elements of peripheral nerves are noted, including Schwann cells, the latter sometimes predominating and being the

chief cellular component, fibroblasts, perineural spindle cells, and axons. The cellular infiltrate may contain mast cells. Hepatic neurofibromas are nonencapsulated and, at their periphery, mainly grow along the portal tracts, sometimes effacing the portal vascular bundle and the septal or interlobular bile ducts. Abnormal growth of peribiliary nerves, associated with a considerable increase in extracellular matrix, may result in biliary obstruction and subsequent cholestasis (Hernandez Alvarez et al. 1991).

Neurofibroma of the Bile Ducts

Introduction

In contrast to schwannoma, neurofibroma of the biliary tract is a very rare lesion. It has been observed in the common hepatic duct (Chu 1950; Lovasz 1970; Mitchell et al. 1995; Taylor et al. 2001), the common bile duct (Claudon et al. 1988; Carbia et al. 1995; Bajor et al. 2002; Li et al. 2005; Béchade et al. 2010; Jiang et al. 2011), and the ampullary region (Simmons 1988). Most cases are sporadic non-syndromic lesions, but few cases have been found in association with neurofibromatosis type 1 (see below).

Clinical and Imaging Features

Bile duct neurofibroma can cause biliary obstruction with obstructive jaundice (Claudon et al. 1988; Carbia et al. 1995; Bajor et al. 2002; Li et al. 2005; Jiang et al. 2011). The lesions produce a circumscribed filling defect on MRI images (Li et al. 2005), but they may also cause complex structures with several submucosal tumor nodules (Taylor et al. 2001).

Biliary Tract Neurofibromas in Neurofibromatosis

The extrahepatic biliary tract, including the ampulla, is well known to be involved in neurofibromatosis von Recklinghausen (Meyer et al. 1982, Mendes Ribeiro and Woodham 2000). The most common neurofibromatosis-associated tumor in this anatomical compartment is somatostatinoma of the ampullary region, discussed in a separate chapter. In contrast, biliary tract neurofibroma is an exceptional finding in von Recklinghausen's disease (Relles et al. 2010). Multiple submucosal neurofibromas causing stricture of the proximal common hepatic duct have been described (Taylor et al. 2001). A collision tumor consisting of ampullary somatostatinoma and a neurofibroma has been observed (Varikatt et al. 2006).

Pathology

In one patient presenting with biliary obstruction, neurofibroma was manifest as a gray, rubbery, hard, and firm tumor with a smooth surface, measuring 1.5 cm in greatest diameter, arising from interior part of the common bile duct.

In neurofibromatosis type 1, bile duct neurofibroma has been observed to be of the plexiform type (Bajor et al. 2002) or to produce multiple neurofibromatous nodules in the submucosa of the bile duct (Taylor et al. 2001). However, plexiform bile duct neurofibroma has also been noted in the absence of neurofibromatosis (Mitchell et al. 1995).

Neurofibrosarcoma of the Liver

In rare instances, signs of malignancy are detectable, both on clinical grounds and histologically, resulting in the diagnosis of neurofibrosarcoma of the liver (Neumaier et al. 1997).

Other Liver Lesions Caused by Neurofibromatosis

Hepatoblastoma has been observed in association with NF1 (Uçar et al. 2007). A 72-year-old female with NF1 developed primary hepatic leiomyosarcoma (Maruta et al. 2004). Angiopathy with potentially catastrophic complications occurs in 1–3 % of patients with NF1 (Von Recklinghausen's vasculopathy; Zochodne 1984;

Oderich et al. 2007). Small, medium, and large arterial vessels are involved, including visceral arteries and the abdominal aorta (middle aortic syndrome), and the lesions are characterized by stenosis, occlusions, aneurysms, pseudoaneurysms, arteriovenous fistulas, and ruptures. Vascular disease associated with NF1 rarely manifests in the liver, e.g., as hepatic artery aneurysm (Hassen-Khodia et al. 1997) and spontaneous rupture of the hepatic artery (Rao et al. 2007). Congenital intrahepatic portosystemic venous shunt has been found in NF1 (Digilio et al. 2005).

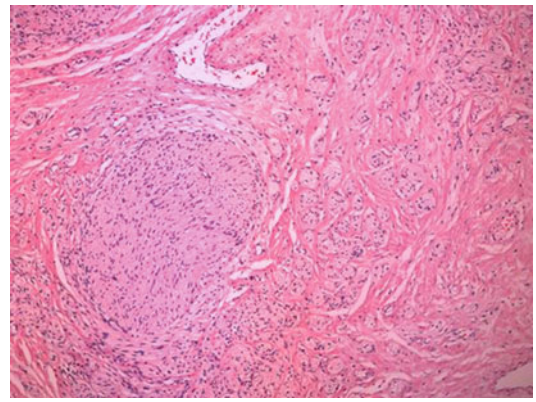

Fig. 3 Amputation neuroma of the biliary tract. The preexistent nerve (left half of figure) is associated with numerous newly formed nerve fibers embedded in collagenous scar tissue (to the right; hematoxylin and eosin stain)

Neuroma of Bile Ducts

Introduction

Neuroma (traumatic neuroma) are reactive lesions that almost always develop at the distal ends of the proximal segments of severed nerves. They are characterized by a neural enmeshment of a disorganized overgrowth of axons, Schwann cells, and perineural cells, forming fascicles of variable dimension embedded in a fibrocollagenous tissue (Figs. 3 and 4; Masson 1942).

Neuroma nodules are not neoplasms but represent thwarted attempts by the damaged nerves to regenerate (Stembridge 1951). Neuromas of the biliary tract derive from the sympathetic and parasympathetic fibers arising from the greater and lesser splanchnic nerves (Shafiroff and Hinton 1950; Loeweneck 1971; Zeff et al. 1976). It has been shown that the area of the common bile duct bifurcation with the cystic duct is a particularly nerve-rich region (Raigorodsky 1928; Womack and Crider 1947).

Traumatic neuroma, called "amputation neuroma," was described in detail in 1920 (Huber and Lewis 1920), but these authors reported that Odier at the beginning of the nineteenth century was the first to record the development of these growths (Odier 1811). Neuroma of the bile ducts was first described in 1928. The author described what he called a growth (Wucherung) of nerve tissue following repeated bile duct surgery (Husseinoff 1928). Neuromas of the cystic duct and common bile duct after cholecystectomy and

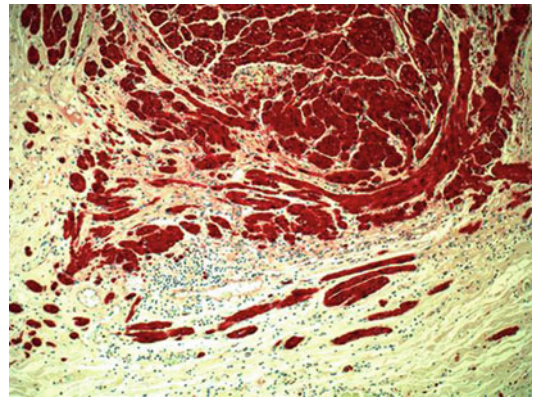

Fig. 4 Amputation neuroma of the biliary tract. In the S100 protein stain, the perineural accumulation of nerve fibers is clearly seen. The original nerve is located to the top of the figure (S100 protein immunostain)

being associated with jaundice were later reported in 1931 (Comfort and Walters 1931; Shapiro and Lifvendahl 1931), followed by a report in 1946 (Cieslack and Stout 1946) and the publication of six cases of post-cholecystectomy bile duct neuromas in 1947 (Womack and Crider 1947).

Epidemiology

Neuromas most commonly develop in the cystic duct after cholecystectomy, both open and laparoscopic, and are the best known example of

traumatic biliary tract neuroma (Berge and Haeger 1967). They develop with a highly variable delay following trauma, after cholecystectomy ranging from several months to more than 40 years (in one patient 45 years; Paquette et al. 2009). How frequent are posttraumatic biliary neuromas? The lesions have been demonstrated in up to 10 % of post-cholecystectomy patients at autopsy in one study (Pickens et al. 1999). But the vast majority of these patients remain asymptomatic for life.

Neuromas of the Cystic Duct

Neuroma of the cystic duct stump is a typical post-cholecystectomy lesion and is a known cause of post-cholecystectomy pain/post-cholecystectomy syndrome (Rosenberg and Matzner 1957; Loutsch 1961; Palagiano and D'Addato 1963; Mattler et al. 1965; Silvestri 1965; Joske and Finlay-Jones 1966; Maheshwari and Agarwal 1969; Zeff et al. 1976; Prinz et al. 1979). However, there are also rare instances of neuroma in the absence of previous surgery (Shapiro and Lifvendahl 1931; Peison and Benisch 1985). Post-cholecystectomy traumatic neuroma of the cystic duct may extend into the wall of the large extrahepatic bile ducts and thus cause biliary obstruction (Iannelli et al. 2003). Neuroma protruding from the cystic stump into the large ducts can be visualized by intraductal ultrasonography (Shimura et al. 2001).

Neuromas of the Hepatic Ducts

Neuroma of the right hepatic has been observed following right hemihepatectomy (Choi et al. 2009). Neuromas of the hepatic ducts can mimic hepatic duct carcinoma (Shumate et al. 1992; Koike et al. 2000) or Klatskin tumor (Martinez Ordaz et al. 1999; Pickens et al. 1999).

Neuromas of the Common Bile Duct

The first report (in German) of neuroma of the common bile duct referred to a patient who had undergone cholecystectomy owing to symptomatic cholecystolithiasis, studied at the Institute of Pathologic Anatomy of the University of Baku, now in Azerbaijan (Husseinoff 1928). It is suggested that neuroma of the extrahepatic large bile ducts produce signs and symptoms only in a very small proportion of patients, common bile duct neuroma being one cause of post-cholecystectomy syndrome (Stibenz et al. 1984). Symptomatic patients tend to present with intermittent right upper quadrant pain. Part of the patients develop jaundice owing to biliary obstruction. The causes of common bile duct neuroma comprise the post-cholecystectomy status, and the lesions also occur after liver transplantation (Colina et al. 1994; Mentha et al. 1999; Herrera et al. 2009), after innocent blunt abdominal trauma (Katsinelos et al. 2002), and in patients without known trauma or surgery (so-called "spontaneous" neuroma; Sugahara et al. 1985; Knapen et al. 1994; Akiyama et al. 1995; Tsitouridis et al. 1998).

Selected References Stembridge 1951; Bartlett and McDermott 1954; Hume and Buxton 1954; Cattell and Ville 1961; Takahara et al. 1981; Kopolovic et al. 1984; Larson and Storsteen 1984; Hochain et al. 1988; Rush et al. 1988; Turani et al. 1988; Van Gulik et al. 1989; Hofmann-Wackersreuther et al. 1991; Saint-Paul et al. 1993; Nagata et al. 1995; Nagafuchi et al. 1998; Chantranuwat and Shuangshoti 1999; Gavelli et al. 1999; Mentha et al. 1999; Watanabe et al. 2001; Wysocki et al. 2002; Capovilla et al. 2005; Cimaschi et al. 2006; Paquette et al. 2009.

In most cases, jaundice occurred late after surgery, the latest development of jaundice occurring 29 years after surgery. The patients sometimes show a slight to moderate elevation of serum CA 19-9, usually around 100 U/ml (normal: $<$34.9 U/ml), what may be a misleading finding in the differential diagnostic work-up (Hyman et al. 2003). The vast majority of patients are diagnosed in retrospect when the surgical pathology specimen is examined (Pickens et al. 1999; Hotta et al. 2004; Ueno et al. 2008; Paquette

et al. 2009). In part of the patients, the lesion may mimic biliary tract cancer (Koh et al. 2008).

Imaging reveals an irregularly shaped mass on CT and MRI scans, sometimes with bulging into the bile duct lumen or circumscribed thickening of the wall (Ueno et al. 2008; Paquette et al. 2009). MR imaging showed a dilatation of the bile ducts and a nodule or nodules with well-defined high-intensity nodules on T2-weighted images, while T1-weighted images showed iso-intense nodules with a low-intensity capsule (Ueno et al. 2008). Cholangiography shows a smooth stricture and a prestenotic duct dilatation (Ueno et al. 2008).

Pathology

A detailed pathologic description of post-cholecystectomy biliary tract neuroma is found in an instructive report as of 1931 (Comfort and Walters 1931). The authors describe a firm resection specimen of the cystic duct stump showing on cross section a central canal whose walls contained the typical interlacing nerve bundles in a groundwork of connective tissue. Neuromas located to the cystic stump may show ulceration of the overlying mucosa (Watanabe et al. 2001). Some neuromas exhibit an exophytic growth and may produce polypoid lesions, e.g., in the gallbladder (Sano et al. 1985).

Histology shows a predominantly eccentric thickening of the duct wall and variable narrowing of the lumen. Are there alterations in the nerves and ganglia that serve the structures giving rise to neuromas? Husseinoff (1928), in his case of a post-cholecystectomy neuroma of the common bile duct, noted fibrosis and a cellular infiltration of the stellate ganglion.

Pathogenesis

Regeneration of injured peripheral nerves involves complex and intimate interactions between axons, Schwann cells, perineural cells, fibroblasts, and components of the extracellular matrix. Neuroma formation is thought to be induced by posttraumatic nerve cell growth after surgery (Zeff et al. 1976; Pickens et al. 1999; Hyman et al. 2003; Hotta et al. 2004; Ueno et al. 2008; Hilliard 2009). The mode of nerve transection plays a role in neuromagenesis, as, e.g., oblique transection prevents neuromas (Marcol et al. 2006).

Axon growth is promoted by nerve growth factor (NGF), Sox11, and matrix proteins, specifically laminin (Tucker and Mearow 2008; Gordon 2009; Jankowski et al. 2009). Axonal guidance and neurite outgrowth are regulated by collapsing response mediator protein-2/CRMP-2, which is a calmodulin-binding protein (Zhang et al. 2009). On the other hand, axon outgrowth is controlled by axon regeneration inhibitors, including myelin-associated glycoprotein, Nogo and Nogo receptor, and chondroitin sulfate proteoglycans (McGee and Strittmatter 2003; Atwal et al. 2008; Yang and Schnaar 2008). Schwann cell proliferation in the regenerating nerve is mediated by ERK1/2 (Seo et al. 2009) and MMP-9 (Chattopadhyay and Shubayev 2009), while stromelysin generates a fibronectin fragment that inhibits Schwann cell proliferation (Muir and Manthorpe 1992). Growing Schwann cells express the receptor for, and are stimulated by, locally synthesized calcitonin gene-related peptide (Toth et al. 2009). Nerve fibroblasts affect the migratory behavior of Schwann cells, via neuregulin (Dreesmann et al. 2009). Schwann cells in regenerating nerves produce glial fibrillary acidic protein, induced by STAT3 which in turn depends on interleukin-6 (Lee et al. 2009). Myelinating Schwann cells express glucose-dependent insulinotropic polypeptide (GIP) and its receptor, GIPR, forming an autocrine and paracrine system regulating Schwann cell function. Schwann cell differentiation in regenerating nerves is regulated by meltrin-beta/ADAM 19, which functions as a modulator of juxtacrine signaling from axons that activate the Akt pathway and the Kros-20 expression, prerequisites of Schwann cell differentiation (Yumoto et al. 2008; Wakatsuki et al. 2009). Brain-derived growth factor (BDNF) is involved in local neuropathic pain development in neuromas, but seems to promote experimental neuroma formation (Marcol et al. 2007). The cells involved in regeneration of damaged nerves also include mononuclear cells

derived from the bone marrow and homing to the injury site. These cells have been shown secrete NGF (Ribeiro-Resende et al. 2009).

Neuromatosis of Bile Ducts

Neuromatosis is a condition characterized by neural hypertrophy and hyperplasia unassociated with ganglion cells, generally found in patients with multiple endocrine neoplasia type IIb (MEN IIb) caused by RET gene mutations and usually located in the gastrointestinal tract (Sachdev 1990; Lee and Norton 2000; Prabhu et al. 2004). Less commonly, neuromatosis has been observed in neurofibromatosis type 1, Cowden's disease, PTEN hamartoma-tumor syndrome, juvenile polyposis coli, Hirschsprung's disease, and colonic adenoma with or without adenocarcinoma (Schaffer et al. 2006; Gustafson et al. 2007). Multiple mucocutaneous neuromas have also been described as an idiopathic entity, i.e., in the absence of MEN IIb or the other conditions listed above (Truchot et al. 2001). There are very few reports on non-MEN IIb-associated neuromatosis of the biliary tract. In 64-year-old women without signs of MEN IIb, a history of cholelithiasis and biliary colic was investigated by ultrasound and CT, showing severe dilatation of the intra-and extrahepatic bile ducts as well as a scleroatrophic gallbladder with numerous calculi. Cholangiography revealed an abrupt blockage of the right hepatic duct without evidence of lithiasis. Based on the suspicion of malignancy, resection of the gallbladder and of part of the bile ducts was performed. The cystic duct contained a white, elastic, well-demarcated nodule of 4 mm diameter. Microscopy showed diffuse neural hypertrophy in the wall of the bile ducts, with the presence of numerous markedly thickened and highly branched nerve bundles. The cystic duct nodule was mucosal neuroma containing proliferated Schwann cells and numerous axons, in the absence of ganglionic cells. The morphology closely resembled that of gastrointestinal neuromatosis in MEN IIb (Tardio 2007). Neuromatosis has been diagnosed in the gallbladder (Cosmacini et al. 1967).

Tumors of a Granular Cell Lineage

69

Contents

Abstract

Granular cell tumor (granular cell schwannoma) is a benign tumor characterized by the proliferation of distinct cells with a granular cytoplasm and unknown histogenesis. The cells are reactive for S100 protein and inhibin-alpha. These neoplasms occur almost ubiquitously in the body, but most lesions are diagnosed in the tongue, oral mucosa, and skin. Hepatobiliary granular cell tumor is a very rare tumor and most cases were detected in the walls of bile ducts. Less than 1 % of all these neoplasms originate from bile ducts. Here, they more often develop in the large extrahepatic ducts, gallbladder, and cystic duct, and there is a predominance in female patients. The lesions are mostly solitary and rarely multifocal. Large solitary lesions can cause biliary obstruction. The histologic presentation is the same for granular cell tumors located elsewhere. There exists a very rare malignant variant. A further rare malignancy with granular tumor cells is alveolar soft part sarcoma.

Hepatobiliary Granular Cell Tumors

ICD-O 9580/0 (malignant granular cell tumor: 9580/3)

Introduction

Granular cell tumor (GCT, synonyms: granular cell myoblastoma, granular cell schwannoma, Abrikossoff's tumor) represents a benign tumor mostly occurring in patients in their second to sixth decades, characterized by a growth of distinct cells with a markedly granular cytoplasm, occurring almost ubiquitously in the body, albeit with certain predilections, most lesions developing in the tongue, oral mucosa, and skin. Although a myogenic origin has been found to be wrong, the histogenesis of GCT is still unknown.

GCT was originally identified in the skeletal muscle of the tongue and termed myoblastic myomata (Abrikossoff 1926). Previous apparent observations of GCT by Virchow (1854) and Weber (1854) as cited by Ordonez (Ordonez 1999) represent, when one reads the original articles, early observations of either true lingual rhabdomyoma (see ▶ Chap. 64, "Tumors of the Striated Muscle Cell Lineage: Hepatobiliary Rhabdomyosarcoma and Rhabdomyoma") or a hamartoma-like hypertrophy of the tongue. Weber described, in his publication written in German, the case of 21-year-old man with a massive enlargement of the tongue ("size of a hand"), leading to displacement of the jaw teeth. Histologically, lingual hypertrophy with interposed adipose tissue, abnormal vascularization, and immature-looking myocytes/myoblasts were found (Weber 1854). Aleksei Ivanovich Abrikossoff (1875–1955) was a Russian pathologist who, from 1918 onwards, worked as a professor of pathological anatomy at the first and second Moscow State University. In his publication of 1926, he proposed that the "myoma" he described originated from the skeletal muscles. In his 1931 publication, he then called the lesion "myoblastic myoma" (Abrikossoff 1931), a term which was modified to "myoblastoma" and widely used in the years to come. The granular cell feature of the lesion was first employed as a diagnostic term in 1927 ("rhabdomyome granulocytaire"; Diss 1927), a term still used in 1952 in one report ("rabdomioma granuloso"; Fialho and Hilario 1952).

A distinct site of GCT is the upper oro-respiratory tract (Strong et al. 1970; Lack et al. 1980), where two groups of GCT develop, i.e., the gingival tumors of infancy (congenital epulis of the granular cell type) and the group of non-gingival tumors (tongue, larynx, bronchi, and trachea). GCT also has a striking predilection for the gastrointestinal tract, 5–10 % of GCT occurring in this system, but specifically in the esophagus. There are more than 100 reported cases of colorectal GCTs, more commonly occurring in men in the 5th decade. Gastrointestinal GCTs also occur with descending frequency in the anal region, stomach, and small bowel.

General Morphological Features of Granular Cell Tumors

As specified in more detail below, the main histologic feature of GCT is the proliferation of medium-sized to rather large cells with a remarkably granular cytoplasm and usually small and dark nuclei. These cells form ill-defined nodular lesions with sometimes invasive-looking borders. Immunohistochemically, GCT is reactive for S100 protein (Stefansson and Wollmann 1982; Dhillon and Rode 1983) and sometimes for a lysosome-associated protein detected by the CD68 antibody (Filie et al. 1996), but S100 protein-negative GCT is also recognized, e.g., the congenital variants (Filie et al. 1996) and GCT in the meninges (Vang et al. 2000). Other and more variable immunoreactivities include vimentin, neuron-specific enolase (NSE), CD57, Leu-7, alpha-1-antitrypsin, alpha-1-antichymotrypsin, inhibin-alpha, and osteopontin (review: Ordonez and Mackay 1999).

Granular Cell Tumors of the Bile Ducts

Epidemiology

The first case of GCT involving the bile duct system was reported in 1952 and involved a 25-year-old black female with obstructive jaundice secondary to GCT located to the distal intrapancreatic part of the choledochus (Coggins 1952). The first reported case of GCT of the cystic duct (albeit interpreted to be a granular

rhabdomyoma) also goes back to 1952 (Fialho and Hilario 1952). GCT of the biliary tract is rare; it has been estimated that less than 1 % of all GCT originate in this compartment (Karakozis et al. 2000). Despite its rarity, granular cell tumor is the most common benign non-epithelial tumor of the extrahepatic bile ducts and occurring more commonly in the bile duct than in the gallbladder. A predilection for large extrahepatic bile ducts is evident from the published observations: most of the tumors were observed either in the common bile duct or the cystic duct, followed by the hepatic ducts and the gallbladder (less than 5 %). Among 77 cases reviewed in 2010, 39 were located to the common bile duct, 19 to the cystic duct (25 when combined with other locations), and 18 to the hepatic ducts (including combinations) (Patel and Jakate 2010). Biliary tract granular cell tumor clearly predominates in female patients. In a review of 77 cases reported in the literature, 65 patients were female, 12 were male (Patel and Jakate 2010). When screening the literature, it is striking to note that about two thirds of the cases have been observed in black women, at a median age of 32 years (Te Boekhorst et al. 2000). Adults are predominantly involved, of rather young age (mean and median based on a review of 42 cases: 40 and 34 years, respectively; Lafreniere et al. 1991), but biliary tract GCT also occurs in the pediatric age group (Reynolds et al. 2000). From the cases reported so far, it is striking to note that more than 90 % developed in female patients, with a preponderance of blacks. Overall, more than 70 reports are found in the literature.

Clinical and Imaging Features

Commonly, the lesions are solitary; in addition, multifocal biliary tract GCT has been found (Martin and Stulc 2000). Most cases present with signs of biliary stenosis, sometimes associated with right upper quadrant pain, jaundice, fatigue, and hepatomegaly. In a review, signs of biliary obstruction were identified in 41 out of 42 reported cases (Lafreniere et al. 1991). This stenosis can mimic cholangiocarcinoma, in particular when the tumor occupies a bile duct in the hilar/perihilar region of the liver, where the lesion may resemble Klatskin tumor (Sanchez and Nauta 1991; Te Boekhorst et al. 2000; Hoda et al. 2005; Lochan et al. 2006; Bilanovic et al. 2008). The sometimes marked dilatation of the bile duct may be confounded with choledochal cyst. Long-standing biliary obstruction by GCT can induce biliary cirrhosis (Fairchild et al. 1999). In part of the cases, GCT of the biliary system occurred concomitantly with calculous disease of the biliary tract (Goldman et al. 1967; Ishii et al. 1977; Mackenzie et al. 1994; Butler and Brown 1998).

Topography of Biliary Tract Granular Cell Tumors

Most biliary GCT develops in the common bile duct. GCT has been observed to originate from the most distal part of the distal common bile duct, sometimes in its intrapancreatic part (Coggins 1952; Manstein et al. 1981; Chandrasoma and Fitzgibbons 1984; Mackenzie et al. 1994; Aubert et al. 1999; Altavilla et al. 2004; Heuer et al. 2004; Hoda et al. 2005; Zaidi et al. 2007; Bot et al. 2008). Marked stenosis of the most distal segment of the common duct may mimic cholangiocarcinoma (Tonsi et al. 2006). Rarely, the tumor location is even more distal, involving the ampullary region (Khalid et al. 2005). In case GCT develops at the hepatic duct confluence, the stenosing lesion may mimic a hilar cholangiocarcinoma (Klatskin tumor) leading to extended duct or hilar resection (Sanchez and Nauta 1991; Te Boekhorst et al. 2000). Several observations document the occurrence of GCT in the cystic duct (Fialho and Hilario 1952; Serpe et al. 1960; Goldman et al. 1967; Mackay et al. 1968; Reul et al. 1975; Hobbiss et al. 1987; Timberlake and Tachovsky 1988). Cystic duct stenosis caused by GCT can induce cholecystitis (Barber 1984), gallbladder hydrops (Reul et al. 1975), or mucocele (Serpe et al. 1960; Mackay et al. 1968; Yamashina and Stemmermann 1984). GCT also develops in the gallbladder itself (Aisner et al. 1982).

Pathology

Macroscopic Features

Biliary GCT is characteristically small and lack a discrete capsule. When sectioned, they are whitish with a rubbery consistency. The lesions vary greatly in size. In a review of 31 cases where the tumor size was identifiable from the reports, 65 % measured less than 1 cm, 20 % were between 1 and 2 cm, 13 % were between 2 and 3 cm, and 3 % were between 3 and 4 cm in diameter. Larger tumors, i.e., those exceeding 2 cm, were localized to the common bile duct or the common hepatic duct (Lafreniere et al. 1991). The local duct extension of the tumor is mostly sectorial, but lesions encircling the duct are also encountered. The intramural growth can cause bile duct obstruction (Altavilla et al. 2004) followed by prestenotic duct dilatation (Chandrasoma and Fitzgibbons 1984). The mucosal surface may be eroded.

Histopathology

Histologically, the duct wall involved is infiltrated by rather large and round to ovoid tumor cells forming nests, fascicles, or sheets, sometimes separating the smooth muscle bundles of the duct wall (Fig. 1). These cells contain numerous small and large eosinophilic granules in the cytoplasm and sometimes PAS-positive granular aggregates. The tumor cells can show longitudinal stripes or streaks in the cytoplasm. These strings, already depicted in Abrikossoff's original in Fig. 3, may have led to the interpretation of a myogenic origin of the cells ("myoblasts" or "sarkoblasts"). These strings represent a distinct cytoplasmic alignment of lysosomes. This view is supported by ultrastructural findings of aligned membrane-limited and lysosome-containing compartments in granular cells (see Fig. 8 on p. 196 in Ordonez 1999 and Fig. 8 on p. 215 in Ordonez and Mackay 1999). More uncommonly, spindle cells are encountered. The nuclei are round and centrally placed; they contain 2–3 small nucleoli. Mitotic figures are not found. The tissue components encircling the GCT cell nests contain the

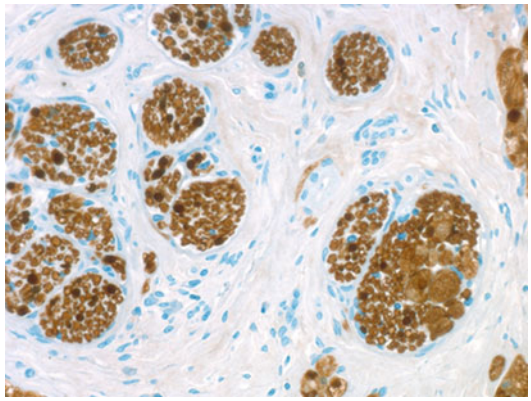

Fig. 2 Granular cell tumor of the bile duct with strong reactivity of the tumor cells for S100 protein (S100 protein immunoreactivity)

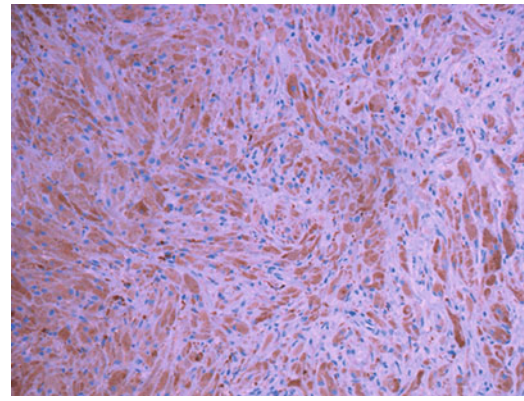

Fig. 3 Granular cell tumor of the bile duct. The neoplastic cells are consistently positive for inhibin-alpha (inhibin-alpha immunostain)

matrix proteins, laminin, and collagen IV (Miettinen et al. 1984; Reibel et al. 1985; Nathrath et al. 1986). In some instances, tumor cells are closely associated with small nerves and seem to invade perineural spaces (Altavilla et al. 2004).

Immunohistochemistry

The cells of granular cell tumors typically express S100 protein in a diffusely granular staining pattern in the cytoplasm and within the nuclei (Fig. 2). GCTs of the extrahepatic bile ducts and the gallbladder are diffusely positive for inhibin-alpha (Fig. 3; Murakata and Ishak 2001). The tumors also express the intermediate filament, nestin, in the cytoplasm and often with prominent membranous enhancement (Parfitt et al. 2006). Part of GCTs is reactive for CD68 (Filie et al. 1996).

Invasive Phenotype in Granular Cell Tumor

Although most GCTs are regarded to be benign, a locally invasive phenotype may be encountered. In a case analyzed by autopsy, the distal portion of the common bile duct displayed an ill-defined yellow homogeneous and rubbery area of thickening measuring up to 3.5 cm, with an intact overlying mucosa. Histologically, the growth occupied the entire wall of the duct and extended beyond the wall of the duct into the interstitial connective tissue of the pancreas, causing focal pancreatic atrophy (Coggins 1952).

Epithelial Hyperplasia Associated with Granular Cell Tumors

GCT developing beneath squamous epithelium of the skin is well known to induce a so-called pseudoepitheliomatous hyperplasia (PEH) of the overlying epithelium (Lack et al. 1980). PEH is sometimes mistaken to be a squamous cell carcinoma. Interestingly, PEH may involve non-squamous epithelial surfaces, in that it was found in the bronchial mucosa in a case of endobronchial GCT (Scala et al. 1999). Is there evidence that, similar to the situation in the skin, bile duct GCT induces a hyperplastic cholangiocyte reaction at the mucosal surface? In few situations, reactive atypia of the overlying epithelium and metaplastic pyloric glands may be observed.

Malignant Granular Cell Tumor: One or Several Entities

The first example of malignant GCT (localized to the urinary bladder) was described in 1945 (Ravich et al. 1945), and numerous cases have

since been reported, albeit not all of these are acceptable as malignant GCT. In a review from 1955 of the earlier reports, Gamboa stated that there were ten acceptable cases and rejected 21 cases that probably were rhabdomyosarcomas or alveolar soft part sarcomas (Gamboa 1955). Malignant GCT developing in the biliary tract has not been reported so far.

Differential Diagnosis

Nests of GCT can be confounded with accumulations of large macrophages/histiocytes with granular cytoplasm, collections of granular carcinoma cells, or amelanotic melanoma. Immunohistochemistry with the strong positivity for S100 protein in case of GCT will avoid interpretational errors.

Tumors with a Granular Cell Phenotype: Histogenetic Considerations, Do Granular Neoplastic Cells Involve a Lysosomal Disorder (Lysosomopathy)?

The cell of origin and the histogenesis of GCT have been a source of controversy (Abrikossoff 1926; Azzopardi 1956; Sobel and Churg 1964; Sobel et al. 1973; reviews: Ordonez 1999; Ordonez and Mackay 1999). The initial interpretation was that of a myogenic origin ("myoblasts" or "sarkoblasts"; Abrikossoff 1926, 1931; see below), but Abrikossoff already noted in his work of 1926 that, irrespective of the term he used ("myomas derived from the cross-striated musculature"), the five tumors he described were in part lacking cross-striation of the cells, in contrast to rhabdomyomas. He used the designation, rhabdomyoma nonstriocellulare ("non-cross-striated rhabdomyoma") to denote such lesions, and suggested a loss of cross-striation in myoblastic growths (Abrikossoff 1926).

Already in 1935, it was suggested that GCT might have a neural origin (Feyrter 1935). These authors and others emphasized the relationship between granular cells and peripheral nerves, resulting in the terms granular cell neuroma and granular cell neurofibroma (Fust and Custer 1948, 1949; Feyrter 1949, 1952). A derivation from (degenerated?) perineural fibroblastoid cells (Pearse 1950) or from neural crest cells (Buley et al. 1988) has also been discussed. Based on ultrastructural studies and on S100 protein reactivity, a Schwann cell origin has been suggested (Fisher and Wechsler 1962; Stefansson and Wollmann 1982; Armin et al. 1983; Mukai 1983), leading to one of the terms used to denote these lesions, i.e., granular cell schwannoma (Fisher and Wechsler 1962). A Schwannian cell derivation was also suggested by the finding of PGP 9.5 reactivity (Mahalingam et al. 2001) and Leu-7 reactivity in GCT cells (Smolle et al. 1985). Leu-7 is directed against a myelin-associated glycoprotein. On the other hand, other authors have suggested that GCT may rather be derived from uncommitted and possibly nerve-related mesenchymal cells (Miettinen et al. 1984).

Ultrastructural studies have found the cause of the light microscopic granularity of the cells' cytoplasm: the cells are rich in abnormally large lysosomes and myelin-like figures and may, albeit inconstantly, contain the so-called angulate bodies (Okada et al. 1990; Carstens and Yacoub 1993). Angulate bodies or lysosomes are, however, not restricted to a certain cell type, or, specifically, to Schwann cells, but occur in many situations and several cell types where the glycolipid composition of lysosomal membranes is changed. A further argument against a consistent role of Schwann cells is the marked reactivity of GCT cells for osteopontin, which is not detectable in schwannomas (Hoshi et al. 2005). It has been suggested that a distinct and possibly nerve sheath-related, CD34/vimentin-positive cell may also be involved (Maiorano et al. 2000).

Alveolar Soft Part Sarcoma

ICD-O code 9581/3

Introduction

Alveolar soft part sarcoma (ASPS) is a tumor entity first described in 1952 (Christopherson et al. 1952). Notwithstanding the characteristic histology, the cell lineage involved in this neoplasm is still unknown. There is no benign counterpart of this tumor. ASPS is rare; only about 0.5–1.0 % of all soft tissue sarcomas are ASPS. The neoplasm occurs predominantly in adolescents and young adults, more frequently in females, specifically in the age group under 25 years. The female predominance of ASPS has been proposed to be related to female possession of an extra X chromosome/non-inactivation of the ASPS X: autosome translocation fusion gene (Bu and Bernstein 2005; Folpe and Deyrup 2006). A little more than two thirds of the lesions have been observed in the buttock/thigh, legs, and chest wall or trunk, all other regions being clearly less common, apart from the tongue, which is relatively often involved in younger patients. About 3 % of the tumors develop in the retroperitoneal space (Weiss and Goldblum 2001; Anderson et al. 2005). ASPS is a malignancy with a characteristic metastatic pattern. Early metastasis to the lung, brain, and bone is common and has occurred in 21–65 % of patients by the time of initial presentation. Typically, the lungs are the first site to shoe metastatic disease, followed by the brain and bone, and other localizations, including the viscera, liver, heart, breast, and kidney. In particular for ASPS with unusual histology and/or locations, the detection of the ASPL/ASPSCR1-TFE3 transcript by the use of RT-PCR has been recommended (Williams et al. 2011). The translocation breakpoint can be identified by FISH, in particular dual-color, break-apart FISH (Zhong et al. 2010).

ASPS of the Hepatobiliary Tract

Primary hepatic ASPS was detected in a 47-year-old woman in whom abdominal imaging was induced by the observation of continuously elevated alkaline phosphatase levels. First CT and MR images showed a 5.1 × 2.8 cm-sized liver mass in the left lobe at the level of the portal hilum. During the next 3 months, CT images showed that the mass nearly doubled in size. Resection was planned but was deemed impossible because of involvement of the hepatic veins and the common hepatic duct. A surgical biopsy revealed the histology of ASPS (see below). Fluorescent ISH assays confirmed a translocation on Xp11.2 (TFE3 gene) in 75 % of tumor cells, consistent with an ASPL/TFE3 fusion. Comprehensive CT and PET studies did not show a lesion outside the liver, and MR findings of both lower extremities were also negative. In a later work-up, the tumor was regarded resectable. The hepatectomy specimen showed a 14.2 × 12.4 × 6.2 cm tan-to-pink, centrally necrotic and focally hemorrhagic tumor of the same histologic presentation as previously. Disease progressed, with metastases, and the patient died 22 months after resection (Shaddix et al. 2008).

General Histologic Features of Alveolar Soft Part Sarcoma

Histologically, the pattern is uniform and characterized by groups or compartments of cells, these structures being separated from each other by thin-walled vascular channels and matrix septa, resulting in a (pseudo)alveolar-like image giving the tumor its name. This alveoloid pattern is furthermore promoted by loss of cell adhesion and thus gap formation caused by regressive changes commonly occurring in the center of the cellular compartments (Weiss and Goldblum 2001; Khanna et al. 2008). At the periphery of the lesion, abnormal and dilated blood vessels are a typical feature, and angioinvasion is typical for this neoplasm. The neoplastic cells are large and rounded, sometimes polygonal, with distinct cell borders and one or more large vesicular nuclei with usually small nucleoli. A part of the cells is diffusely PAS-positive owing to an elevated glycogen content. The mitotic count is rather low.

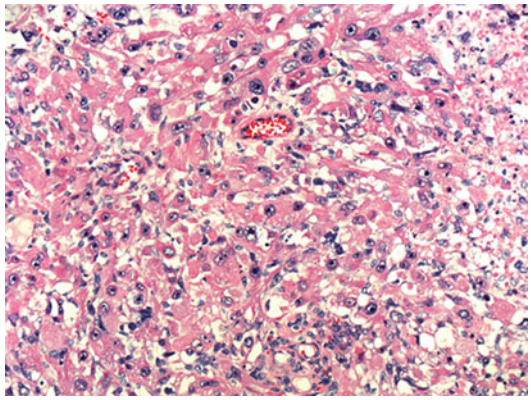

Fig. 4 Hepatic metastasis of alveolar soft part sarcoma. Large and highly atypical neoplastic cells with nuclei having prominent nuclei exhibit an eosinophilic and granular cytoplasm (hematoxylin and eosin stain)

In PAS stains, a fraction of the cells contain PAS-positive, diastase-resistant rhomboid or rod-shaped crystalloid inclusions, originally recognized and described in 1959 (Masson 1959). This phenomenon is found in about 80 % of ASPS (Weiss and Goldblum 2001). A similar type of crystalloids has been observed in large epithelioid smooth muscle cells of angiomyolipoma (Mukai et al. 1992). Apart from crystalloids, uncrystallized granules are found in ASPS cells, consisting of an aggregation of uncrystallized filaments with a diameter of 6 nm (Mukai et al. 1990). The precrystalline cytoplasmic inclusions have been shown to contain monocarboxylate transporter 1 (MCT1) and CD147 (see below; Ladanyi et al. 2002; comment: Weiss 2002). Immunohistochemically, reactivity for vimentin, muscle-specific actin, and desmin seems to be established (Rekhi et al. 2012), but part of the cells may be positive for S100 protein and/or neuron-specific enolase, while cytokeratins are negative. Immunohistochemical positivity for TFE3 (transcription factor E3, see below) is a useful marker for the diagnosis of ASPS (Williams et al. 2011; Rekhi et al. 2012). CD147 (basigin, EMMPRIN) can also serve as a diagnostic marker for ASPS. ASPS harboring the TFE3 gene fusions is immunohistochemically positive for cathepsin K (Martignoni et al. 2011).

Differential Diagnosis

The only pathologic differential diagnosis is ASPS metastatic to the liver (Fig. 4; Font et al. 1982; Casanova et al. 2000; Portera et al. 2001; Pennacchioli et al. 2010; Silas et al. 2010). Liver metastases of ASPS are, however, uncommon events, as this neoplasm usually metastasizes to the lungs, bones, brain, and lymph nodes.

Synovial-Like Neoplasms (Synovial Sarcoma) of the Liver

70

Contents

Abstract

Synovial sarcoma is an aggressive soft tissue sarcoma of uncertain histogenesis with a predilection for the deep soft tissues of paraarticular regions of the extremities. The tumor predominantly develops in younger adults and accounts for 5–10 % of all soft tissue sarcomas. Apart from extremities, this sarcoma also occurs in various other sites, including visceral organs, the heart and large blood vessels. Most instances of hepatic manifestations of this neoplasm are metastases. However, few cases of monophasic primary hepatic synovial sarcoma have been reported. The tumors are sometimes large and hemorrhagic. Histologically, spindle cells and hemangiopericytoma-like cells prevail, with variable admixtures of epithelioid cells. The tumors are associated with the typical SYT-SSX1 or SYT-SSX2 rearrangement and the corresponding fusion proteins, as in soft tissue synovial sarcomas. Very rarely, synovial sarcoma develops as a primary lesion in the biliary tract.

Synovial Sarcoma of the Liver

ICD-O code 9040/3

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_70

Introduction

Synovial sarcoma is a clinically and morphologically well-defined malignant neoplasm of still uncertain histogenesis that develops chiefly in younger adults (median age, 30 years), with a predilection for the deep soft tissues of paraarticular regions of the extremities. The tumor represents 5–10 % of all soft tissue sarcomas. Other important primary locations include the oropharyngeal area, parapharynx and larynx, abdominal and chest walls, skeletal system, retroperitoneal space, heart and blood vessels, genital tract, salivary glands, and several visceral organs, in particular lungs and kidneys.

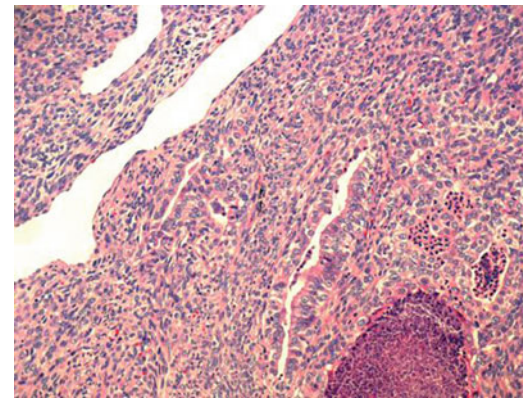

Fig. 1 Synovial sarcoma of the liver. This hypercellular spindle cell sarcoma contains several foci of epithelial formation with a slit-like lumen. Focal necrosis, typical for grade 3 sarcomas, is present (*right bottom* corner; hematoxylin and eosin stain)

Synovial Sarcoma Primary to the Liver

Intra-abdominal synovial sarcoma is a rare manifestation of this neoplasm, accounting to about 3–4 % of the cases (Fisher et al. 2004). Most instances of hepatic manifestations of synovial sarcoma are metastases. In the literature, few cases of monophasic primary hepatic synovial sarcomas are found (Srivastava et al. 2005; Holla et al. 2006; Romeo et al. 2015; Zajak et al. 2015). Hepatic synovial sarcomas show the same histologic and immunohistochemical phenotypes as extrahepatic tumors (Figs. 1, 2, and 3). A female patient (60 years of age) presented with a dominant tumor mass of 10 cm diameter in the right liver lobe, associated with multiple satellite nodules (Srivastava et al. 2005). The resection specimen of the right lobe shows five relatively well-circumscribed, diffusely hemorrhagic, tan-gray nodules, the largest measuring 10 cm in its greatest diameter. Some of the nodules exhibited gross necrosis. Histologically, the nodules were unencapsulated and had a well-defined expansile margin compressing the adjacent liver substance. The tumor was composed of hypercellular neoplastic tissue with spindle cells arranged in a fascicular or storiform pattern. Hypocellular areas with myxoid features and areas with a hemangiopericytoma-like vascular pattern were also in evidence. The tumor revealed a high proliferative activity, with about 20 mitotic figures

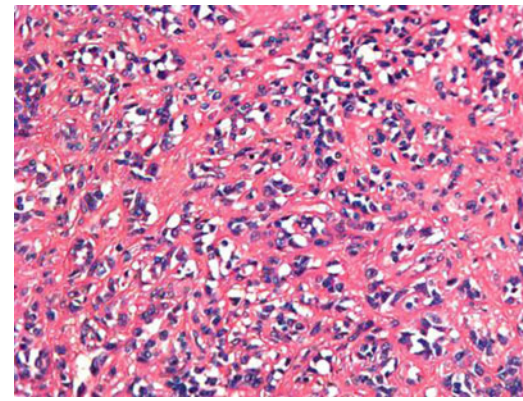

Fig. 2 Synovial sarcoma of the liver. In this case, only abortive epithelial structures are recognizable (hematoxylin and eosin stain)

per 10 HPs, and vascular invasion was detectable. Immunohistochemically, the cells are reactive for vimentin and Bcl-2, and weakly for muscle-specific and smooth muscle actin, but not for desmin, CD34, S-100 protein, and epithelial markers. Cytogenetic analysis showed several clonal abnormalities, among them an abnormal chromosome X due to a translocation of chromosomes X and 18, with the breakpoints in the SSX1 and SSX2 (band Xp11) and SYT (band 18q11) gene regions, confirming the diagnosis of a monophasic synovial sarcoma. The primary location to the liver was based on a detailed physical

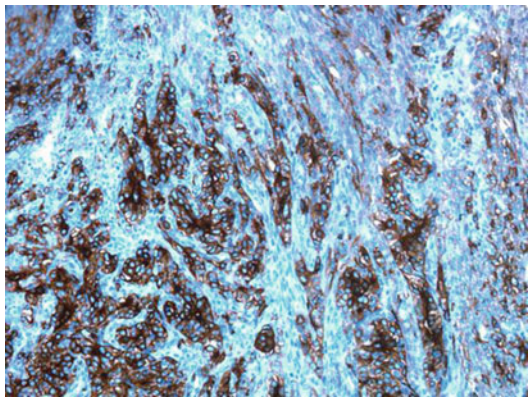

Fig. 3 Synovial sarcoma of the liver. Solid formations of epithelial cells, but not the spindle cells, are strongly cytokeratin reactive (AE1/AE3 cytokeratin immunostain)

examination and imaging workup that failed to reveal a primary tumor elsewhere, but an autopsy was not performed (Srivastava et al. 2005). A second case was that of 18-year-old female patient presenting with a history of fatigue, nausea, vomiting, and abdominal fullness. A CT scan and an angiogram showed a large mass extending from the left lobe of the liver. Liver resection revealed a mass of up to 21 cm diameter. Histology displayed a monophasic synovial sarcoma. Cytogenetic study revealed a reciprocal translocation between the short arm of the X chromosome and the long arm of chromosome 18 with breakpoints at band Xp11.2 and band 18q11.2 (Holla et al. 2006). Primary synovial sarcoma can also develop in ligaments associated with the liver, e.g., the triangular ligament on the superior surface of the liver (Rao et al. 2013).

Primary Synovial Sarcoma of the Biliary Tract

A 51-year-old male patient presented with a 1-month history of obstructive jaundice, and ERCP revealed an irregular mass in the common bile duct. MRCP showed an intraluminal mass in the common bile duct with likely extension into the neck of the gallbladder. The tumor was resected through pylorus-preserving pancreaticoduodenectomy and showed to by synovial sarcoma. No other manifestation of this malignancy was detectable (Qayum et al. 2008).

Visceral Synovial Sarcoma in the Pediatric and Adolescent Age Groups

Synovial sarcoma is a malignancy that also develops in infants, children, and adolescents (Kerouanton et al. 2014; Soole et al. 2014; Ferrari et al. 2015). In infants, this malignancy is extremely rare, with an annual incidence of 0.5 per million (Köse et al. 2014). Pediatric synovial sarcoma can metastasize to the liver. Primary monophasic synovial sarcoma of the liver was diagnosed in 13-year-old boy presenting with a painful mass in the right liver lobe, the tumor having a SS18-SSX1 fusion transcript (Xiong et al. 2013).

Synovial Sarcoma Metastatic to the Liver

Synovial sarcoma is known to metastasize to the liver, both from primary tumors in soft tissues and visceral organs, including primaries in the kidneys or prostate (Wang et al. 2010; Zhang et al. 2014). Soft tissue synovial sarcoma metastasizing to the liver was observed in a premature newborn (Köse et al. 2014).

Differential Diagnosis

The liver may secondarily be involved in those exceptional instances where intravascular synovial sarcoma develops in the inferior vena cava (Shaw and Lais 1993). Synovial sarcoma can develop in structures around the liver compartment, such as the gastrocolic ligament (Ko et al. 1998), the stomach (Billings et al. 2000; Makhlouf et al. 2008), the duodenum (Company Campins et al. 2009), the omentum (sometimes with involvement of the liver substance; Wang et al. 2006), and the retroperitoneal space (Shmookler 1982).

General Histologic and Immunohistochemical Features of Synovial Sarcoma

Synovial sarcoma has a characteristic histologic presentation. The neoplastic cell lineage involves two main types of cells, i.e., epithelial cells resembling those of carcinomas and fibrosarcoma-like spindle cells. Transitions between the two are well recognized and suggest a morphogenetic relationship. Depending on the relative representation of the cell types, synovial sarcoma is classified into (a) a biphasic type, with epithelial and spindle cell components in varying proportions; (b) a monophasic fibrous type; and (c) a very rare monophasic epithelial type. There also exists a poorly differentiated variant, termed poorly differentiated or round cell synovial sarcoma (Weiss and Goldblum 2001). The epithelial components consist of cells rich in a commonly pale cytoplasm and with large vesicular, round to ovoid nuclei. The shape of these cells varies from cuboidal to columnar. The growth patterns of epithelial-type cells include solid cords or nests, glandular profiles, and sometimes papillary structures. Squamous metaplasia may occur. The spindle cell component consists of plump and fusiform, fibroblast-like cells with usually darker nuclei, arranged in the form of compact sheets, resulting in a phenotype resembling that of fibrosarcoma, although long fascicles and a herringbone pattern are rarely seen (Weiss and Goldblum 2001). Hypocellular areas of synovial sarcoma may show hyaline areas, mineralization/calcification, or a myxoid change. While focal myxoid change is well known to occur in synovial sarcoma, there is a subset of these tumors where a myxoid pattern predominates (myxoid synovial sarcoma; Krane et al. 1999). The poorly differentiated or round cell variant is thought to represent a form of tumor progression superimposed on any other type of synovial sarcoma (Weiss and Goldblum 2001). It occurs on one of three patterns, namely, a large cell or epithelioid pattern, a small cell pattern (mimicking other small round cell tumors), and a high-grade spindle cell pattern composed of spindle-shaped cells with pleomorphic nuclei and a high mitotic count. Some tumors exhibit a prominent vascular phenotype, resembling hemangiopericytoma. Few monophasic synovial sarcomas show marked epithelioid features (Weidner et al. 1993), rhabdoid features (Jun et al. 2004), or impressive ossification (Hara et al. 2003). Synovial sarcoma may histologically mimic primitive neuroectodermal tumor (Masui et al. 1999). There are also variants with unique growth patterns, such as a predominantly intravascular growth pattern (intravascular synovial sarcoma (Shaw and Lais 1993) and intraneural synovial sarcoma (Zenmyo et al. 2001; Chu et al. 2004)).

Immunohistochemically, most synovial sarcomas are reactive for cytokeratins and epithelial membrane antigen (EMA), cytokeratin positivity amounting to at least 90 % of all tumors, but reactivity for epithelial markers is more prominent and frequent in epithelial types than in monophasic fibrous or poorly differentiated types. It is important to note that, in contrast to other spindle cell sarcomas, the cells of synovial sarcoma express cytokeratins 7 and 19. Up to 30 % of synovial sarcomas show focal immunoreactivity for S-100 protein, and the cells involved frequently co-express epithelial markers. Furthermore, 60–70 % of synovial sarcomas express CD99, and 75–100 % express bcl-2, while CD34 is consistently negative (Weiss and Goldblum 2001). Synovial sarcoma cells show a reduced expression of SMARCB1/INI1 based on a post-transcriptional regulatory mechanism (Kohashi et al. 2010; Rekhi and Vogel 2015).

Cytogenetic and Molecular Features of Synovial Sarcomas

Based on a frequent and distinct molecular genetic change and the possibility to generate cell lines with self-renewal capacity, synovial sarcoma has been proposed to be a stem cell malignancy (Naka et al. 2010). Cytogenetically, synovial sarcoma is characterized by translocation t(X;18) (p 11.2; q11.2) found in more than 95 % of the neoplasms (reviews: Lazar et al. 2006; Thway and Fisher 2014; Trautmann et al. 2014; Nielsen et al. 2015; murine models: Haldar et al. 2008). This results in

a fusion protein called synovial sarcoma X breakpoint 2 interacting protein or SSX2IP, which is a reliable diagnostic marker (review: Sun et al. 2008), also for extraskeletal synovial sarcomas (Fukuoka 2006) and detectable in paraffin-embedded material (Thway et al. 2010). In most cases, the translocation involves juxtaposition of the SYT (for synovial sarcoma translocation or translocated gene; synonym, SS18) gene on chromosome 18 to the SSX1 or SSX2 genes on chromosome X, thus creating SYT-SSX1 or SYT-SSX2 rearrangements and the respective chimeric fusion proteins. SYT/SSX1 translocations are seen in nearly three times as many synovial sarcomas as SYT/SSX2 translocations. SYT is highly conserved among species. Alternative splicing produces at least four isoforms of SYT, the most prominent being the long (SYT/L) and short (SYT/S) isoforms, which differ by inclusion of exon 8 in SYT/L. In synovial sarcoma, the SYT-SXX1 translocation is correlated with the expression of the differentially expressed gene, transducin-like enhancer of split (TLE1) belonging to the Groucho/TLE family (Knösel et al. 2010). SYT-SSX1 fusion gene expression has also been observed in epithelioid sarcoma (De Torres et al. 2005), but is not present in other sarcomas (Van de Rijn et al. 1999).

The oncoprotein SYT has a conserved N-terminal domain (SNH domain), which interacts with the hBRM and BRG1 chromatin-remodeling proteins, and a C-terminal transactivating sequence rich in glutamine, proline, glycine, and tyrosine (QPGY domain), which interacts with the ribonucleoprotein SIP/CoAA (Iwasaki et al. 2005; Perani et al. 2005), a human nuclear receptor co-activator with similarity to EWS and TLS/FUS family proteins. The latter interaction stimulates estrogen and glucocorticoid receptor-dependent transcriptional activation (Perani et al. 2005). The C-terminal region of SSX1, comprising the SSX1 portion of the SYT-SSX1 fusion protein, binds strongly to core histones and oligonucleosomes and directs nuclear localization of the fusion protein. The chimeric oncoprotein SYT-SSX1 is also capable to induce the cyclin-dependent kinase inhibitor p21 (WAF1/CIP1) by activation of the p21 gene promoter (Tsuda et al. 2005). SYT also interacts with a component of the histone deacetylase complex, mSin3A (Ito et al. 2004). There is also evidence that SYT-SSX1 induces insulin-like growth factor II (IGF2) expression and that SYT-SSX2 is necessary for maintaining IGF2 expression in a synovial sarcoma cell line (Sun et al. 2006). The SYT-SSX2 oncogene antagonizes the polycomb complex protein Bmi1: the fusion protein destabilizes the polycomb subunit Bmi1, resulting in impairment of polycomb-associated histone H2A ubiquitination and reactivation (desilencing) of polycomb target genes (Barco et al. 2009).

The SYT-SSX fusion type has important effects on the biology of synovial sarcoma. The fusion type is associated with sex, reflecting a 1:1 male-to-female ratio for SYT-SSX1 and a 1:2 ratio for SYT-SSX2 cases. SYT-SSX1 cases are more often peripheral or free limb, while there was an excess of SYT-SSX2 tumors among axial sarcomas.

In regard to adhesion and spread of synovial sarcoma cells, it is important to note that the SYT-SSX fusion protein interacts with components of the cytoskeleton and the adhesion protein network. SYT is essential for early embryonic development through the regulation of cell migration (Kimura et al. 2009). Activation of beta1 integrins is associated with formation of SYT/p300 complexes (Eid et al. 2000). Cytosolic isoforms of SYT bind F-actin and are involved in cytoskeletal reorganization. The association of SYT with F-actin bundles is extensive but stops short of the distal ends at focal adhesions. As ablation of SYN causes markedly impaired adhesion and spreading on fibronectin and laminin, but not on collagen types I and IV, SYN affects the tumor cells' ability to bind and react to the extracellular matrix (Kim et al. 2009). Downregulation of SYT-SSX expression in synovial sarcoma cells by small interfering RNA enhances the focal adhesion pathway and inhibits anchorage-independent growth (Takenaka et al. 2010). SYT-SSX2 remodels the cytoskeleton through activation of the ephrin pathway. Synovial sarcoma cells show mutual repulsion in vitro, cell repulsion being a well-known effect

of ephrin (Barco et al. 2007). The SYT protein also interacts with a global transcriptional activator, the SNF/SWI complex, which has been characterized as a chromatin-remodeling factor that enhances accessibility of the transcriptional machinery to DNA within a repressive chromatin structure. SYT has a unique QPGY domain, which is also present in the largest subunits, p250 and the homolog p250R, of the corresponding SNF/SWI complexes (Kato et al. 2002). Moreover, SYT interacts with another important co-activator, p300. The multifunctional co-activator p300 is a member of the Sox9 (Sry-type high mobility group box 9)-related transcriptional apparatus. p300 potentiates Sox9-dependent transcription on chromatinized DNA and is associated with hyperacetylated histones (Furumatsu et al. 2005). p300 and associated factors act as a histone acetyltransferase targeting specific lysine residues in substrate proteins (Dormeyer et al. 2005). Histone acetyltransferase activities of proteins such as p300, CBP, and P/CAF play important roles in activation of gene expression. This activity of p300 is itself promoted via Ser-1834 phosphorylation of p300 by Akt, Akt being activated and translocated to the nucleus in response to tumor necrosis factor-alpha (Huang and Chen 2005). SYT/p300 complex formation promotes cell adhesion to a fibronectin matrix (Eid et al. 2000), via promotion of E-cadherin expression (Liu et al. 2005). The SS18-SSX fusion protein mediates attenuation of a network consisting of EGR1 (early growth response-1) and PTEN that regulates cell survival. EGR1 and PTEN induce apoptosis of synovial sarcoma cells. The fusion protein maintains EGR1 expression at low levels, hence deceasing tumor cell death (Su et al. 2010).

The impact of the fusion type on metastatic spread was controversial in the past (Kawai et al. 1998; Ladanyi et al. 2002; Guillou et al. 2004). There is a relation between the SYT-SSX fusion type and the tumor's morphology. All biphasic synovial sarcomas seem to be associated with SYT-SSX1 fusion, while all monophasic neoplasms appear to be associated with the SYT-SSX2 fusion (Antonescu et al. 2000). Recent analyses showed that tumor stage and tumor grade are clearly superior as prognosticators in comparison with the SYT-SSX status (Guillou et al. 2004; Takenaka et al. 2008; ten Heuvel et al. 2009).

There are several other molecular features identified in synovial sarcoma. A subset of synovial sarcomas show Her-2/neu (ERBB2) oncogene expression, restricted to tumors with the SYT/SSX1 translocation (Allander et al. 2002; Nuciforo et al. 2003; Thomas et al. 2005), a phenomenon associated with epithelial differentiation (Allander et al. 2002) and lower risk of developing metastasis (Sapi et al. 2005).

The Wnt signaling pathway seems to be involved in synovial sarcoma, in that 28 % of the tumors were found to express high level nuclear beta-catenin expression (Saito et al. 2001; Ng et al. 2005), with or without associated beta-catenin gene mutations (Saito et al. 2000; Sato et al. 2001). In synovial sarcoma, nuclear beta-catenin expression correlates with cyclin D1 expression (Horvai et al. 2006), not confirmed in another study (Saito et al. 2006). Nuclear beta-catenin accumulation in synovial sarcoma is caused by recruitment of this protein by the SYT-SSX2 translocation protein (Pretto et al. 2006). The frizzled homologue 10 (FZD10), a member of the Wnt signal receptor family, is highly and specifically upregulated in synovial sarcoma and induces enhanced phosphorylation of the Disheveled (Dvl)2/Dvl3 complex as well as activation of the Rac1-JNK cascade. Activation of this pathway causes lamellipodia formation and enhanced anchorage-independent growth of synovial sarcoma cells (Fukukawa et al. 2009).

Differential expression of E-cadherin seems to affect the differentiation along an epithelial lineage in synovial sarcomas (Sato et al. 1999; Laskin and Miettinen 2002). Mutations of the gene for E-cadherin, participation in the beta-catenin network, frequently occur in this tumor, are correlated with the SYT-SSX fusion, and are correlated with a spindle cell/monophasic phenotype and the absence of epithelial/glandular differentiation (Saito et al. 2001, 2004). Expression of E-cadherin in synovial sarcoma is also associated

with expression of matrix metalloproteinase-2 (MMP-2), the latter having an important role in the epithelial differentiation of this neoplasm (Saito et al. 2002).

Malignant Fibrous Histiocytoma of the Liver: A Neoplasm of the Undifferentiated High-Grade Pleomorphic Sarcoma Group

71

ICD-O code 8830/3

Contents

Abstract

The term malignant fibrous histiocytoma (MFH) previously denoted a malignancy suggested to originate from histiocytes. Later, it was realized that MFH represents a heterogeneous group of sarcomas of variable cell lineages. The current WHO classification includes MFH as subtypes of undifferentiated high-grade polymorphous sarcoma (UPS). The tumors exist in the form of five histologic patterns, i.e., storiform-pleomorphic, myxoid, giant cell, angiomatoid, and inflammatory MFH/UPS. Primary MFH in its original sense is a very rare liver neoplasm that occurs in older individuals. Hepatic MFH can be associated with paraneoplastic syndromes, including hypoglycemia due to secretion of ILF-II, and prominent leukocytosis and leukemoid reactions due to ectopic production of granulocyte colony-stimulating factor. Hepatic MFH/UPS presents as solitary or multiple irregular tumor masses and exhibits the same histologic patterns as its extrahepatic counterparts. MFH/UPS of the liver is an aggressive neoplasm with a high recurrence rate.

Introduction

The term malignant fibrous histiocytoma (MFH) was coined in the 1960s to encompass a group of aggressive soft tissue sarcomas then suggested to originate from "histiocytes" (Ozello et al. 1963;

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_71

O'Brien and Stout 1964). By the mid-1980s, MFH represented the most common sarcoma diagnosis in adults (review: Dei Tos 2006). Later, it was realized that MFH is a collection of malignant neoplasms that are related to liposarcomas, fibrosarcomas, and other sarcomas, rendering the term MFH controversial and signifying a pattern rather than a distinct entity (Enzinger 1986; Hollowood and Fletcher 1995; Meister 1995; Akerman 1997; Erlandson and Antonescu 2004; Al-Agha and Igbokwe 2008). Ultrastructurally, MFH has features of an unusual fibrosarcoma (Orenstein 2014). The current WHO classification no longer includes MFH as a distinct diagnostic category, but rather as subtypes of an undifferentiated high-grade polymorphous sarcoma (UPS; reviews: Dei Tos 2006; Fletcher 2006; Murphey 2007). The term "pleomorphic sarcoma" seems to include, apart from tumors previously classified as MFH, also other sarcomas than can now be more precisely attributed to a distinct cell lineage, probably requiring a further reappraisal of these neoplasms in the future (Goldblum 2014). So far, undifferentiated pleomorphic sarcoma still is an inclusive term, but in particular novel molecular features will subclassify the lesions into, e.g., dedifferentiated liposarcomas, smooth muscle neoplasms, and variants of fibrosarcomas (Kelleher and Viterbo 2013; Toda et al. 2013; Le Guellec et al. 2014; Martin-Broto et al. 2014). In what follows, MFH is discussed as group of neoplasms under its original meaning, without referring to the "true" status of this disease. The reason for doing so is related to the fact that a large proportion of hepatic malignancies classified as "MFH" have been published prior to the redefinition of this tumor group and that many clinicians are still familiar with "MFH" (Orenstein 2014).

The "MFH Patterns"

Histologically, storiform-pleomorphic, myxoid, giant cell, angiomatoid, and inflammatory variants of MFH have been recognized, now allocated to other WHO categories (Table 1), although the variants have prognostic significance (Fletcher et al. 2001). In a large group of tumors formerly classified as MFH (159 cases) reviewed after applying modern diagnostic methods, only 13 % were re-diagnosed as MFH (Fletcher 1992).

The patterns described in Table 1 often show transitions from areas having a highly ordered storiform pattern to less differentiated areas with a pleomorphic appearance (Weiss and Enzinger 1978; Dehner 1988; Fanburgh-Smith and Miettinen 1999; Hasegawa et al. 2000; Coindre et al. 2004; Fisher 2004; Idbaih et al. 2005; Adrien et al. 2010; Chen et al. 2013; Xiang et al. 2013; Kao et al. 2014; Schaefer and Fletcher 2014). Immunohistochemically, the majority of the previous "MFHs" display variable and in part marked reactivities for vimentin, CD68, factor-XIIIa, and antiproteases (Nemes and Thomazy 1988; Binder et al. 1992). Myofibroblastoid cells with SMA reactivity are often noted (Hasegawa et al. 2003).

Primary MFH/UPS of the Liver

Introduction and Epidemiology

Primary MFH in its original sense is a very rare liver neoplasm that was first reported in 1985 (Conran and Stocker 1985). In this first case, a primary location in the liver was confirmed at autopsy. Male patients were slightly more often involved, and the age range at diagnosis was 27–79 years (mean, 51 years; Anagnosto-poulos et al. 2005). In a subsequent review of 27 published cases as of 2008, age at diagnosis ranged from 34 to 87 years (average, 57 years), and there were 16 men and 11 women (Li et al. 2008). In a Chinese study on 76 cases, among 50 were men (male: female = 1.9:1), the mean age of the patients was 51 years, and more than 85 % were older than 40 years at the time point of diagnosis (Yao and Dai 2012). There is evidence that tumors classified as MFH account for a majority of primary hepatic sarcomas (Tan and Xiao 2013). There is no relationship with liver cirrhosis. However, in one patient hepatic MFH was associated with cirrhosis and a synchronous small hepatocellular carcinoma (Hwang et al. 2011).

Table 1 "Classical" histopathologic MFH patterns and WHO interpretation

Storiform-pleomorphic MFH
Up to 70 % of previously reported cases. The high-grade lesions show spindle cells admixed with rounded or polygonal cells, mostly with a storiform pattern. Cells with bizarre, giant cells and mitoses are common
WHO interpretation:
The diagnosis of the neopleomorphic MFH requires the exclusion of any other sarcoma lineage. The tumor is in 2002 still classified under fibrohistiocytic tumors, but is renamed undifferentiated high-grade pleomorphic sarcoma
Myxoid MFH
The second most common pattern (10–20 % of cases). Spindled or stellate cells embedded in an abundant myxoid matrix
WHO interpretation:
The myxoid lesions are no longer an MFH subtype, but are classified as myxofibrosarcoma. As the tumors exhibit myoid cell differentiation, the neoplasms are listed under myofibroblastic tumors
Giant cell MFH
About 10–15 % of cases. Numerous multinucleated giant cells resembling osteoclasts, but with high-grade nuclear atypias
WHO interpretation:
Most cases of the former giant cell MFH are other sarcomas or anaplastic giant cell carcinomas, giant cell being a nonspecific feature. The few cases of giant cell MFH that are left after exclusion of other malignancies are termed undifferentiated pleomorphic sarcoma with giant cells
Angiomatoid MFH
Tumors consist of benign-looking eosinophilic cells arranged in sheets and whorls, with a spindled, oval, or round cell morphology with only slight pleomorphism. Fibrous pseudocapsules and lymphocytic cuffs may be present. There are pseudovascular spaces filled with blood. Part of the tumor cells show myoid or schwannoid features. A subset of the neoplasm presents as myxoid tumors. The tumor most commonly occurs in the extremities of children and young adults, but rare visceral forms are also known. Part of tumors showed EWSR1 gene rearrangements, EWSR1-CREB1 fusion, or EWSR1-ATF1 fusion
WHO interpretation:
This is no longer a subtype of MFH, but is termed angiomatoid fibrous histiocytoma. As these neoplasms have an intriguing immunophenotype, with coexpression of desmin, EMA, and CD99, they are classified under tumors of uncertain differentiation
Inflammatory MFH
The rarest pattern (around 5 %). The neoplasms show a dense inflammatory infiltrate in and around the tumor, consisting of neutrophils, lymphocytes, plasma cells, and macrophages
WHO interpretation:
A significant part is now classified as dedifferentiated liposarcoma with a prominent inflammatory reaction. In case no distinct lineage can be identified, inflammatory MFH is now called undifferentiated pleomorphic sarcoma with prominent inflammation

Clinical and Imaging Features

In a large review, the major clinical presentation (78.4 %) was abdominal pain or discomfort,

sometimes associated with malaise, anorexia, weight loss, and/or fever. 14.9 % of patients were asymptomatic (Yao and Dai 2012). MFH of the liver can present as hepatomegaly. Uncommon signs and symptoms include jaundice and chest pain (Li et al. 2008). The rare inflammatory variant may mimic a pyogenic liver abscess (Hu et al. 2013) and can be associated with an elevated peripheral white blood cell count. Similar to other hepatic mesenchymal tumors, MFH can be associated with hypoglycemia, probably due to secretion of insulin-like growth factor II (ILF-II) of the big isoform (Kageyama et al. 2003). Exceptionally, MFH is associated with prominent leukocytosis/paraneoplastic leukemoid reaction caused by production of granulocyte colony-stimulating factor (Mayumi et al. 2001), but this has not yet been observed in hepatic MFH. The prognosis of hepatic MFH depends primarily on tumor size and stage at the time of diagnosis. After hepatic resection of MFH in 12 patients, local recurrence had occurred in 6 patients and local recurrence plus distant metastasis in 3 at a median follow-up of 11.3 months. The median survival for the R0 liver resection group carried out in patients without extrahepatic metastases was 8.5 months, while the median survival of the debulking group was 7 months (Yin et al. 2011).

Pathology

Macroscopy

Primary MFH of the liver presents as solitary or multiple roundish to irregularly shaped tumor masses. In a study of 27 cases, the lesion was located in the right liver lobe in 9, in the left lobe in 9, and in both lobes in 6 analyzable cases (Li et al. 2008), i.e., without clear lobe predilection. Among 76 cases, 82.9 % were solitary lesions, with tumor diameter ranging from 2.5 to 23.5 cm (average, 10.3 cm; Yao and Dai 2012). In a minority of cases (9 %), hepatic MFHs initially present as multiple liver nodules of variable size, with the largest nodule ranging in diameter from 2 to 9 cm (Li et al. 2008). A single large nodule can be accompanied by several smaller daughter nodules. The tumors usually form circumscribed, but unencapsulated lesions with a form consistency. Less often the neoplasms have a rubbery consistency, and least common is a fleshy phenotype. The cut surface shows a gray to white tissue (seldom yellowish), sometimes with a fascicular texture or a whorly pattern. Hemorrhage is common, and large necroses are noted. Large foci of necrosis can undergo liquefaction, leaving a cystic space. Some MFHs initially present as cystic or multicystic masses. Direct invasion of adjacent organs was noted in almost a third of cases, and tumor thrombi are found in the inferior vena cava (Schweyer et al. 2000). In a review of 34 cases, 32 % of the neoplasms showed local invasion, most often into the diaphragm and lung (Li et al. 2008). Distant metastasis, mainly to lungs, was detected in less than 10 % of patients.

Histopathology

Histopathologically, hepatic MFH reflects all the patterns listed in Table 1. In most cases, however, spindled cells with pleomorphic nuclei predominate, these cells arranged in small fascicles in an often storiform pattern. Myxoid patterns seem to be very uncommon in the liver. In a small series of hepatic MFH, a myxoid variant was seen only once, and this tumor did not show necrosis (Li et al. 2008). Multinucleated giant cells or mononucleated giant cells with highly abnormal or even bizarre nuclei are common. Few tumor cells may reveal a rhabdoid morphology (Li et al. 2008). Necrosis and apoptosis are frequently found. The mitotic count varies considerably and ranged from less 5/10 HPFs to more than 20/10 HPFs (reviewed in Li et al. 2008). MFH may entrap intrahepatic bile duct, which then can undergo cystic change (Fukuyama and Koike 1986).

Ultrastructure

Electron microscopically, three types of tumor cells were identified, viz., cells with prominent endoplasmic reticulum and some with filaments, overall resembling fibroblastoid or myofibroblastoid cells. Other cells resembled histiocytes/macrophages, myoid cells, or undifferentiated

mesenchymal cells (Fukuyama and Koike 1986; Hamasaki et al. 1991; Wunderbaldinger et al. 1998; Li et al. 2008).

Immunohistochemistry

As in extrahepatic MFHs, neoplastic cells of hepatic MFHs are consistently positive for vimentin. Many cells are reactive for CD68 and antiproteases, and part of them stain for lysozyme. MFHs with myoid cells express alpha-SMA and/or desmin (review: Li et al. 2008), and part of the tumors were positive for ezrin (Li et al. 2008; Sugitani et al. 2009), and more than 50 % of MFHs have shown reactivity for promyelocytic leukemia body/PML components (63.9 %; Matsuo et al. 2008).

Liver Metastases of MFH/UPS

MFH as an aggressive neoplasm can metastasize to the liver, sometimes with large metastatic nodules (Ohmori et al. 1996; Atmatzidis et al. 2003; Suzuki et al. 2013; Thomas and Koshi 2013). Apart from spindle cell tumors with a storiform pattern, also neoplasms with myxoid, giant cell, or angiomatoid components metastasize to the liver (Ben Jilani et al. 1993; Chow et al. 1998).

MFH/UPS of the Bile Ducts

There are few observations on MFH taking its origin in the biliary tract, including the hepatic duct, with formation of a stenosing tumor (Kim et al. 2006). Primary MFH has also been observed in the papilla of Vater (Giuliani 2013).

MFH/UPS of the Gallbladder

Several reports have documented MFH primary to the gallbladder. This localization was first reported in 1983 (Kristofferson et al. 1983). Several reports of single cases or small series followed (Sasada et al. 1988; Sreekantaiah et al. 1992; Miyakawa and Hamano 1996; Orii et al. 1998; Tomono et al. 1998; Gruttadauria et al. 2001; Kato et al. 2002; Al-Daraji et al. 2009; Husain et al. 2009). Among seven reported patients, five were female and two were male, with an age range at presentation of 41–75 years. Several of the known histologic phenotypes have been detected in gallbladder MFH, but most of the lesions belonged to the spindle cell-storiform category. An inflammatory variant was found in one patient (Kato et al. 2002), while another study also documented an unusual fibromyxoid sarcoma-like (Evans-like) neoplasm and one tumor which presented a pleomorphic hyalinizing angiectatic tumor-like mixture (Al-Daraji et al. 2009). Most patients died of local recurrence and/or metastases.

MFH/UPS of the Hepatic Ligaments

MFH has been found as a primary neoplasm of the falciform ligament (Toughrai et al. 2007).

Differential Diagnosis

Generally, hepatic MFH has to be distinguished from other rare hepatic sarcomas with a spindle cell component. Intrahepatic cholangiocarcinoma with extensive sarcomatous change may histologically mimic MFH. Multicystic hepatic MFH resembles other cystic liver tumors, in particular cystadenomas, cystadenocarcinomas, or mucinous cystic tumors (Ding et al. 2006). Inflammatory MFH of the liver may clinico-radiologically be confounded with pyogenic liver abscess.

Tumors of the Mesothelial Lineage

Hepatic Mesotheliomas and Related Neoplasms

72

Contents

Abstract

Mesotheliomas form a complex group of neoplasms with a biologic behavior that ranges from benign to malignant. Apart from pleural mesothelioma, which has a strong association with asbestos exposure, these neoplasms also develop in other serosal surfaces, including the liver capsule, and in some inner organs, e.g., the heart and liver. Benign cystic mesothelioma, a neoplasm mainly occurring in middle-aged women with a previous history of gynecological surgery, rarely develops in the liver. Few cases of malignant epithelial monophasic mesothelioma of the liver have been reported. Also mesothelioma with a biphasic pattern was observed in the liver, in part associated with asbestos exposure. A second type of mesothelial neoplasm is adenomatoid tumor. This tumor typically occurs in the genital tract, but several extragenital sites have been found, including the heart, the mediastinum and the gastrointestinal tract. Few observations document primary adenomatoid tumor of the liver.

Hepatic Mesothelioma

ICD-O codes 9050/3-9053/3 (9050/0 for benign neoplasms)

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_72

Introduction

Mesotheliomas form a spectrum of neoplastic mesothelial lesions ranging in biological behavior from benign to highly malignant (review: Mott 2012). The incidence of malignant pleural mesotheliomas has rapidly increased from a rare tumor to the current 2500–3000 cases per year in the USA (review: Yang et al. 2008). In about 80–90 % of patients with pleural mesothelioma, the tumor is related to occupational exposure to asbestos in the air. The latent development period is usually long, about 25–40 years after initial exposure. There are certain differences in asbestos toxicity and induction of cancerogenesis, in that, e. g., occupational exposure to relatively pure chrysotile (a component of asbestos cement) within permissible levels was not associated with a significant increase in lung cancer or with mesothelioma (Sichletidis et al. 2008). Mesothelioma can occur in extrapleural localizations, including the peritoneal and pericardial surfaces (Chua et al. 2009) and, much more rarely, some inner organs. Diffuse malignant mesothelioma typically has a poor clinical course, with death occurring in most patients without 2 years after diagnosis. General morphologic features and classification of mesothelioma are added at the end of the chapter.

Benign Cystic Mesothelioma of the Liver

Benign cystic mesotheliomas (synonym, multicystic peritoneal mesothelioma) occur mainly in adults, predominantly middle-aged females with a previous history of gynecological surgery, and are considered to be benign and curable. They commonly develop in the compartment of the peritoneum, where they have also been termed multilocular peritoneal inclusion cysts (Mennemeyer and Smith 1979; Cusatelli et al. 1997; Datta and Paty 1997; review: Häfner et al. 2002). They are infrequently found after castration or menopause, suggesting some degree of hormonal dependence. However, estrogen and/or progesterone receptors were detected by the use of immunohistochemistry in a minority of lesions only (Sawh et al. 2003). Cystic mesotheliomas have a significant tendency for local recurrence after resection. In a report of 15 cases, recurrence was found to be 26.7 % (Katsube et al. 1982). In another study, 17/38 patients with at least 1 year of follow-up had postsurgical recurrences (Ross et al. 1989). Malignant transformation has been reported, but is an uncommon event (Gonzalez-Moreno et al. 2002). Cystic peritoneal mesothelioma can cause progressive abdominal distension in the pediatric age group, suggesting massive ascites (McCullagh et al. 1994).

Cystic mesotheliomas very rarely occur in the liver (Antropoli et al. 2002; Flemming et al. 2002; Di Blasi et al. 2004). An unusual case of such a tumor has been reported in 2002 (Flemming et al. 2002). A left-sided lobectomy specimen from a 51-year-old female exhibited an 8-cm diameter, gray-brownish, partially cystic, encapsulated mass with a soft-glistening surface. Histopathology revealed a partially cystic, highly vascular, and well-encapsulated neoplasm. Anastomosing, loosely arranged cords of tumor cells were separated by medium-sized and large vessels with a varying thickness of vessel walls, simulating a vascular neoplasm. The cystic spaces were populated by tumor cells which exhibited a hobnail morphology. Immunohistochemically, the neoplastic cells were reactive for pankeratin, cytokeratin 8/18, HBME-1, calretinin, epithelial membrane antigen, and vimentin. About a third of the tumor cell nuclei were positive for estrogen receptor. The estimated proliferation fraction was less than 1 %. Electron microscopy confirmed the mesothelial phenotype of the cells, these elements showing microvilli and desmosomes, and focally tonofibril-like filaments. A similar case was reported in 2004, a multicystic mesothelioma of the liver with secondary involvement of peritoneum and the inguinal region (Di Blasi et al. 2004).

Primary Malignant Mesothelioma of the Liver Capsule

This very unusual lesion has been reported in a 54-year-old female patient presenting with acute

abdominal pain and a heterogeneous mass in the right liver lobe, considered to be hepatocellular carcinoma and presented as a 12-cm-sized tumor arising from Glisson's capsule of the right lobe of the liver (Leonardou et al. 2003).

Hepatic Tubulopapillary Mesothelioma

In one patient, mesothelioma of the liver consisted of papillary and tubular structures and of spindle cell areas, and it was suggested that such tumors may originate from hepatic submesothelial connective tissue (Rout et al. 1999).

Intrahepatic Malignant Epithelial (Epithelioid, Monophasic) Mesothelioma

Relatively few cases of epithelial monophasic mesothelioma primary to the liver have been reported (Fig. 1; Rout et al. 1999; Imura et al. 2002; Leonardou et al. 2003; Gütgemann et al. 2006; Kim et al. 2008; Buchholz et al. 2009). In the case of Imura and coworkers (Imura et al. 2002), a tumor was detected in the right lobe of the cirrhotic liver of a 64-year-old male patient. Histologically, the neoplasm was predominantly composed of single glandular or branching tubules embedded in a desmoplastic stroma. Furthermore, scattered, irregularly arranged, dilated tubules or gland-like spaces were present. Dilated spaces with papillary ingrowths were also recognized. The epithelioid cells were immunoreactive for cytokeratins (including cytokeratin 8), epithelial membrane antigen (EMA), calretinin, and HBME-1, thus reflecting a pattern known for other epithelial mesotheliomas (Ordonez 1999). Tubular together with papillary structures have been noted in another case of epithelial hepatic mesothelioma (see above; Rout et al. 1999). Leonardou et al. (2003) reported on a 54-year-old female patient presenting with a cystic tumor with areas of hemorrhage within the center. Histologically, the tumor was composed of sheets of cytologically bland polygonal cells. The lesion was largely solid, but also contained multiple gland-like spaces and microcysts lined by cuboidal to columnar cells. Immunohistochemistry revealed positivity for vimentin, cytokeratin AE1/AE3, cytokeratin 8, and calretinin. There was no evidence of extrahepatic spread, but the tumor was regarded as malignant. A third case was reported in 2006, based on a 62-year-old male patient showing a 5.8-cm mass in the right liver lobe at incidental CT (Gütgemann et al. 2006). Histologically, the neoplasm consisted of numerous epithelioid cells arranged in cords, solid, and papillary patterns. On higher magnification, the tumor contained islands and cords composed of round to polygonal cells with abundant pale eosinophilic cytoplasm. Other areas showed a more solid proliferation of epithelioid cells containing large atypical nuclei. The immunophenotype was characterized by positivity for pancytokeratin, CK7, D2-40, WT-1, CA 12-5, calretinin, vimentin, and thrombomodulin. In a case reported by Buchholz and coworkers, the tumor had metastasized to periaortic lymph nodes, thus confirming its malignant behavior. A study of lymph node metastases revealed that the vascular endothelial growth factor receptor-1-expressing mesothelioma cells in the lymph nodes were associated with a dense D2-40-positive lymphangiovascular network, suggesting the induction of lymphangiogenesis by the tumor metastases (Buchholz et al. 2009).

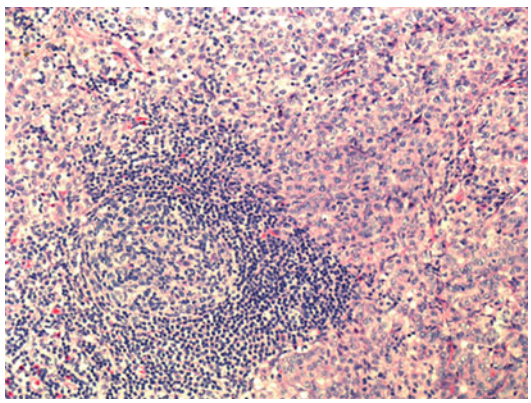

Fig. 1 Epithelial mesothelioma of the liver with lymph follicle formation (hematoxylin and eosin stain)

Intrahepatic Malignant Biphasic Mesothelioma

Similar to mesotheliomas developing in the pleural compartment, very rare cases of hepatic mesotheliomas can show the typical biphasical pattern (Sasaki et al. 2009). In the patient described by Sasaki and coworkers (Sasaki et al. 2009), the tumor was associated with asbestos exposure and presented as a 4.4-cm nodule in the right liver lobe of a 66-year-old male patient. The hepatic resection specimen showed a yellowish-white tumor with well-defined borders and central necrosis. Histologically, this mesothelioma was a mixture of papillary epithelioid structures, microcystic and adenomatoid parts, and sarcomatoid components. Immunohistochemically, the tumor cells were reactive for WT-1, calretinin, D2-40, mesothelin, and thrombomodulin.

Primitive Cystic Neoplasm of the Liver with Mesothelial Differentiation

This is a rare entity characterized by features resembling those of benign cystic peritoneal mesotheliomas (DeStephano et al. 1985; Shing et al. 1997). The patient of DeStephano et al. was a 6-month-old girl with a partially cystic liver tumor. Histologically, a differentiated cystic component had features of cystic peritoneal mesothelioma. Alpha-fetoprotein and alpha-1 antitrypsin were demonstrated in solid, anaplastic portions of the recurrent tumor. Recurrence occurred after surgical resection. Despite chemotherapy, the outcome was fatal after 11 months (DeStephano et al. 1985). A similar case of a malignant epithelial neoplasm consistent with a primitive cystic neoplasm was observed in the liver of a 3-year-old boy, the tumor showing mesothelial differentiation (Shing et al. 1997).

Mesothelioma of the Hepatic Ligaments

Malignant mesothelioma can develop in the falciform ligament, with subsequent metastasis to the liver (Marubayashi et al. 1998). These tumors are discussed in more detail in the chapter on neoplasms of the hepatic ligaments.

Mesothelial Cell Nests and Mesothelial Cysts of the Liver

There are few instances of non-neoplastic mesothelial formations primary to the liver. This includes mesothelial cell nests and mesothelial cysts (Komori et al. 2008; Silva et al. 2009). Mesothelial cysts are known to occur in several organs (spleen, pancreas, adrenal gland, ovary, vaginal process of the testis, and mesentery). Familial occurrence of multiple mesothelial spleen cysts has been reported (Iwanaka et al. 1995). Hepatic mesothelial cyst is characterized by a solitary or multilobular, thin-walled cyst of variable size which exhibits a unicellular lining of normal-looking mesothelial cells. Mesothelial cyst has been observed in a neonate (Komori et al. 2008). In this patient, routine antenatal ultrasound examination had shown an intra-abdominal cystic mass, which increased in size after birth to reach a diameter of 8 cm and became symptomatic, requiring surgical removal. The cyst was located in the anterior part of the liver and protruded into an omphalocele sac. The mesothelial lining of the cyst was positive for calretinin and D2-40. In other observations, mesothelial cysts were detected at the porta hepatis (Augustine et al. 2001), in an accessory liver lobe situated in an omphalocele (Rougemont et al. 2007), and in a supradiaphragmatic accessory liver (Luoma and Raboei 2003). In the latter case, the supradiaphragmatic liver part was surrounded by a collection of multilocular mesothelial cysts mimicking hydrothorax and causing respiratory distress of the neonate. In two neonates described by Rougemont et al. (2007), accessory liver lobes found in the setting of omphalocele showed multilocular cystic lesions, intricately admixed to the liver parenchyma. These cysts were lined by a single layer of cytokeratin-, calretinin-, and podoplanin-positive cells exhibiting a focal hobnail appearance. Mesothelial cyst of the gallbladder has been reported (Hoffman et al. 1989).

Mesothelial cysts also occur in the hepatic ligaments (see the respective ▶ Chap. 116, "Tumors and Tumor-Like Lesions of the Hepatic Ligaments").

Differential Diagnosis

Malignant pleural mesothelioma can metastasize to the liver. In a postmortem study of 318 patients, extrapleural dissemination of tumor was found in 87.7 % of cases, and tumor dissemination in extrathoracic sites was common (55.4 % of patients), involvement of the liver amounting to 31.9 % (Finn et al. 2012). The liver and in particular the liver's capsular surface may be involved in malignant diffuse peritoneal mesotheliomas (Samedi et al. 2010; Nagata et al. 2011), and in some instances this mode of growth may initially suggest primary hepatic malignancy (Matsukuma et al. 1996) and can cause recurrent ascites (Samedi et al. 2010). Rarely, peritoneal mesothelioma produces an omental mass close to the liver (Takeuchi et al. 2008), which may pose differential diagnostic problems. Liver involvement has been noted in peritoneal multicystic mesothelioma (Antropoli et al. 2002), and in well-differentiated papillary mesothelioma (Gong et al. 2005), an uncommon subtype of mesothelioma that typically occurs in the peritoneum of women without a history of asbestos exposure and usually follows an indolent course. There are also instances where pleural or pericardial malignant mesotheliomas metastasized to the liver (Cimbaluk et al. 2006; Doval et al. 2007). Benign cystic mesothelioma is often confused with multicystic abdominal lymphangioma, which is, however, mainly found in males, 60 % of whom are younger than 5 years old. Hepatocellular carcinoma very rarely exhibits a mesothelioma-like dissemination, with extended spread to the abdominal serosal surfaces (Otsuki et al. 2005). As such, HCC rarely metastasizes to the peritoneum (with or without carcinomatosis peritonei; Edmondson and Steiner 1954; Patton and Horn 1964; Anthony 1973; Nakashima et al. 1983; Yuki et al. 1990), and a peritoneal spreading mode masquerading mesothelioma is certainly exceptional. Asbestos fibers have been identified in squamous cell carcinoma of the cystic duct in a patient with asbestos occupational exposure of 5-year duration (Szendröi et al. 1983).

General Remarks on Mesotheliomas: Histological Types

The pathology of mesothelioma has recently been reviewed (Corson 2004; Tischoff et al. 2011). Mesotheliomas occur in several, now well-defined morphotypes (Table 1) that have been defined in the WHO classification of tumors. The most aggressive but the least common variant is sarcomatoid mesothelioma (Klebe et al. 2010). In addition, several

Table 1 Histological types of mesothelioma

WHO classification of mesothelioma	
Diffuse malignant mesothelioma	9050/3
Epithelioid mesothelioma	9052/3

and usually rare variants of mesothelioma have been described, listed in the table.

Immunohistochemical Phenotype of and Markers for Mesothelioma

Mesotheliomas display a distinct expression pattern of several proteins belonging to various families and consequently a typical immunophenotype now allowing a more reproducible morphologic diagnosis (Davidson 2008; Greillier et al. 2008; Addis and Roche 2009; Betta et al. 2012). Mesothelioma cells express C-ERC/mesothelin and soluble mesothelin-related Peptides (SMRP), CEA, Ber-EP4, calretinin, osteopontin-1, megakaryocyte potentiating factor (MPF), Wilms tumor protein-1 (WT-1), HBME 1, podoplanin/D2-40, h-caldesmon, N-cadherin, CD138, intelectin, HMGB1, and vascular endothelial growth factor receptor-1 (VEGFR1; Ohta et al. 1999), thought to play an important role in angiogenesis and lymphangiogenesis in mesothelioma. In addition, asbestos-related malignant pleural mesotheliomas frequently express semaphorin-6D and its receptor plexin-A1, and plexin-A1 forms a complex with vascular endothelial factor receptor-2 (Catalano et al. 2009). A novel immunocytochemical marker that can distinguish between benign and malignant mesothelial lineages is termed IMP3/L523S, a monoclonal antibody directed against KOC, an oncofetal RNA-binding protein (Ikeda et al. 2010). Expression of the chaperone, CD147, has been found to discriminate between reactive mesothelial cells and malignant mesothelioma (Pinheiro et al. 2012). In a meta-analysis of literature data, the most frequently investigated serum marker was soluble mesothelin-related peptide (SMRP), and for noninvasive diagnosis, the markers CEA, Ber-EP4, and calretinin were most valuable in discriminating mesothelioma from other malignancies (van der Bij et al. 2011). In a multicenter study, SMRP and MPF were more closely associated with disease course than osteopontin and are expected to be useful in monitoring patient response in mesothelioma (Hollevoet et al. 2011).

Adenomatoid Tumor of the Liver

9054/0

Introduction

Adenomatoid tumor, first described in 1945 (Golden and Ash 1945), is a benign biphasic tumor now thought to be of mesothelial origin. These nodular and mostly circumscribed lesions typically occur in the female and male genital tracts and mesothelial surfaces, but are also known from extragenital sites, including the adrenal gland (Isotalo et al. 2003; Garg et al. 2005), pancreas (Overstreet et al. 2003), appendix (Hanada et al. 2003), mesocolon and omentum (Yeh et al. 2008), mesentery (Honore and Korn 1976), heart (Natarajan et al. 1997), pleura (Kaplan et al. 1996; Minato et al. 2009), mediastinum (Plaza et al. 2004), and peritoneum (Wang et al. 2005). Adenomatoid tumors may develop as composite lesions, in the adrenal gland, e.g., associated with myelolipoma (Timonera et al. 2008). The relationship between adenomatoid tumor and mesothelioma is underlined by immunohistochemical parallels between the neoplasms (Satoh et al. 1998; Delahunt et al. 2000; Schwartz and Longacre 2004) and the observations that localized malignant mesothelioma may accompany adenomatoid tumor-like lesions (Umezu et al. 2002), that papillary mesothelioma of the omentum can develop in conjunction with adenomatoid tumor (Hanrahan 1963), and that composite multicystic mesothelioma and adenomatoid tumor of the female genital tract have been reported (Zamecnik and Gomolcak 2000).

Morphology of Adenomatoid Tumors

Histologically, the lesions consist of slit-like or gland-like cystic spaces or irregularly shaped spaces lined by flattened cells. There are also solid components composed of similar cells or tubules by cuboidal cells. Distinct thread-like bridging strands crossing the glandular or pseudotubular spaces are a

typical morphologic feature of adenomatoid tumor (Hes et al. 2003). These formations are embedded in a fibrous matrix that shows signs of elastogenesis (Akhtar et al. 1976). The (epi/meso)thelioid cells are either pale or eosinophilic and rarely markedly oxyphilic (oxyphilic adenomatoid tumor; Phillips et al. 2007). Some adenomatoid tumors contain cells with prominent cytoplasmic vacuoles which, similar to the glandular space lumina, contain an Alcian blue-positive material rich in hyaluronic acid. This is also a typical feature of mesothelioma, adding to the striking histologic resemblance between the two tumor types. Adenomatoid tumor can, similar to mesothelioma, produce papillary structures (Glatz and Wegmann 2000). Mitotic figures are almost never seen. The tumors may undergo extensive necrosis (infarcted adenomatoid tumor; Skinnider and Young 2004). Immunohistochemically, adenomatoid tumors, similar to mesotheliomas, are positive for broad-spectrum cytokeratins, cytokeratins 5/6, epithelial membrane antigen (EMA), calretinin, mesothelin, HBME1, Wilms tumor suppressor gene product (WT1), podoplanin, and D2-40, but negative for BerEP4, claudin 5, CD31, and CD34 (review: Marchevsky 2008). Adenomatoid tumors may show a striking resemblance to lymphangiomas, particularly in cases with markedly flattened cells lining the thin spaces. Positivity for D2-40 may be misleading in such cases (Kuroda et al. 2007), and this antibody should, hence, be complemented by calretinin and cytokeratins 5/6, as D2-40 is also a marker for mesothelial cells.

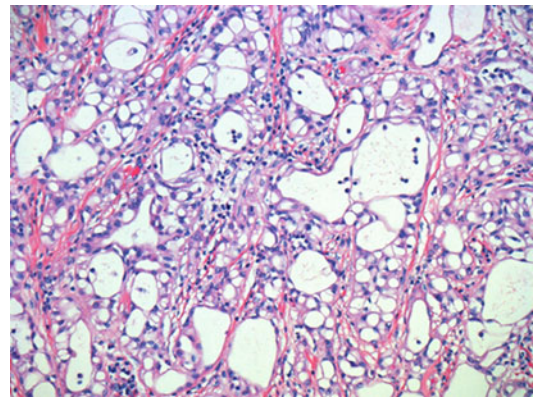

Fig. 2 Adenomatoid tumor of the liver. Epithelioid cell nests embedded in a stroma show marked vacuolar change (hematoxylin and eosin stain)

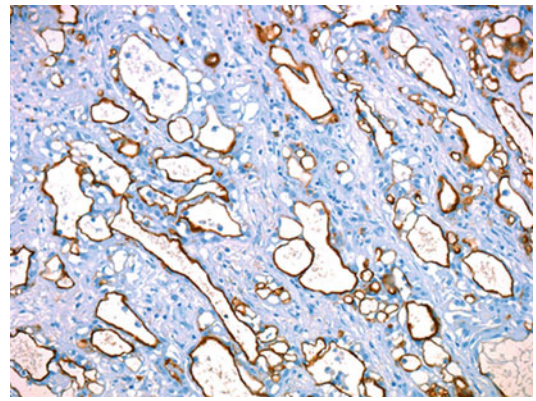

Fig. 3 Adenomatoid tumor of the liver. The epithelioid cells are reactive for podoplanin (podoplanin immunostain)

Solitary Adenomatoid Tumor of the Liver

Adenomatoid tumor can occur in as a primary tumor of the liver, with a histology and immunohistochemical phenotype as in other locations of these lesions (Figs. 2, 3, and 4). The first report of primary solitary adenomatoid tumor of the liver is from 2008 (Nagata et al. 2008). A 39-year-old male patient showed a 2.0-cm hypervascular hepatic tumor in liver segment V, found by ultrasonography during a routine checkup. There was no evidence for another tumor. Abdominal CT demonstrated that the tumor was hypointense in pre-enhancement and highly enhanced in the arterial phase with early washout. In MRI, the tumor was hypointense on T1-weighted images and highly hyperintense on T2-weighted images. Angiography showed the tumor as a hypervascular mass fed by A5 from an arterioportal shunt. Hepatic segmentectomy was performed. The specimen revealed a 1.5-cm nonencapsulated soft mass in the subcapsular region, with a hemorrhagic cut surface with numerous microcystic spongiotic structures. The

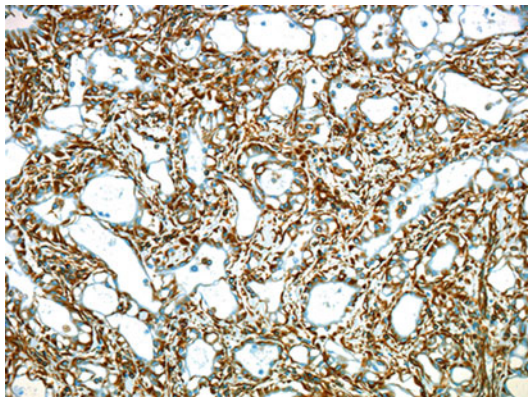

Fig. 4 Adenomatoid tumor of the liver. Intervening stromal spindle cells strongly reactive for smooth muscle actin are myofibroblasts (alpha-SMA immunostain)

interface of the lesion with the adjacent liver substance exhibited a micronodular interdigitation pattern. Histologically, the nodular tumor comprises cystic spaces within a collagenous stroma, lined with cuboidal, low-columnar, or flattened epithelioid cells, the spaces being filled with a colloid-like substance. The lining cells displayed small- to large-sized vacuoles and round to oval nuclei. Mitotic figures or atypias were not seen. Immunohistochemically, the epithelioid cells were reactive for pancytokeratin (AE1/AE3), epithelial membrane antigen (EMA), CAM 5.2, cytokeratins 7 and 19, calretinin, WT1, and D2-40. The adjacent stromal cells had the features of myofibroblasts, with marked positivity or alpha-SMA (Nagata et al. 2008). Since this case report, few other observations have been published (Adachi et al. 2012; Kim et al. 2012). Cystic adenomatoid tumor was detected at the porta hepatis (Grosse-Holz et al. 2013).

Multiple Abdominal Adenomatoid Tumors Involving the Liver

In an old female patient, several left-sided peritoneal adenomatoid tumor nodules located below the dome of the diaphragm (each measuring 0.2 cm) were associated with a further such tumor (0.5 cm) located to the posterior aspect of the left lobe of the liver. This nodule appeared pale yellow and well circumscribed, unencapsulated in the frozen section. The two lesion groups shared the morphologic and immunohistochemical features of adenomatoid tumor, the liver tumor being calretinin positive and negative for BerEP4. Ultrastructural examination performed on the liver lesion showed prominent desmosomes, long microvilli on the luminal surface of tumor acini, and a collagenous stroma typical of an adenomatoid tumor (Hayes et al. 2007).

Tumors of the Perivascular Epithelioid Cell (PEC) System

Perivascular Epithelioid Cell Tumors 73

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_73

Abstract

Perivascular epithelioid cell (PEC) tumors form a complex group of neoplasms that share the presence of a unique cell type of still unknown lineage and source. PEC tumors or PEComas develop in numerous organs, including the hepatobiliary tract. In the liver, primary PEComa exclusively composed of PEC in the absence of heterologous elements is a rare neoplasm that sometimes presents as a large tumor mimicking other primary hepatic neoplasms. Although the course of PEComa is often favorable, tumor recurrence and even metastatic spread may occur. A second hepatic tumor of the PEComa group is angiomyolipoma, well known as a renal tumor occurring in the setting of tuberous sclerosis. Angiomyolipoma is composed of epithelioid cells of the PEC type, adipocytes, myoid cells, and abnormal blood vessels, in variable proportions. Some tumors are predominantly epithelioid, while others almost entirely consist of fat cells and thus mimic lipomas. Very rare hepatobiliary PEC tumors include clear cell myomelanocytic tumors, other clear cell and "sugar" tumors, and lymphangiomyomatosis.

PEComa Family of Tumors and the Concept of Perivascular Epithelioid Cells (PEC)

Perivascular epithelioid cells (PECs) have first been described in 1944 by Apitz in his work on tumors and malformations of the renal cortex (Apitz 1944). This author noted that, in renal angiomyolipomas, myoid cells revealed a particular spatial relationship to proliferated tumor vessels (page 318 and Figs. 11 and 12 of the work of 1944). Figure 11 of Apitz's publication shows a distinct array of medium-sized spindle cells sometimes separating the blood vessels from the lipomatous tumor components. The immature-looking myoid cells had some resemblance to epithelial tumor cells. The author noted this cell type in angiomyolipomas exclusively and argued that these myoid cells were not of angiomatous origin but rather got secondarily involved with the blood vessels. Apitz also found that angiomyolipomas with this specific feature were those with the most prominent growth behavior (Apitz 1944). In 1968, Masson described the cells in more detail, again for renal myolipomas and angiomyolipomas, and noted the distinct relationship between vessels and myoid cells (" . . .les éléments myoides ayant tendance à se grouper sans ordre au pourtour de nombreux vaisseaux") and the epithelioid aspect of some of these cells ("Il arrive enfin qu'à ces éléments faciles à identifier s'en ajoutent d'autres, épithélioides, plus ou moins volumineux, acidophiles, groupés en amas ou en cordons, qu'Apitz considère come des myoblastes anormaux"; although Apitz did not use the term, myoblasts, in his work).

The concept of PEC has been reviewed (Pea et al. 1996; Bonetti et al. 1997). PECs do not seem to have a normal counterpart. Morphologically, PECs occurring in several neoplasms commonly have a medium size with a pale eosinophilic to clear cytoplasm and a centrally located round nucleus showing only slight atypia. But PEC may also occur as spindled cells with an elongated nucleus and thus may reveal a myoid phenotype. Other PEC lineages show a markedly eosinophilic cytoplasm and more prominent epithelioid aspect. Immunohistochemically, the prominent phenotype is that of a coexpression of muscle cell and melanotic cell markers, chiefly HMB-45 (directed against a 46 kD melanosome glycoprotein), Melan-A/MART-1, tyrosinase, microphthalmia transcription factor (MITF), and smooth muscle actin (SMA). PECs are usually not reactive for S-100 protein, cytokeratins, and vimentin. In regard to these key markers, there is considerable variation among several PEC populations, with sometimes only focal reactivity for either HMB-45 or SMA (Bonetti et al. 1997). In contrast to melanomas and clear cell sarcomas, PEComas are reactive for MUM-1, a known lymphocyte marker (Ferenczi et al. 2012). It has also been suggested that PECs have a neural crest origin (Fernandez-Flores 2011) or be derived from telocytes (Ardeleanu and Bussolati 2011).

The neoplastic offspring of PEC comprises a family of neoplasms, termed PEC tumors (Table 1;

Table 1 Classification of PEC tumors

Perivascular epithelioid cell tumor sensu *stricto* (PEComa)
Clear cell myomelanocytic tumor (CCMT)
Clear cell sugar tumor (CCST)
Angiomyolipoma (AML)
Monotypic epithelioid angiomyolipoma (renal epithelioid oxyphilic neoplasm, REON)
Renal microhamartoma (related to AML)
Renal capsular neoplasms (RCN, renal capsulomas)
Pediatric epithelioid renal neoplasm with HMB-45 reactivity
Pulmonary clear cell nodules (CCN)
Lymphangioleiomyomatosis (LAM)
Intranodal palisading leiomyoblastoma
Abdominopelvic sarcoma of perivascular epithelioid cells

review: Armah and Parwani 2009). The WHO defines PEC tumors or PEComas as mesenchymal tumors composed of histologically and immunohistochemically distinctive perivascular epithelioid cells (PECs). PEC as a neoplastic lineage in both angiomyolipomas and clear cell sugar tumor was first noted in 1991 (Pea et al. 1991). In 1992, the concept of a distinct PEC tumor family was advanced, based on the detection of cellular links between angiomyolipoma, clear cell sugar tumors, and lymphangioleiomyomatosis and the recognition that the cells of these tumors were reactive with melanocyte markers, an epithelioid morphology, and a perivascular distribution (Bonetti et al. 1992).

The term, PEComa, to denote neoplasms of "pure" PEC composition was suggested in 1996 (Zamboni et al. 1996) and has since gained wide acceptance. Later, the PEComa family of tumors has grown to comprise a considerable number of entities, including perivascular epithelioid clear cell tumor (PEComa), the closely related clear cell myomelanocytic tumors (CCMT), angiomyolipoma (AML), monotypic epithelioid angiomyolipoma (renal epithelioid oxyphilic neoplasm, REON), renal microhamartomas (related to AML), renal capsular neoplasms (RCN, capsulomas), pediatric epithelioid renal neoplasm with HMB-45 reactivity, pulmonary and extrapulmonary clear cell (sugar) tumors, pulmonary clear cell nodules (CCN), lymphangioleiomyomatosis (pulmonary and extrapulmonary variants, LAM), intranodal palisading leiomyoblastoma, and abdominopelvic sarcoma of perivascular epithelioid cells. In the female genital tract and retroperitoneum, a sclerosing variant of PEComa occurs, which may have an aggressive course (Hornick and Fletcher 2008; Yamada et al. 2011; Santi et al. 2012). In a review, PEComas outside the kidney, lung, and liver, there tended to be a female predominance (Pan et al. 2003), with a wide age distribution. PEC tumors show a wide range of biologic behavior, most lesions being benign or of intermediate behavior, but frankly malignant forms also exist (Bleeker et al. 2012).

Patients with tumors of the PEC family may exhibit lesions of the tuberous sclerosis complex (TSC; Vang and Kempson 2002). In fact, the majority of neoplastic lesions composed of PEC have been suggested to be related to TSC (Bonetti et al. 1997). In addition, a distinct subset of PEComas harbors fusions involving the transcription factor E3 (TFE3). TFE3-expressing PEComas tend to prevail in young age, are not associated with tuberous sclerosis, and tend to show a predominant alveolar architecture and epithelioid features (Argani et al. 2010; Matkowskyj et al. 2013; Shen et al. 2014). Reactivity for TFE3 was not detected in PEComa of the liver (Xia et al. 2013).

Primary PEComa of the Hepatobiliary Tract

Introduction

PEComas sensu stricto, i.e., without cellular elements typical for angiomyolipoma (such as adipose tissue and smooth muscle cells), are very rare hepatic neoplasms. The first case was probably reported in 2006 (Parfitt et al. 2006), followed by several other descriptions.

Clinical and Imaging Features

The clinical presentation of PEComas of the liver is nonspecific and similar to other primary hepatic neoplasms with slow growth and low aggressivity. Generally, abdominal discomfort, indigestion, loss of appetite, nausea, and intermittent colic pain have been noted. Laboratory tests have no diagnostic utility. Most primary hepatic PEComas have been described as solid tumors with an expanding growth pattern. Several of the reported lesions measured few cm in diameter, but these neoplasms may also grow to larger size, e.g., with a diameter of 7 cm (Zimmermann et al. 2008) to 17 cm (Strzelczyk et al. 2009), causing clinically manifest hepatomegaly. In one series of seven cases, the maximum diameters ranged from 2.5 to 8.5 cm (mean = 4 cm; Tan and Xiao 2012). Rarely, hepatic PEComas may undergo intratumoral hemorrhage and cause acute abdomen (Priola et al. 2009). In one patient, a large (15 cm) hepatic PEComa was synchronously associated with multiple focal nodular hyperplasia (Durczynski et al. 2012). The biologic behavior of hepatic PEComas is, similar, the PEComas situated elsewhere, difficult to predict. In one patient, metastases to multiple sites developed nearly 9 years after diagnosis (Parfitt et al. 2006). A second malignant hepatic PEComa was associated with multiple lobulated nodules containing hemorrhagic fluid on the liver surface, peritoneum and omentum, and led to the patient's death 25 days after hospital admission (Selvaggi et al. 2011).

On CT images, the tumors were in some cases centrally hypodense, with enhancement in the arterial phase (Sanchez-Pérez et al. 2009; Selvaggi et al. 2011; Tan and Xiao 2012). In non-enhanced MR, the tumors showed low intensity on T1-weighted images and a high intensity on T2-weighted images (Akitake et al. 2009; Sanchez-Pérez et al. 2009). Fat-suppressive MR did not show suppression of hyperintensity of the tumor, indicating poor or absent fat component (Akitake et al. 2009). Some of the reported tumors resembled focal nodular hyperplasia, hemangioma, or hepatocellular carcinoma at imaging (Parfitt et al. 2006; Fang et al. 2007; Larbcharoensub et al. 2007; Svajdler et al. 2007; Paiva et al. 2008; Zimmermann et al. 2008). Contrast-enhanced ultrasonography demonstrated early-phase enhancement of the tumor and rapid drainage of the contrast agent to veins (Akitake et al. 2009).

Pathology

Macroscopy

At gross examination, hepatic PEComas are nodular and well-circumscribed masses with a grayish-white, yellow-tan to pink cut surface (Fig. 1). Larger tumors may be friable in central parts, have a fragile consistency, and may undergo cystic change (Zimmermann et al. 2008; Strzelczyk et al. 2009), while hemorrhage and necrosis are rare observations.

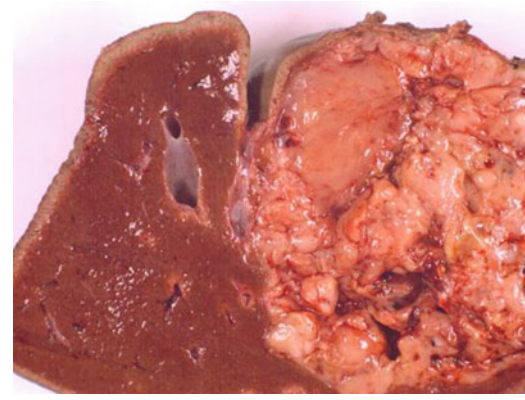

Fig. 1 Primary perivascular epithelioid cell tumor (PEComa) of the liver (non-fixed resection specimen)

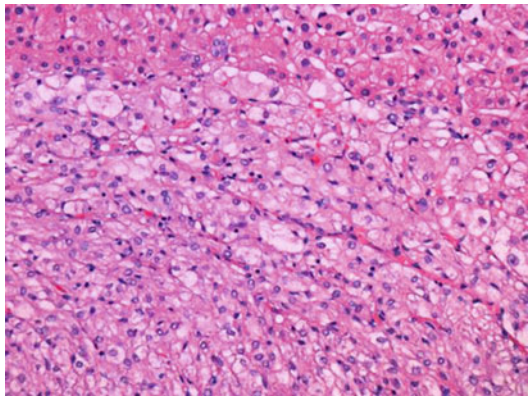

Fig. 2 Primary perivascular epithelioid cell tumor (PEComa) of the liver. The neoplasm consists of large, pale cells with small round and regular nuclei. At the interface with the liver, no stromal interposition is present (hematoxylin and eosin stain)

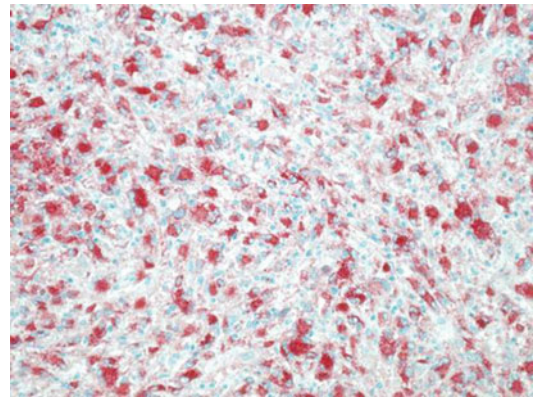

Fig. 3 Primary perivascular epithelioid cell tumor (PEComa) of the liver. The neoplastic cells show strong cytoplasmic reactivity for HMB-45 (HMB-45 immunostain)

Histopathology

Most of the tumor mass is composed of medium-sized polygonal or slightly elongated cells with an epithelioid appearance, showing an eosinophilic, pale, or clear cytoplasm (Fig. 2). These cells form nests, bundles, tiny nodules, or platelike (trabeculum-like) arrangements with intervening, thin-walled vascular channels, a pattern that sometimes mimics hepatocellular carcinoma. Apart from epithelioid cells, spindle cells in variable quantities also occur. These cells display a faintly eosinophilic cytoplasm and ovoid to elongated nuclei, forming bundles and at some places palisade-like structures (Zimmermann et al. 2008). A smaller component is represented by large eosinophilic or pale cells with sometimes pleomorphic nuclei. Mitotic figures are usually rare or not detectable. Reticulin fibers predominate in the spindle cell areas. Part of the lesions display a predominance of clear cells, resulting in the presentation of a clear cell "sugar" tumor (Strzelczyk et al. 2009). Some of the tumors show a high degree of vascularity and the presence of dilated vascular channels (Strzelczyk et al. 2009). A clear cell component similar to that of clear cell myomelanocytic tumors of hepatic ligaments (see below) has also been described (Larbcharoensub et al. 2007). The histology of hepatic PEComas may not serve well to predict the biologic behavior. In a patient with a histologically benign hepatic PEComa, metastases to multiple sites occurred 9 years later (Parfitt et al. 2006).

Ultrastructure

Ultrastructurally, part of the tumor cells (mainly the clear cells) exhibit abundant glycogen. Other cells showed a well-developed rough endoplasmic reticulum, thin filaments, microtubules, and aberrant melanosomes (Larbcharoensub et al. 2007).

Immunohistochemistry

Immunohistochemically, the tumors reported were consistently positive for HMB-45 (Fig. 3) and other melanoma markers (Melan-A, melanoma antigen/PNL2, microphthalmia transcription factor, tyrosinase). Usually, granular cytoplasmic reactivity for HMB-45 prevails, whereas Melan-A is less strongly expressed (Zimmermann et al. 2008). Melanoma antigen/PNL2 was mostly found in larger, epithelioid cells (Zimmermann et al. 2008). The tumors may contain SMA-positive myoid cells (Fig. 4). SMA reactivity is heterogeneous and mainly involves

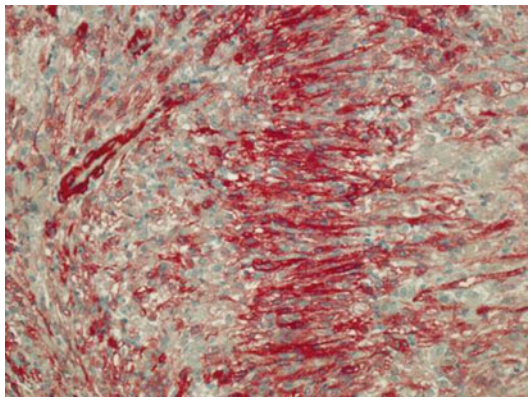

Fig. 4 Primary perivascular epithelioid cell tumor (PEComa) of the liver. Apart from epithelioid cells (*left half of figure*), this tumor contains smooth muscle actin-positive palisading spindled cells (alpha-SMA immunostain)

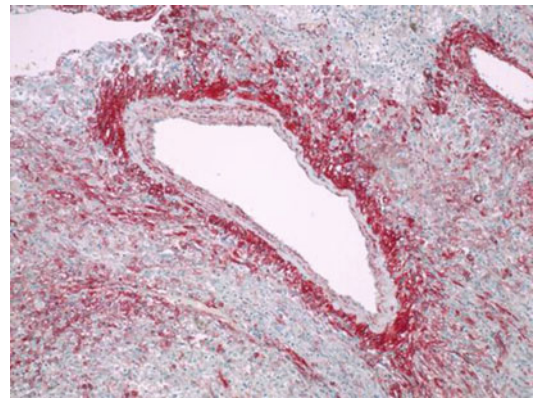

Fig. 5 In hepatic PEComa, smooth muscle cell-positive smooth muscle cells may predominate as perivascular cells, forming a cellular corona (alpha-SMA immunostain)

the slender spindle cells that are arranged in bundles. Sometimes, SMA-positive smooth muscle cells are closely associated with blood vessels, apparently engaging with the vessels' adventitia (Fig. 5; Zimmermann et al. 2008). At contacts of the tumor with portal tracts of the adjacent liver substance, strongly SMA-positive tumor spindle cells being less or not reactive for HMB-45 and Melan-A form a tight interface with the outer contour of arteries and veins, sometimes completely encircling these vessels in a radial fashion (Zimmermann et al. 2008). Beta-catenin is expressed in a mixed cytoplasmic and membranous staining pattern, being more prominent in the epithelioid cell population. This beta-catenin reactivity was more marked in tumor tissue near the tumor boundaries next to the normal hepatic tissue (Zimmermann et al. 2008). In a review of immunohistochemical findings observed in nine published cases, the typical diagnostic constellation was a positivity of the tumor cells for HMB-45, Melan-A, MITF, tyrosinase, HHF35, SMA, h-caldesmon, NKI/C3, and calponin (Strzelczyk et al. 2009). A minority of PEComas are weakly reactive for the lymphocyte marker, MUM-1 expression, while angiomyolipomas are negative (Ferenczi et al. 2012). Reactivity for S100 protein is highly variable and was found in some and not in other reports (Svajdler et al. 2007). Some authors described aberrant

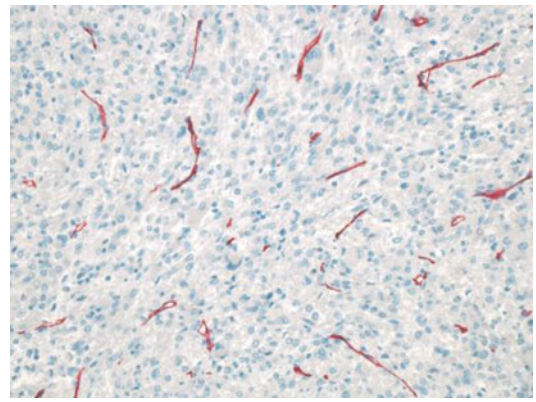

Fig. 6 Vascularization pattern of primary hepatic PEComa (CD31 immunostain)

cytoplasmic reactivity for CD1a in PEComas (Adachi et al. 2006; Adachi et al. 2008; Fadare and Liang 2008), but a more recent investigation emphasized that these tumors fail to show membranous immunostaining and do not truly express CD1a (Ahrens and Folpe 2011). PEComas display a characteristic vascular pattern that is well visualized by CD31 immunostaining (Fig. 6).

Melanotic Hepatic PEComa

Few hepatic PEComas may contain cells with a finely granular dark brown and iron-negative pigment, these cells showing a positive granular,

black cytoplasmic staining in the Fontana-Masson stain, suggesting a melanocytic component (melanotic hepatic PEComa; Zimmermann et al. 2008). A later case was characterized by a huge hepatic PEComa with a diameter of 24 cm showing brownish back areas on the cut surface. Histologically, the tumor revealed abundant melanin pigment in epithelioid neoplastic cells, but otherwise exhibiting epithelioid and spindle cells with clear to eosinophilic cytoplasm (Patra et al. 2013).

PEComa of the Bile Ducts

Primary PEComa of the common bile duct was detected in a 51-year-old male patient who had acute inset of epigastric pain. A CT of the abdomen with contrast showed a soft tissue density extending into the common bile duct at the level of the pancreatic head. ERCP revealed an intraluminal mass causing duct dilatation. The resection specimen showed a tumor within the common bile duct measuring 2.4 cm in greatest dimension. Microscopic examination revealed a well-circumscribed but unencapsulated mass composed of plum epithelioid cells with abundant clear to lightly eosinophilic cytoplasm, arranged in a nested growth pattern with a rich vascular network. Rarely, tumor cells contained a light brown melanin-type pigment. Immunohistochemically, the neoplastic cells were strongly positive for HMB-45 and neuron-specific enolase, but negative for cytokeratin, vimentin, Melan-A, and smooth muscle actin (Sadeghi et al. 2004).

Differential Diagnosis

The most important histological differential diagnosis are variants of hepatic angiomyolipomas with a very low adipocyte content. These monotypic epithelioid forms of angiomyolipoma may present with a more aggressive biology and are very difficult to distinguish from classical PEComa. Metastases of amelanotic melanomas, mainly those with a clear cell component, may be almost undistinguishable from PEComas, because they share a very similar immunophenotype. A careful patient history, also with exclusion of visceral melanomas and ocular melanoma, is mandatory. Very rare instances of liver metastases of extrahepatic PEComas have been reported (Houlle et al. 2010; Nagata et al. 2011).

Perivascular Epithelioid Clear Cell Tumors of the Hepatobiliary Tract: Clear Cell Myomelanocytic Tumors of the Hepatic Ligaments

This is a small group of very rare tumors that have mostly been detected to arise in the falciform ligament. In a report on seven patients, all tumors occurred in or immediately adjacent to the ligamentum teres or ligamentum falciforme and were termed clear cell myomelanocytic tumors (Figs. 7 and 8; Folpe et al. 2000). There were six females and one male, with an age range of 3–21 years (median, 11 years). Macroscopically, the tumors were well-circumscribed masses with a diameter ranging from 5 to 20 cm (median, 11 cm). Histologically, the neoplasms consisted of fascicles and nests of faintly eosinophilic spindle cells with a low mitotic activity. Immunohistochemically, all tumors were reactive for

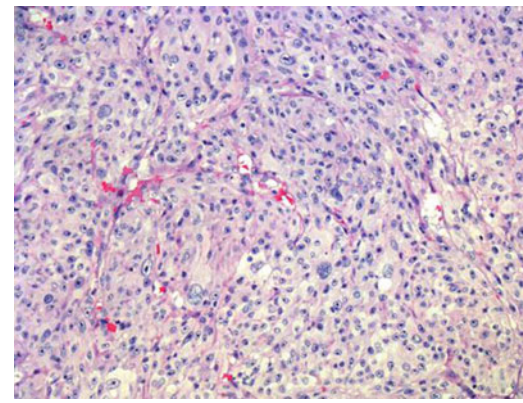

Fig. 7 Clear cell myomelanocytic tumor of the hepatic ligaments (hematoxylin and eosin stain)

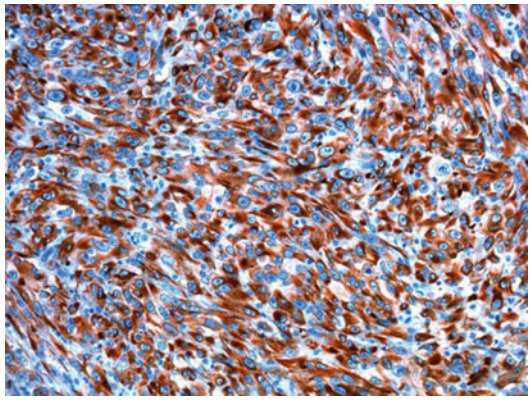

Fig. 8 Clear cell myomelanocytic tumor of the hepatic ligaments, reactivity for HMB-45 (HMB-45 immunostain)

HMB-45 (gp100 protein), and part of the neoplasms were positive for Melan-A, microphthalmia transcription factor (MITF), alpha-SMA, and myosin, but not desmin and S100 protein. Three tumors were analyzed for tuberin expression, with a negative result. Follow-up in six patients revealed that five patients were free of disease and one patient had a presumed lung metastasis. In the same year, Tanaka et al. (2000) reported a similar tumor occurring in the ligamentum teres hepatis of a 13-year-old Japanese girl. The authors used the term HMB-45/Melan-A and smooth muscle actin-positive clear cell epithelioid tumor to denote this lesion. The liver tumor measured up to 9 cm in diameter and was completely removed. Macroscopically, the tumor tissue was homogeneous and tan-white, without necrosis or hemorrhage. Histologically, polygonal or oval-shaped cells with a granular or clear cytoplasm were arranged in nests or sheets. There was moderate nuclear atypical, but mitotic figures were absent. Immunohistochemically, most of the neoplastic cells were reactive for HMB-45, Melan-A, and smooth muscle actin, but were negative for desmin, cytokeratin, CD34, CD68, or CD99. The tumor was interpreted to represent a member of the clear cell "sugar tumors." A similar neoplasm was reported in a 36-year-old woman presenting with acute abdomen caused by intralesional hemorrhage (Priola et al. 2009).

PEComas of the Hepatic Ligaments in Adults

Few cases of PEComas arising in the hepatic ligaments of adults have been reported, both in the falciform ligament (Choi et al. 2009) and the ligamentum teres (Sotiropoulos et al. 2009). In the case of Choi and coworkers (2009), a 30-year-old woman presented with a growing periumbilical mass. A CT scan of the abdomen showed an intra-abdominal, well-enhanced, and focally calcified mass measuring 7.5 cm supposed to originate from the falciform ligament. The resected specimen revealed a uniloculated cystic tumor with a solid portion, and histology was characterized by a population of spindled to epithelioid cells with a clear to eosinophilic cytoplasm and immunoreactivity for HMB-45 and SMA. Also a variant of PEC neoplasms, clear cell myomelanocytic/myomelanocytic tumor, was observed in the hepatic ligaments (Folpe et al. 2000; Priola et al. 2009; Coker et al. 2013), a type of neoplasm further discussed in a separate paragraph.

Angiomyolipoma of the Liver

ICD-O 8693/1

Introduction

The term angiomyolipoma was first used by Morgan and coworkers in 1951 to denote a distinct renal tumor (Morgan et al. 1951). Angiomyolipomas (AMLs) are rare neoplasms and have been detected in only 0.07 % of an autopsy series. The detection of the expression of melanoma-associated markers has shown that AML belongs to the PEComa family of tumors. AML is most often located in the kidneys, almost always follows a benign course, and occurs both sporadically and in association with the tuberous sclerosis complex (TSC; reviews: Blute et al. 1988; Eble 1998). AMLs mostly share a common histologic pattern in all the organs they

arise, characterized by a mixture of epithelioid or spindled perivascular cells, myoid elements/smooth muscle cells, and adipose tissue to variable amounts. However, AML also occurs in a rather broad spectrum of histological variants.

The monotypic epithelioid variant of AML has recently been differentiated as a distinct entity from typical AML. Few cases of AML with locally aggressive behavior and distant metastases have been described, considered malignant variants of AML (multicentric aggressive angiomyolipoma). These tumors are usually multicentric lesions with associated renal AML and are histologically of the epithelioid-predominant type (review: Lai et al. 2006). One variant of AML is composed exclusively or predominantly of smooth muscle cells (smooth muscle cell-predominant AML), and tumors with this phenotype were observed in the liver and in the renal capsule (Nonomura et al. 1998). Renal angiomyolipoma with epithelial cysts (AMLEC) is a recently recognized entity characterized by three distinct histologic components.

Angiomyolipoma of the liver (hepatic angiomyolipoma, HAML) is a rare lesion that has first been reported in 1922 at the scientific session of the association of middle-German pathologists in Dresden (Mittasch 1922). The tumor was again described in 1976 based on two tumors incidentally found at autopsy (Ishak 1976). However, it appears that the liver is the second most common site of AML. The first clinical case was presented in 1983 (Kawarada and Mizumoto 1983). Since then, more than 200 cases have been described in the literature (reviews: Nonomura et al. 1994a; Chung et al. 2002; Petrolla and Xin 2008; Ding et al. 2011; Yang et al. 2013). In about 20 % of the patients, an association with the tuberous sclerosis complex (TSC) has been identified, similar to AML occurring in other organs (Compton et al. 1976; Dumortier et al. 2010).

Epidemiology

In a retrospective study of eight female patients with HAML, age ranged from 30 to 66 years (mean, 45.3 years) (Yeh et al. 2001). In a review of 74 cases reported in the literature, HAMLs were noted between the first and eight decade, and the lesions ranged from 0.3 to 36 cm in diameter (Hoffman et al. 1997). Among 156 patients with angiomyolipoma originating from different organs, the liver was involved in 14 % (Yang et al. 2012). In a study on 30 patients with HAML, female patients were diagnosed as having this lesion more often than males (5:1), and mean age at diagnosis was 48.7 years (range, 29–68 years). Among 26 other patients, the female predominance was 21:5 (Ren et al. 2003), while in a more recent analysis of 51 patients, 41 were female (Li et al. 2009), and in a study on 79 patients, there were 58 women and 21 men (Ding et al. 2011). A clear predominance of female subjects was observed in another recent study (54 females vs. 20 males; Hu et al. 2011).

Clinical Features

Most tumors are located to the right liver lobe (in 56.8 % of 169 patients; Yu et al. 2010), and there is a clear female predominance. Similar to renal AML, HAML may manifest in the form of multiple angiomyolipomas, more often in patients with tuberous sclerosis (Kyokane et al. 1995; Nonomura et al. 1995; Arblade et al. 1996; Strotzer et al. 1999; Fricke et al. 2004; Saito et al. 2004; Takamura et al. 2005), but multiple HAMLs, sometimes with up to 15 nodules of variable diameter, have also been observed in the absence of tuberous sclerosis (Tang et al. 2002; Saito et al. 2004; Dumortier et al. 2010). Hepatic AML may be associated with unilateral or bilateral renal AML (Kimura et al. 1994; Hirasaki et al. 1999; Chao et al. 2004; Mongha et al. 2008). In a study on 205 patients with tuberous sclerosis complex, the presence of HAML was significantly associated with the presence of renal AML (Black et al. 2012). In one review, 13 of 60 cases of HAML were associated with concurrent renal AML (Hoffman et al. 1997). HAML has been observed in association with pulmonary angiomyolipoma (Garcia and Mestre de Juan 2002), pulmonary

lymphangioleiomyomatosis (Kim et al. 2003), focal nodular hyperplasia, bile duct adenoma and cavernous hemangioma of the liver (Langner et al. 2001), splenic hamartoma (Irie et al. 2002), hepatocellular carcinoma (Chang et al. 2001; Yang et al. 2008), and high-grade sarcoma of the liver (Bralet et al. 2000).

In a series of 52 cases (Nonomura et al. 1994a), the disease was symptomatic in 60 % of the patients, with abdominal pain or distress found in 37 % of the patients, followed by malaise and upper abdominal mass or hepatomegaly. Among ten patients from China, HAML was detected incidentally via routine examinations in eight patients (Ji et al. 2001). Among 26 patients (18 females), most patients presented no significant symptoms except for one who had spontaneous rupture hemorrhage (Zhou et al. 2008). Among 94 Chinese patients from four institutions, 52 patients (55.3 %) showed no significant clinical symptoms (Chang et al. 2011). Complications of HAML are seldom encountered. This is contrast to renal AML, where spontaneous and sometimes massive retroperitoneal hemorrhage from the tumor (Wunderlich's syndrome) can occur in up to 10 % of the patients. HAML complications comprise acute abdomen induced by intratumoral hemorrhage (Priola et al. 2009), rupture (Zhou et al. 2008; Ding et al. 2011), and Budd-Chiari syndrome (Kelleher et al. 2004). All of 26 patients of one series that had hepatic resection of HAML showed a benign course with no signs of recurrence (Ren et al. 2003). In a series of 25 cases, all patients underwent partial hepatectomy, and there was no evidence of recurrence after a median follow-up of 43 months (Li et al. 2008). Follow-up analysis of 94 Chinese patients with HAML and treatment with surgical resection (follow-up rate, 91.5 %) showed no signs of recurrence or metastasis (Chang et al. 2011). HAML may show progressive growth, but this is slow and usually does not indicate a transition to malignancy. It was found that particularly the adipose tissue component can undergo a considerable increase in mass with time (Rimola et al. 2003). However, late recurrence of HAML has been reported, usually in cases with an epithelioid morphology and sometimes several years after surgical treatment (Croquet et al. 2000; Dalle et al. 2000; Deng et al. 2008; Nguyen et al. 2008). Epithelioid HAML may show macroscopic angioinvasion, with invasion and thrombosis of the portal vein. In one patient with this alteration, no tumor recurrence following resection was noted during the subsequent 24-month follow-up (Rouquie et al. 2006). Aggressive HAML with fatal progressive disease has also been observed in the pediatric age group (McKinney et al. 2005).

Pathology

Macroscopy

Commonly, HAMLs are sharply demarcated masses without a capsule. The cut surface of resected HAML is whitish yellow to yellow or tan and relatively homogeneous. The tumor tissue is mostly soft and sometimes friable. Calcification is an exceptional finding. The majority of the tumors have no fibrous pseudocapsule, but such a structure may be mimicked macroscopically by the rim of peritumoral liver atrophy. Necrosis and hemorrhagic foci may be in evidence (Yuan et al. 2001). Rarely, HAMLs are pedunculated lesions (Akatsu et al. 2004). In HAML developing in the context of tuberous sclerosis, hepatic tumors are more often multiple and smaller lesions (Mittasch 1922; Fricke et al. 2004; Saito et al. 2004), sometimes clustered in subcapsular parts of the liver.

Histopathology

The histopathology of HAML has been described in detail (Nonomura et al. 1994a; Tsui et al. 1999; Yuan et al. 2001; Shao et al. 2003). The pathologic diagnosis of HAML is mostly made based on the recognition of the four major components of AML, i.e., abnormal blood vessels, PEC cells, smooth muscle cells, and adipose tissue (Figs. 9 and 10). These tissue elements of HAML are, however, highly variable in expression from case to case and even between different areas of the same tumor. In one series, the most common pattern was solid sheets of myoid cells intermixed

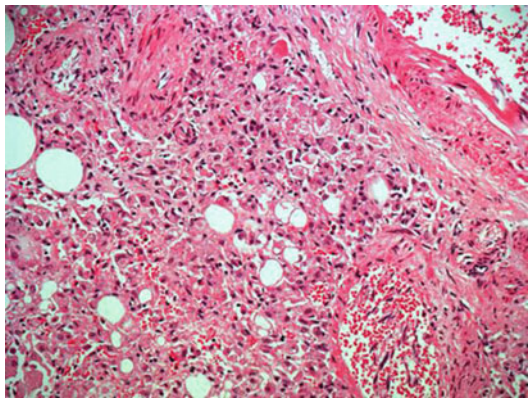

Fig. 9 Angiomyolipoma of the liver. This tumor consists of a complex mixture of macrovesicular adipose cells, epithelioid cells, spindle cells, and abnormal blood vessels (hematoxylin and eosin stain)

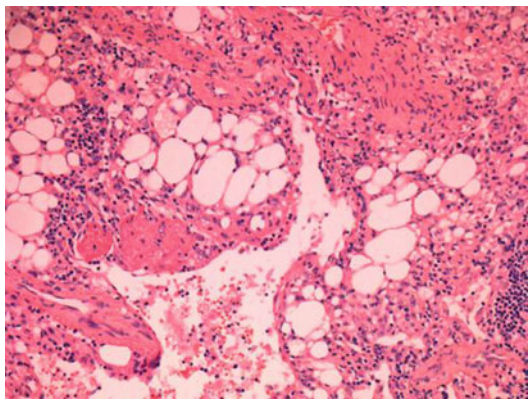

Fig. 10 Angiomyolipoma of the liver with ectatic blood vessels and myoid cell nests (hematoxylin and eosin stain)

with adipose cells and decorated by abnormal thick-walled vessels, the myoid cells being either epithelioid, spindled, or intermediate (Yuan et al. 2001). The epithelioid cells may be large and polygonal shaped or may represent so-called spider-web cells. The cytoplasm of epithelioid cells is eosinophil and granular or clear and vacuolated at the periphery, and the nucleus is commonly eccentrically placed. Nuclear atypias of epithelioid cells are usually slight, but markedly pleomorphic and hyperchromatic nuclei had been found in the rare cases of HAML with a malignant behavior (Deng et al. 2008). The epithelioid cells may contain PAS-positive, diastase-resistant cytoplasmic granules, and part of the cells show nuclear pseudoinclusions. In contrast, spindled myoid cells show a usually clear and slightly vacuolated cytoplasm and oval to fusiform nuclei. The characteristic blending of myoid cells into the walls of abnormal vessels, already described in 1944 for renal AML (Apitz 1944; see above), has also been described in HAML (Yuan et al. 2001). Intermediate cells are smaller, ovoid, or short spindle cells intermingled with polygonal epithelioid cells and present in mostly small areas as sheets of loosely arranged whorled and interlaced fascicles (Yuan et al. 2001). Adipose cells are morphologically mature and are arranged in sheets or as individual cells isolated between myoid cells, but lipoma-like lesions or angiolipomatous lesions sometimes occupying more than 80 of the tumor also occur. Within the lipomatous areas, lipoblast-like cells with multivacuolated, Oil red O-positive cytoplasm and indented nuclei have been recognized (Yuan et al. 2001). Mitotic figures are usually sparse. The development of the vascular component may be variable, but frequently one notes conspicuous tortuous and partially abnormal thick-walled blood vessels that commonly lack an elastic lamella. Large HAMLs (diameter more than 5 cm) showed a significantly increased microvessel density and lymph vessel density as compared with smaller tumors (Xian et al. 2011). The blood vessels may be cuffed by SMA-positive myoid cells which typically blend into the peripheral part of the vascular wall, as originally described by Apitz (1944). Reactive changes include focal lymphocytic infiltrations (Nonomura et al. 2012), foamy macrophages (sometimes lipogranulomas), and cholesterol crystal clefts and cholesterol granulomas.

Most HAMLs are histologically expanding lesions, with peritumoral atrophy of the liver substance. However, HAML can show microscopic invasive growth at the tumor periphery, with growth of epithelioid tumor cells into sinusoidal vascular channels, suggesting malignancy. Also other normal hepatic structures may be invaded. In a systematic study of 39 cases, an invasive growth pattern into surrounding hepatic parenchyma, portal triads, and/or around hepatic veins

was found in 62 % of the cases, invasion usually presenting as perivascular growth. Distant metastases were not found in any of the cases within the mean follow-up period of 6.8 years (Nonomura et al. 2006). The significance of this intriguing phenomenon is currently unknown, and it is not clear, whether this distinct growth pattern in fact represents invasion as seen in frankly malignant neoplasms.

Electron Microscopy

In HAML, epithelioid cells were ultrastructurally found to be in close association with endothelial cells and characterized by unusual cytoplasmic organelles such as myofilaments having focal densities and dense attachments, numerous large electron-dense bodies, and a large number of glycogen particles and lipid droplets, suggesting that these cells may represent immature mesenchymal cells having the ability to differentiate toward both smooth muscle and adipose cells (Okada et al. 1989). Epithelioid cells also contain electron-dense granules with transverse striations like those found in melanosomes (Weeks et al. 1991).

Immunohistochemistry

It is now well established that, similar to PEC tumors, HAMLs express reactivity for HMB-45 (Weeks et al. 1991; Yuan et al. 2001; Ren et al. 2003; Saito et al. 2004; Yeh et al. 2005), chiefly in the myoid cell component. HMB-45 (human melanoma, black) is an organelle membrane-specific marker related to the pmel 17 gene product (review: Bacchi et al. 1996). HAML cell is also reactive for Melan-A (Nonomura et al. 1996). Myoid/smooth muscle cells expressed HMB-45 in 100 % of cases, Melan-A in 14/15 lesions, MITF in 5/12, and tyrosinase in 3/12 hepatic AML, immunoreactivity being generally stronger in the epithelioid component (Makhlouf et al. 2002a). Part of the spindled cells express vimentin and/or smooth muscle actin (Yuan et al. 2001). Angiomyolipomas, including those of the liver, express KIT (CD117) in epithelioid, spindle, and intermediate round cells in a diffuse cytoplasmic staining pattern (Makhlouf et al. 2002b). In 12 patients with HAML, no reactivity for estrogen and progesterone receptors was found (Yeh et al. 2005). This is in contrast to renal AML, where both estrogen and progesterone receptor have been observed in some investigations.

Variants of Hepatic Angiomyolipoma

Fat-Predominant HAML

A subset of HAML is characterized by predominance of adipose tissue, resembling hepatic lipoma and sometimes occurring as multiple lesions (Shima et al. 1986; Blumgart et al. 1987; Nonomura et al. 1996; Hirasaki et al. 1999). The absence of adipose tissue in HAML may be associated with the epithelioid phenotype (Kimura et al. 1994). Hepatic lipoma may radiologically mimic fat-rich HAML (Nakamura et al. 2009). A very rare variant of HAML with a significant fat cell component displays myelolipoma-like features (Agaimy et al. 2012).

Monotypic Epithelioid HAML

The epithelioid variant of AML (monotypic epithelioid AML) has been observed in the liver (Kimura et al. 1994; Koide et al. 1998; Flemming et al. 2000; Leenman et al. 2009) and may account for 50 % or more of the tumor cells (Shao et al. 2003). In few cases, the epithelioid phenotype was associated with lack of adipose tissue (Kimura et al. 1994). In a study of 15 hepatic AML, the tumors exhibited a predominance of the epithelioid smooth muscle cell component, in contrast to renal counterparts which were more frequently spindled (Makhlouf et al. 2002a). Very rarely, the epithelioid phenotype may result in a trabecular growth pattern mimicking hepatocellular carcinoma (trabecular angiomyolipoma; Tsui et al. 1992). Resemblance to hepatocellular carcinoma is also encountered in those variants of

HAML that produce a polygonal epithelioid cell component (Koide et al. 1998).

Smooth Muscle Cell-Predominant HAML

A further variant observed in the liver is smooth muscle cell-predominant HAML (Nonomura et al. 1998). In most HAMLs, the morphology and frequency of smooth muscle cells are quite variable (Nonomura et al. 2012). But there are rare HAMLs with an impressive smooth muscle component. The so-called myomatous HAML has distinct imaging features, being hypoechoic on US and hypointense in MR images (Boraschi et al. 2012). Histologically, these lesions show a prominent component of SMA-positive myoid cells forming fascicles and bundles intermingled with clear cells and sometimes fat-storing cells. Few cases have shown pleomorphic histological features (Nonomura et al. 1994b).

Clear Cell HAML

This extremely rare variant, characterized by a high content of clear cells mimicking clear cell hepatocellular carcinoma, has been observed in the liver of a 47-year-old Chinese women (Chen et al. 2009). The lesion was resected, and macroscopy revealed a white, oval mass which had now a diameter of 3 cm. Histology showed HAML with variable proportions of adipose tissue, smooth muscle cells, and large epithelioid cells with a clear cytoplasm, many cells with peripheral clearing and radiating strands of cytoplasm adhering to the nucleus producing a spider cell appearance. Immunohistochemically, the tumor cells were positive for HMB-45.

Oncocytic HAML

Similar to other AMLs with oncocytic features (Martignoni et al. 2002; Sironi and Spinelli 2003), HAML may present with an oncocytic phenotype (oncocytic HAML; Salisbury and Portmann 1987; Tsui et al. 1999; Yuan et al. 2001). In a series of 30 HAML, the oncocytic variant was detected in three cases (Tsui et al. 1999).

Giant Cell HAML

HAML with numerous giant cells was observed in a 23-year-old female with tuberous sclerosis and multiple masses throughout the liver, measuring from 4 to 11 cm. A CT-guided fine-needle aspiration biopsy was performed, and cytology smears revealed epithelioid, HMB-45-positive HAML with a contribution of numerous large, multinucleated epithelioid cells, which also were HMB-45 positive (Alatassi and Sahoo 2009).

Inflammatory HAML

Rarely, HAML histologically presents as a lesion with a dense leukocytic infiltration, resembling inflammatory pseudotumor of the liver (Kojima et al. 2004; Liu et al. 2012). This HAML with HMB-45-positive epithelioid, myoid, and adipose cells exhibited a histologic picture resembling an inflammatory pseudotumor, with a dense infiltrate consisting of small lymphocytes, macrophages, and plasma cells. In a series of five cases without signs of tuberous sclerosis, the patients were four females and one male, with an age range of 21–48 years at diagnosis (mean, 39.2 years). The tumor size was from 5.5 to 10 cm in the greatest dimension (mean, 7.46 cm). Histology was a mixture of epithelioid, myoid, and scattered adipose cells. More than 50 % of the tumor areas showed a heavy inflammatory infiltration. The patients had no evidence of disease during a follow-up period from 3 to 9 years (Shi et al. 2010).

Malignant HAML

A malignant potential of HAML is difficult to judge. This is in part due to the fact that HAML can show significant cellular atypia, seen in up to 25 % of cases. In addition, signs of invasive

growth were noted in 69 % of cases (Nonomura et al. 2012). All of the few examples of HAML with a malignant behavior were histologically characterized by increased nuclear atypia, sometimes with pleomorphic tumor cells, and the development of hemorrhagic and coagulative necrosis (Dalle et al. 2000; Nguyen et al. 2008). All tumors exhibited only a low mitotic rate. In one report, spindle cells displayed rectangular, hyperchromatic nuclei, and part of the epithelioid cells showed enlarged vesicular nuclei with macronucleoli. Few cells had a Reed-Sternberg cell-like appearance. In this case, tumor cells invaded the sinusoids between the adjacent hepatocyte plates (Nguyen et al. 2008). It has, however, been shown that an invasive behavior of HAML is not correlated with a malignant phenotype (see above; Nonomura et al. 2006).

Differential Diagnosis

Fat-predominant HAML may be confounded with rare hepatic lipomas, while variants with a predominant smooth muscle cell component can mimic leiomyomatous tumors of the liver. In rare situations, extrahepatic malignant epithelioid angiomyolipomas can metastasize to the liver, e.g., renal AMLs (Vicens et al. 2014).

Pathogenesis

AML has been recognized as a clonal neoplasm, based on the finding of nonrandom inactivation of the X chromosome. Clonality of AML has also been documented for those tumors primary to the liver (Flemming et al. 2000). DNA flow cytometric studies revealed a diploid DNA pattern in HAML (Terris et al. 1996). Methylation pattern analysis of the human androgen receptor gene on chromosome Xq11-12 has shown that adipose tissue and smooth muscle cells of renal AML are both monoclonal but may arise independently, suggesting the coexistence of tumor subclones in these lesions (Cheng et al. 2001). However, another study observed clonal smooth muscle and blood vessel cell populations, while adipose tissue was polyclonal and thought to be metaplastic or reactive (Saxena et al. 1999).

Extrapulmonary Clear Cell ("Sugar") Tumors of the PEC Type

Introduction

Clear cell "sugar" tumors were described in the lung (Liebow and Castleman 1963, 1971) and are related to angiomyolipoma and other PEC tumors (Bonetti et al. 1994), but may also occur in extrapulmonary sites (primary extrapulmonary sugar tumor, PEST), including the skin, breast, rectum, vulva, heart, and pancreas (Zamboni et al. 1996; Govender et al. 2002; Tazelaar et al. 2001; de Saint Aubain Somerhausen et al. 2005; Baez et al. 2009). The cell of origin and direction of differentiation of these neoplasms remains enigmatic, but recognition of HMB-45 immunoreactivity and identification of melanosomes have suggested a relationship to angiomyolipoma of the kidney or liver and lymphangiomyomatosis. The potential relationship between clear cell sugar tumor and lymphangiomyomatosis, a lesion connected to tuberous sclerosis, is underlined by the observation of clear cell proliferations of the lung with lymphangiomyomatosis-like change (Pileri et al. 2004).

Clear Cell ("Sugar") Tumors of the Hepatobiliary Tract

"Sugar" clear cell tumors of PEC lineage are very uncommon in the liver and biliary tract. Alexandrakis and Klinge (1998) described a 10 cm-sized tumor incidentally found in the right liver lobe of a 32-year-old man. Histology revealed a clear cell tumor characterized by a uniform population of large epithelioid cells with a mostly water-clear and sometimes also eosinophilic and granular cytoplasm. In the clear cells, the rough endoplasmic reticulum (ergastoplasm) was concentrated in a perinuclear compartment, forming threads leading from the nuclei to the

periphery of the clear cytoplasm. The cytoplasm contained granular PAS-positive material, digestible with diastase treatment, while melanin granules were not detected. Very few univacuolated or multivacuolated adipocyte-like cells were found within the neoplasm. Groups of cells or single cells were surrounded by a network of reticulin fibers. In addition to clear epithelioid cells, spindle-shaped cells were also noted, forming whorl-like formations around small blood vessels. The tumor contained foci of erythroblasts and of foamy macrophages and lymphocytes. Immunohistochemically, the neoplastic cells were reactive for HMB-45, and spindle cells were in part reactive for smooth muscle actin. It is possible that this neoplasm was related to angiomyolipoma variants.

Differential Diagnosis

In the alimentary tract, EPSG should be distinguished from other lesions with a clear cell phenotype, including gastric clear cell carcinoma; clear cell carcinomas of the bowel, biliary tract, liver, and pancreas; clear cell well-differentiated neuroendocrine carcinomas; and clear cell variants of alimentary tract melanoma (review: Ritter et al. 1997).

Extrapulmonary Lymphangiomyomatosis

Introduction

Lymphangiomyomatosis (lymphangioleiomyomatosis, LAM) is a proliferative lesion of smooth muscle cells from lymphatic vessel origin. The process is well recognized in the lung (pulmonary lymphangiomyomatosis, PLAM), in lymphatic trunks, and in lymph nodes and seems to be restricted to female patients usually during their reproductive age. In the lungs, LAM is characterized as the cystic destruction of pulmonary parenchyma; obstruction of airways, blood vessels, and lymphatics; and loss of pulmonary function. The disease is a partial presentation of tuberous sclerosis (reviews: Zhang and Travis 2010; Cottin et al. 2011; Harari et al. 2011). This is supported by the observation that renal angiomyolipomas, of which at least 40 % occur in the setting of tuberous sclerosis, are often detected in patients with LAM. Both lesions are characterized by the involvement of HMB-45-reactive myoid cells (Chan et al. 1993; Hironaka and Fukayama 1999). In LAM, the proliferating myoid cells are benign looking, but they may undergo metastatic spread. The smooth muscle cells coexpress muscle cell markers (SMA and desmin), melanocyte markers (HMB-45, Melan-A/MART-1, and microphthalmia transcription factor), steroid hormone receptors, and a member of the Wnt signaling pathway, beta-catenin. Disseminated LAM cells have been shown to exhibit TSC2 LOH in about half of the patients examined (Crooks et al. 2004). LAM or LAM-like lesions are known to develop in extrapulmonary compartments (extrapulmonary LAM), most often in the retroperitoneal space (Hamada et al. 1997; Jaiswal et al. 2003). Other extrapulmonary sites comprise the pelvic cavity (Kim et al. 2005) and the uterus (Torres et al. 1995) and very uncommonly other organs and tissues.

Lymphangiomyomatosis of the Hepatobiliary Tract

Involvement of the liver by LAM has been observed in female patient with pulmonary LAM, bilateral renal angiomyolipomas, and LAM manifestations in the ovaries and periadrenal vessels (Lack et al. 1986). In this case, the pattern of LAM manifestations suggests metastatic spread from pulmonary LAM. Retroperitoneal extrapulmonary LAM was found to infiltrate the papilla of Vater, causing biliary tract obstruction (De Groot et al. 2008). In this patient, a 23-year-old, otherwise healthy woman, a CT scan of the abdomen showed a large retroperitoneal mass, up to 16 cm in diameter, with cystic and solid components in the lower right abdomen which extended around the abdominal aorta and inferior vena cava. Later examinations revealed pulmonary LAM. In the course of the disease, the process extended to the ampullary region, causing bile duct stenosis

and dilated bile ducts. An ampullary biopsy displayed a lymphangiectatic pattern typical for LAM.

Lymphangiomyomatosis Associated with Other Liver Tumors

Pulmonary LAM is well known to be associated with renal angiomyolipomas, in some studies in more than 50 % of cases (Valensi 1973; Monteforte and Kohnen 1974; Lack et al. 1986; Bernstein et al. 1995; Torres et al. 1995; Maziak et al. 1996). A less common emerging entity is pulmonary LAM associated with the synchronous development of hepatic angiomyolipoma (Kim et al. 2003; Ciftci et al. 2007; Lu et al. 2009; Ishitobi et al. 2011). In a series of 14 cases of LAM, hepatic angiomyolipoma was noted in 7.14 % of patients (Lu et al. 2009). One patient with pulmonary LAM was found to have a large hepatic hemangioma (Cagnano et al. 1991).

Lymphangiomyomatosis Associated with Nonneoplastic Liver Lesions

Extrapulmonary LAM located to the retroperitoneal space, with formation of a large cystic tumor, was associated with peliosis hepatis (Hamada et al. 1997).

Peritoneal PEComatosis

This alteration was first described in a 70-year-old female patient and was characterized by a diffuse myomelanocytic tumor of the peritoneum clinically simulating peritoneal malignant mesothelioma. Exploratory laparoscopy revealed diffuse encasing of the peritonealized organs by a fleshy tissue rind, and scattered nodules were also present. One of the tumor masses measured 6 cm and was considered as the dominant lesion. The cells were of the epithelioid type and positive for HMB-45, Melan-A, and SMA, but negative for S-100 protein (Salviato et al. 2006).

Hepatic Hamartomas in Tuberous Sclerosis

The older literature reveals several reports of hepatic nodular lesions occurring in the context of tuberous sclerosis and termed liver hamartomas (Viamonte et al. 1966; Compton et al. 1976; Fleury et al. 1987; Jozwiak et al. 1992; Cheung et al. 1993). In most reports, no histologic diagnosis was performed. Based on the radiological descriptions, emphasizing the similarity between these "hamartomas" and renal angiomyolipomas, it can safely be assumed that most of these "hamartomas" were in fact hepatic angiomyolipomas. Cheung et al. (1993) specify in their discussion of three observations that, although the imaging features of the lesions on CT and US images are similar in many ways to renal angiomyolipomas, there has been a lack of pathological evidence that (some) of the liver lesions in tuberous sclerosis are indeed angiomyolipomas. Thus, these liver nodules were widely referred to as hamartomas. As hepatic angiomyolipomas can present as homogeneously enhancing masses that are nearly isodense to normal liver tissue on plain CT scans, focal nodular hyperplasia of the liver may be assumed in such cases (Strotzer et al. 1999).

Hepatic Dysplastic Lesions in Tuberous Sclerosis

In a minority of pediatric patients with tuberous sclerosis, unusual hepatocyte alterations characterized by cytomegaly and/or dysplastic changes have been observed (Grasso et al. 1982; Drut 1990; Ruggieri et al. 1997). Necropsy of an 8-month-old male infant with tuberous sclerosis showed microscopic collections of large cells having a pale, faintly eosinophilic cytoplasm and a large nucleus located in the liver, thymus, lungs, and heart (Drut 1990). Some of these highly atypical cells formed clusters in the liver parenchyma, resembling a sympathetic neuronal ganglion, associated with smaller, satellite-like cells. A 3-day-old male patient with tuberous sclerosis

complex showed, at necropsy, a liver disorganized in some places by the presence of a few to as many as 50 rounded hepatocytes, 80 μm in diameter, with an eosinophilic cytoplasm and containing one or two vesicular nuclei with a prominent nucleolus. Some of these hepatocytes were irregularly shaped and extremely vacuolated, morphologically resembling the glycogenated "spider cells" of cardiac rhabdomyoma (Ruggieri et al. 1997).

The dysplastic large and giant cells of the liver described in these reports resemble the splenic "histiocytoid" cells (so-called splenic histiocytosis) found mostly in newborns and rarely in adults with tuberous sclerosis, sometimes forming nodules or tumor-like lesions in the spleen (Ostor and Fortune 1978; Bender and Yunis 1981; Bender and Yunis 1982; Tunali et al. 2004; Rudzki et al. 2005). The pathogenesis of these peculiar hepatocyte changes is currently unknown.

Abstract

Extra-adrenal paragangliomas are a group of neoplasms that derive from extra-adrenal sympathetic and parasympathetic paraganglia and related neuroendocrine cell systems in various organs. The biological behavior of these neoplasms ranges from a relatively benign course to frankly malignant behavior. Primary hepatic paraganglioma is a very rare neoplasm that is usually situated within the liver substance and is nonfunctional. The tumors can grow to a size exceeding 5 cm in diameter, may show a fibrous capsule, and can undergo cystic change. Hepatic paraganglioma can metastasize to locoregional lymph nodes. Histologically, the leading cell type is the large eosinophilic cell that forms paraganglia. These cells are strongly reactive for chromogranin A and synaptophysin. The complex stroma of paragangliomas contains S100 protein-positive sustentacular cells. Paraganglioma can also develop in extrahepatic bile ducts and cause biliary obstruction. Exceptionally, paraganglioma synchronously involves liver and bile ducts. The tumor was also observed in the gallbladder and hepatic ligaments.

Introduction

Pheochromocytomas, intra-adrenal paraganglioma, and extra-adrenal sympathetic and parasympathetic paragangliomas are neuroendocrine tumors derived from adrenal chromaffin cells or similar cells in extra-adrenal sympathetic and parasympathetic paraganglia, respectively (Chen et al. 2010). The term, paraganglioma, is a generic one applied to tumors arising from paraganglia regardless of location. The 2004 WHO classification of endocrine tumors defines pheochromocytoma as a tumor arising from chromaffin cells in the adrenal medulla. Closely related neoplasms in extra-adrenal sympathetic and parasympathetic paraganglia are classified as extra-adrenal paragangliomas; hence, a pheochromocytoma is an intra-adrenal paraganglioma (Tischler et al. 2006; Tischler 2008). The current strategies for the biochemical diagnosis of this tumor group have recently been reviewed (Eisenhofer et al. 2008; Joynt et al. 2009).

General Clinicopathologic Features

Extra-adrenal paragangliomas have nearly identical imaging features as the adrenal counterparts, including a homogeneous or heterogeneous hyperenhancing soft tissue mass at CT, multiple areas of signal void interspersed with hyperintense foci (salt-and-pepper appearance) within the tumor masses at MRI, and an intense tumor blush with enlarged feeding arteries at angiography (Lee et al. 2006). It has been observed that diffusion-weighted imaging (DWI) was superior to FDG-PET in the detection of lymph node and liver metastases of malignant paraganglioma and pheochromocytoma (Takano et al. 2008).

The pathology of paragangliomas has been described in detail, also in regard to the identification of potentially malignant variants (McNicol 2006; Tischler et al. 2006). In an analysis of 120 adrenal and extra-adrenal cases, features noted more frequently in malignant tumors included male predominance, extra-adrenal location, greater tumor weight, coarse nodularity of the primary tumor, confluent tumor necrosis, and the presence of vascular invasion and/or extensive local invasion. Intracytoplasmic hyaline globules were more frequently found in benign than in malignant tumors (Linnoila et al. 1990). In an immunohistochemical study, assessment of the proliferative activity by use of the MIB-1 antibody was found to be a useful adjunct marker to predict malignant behavior (Kumaki et al. 2002). In particular, MIB-1 (Ki-67) immunostaining combined with hTERT expression analysis aided in the distinction between benign and malignant forms (Elder et al. 2003). At the molecular level, recent studies suggest that methylation of the p16INK4A promoter is associated with malignant behavior of abdominal extra-adrenal paragangliomas but not pheochromocytomas (Kiss et al. 2008). Part of paragangliomas show the features of a CpG island methylator phenotype (CIMP), defined as concerted hypermethylation in three or more genes, and the CIMP phenotype in abdominal paragangliomas was associated with malignant behavior (Geli et al. 2008).

Paraganglioma of the Liver

Hepatic paragangliomas have been reported to be nonfunctional and show the typical histology of paragangliomas located elsewhere (Fig. 1; Ferrell et al. 1990; Kang et al. 1991; Corti et al. 2002;

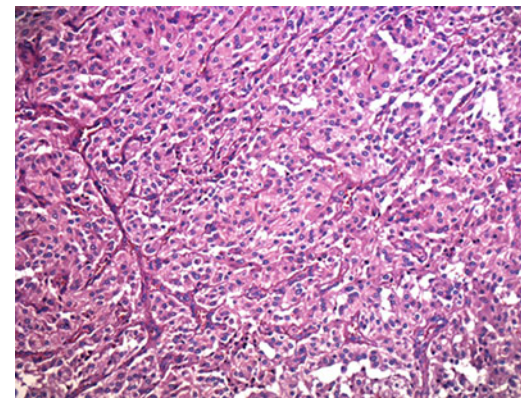

Fig. 1 Primary paraganglioma of the liver. Numerous cell nests ("zellballen") with strongly granular cytoplasm are recognized (hematoxylin and eosin stain)

Hong et al. 2013; Koh et al. 2013) or functional (Chang et al. 2006; Roman and Sosa 2007) and are usually situated within the liver substance. In one case, primary paraganglioma simultaneously involved the liver, gallbladder, and common bile duct. The tumor had metastasized to portal and celiac lymph nodes (Ferrell et al. 1990). In one patient (a 16-year-old girl), paraganglioma was localized to the falciform ligament of the liver (Delbridge and Connolly 1982).

Paraganglioma of Bile Ducts

Primary paraganglioma also takes its origin from the hepatic duct and at the hepatic hilum, sometimes causing biliary obstruction (Sarma et al. 1980; Hitanant et al. 1984; Albores-Saavedra et al. 2000; Caceres et al. 2001; Sarma 2006). One patient was a 28-year-old otherwise healthy woman with a history of abdominal pain and cholelithiasis. At laparoscopy, a round, 3-cm mass was detected encircling the median portion of the common bile duct. Examination of the resection specimen showed a mass attached to the junction of the cystic and common bile ducts. Microscopic study revealed a tumor composed of clustered, uniform small round cells, separated by capillaries and packed with dense granules positive for chromogranin (Caceres et al. 2001).

Paraganglioma of the Gallbladder

Rarely, paraganglioma of the gallbladder has been described (Miller et al. 1972; Wolff 1973; Ferrell et al. 1990; Freschi and Sassi 1990; Hirano 2000; Cho et al. 2001; Rodriguez-Merchan et al. 2006). It may occur in the context of multiple endocrine neoplasia syndrome (Mehra and Chung-Park 2005). Among eight cases of gallbladder paragangliomas, five patients were female, and the age at presentation ranged from 32 to 67 years. The diameter of the lesions varied from 1.3 to 3 cm. In at least one case, the hemorrhagic tumor has been suggested to have caused acute cholecystitis (Cho et al. 2001).

Paraganglioma of the Ampullary/Periampullary Region

Classical paraganglioma has been observed in the ampullary/periampullary region of the duodenum. More than 130 cases are found in the literature (Carter et al. 2008; Sankot and Svarcova 2008). An intriguing lesion of the periampullary region is a tumor termed gangliocytic paraganglioma. About 20 % of duodenal-ampullary paragangliomas belong to this category (Parini et al. 2007), and this distinct tumor variety is further discussed in a separate chapter.

Pathology

Macroscopy of Classical Hepatic Paraganglioma

Primary hepatic paragangliomas reach 6 cm (Chang et al. 2006) to 8 cm (Corti et al. 2002) in diameter. In the 46-year-old male patient reported by Corti et al. (2002), the right hepatic lobe presented an 8-cm resiliently firm nodular mass. The cut surface was pale gray, with a large central area of fibrosis. A thin fibrous capsule separated the tumor from the surrounding liver tissue, which showed no evidence of fibrosis or cirrhosis. Cystic variants, radiologically mimicking a liver cyst, have been reported (Laca et al. 2008).

Histopathology and Immunohistochemistry of Classical Hepatic Paraganglioma

The histological and immunohistochemical features of paragangliomas are well established (review: Kliewer and Cochran 1989). Paragangliomas display a characteristic vascular architecture, and these lesions have also been described as highly vascular at imaging (Chang et al. 2006). The leading cell type of paraganglioma reflects the chief cell found in normal paraganglia. These are polygonal eosinophilic cells with round nuclei lacking conspicuous nucleoli. S100 protein-positive sustentacular cells

are found in variable numbers. Immunohistochemically, the neoplastic cells are strongly positive for chromogranin A, synaptophysin, neuron-specific enolase, and IGF-II protein, but negative for vimentin, CD10, and keratins. The expression of IGF-II transcripts has also been demonstrated by use of in situ hybridization (Corti et al. 2002). The stroma of paragangliomas is a complex tissue that contains several classes of stromal cells. One stromal cell component consists of typical fibroblastoid cells. A second group is represented by alpha-SMA-positive cells that may correspond to the myofibroblast lineage and mainly occur in fibrous bands and the tumor capsule (Kuroda et al. 2008). A third category of cells is spindle cells that are caldesmon positive. Within the stroma of paragangliomas, sustentacular (reactive for S100 protein; Schröder and Johannsen 1986) and dendritic cells (reactive for HLA-DR; Furihata and Ohtsuki 1991) are typically observed.

Variants of Classical Paraganglioma

Some variants of paraganglioma have been described. Composite paraganglioma-ganglioneuroma is characterized by the presence of neuronal cells in the tumor. These neoplasms have been found more frequently in the ampullary region of the duodenum (see above). The melanin-containing pigmented paraganglioma variant (melanotic paraganglioma) has been identified in the retroperitoneal space, the heart, the urinary bladder, the uterus, and the nodose vagal ganglion (Tavassoli 1986; Küchemann 1995; Moran et al. 1997; Lack et al. 1998; Mikolaenko et al. 2001; Dundr et al. 2003; Reddy et al. 2003), but has not yet been detected in the hepatobiliary tract. These special features of paraganglioma differentiation support the hypothesis that these neoplasms may be derived from neural crest cells.

Gangliocytic Paraganglioma

This tumor is briefly discussed in a separate paragraph, because it deviates considerably from the concept of classical paraganglioma and shows a distinct anatomical distribution. First described in 1962 (Taylor and Helwig 1962), this is a rare tumor of the gastrointestinal tract of still unknown histogenesis. In particular, it is not yet clear whether this neoplasm in fact belongs to the paraganglioma group, irrespective of the term employed to denote this lesion. The significance of this neoplasm in the context of the present chapter refers to the fact that gangliocytic paraganglioma almost always occurs in the second part of the duodenum and often in the ampulla of Vater or the periampullary region. This tumor has a slight male predominance, with a male-female ratio of 1.6:1. It is usually diagnosed in the fifth or sixth decade of life, and in about 60 % the clinical presentation is that of gastrointestinal bleeding, but patients with biliary obstruction have also been reported (Gemer and Feuchtwanger 1966; Reed et al. 1977; Babaryka 1978; Williams et al. 1980; Anders et al. 1987; Barbareschi et al. 1989; Evans et al. 1996; Sakhuja et al. 2001; Girgis and Henthorne 2002; Hüffer et al. 2003; Ghouti et al. 2004; Sankot and Svarcova 2008; Von Loga et al. 2010). Most gangliocytic paragangliomas seem to undergo a benign course, but several of these tumors have shown malignant spread with locoregional lymph node metastases (Büchler et al. 1985; Korbi et al. 1987; Burke and Helwig 1989; Inai et al. 1989; Hashimoto et al. 1992; Dookhan et al. 1993; Sundararajan et al. 2003; Bucher et al. 2004; Wong et al. 2005; Witkiewicz et al. 2007).

Histologically, gangliocytic paraganglioma is characterized by a complex admixture of epithelioid cells, spindle cells, carcinoid tumor-like cells, and ganglion cells of varying levels of differentiation/maturation, all these lineages emerging in highly variable proportions within a given tumor. The lesions are usually not encapsulated and reveal a rather infiltrating tumor border. The immunohistochemical phenotype is also complex, in that the epithelioid cells may be reactive for neuroendocrine markers (chromogranin A, synaptophysin, and NSE) and for several hormones, including serotonin, pancreatic polypeptide, somatostatin, vasoactive intestinal peptide, and Leu-enkephalin. The spindle cells are reactive

for S100 protein and vimentin and sometimes for NSE and neurofilament proteins. The ganglion cells stain for neurofilaments and NSE (Perrone et al. 1985; Scheithauer et al. 1986; Anders et al. 1987; Barbareschi et al. 1989; Watanabe et al. 1995; Furihata et al. 1996; Altavilla et al. 2001; Ohtsuki et al. 2009).

Differential Diagnosis

The differential diagnosis includes liver metastases of malignant paragangliomas (in case of carotid body tumors, there may be delay of many years; Prados et al. 1981; Mall et al. 2000; Christie et al. 2006; Oakes et al. 2014). Also, periampullary gangliocytic paraganglioma can metastasize to the liver (Amin et al. 2013). Paragangliomas located close to the liver may be confounded with hepatic primary tumors, e.g., greater omentum (Archontovasilis et al. 2007) and mesenterium (Jaffer and Harpaz 2002; Canda et al. 2004).

Normal Hepatobiliary Paraganglia as a Potential Source of Paragangliomas

Kohn (1903) coined the term paraganglia paraganglioma to denote anatomic structures formed by collections of neuroendocrine cells spatially and functionally related to ganglia of the autonomic nervous system (Kuo et al. 1974). Paraganglia are a neuroendocrine cell system near or in the autonomic nervous system, with a roughly symmetric distribution with extension from the skull base to the pelvic floor. All paraganglia have a similar histologic appearance characterized by well-defined cell nests (zellballen) consisting of chief cells (type 1 cells) and a thin layer of sustentacular cells (type 2 cells). Chief cells contain membrane-bound, electron-dense secretory granules that contain catecholamines. Abdominal nonchromaffin paraganglia (glomera) have been noted principally in close proximity to major branches of the aorta, superior mesenteric and celiac arteries in man and animals, and along the vagus nerve branches mainly in animals. The liver is innervated by aminergic, cholinergic, peptidergic, and nitrergic nerves (review: McCuskey 2004). In the normal situation, paraganglia in the subdiaphragmatic compartment closely follow the ramifications of the vagus nerve. In the rat a mean of eight paraganglia were found to be associated with branches of the subdiaphragmatic vagus, and 94 % of the paraganglia were located at nerve branch points. Some of the larger paraganglia contained at their central poles one to six neurons (Prechtl and Powley 1985). Retrograde and anterograde tracing studies in the rat have shown that only a minor portion of the common hepatic vagal branch innervates the liver area proper, but hepatic paraganglia, bile ducts, and portal vein branches receive the densest vagal afferent innervation (Berthoud 2004). The clusters of hepatic paraganglia are nestled between and within the fascicles of the common hepatic vagal branch as it travels along the hepatoesophageal artery from the subdiaphragmatic vagal trunk on the esophagus toward the hepatic artery proper. Most of these glomus cells are clustered around capillary spaces (Prechtl and Powley 1987; Berthoud et al. 1992; Berthoud and Patterson 1996; Goehler et al. 1997). Hepatic vagus-associated paraganglia contain catecholamines, mainly norepinephrine and dopamine, but also epinephrine (Pinon et al. 1999). The vagal paraganglia, including those at the hepatic hilum and in the liver, may cooperate in an immune-to-brain communication, in that these vagal glomus cells bind IL-1 receptor antagonist (Goehler et al. 1997).

Nonneoplastic paraganglionic tissue in the gallbladder wall has been described in several reports (Kuo et al. 1974; Fine and Raju 1980; Raju and Fine 1980; McDonald 1990; Kawabata 1999) and also in textbooks (Weidner and Goldman 1996; Fierson 1997; Tischler 1997). In the case described by Kuo et al. (1974), a gallbladder resected because of stones showed, within the perimuscular connective tissue, a 0.3-mm sharply circumscribed, round and highly vascularized structure composed of nests of large cells having a central nucleus and a moderate amount of granular amphophilic cytoplasm. The

cells had the same features as the cells of the carotid body and the organ of Zuckerkandl. In the analysis of Fine and Raju (1980), one to five glomera were observed in nine of ten gallbladder specimens examined. The glomera were situated in the subserosal space in intimate association with blood vessels and small nerves, but in only one instance was a single ganglion cell found adjacent to a paraganglion. Their size ranged from about 60 to 200 mm. The nests were similar regardless of size, being composed on two types of cells arranged as poorly defined lobules in close association with a delicate capillary network. The chief cell was characterized as large and uniform cell with a round or oval vesicular nucleus and an eosinophilic, finely granular cytoplasm containing silver-positive (Bodian Protargol) granules. The second cell type is more seldom and is spindle-shaped supporting cells (Fine and Raju 1980). In the two observations of Kawabata (1999), paraganglionic tissue nests were seen in the subserosal connective tissue of gallbladders. The chief cells were positive for chromogranin A and in part for dopamine beta-hydroxylase and enkephalins, and there were typical S100 protein-positive sustentacular cells. Ultrastructurally, gallbladder paraganglia are identical to that of other nonchromaffin paraganglia featuring granule-bearing chief cells with many axons ensheathed by supporting cells (Raju and Fine 1980).

Genetic and Molecular Features

The majority of paragangliomas are sporadic lesions. In addition, there are several paraganglioma syndromes caused by alterations in the following genes: VHL, RET, NF-1, SDHB, SDHC, SDHD, SDHAF2, KIF1Bbeta, PHD2, and TMEM127 (reviews: Chetty 2010; Opocher and Schiavi 2010). About 10–15 % of paragangliomas are associated with germline mutations of the mitochondrial succinate dehydrogenase A, B, C, or D genes (SDHB, SDHC, and SDHD mutations; Astuti et al. 2001; Neumann et al. 2004; Schiavi et al. 2005; Benn et al. 2006; Ogawa et al. 2006; Papaspyrou et al. 2008; Bayley et al. 2009; Pasini and Stratakis 2009; Oishi et al. 2010; Schimke et al. 2010). The mitochondrial succinate-coenzyme Q reductase (complex II) consists of four succinate dehydrogenase subunits which are assumed to be involved in deranged mitochondrial respiration in tumors, according to Otto Warburg's hypothesis ("Warburg tumors"; Bayley and Devilee 2010a). A heterozygous germline SDHA mutation was found in a female patient suffering from a catecholamine-secreting abdominal paraganglioma (Burnichon et al. 2010). SDHB mutations predispose to paraganglioma syndrome type 4 (PGL-4), and SDHD mutations predispose to paraganglioma syndrome type 1 (PGL-1). In both syndromes, pheochromocytomas as well as head and neck paragangliomas occur. In contrast with SDHD mutation carriers (PGL-1) who have more frequent multifocal paragangliomas, SDHB mutation carriers (PGL-4) are more likely to develop malignant disease and possibly extraparaganglial neoplasms, including renal cell and thyroid carcinomas (Neumann et al. 2004; Ricketts et al. 2008). SDH gene mutations are also strongly associated with paragangliomas of the organ of Zuckerkandl (Lodish et al. 2010). There is also a paraganglioma syndrome caused by SDHAF2 (SDH5) mutations. The SDHAF2 gene encodes an SDH cofactor related to the function of the SDHA subunit and required for SDH flavination and is currently exclusively associated with head and neck paragangliomas (Hao et al. 2009; Bayley et al. 2010b).

Apart from pheochromocytomas and paragangliomas, other tumors have been associated with SDH mutations, such as gastrointestinal stromal tumors (GISTs), specifically in the context of the Carney triad and the Carney-Stratakis syndrome. Carney triad describes the association of paragangliomas with GISTs and pulmonary chondroma. A number of other lesions have been reported in this condition including pheochromocytomas, esophageal leiomyoma, and adrenocortical adenomas (Carney 2009). Carney-Stratakis syndrome is characterized by

the combination of GISTs/gastric stromal sarcomas and paragangliomas and is inherited as an autosomal dominant trait. In this syndrome, germline mutations of the SDHB, SDHC, and SDHD genes have been found (Stratakis and Carney 2009). Germline mutations and variants of succinate dehydrogenase genes have also been found in PTEN mutation-negative patients with Cowden syndrome or Cowden-like syndromes (Ni et al. 2008).

TMEM127 is a new pheochromocytoma susceptibility gene associated with LOH 2q11. Germline TMEM127 mutations are associated with pheochromocytoma, including bilateral forms. Transcriptome and immunohistochemical analyses showed that TMEM127-related pheochromocytoma clustered with NF1-related and RET-related tumors in a large series of pheochromocytomas and paragangliomas. TMEM127 associates with the endomembrane system and co-localizes with perinuclear (activated) mTOR, suggesting that it is a negative regulator of mTOR (Qin et al. 2010; Burnichon et al. 2011).

Neuroendocrine Tumors of the Hepatobiliary Tract

75

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_75

Abstract

Neuroendocrine neoplasms of the hepatobiliary tract are rare neoplasms that derive from neuroendocrine cells located in the bile duct mucosa and several compartments of the liver proper. These neoplasms are divided into neuroendocrine tumors (NET) and neuroendocrine carcinomas (NEC). Well-differentiated NET (G1) have previously been termed carcinoid tumors. Most of neuroendocrine neoplasms that are known from extrahepatic organs and tissues also develop in the hepatobiliary tract, except tumors that originate from distinct specialized neuroendocrine/endocrine cell types that do not exist in this organ. The bile ducts are a well-known primary location of well-differentiated carcinoid-type NETs. Neuroendocrine carcinomas can also develop in bile ducts and the liver, but are unusual lesions. Intriguing primary neuroendocrine neoplasms of the liver are undifferentiated small cell and large cell carcinomas, which have to be distinguished from the more common liver metastases of extrahepatic tumors with this morphology.

ICD-O codes:

Neuroendocrine tumor (NET)	
NET G1 (carcinoid)	**8240/3**
NET G2	**8249/3**
Neuroendocrine carcinoma (NEC)	**8246/3**
Large cell NEC	**8013/3**
Small cell NEC	**8041/3**
Mixed adenoneuroendocrine carcinoma (MANEC)	**8244/3**

Introduction

Neuroendocrine tumors of the hepatobiliary tract are rare neoplasms that derive from neuroendocrine cells located in the bile duct mucosa and probably in certain parts of the liver parenchyma. These tumors are now divided into

neuroendocrine tumors (NETs) and neuroendocrine carcinomas (NECs). Part of NETs (the NET G1 variants) have previously been termed carcinoid tumors or argentaffinomas (reviews: DeLellis and Osamura 2006; Chetty 2008). In the WHO classification, the term carcinoid tumor has been replaced with the term endocrine tumor to designate all gastrointestinal neoplasms with evidence of endocrine differentiation. It comprises the entire spectrum from well-differentiated (previously known as carcinoid tumors) to poorly differentiated tumors with endocrine features, particularly small cell and large cell carcinomas. Specifically, the term carcinoid tumor has been replaced by the term well-differentiated neuroendocrine tumor (now NET G1) by Capella et al. (2000) in the WHO classification of tumors.

Apparently, Langerhans seems to be the first to have described carcinoid tumor (Ogilvie 1947). The low-grade malignancy of carcinoids led Lubarsch (1888) to call them "little carcinomas." The term carcinoid ("carcinoma-like") was coined in 1907 in the first volume of the Frankfurter *Zeitschrift für Pathologie*, based on tumors found in the small intestine which, by using this novel term, the author wished to distinguish from cecal adenocarcinomas (Oberndorfer 1907). Seven years later, Gosset and Masson reported the presence of silver-reducing granules in the cytoplasm of carcinoid tumor cells (Gosset and Masson 1914). The carcinoid syndrome, found in patients with metastases of a carcinoid tumor, was first described in 1953 (Isler and Hedinger 1953). Endocrine/neuroendocrine tumors originate from neural crest-derived neuroendocrine cells that migrated to the foregut, midgut, and hindgut during embryogenesis. These cells are or were also termed enterochromaffin cells or, owing to distinct histochemical features, amine precursor uptake and decarboxylation (APUD) cells. The last mentioned name has led to the designation APUDOMA for neoplasms derived from APUD cells and are so-called type A carcinoids. APUDOMA is a terminology that is now obsolete. The cells are normally detectable along the entire digestive tract (from the oral cavity to the anal region) and in the associated inner organs, most of the cells being located in the appendix and small intestine (Kulke and Mayer 1999). There is a striking difference between the pancreas and the hepatobiliary tract in regard to the amount and diversity of endocrine cells. The pancreas contains large numbers and highly diverse types of these cells, while the biliary tract contains relatively few, and in the liver substance proper, the cells are hardly detectable (see below).

Epidemiology and Localizations

Overall, NETs account for only 0.2–2 % of all gastrointestinal malignancies. The change in our understanding of biology and terminology of the lesions in question has altered figures about the anatomical distribution and incidence of these neoplasms. Formerly, it was estimated that around 90 % of carcinoids were located to the appendix (Van Weel 1962), but this figure has now dropped to 54 % (Kinley and Penner 1962), the remaining carcinoids being found in other parts of the gastrointestinal tract, the bronchopulmonary system (30.1 %), pancreas (2.3 %), reproductive system (1.2 %), biliary tract (1.1 %), head and neck (0.4 %) (Kinley and Penner 1962; Maggard et al. 2004), and other endocrine /neuroendocrine tumors with a histology different from classical carcinoids being found in the pancreas and other internal organs (review: Soga 2003). NETs and NECs of the hepatobiliary system are very rare lesions. Gallbladder NETs represent 0.2 % and bile duct NETs 0.01 % of the cases. Bile duct NETs are equally distributed between males and females, while gallbladder NETs show a slight female preponderance (F/M = 1.8/1). The average age at presentation is about 60 years for bile duct NETs and 65 years for gallbladder NETs.

Classification and Grading of Neuroendocrine Tumors

Introduction

The more complex classifications of neuroendocrine tumors and the redefinitions of carcinoid tumors are mainly based on the recognition that

neuroendocrine tumors, and particularly those derived from foregut cells, are heterogeneous in regard to their morphologic and biologic features. Several systems to standardize diagnosis, classification, staging, and care of neuroendocrine tumors have been developed. TNM staging and grading of foregut neuroendocrine tumors has been standardized by a consensus panel of the European Neuroendocrine Tumor Society/ENETS (Rindi et al. 2006; Klöppel et al. 2009, 2010). In the ENETS publication as of 2010, specific staging of neuroendocrine tumors of the hepatobiliary tract was specified (Rindi 2010).

Classification

The novel classification proposed in the 2010 WHO classification (Rindi et al. 2010) is shown in Table 1. It is seen that the lesions are divided into five categories, similar to the WHO 2000 classification, but with a change in nomenclature.

According to this novel classification, a NET is defined as "a well-differentiated neuroendocrine neoplasm composed of cell with features similar to those of the normal gut endocrine cells, expressing general markers of neuroendocrine differentiation and hormones according to site, with mild-to-moderate nuclear atypia and a low number of mitoses (<20 per 10 HPF)" (Rindi et al. 2010). The neoplasms are graded as shown below. G1 lesions are the former carcinoid tumors or carcinoids. In contrast to NET, a NEC is defined as a poorly differentiated, high-grade neuroendocrine neoplasm composed of large, small, or intermediate cells. Some of the tumors may show organoid features similar to NET. NECs diffusely express general neuroendocrine markers, have an elevated mitotic rate (>20 per 10 HPF), and are G3 lesions (Rindi et al. 2010).

Table 1 WHO 2010 classification of neuroendocrine neoplasms of the digestive system (transition scheme, Rindi et al. 2010, modified), compared with the 2000 system

WHO 2010	WHO 2000
1. NET G1 (carcinoid)	Well-differentiated endocrine tumor
2. NET G2	Well-differentiated endocrine carcinoma
3. NEC (large cell or small cell)	Poorly differentiated endocrine carcinoma
4. Mixed adenoneuroendocrine	Mixed exocrine-endocrine carcinoma (MANEC)
5. Hyperplastic and preneoplastic	Tumor-like lesions

Grading

The grading system was developed in the light of the findings that proliferative activity can be employed to stratify the tumors in regard to their potential behavior (Table 2).

Generally, G1 and G2 should refer to well-differentiated neuroendocrine tumors showing diffuse positivity for chromogranin A and synaptophysin. Punctate necrosis is per se regarded as an indication for a more aggressive tumor, pointing at a G2 situation. G3 is a poorly differentiated, highly proliferative neuroendocrine carcinoma, which may have more extensive necrosis and shows an irregular and variable staining for chromogranin A and synaptophysin. The pathology reporting of neuroendocrine tumors has also been standardized by a consensus procedure employing the Delphic consensus process (Klimstra et al. 2010).

General Macroscopic Pathology of Neuroendocrine Neoplasms of the Liver and Biliary Tract

Most neuroendocrine neoplasms primary to the liver and biliary tract display a macroscopic pathology that is nonspecific, although some of the tumor may show a yellowish or tan color, in particular well-differentiated NETs (carcinoids).

Table 2 ENETS grading of neuroendocrine tumors (Rindi et al. 2006)

Grade	Mitotic count (10 HPF)	Ki-67 index (%)
G1	<2	<=2
G2	2–20	3–20
G3	>20	>20

Fig. 1 Primary neuroendocrine carcinoma of the liver with multiple intrahepatic metastases

Fig. 2 Primary neuroendocrine tumor of the liver manifesting as a well-circumscribed white nodule

Depending on their differentiation, the growth patterns of the lesions ranges from well-circumscribed spherical nodules to ill-defined and highly invasive neoplasms with satellite lesions and signs of intrahepatic spread (Figs. 1, 2, and 3).

Intrahepatic Well-Differentiated Neuroendocrine Tumors (NET G1): Carcinoid-Type Variants

Introduction

Primary intrahepatic carcinoid tumor (IHNET) is a rare neoplasm arising in the liver itself (review: DeLellis and Osamura 2006). Intrahepatic

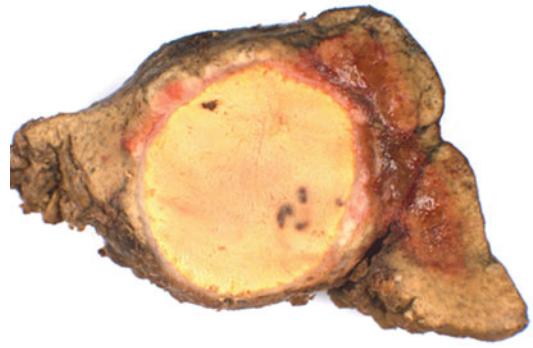

Fig. 3 Liver metastasis of neuroendocrine tumor with extensive necrosis. Only a thin peripheral rim of preserved tumor tissue is present

carcinoid was first described in 1958 (Edmondson 1958). As carcinoid tumors of the gastrointestinal tract frequently metastasize to the liver, the liver in fact being the most frequently involved organ due to metastatic disease from extrahepatic neuroendocrine neoplasms, diagnosis of primary hepatic carcinoid must exclude extrahepatic primary disease. In fact, a meticulous follow-up is required in order to rule out occult extrahepatic malignancy to confirm the primary nature of the hepatic tumor. Traditionally, these tumors have been classified as typical carcinoids (amounting to 80 % of the lesions), atypical carcinoids, and variant types (Soga and Tazawa 1971).

Primary intrahepatic lesions are much rarer than hepatic metastases of carcinoid tumors located elsewhere. One group examined 2837 consecutive patients with carcinoid tumors without identifying a single primary tumor of the liver (Godwin 1975). Among 184 liver tumors, 46 resections were performed, and 1 of them was a carcinoid tumor (Holbrook et al. 1996). Recent reports presented surveys of 95 cases (Modlin et al. 2005a, b). Notwithstanding the rarity of primary hepatic carcinoid, numerous reports have described lesions that were classified or interpreted as primary well-differentiated hepatic neuroendocrine tumors or, in most publications, as carcinoid tumors. Few cases have been reported in the pediatric age group (Foley et al. 2008).

Epidemiology and Clinical Features

In a review of 69 published cases (Gravante et al. 2008), 40.6 % were male, and the median age at diagnosis was 50 years (range: 8–83 years). The clinical presentation is often nonspecific, either without symptoms (23.2 %) or with upper abdominal pain (33.3 %), but patients with large tumors that secrete 5-HIAA may show flushing and diarrhea (the carcinoid syndrome; Mehta et al. 1996; Furrer et al. 2001; Touloumis et al. 2008; Zhang et al. 2008). In the review of Gravante et al. (2008), 18.9 % of the patients revealed symptoms of carcinoid syndrome. Few instances of carcinoid heart disease have been reported (Tohyama et al. 2005). Carcinoid syndrome, characterized by paroxysmal vasomotor disorders, flush, diarrhea, tachycardia, hypotension, salivation, and tremor, is caused by the secretion of the active substances, 5-hydroxytryptamine (serotonin), 5-hydroxytryptophane, kallikrein, bradykinin, histamine, and prostaglandin E. Carcinoid heart disease is characterized by right-sided endocardial fibrosis of atrium and ventricle and fibrous thickening of tricuspid and pulmonary valves, causing valvular stenosis and regurgitation (Pellikka et al. 1993; Bernheim et al. 2007). Part of the patients may present other endocrine syndromes, such as severe hypoglycemia caused by insulin secretion (Ali et al. 1978; Furrer et al. 2001), or Cushing's syndrome (Shah et al. 2007). Hepatic carcinoids have been shown to produce gastrin (Larriva-Sahd et al. 1992; Inoue et al. 1993; Moriura et al. 1993; Krishnamurty et al. 1996; Kehagias et al. 1999; see below) or pancreatic polypeptide (Warner et al. 1980). Primary hepatic carcinoid tumor may be detected as an incidentaloma (Liu et al. 2004).

Primary hepatic carcinoid tumors are usually solitary lesions, single nodules having been identified in 69 % of patients. The tumors are usually heterogeneous solid masses at ultrasound and on CT images (Takayasu et al. 1992; Ulasan et al. 2005; Yeung et al. 2008), but they may also present as a large solitary cystic lesion (Lemaire et al. 1995) or as large multicystic lesions of the liver (Shih et al. 2005). CT with intravenous contrast shows enhancing, but often poorly marginated masses. MRI is advocated as the imaging modality of choice, with improved visualization of the tumors on T2-weighted images (Takayasu et al. 1992; Imaoka et al. 1993; Fujino et al. 1998; Yeung et al. 2008). Some of the tumors reveal calcifications and/or fibrous scarring. Angiography shows, owing to the high vascularity of the lesions, a tumor blush, usually without malignant neovascularity (Walter et al. 1978; Takayasu et al. 1992; Inoue et al. 1993). Part of the tumors exhibit a centrally located radiolucent area in angiography (Modlin et al. 2005a). The tumors and their spread can be successfully assessed by the use of 111 In-pentetreotide/octreotide scintigraphy (Octreoscan imaging) analyzing high

somatostatin analog uptake by the tumor cells (Nemes et al. 1999; Fenoglio et al. 2009). Octreotide binds with high affinity to the somatostatin subtype 2 receptor/SSTR2, which is widely expressed on the cell surface of neuroendocrine cell systems. Nuclear medicine imaging utilizing technetium-99m isotopes may be helpful in diagnosis (Shih et al. 2005; Schwartz et al. 2008).

Pathology

Macroscopically, the tumors are either solitary, roundish, and well-delineated nodules, or they form complex lobulated masses that may show one to several daughter nodules. In solitary lesions, a study reviewing 61 cases found an average diameter of 11.1 cm (Nikfarjam et al. 2004b). In another study of 88 cases, the mean tumor diameter was 9.5 cm (Soga 2002). The color of the cut surface ranges from light-gray or white-yellowish to yellow-orange or tan. Extensive necrosis and/or hemorrhage can occur, mainly in the center of large tumors.

Histologically, the tumors show the characteristic features known for other NETs/carcinoids, i.e., nests of small- to medium-sized round to ovoid cells with a finely granular cytoplasm and centrally placed, round nuclei with a rather dense chromatin and very small nucleoli (Fig. 4). Mitotic figures are typically rare, less than 20 per 10 HPF. Many cells are positive in the Grimelius and Fontana-Masson stains, but this reaction is not positive in all tumors. The tumor stroma is delicate, sometimes fibroblastic. Stromal hyalinization may occur (Schwartz et al. 2008). Similar to extrahepatic carcinoids, the neoplasms show scattered nests and cells outside the main contour of the tumor, whereby it is often difficult to decide whether this represents true invasion. However, true sinusoidal invasion in liver parenchyma can occur (Lingamfelter et al. 2007). Immunohistochemically, the cells are reactive for neuroendocrine lineage markers, i.e., chromogranin A (Fig. 5), synaptophysin, and neuron-specific enolase. Part of the tumors are reactive for serotonin. The tumors show a low level of proliferative activity (Fig. 6).

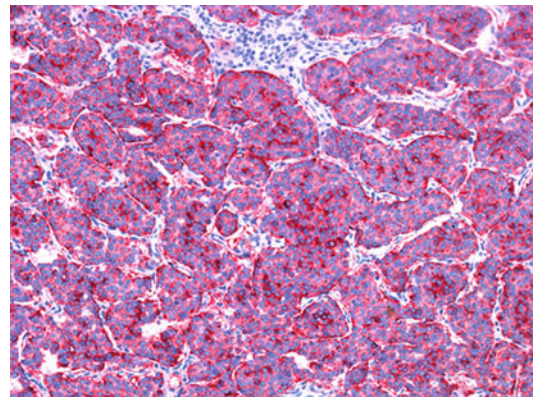

Fig. 5 Chromogranin A reactivity of a hepatic well-differentiated neuroendocrine tumor (chromogranin A immunostain)

Biology of Disease and Characteristics of Tumor Spread

The clinical course of PHCT is generally less aggressive than that of several other types of neuroendocrine tumors. However, it is well established that, in principle, carcinoids have a malignant potential, as this also holds true for primary carcinoid tumors of the liver. Among 69 patients that had been reviewed (Gravante et al. 2008), 39.1 % of the patients had died and 52.2 % had survived, 63.8 % having undergone hepatic resection and 4.3 % liver transplantation.

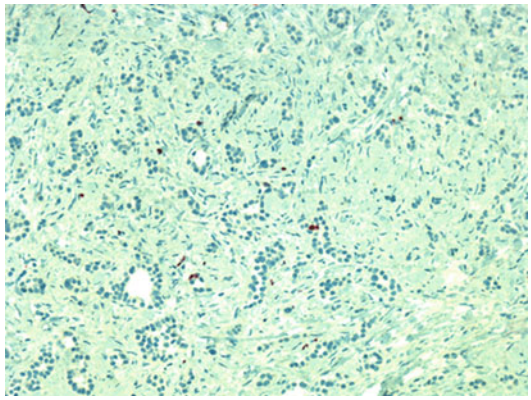

Fig. 6 Proliferative activity of well-differentiated neuroendocrine tumor of the hepatobiliary tract (MIB1 immunostain)

A study of 2003 revealed a favorable prognosis at 5 years in 74 % of surgically treated patients, with an 18 % recurrence rate (Knox et al. 2003). Tumor recurrence, sometimes causing death, may occur more than 10 years after the first intervention (Nishimori et al. 2005; Abdel Wahab et al. 2006).

As a general principle for prognostication or stratification in regard to risk, tumors smaller than 1 cm of diameter, in any anatomical location, usually are favorable lesions with only rare local recurrence or distant spread, whereas those exceeding 2 cm in diameter are often more aggressive (Graeme-Cook 2003). However, this general rule may not be applicable to carcinoid tumors of the liver, or only with modifications, because hepatic carcinoid tumors generally tend to be diagnosed when they have larger sizes (not rarely exceeding 15 cm in diameter), and large tumor sizes have either been associated with a favorable course (Fenwick et al. 2004) or with poor outcome (Pilichowska et al. 1999), hence requiring a refinement of prognostic stratification. In an analysis of 64 cases, extrahepatic metastases were detected in 16 % of patients, either at the time point of diagnosis or after the establishment of non-surgical therapies. Bone and lung are the most common sites of remote metastases (review: Nikfarjam et al. 2004b). One study (88 cases) found extrahepatic metastases more often in primary tumors being >5 cm in diameter, lymph node, bone, and lung metastases being identified in 22 % of cases (Soga 2002). PHCTs are known to metastasize to locoregional lymph nodes. In a study of 53 cases of PHCT reported in the English literature, lymph node involvement occurred in 60 % of the cases (Iwao et al. 2001). Post-resection perihepatic lymph node involvement has been infrequently observed in the absence of hepatic involvement, but metachronous lymph node metastasis was detected after a 5-year follow-up in one case of surgically treated PHCT (Iimuro et al. 2002).

Intrahepatic Neuroendocrine Tumors (NETs): Special Types

Primary Intrahepatic Somatostatinoma

Somatostatinomas are rare neuroendocrine tumors that account for approximately 1 % of all gastrointestinal neuroendocrine neoplasms. The neoplasms may be sporadic lesions or associated with neurofibromatosis type 1, MEN1, or von Hippel-Lindau disease. Hormonally inactive somatostatinomas are asymptomatic or oligosymptomatic, while functional somatostatinomas secrete large amounts of somatostatin which suppresses gallbladder motility and inhibits the secretory activity of several endocrine cell systems. This may cause the somatostatinoma/inhibitory syndrome, which is characterized by the triad, mild diabetes mellitus, cholelithiasis, and diarrhea/steatorrhea. Very few primary intrahepatic somatostatinomas have been described (Grundmann et al. 1985; Ohwada et al. 2003; Morisawa et al. 2006). The few patients reported had nonspecific symptoms and signs of a primary liver tumor. In one patient, the tumor has developed in the context of von Recklinghausen's disease (Morisawa et al. 2006). Primary intrahepatic somatostatinoma has to be distinguished from hepatic metastases (Do Cao et al. 2010).

Primary Intrahepatic Gastrinoma

Gastrinomas are rare NETs that produce gastrin, a peptide that is secreted into circulation in at least part of cases, inducing Zollinger-Ellison syndrome.

Only 5.6 % of gastrinomas occur in extraduodenal, extrapancreatic, and extranodal locations. Genetically, nonhereditary (sporadic) gastrinomas are distinguished from hereditary gastrinomas, the latter being associated with multiple endocrine neoplasia type 1 (MEN1) syndrome. In about 75 % of the patients with gastrinoma, this tumor is a solitary lesion (sporadic gastrinoma), and sporadic gastrinomas occur mainly in the duodenum and pancreas, while the hereditary gastrinomas almost all occur in the duodenum (review: Anlauf et al. 2006). As other carcinoid-type tumors, gastrinomas have a malignant potential. It is estimated that about 65 % of gastrinomas will show signs of malignancy, and up to 40 % of the patients will show metastatic disease at the time point of diagnosis, but even metastatic lesions may show a slow and protracted growth.

Primary intrahepatic gastrinoma is a very rare neoplasm of the liver. Relatively few reports have convincingly documented gastrinoma primary to the liver (Smith and Auldist 1984; Larriva-Sahd et al. 1992; Inoue et al. 1993; Moriura et al. 1993; Smyrniotis et al. 1994; Krishnamurty et al. 1996; Tiomny et al. 1997; Kehagias et al. 1999; Bello Argues et al. 2001; Chien et al. 2001; Deol et al. 2003; Shibata et al. 2006; Ishikawa et al. 2008; Denève et al. 2009; Rascarachi et al. 2009; Tsalis et al. 2011; Naoe et al. 2012; Ogawa et al. 2014). It is of special interest because it may, as gastrinomas in other locations, be associated with Zollinger-Ellison syndrome (Naoe et al. 2012). . Intrahepatic gastrinoma is a diagnostic challenge because, apart from its rarity, the tumor may be small, difficult to detect even with advanced imaging techniques, and has to be distinguished from the much more frequent extrahepatic gastrinomas. Furthermore, the liver is a very common site of gastrinoma metastases (Massironi et al. 2014; Sun et al. 2014). Histopathologically, gastrinomas are composed of compact groups of medium-sized to rather large cells with a granular eosinophilic cytoplasm and large nuclei with some atypia and sometimes intranuclear inclusions. The tumor cells are embedded in a fibrous stroma forming thin septa and are arranged in a so-called insular pattern. Intrahepatic tumors with calcifications have been described (Chien et al. 2001). Immunohistochemically, the tumor cells are reactive, apart from neuroendocrine lineage markers (chromogranin A, NSE, synaptophysin), for gastrin.

Primary Intrahepatic Glucagonoma

Glucagonoma is a NET arising from alpha-cells of the pancreas or analogous neuroendocrine cells in other organs, with extrapancreatic glucagonomas accounting for less than 1 % of all cases. It can be associated with a typical endocrine syndrome, i.e., weight loss, anemia, stomatitis, thromboembolism, and necrolytic migratory erythema (NME), a paraneoplastic dermatosis (the glucagonoma syndrome). NME occurs in only about 50 % of glucagonoma patients, but its presence is highly suggestive of glucagonoma. Primary hepatic glucagonoma is very rare, while pancreatic glucagonoma is well known to metastasize to the liver (Sheehan-Dare et al. 1988). A 37-year-old male patient was found to have a liver mass identified as a glucagon-producing tumor, in the absence of another extrahepatic manifestation (De Giorgio et al. 1998). In a 73-year-old female patient with necrolytic migratory erythema and hyperglucagonemia, autopsy revealed a large hepatic tumor measuring up to 8 cm in diameter with a macroscopic pattern of white and dark brown stripes located in the left lobe, while two smaller white nodules were also found in the right lobe. No other tumor was observed. Histology and immunohistology identified the tumor as malignant hepatic glucagonoma (possibly NET G2). The tumor consisted mainly of cords or a cobblestone-like pattern of medium-sized cells with moderate nuclear atypia and two to five mitosis per ten HPFs. Hemorrhage and necrosis were noted. Immunohistochemically, the cells were positive for glucagon, chromogranin A., and synaptophysin (Obi et al. 2009).

Primary Intrahepatic VIPoma

Vasoactive intestinal peptide (VIP)-producing tumor (VIPoma) causing Verner-Morrison

syndrome (so-called pancreatic cholera; WDHA syndrome) is a very rare neuroendocrine tumor of the gastrointestinal tract, with an estimated incidence of 0.1 per million per year. 70–80 % of these neoplasms arise in the pancreas, where VIPoma accounts for less than 10 % of islet cell tumors. The distinct endocrine syndrome is characterized by profuse watery diarrhea, hypokalemia, hypercalcemia, and metabolic acidosis. The syndrome is usually induced by the secretion of VIP by the tumor cells, but other cosecreted peptides may also be involved, including pancreatic polypeptide (PP), the oligopeptide histidine isoleucine, neurotensin, or gastric inhibitory peptide.

Primary hepatic VIPoma is an exceptional finding, with only few reports available (Ayub et al. 1993; Lundstedt et al. 1994; Hachicha et al. 2003). Primary VIPoma of the liver has been found to cause typical Verner-Morrison syndrome, which disappeared after resection of the tumor (Ayub et al. 1993; Hachicha et al. 2003). Histologically, VIPoma is composed of uniform small to medium-sized cells that form nests or trabecular structures, with few pseudorosettes. The cells are variably immunoreactive for VIP, in addition to general neuroendocrine markers. Differential diagnostically, gastrointestinal and pancreatic VIPoma is known to metastasize to the liver (Johnston et al. 2010; Li et al. 2010; Abu-Zaid et al. 2014). In hepatic metastases, an increased expression of CXCR4 was found, suggesting a role in the metastatic process (Müller et al. 2012).

Primary Intrahepatic Signet-Ring Cell Carcinoid (Primary Intrahepatic Signet-Ring Cell NET)

Primary hepatic signet-ring cell carcinoid is an unusual variant of carcinoid tumor, characterized by cytoplasmic mucin-negative keratin aggregate inclusions that mimic the cytologic features of other signet-ring cells. The paranuclear inclusions are pale, vacuole-like structures on an eosinophilic cytoplasmic background (Aoki et al. 1992; Zhu et al. 2010).

Primary Well-Differentiated Intrahepatic Neuroendocrine Carcinoma (NET G2; WHO 2000: WDEC)

Relatively few intrahepatic neoplasms corresponding to NET G2/WDEC have been observed (Figs. 7, 8, 9, 10, 11, 12, 13, and 14; Hsueh et al. 1993; Fukunaga 1998; Yasuda et al. 2006; Chen et al. 2014; Masunaga et al. 2014; Rocca et al. 2014; review: Shinkawa et al. 2013), with few detailed pathology findings. In the course of the autopsy of a 71-year-old man with dermatomyositis, multiple tumors were detected in his noncirrhotic liver. These tumors were composed of small- to medium-sized cells with clear cytoplasm, arranged in nests, sheets, and rosettes. Immunohistochemically, the tumor cells were reactive for CK7, CK19, epithelial membrane antigen (EMA), chromogranin A, NSE, and CD56, but not for synaptophysin. The tumor had metastasized to locoregional lymph nodes, the gallbladder, and the lung (Yasuda et al. 2006). Primary WDEC can produce important mass lesions in the liver, sometimes exceeding a diameter of 20 cm, so-called giant tumors (Rocca et al. 2014; Sotiropoulos et al. 2014). In fact, WDECs/NET G2 tumors typically manifest as a large dominant hypervascular mass at imaging, often accompanied by satellite nodules (Li et al. 2013).

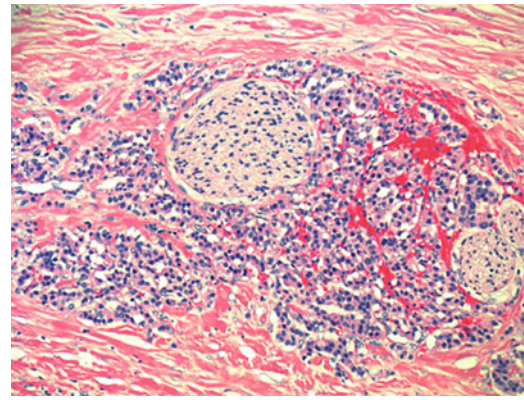

Fig. 10 Perineural invasion of hepatic neuroendocrine carcinoma (hematoxylin and eosin stain)

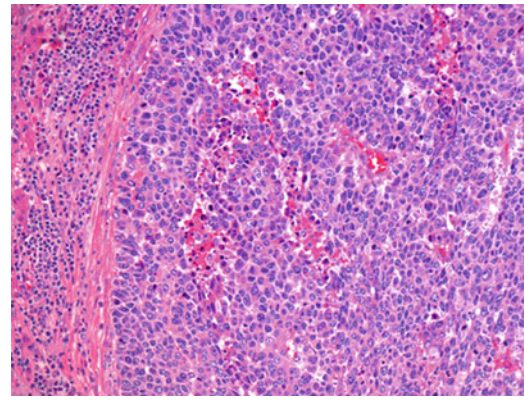

Fig. 11 Poorly differentiated variant of hepatobiliary neuroendocrine carcinoma with focal necrosis (hematoxylin and eosin stain)

Poorly Differentiated Intrahepatic Neuroendocrine Carcinoma (NEC)

In contrast to extrahepatic bile ducts, intrahepatic NEC is an exceptional observation. Primary hepatic small cell carcinoma of the neuroendocrine type (PHSCC-NE) forms the poorly differentiated end of the spectrum of neuroendocrine carcinomas (Balta et al. 2008). Immunohistochemically, the tumors are reactive for CD56 and focally for cytokeratins 8, 18, and w0, but are negative for TT1 and CDX2 (Balta et al. 2008).

Mixed Intrahepatic Adenoneuroendocrine Carcinoma (MANEC)

Very rarely, hepatic carcinoid arises as a composite tumor consisting of a neuroendocrine tumor and an adenocarcinoma/cholangiocarcinoma (Hidaka et al. 2000; Koplin and Agni 2009). The cases histologically present as well-differentiated adenocarcinoma with components of argyrophil carcinoid tumor cells, the latter sometimes being immunohistochemically positive for serotonin.

Well-Differentiated Neuroendocrine Tumors (NET G1; Carcinoid Tumors) of the Extrahepatic Bile Ducts

Introduction and Epidemiology

Well-differentiated endocrine tumors (carcinoids) of the common bile duct are relatively uncommon lesions, the first example having been reported in 1959 (Davies 1959). Since, more than 50 cases have been reported. Carcinoid tumor of the common bile duct has also been observed in adolescents (Volpe et al. 2003) and in the pediatric age group

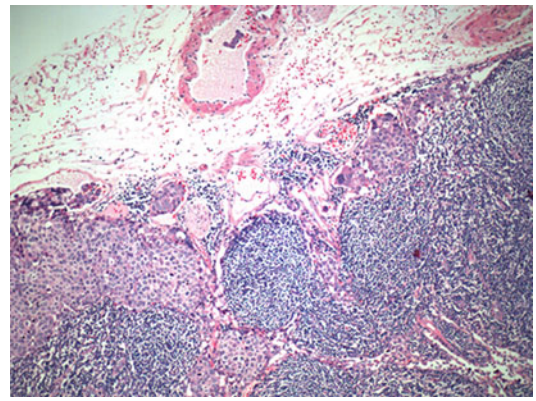

Fig. 14 Locoregional lymph node metastasis of hepatic neuroendocrine carcinoma (hematoxylin and eosin stain)

(Tonnhofer et al. 2009; Song et al. 2011). Most of the tumors were detected in the common bile duct and the cystic duct, and the lesions are less commonly encountered in the hepatic ducts. In a review of 44 cases, 34 tumors were located in the common bile duct (Nesi et al. 2006). In this review, tumors were more often diagnosed in female patients (25 F, 16 M). Up to 2009, about 55 primary carcinoid tumors of the cystic duct were reported (review: Felekouras et al. 2009).

Clinical Features

The most frequent clinical signs observed in these patients were jaundice, right upper quadrant pain, biliary colic, nausea, and vomiting. In a more recent review of 62 cases, 36 were women and 24 men, and their mean age at presentation was 47.5 years (range 12–79 years). The most common sign was painless jaundice (42 of 58 patients), followed by right upper quadrant pain (16 of 58 patients). Eighteen patients showed metastases to the liver, pancreas, gallbladder, and regional lymph nodes, while 40 had disease confined to the bile ducts. Thirty-six tumors were located in the common bile duct, 16 to the perihilar region, 7 to the cystic duct, and only 3 to the common hepatic duct. In these reviewed cases, most tumors were nonfunctioning (Felekouras et al. 2009). Carcinoid tumor has also developed in the wall

of a congenital bile duct cyst (Ueyama et al. 1992). Tumors located at the confluence may mimic Klatskin tumor (Chan et al. 2000). Rarely, carcinoids of the extrahepatic bile ducts may be associated with distinct endocrine syndromes. ACTH production causing Cushing's syndrome has been reported (Dahm et al. 1993). Carcinoid tumor of the common bile duct or the common hepatic duct has been observed as a complication of von Hippel-Lindau syndrome (Fellows et al. 1990; Nafidi et al. 2008). Numerous cases have been compiled in the literature, with in part detailed descriptions of clinical, imaging, and histologic features.

Pathology

Macroscopically, biliary tract carcinoids have been found to measure 1.1–5.5 cm in diameter at diagnosis (Felekouras et al. 2009). The tumors have a whitish to yellow to tan color and are circumscribed nodules with usually well-defined borders. The histology and immunohistochemistry are those of other carcinoids.

Differential Diagnosis

Hepatic metastases (so-called carcinoidosis) are common complications of neuroendocrine tumors of the gastrointestinal tract. It has been reported that the neoplasms metastasize to the liver in 5–10 % of the cases (Dejong et al. 2002). In fact, most hepatic carcinoids are metastases rather than primary tumors. The most common primary sites in the GIT are the appendix (35 %), small intestine (25 %), and rectum (12 %).

Neuroendocrine Tumors (NETs) of the Extrahepatic Bile Ducts: Special Types

Gastrinoma

The majority of the rare hepatobiliary gastrinomas are observed within the liver substance (see above), but few tumors were detected in the walls of the extrahepatic bile ducts (Mandujano-Vera et al. 1995; Hao et al. 1996; Martignoni et al. 1999; Price et al. 2009; Tarçin et al. 2011). As with intrahepatic gastrinomas, these neoplasms may cause Zollinger-Ellison syndrome. In the patient described by Mandujanovera et al. (1995), a 53-year-old woman, a stenosing small tumor was found in the lower third of the common bile duct, showing diffuse gastrin production and focal reactivity for serotonin and pancreatic polypeptide. The ulcerogenic syndrome ceased after resection of the tumor. Bile duct gastrinomas can grow to large size. One patient had a solitary, well-encapsulated mass of 8 cm

diameter in the common bile duct (Tarçin et al. 2011). Among three patients reported by Price et al. (2009), two had MEN1 syndrome. An association of biliary tract gastrinoma and MEN1 was confirmed by a later report (Tonelli et al. 2013).

Somatostatinoma

One case of somatostatinoma of the cystic duct was reported (Goodman et al. 1984).

Clear Cell Carcinoid Tumor

This rare tumor was detected in the most distal (intrapancreatic) portion of the common bile duct in a 73-year-old man suffering from epigastric pain (Todoraki et al. 2007). CT revealed a slight dilatation of the extra- and intrahepatic bile ducts and a slightly protruding nodular lesion in the distal common duct. The resection specimen showed a golden-yellowish polypoid mass measuring up to 1.2 cm in diameter. Histologically, the neoplasm consisted of uniformly sized polygonal cells with small round nuclei and a clear, abundant cytoplasm. Mitotic figures were not in evidence, but there were signs of perineural and vascular invasion. Immunohistochemically, the tumor cells were reactive for chromogranin A, synaptophysin, NSE, and pancreatic polypeptide, but not for CD56, somatostatin, serotonin, or cytokeratin.

Well-Differentiated Neuroendocrine Carcinoma (NET G2, WDEC, "Malignant Carcinoid") of the Extrahepatic Bile Ducts

This still incompletely defined group of neuroendocrine tumors is characterized by features of atypical carcinoid tumor with clear signs of invasion and metastasis at diagnosis (Yamamoto et al. 1986; Oikawa et al. 1998; Yamaguchi et al. 2009; Squillaci et al. 2010). In one 79-year-old male patient, the tumor was located to the bile duct confluence and was histologically composed of a well-differentiated tubular carcinoma, numerous tumor cells being argyrophil and/or argentophil and immunoreactive for serotonin, somatostatin, and gastrin (Yamamoto et al. 1986). In two other patients, the tumors showed transmural invasion, lymph node metastasis, and subcapsular liver tissue infiltration (Squillaci et al. 2010). In one case, reactivity for gastrin-releasing peptide was the prominent immunohistochemical feature (Oikawa et al. 1998). NET G2 was also observed in the cystic duct (Felekouras et al. 2009). These authors reviewed six previously reported cases.

Mixed Adenoneuroendocrine Carcinoma (MANEC) of the Biliary Tract

Neuroendocrine carcinoma of the bile ducts can very rarely occur as mixed adenoneuroendocrine carcinoma/MANEC (Yamamoto et al. 1998).

Poorly Differentiated Neuroendocrine Carcinomas (PDEC; WHO 2010: NEC) of the Extrahepatic Bile Ducts

Small Cell Neuroendocrine Carcinoma (SCNEC)

Small cell neuroendocrine carcinoma (SCNEC) of the extrahepatic bile duct system is a rare high-grade malignancy morphologically resembling in many aspects the counterpart so often arising in the bronchopulmonary tract (Fig. 15). Only around 4 % of the small cell carcinomas arise in organs other than the lung. When SCNEC occurs in the biliary tract, it develops mainly in the gallbladder, while relatively few cases have been reported for the common bile duct (Sabanathan et al. 1988; Van der Wal et al. 1989; Nishihara et al. 1993; Miyashita et al. 2001; Hazama et al. 2003; Kuraoka et al.

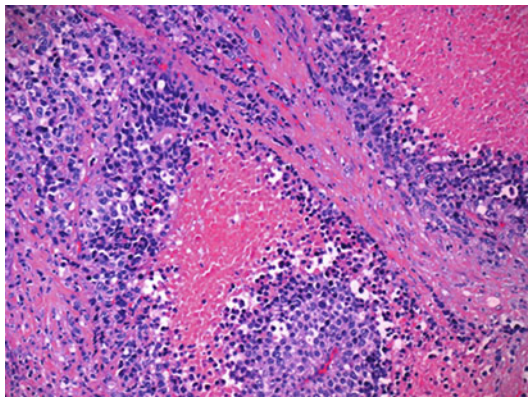

Fig. 15 Small cell undifferentiated neuroendocrine carcinoma of the hepatobiliary tract with coagulation necrosis (hematoxylin and eosin stain)

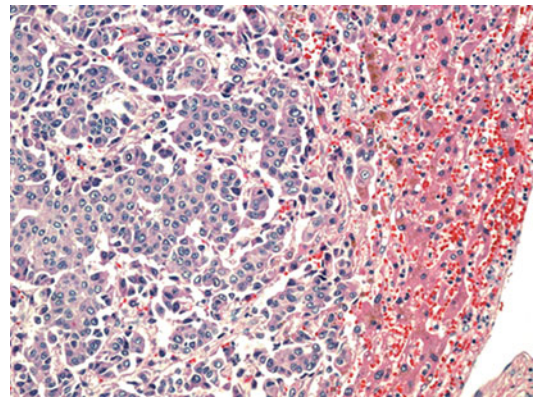

Fig. 16 Large cell undifferentiated hepatobiliary neuroendocrine carcinoma (hematoxylin and eosin stain)

2003; Kaiho et al. 2005; Nassar et al. 2005; Jeon et al. 2006; Jun et al. 2006; Hosonuma et al. 2008; Albores-Saavedra et al. 2009; Cho et al. 2009; Okamura et al. 2009). In a SEER study (Albores-Saavedra et al. 2009), the mean age at diagnosis was 68.4 years, while it was 58.2 years in bile duct carcinoids. The 10-year survival was 0 %. In a review of 17 cases of small cell carcinoma of bile ducts, nine tumors were located to the distal part of the common bile duct and eight tumors in its middle portion, 14/17 patients presented with jaundice (Hosonuma et al. 2008). SCNEC of the extrahepatic bile ducts can show a stenosing growth pattern resembling that of cholangiocarcinomas, e.g., with irregular luminal narrowing situated at the confluence of the common bile duct, cystic duct, and common hepatic duct (Hosonuma et al. 2008). The prognosis of biliary tract SCNEC is very poor, the longest reported survival being 23 months after initial diagnosis and 20 months after combined surgery, radiotherapy, and chemotherapy (Okamura et al. 2009). Histologically, the presentation is characterized by an almost diffuse growth of small-sized, round, Grimelius-positive cells with scant cytoplasm and hyperchromatic, oval nuclei. The mitotic count is high. Part of the tumors may develop glandular or squamous epithelia, or may be composite tumors of SCNEC, adenocarcinoma, or squamous cell carcinoma (Hosonuma et al. 2008). Immunohistochemically, most cells are variably positive for cytokeratins, EMA, NSA, Leu-7, CD56, synaptophysin, and chromogranin A.

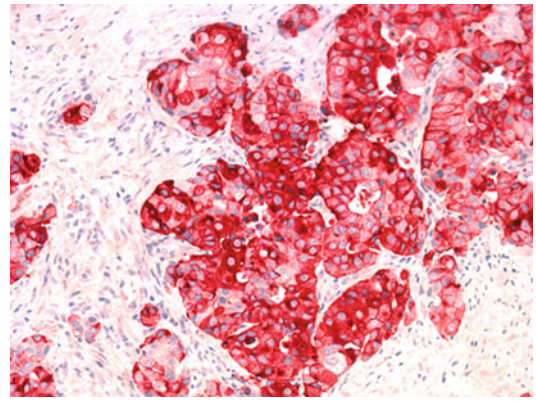

Fig. 17 Large cell undifferentiated hepatobiliary carcinoma; expression of chromogranin A (chromogranin A immunostain)

Large Cell Neuroendocrine Carcinoma (LCNEC)

Only few examples of LCNEC of the extrahepatic bile ducts have been described in the literature (Figs. 16 and 17; Jun et al. 2006; Carter et al. 2009; Demoreuil et al. 2009). Composite

large cell neuroendocrine carcinoma and adenocarcinoma has been observed (Sato et al. 2006).

Bile Duct Adenoma with Neuroendocrine Features

In one case of bile duct adenoma, there were periductular nests and clusters of uniform round cells, suggestive of a neuroendocrine cell proliferation. Immunohistochemistry showed decoration of these cells with several neuroendocrine markers, while neuroendocrine marker expression was not found in the epithelial cells of the ductules (O'Hara et al. 1992).

Combined Hepatic Tumors

Amphicrine Carcinoma of the Liver

Amphicrine tumors are defined as neoplasms that display both glandular and neuroendocrine differentiation in the same cell system. A single case of this type of tumor has been reported for the liver. A 47-year-old man presented with abdominal pain and MR revealed a 5.2 × 4.4 × 4 cm mass in the medial segment of the left liver lobe. Ultrasound showed a focal well-circumscribed lesion with heterogeneous echogenicity, while CT showed a solitary hyperenhancing lesion. On MR, the tumor was hyperintense relative to surrounding parenchyma on T2-weighted images. In the resection specimen, the well-delimitated tumor had a maximum diameter of 5 cm and histologically consisted of sheets of poorly cohesive malignant cells separated by thin fibrous septa. The cytoplasm was rich and eosinophilic, with many prominent intracytoplasmic vacuoles, imparting a signet-cell phenotype. These vacuoles were focally PASD and mucicarmine positive. However, no glandular structures were noted. Focal vascular invasion was found. Immunohistochemically, the neoplastic cells were reactive for synaptophysin and chromogranin, and for cytokeratins 7 and 20. Furthermore, the tumor was strongly positive for villin and pancytokeratin (Ganesan et al. 2011).

Combined Primary Neuroendocrine and Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) with neuroendocrine components is an extremely rare tumor (Barsky et al. 1984; Artopoulos and Destuni 1994). In the case of Barsky et al. (1984), the tumor ultrastructurally consisted of HCC cells, carcinoid tumor cells, and cells showing both of these features. In an HCC arisen in a patient with MEN1, HCC cells with expression of chromogranin A were detected (Nakajima et al. 2000). Aboelenen and coworkers reported on a large (20 cm) hepatic tumor that consisted of a combination of neuroendocrine tumor cells and cells reactive for Hep Par1, however without glypican-3 staining (Aboelenen et al. 2014). Combined neuroendocrine and hepatocellular carcinomas can also contain a poorly differentiated neuroendocrine lineage (NEC), mostly of small cell type (Yamaguchi et al. 2004; Yang et al. 2009). In a rapidly growing HCC, the moderately differentiated HCC component contained nests of small cell NEC expressing several neuroendocrine lineage markers (Yamaguchi et al. 2004).

Collision Tumors

A collision tumor of the liver was composed of a small cell high-grade neuroendocrine carcinoma and hepatocellular carcinoma, the two tumors separated by fibrous bands (Garcia et al. 2006). Extrahepatic collision tumors containing a neuroendocrine component can metastasize to the liver (Mroz et al. 2009). Neuroendocrine collision tumors should not be confounded with situations in which hepatic neuroendocrine tumor is synchronously associated with HCC located elsewhere in the liver (Ishida et al. 2003).

Hepatobiliary Cellular Sources of Neuroendocrine Tumors

Neuroendocrine Cells in the Biliary Tract Mucosa

Endocrine cells present in the epithelial lining of the normal human intrahepatic biliary tract are mostly argyrophilic cells and are found both in children and adults. These cells are mostly immunoreactive for somatostatin (Kurumaya et al. 1989). Also the mucosa of the extrahepatic bile ducts and of the ampulla of humans, but not the gallbladder, harbors somatostatin-containing cells detectable with immunohistochemistry (Dancygier et al. 1984).

Neuroendocrine Features of Cholangiocytes and the Neurobiliary Interactome

Proliferating cholangiocytes can acquire the phenotype of neuroendocrine cells. Particularly, cells of human ductular proliferations display neuroendocrine features, and neuroendocrine factors themselves regulate cholangiocyte proliferation (Roskams et al. 1990, 2004; Alvaro et al. 2007; Mancino and Alvaro 2007; Marzioni et al. 2009; Munshi et al. 2011). Cholangiocytes express the neural cell adhesion molecule, N-CAM (CD56), including the cells of ductular proliferations (Roskams et al. 1991; Fabris et al. 2000). Cells located to ductular proliferations express parathyroid hormone-related peptide (Roskams et al. 1993).

Cholangiocytes express several hormone and neurohormone receptor systems. They possess serotonin 1A and 1B receptors. The activation of these receptors inhibits the growth and choleretic activity of the biliary tree in bile duct-ligated rats, associated with enhanced protein kinase C signaling. Cholangiocytes also secrete the ligand, serotonin, suggesting an autocrine/paracrine regulation of cholangiocyte growth and function (Marzioni et al. 2005). Glucagon-like peptide-1 (GLP-1) induces the neuroendocrine transdifferentiation of pancreatic ductal cells and also plays a role in cholangiocyte turnover in the course of cholestasis. Cholangiocytes express the GLP-1 receptor which is upregulated during cholestasis. GLP-1 and its receptor agonist exendin-4 increase cholangiocyte growth both in vivo and in vitro, whereby the GLP-1 signaling is mediated by phosphatidyl-inositol-3-kinase, cAMP/protein kinase A, and Ca^{2+}-CamKII alpha. Proliferating cholangiocytes themselves secrete GLP-1, suggesting an autocrine/paracrine loop (Marzioni et al. 2007). Normal and diseased cholangiocytes express components of the neurotrophin-neurotrophin receptor system. Both nerve growth factor (NGF) and its TrkA receptor are expressed by normal rat cholangiocytes, and these proteins are upregulated in bile duct-ligated rats. Normal cholangiocytes secrete NGF and this secretion is increased in proliferating cholangiocytes. In vitro, NGF and estrogens have an additive effect on cholangiocyte proliferation by acting on phosphorylated TrkA and p-ERK1/2 (Gigliozzi et al. 2004). The proliferation of cholangiocytes is coordinatively controlled by the parasympathetic and sympathetic innervation of the liver and biliary tract. The sensory neuropeptides, alpha and beta calcitonin gene-related peptide (alpha-CGRP and beta-CGRP), stimulate the proliferation of cholangiocytes, induce elevated cAMP levels, and stimulate the activation of cAMP-dependent protein kinase A and cAMP response element-binding protein DNA binding (Glaser et al. 2007). Murine cholangiocytes express the neurokinin-1 receptor (NK-1R) with expression upregulated following bile duct ligation. In NK-1R knockout mice, the number of CK19-positive cholangiocyte decreases and enhanced cholangiocyte apoptosis ensues (Glaser et al. 2011). The observation that many hormones, neuropeptides, and neurotransmitters regulate the homeostasis of normal cholangiocytes and affect the behavior of cholangiocellular carcinoma cells suggests the

existence of a distinct neurobiliary network or a neurobiliary interactome.

Neuroendocrine Cells in Metaplastic Lesions of the Biliary Tract

In metaplastic lesions of the extrahepatic bile ducts (the most common lesion being pseudopyloric gland metaplasia), endocrine cells were detected in 56 % of metaplastic areas (Hoang et al. 2001). In the liver with hepatolithiasis, pseudopyloric gland metaplasia and intestinal metaplasia may be prominent in intrahepatic bile ducts, and the metaplastic lesions contained endocrine cells, including argyrophil, argentaffin, and gut hormone-containing cells in 59 % of the cases. The occurrence of these endocrine cells was closely associated with intestinal metaplasia, although there were a few endocrine cells in metaplastic pseudopyloric glands (Kurumaya et al. 1990).

Development and Morphogenesis of Hepatobiliary Neuroendocrine Cells

In vitro, adult hepatic stem cells of the rat are capable to transdifferentiate into pancreatic endocrine hormone-producing cells. These differentiated cells can self-assemble to form three-dimensional islet cell-like clusters that express pancreatic islet cell differentiation-related transcripts, such as PDX-1, PAX-4, PAX-6, Nkx2, Nkx6, insulin I and II, glucose transporter 2 and glucagon, while these cells lose the expression of the hepatocyte lineage marker, Hep-Par (Yang et al. 2002).

Biliary epithelium explants cultured in vitro have been shown to undergo transdifferentiation into pancreatic-type endocrine cells. These cholangiocyte-born cells express the pancreatic transcription factors Pdx1, HNF6, and Sox9, while the expression of Ngn3, a proendocrine transcription factor, is transient, consistent with an early stage of endocrine cell differentiation (Eberhard et al. 2008).

What drives the neuroendocrine-like transdifferentiation of cholangiocytes?

The mechanisms driving cholangiocytes to a neuroendocrine-like phenotype are only partially known. The transcription factor pancreatic duodenal homeobox-1 (PDX-1) is required for pancreatic development and induces neuroendocrine-like transition of pancreatic ductal cells. Cholangiocytes of bile duct-ligated rats, but not normal rat cholangiocytes, express PDX-1. The expression and nuclear translocation of PDX-1 is promoted by GLP-1, which is secreted by proliferating cholangiocytes in obstructive cholestasis. The de novo expression of PDX-1 by cholangiocytes allows these cells to synthesize IGF-1 and VEGF (Marzioni et al. 2010).

Hepatobiliary Tumors with a Small Cell Undifferentiated Lineage

Undifferentiated Small Cell Tumors of the Hepatobiliary Tract

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_76

Abstract

A small group of primary hepatobiliary tumors is characterized by the presence of morphologically undifferentiated small cells. These small cell tumors (SCTs), which histologically appear as "small cell blue tumors" due to the dense crowding of nuclei together with poorly developed cytoplasm, have several cell lineage courses that can only be identified by means of immunohistochemistry and molecular methods. One type of hepatic SCT is a member of the complex family of neuroectodermal tumors that predominantly occur in the skeleton and soft tissues of adolescents and young adults (primitive neuroectodermal tumors or PNETs). Hepatic PNETs are very rare neoplasms with an aggressive course, and the tumor also develops in the biliary tract. Other hepatobiliary SCTs include desmoplastic small round cell tumor, NUT midline carcinoma, and hepatic neuroblastoma and its variants. As all hepatobiliary SCTs are very rare neoplasms, they have to be distinguished from the more common metastatic lesions of these tumors.

Primitive Neuroectodermal Tumors (PNETs) of the Liver

ICD-O code 9364/3

Introduction

Primitive neuroectodermal tumors (PNETs) constitute a family of malignant neoplasms of presumed neuroectodermal origin that predominantly present as bone and soft tissue tumors in adolescents and young adults, but also occurs in adults of more advanced age. The Ewing's family of tumors (EFTs) comprises Ewing's sarcoma of the bone (which was formerly believed to be of reticulum cell or perivascular cell origin), extraosseous Ewing's sarcoma, PNET (extraosseous Ewing-like neoplasms that have progressively been allocated to tumors with a neuroectodermal lineage), and malignant small cell tumor of the thoracopulmonary region, also called Askin's tumor (reviews: Carvajal and Meyers 2005; Khoury 2005, 2008; Armbruster et al. 2008).

While Ewing's sarcoma is a primary bone tumor and follows osteosarcoma as the second most common malignant bone tumor in children, PNETs either occur in the CNS (CNS-PNET) or develop in soft tissues of the thoracopulmonary region, pelvis, and lower extremities and rarely in visceral organs, the myocardium, and the skin (peripheral PNET, pPNET). Most PNET family members are diagnosed before the age of 35 years, with a slight male predominance. Once considered to be uncommon, PNET now accounts for almost 20 % of malignant soft tissue tumors in children. Increased recognition of PNET is due to advances in definition of the diagnostic features, immunohistochemistry, and molecular diagnostics, which have led to the identification of the tumor in nonclassical sites. These neoplasms all exhibit a neural phenotype, express the MIC2 protein (CD99), and display the chromosomal translocation t(11;22)(q24;q12), causing the EWS-FLI1 fusion transcript in about 90 % of the cases. Many, if not all, of the remaining cases of PNET are associated with translocations resulting in the fusion of the EWS gene to other members of the ETS family (reviews: Seth and Watson 2005; Maire et al. 2008). Apart from the bone and soft tissue, PNETs occur in several internal organs, including the lung, myocardium, stomach, pancreas, and hepatobiliary tract. After the lung, the kidney is now the most common visceral site of PNET. In the pediatric age group, primary cutaneous PNET represents a distinct clinical entity (Lee et al. 1995).

Primary PNET of the Liver

Few examples of primary hepatobiliary PNET have been reported (Sarangarajan et al. 2001; Song et al. 2004; Ousadden et al. 2005; Mani et al. 2010; Cambruzzi et al. 2011). For the liver, one tumor was detected in a 58-year-old female who complained of right-sided hypochondrial

pain of 1 year duration. Sonography revealed a cystic tumor of 10 cm diameter in segments VII and VIII, confirmed by CT. Serum AFP was normal (Ousadden et al. 2005). A second reported patient was a 20-year-old lady presenting with massive hepatomegaly. Liver biopsy revealed nests of small round tumor cells expressing MIC2 and Fli-1, compatible with PNET. Extensive search regarding any possible different site of origin was negative (Mani et al. 2010). A third patient with PNET primary to the liver was an 18-year-old male with clinical complaints of pain in the right upper abdominal quadrant, due to a large tumor in the right liver lobe. The hepatic resection specimen showed that the right lobe was replaced by a yellow-red solid mass measuring up to 21 cm in diameter. Histology showed typical PNET with immunoreactivity for CD99 and vimentin (Cambruzzi et al. 2011).

PNET can also develop in the biliary tract. A 14-year-old female patient developed obstructive jaundice caused by a pedunculated submucosal tumor of 1.5 cm size located to the common hepatic duct. Histology was typical for PNET, part of the cells having a moderate amount of clear cytoplasm that was PAS positive. The cells were markedly positive for CD99, and PCR revealed the EWS-FLI1 fusion (Sarangarajan et al. 2001). PNET also takes its origin from the gallbladder. A 53-year-old female showed, in the fundus of the gallbladder, a polypoid mass measuring 7 × 4 × 3.5 cm, whitish tan, friable, and mostly necrotic. The tumor cells were MIC2 positive (Song et al. 2004).

Pathology

The histological picture is characterized by a diffuse growth of small cells with scant, amphophilic, or clear cytoplasm. In the silver stain, groups or nests of tumor cells are surrounded by delicate reticulin fibers (Figs. 1, 2, and 3). Tumor cell rosettes may be encountered. Small areas with discrete desmoplastic stroma may be noted, but not of the type observed in desmoplastic round cell tumors discussed below.

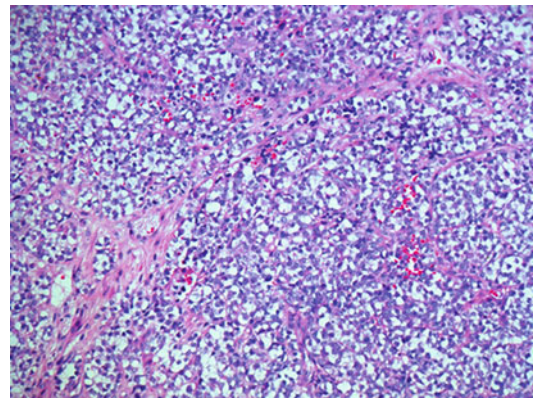

Fig. 1 Primary PNET of the liver. There is a diffuse growth of small- to medium-sized poorly differentiated tumor cells (hematoxylin and eosin stain)

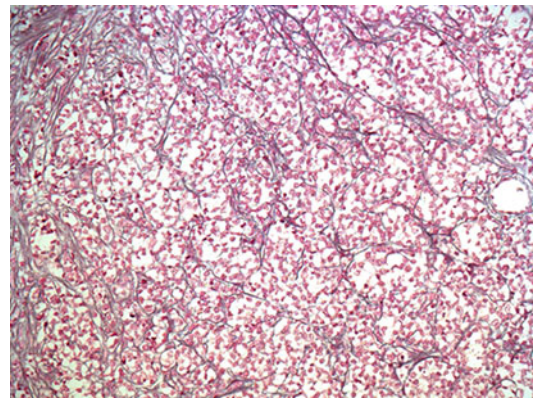

Fig. 2 Primary PNET of the liver. Nests and strands of small tumor cells are separated from each other by reticulin fibers, whereas reticulin is not detectable within nests or strands themselves (Gomori silver stain)

Immunohistochemistry

The typical diagnostic feature is the presence of marked positivity for MIC2 (CD99 antibody), in a predominantly membranous staining pattern (Fig. 4). It is important to note that other mesenchymal tumors may express MIC2, including poorly differentiated synovial sarcoma and rhabdomyosarcoma. Immunohistochemical expression of the FLI-1 protein may be valuable in confirming the diagnosis of EWS/PNET in cases where molecular genetic evaluation is not feasible (Folpe et al. 2000).

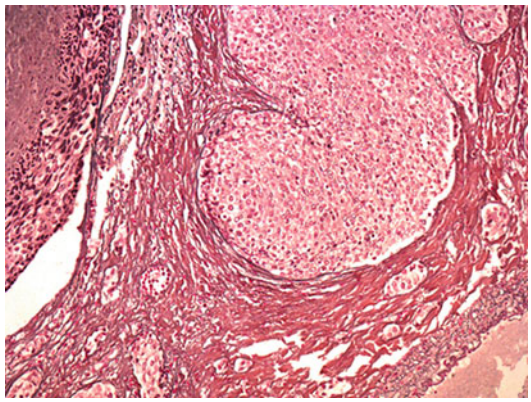

Fig. 3 In this reticulin stain, lack of fibers within the PNET nodule is in evidence (Gomori silver stain)

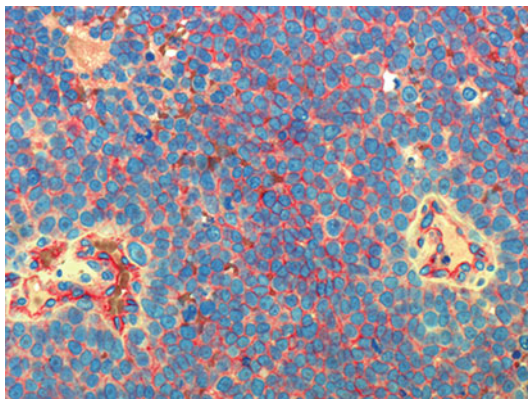

Fig. 4 Primary PNET of the liver. The neoplastic cells exhibit strong membranous staining for CD99 (CD99 immunostain)

PNET Metastatic to the Liver

PNET and Ewing's sarcoma are known to metastasize to the liver (Centenera Fondon et al. 1952; Mackenzie et al. 1992). Metastatic PNET of the liver may present of cystic lesions (Shah and McHugh 2000) or masquerade as liver abscess (Hyun et al. 2002). Ultrasound of cystic metastases showed multiple anechoic cystic lesions with posterior enhancement, and CT confirmed multiple cysts of varying size, sometimes with a rim of calcification (Shah and McHugh 2000). Ewing's sarcoma of the ribs was found to have metastasized into a focal nodular hyperplasia (FNH) of the liver (Hagay et al. 1986).

Desmoplastic Small Round Cell Tumors

Introduction

Desmoplastic small round cell tumor (DSRCT) is an uncommon, highly aggressive (high-grade) malignancy usually arising in the abdomen of young males, forming intraperitoneal and peritoneal masses, often with numerous peritoneal implants. This distinct tumor type was first described in 1989 (Gerald and Rosai 1989) and then in 1991 (Layfield and Lenarsky 1991), specified in detail 1 year later based on 19 cases (Gerald et al. 1991). The typical abdominal presentation is in the form of numerous nodules growing out of the peritoneal surface, these nodules ranging in diameter from few millimeters to more than 10 cm (mean diameter in one study of 14 patients, 5 cm; Pickhardt et al. 1999). DSRCT also occurs in abdominal internal organs, including the pancreas, and extraabdominal tumors have been reported, such as the kidney (Eaton and Cendron 2006; Janssens et al. 2009), soft tissues, ovary, heart, lung, central nervous system, and major salivary glands.

DSRCT is immunohistochemically characterized by the polyphenotypic expression of vimentin, cytokeratins, desmin (dot pattern), WT-1, neuron-specific enolase, CD15, Ber-EP4, and CD99 (about one fifth of cases) (Ordonez 1998; Zhang et al. 2003; Chang 2006; Lee and Hsiao 2007) and ultrastructurally by signs of divergent differentiation and a characteristic paranuclear aggregate of intermediate filaments (Wills 1993). A rare subset of DSRCT is characterized by the lack of epithelial differentiation, i.e., without cytokeratin staining (Trupiano et al. 1999). Similar to other small cell tumors, such as neuroblastoma and medulloblastoma, a large cell variant of EWS/WT1 translocation-positive DSRCT is known (Pasquinelli et al. 2000).

Epidemiology

In a review of 32 cases, there were 29 male and 3 female patients, with ages at diagnosis from 6 to 54 years (mean, 25 years). 88 % of the tumors were

located in the abdominal cavity; others involved soft tissues and ethmoid sinus (Lae et al. 2002).

DSRCT of the Liver

Among 28 DSRCTs located to the abdominal cavity, nine tumors also involved the liver (Lae et al. 2002). DSRCT of the liver can be associated with multiple intraperitoneal tumors (Li et al. 2014). A further published case was located in the perihepatic space (Chouli et al. 2005). In many situations of the liver involved, metastatic disease from primary tumor outside the liver is present (Arra et al. 2013; Hirano et al. 2013). Among 62 patients with primary intraabdominal disease, 40 % presented liver metastases (Arra et al. 2013).

Macroscopy

DSRCTs are typically solid, multilobated, firm, and focally fleshy masses with a gray-white cut surface. However, cystic lesions have also been found (Li et al. 2014). Hemorrhages and necroses are often noted.

Histopathology

The neoplasms consist of solid sheets, clusters, cords, or large nests of small round, ovoid, or spindled cells with a scanty, ill-defined, and slightly eosinophilic to amphophilic cytoplasm. The nuclei are hyperchromatic, round to elongated, with small nucleoli and coarse, clumped chromatin. These cells are embedded in a hypocellular, desmoplastic stroma. Rarely, the tumor cells form tubules, rosettes, or gland-like structure. The mitotic count is usually high to very high. Necroses, sometimes with small calcifications, are often seen.

Pathogenic Pathways

The tumors reveal a translocation of chromosomes 11 and 22 [t(11;22)(p13;q12)] (Sawyer et al. 1992) resulting in the formation of the chimeric EWS-WT1 fusion gene (Ladanyi and Gerald 1994; Brodie et al. 1995; Gerald et al. 1998; Lee and Hsiao 2007; review: Gerald and Haber 2005). Most chimeric genes consist of the first seven exons of EWS and the last three exons (zinc finger domains) of WT1. WT1 immunohistochemistry reliably differentiates DSRCT from PNET (Barnoud et al. 2000; Hill et al. 2000) and reflects the EWS-WT1 fusion transcript in most DSRCT, but some cases express full-length WT1 or have variant transcripts, resulting in atypical staining patterns (Murphy et al. 2008).

EWS-WT1 chimeras are heterogeneous as a result of fusions at different regions of the EWS gene to the WT1 gene (Kim et al. 1998; Chan et al. 1999; Liu et al. 2000), which leads to the expectation of different targets of the fusion transcripts. Two isoforms of the EWS-WT1 fusion product transcriptionally activate the adenosine transporter ENT4, which is highly expressed in DSRCT (Li et al. 2008), and platelet-derived growth factor-A/PDGFA, a potent secreted mitogen (Lee et al. 1997). EWS-WT1(-KTS), a variant which lacks three amino acid residues (Lys-Thr-Ser) in the DNA-binding domain and which transforms NIH3T3 cells, induces a tetraspanin-family protein, TALLA-1 (T-cell acute lymphoblastic leukemia-associated antigen 1), a protein which regulates cell adhesion, migration, and metastasis (Ito et al. 2003). A rare fusion variant, EWS-WT1 5/10, is a potential transactivator of the insulin-like growth factor-I receptor gene (Werner et al. 2007). Unusual instances of so-called hybrid tumors in the abdominal cavity of young males, showing a combination of PNET morphology, immunophenotype of DSRCT, and EWS/FLI-1 fusion instead of EWS/WT1 fusion, have been observed (Katz et al. 1997).

NUT Midline Carcinoma

Introduction

NUT midline carcinoma (NMC) is a rare and aggressive malignant neoplasm of the upper aerodigestive tract, mainly occurring in children

and young adults and characterized by a rearrangement on the nuclear protein in testis (NUT; HUGO symbol, C15orf55) gene on chromosome 15q14. This rearrangement results in distinct fusion oncogenes, whereby NUT engages in a balanced translocation with BRD4 (bromodomain-containing protein 4) located on chromosome 19p13.1 (BRD4-NUT fusion oncogene) in up to 75 % of cases, while the remaining cases exhibit rearrangement of NUT with various other fusion partners, such as BRD3 and NSD3 (French et al. 2014). NMC is predominantly located to the midline structures, i.e., the nasopharynx, orbit, salivary glands, mediastinum, thymus, and other compartments of the thoracic cavity, including the trachea and lung. Very rarely, the upper abdominal cavity and its organs are involved (Kees et al. 1991; Kubonishi et al. 1991; French et al. 2001, 2004, 2008; Stelow and French 2009; French 2010a, b, 2013; Stelow 2011; Bauer et al. 2012; Fang et al. 2013; French 2013; Thompson-Wicking et al. 2013).

Epidemiology

From the relatively few patients reported so far, it surfaced that NMC mainly occurs in a young age group, but patients older than 70 years have been described. In a review of 28 patients, 14 were female and 14 male. Twenty-five out of twenty-eight patients had tumors in the head and neck or chest regions (Stelow 2011). Shehata and coworkers found an age range at presentation of 0–78 years, with a mean of 23 years (Shehata et al. 2010).

Clinical Features

In most patients, NMC presents as a mass lesion in midline structures, i.e., the head, neck, mediastinum, and chest (French 2010a; Hsieh et al. 2011; Evans et al. 2012). In a study of 114 poorly differentiated carcinomas or unclassified malignancies of the mediastinum, 3.5 % of cases showed nuclear NUT expression (Evans et al. 2012). In a minority of patients, the neoplasm mainly manifests below the diaphragm or shows a multifocal distribution (French et al. 2004; Shehata et al. 2010; Polsani et al. 2012). Advanced local disease is frequently accompanied by distant hematogenous metastases (Kees et al. 1991; Vargas et al. 2001; Toretsky et al. 2003; Mertens et al. 2006; den Bakker et al. 2009; Engleson et al. 2006; Stelow et al. 2008; Nelson et al. 2010; Ziai et al. 2010; Hsieh et al. 2011; review: Stelow and French 2009).

Liver Involvement

A primary localization in the liver or pancreas with subsequent metastatic disease is very rare (Shehata et al. 2010). Metastatic liver involvement by NMC was found in patients with extensive multiorgan disease. Similar to other metastatic sites, liver metastases of NMC present as bulky masses of friable tumor tissue with marked necrosis.

The main histologic features of NMC are that of a poorly differentiated small cell blue tumor with variable degrees of squamous cell differentiation. The cells grow in sheets or show nested pattern in a desmoplastic stroma. The cytoplasm is scant, amphophilic, or eosinophilic. The nuclei are mostly uniform, but nuclei with irregular shape also occur. Nucleoli are prominent, and mitotic figures are abundant (Fig. 5).

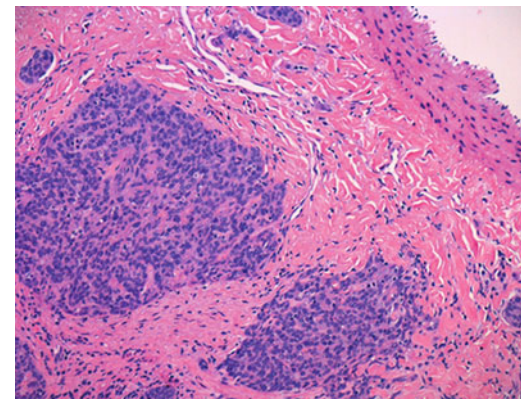

Fig. 5 Metastasis of NUT carcinoma in the liver (hematoxylin and eosin stain)

Transition from the small cell population to squamous cell areas is typically abrupt. The tumor usually shows extensive necrosis and sometimes numerous apoptotic bodies. Ultrastructurally, the tumor cells displayed prominent bundles of tonofilaments, clusters of pleomorphic granules, stubby microvillous projections, desmosomal-type junctions, and junctional complexes (Wartchow et al. 2012).

NMC cells are epithelial and are reactive for cytokeratins, mainly CK7 and focally CK20. The squamous differentiation is seen as reactivity for p63 (Stelow 2011). The NUT fusion protein is visualized in NMC tumor tissue with a monoclonal antibody (Haack et al. 2009; French 2010a). NUT rearrangement can be detected by fluorescent in situ hybridization (Shehata et al. 2010) and by reverse transcriptase PCR (French 2010b).

Molecular Pathways

The NUT-BRD fusion proteins induce uncontrolled growth of cells associated with a block in differentiation (French et al. 2008; French 2010a, 2012; Yan et al. 2011). BRD4 is a member of the BET (bromodomains and extraterminal) family that includes mammalian BRD2 to BRD7, BRDT, *Drosophila* fsh, yeast Bdf1, Bdf2, and corresponding homologs in other species. The BRD partner of the fusion oncogene contains two bromodomains (bromo and extra C-terminal domain/BET family of bromodomains) that bind to acetylated histones. Generally, bromodomains are acetyl-lysine-binding modules (acetyl-lysine recognition motifs) that promote the establishment of nucleosome acetylation in a wide array of organisms. BRD4 is a chromatin adaptor containing tandem bromodomains (BD1 and BD2) binding to acetylated histones H3 and H4. This molecular recognition allows BRD4 to associate with acetylated chromatin throughout the cell cycle and to regulate transcription of targeted loci, affecting cell cycle control in normal and neoplastic cells. Bromodomains found in chromatin-associated proteins and almost all histone acetyltransferases function as the sole protein module known to bind acetyl-lysine motifs/lysine-acetylated peptides and represent an evolutionarily conserved epigenetic regulator system (reviews: Zeng and Zhou 2002; Mujtaba et al. 2007). BRD4 directly interacts with a member of a subfamily of H3K36 methyltransferases, NSD3. One isoform of NSD3 is an adaptor protein that couples BRD4 to the CHD8 chromatin remodeler (Shen et al. 2015).

Histone acetylation is central to the epigenetic control of transcription, and here bromodomains are operational as epigenetic "writers and erasers" (Sanchez and Zhou 2009). BRD4 is found in several transcription complexes, including the general cofactor mediator and the P-TEFb elongation factor (Chiang 2009). In its fusion with NUT, BRD4 becomes a member of a potent chromatin regulator that drives aberrant transcription within large topological domains (Alekseyenko et al. 2015). The dual bromodomains and a p300-binding portion of BRD4-NUT cause sequestering of p300 to distinct regions of chromatin, thus promoting global transcriptional repression (review: French 2013). BRD4 also affects the metabolism of microRNAs and controls the essential epigenetic regulators, long noncoding RNA, e.g., HOTAIR (Pastori et al. 2015).

BRD4 localizes to chromosomes during mitosis ad is implicated in holding mitotic memory. Throughout mitosis, BRD4 remains bound to the transcription start sites of many M/G1 genes that are programmed to be expressed at the end of, or immediately after, mitosis. BRD4 binding to M7G1 genes increases at telophase, goes in line with recruitment of P-TEFb, and coincides with increased acetylation of histones H3 and H4 (Dey et al. 2009). At late mitosis, BRD4 also functions as an associated factor and positive regulator of P-TEFb (positive transcription elongation factor b), a Cdk9-cyclin T1 heterodimer that stimulates transcriptional elongation by phosphorylating the C-terminal domain of RNA polymerase II, via phosphorylation of serine 2 (Devaiah et al. 2012). The cyclin-dependent kinase 9 (Cdk9) is activated by T-type cyclins and cyclin K-generating P-TEFs. Phospho-Cdk9 displays a punctate distribution throughout the nucleoplasm and co-localizes with cyclin T1 within nuclear speckle domains, and phospho-Cdk9 also co-localizes with the hyperphosphorylated form of

RNA polymerase II, suggesting that nuclear speckles are the resident site of active P-TEFb (Dow et al. 2010). The BRD4-P-TEFb interaction increases in cells progressing from late mitosis to early G1 phase. Concurrently, P-TEFb is recruited to chromosomes, beginning around mid- to late anaphase and before nuclear lamina formation and nuclear import of other transcription factors. BRD4 recruitment to chromosomes at late mitosis marks those genes whose active transcription mode must be preserved across cell division (Yang et al. 2008). The recruitment of P-TEFb through BRD4 induces the release of the promoter-proximal paused RNA polymerase II and the increase of its processivity. The nucleosome platform allowing the binding of BRD4 and its interaction with P-TEFb is constructed by a histone cross talk between H3S10ph and H4K16ac to generate a nucleosomal histone recognition code (Zippo et al. 2009). Therefore, BRD4 marks select genes on mitotic chromatin, directs postmitotic transcription, and is implicated in transmitting epigenetic memory through mitosis. The downstream targets of BRD-NUT are highly enriched for genes upregulated by MYC. BRD4-NUT associates with the MYC promoter and is required for maintaining MYC expression in NMC cells, suggesting that MYC is an important factor for the maintenance of a proliferative state in NMC (Grayson et al. 2014).

In interphase, BRD4 interacts with P-TEFb and functions as a global transcriptional coactivator. Expression of BRD4 is associated with globally decreased histone acetylation and transcriptional repression, and experimental restoration of bulk chromatin acetylation engages a program of squamous differentiation (Schwartz et al. 2011), suggesting a mechanism for the typical squamous differentiation in NUT midline carcinomas. NUT can also fuse to other genes, such as NSD3, the NSD3-NUT fusion oncogene binding to BRD4 and thus blocking cell differentiation and maintaining proliferation (French et al. 2014).

Through its important role in the regulation of transcription, BRD4 affects the expression of numerous proteins that are involved in programming pathways in stem cells and neoplastic cells. The BRD4-NUT fusion oncogene is required for an abnormal activation of SOX2, a pathway that drives stem cell-like growth and cellular transformation of NMC (Wang et al. 2014a). BRD4 is involved in the behavior of cancer cells other than NUT, including acute myeloid leukemia and hepatocellular carcinomas (HCCs). In HCC, BRD4 induces cell migration and invasion through activation of matrix metalloproteinases 2 and 9 (Wang et al. 2015) and promotes tumor growth and epithelial-mesenchymal transition (Zhang et al. 2015).

Hepatic Neuroblastoma and Related Neoplasms (Manifestations of Peripheral Neuroblastic Tumors)

ICD-O codes:

Neuroblastoma	9500/3
Ganglioneuroblastoma	9490/3
Ganglioneuroma	9490/0

Introduction

Peripheral neuroblastic tumors (NTs), which include neuroblastomas, ganglioneuroblastomas, and ganglioneuromas, are defined as embryonal tumors of the sympathetic nervous system and originate from immature sympathetic neuroblasts derived from the neural crest. NT chiefly arises in the adrenal medulla, paravertebral sympathetic ganglia, and sympathetic paraganglia, such as the organ of Zuckerkandl. The concept of neuroblastoma is based on the seminal works of James Homer Wright, William Pepper, and Robert Hutchinson (review: Rothenberg et al. 2009). NTs clearly show the capability to undergo neuronal differentiation and are, therefore, neoplasms different from peripheral primitive neuroectodermal tumors/PNETs, irrespective of certain morphologic similarities. NTs typically exhibit deletion of chromosome 1p parts and N-Myc amplification, but lack the EWS/ETS translocation of PNET. NTs show a broad spectrum of lineages, ranging from primitive neuroblasts, resembling cells of other small cell blue tumors, to differentiating neuroblasts and mature-looking ganglionic cells, and part of the tumors display Schwannian stromal development. Clinical and basic research has shown that NTs

form a heterogeneous group of neoplasms with favorable and unfavorable biologies. Biologically unfavorable NTs (high-risk NTs) reveal an aggressive course and still often cause fatal outcome (reviews: Shimada 2006; Maris et al. 2007; Bell et al. 2014).

Liver involvement by NTs is metastatic in the large majority of cases, the liver being a frequent metastatic site of neuroblastoma. Exceptionally, neuroblastoma was detected in the liver in the absence of (proven) extrahepatic NT, lesions therefore thought to be primary hepatic neuroblastoma.

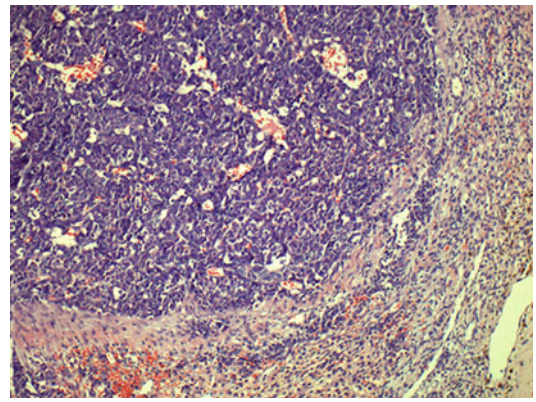

Fig. 6 Metastatic neuroblastoma of the liver (hematoxylin and eosin stain)

Primary Neuroblastoma of the Liver

There are very rare instances of neuroblastoma apparently primary to the liver. Hepatomegaly caused by metastases was found as the presenting sign of stage pattern 4S neuroblastoma in the absence of a primary site outside of the liver (Bujanover et al. 1990). Apparently primary neuroblastoma has been found in adults (Ouakaa-Kchaou et al. 2010; Jung and Kim 2011). In one case, a female patient of age 51 years presented with 9 cm-sized hypodense hepatic tumor with a histology of differentiated neuroblastoma and lymph node metastasis (Ouakaa-Kchaou et al. 2010). In a second patient, a 29-year-old woman, the neoplasm manifested as a solitary hepatic mass. Grossly, this mass was a large, creamy, rubbery form with focal hemorrhage and central cavitation. Despite a thorough systemic survey, including CT scans, no extrahepatic mass was detected. Histology, immunohistochemistry, and electron microscopy revealed a neuroblastic neoplasm. Liver and bone manifestations of neuroblastoma may occur in adults in whom no primary site was determined (Mackay et al. 1976).

Neuroblastoma Metastasis of the Liver: Pepper Type of Neuroblastoma

Liver metastases of neuroblastoma are a typical feature of this neoplasm, particularly in stage pattern 4S (Fig. 6; Bond 1976; Franken et al. 1986).

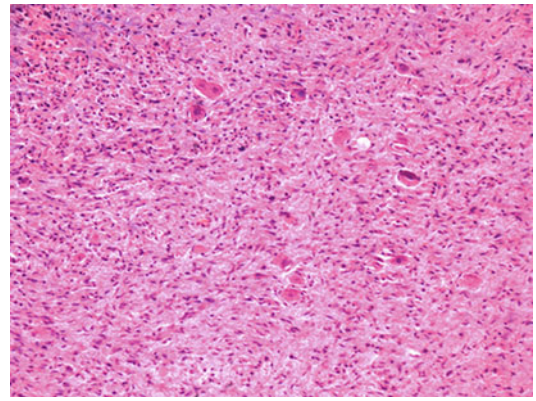

Fig. 7 Metastatic ganglioneuroma of the liver. In a Schwannian stromal background, several ganglionic cells are seen (hematoxylin and eosin)

A predominantly hepatic metastasis pattern is called the Pepper type of neuroblastoma. The most characteristic feature of the Pepper type is the often excessive hepatomegaly (Pepper 1901). In the Hutchinson type, on the other hand, metastases in the skeleton, and particularly the skull, predominate (Hutchinson 1907). Several authors emphasized the significance of these two major metastasis patterns, while other refused to attach any special importance to these types of metastasis. The pathogenic mechanisms involved in these two spreading patterns are still unknown.

Apart from stroma-poor neuroblastoma, also stroma-rich variants, including ganglioneuroma, can metastasize to the liver (Fig. 7).

Metastases are often multiple and thus cause a rapidly enlarging liver (Wyatt and Farber 1941; Schnaufer and Koop 1975; Bond 1976; Halperin 1987). The lesions may later undergo calcification (Ross 1965). Extensive metastatic deposits to the liver have been observed in congenital neuroblastoma (Gupta and Bansal 2012). In one patient with congenital adrenal neuroblastoma and liver metastases, the disease process was associated with Hashimoto-Pritzker disease, a congenital self-healing cutaneous reticulohistiocytosis (Jacob et al. 2009). Liver metastasis of neuroblastoma may also occur via transplacental twin-to-twin metastasis in monozygotic twins (Tajiri et al. 2010). There is a correlation between the frequency of hepatic neuroblastoma metastases and patient age. Analysis of data compiled in early years (Scott et al. 1933; Redman et al. 1938) revealed that the frequency of hepatic metastases above the age of 6 months shows only slight variation, while below that age there is a strong increase in frequency up to birth, reaching the highest values in neonates (Wieberdink 1957). In fact, typical "Pepper patients" are very young. In Pepper's own autopsy series, the age of patients with liver metastases ranged from 1.5 to 16 weeks. This frequency distribution pattern also holds true for extensive hepatic metastasis. After age 6 months, extensive hepatic metastasis is clearly less frequent than metastases in the liver in general (Wieberdink 1957). A rare variant of neuroblastoma prone to produce liver metastases, or bilateral adrenal cystic neuroblastoma, is a distinct phenotype associated with MYCN amplification. The tumors, which are sometimes diagnosed prenatally, present as masses that contain macrocysts and a histology characterized by multiple microcysts (Herman and Siegel 1995; Lee et al. 1998; Chou and Lin 1999; Petit et al. 2001; Pederiva et al. 2007; Haberal et al. 2008). The majority of unilateral cystic neuroblastomas are favorable stage, stroma-poor, but with low or intermediate mitotic-karyorrhectic indices, MYCN amplification negative, and with a favorable outcome (Kozakewich et al. 1998), while bilateral forms show MYCN amplification and marked hepatic spread. Typically, the cystic morphology can be recapitulated in the hepatic metastases (Chacko et al. 2007). Cystic neuroblastoma can undergo massive intracystic hemorrhage (Lee et al. 1998). Due to intratumoral hemorrhage, both primary tumors and their metastases may reveal a three-layer fluid level (Chou and Lin 1999). In part of patients, liver metastases of neuroblastoma may undergo spontaneous regression (D'Angio et al. 1971; Schwartz et al. 1974). It was suggested that congenital neuroblastoma might have the greatest propensity for regression (Komuro et al. 1998).

The metastatic potential of neuroblastomas is regulated by distinct factors and mechanisms. It is well known that amplification of N-myc in untreated human neuroblastoma correlates with advanced disease stage (Brodeur et al. 1984; Schwab 1994; Tsuchida et al. 1996). N-myc enhances cell growth, IGF-IR expression, and tumorigenicity in combination with Bcl-2 (Castle et al. 1993; Ikegaki et al. 1995). N-myc repression of beta1-integrin expression may result in a less differentiated phenotype (van Golen et al. 2003). In a multivariate analysis, it surfaced that N-Myc amplification and Shimada UH both emerged as independent prognostic factors and that most N-myc-amplified tumors had in fact an unfavorable histology and a poorer prognosis (George et al. 2001). In aggressive N-myc-amplified neuroblastomas, the c-kit receptor and its stem cell factor (SCF) ligand are preferentially expressed, and their signaling is active in promoting neuroblastoma cell proliferation (Vitali et al. 2003). Expression of full-length trkB (p145; BDNF/neurotrophin-4/5 receptor) can be found in some highly aggressive neuroblastomas with N-myc amplification, and trkB expression is induced by all-trans retinoic acid (Edsjo et al. 2003). Activation of the PI3K/AKT pathway correlates with poor prognosis in these neoplasms and requires expression of the N-myc oncogene. Specifically, N-myc expression is regulated by the AKT2 isoform of AKT. AKT2 promotes migration and invasion of neuroblastoma cells and induces hepatic metastasis (Qiao et al. 2013). Metastasis of neuroblastoma to the liver is also linked to the expression of gastrin-releasing peptide receptor (GRP-R) expression in neuroblastoma cells. Focal adhesion kinase/FAK is a critical

downstream target of GRP-R. FAK and GRP-R are co-expressed in neuroblastoma, and their overexpression promotes flattening of tumor cells, migration, and metastasis (Lee et al. 2012b). Inhibition of FAK decreases cell invasion, migration, and metastasis in N-Myc-amplified neuroblastoma (Megison et al. 2013). Anaplastic lymphoma kinase (ALK), the gene of which is a predisposition gene for familial neuroblastoma (Mossé et al. 2008), plays a role in neuroblastoma growth and may be involved in tumor spread. As hepatic metastasis in neuroblastoma is a predominant feature of poorly differentiated neuronal phenotypes of tumors, factors affecting differentiation pathways may influence metastatic spread. Certain microRNAs define distinct neuroblastoma cell phenotypes. MicroRNA-124 induces terminal neuronal differentiation with reduced malignancy, while increased levels of microRNA-21, microRNA-221, and microRNA-335 characterized nonneuronal, nonmalignant phenotypes by blocking neuronal differentiation (Samaraweera et al. 2014). The metastatic features of neuroblastoma are also modulated by tumor-associated inflammatory cells. Metastatic neuroblastomas showed higher infiltration levels of tumor-associated macrophages/TAMs than locoregional tumors (Asgharzadeh et al. 2012).

Neuroblastoma as a Component of Mixed Hepatic Tumors

A large hepatic tumor detected in a 3-year-old child displayed a mixture of hepatoblastoma, neuroblastoma, and malignant teratoma with rhabdomyosarcomatous differentiation (Moll et al. 2009).

Focal Nodular Hyperplasia (FNH) of the Liver in Patients with Neuroblastoma

Similar to other solid pediatric tumors treated with chemotherapy, long-term survivors of neuroblastoma can develop focal nodular hyperplasia (FNH) of the liver, FNH being regarded as a late effect of cytotoxic therapies (Bouyn et al. 2003; Joyner et al. 2005; Freidl et al. 2008; Marabelle et al. 2008; Benz-Bohm et al. 2010; Sugito et al. 2011). In a retrospective study of 14 cases of FNH found in children following chemotherapy of malignancy, FNH was discovered by chance during routine examination in 78 % of patients (Bouyn et al. 2003). In an analysis of four pediatric patients with neuroblastoma, nephroblastoma, and GISTs, FNH developed 2, 2.5., 3, and 8 years after successful treatment of their primary malignancies (Freidl et al. 2008). Pathogenetically, it has been proposed that high doses of alkylating agents, veno-occlusive disease, and hepatic radiotherapy may be responsible for vascular injury favoring the development of hepatocyte hyperplasia and FNH (Bouyn et al. 2003). The overall incidence of FNH in this target population of patients varied markedly, being 0.45 % in one (Bouyn et al. 2003) and 9.4 % in another study (Sugito et al. 2011).

Hypervascular Hepatic Nodules in Childhood Neuroblastoma Survivors

Children with a history of solid tumors treated with chemotherapy, including neuroblastoma, can develop hypervascular hepatic nodules (HHNs) in their livers. The time interval between therapy and the diagnosis of HHNs ranged from 3.2 to 8.5 years, and HHNs present as small and often multiple hypo-or isoechoic nodules, showing a strong enhancement on sequential early-phase postcontrast CT images, turning to isoattenuated lesions during the later phase (Lee et al. 2012a; Yoo et al. 2013).

Morphology of Neuroblastic Tumors

Neuroblastoma tumors (NTs) and cell lines are heterogeneous in regard to cell lineages and differentiation patterns. Basically, neuroblastomas consist of a tumorigenic neuroblastic phenotype and a nonneuronal non-tumorigenic phenotype (S-cells). Neuroblastic cells can undergo neuronal differentiation and include stem cells (I-cells) and neuronal cells (N-cells).

Morphology of Neuroblastic/Neuronal Lineages

Cells of the neuroblastic lineage are mostly small elements with scant cytoplasm, indistinct cell borders, and a high nuclear-to-cytoplasmic ratio. The cells resemble those of other small cell blue tumors. The nuclei are small and round and display a stippled ("salt-and-pepper") chromatin. Undifferentiated and poorly differentiated neuroblastomas may show larger cells with prominent nucleoli. The neuroblastic cells form solid cellular masses, with necroses and sometimes calcifications. Neuroblastomas exhibit variable infiltrates of lymphocytes, indicating an antitumor immune response. Differentiating neuroblastic tumors form focal eosinophilic neuropil clusters, around which the tumor cells may be arranged in a radiating pattern. These structures are termed Homer Wright rosettes or, more correctly, Homer Wright pseudorosettes, as true rosettes, such as Flexner-Wintersteiner rosettes, contain an empty lumen. Note that Homer Wright should be written without a hyphen: James Homer Wright (1869–1928; Massachusetts General Hospital) described the structures in 1910 and is well known for the Wright stain in hematology (Wright 1910; reviews: Yanoff 1990; Lee et al. 2002; Rothenberg et al. 2009). Immunohistochemically, the tumor cells are reactive for synaptophysin, neuron-specific enolase, chromogranin A, and, as a function of neuronal differentiation, neurofilaments. Early members of the NT lineage can be identified by positivity for PHOX2B. Ganglioneuroblastomas and ganglioneuromas contain differentiating or differentiated neuronal/ganglionic cells with abundant cytoplasm containing basophilic Nissl substance (rough endoplasmic reticulum) and large round-to-oval nuclei with prominent nucleoli.

The differentiation pathways leading from stem-like undifferentiated cells (I-cells) to mature neuronal cells have in part been elucidated and are currently tested in the light of future treatment strategies. The self-renewal of tumor-initiating I-cells is linked to kit expression (Lau et al. 2014). Factors promoting neuroblast formation and differentiation comprise N-Myc expression (Guglielmi et al. 2014) and certain cell adhesion molecules (exendin-4; Luciani et al. 2013). N-Myc/MYCN promotes the expansion of PHOX2B-positive neuronal progenitors to become N-cells (Alam et al. 2009). A central role in differentiation is played by the homeobox protein HOXC9 (Wang et al. 2014b). Neuronal differentiation associated with cell cycle exit is induced by the Down syndrome-related protein kinase, DYRK1A, which phosphorylates p27 (KIP1) and cyclin D1 (Soppa et al. 2014). Differentiation of neuroblastoma cells is also programmed by distinct sets of microRNAs (Zhao et al. 2014).

Morphology of Nonneuronal Cell Lineages

Schwannian stromal cells (S-cells) are pale or eosinophilic spindled elements that form a cellular background or clusters of cells interspersed with neuronal cells. Cells of this Schwannian stroma are S100 protein positive. A Schwannian cell component varies markedly among NTs, ranging from complete lack of such cells to Schwannian stroma-rich neoplasms. S-cells modulate the behavior of N-cells in a complex fashion (Liu et al. 2005). There is evidence that S-cells prevent the activation of fibroblasts in NTs (Zeine et al. 2009). The cellular origin of nonneuronal S-cells that form a Schwannian stromal component is not yet fully clarified, but there is evidence that these cells form the stromal component recruited by the neuroblastic tumor cells (review: Shimada 2006). In vitro, neuroblastoma cells can promote Schwann cell proliferation (Ambros et al. 2001). It was proposed that N-cells and S-cells originate from a tumor progenitor cell (Mora et al. 2001), but a later study showed that S-cells do not harbor the genetic alterations of N-cell but may share the same clonal origin (Bourdeaut et al. 2008). Gene expression profiling revealed that N-cells differ from S-cells with respect to the degree of DNA imbalance (Coco et al. 2005). In a human neuroblastoma cell line model, transitions between N-cells and S-cells were found, S-cell formation being induced by

depletion kinase D-interacting substrate of 220kD/Kidins220 (Rogers and Schor 2013).

Classifications of Neuroblastic Tumors

The classification of the International Neuroblastoma Pathology Committee (the International Neuroblastoma Pathology Classification (INPC); Shimada et al. 1999a, b) is shown in Table 1. This classification was found to have prognostic value (Burgues et al. 2006).

Schwannian stroma-poor neuroblastoma (NB) has a more favorable subgroup (favorable histology, FH) and an unfavorable subgroup (unfavorable histology, UH). The favorable subgroup in <1.5 year patients consists of poorly differentiated or differentiating and low or intermediate MKI tumors and in 1.5–5 year patients of differentiating and low MKI tumors. The unfavorable group in <1.5 year patients consists of (a) undifferentiated tumor (a rare subtype) and (b) high MKI tumor; in 1.5–5 year patients, it consists of (a) undifferentiated or poorly differentiated tumor and (b) intermediate or high MKI tumor; and in >5 year patients, all tumors. The Schwannian stroma-rich NT represents ganglioneuroblastoma, intermixed (GNBi), while the Schwannian stroma-dominant NT includes ganglioneuroma (GN), maturing and mature. The composite Schwannian stroma-rich/stroma-dominant and stroma-poor tumors form ganglioneuroblastoma, nodular (GNBn). The only differences between the original Shimada classification and the INPC are (1) to subdivide the "undifferentiated" subtype in the former classification into two subtypes or undifferentiated and poorly differentiated in the latter classification and (2) to change the name of "stroma rich, well differentiated" in the former classification to " ganglioneuroma, maturing" in the latter classification.

Table 1 International Neuroblastoma Pathology Classification (INPC)

Four basic categories of NTs
Neuroblastoma (Schwannian stroma poor), NB
Ganglioneuroblastoma, intermixed (Schwannian stroma rich), GNBi
Ganglioneuroma (Schwannian stroma dominant), GN
Ganglioneuroblastoma, nodular (composite, Schwannian stroma rich/stroma dominant and stroma poor), GNBn
Subcategories (subtypes) of neuroblastoma/NB (grade of neuroblastic differentiation)
Undifferentiated
Poorly differentiated
Differentiating
Subcategories of ganglioneuroma/GN (complete or incomplete stage of final maturation)
Maturing
Mature
Subcategories of ganglioneuroblastoma, nodular/ GNBn
Favorable
Unfavorable

In an analysis of the morphologic features in clinically favorable and unfavorable groups of Schwannian stroma-poor neuroblastomas, it turned out that nuclear size, cellularity, prominent nucleoli in undifferentiated or poorly differentiated neuroblasts, and the number of mitotic or karyorrhectic cells (MKI) showed a significant correlation with clinical groups, identifying an unfavorable clinical course (Ambros et al. 2002). Subsequently it turned out that the combination of histopathologic evaluation and N-myc status distinguished four clinical and biologic tumor subsets in patients with NT. Expression of N-myc, which is known to cause DNA instability, in an amplified state can be a powerful driving force for preventing neuroblastic differentiation age independently and for increasing mitotic and karyorrhectic activities age dependently (Goto et al. 2001).

Abstract

Malignant melanoma (MM) is an aggressive malignancy that frequently involves the hepatobiliary tract, due to the frequent metastases to the liver. Therefore, most of malignant melanotic lesions detected in the liver and bile ducts are metastases of skin melanomas. But there is a small group of MM that takes its origin in the hepatobiliary tract, albeit the cell of origin is not yet known, possibly a neural crest cell that homed to this organ during embryogenesis. Primary MM is well documented for extrahepatic bile ducts and the gallbladder, where primary MMs have been described since long. In particular, primary gallbladder MM is a recognized entity with characteristic growth patterns. In contrast, primary hepatic MM is less well defined and numerous cases published in the old literature may be misinterpretations because metastatic disease is difficult to exclude in many cases, because the primary tumor may have been missed or had regressed. A distinct situation is ocular MM which is known to produce liver metastases after a long time delay. There are rare other melanotic tumors that can manifest in the liver, including melanotic progonoma. A tumor related to MM and known to have visceral manifestations is clear cell sarcoma or melanoma of soft parts.

Primary Malignant Melanoma of the Liver

Introduction

In contrast to primary malignant melanomas of the bile ducts and the gallbladder, which are well-recognized entities and are discussed in the following paragraphs, melanoma primary to the liver not related to the biliary tract is an exceptional finding. As with other melanomas in this anatomical compartment, diagnosis of a primary localization to the liver requires careful exclusion of metastatic disease, in particular metastasis of uveal melanoma, which is known to produce liver metastasis after long delays (see below). The difficulty in excluding extrahepatic primary melanoma renders at least part of the older reports questionable. In a study on 473 extraorbital malignant melanomas published in 1900, 362 tumors had taken their origin in the skin, 65 were related to the intestinal tract and the genital organs, and 46 to inner organs. Among the latter, a primary site to the liver was regarded as possible in seven cases (Luther 1900). At the end of this chapter, the older literature referring to well-documented or purported primary malignant melanomas is summarized.

Selected References von Frerichs 1861; Block 1875; Hanot and Gilbert 1888; Nencki and Sieber 1888; Luther 1900; Nazari 1906; Mansson 1926; Smith 1926; Koch 1930; Konschegg and Hada 1937; Lence 1937; Boj 1954; Tacquet et al. 1959; Ogan et al. 1961; Vido et al. 1964; Adel'shinova 1969; Furuta et al. 1995; Zhang and Zhao 1995; Li et al. 2003; Wang et al. 2005; Hu 2006; Gong et al. 2008.

Pathology

Malignant melanoma primary to the liver shares histopathology and immunohistochemistry with extrahepatic melanomas (Figs. 1, 2, 3, 4, and 5).

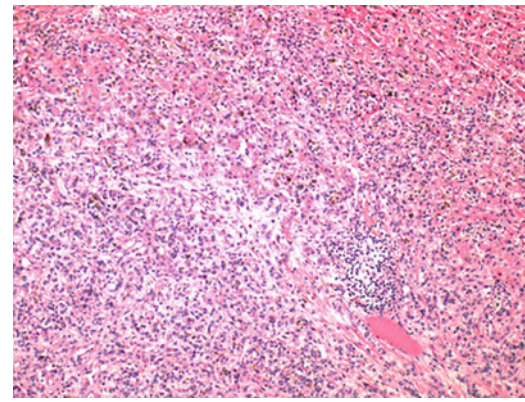

Fig. 1 Malignant melanoma with apparent primary localization to the liver. The pigment-containing tumor cells have partially destroyed the liver parenchyma (hematoxylin and eosin stain)

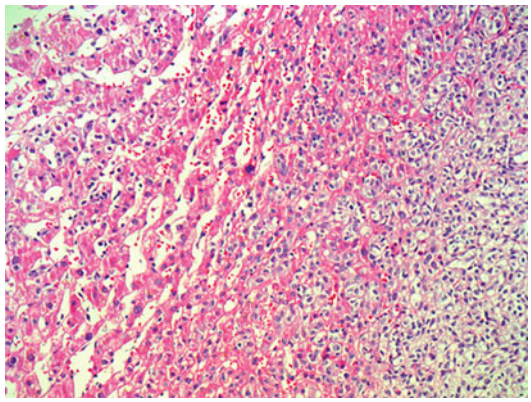

Fig. 2 Metastasis of malignant melanoma in the liver. Neoplastic cells invade the hepatic sinusoids (hematoxylin and eosin stain)

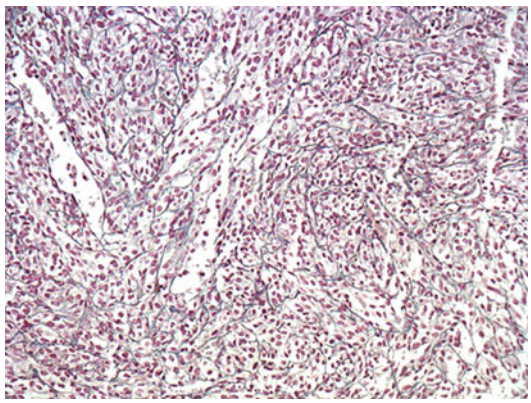

Fig. 3 Malignant melanoma in the liver. Clusters and nests of melanoma cells are surrounded by reticulin fibers (Gomori silver stain)

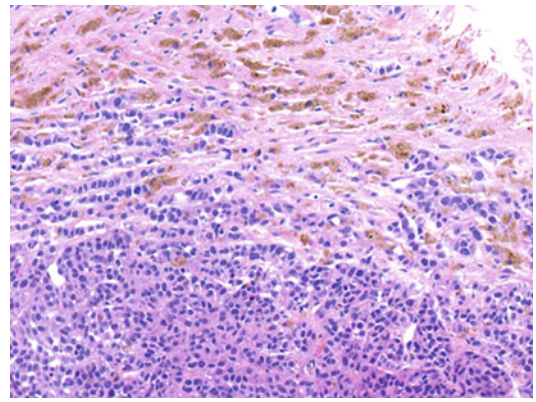

Fig. 4 Malignant melanoma in the liver. The tumor has a low level of melanin pigmentation, but melanin has accumulated in tumor-associated macrophages (melanophores, upper part of figure; hematoxylin and eosin stain)

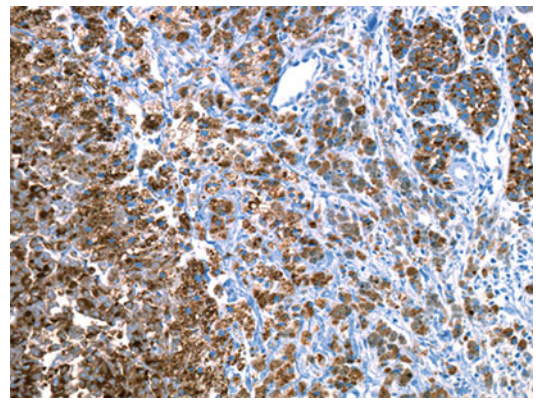

Fig. 5 Malignant melanoma in the liver. Tumor cells are strongly HMB-45 reactive (HMB-45 immunostain)

An autopsy report described the lesion as a large black mass surrounded by fibrous tissue (Furuta et al. 1995). In another patient who had undergone liver resection, the oval and well-delineated tumor, measuring up to 12 cm in diameter, had grayish-yellow cut surface, reflecting hypomelanotic melanoma (Gong et al. 2008).

Histopathology

In the case described by Gong et al. (2008), the histology was characterized by typical spindled and pleomorphic melanoma cells with or without pigment, immunoreactive for HMB-45, and showing few melanosomes in electron micrographs.

Malignant Melanoma of the Bile Ducts

Introduction

Primary malignant melanoma of the bile duct system is very rare, and certainly much less common than gallbladder melanomas. As outlined in more detail in the paragraph on melanoma of the gallbladder, identification of the bile duct as a

primary site of melanoma may be difficult to distinguish from metastatic disease. Similar to the gallbladder, careful exclusion of melanoma situated elsewhere and the observation of junctional activity in the biliary mucosa are important criteria (Wagner et al. 2000). The first case reported was a melanoma located in the distalmost common bile duct and Vater's diverticulum (Duval 1908), followed by the description of an apparently isolated tumor in the common duct only 55 years later (Zaide 1963). The 47-year-old male patient described by Zaide presented with a 3-month history of obstructive jaundice, and common duct resection showed typical melanoma.

Localizations and Clinical Features

Primary malignant melanoma of the biliary tract has been detected in all parts of the extrahepatic duct system, i.e., involving the bifurcation (confluens) of the large duct (Washburn et al. 1995; Gonzalez et al. 2001), hepatic and common bile ducts combined (Deugnier et al. 1991), the common bile duct (Duval 1908; Shepherd 1908; Zaide 1963; Breatnach et al. 1985; Carstens et al. 1986; Wright and Brewer 1988; Cohen et al. 1990; Zhang et al. 1991; Gates et al. 1996; Wagner et al. 2000; Medina et al. 2003; Bejarano Gonzalez et al. 2005), and the ampulla of Vater (Duval 1908; Washburn et al. 1995; Fléchon et al. 2002). Melanoma of the common bile duct may be combined with melanoma in the gallbladder (Zhang et al. 1991; Medina et al. 2003).

The first case, reported in 1908 (Duval 1908), is instructive owing to its morphology and was described as melanoma of Vater's diverticulum and lower portion of the common bile duct. The neoplasm ("melanophoroma") had developed in a 44-year-old man who presented with deep jaundice. It had caused complete obstruction of the distal common duct and was a dark-brown cylindrical mass of 2.5 cm in diameter. A careful search during autopsy failed to establish the metastatic nature of this growth. Interestingly, this melanoma revealed a papillary growth pattern, described as showing "innumerable densely arranged flattened fingerlike projections which floated free in their distal extremities, but remained firmly attached at their bases".

Both common bile duct and ampullary melanoma may, expectedly, cause obstructive jaundice (Zaide 1963; Wright and Brewer 1988; Washburn et al. 1995; Bejarano Gonzalez et al. 2005), and complete obstruction was already described in 1908 (Duval 1908). Sonography and CT usually display dilatation of intra- and extrahepatic bile ducts caused by tumor-induced stenosis (Wagner et al. 2000; Van Bokhoven et al. 2006). Melanoma primary to the common bile duct has low signal intensity on T2-weighted images and high signal intensity on unenhanced T1-weighted images (Medina et al. 2003). Endoscopic retrograde cholangiopancreatography (ERCP) has revealed lobulated filling defects in the common duct (Wagner et al. 2000).

Pathology

Macroscopy

Relatively few cases contained a documentation of gross findings. Zaide (1963) described a cauliflowered, friable, black tumor in the common bile duct. In the case of Carstens and coworkers (1986), the Whipple resection specimen disclosed a brown polypoid mass of the common bile duct, measuring up to 1.3 cm. The tumor may infiltrate the common duct wall over longer distances, over a length of 10 cm in one patient (Deugnier et al. 1991). Zhang et al. described a 58-year-old man with a 1-cm, lobulated, soft black mass of the common bile duct, as well as a concurrent mass involving the gallbladder (Zhang et al. 1991). In the case reported by Wagner and coworkers, the resected specimen (Whipple procedure) demonstrated a dilated common bile duct that contained a large, fungating and polypoid, pediculated, white-tan to gray-brown mass located to the midportion of the duct and measuring 4.0 × 2.0 × 1.9 cm (Wagner et al. 2000). The lesions developing in the common bile duct have been described as polypoid, similar to primary melanoma of the gallbladder, in another report (Medina et al. 2003),

Histopathology

Primary common duct and ampullary melanomas show polypoid, mucosal, and/or submucosal tumor nodules of variable size, immunoreactive for HMB-45 and Melan-A (Wagner et al. 2000; Fléchon et al. 2002). Electron microscopy demonstrated premelanosomes type I, electron-dense granules consistent with melanin pigment, and coiled, vesicular, and spiral filaments in the cytoplasm (Wagner et al. 2000).

Immunohistochemistry

Malignant melanoma cells express a characteristic spectrum of markers (reviews: Ohsie et al. 2008; Prieto and Shea 2011). More than 90 % of the tumors are positive for S100 protein. Both polyclonal and monoclonal anti-S100 protein antibodies label melanocytic lesions, with a cytoplasmic and nuclear pattern. HMB-45 antibody detects gp100, a glycoprotein that is fairly specific for cells of the melanocyte linage and melanomas (Rothberg et al. 2008), but HMB-45 also stains perivascular epithelioid cells and their tumors (PEComas). An important marker is MART1 (melanoma antigen recognized by T cells-1; Busam et al. 1998). This antigen is detected by two antibodies, Melan-A and A-103. MART1 is expressed by both benign and malignant melanocytic cells. It has to be noted that MART1 is also expressed by PEComas (similar to HMB-45) and that A-103 also stains cells of steroid hormone-producing tumors. Tyrosinase is expressed in cells of the melanocyte lineage. Microphthalmia transcription factor (MITF) is a nuclear protein involved in the development of melanocytic cells and synthesis of melanin. It is expressed in melanomas with a nuclear staining pattern, but it may also be expressed by macrophages, lymphocytes, and fibroblasts. Schwann cells and smooth muscle cells. Melastatin-1 (MLSN1, TPRM1) is highly expressed in melanocytic nevi, but it is absent from melanoma metastases. The expression of MLSN1 inversely correlated with tumor thickness (review: Dadras 2011).

Malignant Melanoma Metastatic to the Bile Ducts

An autopsy study demonstrated that patients with metastasizing melanoma had biliary duct metastases in 6 %, in contrast to 15 % with metastases to the gallbladder (Das Gupta and Brasfield 1964). The metastatic sites involve the common bile duct (Armbruster 1973; Cole and Freston 1973; Bowdler and Leach 1982; Daunt and King 1982; McArthur and Teergarden 1983; O'Connell et al. 1984; Kohler and Riemann 1987; Cohen et al. 1990; England and Sarr 1990; Parquier et al. 1991; Thompson et al. 1993; Garas et al. 2000; Grasso et al. 2003; Uchikov et al. 2004; Cardot-Leccia et al. 2005; Van Bokhoven et al. 2006; Colovic et al. 2007; Rezanko et al. 2008), the cystic duct (O'Connell et al., 1984), and the ampullary region (Sans et al. 1996; Van Bokhoven et al. 2006). Metastasis to the common bile duct may cause obstructive jaundice with marked cholestasis, sometimes combined with hemobilia (Cole and Freston 1973; McArthur and Teergarden 1983; Kohler and Riemann 1987; England and Sarr 1990; Parquier et al. 1991; Thompson et al. 1993; Brankamp et al. 2007).

Metastasis-induced common bile duct stenosis can be demonstrated by the use of endoscopic retrograde cholangiopancreatography, showing filiform stenosis in one reported patient (Brankamp et al. 2007) and a complex filling defect in another (Garas et al. 2000). The lesions are also demonstrated by intraoperative cholangiography (Colovic et al. 2007). Expectedly, also melanoma metastatic to the ampulla may cause massive stenosis and obstructive jaundice (Sans et al. 1996; Caballero-Mendoza et al. 1999). At imaging, metastatic melanoma of the common bile duct may appear as a vegetating lesion on CT images (Grasso et al. 2003) or produce a spherical filling defect (Thompson et al. 1993). Retrograde cholangiopancreatography (ERCP) shows bile duct compression and intraluminal impressions that resist removal with a basket or balloon (Garas et al. 2000), lobulated filling defects (Van Bokohoven et al. 2006), or large intraductal masses (Garas et al. 2000). During ERCP, cell material can be obtained. It has been reported that metastatic melanoma of the common bile duct can be diagnosed with brush cytology

(Brankamp et al. 2007; Rezanko et al. 2008). In case of ampullary metastasis, endoscopy has revealed a dark-brown, easily bruising lesion bulging from the mucosal surface (Van Bokhoven et al. 2006).

Few gross findings are available from the literature. In one patient, the choledochal resection specimen revealed a large lobulated and polypoid mass stenosing the duct (Brankamp et al. 2007).

Primary Malignant Melanoma of the Gallbladder

Introduction

The gallbladder is one of the rarest sites of visceral malignant melanoma. The first case was reported in 1907 under the term melanoblastoma of the gallbladder (Wieting and Hamdi 1907). In this 40-year-old female patient, generalized metastases owing to melanoma were found, caused by primary gallbladder melanoma. Relatively few cases have since been described. As with other mucosal malignant melanomas, most of the patients are in the fourth of fifth decade of life at the time point of diagnosis (Velez et al. 1995). Among 29 cases reviewed from the literature, age at presentation ranged from 25 to 74 years, with 17 males and 12 females (Ricci et al. 2001). Primary gallbladder melanoma has been observed in conjunction with dysplastic nevus syndrome (Ricci et al. 2001).

Selected references Rosenthal 1931; Pautler and Gallavan 1951; Thayer et al. 1955; Kazmann and Zukaukas 1956; Walsh 1956; Larmi 1960; Jones 1961; Raffensberger et al. 1963; Simard et al. 1966; Das Gupta et al. 1969; Balthasar and Javors 1975; Peison and Rabin 1976; Sierra-Calejas and Warecka 1976; Hatae et al. 1978; Carle et al. 1981; Anderson et al. 1983; Borja et al. 1984; Naguib and Aterman 1984; Seul and Lüchtrath 1984; Rudolph et al. 1985; Verbanck et al. 1986; Heath and Womack 1988; Guerini et al. 1990; Zhang et al. 1991; Habeck 1993; Hatanake et al. 1993; Higgins and Strutton 1995; Velez et al. 1995; Longwitz et al. 1996; Saoshiro et al. 1996; Dong et al. 1999; De Simone et al. 2000; Ricci et al. 2001; Medina et al. 2003; Rea and van Heerden 2004; Safioleas et al. 2006; Martel et al. 2009.

It is difficult to judge whether all the reported cases were in fact bona fide primary tumors or rather melanoma metastases, which are well known to occur in the gallbladder (see below; Higgins and Strutton 1995; Safioleas et al. 2006). Heath and Womack (1988) suggested that certain criteria should be fulfilled before primary melanoma is diagnosed: (1) tumors must be solitary and arise from the mucosal surface of the gallbladder; (2) they must either by papillary or polypoid; and (3) they must either display junctional activity or have any other primary sites excluded by history taking, examination, and investigation. Using these guidelines, these authors have identified 15 cases in the literature that did not fulfill the required criteria. Ricci and coworkers (2001) proposed the following criteria: (1) the exclusion of a previous primary melanoma, (2) the absence of synchronous involvement of sites other than the considered one, (3) the unicity of the lesion, (4) its polypoid or papillary shape, and (5) the presence of a junctional melanocytic component. However, the authors emphasized that these criteria are weak, particularly if singly taken. It is, e.g., known that melanoma metastatic to the gallbladder can be polypoid or show intraepithelial spread with junctional activity (Murphy et al. 1987; Dong et al. 1999). In case all of the mentioned criteria must be fulfilled, the number of bona fide primary gallbladder melanomas would probably be reduced to less than 10.

Clinical and Imaging Features

Clinically, this lesion may mimic gallstone disease and/or may present as acute acalculous cholecystitis (Peison and Rabin 1976; Dong et al. 1999; De Simone et al. 2000). Ultrasound demonstrates hyperdense intraluminal strands of tumor, sometimes with hyperechogenic intraluminal "school of fish" reflections (Longwitz et al. 1996). CT often reveals solid intraluminal masses with a hypodense and partially hyperdense reticular structure, reflecting

the common polypoid growth pattern of these melanomas. Gallbladder melanoma often gives rise to metastatic disease (in 9/13 cases reviewed by Carle et al. 1981). Primary gallbladder melanoma may metastasize to the common bile duct, eventually via mucosal implants (Verbanck et al. 1986). Information about the metastatic involvement of the cystic duct lymph node is very sparse. In one report, it was specified as not involved (Ricci et al. 2001).

Pathology

Macroscopy

Primary malignant melanoma of the gallbladder shows several distinct growth patterns (Table 1).

In the first reported case, gallbladder melanoma presented as a polypoid tumor sitting on a rather broad base and measuring up to 2 cm. The surface of the polyp was irregularly nodular, and the mucosal covering was missing. This melanoma was much lighter in color than the numerous metastases (Wieting and Hamdi 1907). Polypoid growth with formation of sometimes black polyps has subsequently been observed several times (e.g., Rosenthal 1931; Peison and Rabin 1976; Carle et al. 1981; Borja et al. 1984; Habeck 1993; Ricci et al. 2001). Polypoid melanoma is probably the most common pattern encountered: in a compilation of 13 cases of primary gallbladder melanoma (Carle et al. 1981), 11 tumors showed a polypoid growth pattern. In a study of 29 patients collected from the literature, 24 lesions were polypoid or papillary, and 13 were described as single polypoid (Ricci et al. 2001).

Of differential diagnostic importance is the size of primary gallbladder melanomas. In the five cases reviewed by Walsh (1956), the size of the exclusively polypoid lesions ranged from 2 to 7.5 cm in length and 2–4 cm in width, what is in contrast to the few millimeters given by Willis for the usual size of metastatic deposits (Willis 1952). Beneath the melanoma polyp, smaller tumor nodules may penetrate deeper layers of the gallbladder wall (Borja et al. 1984). Gallbladder melanoma may also show a diffuse mucosal growth. A further morphotype is the presentation as brown to black patches and slightly raised plaques (Rosenthal 1931). Nodular or mass-forming melanoma has also been noted (Pautler and Gallavan 1951; Walsh 1956). The case of Walsh (1956) was a 45-year-old male patient admitted for biliary colic. Under suspicion of stones cholecystectomy was performed. The patient had a small scar in the center of the forehead, but there was no history of cutaneous melanoma and no evidence of ocular melanoma. The resection specimen showed a mottled yellow-brown trilobulated tumor mass extending from the midportion of the gallbladder almost to the fundus, measuring 7.5 × 2.5 × 1.0 cm.

Table 1 Gross growth patterns of gallbladder melanoma

Growth as plaques or patches
Polypoid (exophytic) pattern
Nodular pattern
Mass-forming pattern

Histopathology

In the few available reports, the histology of gallbladder melanoma is more or less the same as that in other visceral locations. The lesions may be surrounded by clusters of melanin-containing macrophages (melanophores, melanophages; Hatae et al. 1978). The gallbladder epithelium overlaying the melanoma nodules may be infiltrated by lymphocytes (Borja et al. 1984). Of interest is the observation of active junctional changes in scattered foci of altered mucosa overlying a melanoma: in one case, large round cells with hyperchromatic nuclei and spongy cytoplasm were scattered at or near the basal layer of the gallbladder mucosa, at one place associated with squamous metaplasia of the surface epithelium. In this multilayered squamous epithelium, a pagetoid pattern of large atypical melanocytes was seen (Walsh 1956). Small clusters as well as individual tumor cells containing fine granular pigment within the columnar epithelium or forming a junctional component were seen in other cases (Peison and Rabin 1976; Carle

et al. 1981; Borja et al. 1984; Heath and Womack 1988; Ricci et al. 2001). In one case, a focus of active junctional changes was found in normal mucosa at a distance from the tumor, and the melanocytes, which appeared wedged between the columnar cells, showed no nuclear atypia (Peison and Rabin 1976). In Fig. 8 of their report, it is seen that slender and highly pigmented cells are intercalated between epithelial cells, sometimes occupying the entire space between two neighboring columnar cells from their basal to apical portions. At other places, larger but again markedly melanized cells occupy the junctional area, but rather at locations lacking intercalated melanocytes. These findings suggest changes derived from preexisting mucosal melanocytic cells or neural crest cells. It has been argued that an activated junctional nevus is a prerequisite of mucosal melanoma (Allen and Spitz 1953). Walsh (1956) who noted the combination of a squamous metaplasia and junctional activity thought that melanoma may have developed in this squamous cell epithelium of the gallbladder. This is worth considering because a squamous epithelium may represent a homing site for melanocyte precursors. Taken together, junctional activity has been suggested to be an important criterion for the diagnosis of primary melanoma of the gallbladder (Heath and Womack 1988). The apical portion of columnar mucosal epithelial cells may contain melanin pigment granules, probably representing shedded melanosomes phagocytosed from the gallbladder lumen (Hatae et al. 1978; Carle et al. 1981).

Malignant Melanoma Metastatic to the Gallbladder

The most important differential diagnosis of primary gallbladder melanoma is malignant melanoma metastatic to the gallbladder, a metastasis pattern that is well recognized in the literature. It has been reported that involvement of the gallbladder occurs in about 15 % of all gastrointestinal metastatic localizations in postmortem case records (Das Gupta and Brasfield 1964). In a study of 19 patients, the median age at presentation was 46.7 years; ten of the primary cutaneous melanomas were of the superficial spreading type, three were nodular, and most lesions showed Clark levels of either III or IV (Dong et al. 1999). Both abdominal CT and right upper quadrant ultrasonography are useful in uncovering the presence of gallbladder metastases. Metastatic melanoma lesions are usually smaller than primary tumors of the gallbladder and often present as flat intramural nodules in addition to the well-known polypoid lesions. Involvement of the gallbladder seldom produces symptoms, but melanoma metastases in the gallbladder may rarely cause acute cholecystitis (Henriques 1955; Ostick and Haqqani 1976; Langley et al. 1997) or masquerade cholelithiasis (Herrington 1965).

Selected references Das Gupta and Brasfield 1964; Zemlyn 1966; Shimkin et al. 1972; McFadden et al. 1979; Bundy and Ritchie 1982; Murphy et al. 1987; Stutte et al. 1989; Goldin 1990; Hahn et al. 1993; Avila et al. 1994; Gawenda et al. 1995; Abdelli et al. 1996; Bedo et al. 1996; Holloway and King 1997; Seelig and Schönleben 1997; Dong et al. 1999; Hallal et al. 1999; Paolini et al. 1999; Cellerino et al. 2000; Köhler et al. 2000; Guida et al. 2002; Gogas et al. 2003; Crippa et al. 2004; Gassler et al. 2004; Uchikov et al. 2004; Rehani et al. 2006; Romero et al. 2006; Varsamidakis et al. 2006; Katz et al. 2007; Marone et al. 2007; Nelms et al. 2007; Takayama et al. 2007; Tuveri and Tuveri 2007; Samplaski et al. 2008.

Macroscopy

The majority of the metastatic lesions are serosal implants. Mucosal metastases were seen in 7/19 patients at autopsy (Das Gupta and Brasfield 1964). A polypoid, intraluminal growth pattern has also been noted in metastatic gallbladder melanoma, but is a rare finding, in contrast to primary gallbladder melanoma (Henriques 1955; Das Gupta and Brasfield 1964; Ostick and Haqqani 1976). In one case, this metastatic growth pattern

was associated with cholecystitis, probably cause by obstruction (Henriques 1955). Gallbladder metastasis may develop in association with melanoma metastasis to the common bile duct (Uchikov et al. 2004).

Liver Metastases of Cutaneous and Visceral Melanomas

Introduction and Epidemiology

The liver is a major metastasis-susceptible site and is thought to possess a distinct prometastatic microenvironment (Vidal-Vanaclocha 2008). Malignant melanoma frequently metastasizes widely to many organs, and the liver is involved in at least 10–20 % of cases (Rose et al. 2001) and, probably, in up to one third of cases. However, these figures markedly depend on the methods employed to detect metastasis and on the stage of disease at the moment of metastasis assessment. Among a total of 652 patients with malignant melanoma treated between 1935 and 1960 at a North American center, only 27 or 4 % presented with evidence of the liver as the first site of metastasis, initial clinical evidence of metastasis being hepatomegaly and abnormal liver tests. In contrast, 84 out of 124 patients (60 %) with stage III disease (melanomatosis) had hepatomegaly and 44 % of this group (37 patients) had laboratory evidence of liver malfunction, but only 7 (8 %) of the 84 patients had clinical jaundice. Among 125 autopsy cases, the incidence of metastasis to the liver was 68 % (Das Gupta and Brasfield 1964).

Clinical Features

Hepatic melanoma metastases cause sometimes massive hepatomegaly associated with ascites. They may rupture and cause massive bleeding (Cooperman et al. 1976; Dousei et al. 1991). In cases with massive tumor load and tumor cell decay, diffuse melanosis and melanuria (Virchow) may occur. Typically, the urine darkens with time and may then turn deeply black, with a positive melanogen test (Thormälen's test; Feigl and Querner 1917). Liver metastasis of malignant melanoma has been shown to portend a grave prognosis, with a median survival time of about 4 months. Most cases of melanoma liver metastases have their primary tumor in the skin, but primary visceral melanomas also metastasize to the liver, and metastases are sometimes caused by melanoma of unknown primary site (MUP), MUP accounting for 3.7–6 % of all incident melanomas (Dasgupta et al. 1963; Milton et al. 1977; Katz et al. 2005).

Pathology

Macroscopy

Enlargement of the liver due to multiple metastatic melanoma nodules is common, and sometimes a gigantic enlargement of the liver is noted (Das Gupta and Brasfield 1964). The common type of metastasis pattern is multiple, with nodules ranging from few mm to more than 10 cm in diameter, with no predilection for any liver lobe among 125 autopsy cases (Das Gupta and Brasfield 1964). Rare cases show a diffuse infiltration of the organ, with nodules being hardly visible. A predilection for the hepatic capsular compartment may occur, with liver parenchyma remaining remarkably normal.

Histopathology

As in other melanoma metastases in parenchymal organs, the melanoma cells seen in hepatic metastases are often spherical, smaller cells forming nests with alveolar features. These alveolar formations contain a network of reticulin and collagen fibers. Nests of small to medium-sized melanoma cells may grow within the sinusoidal channels, but they are sometimes also intercalated with liver cell plates. Marked involvement of the sinusoidal vascular compartment may cause liver atrophy and portal hypertension (Block 1875). There are metastases with a predominant growth of melanoma cells in portal tracts and septa. In the center of larger cell nests, apoptosis and/or

necrosis is found, with melanin granules situated in the intercellular space and signs of melanosome phagocytosis (melanophagy) by Kupffer cells (melanophores). Similar to situations with massive iron overload of the liver, dark-brown melanin-containing Kupffer cell nodules occur. In case of large necrosis, the involved area is overpigmented at low magnification and reveals heaps and coarse granular masses of condensed melanin pigment. Large and pleomorphic cells or cells reminiscent of poorly differentiated sarcoma may occur, large cells sometimes forming syncytia. An alveolar pattern is not seen in large cells, and syncytial cells often have less melanin than the smaller cells (Konschegg and Hada 1937). Some metastases contain melanin-containing spindle cells as found in part of primary malignant melanomas. Apart from apoptosis and necrosis, melanoma cells in metastases may undergo other secondary changes, in particular fatty change. Neutral fat is more commonly noted in large tumor cells than in small ones. The stainable fat droplets are usually present in close association with pigment granules.

Liver Metastases of Choroidal (Uveal) Melanoma

Introduction

Choroidal (uveal) melanoma is a distinct entity with considerable differences in regard to skin melanomas (Laver et al. 2010). It is the most common intraocular malignant neoplasm, with an incidence of about six cases per million population per year in the Caucasian population (Singh and Topham 2003). Uveal melanoma may be associated with an increased incidence of other neoplasms. Choroidal melanoma has a characteristic chromosomal configuration. Monosomy 3 is an early event present in 50–60 % of tumors, often associated with the long arm of chromosome 8. Ocular melanoma has a complex biology in regard to local recurrence and metastasis, only partly related to the histologic type. Uveal melanomas are typically slow-growing tumors that show local infiltrative properties but little tendency to produce metastatic disease unless extraocular extension is present or enucleation has taken place, which has an adverse effect on prognosis (Zimmerman and McLean 1979; McLean et al. 1980). In regard to biology of disease, two classes of ocular melanoma are distinguished, Class 1 tumors having low risk and Class 2 having a high risk for metastatic death (Onken et al. 2004). In metastatic disease, the liver is frequently involved. In contrast to choroidal melanoma, iris melanoma has a much lesser tendency to metastasize.

Liver Metastasis of Uveal Melanoma

Liver metastases of ocular (choroidal; uveal) melanoma are a well-recognized event and may develop with considerable delay (Newton 1965; Lorigan et al. 1991). Cases manifesting 15 years or more after ocular melanoma diagnosis have been reported (Hosonuma et al. 2005). Sometimes, a long delay may camouflage the fact that ocular melanoma was present many years ago, e.g., until examination and inquiry reveal the presence of a glass eye post enucleation (Lubarsch 1920). Hence, ocular melanoma is one of the tumors that may produce hepatic CUP (cancer of unknown primary). However, in a study on 40 patients with hepatic melanoma metastasis undergoing liver resection (16 ocular and 24 cutaneous melanomas), the median disease-free interval from the time of primary tumor treatment to hepatic metastasis was the same for both groups, but patients with primary ocular melanoma were more likely to experience recurrence within the liver after hepatic resection, whereas patients with a cutaneous primary tumor more often developed extrahepatic involvement (Pawlik et al. 2006). For many patients, the liver is the primary and only site involved at the time of detection of systemic metastases (Patel et al. 1978). Ocular melanoma may occasionally metastasize to the liver before enucleation (Wilhelm and Zakov 1982).

What determines the risk of uveal melanoma metastatic disease and hence outcome in general? In a very large study of 3,432 cases of malignant melanoma of the choroid and ciliary body,

mortality from metastasis 15 years after enucleation was 46 % (McLean et al. 1982). Well-known risk factors comprise tumor size, epithelioid tumor cell type (see below), mitotic activity, vascular loops, lymphocytic infiltration, extraocular extension (scleral invasion), and enucleation (Singh et al. 2001; McLean et al. 2004; Coupland et al. 2008).

What are more refined parameters predicting metastatic disease? Extraocular spread via aqueous channels, ciliary arteries, vortex veins, ciliary nerves, optic nerve, and a variety of other routes occurred in 124/847 patients analyzed. This extraocular extension correlated with anterior tumor extension, large basal tumor diameter, epithelioid cell type, closed loops, high mitotic rate, and monosomy 3, and was a significant predictor of metastatic disease and death (Coupland et al. 2008). In the liver, an infiltrative growth pattern is associated with ciliary body involvement and extrascleral tumor extension of the primary ocular tumor (Dayani et al. 2009).

There are distinct molecular changes affecting invasion and spread in uveal melanoma (Bakalian et al. 2008). Cyclooxygenase-2 (COX-2) is expressed in more than 50 % of uveal melanomas, and it correlates with markers of poor prognosis, such as an epithelioid cell type, the presence of lymphocytic infiltration, and vascular closed loops. In addition, mixed-cell tumors are further subdivided into two subclasses by the presence and absence of COX-2 expression, expression of COX-2 having an adverse effect on outcome (Figueiredo et al. 2003). The histologic detection of laminin-rich vasculogenic mimicry patterns in uveal melanoma is associated with death from metastasis, although uveal melanoma cells forming a vasculogenic mimicry pattern in a laminin-containing three-dimensional microenvironment upregulate genes associated with differentiation and downregulate proliferation- and invasion-associated genes (Folberg et al. 2006). Class 2 tumors prone to liver metastasis and poor outcome show loss of the helix-loop-helix inhibitor ID2, and this downregulation triggers upregulation of E-cadherin, which in turn promotes anchorage-independent growth as a likely antecedent to metastasis (Onken et al. 2006). Class 2 tumors possess a distinct signature in gene expression profiling (Onken et al. 2004; Worley et al. 2007; Chang et al. 2008; Van Gils et al. 2008; Trolet et al. 2009) and reveal distinct patterns of microRNA expression (Radhakrishnan et al. 2009), and a classifier that includes six microRNA discriminators accurately distinguishes Class 1 from Class 2 tumors (Worley et al. 2008).

Ocular melanoma metastasis in the liver has a poor prognosis, despite improvement of therapeutic measures (Class 2 ocular melanoma). Commonly, median survival is reported to be less than 1 year. Among 201 studied patients, serum alkaline phosphatase, total bilirubin, and lactic dehydrogenase plus response to treatment showed a strong relation to survival, but not patient age and gender, metastasis-free interval, presence of extrahepatic metastases, and type of therapy (Bedikian et al. 1995). In a more recent study, prolonged survival was correlated with an interval from primary tumor diagnosis to liver metastasis >24 months and with the absence of a military metastasis mode (Mariani et al. 2009). In another study, two independent favorable prognostic factors were fewer than ten liver metastases at screening and, for the primary ocular tumor, absence of ciliary body involvement (Kodjikian et al. 2005). Metastatic tumor burden in the liver has an impact on outcome. In addition, the metastases may induce local vascular complications. The tumor can induce Budd-Chiari syndrome in the absence of chemotherapy (Caya et al. 1983). Today, hepatic arterial chemoembolization of ocular or cutaneous melanoma liver metastases results in longer survival, and patients with lesions that have a nodular tumor appearance on angiography survive longer than patients with infiltrative lesions (Sharma et al. 2008; Dayani et al. 2009). However, this procedure may be complicated by post-necrotic giant hemorrhagic cysts and eventually hepatic failure (Ataergin et al. 2009). Hyperthermic isolated hepatic perfusion with melphalan leads to immediate changes in tumor gene expression. In pre-therapy tumors, the Ras GTPase activator, ecotropic viral integration site 5 (EVI5), and several other melanoma-associated genes are overexpressed.

Pathology

Macroscopy

Liver metastasis of choroidal melanoma comes in three main patterns, viz., large mass lesions, nodular lesions, and infiltrative lesions.

Histopathology

Primary tumors of ocular melanoma are histologically described by the Callender-Wilder classification or modified versions of it (Callender 1931; Callender and Wilder 1935). The histologic patterns of ocular melanoma may be recapitulated in its hepatic metastases. But how are the distinct cytologic and histopathologic features reflected in liver metastases of ocular melanoma? In a study of 29 uveal melanomas and their metastases, a significant difference in cell type was found. The metastases revealed 82.5 % epithelioid or nonclassifiable cells. Cells in metastases have a similar reactivity for HMB-45, but show more frequently NKI-3 expression than the primary tumor. The findings suggest that metastases consist of a greater fraction of high-grade malignant melanoma cells (Luyten et al. 1996).

Diffuse Liver Infiltration by Melanoma: A Cause of Liver Failure

Multiple metastases of malignant melanoma causing diffuse hepatic infiltration (miliary melanoma metastases) is a well-known clinicopathologic entity (Pichon et al. 2004; Shan et al. 2009). The patient may present with anorexia and abdominal distension, and both sonography and CT reveal an enlarged liver without detectable nodules. Liver biopsy usually shows an almost diffuse infiltration of the sinusoidal spaces with melanoma cells. This massive hepatic involvement can result in liver failure with striking elevations of liver tests, particularly lactate dehydrogenase, and causing death in part of the patients (Bouloux et al. 1986; Lesur et al. 1992; Te et al. 1999; Jose et al. 2002; Montero et al. 2002; Tanaka et al. 2004; Kaplan et al. 2005; Rubio et al. 2005; De Castro et al. 2007). Melanomas involved in this catastrophic event are usually skin melanomas, but the syndrome has also been found in ocular melanoma (Lesur et al. 1992). Liver failure has also been observed in marked hepatic melanoma metastasis of the non-diffuse type (Muehlenberg and Wardelmann 1992). There are, however, situations where even marked diffuse hepatic metastasis is not associated with hepatocellular disease and shows normal serum liver enzyme levels (Donoso et al. 1985). Such differences have not been pathophysiologically clarified, but one may assume that there is a relevant pathogenic difference between the mere presence of multiple but circumscribed metastases and massive and, in particular, intrasinusoidal infiltration, the latter severely compromising hepatocyte metabolism. Hepatocyte malfunction caused by sinusoidal tumor cell infiltration has been observed in lymphomas, leukemias, and carcinomas (Martelli et al. 2000; Ihara et al. 2001), and also in plasmacytoma (Rahhal et al. 2009), but is probably a rare event, observed in 18 patients among 4,020 admissions of acute liver failure in on study (Rowbotham et al. 1998).

Congenital Metastasizing Malignant Melanoma

Congenital melanoma is a very rare neoplastic process that is often associated with giant melanocytic nevi (Coe 1925; Sweet and Connerty 1941; Schneiderman et al. 1987; Koyama et al. 1996; Richardson et al. 2002). Congenital melanoma can develop in the eye (Greer 1966; Palazzi et al. 2005). The fetus can also be affected by melanoma metastases derived from malignant melanoma of the mother (transplacental metastases; Holland 1949; Brodsky et al. 1965). The relation between congenital nevi and the development of melanocyte malignancy is not clarified, because metastasis alone is not a reliable criterion for malignancy in these lesions. A congenital giant but bland-looking melanocytic nevus may be associated with placental metastasis showing the same bland cellular features, and the infant suffering no ill effects (Holaday and Castrow

1968; Mancianti et al. 1990; Carroll et al. 1994). Congenital melanoma may give rise to multiple prenatal or postnatal metastases, including the lymph nodes and liver (Naraysingh and Busby 1986; Campbell et al. 1987; Schneiderman et al. 1987; Ishii et al. 1991). In the case of Schneiderman and coworkers (1987), a huge dorsal malignant melanoma found in a fetus delivered at 33 weeks' gestation had given rise to multiple pulmonary and placental metastases and to two liver metastases, one subcapsular and the other internally. The authors emphasized that the liver metastases contained scant melanin, whereas the placental metastases contained abundant melanin.

Animal-Type/Equine-Type Melanoma

A minority of pigmented skin neoplasms in humans, characterized by nodules of heavily melanized cells and low mitotic rate, resemble melanocytic neoplasms observed in horses and laboratory animals. The primary tumors are asymmetrical, predominantly intradermal neoplasms formed of deeply pigmented, round or short, spindle-shaped dendritic melanocytes with some degree of nuclear hyperchromatism and a single nucleolus, but with only minor nuclear atypia and low mitotic count. A prominent population of pigment-containing macrophages (melanophages/melanophores) is invariably present. The biology of disease of these animal-type melanomas is complex and unpredictable (Crowson et al. 1999; Kazakov et al. 2004; Ludgate et al. 2010). They show a long indolent phase, but may then metastasize. Liver metastasis has been reported (Levene 1979; Crowson et al. 1999; Anthony et al. 2006; Ludgate et al. 2010).

Pigmented Epithelioid Melanocytoma (PEM)

PEM is a low-grade melanocytic tumor (or a unique variant of low-grade melanoma) with a distinct locoregional metastatic potential (Zembowicz et al. 2004). PEM occurs sporadically or in the context of the Carney complex (complex of spotty skin pigmentation, myxomas, endocrine hyperactivity, and schwannomas; reviews: Boikos and Stratakis 2006; Boikos and Stratakis 2007) caused by mutations of the protein kinase A regulatory subunit type 1 alpha, coded by the PRKAR1A gene (Stratakis 2002). Loss of expression of this PKA subunit has been found in PEM, but not in malignant melanoma or other melanocytic lesions (Zembowicz et al. 2007). The lesions chiefly occur in the skin of the extremities, and the sometimes ulcerated tumors are formed by deep dermal proliferation of heavily pigmented epithelioid and/or spindled melanocytes. PEM tends to produce lymph node metastases, but the clinical course is usually indolent. In a series of 41 consecutive PEM, only one patient developed liver metastases (Zembowicz et al. 2004).

Neurocutaneous Melanosis

Neurocutaneous melanosis (NCM; OMIM 249400) is a rare phakomatosis characterized by a focal or diffuse proliferation of melanin-containing cells in both the skin and the leptomeninges, with a high risk of melanoma formation, mainly in the CNS (review: Di Rocco et al. 2004). NCM is thought to be caused by a migration disorder of neural crest-derived progenitor cells. About two thirds of patients with NCM have giant congenital melanocytic nevi; the remaining third exhibits numerous nevoid lesions but no giant nevi. In a study of 39 reported cases, most patients presented in the first 2 years of life with neurologic manifestations of CNS mass lesions, increased intracranial pressure, or spinal cord compression. Leptomeningeal melanoma was found in 62 % of the cases, but even in the absence of melanoma, symptomatic NCM had an extremely poor prognosis (Kadonaga and Frieden 1991). In an adult man with NCM, multiple primary intracranial melanomas developed, and autopsy showed numerous hepatic melanoma metastases (Arunkumar et al. 2001).

Melanotic Neuroectodermal Tumors of Infancy (Melanotic Progonoma)

Melanotic neuroectodermal tumor of infancy (MNTI; synonyms: melanotic progonoma; retinal anlage tumor; pigmented neuroectodermal tumor of infancy; pigmented epulis; melanotic ameloblastoma/adamantinoma; melanotic epithelial odontoma), first described 1918 (Krompecher 1918), is a rare neoplasm affecting infants, with a peak between the second and sixth month of age. A small number of cases have been reported in older children and adults. Only 8.9 % of the manifestations of MNTI were found at an age more than 12 months (Kruse-Lösler et al. 2006).

In the oldest reports, the lesion was termed melanotic epithelial odontoma (Mummery and Pitts 1926), congenital melanocarcinoma of the jaw (Dudits and Szabo 1935), and unusual melanoma of the alveolus and maxilla (Söderberg and Padgett 1941). Stowens (1957) believed that the tumor resembled the vomeronasal organ of Jacobson and assumed that the tumor may represent an atavism of sensory neuroectodermal origin, therefore proposing the term melanotic progonoma. In a first detailed literature covering reported cases until 1981, 139 patients with MNTI were identified (Hupp et al. 1981). Between 1900 and 2004, 140 patients could be reviewed, and the authors identified a total of 355 cases reported between 1918 and 2004 (Kruse-Lösler et al. 2006). This tumor is discussed in the present chapter owing to its likely derivation, similar to melanoma, from neural crest cells.

Most commonly the neoplasms affect the maxilla of infants during the first year of life (68–80 %), but it may also develop in the mandible (5.8 %), other regions of the skull (10.8 %), dura, brain, pineal gland, epididymis, ovary, uterus, mediastinum, and long bones. MNTI is commonly slow-growing and appears benign, but the tumors show a rapid expansile growth and a rather high rate of recurrence, and a minority of the lesions have a frankly malignant potential, with metastatic spread.

Histologically, the tumor cells resemble abnormal and often heavily melanized melanocytes, with variable complements of melanosomes, but there is also a subset of cells resembling neuroblasts. The pigmented cells are arranged either as strands or clusters often forming the lining of small cleft-like or tubular spaces, or as alveolar structures surrounded by a fibrovascular stroma. Ultrastructurally, the pigment corresponds to the cutaneous type of neural crest-type melanin (Stiller et al. 1983). Many tumor cells contain a single cilium. The blast-like cells are immunoreactive for synaptophysin and neuron-specific enolase, whereas the larger, and in part pigmented, epithelioid cells are positive for HMB-45 and vimentin.

Malignant varieties of MNTI may metastasize, including the lymph nodes (De Chiara et al. 1992) and liver (Schulz 1957; Lindahl 1970; Dehner et al. 1979; Block et al. 1980). Hepatic metastases histologically show small and dark, blast-like cells and thus resemble those of neuroblastoma (Dehner et al. 1979; Block et al. 1980). In the patient described by Block and coworkers (1980), locally recurrent tumor started to spread first to cervical lymph nodes, followed by lymph node metastasis to nearly all major lymph node groups above and below the diaphragm and to the visceral pleura, the bone marrow, and the liver. At autopsy, the liver showed multiple grayish to hemorrhagic metastatic nodules. Histologically, clusters and clumps of small, nonpigmented cells were also found outside the gross metastases, mainly within sinusoids. A hepatic intrasinusoidal growth pattern was also reported by Dehner et al. (1979).

Differential Diagnosis of Metastatic Liver Melanoma: Rare Other Melanotic Neoplasms Metastasizing to the Liver

Apart from malignant melanoma, other tumors may contain melanin, and part of them have been found to metastasize to the liver, giving rise to differential diagnostic problems in biopsies. They include pigmented squamous cell carcinoma (Jurado et al. 1998), pigmented mucoepidermoid carcinoma (Takeda and Kurose 2006), heavily pigmented renal cell carcinoma (Rossi et al. 2009), pigmented neuroendocrine tumors

(Iihara et al. 2002), primary clear cell sarcoma (Taminelli et al. 2005), melanotic schwannoma (Janzer and Makek 1983), and meningeal melanocytoma (Wang et al. 2007).

Historical Outline of Melanotic Liver Tumors

The 50-year-old female patient reported by von Frerichs exhibited hepatic melanoma, the other melanoma manifestations being restricted to the retroperitoneal lymph nodes, lung, and pleura (von Frerichs 1861). Nencki and Sieber reported on a patient with exclusive localization of a sarcomatoid melanoma to the liver, with formation of an enormous liver tumor, but had to admit that the orbits were not examined (Nencki and Sieber 1888). Hanot and Gilbert, in their monograph on diseases of the liver (1888), mention a case of melanoma apparently primary to the liver. An early case (53-year-old male) by Nazari (1906) was described as a primary melanosarcoma of the liver. Autopsy revealed a partly melanized tumor with nut- to orange-sized nodes mainly in the left liver lobe and a granite-like aspect of the right liver lobe. The carefully performed necropsy did not show any other potential primary tumor, but there is no information regarding the eyes. Ewing, in his *Neoplastic Diseases*, quotes Rolleston as referring to nine cases reported as primary melanoma of the liver. He also mentions a case of Johnston's of a large pigmented tumor of the liver with no demonstrable primary tumor found elsewhere. Early observations reveal the sometimes unique gross aspect of liver melanoma, which impressed the authors. Mansson (1926) described a 4-year-old boy with signs of Addison's disease who had, based on autopsy findings, a multinodular malignant melanoma primary to the liver, with coal-black nodules having destroyed most of the parenchyma, associated with massive ascites. If this patient really suffered from primary hepatic melanoma, this would be the youngest patient reported. This boy, however, suffered from extensive skin pigmentations, which were interpreted to be due to Addison's disease, but a skin biopsy is not reported, leaving the question of a melanotic disorder open. The 68-year-old female patient described by Smith (1926) had atrophic liver cirrhosis in the final stage, with rapidly evolving jaundice and death. Necropsy showed a cirrhotic liver with an extraordinary color, which "was a mottled yellowish-greenish black resembling granite. The cut section of the liver presented the same mottled granite surface. Throughout the organ there were areas of black or gray which resembled the anthracosis usually in the lungs and mediastinal lymph nodes. The retroperitoneal lymph nodes, which were enlarged to almond size, in the region of the bile ducts, showed similar pigmented changes." The gross features resembled the change termed Welch's cirrhosis hepatis anthracotica (Welch 1891). Histologically, the tumor cells were epithelioid or spindled and contained large amounts of melanin pigment, representing malignant melanoma. At no time did the physical examination of the patient or the subsequent examination at necropsy reveal any potential tumor nodule or pigmented nevus which could be considered as a possible primary focus. Part of the neoplastic cells had assumed an alveolar growth pattern. The patient of Brandt had a tumor in the liver termed melanocytoblastoma, without any other pigmented lesion at autopsy (Brandt 1930). Koch described the case of 35-year-old female patient with massive hepatomegaly owing to liver melanoma in the absence of nevi or any other melanoma manifestations, including the eyes. At necropsy, the liver weighed 7,990 g and contained numerous blackish nodules (Koch 1930). An autopsy case described in 1937 (Konschegg and Hada 1937) was interpreted as primary "melanotic liver carcinoma" but was clearly a malignant melanoma. Lence's case (1937) was 31-year-old female having died of endometritis puerperalis suppurativa. Autopsy revealed a melanotic liver tumor ("melanosarcoma hepatis cum necrosi disseminata textus hepatici"), i.e., malignant melanoma. No other melanotic lesions were seen, and there were neither nevi, skin scars, or ocular findings (Lence 1937). The 58-year-old patient died of metastasizing melanoma with involvement of all internal organs, except the brain, adrenals, and

spleen. The liver as a primary site of the melanoma was purported based on the fact that the liver manifestations were exceedingly large and that the liver cells contained a brown and coarse pigment showing the same histochemical features as the pigment in the melanoma cells, in the absence of generalized melanosis, suggesting a transition from pigmented hepatocytes to the tumor. However, when carefully reading the original report, including the histochemical appendix written by Hada, there is strong suspicion that this patient may have had Dubin-Johnson's syndrome with liver metastases of a malignant melanoma having arisen elsewhere. The case of Gong and coworkers (2008) was a 36-year-old male patient with a well-defined, solitary and oval, low-dense liver mass (right lobe) in CT, measuring 12.8 × 10.1 cm. This mass had been detected in a routine checkup. The mass was resected and shown to be a rather hypomelanotic malignant melanoma.

Visceral Clear Cell Sarcomas (Melanoma of Soft Parts)

Introduction

Clear cell sarcoma (CCS; previously also termed melanoma of soft parts) is a distinctive soft tissue malignancy that shows melanocytic differentiation. CCS also develops in the skin and causes difficulties in the differential diagnosis from primary malignant melanoma (Hantschke et al. 2010). CCS differs from malignant melanoma in the expression of mismatch repair proteins (Garcia et al. 2006a), and in contrast to malignant melanoma, CCS cells are CD117-negative (Garcia et al. 2006b), and CCS differs from malignant melanoma in the expression of mismatch repair proteins (Garcia et al. 2006b).

CCS has a specific genetic background that includes the chromosomal translocations, t(12;22)(q13;q12), causing an EWSR1/ATF1 chimeric gene, or t(2;22)(q34;q12), causing an EWSR1/CREB1 fusion gene (Zucman et al. 1993; Antonescu et al. 2002; Panagopoulos et al. 2002; Jishage et al. 2003; Wang et al. 2009; Song et al. 2010). Four types of EWS-ATF1 chimeric transcripts, termed types 1–4, have been identified. The most frequent chimeric transcript (type 1) is an in-frame fusion of exon 8 of EWS with exon 4 of ATF1. The type 2 transcript of EWS-ATF1 is an in-frame fusion of exon 7 of EWS with exon 5 of ATF1, that of type 3 an in-frame fusion of EWS exon 10 with ATF1 exon 5, while type 4 is an in-frame fusion of EWS exon 7 with ATF1 exon 7 (Panagopoulos et al. 2002). The EWS-CREB1 fusion characterized CCS located in the gastrointestinal tract (Antonescu et al. 2006).

CCS rarely occurs in the gastrointestinal tract, including the stomach, jejunum, ileum, and colon (Donner et al. 1998; Fukuda et al. 2000; Taminelli et al. 2005; Antonescu et al. 2006; Granville et al. 2006; Marcon et al. 2007; Lagmay et al. 2009; Terazawa et al. 2009) and has been reported to have either the EWS-ATF1 fusion (Granville et al. 2006) or the EWS-CREB1 fusion (Antonescu et al. 2006). It may occur in association with IgG4-related sclerosing disease (Joo et al. 2009). A subset of GIT tumors resembling malignant melanoma in fact show t(12;22)(q13;q12) translocation causing the EWS-ATF1 fusion and are therefore visceral CCS (Covinsky et al. 2005).

Clear Cell Sarcoma Metastasis of the Liver

Primary CCS of the liver has not yet been reported, but metastatic liver disease was described. Primary CCS of the small intestine metastasized to the liver (Taminelli et al. 2005; Joo et al. 2009). Multiple liver metastases were also observed following resection of CCS of the rectus sheath (Xu et al. 2007). Extensive metastasis to liver and lung was noted in a young patient with CCS primary to the kidney (Rubin et al. 1999). Histologically, CCS is characterized by diffuse sheet-like or nested patterns of usually large and round cells with a pale, slightly eosinophilic to clear cytoplasm and nuclear pleomorphism. Nuclei are vesicular with prominent nucleoli, and numerous mitotic figures are in

evidence. The nests or sheets are separated from each other by a delicate vascularized connective tissue. Immunohistochemically, the cells are reactive for vimentin, Melan-A, HMB-45, calponin, and S100 protein.

Clear cell sarcoma-like tumor with osteoclast-like giant cells of the gastrointestinal tract (osteoclast-rich tumor of the gastrointestinal tract with features resembling clear cell sarcoma of soft parts): A malignant tumor spreading to the liver

In 2003, six cases of a novel tumor entity has been reported, characterized by CCS associated with osteoclast-like multinuclear giant cells (Zambrano et al. 2003). Five of the cases were located in the small bowel and one in the stomach. The age of patients ranged from 13 to 37 years. The neoplasms behaved aggressively, with metastases to the locoregional lymph nodes, liver, and other intraabdominal sites. The neoplasms consist of medium-sized, predominantly oval, relatively monomorphic cells that are diffusely immunoreactive for S-100 protein, but are negative for CD117 and HMB-45. The giant cells are positive for CD68, a macrophage marker. The tumor displays t(12;22)(q13;q12), as in CCS of the soft parts (Zambrano et al. 2003; Friedrichs et al. 2005). The lesion has been described in a later reports, the tumor being situated in the stomach or the small bowel (Friedrichs et al. 2005; Huang et al. 2006; review: Kosemehmetoglu and Folpe 2010). In contrast to the original description, a later case was HMB-45 positive and Melan-A positive (Friedrichs et al. 2005).

Hepatobiliary Tumors with a Rhabdoid Cell Lineage

Malignant Rhabdoid Tumors and Tumors with Rhabdoid Features

78

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_78

Abstract

Several tumors are characterized by the presence of a distinct cell type, the rhabdoid cell. This cell of still unknown origin shows a striking cytoskeletal inclusion that is visualized as an eosinophilic eccentrically placed cell body. Certain neoplasms, malignant rhabdoid tumors, are entirely composed of rhabdoid cells, while numerous other tumors contain subsets of rhabdoid cells or rhabdoid-like cells (neoplasms with rhabdoid features). The presence of rhabdoid cells generally confers a highly malignant phenotype. Rhabdoid tumors consistently show absence of nuclear reactivity for the chromatin-remodeling factor, SRF5/INI1. Malignant rhabdoid tumor is a well-known cancer of the kidney, but it also rarely occurs as a primary tumor in the liver of infants and children and exceptionally in adolescents and adults. The liver can also be involved in a rare and fatal condition of early infancy, congenital disseminated malignant rhabdoid tumor. There are few other complex pediatric liver neoplasms with rhabdoid cell elements. In adults, several hepatobiliary neoplasms, including cholangiocarcinoma, can exhibit rhabdoid features.

The Rhabdoid Tumor Family

Malignant rhabdoid tumor (MRT) is a rare and high-grade neoplasm chiefly occurring in infants and very young children and more uncommonly in adults. MRT was first described as an aggressive, rhabdomyosarcomatoid variant of Wilms' tumor (Beckwith and Palmer 1978) and later confirmed to be a distinct clinicopathologic entity of pediatric renal tumors, under the term rhabdoid tumor (Palmer and Sutow 1983; Weeks et al. 1989a; Berry and Vujanic 1992; Beckwith 2002; Tomlinson et al. 2005). Early, the term "rhabdomyoblastoma" has been used as synonymous with RT (Hajdu 1986), but there is no evidence of a myoblast lineage involved in these neoplasms. All of these lesions are characterized by a distinct, albeit intriguing, cell, the rhabdoid cell. Cancer cells showing morphologic changes resembling a rhabdoid cell are termed cells with rhabdoid features.

The Rhabdoid Cell, Hallmark of Rhabdoid Tumors

The term, rhabdoid cell, may have been chosen to suggest some resemblance to an immature rhabdomyoid cell, but it correctly derives from the Greek word *rhabdoides*, which means shaped like a rod or striped, and is thus a misleading term for describing the morphologically distinct cell found in RT. The rhabdoid cell, whether being the leading cell type of a neoplasm or only representing one tumor cell type among others (tumors with rhabdoid features), is now known to act as a highly aggressive indicator of many malignant tumors. The characteristic cytoskeletal inclusion has been analyzed on a molecular level. By investigating the complete human CK8 gene, it surfaced that all MRT samples have missense mutations in the human KRT 8 gene, none of which was found in any control samples. Remarkably, some of these mutations involve domains known to be important for lateral protofilament-protofilament interactions, mutations in MRT thus probably causing conformational changes of cytokeratins in RT (Shiratsuchi et al. 2002). There are cytoplasmic structures which mimic the inclusions seen in RT. "Pseudo-rhabdoid cells" have, e.g., been found in pancreatic endocrine neoplasms (Chetty and Asa 2004), and these inclusions are characterized by whorls of intermediate filaments with entrapped neurosecretory granules (Shia et al. 2004). The cells of RT seem to be capable to undergo epithelial differentiation, with production of a basal lamina and convergent tight junctions (Seo et al. 1988).

Classifications of Rhabdoid Tumors and Tumors with Rhabdoid Features

Apart from the "classical" renal RT, the first example of an RT, several extrarenal tumors containing rhabdoid cells have been described (Weeks

et al. 1989b). Extrarenal RT is now conceived as a counterpart of RT of the kidney and had formerly been defined as a distinct tumor type based largely or entirely on the cytological resemblance of its constituent cells to those of classical renal RT, characterized by the typical cytoplasmic inclusions (Parham et al. 1994). Later, the concept of extrarenal RTs has been modified, based on the observation of so-called rhabdoid cells (Sobrinho-Simoes 1991; or "hyaline cells") in numerous neoplasms not obviously directly related RT. Malignant tumors containing variable amounts of rhabdoid cells commonly exhibit a more aggressive biology. Therefore, the identification of rhabdoid features is an important diagnostic procedure.

The nomenclature of the lesions is not yet standardized. Several terms have been employed to denote the presence of rhabdoid cells or rhabdoid-like cells in neoplasms, including rhabdoid tumors, tumors with rhabdoid features, rhabdoid phenotype, rhabdoid differentiation, rhabdoid transformation, rhabdoid areas, and rhabdoid as an adjective preceding the name of the tumor (such as rhabdoid adenocarcinoma). Widely used are the terms extrarenal rhabdoid tumors (ERRT; related to the fact that malignant rhabdoid tumor was first described in the kidney) or malignant extrarenal rhabdoid tumors (MERT). ERRT and MERT as a discrete pathologic entity have been a controversial issue despite rather frequent reports of their occurrence (Ogino et al. 2000). Based on the heterogeneity of ERRT, it has been proposed that the term, ERRT, is not valid as representing a specific diagnostic entity and that the term "poorly differentiated neoplasm with rhabdoid features" would be preferable for these undifferentiated tumors (Parham et al. 1994). Generally, the uncertainty as to what a rhabdoid tumor might be is furthered by the observation that the leading identifier, the rhabdoid cell, is expressed in such lesions in a highly variable way, ranging from "purely" rhabdoid tumors to those with only focal rhabdoid features, raising the still open question where the cutoff value for the definition of a bona fide rhabdoid tumor might be. The conceptual discussion referring to these questions has been reviewed (Wick et al. 1995). Apart from the "classical" renal malignant rhabdoid tumor (RRT), one may tentatively group, as a working formulation (Table 1), the remaining lesions into (a) malignant extrarenal rhabdoid tumors (MERT; or ERRT, as they are also termed) which should morphologically closely reflect the renal counterpart in its original definition; (b) composite extrarenal rhabdoid tumors (CERT) in which recognizable parent neoplasms are admixed with MERT; (c) congenital disseminated RT (with or without the features of the rhabdoid tumor disposition syndrome; White et al. 1999; Fernandez et al. 2002); (d) small cell undifferentiated hepatoblastoma with rhabdoid features; and (e) tumors (usually in adults) with rhabdoid features, comprising a growing spectrum of neoplasms that have subsets of cells resembling, or corresponding to, rhabdoid or rhabdoid-like cells.

Table 1 Working formulation for the classification of malignant rhabdoid tumors (MRTs)

Renal malignant rhabdoid tumor (RMRT)
Malignant extrarenal rhabdoid tumors (MERT)
Composite extrarenal rhabdoid tumors (CERT)
Congenital disseminated RT and rhabdoid tumor disposition syndrome
Small cell undifferentiated hepatoblastoma with rhabdoid features
Intrahepatic cholangiocarcinoma with rhabdoid features
Malignancies with rhabdoid features in adults

MERT have been described at several different sites including the central nervous system (atypical teratoid tumors rhabdoid tumor/AT/RT), orbit, lung, esophagus, liver, colon, bladder, female genital tract (vulva, uterus, ovary), paratesticular area, pelvis, soft tissues, mesentery, and chest (Frierson et al. 1985; Sotelo-Avila et al. 1986; Gururangan et al. 1993; Hsueh and Chang 1996; Marcus et al. 1996; Rubenchik et al. 1996; Gunduz et al. 1998; Figarola and Khader 1999; Brand and Covert 2001; Leath et al. 2003; Ng et al. 2003; Ohgaki et al. 2003; Chang et al. 2004; Salamanca et al. 2004; Gottlieb et al. 2005; Garces-Iñigo et al. 2009). Soft tissue rhabdoid tumor (STRT) was defined as a tumor

composed of noncohesive single cells, clusters, or sheets of large tumor cells with abundant glassy eosinophilic cytoplasm, an eccentric vesicular nucleus, positivity for vimentin and/or cytokeratin or other epithelial markers, and exclusion of other neoplasms with rhabdoid inclusions (Fanburg-Smith et al. 1998). Some of the MERT are fetal or congenital tumors (Maschek et al. 1992; Pizer et al. 1997; Stidham et al. 1999; White et al. 1999; Hosli et al. 2001; Fernandez et al. 2002; Leader et al. 2002; Sajedi et al. 2002; Gottlieb et al. 2005).

Tumors with rhabdoid features, i.e., with a variable component of neoplastic cells with a rhabdoid phenotype as defined above, form a very heterogeneous group of lesions. It has not yet been defined what the minimum requirements to place such tumors into this category are. These lesions do not seem related to renal and extrarenal true rhabdoid tumors and are generally poorly differentiated tumors, the presence of cells with rhabdoid features being a hallmark of a dedifferentiated state of the neoplastic cell population, albeit with some exceptions. Neoplasms with rhabdoid features include, among others, meningiomas (Perry et al. 1998), rhabdoid glioblastoma (Kleinschmidt-DeMasters et al. 2010; Momota et al. 2011), thyroid carcinomas, including the differentiated follicular variant (Chetty and Govender 1999; Lai et al. 2005; Agarwal et al. 2006), lung carcinomas (Miyagi et al. 2000; Kaneko et al. 2002), esophagus carcinomas (Varghese et al. 2005), stomach cancer (Ueyama et al. 1993; Pinto et al. 1997), small intestinal carcinoma (Amrikachi et al. 2002), colorectal cancer (a distinct entity with a very aggressive behavior; Chetty and Bhathal 1993; Remo et al. 2012), pancreatic carcinoma (Al-Nafussi and O'Donell 1999; Kuroda et al. 2000; Cho et al. 2006), neuroendocrine tumors (Perez-Montiel et al. 2003), gastrointestinal stromal tumor (Richmond et al. 2004), renal cell carcinomas (Gokden et al. 2000; Humphrey 2011), malignant melanoma (Chang et al. 1994), squamous cell carcinomas (Aoyagi et al. 2009), proximal-type epithelioid sarcoma with rhabdoid features (Guillou et al. 1997), and other certain sarcomas (Kim et al. 2010).

Malignant Rhabdoid Tumor of the Liver in Infants and Children

Introduction

The first infant with a primary hepatic RT (hepatic MERT) was described in 1982 as a form of infantile sarcoma (Gonzalez-Crussi et al. 1982). In this work, the characteristic intracytoplasmic inclusions were recognized, but it was discussed whether the neoplasm was of histiocytic origin. Since then, several examples of infantile and childhood hepatic RT have been reported, and the majority of the lesions occurred in patients less than 1 year of age.

Selected References Sotelo-Avila et al. 1986; Parham et al. 1988, 1994; Hunt and Anderson 1990; Mann et al. 1990; Foschini et al. 1992; Maschek et al. 1992; Di Cori et al. 1993; Gururangan et al. 1993; Weyman et al. 1993; Scheimberg et al. 1996; Jimenez-Heffernan et al. 1998; Kelly et al. 1998; Donner et al. 2000; Ravindra et al. 2002; Rosito et al. 2002; Katzenstein et al. 2003; Halasz et al. 2004; Yuri et al. 2004; Kuroda et al. 2005; Clairotte et al. 2006; Jayaram et al. 2007; Wu et al. 2008; Abe et al. 2009; Abdullah et al. 2010; Trobaugh-Lotrario et al. 2011; Martelli and Liu 2013.

From these reports, it is difficult to judge whether these lesions form a distinct entity or rather a heterogeneous group of neoplasms sharing the phenomenon of a variable contribution of rhabdoid cells. This difficult issue had already been addressed in an early report (Parham et al. 1994). These authors found three hepatic tumors among 42 cases of ERRT, and each of the three was in some way different from the others. One rhabdoid lesions displayed epithelial features with a striking accumulation of tonofilaments and reactivity for epithelial markers. The second tumor had the cytohistologic features of renal RT but with areas of desmoplasia, and it was discussed whether this lesion might represent a tumor of the intra-abdominal desmoplastic small cell tumor group. The third neoplasm again shared morphologic features with renal RT, but expressed epithelial markers (Parham et al. 1994).

Clinical Features

The tumor usually presents as a right upper quadrant mass (Scheimberg et al. 1996). The serum AFP is consistently normal. Imaging shows large, homogeneous or lobulated, hypodense tumors with blurred margins, sometimes with calcifications (Jimenez-Heffernan et al. 1998). In some children with hepatic RT, hypercalcemia was observed (Jimenez-Heffernan et al. 1998; Donner et al. 2000). Hypercalcemia is known to be associated with certain pediatric renal tumors, in particular rhabdoid tumor and congenital mesoblastic nephroma, and thought to be caused by ectopic production of parathyroid hormone-related peptide (Mayes et al. 1984; Jayabose et al. 1988; Rousseau-Merck et al. 1988; McKay and Furman 1993; Papadakis et al. 1995; Amar et al. 2001). In one study, renal rhabdoid tumor was associated with hypercalcemia in 23 % of the patients (Amar et al. 2001). It has also been found that hepatic RT may secrete vasointestinal peptide causing watery diarrhea (Weyman et al. 1993). Local complications of hepatic RT include spontaneous rupture and hemorrhage (Kelly et al. 1998; Ravindra et al. 2002; Clairotte et al. 2006).

Biology of Disease

Hepatic RTs are highly aggressive neoplasms which often present with metastases at the time of diagnosis and which are difficult to treat and to cure. In a recent review of 34 patients with a median age at presentation of 8 months, 30 patients died of disease or treatment complications. Most deaths occurred within 12 months after diagnosis. Of the four patients alive without disease, all were treated with chemotherapy, and three had surgery or liver transplantation (Trobaugh-Lotrario et al. 2011).

Pathology

Macroscopy

Hepatic RTs are often large tumors, sometimes with a diameter of more than 15 cm. The masses are solitary (Kelly et al. 1998) or multinodular (Yuri et al. 2004) and present as friable, grayish white tumors with necroses and hemorrhages. The necrosis may predominate in the tumor's center, with radiating streaks of necrosis to the periphery and sometimes with formation of cystic cavities. In some cases, the main tumor mass is associated with few to numerous satellite nodules probably representing intrahepatic metastases. The cut surface is typically variegated in appearance, sometimes with pseudocyst formation. It may show a lobulated texture (Hunt and Anderson 1990). The margins of the tumor are ill-defined and infiltrative, always without capsule formation, but perifocal liver atrophy is in evidence. The tumor may breach the liver capsule and invade adjacent organs, the diaphragm, or the abdominal wall and/or surround the gallbladder, the extrahepatic biliary tract, and the inferior vena cava (Scheimberg et al. 1996). Subcapsular hematoma was noted in some cases (Kelly et al. 1998; Yuri et al. 2004). Larger tumors may undergo spontaneous rupture (Kelly et al. 1998; Ravindra et al. 2002). In one patient, a long capsular tear of the involved liver lobe was detected at laparotomy, associated with free intraperitoneal blood having caused shock (Kelly et al. 1998).

Histopathology

RTs are highly cellular neoplasms that show somewhat monotonous noncohesive or poorly cohesive sheets of cells. The neoplastic cells of RT are medium-sized to large, and round, ovoid to polygonal in shape. They may be embedded in a sometimes myxoid stroma rich in glycosaminoglycans. The cells have a vesicular or sometimes irregularly shaped nucleus showing one to several prominent nucleoli, typically with a rather clear blue color in H&E sections. At least part of the cells contain the characteristic paranuclear inclusion body which may be hyaline (Figs. 1 and 2). This paranuclear inclusion displaces the nucleus into an eccentric position. The rhabdoid features of the neoplastic cells are particularly well recognizable in aspiration cytology specimens (Akhtar et al. 1994; Yusuf et al. 1996; Pogacnik and Zidar 1997; Barroca et al. 2003). Part of the neoplastic

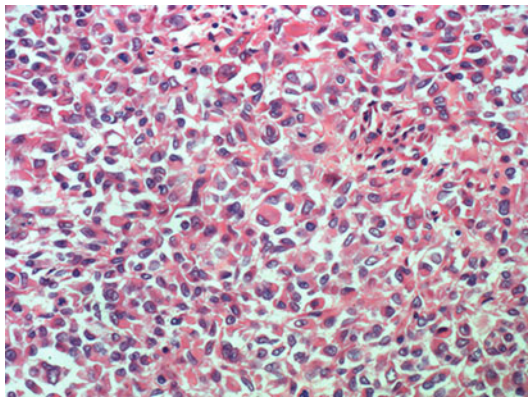

Fig. 1 Malignant rhabdoid tumor of the liver. A diffuse growth consists of mostly medium-sized cells which sometimes reveal an eccentrical eosinophilic cytoplasmic part (hematoxylin and eosin stain)

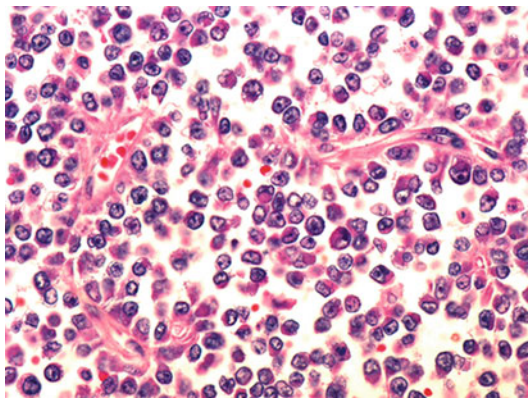

Fig. 2 Malignant rhabdoid tumor of the liver. Part of the tumor cells display a small eosinophilic paranuclear body (hematoxylin and eosin stain)

cells may reveal signs of epithelial differentiation (Parham et al. 1988). In silver stains, the neoplastic cells are grouped to nests or small clusters by reticulin fibers. The growth is markedly invasive, with intrasinusoidal invasion and entrapment of hepatocytes and small bile ducts and ductules within the tumor.

Electron Microscopy

Ultrastructurally, the cytoplasmic paranuclear inclusions are composed of whorled filaments measuring 10 nm in diameter, representing (modified) intermediate filaments of the cytoskeleton (Haas et al. 1981; Yuri et al. 2004). The dense aggregation of intermediate filaments seems to indent the adjacent nucleus, but without obliteration of the nuclear lamina and without visible alterations of peripheral chromatin structures in this region. The area containing the intermediate filament condensation displays few organelles, whereas mitochondria, elements of the SER and RER, and glycogen particles are interposed between the inclusion and the nucleus or the cytoplasmic membrane (Hunt and Anderson 1990). In peripheral part of the filament aggregate, small vesicles of the SER, mitochondria, or lipid droplets may be trapped. As an indication of epithelial differentiation, hemidesmosomes or desmosome-like structures, focal tonofilament-like condensations, and primitive junctional complexes may be encountered (Maschek et al. 1992; White et al. 1999).

Immunohistochemistry

The paranuclear inclusion bodies of renal and extrarenal RT rhabdoid cells express both CK8 and CK18 (Fig. 3; Shiratsuchi et al. 2001; Yuri et al. 2004), which seems to be a rather constant feature, and sometimes CK 7 and CK19 (Kaiserling et al. 1996; Foschini et al. 1992; Shiratsuchi et al. 2001; Yuri et al. 2004), while other cytokeratins are rarely, weakly, questionably or not expressed. There is almost constant reactivity for vimentin (Fig. 4), but not desmin and AFP. S-100 protein, neuron-specific enolase, CD99, Leu-7, GFAP, neurofilament, muscle-specific actin, alpha-1-antitrypsin, and epithelial membrane antigen (EMA) may be expressed in a variable fashion, reflecting the so-called "polyantigenic" character of RTs (Parham et al. 1988; Scheimberg et al. 1996; Machado et al. 2010). About two thirds of RT express E-cadherin, while these tumors are not reactive for beta-catenin (Saito et al. 2001). Some RT reveal immunohistochemical features of stem cells, including positivity for SALL4 and/or Lin28 (Deisch et al. 2011). RT cells are often reactive for claudin-6, which is a nonspecific

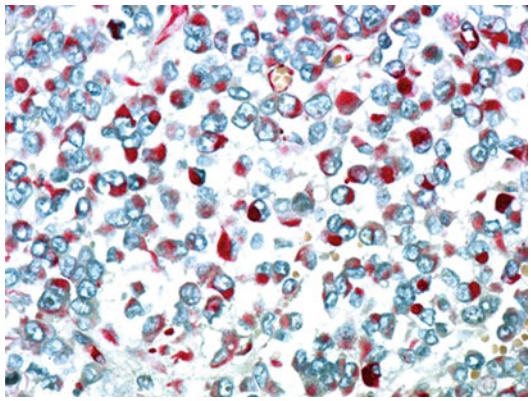

Fig. 3 Malignant rhabdoid tumor of the liver. In this cytokeratin stain, paranuclear bodies appear as *red eccentrical dots* (CAM5.2 immunostain)

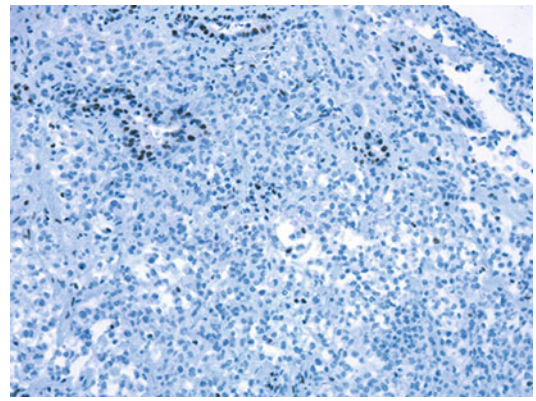

Fig. 5 Malignant rhabdoid tumor of the liver. In contrast to nuclei in normal cholangiocytes and endothelial cells, tumor cell nuclei are INI1 negative (INI1/BAF47 immunostain)

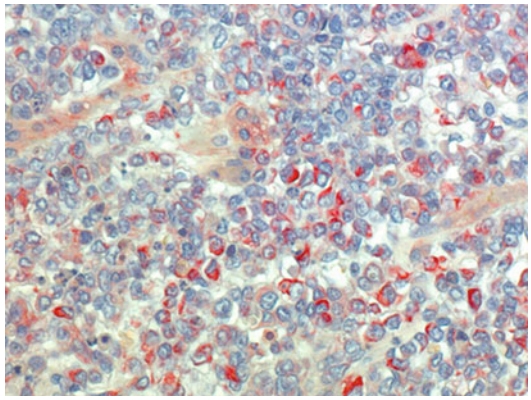

Fig. 4 Malignant rhabdoid tumor of the liver. Paranuclear bodies as visualized by vimentin expression (vimentin immunostain)

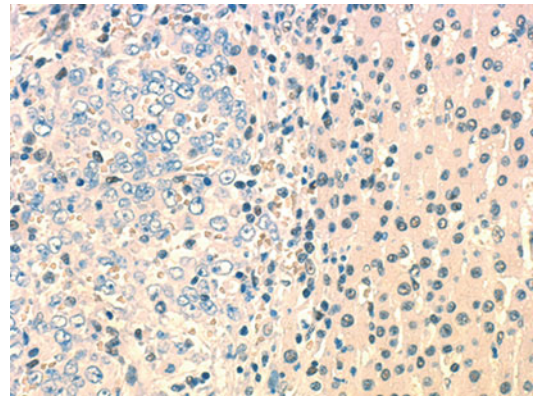

Fig. 6 Malignant rhabdoid tumor of the liver, INI1 expression pattern at higher magnification. INI1-negative tumor cells are seen to the left. Note the nuclear INI1 positivity of normal hepatocytes (to the *right*), endothelial cells, and infiltrating lymphocytes (INI1/BAF47 immunostain)

marker for malignant RT and other pediatric tumors (Sullivan et al. 2012). At least part of hepatic RT cell are reactive for glypican-3 (Kohashi et al. 2013; Chan et al. 2014).

As a central feature of pediatric rhabdoid tumor is the truncation of the hSNF5/INI1 gene (see below), nuclear expression of the respective protein has been analyzed by immunohistochemistry in such tumors. Typically, RT cells lack nuclear immunostaining for SRF5/INI1 (Figs. 5 and 6). The lacking nuclear expression of INI1 contrasts clearly with adjacent normal cells and infiltrating leukocytes, with their positive nuclear signals. The loss of the INI1 protein was observed in all RT tested, in contrast to a positive nuclear signal in non-rhabdoid neoplasms (Hoot et al. 2004; Al Nassan et al. 2010).

Differential Diagnosis

Primary hepatic RT has to be distinguished from liver metastases of RT primarily located elsewhere, predominantly in the kidney. Metastasis of rhabdoid meningioma to the liver has been reported (Wang et al. 2011).

Congenital Disseminated Malignant Rhabdoid Tumor

Congenital disseminated malignant rhabdoid tumor (CDMRT) is a rare, highly aggressive and fatal tumor of early infancy, with tumor manifestations in the CNS, kidney, liver, head and neck region, and placenta and sometimes a dominant tumor mass in various body regions. CDMRT is associated with 22q11.2 deletions or translocations (White et al. 1999; Fernandez et al. 2002; Gottlieb et al. 2005; Yurdakul et al. 2007). In a series of nine patients, five neonates had tumor evident at birth, and two of these had placental metastases (White et al. 1999).

Malignant Rhabdoid Tumor of the Liver in Adolescents and Adults

Malignant hepatic RT is a very rare neoplasm in adults (Marzano et al. 2009; Sibileau et al. 2011; Kang et al. 2013). The first two cases were observed in a 27-year-old male and a 15-year-old male, both with a heterogeneous liver tumor of 17 cm and 15 cm diameter, respectively. The tumor histology was typical for rhabdoid tumor, associated with lack of nuclear INI1 expression (Marzano et al. 2009). A young adult showed a voluminous heterogeneous, partially necrotic mass in the left liver lobe, measuring up to 17 cm in diameter, displaying RT histology, lack of INI1 expression, and a molecular analysis highly suggestive of INI1 biallelic mutation. The patient was treated with resection and chemotherapy and was alive without signs of recurrence 41 months after therapy (Sibileau et al. 2011). The patient reported by Kang and coworkers (2013) was a 50-year-old male presenting with a large hepatic mass. CT showed a very large multinodular hypoattenuating tumor with rim enhancement in the entire left lobe of the liver. A needle biopsy yielded a hypercellular tumor with necrosis and hemorrhage, composed of loosely cohesive cell clusters separated by intervening fibrous septa. The neoplastic cells showed the typical features of rhabdoid cells and were immunoreactive for cytokeratin 19 and vimentin and focally for cytokeratin 7. These cells displayed partial loss of INI1 reactivity (Kang et al. 2013).

Congenital Primitive Epithelial Tumor of the Liver with Rhabdoid Features

This is a rare congenital malignancy characterized by an immature, non-hepatocyte epithelial cell lineage with rhabdoid features and clinical manifestations mimicking disseminated neuroblastoma, with placental metastases. Autopsy of the index patient who had died at the age of 4 days showed a 6-cm yellowish tumor with marked hemorrhage in the left liver lobe and up to 2-cm multiple hemorrhagic lesions distributed in both liver lobes. Histologically, this tumor consisted of large atypical cells which often formed glandular or tubular structures and lacked blastemal features. Bizarre giant cells were scattered through the neoplasm. About 5 % of the tumor cells displayed rhabdoid features, with cytokeratin- and vimentin-positive inclusions, which showed the typical arrangement of intermediate filament aggregates in electron micrographs. Tumor emboli with occasional extravascular extension were noted in the liver, lung, heart, intestine, adrenal glands, and brain. The placenta was infiltrated by the same or similar tumor cells, often with invasion of the villous stroma and extending into the marginal sinus (Ohyama et al. 2000).

Fatal Primitive Childhood Tumor with Rhabdoid Features

Fatal primitive childhood tumor with rhabdoid features is a novel malignancy characterized by a small round cell neoplastic process with focal expression of rhabdoid features, a stromal reaction, and the potential for differentiation along different cell lineages (Gaffney and Breatnach 1989).

Hepatoblastomas with Rhabdoid Features

Part of hepatoblastomas of the small cell undifferentiated (SCUD) type show rhabdoid-like cells. These neoplasms have been termed small cell undifferentiated hepatoblastomas with rhabdoid features or SCUD-HB with rhabdoid features (Zimmermann and SIOPEL Group 2003, 2011). Later, malignant hepatic rhabdoid tumor being INI1 negative and morphologically mimicking hepatoblastoma was reported (Wagner et al. 2007). This variant of hepatoblastoma makes part of the group of hepatoblastomas with a low serum AFP level at diagnosis, a high-risk biology, poor response to chemotherapy, and poor outcome (De Ioris et al. 2008). Within a group of 11 patients with SCUD hepatoblastoma, all patients with reported AFP results exhibited normal or minimally increased serum AFP levels. None of these patients survived. Immunostaining revealed that tumors from six of six patients tested were INI1 negative (Trobaugh-Lotrario et al. 2009). Therefore, at least a subset of SCUD hepatoblastomas share morphologic and molecular features and a very aggressive course, with malignant rhabdoid tumors of the liver. Hepatoblastomas with rhabdoid features show SMARCB+/INI1 alterations (Russo and Biegel 2009).

Intrahepatic Cholangiocarcinoma with Rhabdoid Features

Intrahepatic cholangiocarcinoma with rhabdoid features (rhabdoid cholangiocarcinoma; intrahepatic cholangiocarcinoma with rhabdoid transformation) is so far classified as a rare variant of sarcomatoid cholangiocarcinoma characterized by the presence of neoplastic cells with a rhabdoid phenotype (Honda et al. 1996; Lim et al. 2004; Sugano et al. 2013). Similar to other sarcomatoid cholangiocarcinomas (Nakajima et al. 1993), the variant with rhabdoid features reveals a very aggressive course (Lim et al. 2004). In one patient, a 61-year-old female with multiple liver masses at imaging, the tumor consisted of two distinct components, i.e., a tubular adenocarcinoma and a sarcomatous component showing rhabdoid cells expressing both vimentin and cytokeratins (Honda et al. 1996). In the patient reported by Lim and coworkers (2004), a huge intrahepatic tumor in the left liver lobe measuring up to 17 cm was detected, showing extensive necrosis and hemorrhage and an infiltrative border. Viable tumor, found only in the peripheral portion of the mass, was reddish yellow to tan and hemorrhagic. Histologically, the entire neoplasm was composed of loosely cohesive, round to polygonal cells with abundant eosinophilic, glassy cytoplasm and eccentrically placed, vesicular nuclei. Close to the nuclei, the cytoplasmic bodies typical for rhabdoid cells were noted. Immunohistochemically, the tumor cells co-expressed both vimentin and epithelial markers. Some of the cells had mucin-containing vacuoles, but, in contrast to the tumor described by Honda and coworkers, a carcinomatous component was not found in this lesion.

Primary Rhabdoid Tumor of the Gallbladder

In a 46-year-old male patient, the gallbladder showed a slight thickening in the body wall, measuring 1 cm. The lesion was located on the peritoneal side, i.e., away from the liver bed. Sections from this area revealed collections of loosely arranged plump cells with the features of rhabdoid cells, which showed the typical eccentric paranuclear positivity for vimentin (Suri et al. 2003). A second case of gallbladder carcinoma with a rhabdoid component, but associated with sarcomatoid features, was reported in a 61-year-old female patient. This tumor of 4.5-cm size was situated in the neck portion of the gallbladder (Kim et al. 2003).

Intra-abdominal Tumors with Rhabdoid Features Mimicking Hepatic Neoplasms

Localized malignant peritoneal mesothelioma with rhabdoid cells appearing as a liver neoplasm has been reported (Matsukuma et al. 1996).

Pathogenesis

Distinct Presentation Patterns of RT and Their Relation to Distinct Chromosomal Changes

Apart from isolated MRT occurring in a variety of organs, there are distinct clinical MRT entities that have opened the way for the identification of molecular pathogenic pathways. As discussed below, germline mutations of the hSNF5/INI1 gene predispose children to the development of RT. However, familial cases are extremely rare. Pedigrees in which two or more individuals carry germline mutations of this gene characterize the rhabdoid predisposition syndrome (RPS). The term, RPS, was first coined in 1999 (Sevenet et al. 1999). The tumors associated with RPS include AT/RT, choroid plexus carcinoma, medulloblastoma, extrarenal RT, and rarely renal RT (Sevenet et al. 1999; Taylor et al. 2000; Lee et al. 2002a; Janson et al. 2006; review: Roberts 2006). There is evidence for a favorable outcome of patients affected by RT due to RPS (Kordes et al. 2014). The genetic causes of RPS are complex in that not all patients show mutations of the hSNF5/INI1 locus. In fact, non-linkage of familial RT to hSNF5/INI1 (SMARCB1) has implied a second locus for RPS (Frühwald et al. 2006). The complexity of RPS is furthermore illustrated by the finding of unaffected carriers in a family segregating a germline mutation of INI1 and RT, supporting the hypothesis that there may be variable risks of development of RT in the context of a germline mutation and suggesting that there may be a developmental window in which most RT occur (Janson et al. 2006).

Atypical teratoid/rhabdoid tumor (AT/RT) of the central nervous system is a distinct entity among malignant pediatric brain tumors (Briner et al. 1985; Rorke et al. 1995; Ho et al. 2000; Lee et al. 2002b; Packer et al. 2002; Wharton et al. 2003; review: Tekkok and Sav 2005). AT/RT commonly develops in the posterior fossa, similar to medulloblastoma. The tumor's incidence is still undefined, but may comprise as high as one in four primitive CNS tumors in infants (report on a workshop; Packer et al. 2002). AR/RT occurs almost exclusively in children, most of whom are 5 years old or less, but the neoplasm can also develop in adults (Raisanen et al. 2005). Histologically, AT/RT is defined as a polymorphous malignant neoplasm often featuring rhabdoid, PNET, epithelial, and mesenchymal components (Oka and Scheithauer 1999; Ho et al. 2000), these various features having led to the term, teratoid, but of course AT/RT is not a germ cell tumor. The lesion has been shown to involve aberrations of chromosome 22q (Biegel et al. 1989, 1990, 1992; Lee et al. 2002b; Wharton et al. 2003), also in adult cases (Raisanen et al. 2005), and the gene involved in this situation is hSNF5/INI1, as discussed below. Histologically, AT/RT is rarely mimicked by another unusual pediatric cerebellar tumor with rhabdoid cells and unique cytoplasmic inclusions in the presence of INI1 gene product (Sasaki et al. 2005).

Cytogenetic Features of RT and the Identification of a Relevant Rhabdoid Tumor Gene

As discussed above, numerous reports have documented anomalies of chromosome 22 in RT, chiefly deletions, translocations, and monosomy involving 22q and a chromosomal site encoding a tumor suppressor gene (Biegel et al. 1989, 1990, 1992; Schofield et al. 1996; Rosty et al. 1998; White et al. 1999; Roberts and Orkin 2004; Halliday et al. 2009; Roberts and Biegel 2009; Stojanova and Penn 2009), although other translocation partners have also been identified (Donner et al. 2000). The gene located on 22q11.2 is called hSNF5 or INI1 (BAF47; SMARCB1: SWI/SNF-related, matrix-

associated, actin-dependent regulator of chromatin). Mutations of this gene are detectable in about 75 % of patients with RT (Biegel et al. 2000; Bourdeaut et al. 2011; Hollmann and Hornick 2011). The gene product is a member of the ATP-dependent SWI/SNF chromatin-remodeling complex that was first identified as a homologue of the yeast Snf5 protein and as a protein that interacts with the HIV integrase protein (hence the alternative term, integrase interactor 1; Kalapan et al. 1994; Muchardt et al. 1995). Its role as a tumor suppressor gene in the pathogenesis of rhabdoid tumors has been reviewed (Biegel et al. 2002). However, deficient hSNF5/INI1 gene function is not restricted to rhabdoid tumors but also occurs in other neoplastic processes, including choroid plexus carcinoma, medulloblastoma, and central primitive neuroectodermal tumors (Sevenet et al. 1999) and chronic myeloid leukemia (Grand et al. 1999). In rhabdoid tumors, hSNF5/INI1 inactivation is mainly associated with homozygous deletions and mitotic recombination causing truncated gene products (Versteege et al. 1998; Rousseau-Merck et al. 1999; Uno et al. 2002; Eaton et al. 2011; Kosho et al. 2013; Shain and Pollack 2013). Gene targeting experiments confirmed that INI1 also functions as a tumor suppressor in mice. While INI1-null mice are embryonic lethal, 15–30 % of mice heterozygous for INI1 develop malignant tumors with variable rhabdoid features (Roberts et al. 2000; Guidi et al. 2001, 2004). The effects of mutationally changed INI1 on cellular functions are complex. The nuclear export of INI1 depends on a masked nuclear export signal (NES) in the highly conserved repeat 2 domain of INI1 that mediates regulated hCRM1/exportin1-dependent nuclear export, and mutations in this region cause mislocalization in the cytoplasm (Craig et al. 2002). Interestingly, rhabdoid tumors with biallelic loss of SMARCB1 have these features as almost the sole recurrent event, otherwise showing an extremely low rate of mutations (Lee et al. 2012). SMARCB1-deficient neoplasms showed downregulation of the BIN1 tumor suppressor through epigenetic mechanisms, thus identifying BIN1 as and SNF5 target gene (McKenna et al. 2012).

What Is hSNF5/INI1?

The hSNF5/INI1 (SMARCB1/Baf47) tumor suppressor is an integral component of mammalian SWI/SNF chromatin-remodeling enzymes that contain more than ten proteins, including SNF2 family ATPases BRM (Brahma in Drosophila) or BRG1 (Brahma-related gene 1; BRM), hSNF5/INI1 (BAF47), BAF155, BAF170, BAF60, and BAF57, and that contribute to the regulation of many genes (reviews: Hargreaves and Crabtree 2011; Euskirchen et al. 2012). This multisubunit machine utilizes ATP hydrolysis to modulate chromatin structure and to regulate promoter nucleosome. Generally, BAF complexes establish nucleosome occupancy patterns, which are crucial to epigenetic regulation. SMARCB1 is responsible for generating nucleosome-depleted regions or NDRs (Montecino et al. 2007; Sims et al. 2007; Lu and Roberts 2013; Tolstorukov et al. 2013; You et al. 2013). During carcinogenesis, the functions of chromatin regulators are often disrupted by genetic mutations and/or epigenetic alterations, causing genome-wide derangements of gene function (Wilson and Roberts 2011; Shu et al. 2012; reviews: Lee and Roberts 2013; Oike et al. 2013; Wang et al. 2014). The expression levels of these core SWI/SNF subunits are stoichiometric, with few or no unbound molecules in the cell. The subunit levels are regulated through protein-protein interactions and via proteasomal degradation (Chen and Archer 2005). The SWI/SNF complex also makes part of a protein complex associated with regulatory DNA sequences (locus control regions, LCR) that protect transgenes from position-effect variegation and heterochromatinization and also promote copy-number dependence of the levels of transgene expression. This LCR-associated remodeling complex (LARC) contains, apart from SWI/SNF, heterogeneous nuclear ribonucleoprotein C1/C2 and the gene silencer, nucleosome remodeling and deacetylating protein (NuRD)/MeCP1 (Mahajan et al. 2005). Truncation of INI1 causes deficient gene function, but SWI/SNF enzyme complex formation as such and the expression of many BRG1-dependent genes are independent of INI1

(Doan et al. 2004), indicating the complex construction features of this protein network. SWI/SNF chromatin-remodeling enzymes utilize the energy of ATP hydrolysis to alter histone-DNA contacts, resulting in an altered nucleosome structure that can lead to repositioning, or sliding, of nucleosomes along the DNA (Becker 2002; Becker and Horz 2002; Narlikar et al. 2002). But the entire protein network of the complexes also depends on the differential functions of single proteins involved, apart from hSNF5/INI1. Human Brahma (hBRM), a catalytic component of the SWI/SNF complex, associates with the methyl-CpG-binding protein, MeCP2, which mediates transcriptional repression of methylated genes, BRM thus being functionally linked to gene silencing (Harikrishnan et al. 2005). BRM-deficient mice also show methylation and silencing of gene promoters (Banine et al. 2005). The chromatin-remodeling and mRNA splicing functions of the Brahma complex are mediated by the SMARCB1 subunit (Zraly and Dingwall 2012).

BAF57 is a subunit in the SWI/SNF complex that is required for maintaining the proper subunit composition of the complex (Hah et al. 2010). It is associated with the BRG1 ATPase and with hBRM (human Brahma) ATPase and regulates cell cycle progression through the transcriptional regulation of certain cell cycle-related genes. Furthermore, it induces apoptosis by stimulating CYLD, the tumor suppressor involved in familial cylindromatosis, an autosomal dominant predisposition syndrome of multiple tumors of skin appendages (Wang et al. 2005). Mutations in the CYLD gene are also involved in two other disorders, Brooke-Spiegler syndrome and multiple familial trichoepithelioma (Salhi et al. 2004), all of which might however represent phenotypic variation of a single entity (Bowen et al. 2005). CYLD is a deubiquitinating enzyme (Trompouki et al. 2003) which attenuates NF-kappaB signaling by selectively removing K63-linked polyubiquitin chains (deubiquitination) that activate IkappaB kinase (IKK) which phosphorylates IkappaB, via interaction of CYLD with NEMO, the regulatory subunit of IKK (Kovalenko et al. 2003; Saito et al. 2004). CYLD also deubiquinates other proteins, including TNF receptor-associated factor 2 (TRAF2; Trompouki et al. 2003). The deubiquinating activity of CYLD is regulated via IkappaB kinase gamma-dependent phosphorylation (Reiley et al. 2005). BAF60a (BRG1-associated factor 60a) mediates critical interactions between nuclear glucocorticoid receptors and the BRG1 chromatin-remodeling complex (Hsiao et al. 2003). As other proteins, the expression of chromatin-remodeling proteins is subject to the action of distinct types of microRNAs. Studies on the differential microRNA expression profiles between malignant rhabdoid tumor and epithelioid sarcoma uncovered that microRNA193a-5p seems to downregulate SMARCB1 mRNA expression (Kohashi et al. 2014).

What Are the Cellular Actions of SWI/SNF?

Via several mechanisms, components of the SWI/SNF protein system including hSNF5/INI1 affect several cellular biochemical pathways and associated functions. Main cellular function pathways regulated by this system are the cell division cycle, cell differentiation, cytoskeletal functions, and epigenomic effects. In addition to cellular structures and components, SMARCB1 can also interact with foreign proteins, including the cytomegalovirus proteins UL114 and UL44 (Ranneberg-Nilsen et al. 2012).

Cell Division and Cell Survival

The cell cycle arrest machinery generally depends on components of SWI/SNF-related complexes (Ae et al. 2002; Betz et al. 2002; Versteege et al. 2002; Sansam and Roberts 2006; Kuwahara et al. 2010). The loss of hSNF5/INI1 function in RT-derived cells leads to polyploidization and chromosomal instability by compromising the mitotic checkpoint of the cell cycle (Imbalzano and Jones 2005; Vries et al. 2005). hSNF5/INI1 represses cyclin D1 transcription in rhabdoid cells

by directly recruiting histone deacetylase 1 complex to its promoter, and genetic ablation of cyclin D1 abrogates the genesis of rhabdoid tumors resulting from INI1 loss in INI1 heterozygous mice with targeted INI1 disruption (Tsikitis et al. 2005). Apart from the enzymatically active hSNF5/INI1, the complexes contain noncatalytic subunits, including p270/ARID1A and ARID1B. It has been shown that the p270 (ARID1A/SMARCF1) subunit is essential for normal cell cycle arrest (Nagl et al. 2005). The tumor suppressor activity of SNF5/INI1 depends on its regulation of cell cycle progression, where it interacts and cooperates with retinoblastoma protein (Chai et al. 2007). Its inactivation leads to aberrant upregulation of E2F targets and increased levels of p53 that are accompanied by apoptosis, polyploidy, and cell cycle progression or cell cycle arrest (Isakoff et al. 2005; Kato et al. 2007). One downstream target of SNF5 is Aurora kinase A. SNF5/INI1 represses Aurora A transcription in a cell-specific manner, and the loss of SNF5 function as found in RT leads to aberrant overexpression of Aurora A in these neoplasms, required for survival (Lee et al. 2011). The loss of SMARCB1, as found in rhabdoid tumor cells, is associated with persistent AKT activation, contributing to proliferation and survival (Darr et al. 2014). In RT, the core component of SNF5 can block the Hedgehog signaling effector, glioma-associated family member-1/GLI1, which promotes malignant RT growth when SNF5 is lost (Jagani et al. 2010; Reiter 2010). The loss of SNF5 phenocopied beta-catenin hyperactivation and was essential for regulating Wnt/beta-catenin pathway target expression (Mora-Blanco et al. 2014).

Cell Differentiation

Chromatin modifiers, apart from a broad array of transcription factors, are important for cell differentiation pathways (Albanese et al. 2006). In an animal model, it was shown that hepatic SNF5 deletion caused neonatal death and the formation of a hepatic epithelium was also affected in SNF5-deficient livers, due to gene misexpression, suggesting a role of chromatin remodeling in hepatic cell lineage differentiation (Gresh et al. 2005).

Cell Size, Cell Shape, Nuclear Shape, and Cell Motility

hSNF5/INI11 modulates cell growth and actin cytoskeleton organization.

It has been shown that this tumor suppressor induces marked modifications of the cell shape including complete disruption of the actin stress fiber network and disappearance of focal adhesions associated with upregulation of genes involved in the organization of the actin cytoskeleton (Medjkane et al. 2004). The chromatin-remodeling ATPase, BRG1, contributes to the regulation of overall cell size and shape. BRG1 also affects nuclear morphology. Knockdown of BRG1 induced groves in the nuclear periphery of epithelial cells, an alteration independent of cytoskeletal connections (Imbalzano et al. 2013). SMARCB1 interacts with SCAI (suppressor of cancer cell invasion), a transcriptional modulator regulating cancer cell motility through suppression of MAL-/SRF-dependent gene transcription (Kressner et al. 2013). SNF5/INI1 regulates cell migration in a RhoA-dependent manner (Caramel et al. 2008).

Endocytosis

The SMARCB1 subunit of the SNF complex interacts with dynamin-2 in the cytoplasm, a large GTPase involved in endocytosis and vesicle dynamics. SMARCB1 inhibits assembly stimulated dynamin-2 GTPase activity and thus modulates endocytosis (Alfonso-Pérez et al. 2014).

Epigenetic Mechanisms

Due to its functions as a chromatin-remodeling protein, SMARCB1 affects epigenomic mechanisms linked to DNA methylation (review: Weichenhan and Plass 2013).

Other Chromatin-Remodeling Proteins

Apart from SWI/SNF and the associated protein network, other proteins act as chromatin remodelers and can potentially cause disease when altered in function. The nucleosome-binding family of high mobility group proteins (HMGN), which facilitate the formation of critical chromatin structures more conducive for transcription, seem to act independently of SWI/SNF (Hill et al. 2005). Chromatin remodeling is affected by the evolutionarily conserved Swi3p, Rsc8p, and Moira (SWIRM) domain that is found in many chromosomal proteins involved in chromatin modifications (Qian et al. 2005). The SWI/SNF-like chromatin remodeler ATRX is involved in the regulation of histone variant deposition. ATRX is mutated at high percentages in multiple tumor types, and its mutations are also found in a syndrome after which it is named, alpha thalassemia/mental retardation, X-linked (Ratnakumar and Bernstein 2013). Chromatin remodeling in mammals is also mediated by proteins of the hINO80 family (human inositol auxotrophy 80) which catalyze ATP-dependent nucleosome remodeling (Bakshi et al. 2006; Chen et al. 2011), including the mammalian Tip49a and Tip49b proteins belonging to the conserved RVB family of ATPases (Jin et al. 2005). The hINO80 SNF2 ATPAase is subject to regulation at multiple levels in the INO80 chromatin-remodeling complex (Chen et al. 2013). hINO80 exhibits complex interactions with cytoskeletal proteins. Its chromatin-remodeling complex interacts with nuclear actin which acts as a monomer in the nucleus (actin-containing chromatin-modifying complexes; Kapoor and Shen 2014). Human INO80 binds to microtubules through the E-hook of tubulin and thus affects spindle assembly (Park et al. 2011). A factor involved in chromatin remodeling is called the "facilitates chromatin transcription (FACT) complex" which affects chromatin function during transcription, replication, and DNA repair. Via selective chromatin remodeling of genes that stimulate proliferation, inhibit cell death, and regulate cellular stress responses, FACT complex is an accelerator of tumor transformation (Garcia et al. 2013). The chromatin-remodeling complex NoRC silences a fraction of rRNA genes and promotes a repressive heterochromatin structure at centromeres and telomeres, a structure required for sustaining genomic integrity (Postepska-Igielska et al. 2013).

Neoplasms Other Than Rhabdoid Tumors Associated with Alterations and Mutations of Chromatin-Remodeling Factors

Deficiency of SNF5/INI1 is characteristic for RT, but it also occurs in other neoplastic processes (Bourdeaut et al. 2007). Whereas the loss of SMARCB1 is a typical feature of RT, mutations of BRG1/SMARCA4 were found in diverse cancers (Medina et al. 2008), including hepatocellular carcinoma (Endo et al. 2013). Genetic changes in the SMARCB1 gene have been detected in families with schwannomatosis (familial schwannomatosis; Hulsebos et al. 2007; Swensen et al. 2009; Brennan et al. 2011; Melean et al. 2012; Rizzo et al. 2012; Smith et al. 2012a, 2012b; Plotkin et al. 2013; Val-Bernal et al. 2013). Schwannomatosis, characterized by schwannomas synchronously occurring at several sites in the absence of bilateral vestibular schwannomas, is the third major form of neurofibromatosis and may be associated with meningiomas and meningiomatosis (Bacci et al. 2010). These neoplasms seem to develop through a mechanism that is distinct from that of rhabdoid tumors in which the SMARCB1 protein is completely absent (Smith et al. 2012a). Apart from SMARCB1 mutations, multiple diffuse schwannomas also develop in the setting of germline KRAS mutations as a RASopathy phenotype (Bertola et al. 2012), and an autosomal dominant form of multiple schwannomas is caused by germline loss of function in LZTR1 (Piotrowski et al. 2014).

Roles of Deranged Chromatin-Remodeling Factor Functions in Nonneoplastic Disorders

Heterozygous germline mutations in components of the SWI/SNF chromatin-remodeling

complexes were observed in patients with non-syndromic intellectual disability and in Coffin-Siris syndrome and Nicolaides-Baraitser syndrome, disorders associated with severe speech delay (review: Santen et al. 2012). In particular, germline variants in the ARID1A (p270) complex of BAF, involving a protein essential for normal cell cycle arrest, and mutations in SMARCB1, SMARCA4, and ARID1B were observed in patients with Coffin-Siris syndrome.

Other Genes and Gene Products Involved in the Pathogenesis of Rhabdoid Tumors

In AT/RT, aberrant methylation of the RASSF1A gene promoter has been found and suggested to play a role in origination and progression of these tumors (Mühlisch et al. 2006). What is RASSF1A? It is a tumor suppressor gene (RAS association domain family 1 gene) assigned to chromosome 3p21.3 in humans. The isoforms RASSF1, RASSF1A, and RASSF1C are distinguished by alternative NH(2)-terminal exons and the transcripts initiate separate CpG islands as methylation targets. Homologues of RASSF1, however located on other chromosomes, are the RASSF3 and NORE1 genes (Tommasi et al. 2002). The loss of RASSF1A (but not RASSF1C) expression by either promoter silencing or loss of heterozygosity (LOH) is a frequent event in several human cancers, and this holds particularly true for epigenetic inactivation of the gene's promoter via methylation mechanisms (Pfeifer et al. 2002; Dammann et al. 2003, 2005; Pfeifer and Dammann 2005). In other tumors, overexpression of RASSF1A is involved (Agathanggelou et al. 2005). RASSF1A-knockout mice exhibit increased susceptibility to spontaneous and carcinogen-induced tumors (Tommasi et al. 2005). RASSF1A has several known actions. It can delay cell cycle progression at the G1/S checkpoint by association with the cyclin A transcription repressor, p120E4F (Fenton et al. 2004), and can cause mitotic arrest through interaction with cdc20 and the inhibition of the anaphase-promoting complex (Song et al. 2004). It furthermore promotes apoptosis mediated through interaction with NORE1, MST1, and MST2 (Dammann et al. 2003). The RASSF1A gene product also associates with microtubules in a paclitaxel-like manner (Dallol et al. 2005), and the centrosomal RASSF1A-binding protein 1 regulates mitotic progression by recruiting RASSF1A to spindle poles (Song et al. 2005), these mechanisms affecting cytokinesis and cell migration. With respect to the microtubule cytoskeleton, RASSF1A interacts with a microtubule-associated protein (MAP-1) homologue, C19ORF5, which specifically associates with microtubules stabilized by RASSF1A, and can cause mitochondrial aggregation and genome destruction (MAGD; Liu et al. 2005). On the other hand, RASSF1A and MAP-1 link death receptor signaling to Bax conformational change and cell death (Baksh et al. 2005), illustrating that RASSF1A is involved in both cell cycle regulation and apoptosis. A rhabdoid morphology in gastrointestinal stromal tumors is associated with PDGFRA mutations (Schaefer et al. 2014).

Hepatobiliary Germ Cell Tumors

Germ Cell Tumors of the Liver

79

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_79

Abstract

Most germ cell tumors develop in the gonads, but, due to germ cells misplaced during embryogenesis, these neoplasms can arise in numerous extragonadal sites, including the hepatobiliary tract. Primary teratomas of the liver are known for a long time and can present as liver tumors in the prenatal period already. Hepatic teratomas diagnosed in adults must be distinguished from germ cell tumor metastases that underwent differentiation into teratoma. Furthermore, hepatic teratomas have to be distinguished from mixed tumors and teratoid hepatoblastomas.

Yolk sac tumor can develop in the liver both in the pediatric age group and in adults. This neoplasm is frequently associated with elevated serum levels of alpha-fetoprotein. Non-gestational and extragonadal choriocarcinoma very rarely develops in the liver of children and adult patients. A distinct condition is infantile choriocarcinoma syndrome, where gestational placental choriocarcinoma spreads to the fetus. Other rare hepatobiliary germ cell tumors include mixed germ cell tumors and dermoid cyst.

Introduction

ICD-O codes:

Yolk sac tumor	9071/3
Choriocarcinoma	9100/3
Teratoma	9080/3
Dermoid cyst	9084/0
Teratoma with somatic-type malignancies	9084/3
Mixed germ cell tumors	9085/3

Germ cell tumors represent a complex group of neoplasms derived from germ cells located in various organs and tissues. Most germ cell tumors develop in the gonads, mainly in the testis, but they also originate from misplaced germ cells that occur in extragonadal locations, mostly along the central body axis, beginning in the CNS (pineal gland area) and ending in the sacrococcygeal region. Testicular germ cell tumors represent the most common solid organ malignancy afflicting young adult men with peak incidences ranging between 25 and 35 years of age. A report of the SEER Program revealed that its incidence has increased by 44 % between 1973 and 1998, including a 24 % rise in the incidence of non-seminomatous tumors and a 64 % rise in seminomas (McGlynn et al. 2003).

With few exceptions, almost all types of germ cell tumors listed below have been diagnosed in the liver and/or biliary tract either as primary neoplasms or metastatic disease. A part of germ cell tumors cause solitary liver masses, while others, especially choriocarcinoma, often present as multiple hepatic lesions. Similar to gonads and certain extragonadal sites, germ cell tumors, and in particular teratomas, are manifest in the form of cystic liver lesions that may mimic other cystic processes of the liver, both in adults and children.

Classifications

Mainly in a clinical-oncological setting, the tumors are classified into two major histological types: seminoma and non-seminomatous germ cell tumors, with seminomas comprising about 40–50 % of germ cell tumors (reviews: Ulbright 2005; van de Geijn et al. 2009). A different classification systems divided germ cell tumors into five types. Type I germ cell tumors include the teratomas and yolk sac tumors that occur in neonates and infants. Besides the testis, these neoplasms also occur in the sacrococcygeal region, head and neck, liver and other visceral organs, and midline of the brain. The cell of origin is thought to be an embryonal germ cell with a partially erased pattern of genomic imprinting. Type II germ cell tumors comprise seminomatous and non-seminomatous tumors. The seminomas are termed dysgerminoma in the ovary, gonadoblastoma in dysgenetic gonads, and germinoma in the brain. Seminomas are composed of malignant cells resembling gonocytes (Culty 2009). The non-seminomatous tumors can consist of undifferentiated cells, forming embryonal carcinoma, whose cells are the malignant counterpart of the pluripotent stem cells of the embryonal inner cell mass, which can differentiate into yolk sac tumor, choriocarcinoma, and

Table 1 WHO classification of germ cell tumors (Eble et al. 2004)

Intratubular germ cell neoplasia, unclassified type (IGCNU; ICD-O code 9064/2)
Tumors of one histological type
Seminoma (ICD-O code 9061/3)
Variants: cribriform, pseudoglandular, and tubular variants; seminoma with high
Mitotic rate; seminoma with syncytiotrophoblastic cells
Spermatocytic seminoma (ICD-O code 9063)
Spermatocytic seminoma with sarcoma
Embryonal carcinoma (ICD-O code 9070/3)
Yolk sac tumor (ICD-O code 9071/3)
Choriocarcinoma (ICD-O code 9100/3)
Teratoma (ICD-O 9080/3)
Dermoid cyst (ICD-O code 9084/0)
Teratoma with somatic-type malignancies (ICD-O code 9084/3)
Tumors with more than one histological type (mixed forms)
Mixed germ cell tumors (ICD-O code 9085/3)
Polyembryoma (ICD-O code 9072/3)

teratoma. Type III germ cell tumors consist of spermatocytic seminoma, only found in the testis of elderly men. Type IV and V germ cell tumors are the dermoid cysts found predominantly in the ovary and hydatiform moles, respectively. These two tumor forms are characterized by their exclusively somatic and trophoblastic differentiation, respectively. This previous classification has now been revised and changes in significant parts, resulting in the current 2004 WHO classification (Eble et al. 2004). The WHO classification is summarized in Table 1.

A distinct entity is teratoma with a malignant somatic component (TMSC), a rare disorder diagnosed when a somatic-type malignancy occurs in the context of a germ cell tumor. TMSC predominantly occurs in adults (with a mean age at presentation of 31 years in one study of testis tumors; Colecchia et al. 2011) and exceptionally in the pediatric age group.

In 1997, the International Germ Cell Consensus Classification (IGCCC) was published, having two prognostic categories (good and intermediate) for seminomas and three prognostic categories (good, intermediate, poor) for non-seminomatous germ cell tumors. The classification is based on the following independent prognostic variables: histology of the primary tumor, site of the primary tumor, degree of pretreatment tumor marker elevation (AFP, beta-HCG, LDH), and the presence of nonpulmonary visceral metastases (International Germ Cell Cancer Collaborative Group 1997).

Teratoma of the Liver (ICD-O Code 9080/3)

Introduction

Teratomas are germ cell neoplasms that develop from the three embryonic germ layers (teratoma triphyllicum) and are characterized by virtually any tissue type. Mature teratomas are benign tumors which are usually cystic. Dermoid cyst (type IV germ cell tumor) is often regarded as a special form of mature teratoma with a predominantly ectodermal derivation but seems to be a distinct entity. Immature teratomas are always potentially malignant, but their biology and prognosis depend on the anatomic site of the tumor, patient age, and the fraction of immature elements within the tumor.

Teratoma has been described to arise as a primary tumor in the liver. A first report appeared in 1898 under the term teratoma hepatis (Misick 1898). However, an analysis of this case report shows that this lesion has now be reclassified as mixed epithelial and mesenchymal hepatoblastoma. True teratoma of the liver is a rare lesion. In a review of 70,000 consecutive surgical specimens, only one such tumor was found (Pollice 1973). Among the cases reported, there is, as in other teratomas, a female preponderance. Hepatic teratomas occasionally present as tumors prenatally, including one case observed in an anencephalic fetus (Robinson and Nelson 1986). At necropsy, the liver contained a solid, gray-brown, firm, irregular, and in part nodular mass situated predominantly in the midportion of the right liver lobe. Histologically, the tumor consisted of small to medium spaces lined by biliary-type epithelium, a cystic focus of

squamous epithelium, striated muscle cells, and fascicles of peripheral nerves. The tumors can grow to large size during the fetal period and cause an absolute obstacle to delivery (Froboese 1952). True teratomas of the liver can occur in infants and children.

Selected References Misick 1898; Nissel 1928; Yarbrough 1944; Hartz and Van der Sar 1945; Froboese 1952; Yarbrough and Evashwick 1956; Potter 1962; Misugi and Reiner 1965; Kiryabwire and Mugerwa 1967; Dehner 1968; Nikaidoh et al. 1970; Grave 1972; Pear and Boline 1972; Pollice 1973; Clatworthy et al. 1974; Fabre et al. 1977; Dische and Gardner 1978; Witte et al. 1983; Kraudel and Williams 1984; Robinson and Nelson 1986; Rao et al. 1987; Schnater et al. 2005; Dong et al. 2009; Gupta et al. 2013.

Several cases of hepatic teratomas have been observed in adults.

Selected References Sissoew 1922; Ehrich 1924; Imai 1934; Leschke 1959; Weis and Luechtrath 1964; Marennyi 1971; Ishak 1976; Todani et al. 1977; Watanabe et al. 1978; Gonzalez-Crussi 1982; Teleshov 1989; Winter and Freeny 1993; Kobayashi and Inoue 1995; Alam et al. 1998; Theegarten et al. 1998; Cöl 2003; Nirmala et al. 2003; Martin et al. 2004; Strunk et al. 2005; Rahmat et al. 2006; Certo et al. 2008; Dong et al. 2009; Madan et al. 2010; Zhao et al. 2010.

Clinical and Imaging Features

The common initial sign was abdominal enlargement, although obstructive jaundice and anemia were also reported. Many germ cell tumors secrete AFP, in particular yolk sac tumor. Also immature teratomas often secrete AFP (Arai et al. 1997; Cöl 2003). Lectin-reactive AFP (L3) may be employed as a discriminator, as hepatoblastomas and yolk sac tumors have a high or very high L3 fraction, whereas immature teratomas show an L3 fraction that is around 10 % (Kinoshita et al. 2008). Hepatic teratomas can very rarely give rise to secondary neoplasms, such as squamous cell carcinoma (Imai 1934). The typical X-ray feature of benign hepatic teratomas is a liver mass with focal calcifications. Benign teratomas of the liver are usually cystic lesions which show a mixed echo pattern in US. Hypo- or anechoic components represent the cystic portions of the masses. Hyperechoic foci could represent either calcifications or macroscopic fat. These components are differentiated by the abrupt posterior acoustic shadowing behind calcifications but gradual attenuation of the sound beam behind fat. Fat-fluid levels occurring owing to the presence of sebum are pathognomonic findings (Martin et al. 2004). CT reveals semisolid heterogenic structures with multiple low-density cystic and solid elements. However, this pattern has also been observed in immature hepatic teratomas (Cöl 2003). Hepatic teratomas are usually well-delineated lesions that are easily resectable from the surrounding hepatic parenchyma.

Pathology

Macroscopy

Immature teratomas are bulky and usually have a smooth external surface. On section they exhibit a solid or predominantly solid structure, large cystic spaces being less prominent than in mature teratomas. But as in the mature variants, grossly visible adipose tissue, bone, mineralized parts, sticky masses within cysts, and even hair may be noted. The viscous, yellowish masses found within cysts grossly resemble the contents of epidermoid cysts and may contain glittering crystals of cholesterol and few to numerous hairs.

Histopathology, Immunohistochemistry, and Ultrastructure

The typical tissual and cellular composition of hepatic teratomas reflects that teratomas located elsewhere (Figs. 1 and 2). The features of a triphyllic teratoma have been illustratively described in a report from 1945 already

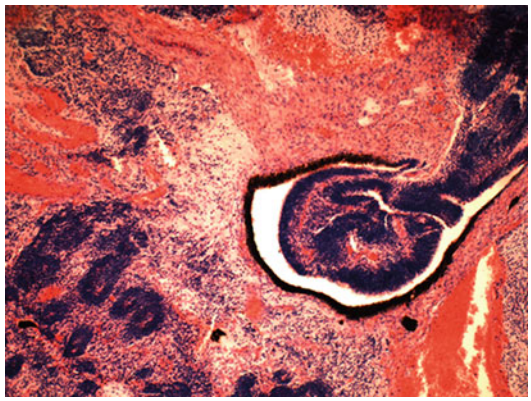

Fig. 1 Mature teratoma of the liver. In the *right half* of the figure, an abortive eye equivalent with a pigment epithelium layer is seen (hematoxylin and eosin stain)

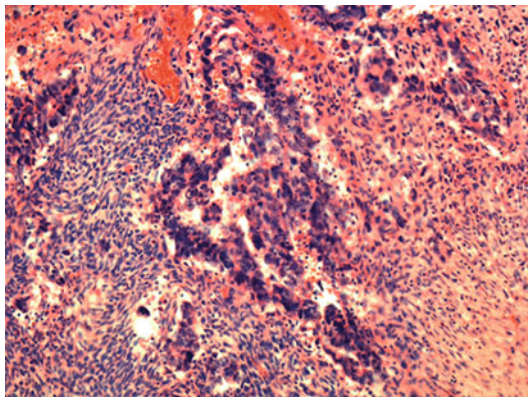

Fig. 2 Immature teratoma of the liver. There is a complex mixture of primitive mesenchyme and highly atypical epithelial structures (hematoxylin and eosin stain)

(Hartz and van der Sar 1945; see above). Neuroectodermal tissues including the brain and melanin-producing cells have been reported several times (Imai 1934; Hartz and van der Sar 1945; Froboese 1952; Watanabe et al. 1978). A part of hepatic teratomas showed distinct histologic patterns. The 32-year-old male patient described by Imai (1934) is of special interest insofar as a tumor in the epigastric region was known since infancy. The tumor had increased in size in the last year. The tumor was unresectable and the patient died. Autopsy revealed a large globular tumor on the inferior surface of the right lobe. Histologically, the tumor was a mature triphyllic teratoma containing the skin, bone, cartilage, bronchial mucosa, salivary glands, nerve fibers, and an eye anlage. The mature teratoma had now started to grow because a squamous carcinoma had arisen in it. The case described by Yarbrough (1944) was a 6-week-old female infant presenting with irritability, vomiting, constipation, and a rapidly enlarging abdomen. Imaging revealed a large abdominal tumor, and surgery revealed a partially cystic tumor mass at the margin of the liver, weighing 3.5 lb. Histology disclosed a mixture of connective tissue, adipose tissue, cartilage and bone, skin with hair follicles, intestinal and bronchial mucosa, liver, pancreas, cysts with squamous epithelium, brain tissue with choroid plexus, and hypophyseal tissue. The presence of hypophysis in this case is remarkable, as pituitary tissue is almost never found in teratomas. Choroid plexus components are also rare; in the figure published of Yarbrough, we note typical papillary fronds covered by the one-layered epithelium characteristic of choroid plexus. A further exemplary case of neonatal hepatic teratoma is the patient described by Hartz and Van der Sar (1945). The medial part of the right liver lobe was occupied by a large, nodular soft tumor, measuring $8 \times 6 \times 5$ cm. On sections it appeared that the nodes were really thin-walled cysts, giving the cut surface a honeycombed appearance. The tissue between the cysts contained few islands of cartilage. Histologically, the tumor was composed of tissues, derived from the three germ layers. One of the cysts was lined by skin with hair follicles and sebaceous glands. Other cysts contained gastric mucosa with parietal cells or colonic-type mucosa. Between the cysts, one noted salivary gland tissue, glioneural tissue, striated muscle tissue, cartilage, and adipose tissue. The fetus with hepatic teratoma reported by Dische and Gardner (1978) had trisomy 13 and an additional teratoma in the neck region. At autopsy, the liver weighed 7 g and grossly was not remarkable except for a few discrete pale areas in both lobes. Histology disclosed parenchyma intimately mixed with squamous epithelium, hair, and clusters of glomeruloid structures with adjacent tubules. Connective tissue components containing large nerve trunks, skeletal muscle cells, ducts with sloughed lining cells, and dystrophic calcifications were present. The case of a 20-year-old female patient, reported by Watanabe et al. (1978), having

a true teratoma of the liver is difficult to judge because she had had dysgerminoma of her left ovary resected 8 years prior to the resection of the liver tumor. Problematic is the case described by Misugi and Reiner (1965). A hepatic tumor found in two-and-a-half-year-old boy and fully analyzed based on autopsy was diagnosed as being malignant true teratoma. However, most of the tumor consisted of polyhedral epithelial cells with eosinophilic cytoplasm, associated with extramedullary hematopoiesis, and Fig. 1 of the publication clearly shows the features of fetal-type hepatoblastoma. The remaining tumor components revealed ciliated epithelial lumens with cartilage (resembling bronchial structures), mucoid epithelia, keratinizing squamous epithelium, osteoid, striated muscle cells, and central nervous tissue with ganglion cells. Therefore, this tumor today qualifies for mixed epithelial and mesenchymal hepatoblastoma, with teratoid features.

Immunohistochemistry

A part of hepatic germ cell tumors, including immature components of teratomas, express germ cell markers, including nuclear labeling for SALL4 (Trinh et al. 2012; Bai et al. 2013; Camparo and Comperat 2013), NANOG (Bai et al. 2013), and CD133. SALL4 is typically positive in yolk sac tumors and yolk sac tumor components, as is CD117 (Trinh et al. 2012). The tumors can contain glypican-3-positive cells (Bai et al. 2013). Mature teratomas may contain neuroendocrine cell lineages with neurosecretory granules expressing neuron-specific enolase and chromogranin A. Focal expression of pancreatic polypeptide and somatostatin has been observed (Nirmala et al. 2003). Ultrastructurally, these cells show dense-core granules (Nirmala et al. 2003).

Calcified Mature Teratoma of the Liver with Bone and Tooth Formation

Whereas the bone and cartilage are often seen in hepatic teratomas, tooth-forming teratoma is a very rare primary tumor in the liver (Froeboese 1952; Leschke 1959; Kalinin 1964; Kiyabwire and Mugerwa 1967; Han 1970; Watanabe et al. 1978; Gupta et al. 2013). Kalinin (1964) reported a 25-year-old female with a cyst in the right liver lobe, showing an egg shell-like calcification and teeth at radiography. In the case described by Han (1970), a 46-year-old man showed a 10 cm-sized calcified mass in the right upper quadrant near the midline. Two rows of teeth partially embedded into a plaque of bone were seen. At surgery, a 10 cm cystic mass was found in the quadrate lobe of the liver. On exploration of the common bile duct, several hairs were noted within it ("trichophilia"), and a probe could be easily passed from the common duct into the cyst. Compression of the cyst resulted in the extrusion of a yellowish fluid mixed with hairs through the common bile duct (Han 1970). In a mature hepatic cystic teratoma diagnosed in a 4-year-old boy, tooth enamel and pulp, but no fully developed teeth, were detected (Gupta et al. 2013).

Teratoma with Somatic-Type Malignant Component in the Liver (ICD-O Code 9084/3)

Teratoma with a malignant somatic component (TMSC) is rare variant of teratoma characterized by the evolution of a somatic malignant neoplasm in connection with a germ cell tumor. TMSC mainly develops in adults (Hong et al. 2013; Oosterhuis et al. 2013; Paliwal et al. 2013; Schaefer et al. 2013). Sarcomatous components are rare in germ cell tumors; they have been observed more often in mediastinal germ cell tumors than those of other locations. It has been proposed that they evolve via malignant transformation of a mesenchymal lineage in the germ cell tumor, from a primitive germ cell, or through dedifferentiation. TMSC was also found as hepatocellular carcinoma arising in testicular teratoma (Jain et al. 2013). In the liver, the only observations that may represent TMSC are hepatoblastoma associated with cystic teratoma (Conrad et al. 1993), squamous cell carcinoma arising in hepatic teratoma (Imai 1934), and

mixed hepatic germ cell tumor with sarcomatous components (Xu et al. 2010).

Dermoid Cyst of the Liver (ICD-O Code 9084/0)

This denotes tumors exclusively consisting of skin components, i.e., keratinizing epidermis and associated adnexal structures. This is an excessively rare lesion in the liver (Meckel 1894; Caroli et al. 1963; Yong Hin Nam 1970). In one case, the cyst was filled with the typical fatty and sticky, sebum- and hair-containing mass but histologically also showed a focus of cartilage (Meckel 1894). A second case, referring to a 25-year-old male patient, was characterized by a partly calcified mass of the retroperitoneal space that was in connection with the left hepatic duct. Upon incision of the common hepatic duct, a large amount of sebum-like material and a mèche of long hair could be extracted, this material having been discharged from the cavity of the dermoid cyst (Caroli et al. 1963).

Primary Yolk Sac Tumor (Endodermal Sinus Tumor) of the Liver (ICD-O Code 9071/3)

Introduction

Yolk sac tumor (YST; endodermal sinus tumor, EST) is a rare malignant tumor which usually arises in the gonads, but in 10–15 % of cases occurs in extragonadal sites, mostly in the anterior mediastinum, the retroperitoneal space, and the sacrococcygeal region. Unusual primary sites are the cerebrum and cerebellum, the pineal gland, the eye, the thymus, the stomach, the uterus, the vulva, the urinary bladder, the prostate gland, and the liver.

YST belongs to the group of tumors that can secrete AFP. AFP has three isoforms (L1, L2, and L3), and the L3 fraction is a well-established diagnostic marker for hepatocellular carcinoma. Similar to hepatoblastomas, YST reveals elevation of both total AFP and the L3 fraction (Kinoshita et al. 2008). YSTs have been shown to secrete an AFP isoform (AFP-C) that is normally produced by fetal liver. This AFP mRNA isoform lacks exon 1 and is transcribed form the intron A, the intron between exons 1 and 2. It is assumed that AFP-C located in the cytoplasm plays functional roles different from those of common AFP (Fukusawa et al. 2005). The production of plasma proteins, and in particular of AFP, by YST is regulated by a transcription factor implicated in the regulation of plasma protein production in the liver, CCAAT/enhancer binding protein (C/EBP)-beta (Hirashiki et al. 2005).

Yolk Sac Tumor of the Liver

A primary localization to the liver (hepatic yolk sac tumor) is uncommon but is known both for the pediatric age group and adults. Most of the neoplasms grow within the liver substance. Yolk sac tumor also occurs in the common bile duct (Munghate et al. 2011), in combination with benign teratoma in the common bile duct (Kim et al. 1993b) and in conjunction with hepatocellular carcinoma (Morinaga et al. 1996). The first observation has been published in 1975 (Hart 1975): the tumor was detected in an 18-month-old boy who had an elevated AFP concentration in the preoperative serum sample; after extended right hepatectomy, widespread metastases developed, resulting in death 6 and a half months after resection. Since then, relatively few cases of this lesion have been reported for the liver, both in children and in adults, and most of them presented, and had a similar outcome, as the case originally described in 1975, albeit successful treatment by chemotherapy and liver transplantation has been reported (Abramson et al. 2005). Primary hepatic YST has been observed in patients as old as 64 years (Lenci et al. 2008). In reviewing the literature which we could consult, 7/13 were female and 6/13 male patients; 4/13 were small children (6–27 months) and 9/13 adults, the age at presentation for adults ranging from 24 to 62 years, however, 6/9 being within their 20s. In the 12 patients where serum AFP had been determined, the levels were elevated

throughout, sometimes exceedingly high (up to 255,000 ng/ml; Wakely et al. 1991). The clinical signs are nonspecific and comprise increasing abdominal girth, mass effect with gradually increasing upper abdominal swelling and hepatomegaly, and chest pain. US and CT usually show a well-circumscribed solid and spherical mass.

Selected References Hart 1975; Okamatsu et al. 1980; Yan 1982; Natori et al. 1983; Narita et al. 1988; Wakely et al. 1991; Villaschi and Balistreri 1991; Whelan et al. 1992; Cross and Variend 1992; Higuchi and Kikuchi 1993; Morinaga et al. 1996; Wong et al. 1998; Gunawardena et al. 2002; Toumi et al. 2004; Abramson et al. 2005; Gilbert et al. 2006; Lenci et al. 2008; Moore et al. 2008; Kajo et al. 2009; Warren and Thompson 2009.

The diagnosis of primary hepatic YST obviously requires the exclusion of metastatic disease of a YST located to a more typical compartment, and one may argue that a small extrahepatic primary tumor may have been missed, but at least one autopsy study documented the absence of a primary tumor remote to the liver, resulting in the proof or at least a very high likelihood that primary hepatic YST does in fact exist (Natori et al. 1983). This is further underlined by the two observations where hepatic YST was directly associated with two certainly hepatic primaries, i.e., hepatoblastoma (Cross and Variend 1992) or hepatocellular carcinoma (Morinaga et al. 1996). The 6-month-old boy described by Cross and Variend (1992) had a large tumor of the right hepatic lobe consisting of mixed epithelial and mesenchymal hepatoblastoma (epithelial component mixed fetal-embryonal, osteoid formation) and of yolk sac tumor with typical Schiller-Duval bodies.

Macroscopy

Macroscopically, YSTs of the liver are solitary lesions of mostly large size (reported diameters ranging from 10 to 17 cm). The tumors show gross necroses and hemorrhages and are mostly solid, but hepatic YST may also present as a cystic lesion (Wong et al. 1998). Gross invasion of large portal vein and hepatic vein branches may occur (Morinaga et al. 1996).

Histopathology

The histology of hepatic YST reflects the patterns typical for this tumor (Fig. 3; Wold et al. 1984; Eble et al. 2004). It shows a reticular cellular pattern characterized by a meshwork of communicating spaces mixed with solid sheets of medium-sized to large cells, intermingled with glandular structures and canalicular profiles (the reticular-microcystic pattern). A macrocystic pattern may also occur. About 10 % of the tumors contain, to a variable degree, components with a polyvesicular vitelline pattern, consisting of small cysts embedded in a loose connective tissue and lined by a flat or cuboidal epithelium. Furthermore, papillary structures lined by neoplastic cells arranged around a fibrovascular core are observed, the so-called Schiller-Duval bodies (the endodermal sinus pattern). Parietal yolk sac differentiation denotes the presence of an abundant and hyaline extracellular matrix representing basement membrane-type material. Less frequent components include solid (5 %), papillary (5 %), spindle cell, myxoid, enteric, and hepatoid patterns. Hepatoid YSTs form a distinct subset of

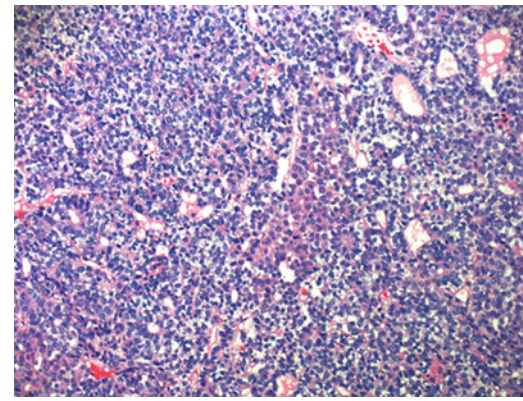

Fig. 3 Yolk sac tumor of the liver. The neoplasm shows several acinar-like structures, but Schiller-Duval bodies are not found (hematoxylin and eosin stain)

YSTs. The possible liver cell differentiation in YST (Jacobsen and Jacobsen 1983; Nakashima et al. 1987) is of particular interest in the present context and is further discussed below. Very rarely, hepatic YST is combined with other components of germ cell tumors, e.g., mature teratoma (Verma et al. 2003) or immature teratoma (Xu et al. 2010). In at least part of the tumor (and in roughly 85 % of cases), hyaline globules of varying size are observed both, intracellularly and extracellularly, chiefly in the areas of a reticular and solid growth pattern, whereas they are rarer in polyvitelline regions. The globules are PAS positive and diastase resistant and may be reactive for alpha-1-antitrypsin and AFP.

Immunohistochemistry

Immunohistochemically, YST cells can express AFP (Fig. 4), alpha-1-antitrypsin, and PLAP in a cytoplasmic pattern but are negative for hCG and Ki-1. Most YSTs are markedly positive for glypican-3 (Esheba et al. 2008). Glypican-3 has a higher sensitivity than AFP for yolk sac tumors (Zynger et al. 2010). SALL4, a stem cell marker, is expressed in the majority of YSTs and is very reliable marker also for metastatic disease of these tumors (Cao et al. 2009). Another marker of embryonic stem cells, the RNA-binding protein LIN28, is also expressed in YSTs and their metastases (Cao et al. 2011). Carcinoembryonic antigen (CEA) and glutathione S-transferase p reactivities can be found in cells of the glandular components but not in other cells.

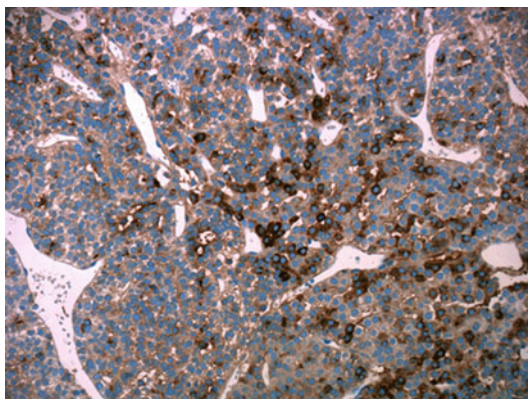

Fig. 4 Focal alpha-fetoprotein (AFP) reactivity in hepatic yolk sac tumor (AFP immunostain)

Yolk Sac Tumor in Other Parts of the Hepatobiliary Tract

YST has been found as a primary tumor in the common bile duct (Munghate et al. 2011) and in the falciform ligament of the liver (Atkinson et al. 1992).

Differential Diagnosis

As the histological presentation of YST is unique, the only relevant differential diagnosis is hepatic metastatic disease, mainly from primary gonadal, retroperitoneal, or sacrococcygeal tumors (Chen et al. 1999; Yalcin et al. 2002). Also the rare gastric and pancreatic YSTs have been found to metastasize to the liver (Tahara et al. 2008; Zhang et al. 2010). As hepatic YST sometimes develops in the cirrhotic liver of an older patient (e.g., 64 years; Lenci et al. 2008) and is associated with elevated serum AFP, this tumor may be misinterpreted as hepatocellular carcinoma.

Primary Choriocarcinoma of the Liver in Adult Patients (ICD-O Code 9100/3)

Non-gestational and extragonadal choriocarcinomas are unusual in adult individuals and, e.g., include primary sites in the esophagus, the stomach, the colon, the lung, and the liver (Fig. 5).

Primary hepatic choriocarcinomas in adults are not only exceedingly rare, but also enigmatic lesions, because it is very difficult to exclude an eventually occult placental or gonadal primary tumor in such situations. Furthermore, a choriocarcinoma phenotype may be mimicked by other tumors occurring in the liver, including the production of hCG. The respective observations have, therefore, raised some criticisms (Anthony 1992), and it remains to be proven in part of the cases whether such neoplasms really occurred primary

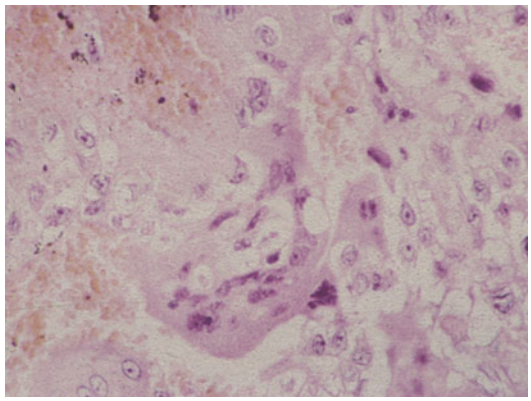

Fig. 5 Choriocarcinoma in the liver. The *center* shows multinucleated syncytiotrophoblastic cells (hematoxylin and eosin stain)

to the liver in these adult patients. To our knowledge, less than 20 cases of primary hepatic choriocarcinomas have been reported (Guretwitsch 1911; Fischer 1913; Stoy 1921; Christeller and Oppenheimer 1925; De Zalka 1927; Benitz 1950; Fine et al. 1962; Heaton et al. 1986; Fernandez-Alonso et al. 1992; Arai et al. 2001; Sekine et al. 2013). Gurewitsch (1911) described the case of a 31-year-old woman who had died 18 months after a hydatiform mole. Tumor nodules were detected in the liver, one nodule invading the small intestine. There was no evidence of tumor in the uterus, but decidual changes and lutein cysts of the ovaries were present. A second instance was reported in 1913 (Fischer 1913). The author described a 45-year-old female who had had two deliveries, the last 18 months prior to admission. At autopsy, numerous hepatic nodules measuring 2–6 cm in diameter were noted, and there was tumor invasion of the hepatic veins. Histology revealed choriocarcinoma. The uterus did not show any tumor tissue. In 1925, a 52-year-old woman was reported with a history of ten normal deliveries, that last of which dating back 12 years. At autopsy, the liver weighed 2,000 g and was filled with choriocarcinoma nodules, the largest having a diameter of 6 cm. Smaller tumor nodules were present in the lungs and intestinal wall. The uterus showed no tumor but displayed decidual change, and lutein cysts were seen in the ovaries (Christeller and Oppenheimer 1925).

In a 40-year-old male, chorionepitheliomatous nodules were observed in the liver, in the absence of any testicular tumor but with nodules regarded as metastatic foci in the lungs, gastric and intestinal mucosa, spleen, and perihepatic lymph nodes (Stoy 1921). The case of De Zalka (1927) was that of 46-year-old woman who had had five pregnancies. She later observed a small tumor in the right abdominal region which about 10 months later occupied the entire right abdomen. In hospital, a liver mass was detected, and she died the following month. Autopsy revealed a liver weight exceeding 4 kg, and the organ was studded with brownish to blue, soft, fragile, and spongy nodules up to 7 cm in diameter. The uterus was normal (also histologically), as were the ovaries, except a hemorrhagic cyst. Histology of the liver nodules disclosed choriocarcinoma. The case of Fernandez Alonso et al. (1992) is important insofar as necropsy was performed, with no evidence of a testicular primary tumor in a detailed workup. The tumors observed in the cirrhotic liver of this 62-year-old male patient were typically hemorrhagic and partially necrotic, and the histologic pattern was characterized by cells with the features of both cytotrophoblast and syncytiotrophoblast, the latter with immunoreactivity for hCG. In a 52-year-old with a large hepatic mass and elevated serum AFP and beta-HCG levels, autopsy revealed multilocular primary hepatic choriocarcinoma combined with embryonal carcinoma (Theegarten et al. 1998). In a group of five males having primary hepatic choriocarcinoma, the average age at diagnosis was 41.6 years, and all patients presented with a large hepatic mass on ultrasonography measuring 11 cm in diameter on average. Three patients showed extrahepatic metastases. None of the patients had evidence of a testicular tumor or a testicular scar (Shi et al. 2010).

Liver Tumors with So-Called Choriocarcinomatous Metaplasia

In exceptional situations, non-germ cell malignancies localized to the liver can contain choriocarcinoma components. Liver metastases of

colorectal adenocarcinoma can undergo so-called choriocarcinomatous metaplasia (Kiran et al. 2001).

Metastatic Choriocarcinoma and the Choriocarcinoma Syndrome

In adult patients, liver metastases of gestational choriocarcinoma (Kang et al. 2002; Lok et al. 2005; Mousavi and Behnamfer 2009), gonadal choriocarcinoma (Stärk 1917; Blanke et al. 2000; Worster et al. 2002), and extragonadal choriocarcinoma (Walthard 1907; Ebisawa et al. 2007; Waseda et al. 2012) have been described. In rare cases, choriocarcinoma metastases in the retroperitoneal space encroach on the hepatic hilum and/or the extrahepatic bile ducts, causing obstructive jaundice (Ahsaini et al. 2012). In part of patients with metastatic choriocarcinoma, including liver metastases, massive tumor hemorrhage followed by sometimes fatal hemorrhagic shock can ensue. This condition is termed choriocarcinoma syndrome (Lok et al. 2005; Baagar et al. 2013; Nakamura et al. 2013).

Primary Choriocarcinoma of the Liver in Infants and Children

Pediatric Gestational Choriocarcinoma

Pure gonadal or extragonadal choriocarcinoma (synonym: malignant teratoma, trophoblastic; MTT) presenting in the pediatric age group is a rare entity, and non-gestational extragonadal choriocarcinoma in children has chiefly been observed in the pineal gland, the region of the third brain ventricle, and the anterior mediastinum. Apart from these non-gestational forms, pediatric gestational choriocarcinoma occurs in few situations, including girls of reproductive age and neonates or infants with visceral manifestations of this tumor. Neonatal/infantile choriocarcinoma is a distinct variant of gestational choriocarcinoma (*infantile choriocarcinoma syndrome*; Witzleben and Bruninga 1968; Belchis et al. 1993), and the placenta is the site of origin of this trophoblastic neoplasm, with subsequent spread into the fetus. The "syndromatic" features are characterized by a presentation at 5 weeks to 7 months of age, an acute illness, anemia and/or pallor, and hepatomegaly (Blohm and Gobel 2004). Further signs comprise a complex hemorrhagic disorder, including hemoperitoneum (rupture of hepatic tumor); multiple pulmonary hemorrhages with hemoptysis, hematemesis, melena, or hematuria; and CNS malfunction (Lazure et al. 2003). Idiopathic massive fetomaternal hemorrhage may occur (Blackburn 1976; Kruseman et al. 1977; Tsukamoto et al. 1986; Chou et al. 2002). The uniform overproduction of b-HCG by the neoplastic trophoblastic cells (chiefly hyperglycosylated hCG, playing a role in invasion; Bahado-Singh et al. 2002), sometimes associated with high serum levels, may result in signs and symptoms of precocious puberty. Infantile choriocarcinoma has an aggressive biology, with only few surviving children reported among patients described in the earlier literature.

Selected References Emery 1952; Kay and Reed 1953; Buckell and Owen 1954; Mercer et al. 1958; Daamen et al. 1961; Witzleben and Bruninga 1968; Kruseman et al. 1977; Nieuwenhuizen Krusemann et al. 1977; Feldman 1977; Aozosa et al. 1981; Kalifa et al. 1981; Tsukamoto et al. 1986; Fraser et al. 1992; Hongo et al. 1992; Belchis et al. 1993; Shitara et al. 1993; Szavay et al. 2000; Blohm et al. 2001; Heath and Tiedemann 2001; Chou et al. 2002; Dumesnil et al. 2005.

Neonatal gestational choriocarcinoma has also been described several times (Kelly et al. 1971; Avril et al. 1986; Flam et al. 1989; Chandra et al. 1990; Belchis et al. 1993; Kim et al. 1993a; Moon et al. 1993; Picton et al. 1995; Sashi et al. 1996; Andreitchouk et al. 1996; Kishkurno et al. 1997). Involvement of the liver in neonatal or infantile gestational choriocarcinoma has been well documented (Hongo et al. 1992; Kim et al. 1993a; Sashi et al. 1996; Andreitchouk et al. 1996; Kishkurno et al. 1997; Szavay et al. 2000; Blohm et al. 2001; Chou et al. 2002;

Liu and Guo 2006; Getrajdman et al. 2012), also in neonates (Moon et al. 1993). In fact the liver is the most frequently involved organ in neonates. In a review of 26 patients reported until 2001, 19 (73 %) showed hepatic tumors (Blohm et al. 2001), and the liver neoplasms are considered as hematogenous metastases of a placental primary tumor, even though one report also considered a primary liver tumor, in the absence of gross placental disease; however, the placenta was not histologically examined (Kim et al. 1993a). The primary placental tumor can be microscopic in size and may be missed on inspection of the placenta (Szavay et al. 2000). At MR imaging, hemorrhage within the hepatic tumors is suggested by the finding of hyperintense T2-weighted images, whereas central portions were hypointense on T1-weighted images and bright on T2-weighted images. T1-weighted postgadolinium imaging showed peripheral enhancement of tumor nodules (Moon et al. 1993; Van der Hoef et al. 2004).

Primary Hepatic Choriocarcinoma in the Pediatric Age Group

Primary infantile hepatic choriocarcinoma (solitary infantile choriocarcinoma of the liver) is a very rare tumor that has first been reported in 1993, based on the observation of an infant with hepatic choriocarcinoma in the absence of gross placental involvement, however, without placental histology (Kim et al. 1993a). Since then, few other infantile or neonatal patients with this intriguing disease have been described, usually with massive liver involvement in the absence of extrahepatic germ cell tumor (van der Hoef et al. 2004; Yoon et al. 2007; Hanson et al. 2011).

Pathology

Macroscopically, hepatic choriocarcinomas are solitary or multiple, sometimes large tumors with characteristically highly vascularized, hemorrhagic, and very friable features (Kim et al. 1993a; Sashi et al. 1996), therefore lesions prone to rupture with fatal intra-abdominal hemorrhage and difficult respectability. Histologically, hepatic manifestations of choriocarcinoma closely reflect the morphologic phenotype known for other malignant trophoblastic tumors. Usually, the tumor is mainly composed of two cell types, syncytiotrophoblasts and cytotrophoblasts, but mononucleated cells intermediate between these two may also occur which, in case syncytiotrophoblasts are rare, result in a monophasic pattern of the tumor. The syncytiotrophoblastic giant and multinucleated cells typically cap or wrap the cytotrophoblastic cells, this configuration sometimes producing villus-like structures. Immunohistochemically, both trophoblastic cell types are reactive for cytokeratins; in particular, and similar to partial and complete moles, cytokeratin 20 is a biomarker of neoplastic gestational trophoblastic disease (Stackievicz et al. 2002). CEA may be positive, but vimentin is negative. All three trophoblast cell types are reactive for CD10 (common acute lymphoblastic leukemia antigen, CALLA), a monomeric type II integral membrane peptidase (Ordi et al. 2003). b-hCG is expressed in syncytiotrophoblasts and intermediate cells. Human placental lactogen is also positive, albeit less markedly so. Alpha-inhibin is expressed in both syncytiotrophoblasts and intermediate cells but not in cytotrophoblasts (Shih and Kurman 1999).

Pathogenesis

What is the evidence that infantile choriocarcinoma derives via spread from overt or occult placental trophoblastic disease? How frequently is a primary placental tumor detectable? In an analysis of 26 reported neonatal/infantile choriocarcinoma patients, maternal gestational trophoblastic disease was present in 16 (62 %; Blohm et al. 2001). However, only in 2 of these 26 cases was the placenta histologically examined, and a placental choriocarcinoma could not be detected (Nieuwenhuizen Krusemann et al. 1977; Tsukamoto et al. 1986).

In case a primary trophoblastic tumor is not found in the placenta, occult gestational

choriocarcinoma or a primary hepatic lesion has been suggested (Kim et al. 1993a). In fact, primary choriocarcinoma of the liver has been proposed to occur (Fernandez Alonso et al. 1992). The concept that infantile choriocarcinoma syndrome may originate from focal placental trophoblastic disease is supported by the finding of Y chromosomes in the tumors (Blohm et al. 2001). What are the cytogenetic patterns in such neoplasms? Germ cell tumors from adult male patients frequently show isochromosome 12i (12q) or gain of the short arm of chromosome 12 (Samaniego et al. 1990), whereas chromosome 12 anomalies are less frequent in the respective tumors of female patients (Rodriguez et al. 1995) and, in contrast to other anomalies, are much less frequent in pediatric germ cell tumors (Perlman et al. 1994). The majority of pediatric embryonal carcinomas and yolk sac tumors display deletions at 1p36 or imbalances of the short and long arms of chromosome 1 (Perlman et al. 1994, 1996; Stock et al. 1994), but the 1p36.33 deletion/imbalance has only once been found in pediatric choriocarcinoma (Blohm et al. 2001), suggesting differences regarding the differentiation along the cell lineages involved. So far, there are no sufficient cytogenetic or molecular data available for successfully tracing the spreading pathway from overt or putative placental disease to neonatal/infantile choriocarcinoma syndrome.

Mixed Germ Cell Tumors of the Liver (ICD-O Code 9085/3)

This is the most exceptional form of hepatic germ cell tumors. In a two-and-a-half-year-old boy with a gradual increase in abdominal distension, ultrasonography and CT of the abdomen revealed a large hepatic mass. Serum AFP was elevated. The left hepatic lobectomy specimen showed a combined yolk sac tumor and mature teratoma. Despite chemotherapy, widespread intrahepatic metastasis developed and the patient died due to liver dysfunction after 6 months (Verma et al. 2003). Another case was observed in a 34-year-old man, this mixed germ cell tumor (immature teratoma and yolk sac tumor) having a sarcomatous component with rhabdomyoblasts, interphase cytogenetics revealing that both the germ cell tumor and the sarcomatous tissue were positive for i(12p) and 12p overrepresentation (Xu et al. 2010).

Germ Cell Tumors of the Biliary Tract

Germ cell tumors (in first-line teratomas) arising as primary tumors from the biliary tract are extremely rare neoplasms (Pfefferkorn and Commichau 1955; Frexes et al. 1986; Kim et al. 1993b; Demircan et al. 2004). The 54-year-old female patient described by Pfefferkorn and Commichau (1955) presented with upper abdominal pain and progressive jaundice with acholic stools. Laparotomy revealed in intraluminal tumor extending from the common bile duct to the cystic duct. Choledochotomy uncovered a large intraluminal, form tumor mass that originated from the posterior common duct wall, where it was attached as a pedunculated mass. Histology showed an immature teratoma with epithelial cysts and osteoid and chondroid components. The tumor showed a transition to osteochondrosarcoma and therefore contained a component of teratoma with a malignant somatic component (MSC). In the patient of Frexes et al. (1986), a teratoma was located to the common hepatic duct. In the 5-year-old boy described by Kim and coworkers (1993b), a benign cystic teratoma of the common bile duct was associated with an endodermal sinus tumor. Demircan and colleagues (2004) reported on a benign cystic teratoma arising from the distal common hepatic duct of a 4-month-old girl with anomalous common bile ducts, where the common bile duct originated from the apex of the gallbladder and reached the duodenum passing over the tumor. The latter presented as 15 cm-sized cystic mass with solid components.

The differential diagnosis of biliary tract germ cell tumors includes germ cell tumors of the retroperitoneal space secondarily invading the ampullary or biliary region (Caroli et al. 1963; Simpson et al. 2005), metastatic germ cell tumors (Rentsch et al. 1977), epidermoid cysts of the

intrahepatic ducts (Chiu et al. 2005), and pseudoepidermoid cysts arising from squamous metaplasia of the gallbladder (Teo et al. 2005). Infantile epidermoid cyst of the intrahepatic bile ducts is a very rare disorder where an epidermoid cyst is in direct communication with bile ducts and drains via the common bile duct (Chiu et al. 2005).

Germ Cell Tumors of the Hepatic Hilar Region

Mature cystic teratoma has been observed at the porta hepatis, preoperatively sometimes diagnosed as a choledochal cyst (Marennyi 1971; Brown et al. 2008). In one patient, a 10-month-old girl, laparotomy revealed a thick-walled cyst obscuring the entire subhepatic space and displacing the bowel medially. A small tubular structure was noted running from the cyst to the distal common bile duct. This was found to leak bile when the cyst was excised. Histologically, the cyst was lined by respiratory epithelium, intestinal epithelium, skin and skin adnexa, pancreatic tissue, and lymphoid tissue. The second patient, a 14-month-old girl, had a cystic mass attached to the portal vein, splenic vein, common hepatic duct, common bile duct, and cystic artery. Histology disclosed a mature teratoma lined with intestinal and respiratory epithelium, with the cartilage, bone, pancreatic tissue, skeletal muscle, and lymphoid tissue (Brown et al. 2008).

Teratomas of the Hepatic Ligaments

Few reports described teratomas arising in the falciform ligament (Bowen et al. 1987; Atkinson et al. 1992; Ayyappan et al. 2007; Gangopadhyay et al. 2009; Srivastava et al. 2011). In the case reported by Srivastava et al. (2011), a congenital mature cystic teratoma of the falciform ligament was situated within an omphalocele. Teratoma has also been diagnosed in the ligamentum teres (Abe et al. 1976). Primary germ cell tumors also occur in the hepatoduodenal ligament, e.g., mature teratoma/dermoid cyst (Akimov 1989; Wang and Dong 2004; Sasaki et al. 2005; Souftas et al. 2008).

Germ Cell Tumors of the Liver Synchronously Combined with Other Hepatic Neoplasms

Teratoma of the liver has seldom been observed in conjunction with a synchronous other hepatic tumors, e.g., combined cystic teratoma and hepatoblastoma (Conrad et al. 1993). Hepatocellular carcinoma associated with hepatic yolk sac tumor has been observed (Morinaga et al. 1996).

Growing Teratoma Syndrome

Introduction

The growing teratoma syndrome (GTS) refers to the phenomenon whereby germ cell tumors enlarge after chemotherapy despite apparently complete eradication of malignant cells and normalization of serum tumor markers (Logothetis et al. 1982). Previously, the phenomenon of benign distant metastases appearing during follow-up was designated, "chemotherapeutic retroconversion" (DiSaia et al. 1977). Specifically, the criteria for the diagnosis of growing teratoma syndrome include non-seminomatous germ cell gonadal or extragonadal mature or immature teratomatous elements; normalization of elevated serum AFP, beta-HCG, and lactate dehydrogenase after therapy; evidence of enlarging metastases, despite chemotherapy and normalization of serum markers; and exclusively mature teratomatous elements on histopathology of the metastases (review: Gorbatiy et al. 2009). The mature elements may consist of few cell lineages and may, e.g., exclusively consist of glial elements, causing military or nodular gliomatosis peritonei (Hsieh and Liu 2009). The syndrome appears in 1.9–7.6 % of the patients after treatment for non-seminomatous germ cell tumors (Jeffery et al. 1991). In men who develop growing teratoma syndrome, the testis is the primary site of origin in as many as 93 % of the patients, followed by the mediastinum and the pineal gland. Growing teratoma syndrome is also known from teratomas of the ovaries. The most common site of growing metastases is the retroperitoneal space. The pathogenesis of growing

teratoma syndrome is not clarified, but hypotheses include selective survival and growth of the mature teratoma component of a germ cell tumor after chemotherapy and differentiation of the cells of the original germ cell tumor into a more benign mature teratoma (Andre et al. 2000). Mature teratoma may present as pelvic and abdominal masses many years after treatment of a gonadal teratoma (Djordjevic et al. 2007).

Manifestations of Growing Teratoma Syndrome in the Liver

Growing teratoma syndrome may manifest in the liver, with sometimes rapidly growing teratomatous hepatic masses (Lentini et al. 1986; Connor and Guest 1999; Eghtesad et al. 2003; Kapoor et al. 2003; Lorusso et al. 2011). The hepatic metastases may form fatty and cystic structures at CT, suggesting maturation of the tumor (Connor and Guest 1999). One patient who had been operated because of testicular mixed germ cell tumor developed marked hepatomegaly from numerous masses with cystic, solid, and calcified components replacing almost the entire liver (Kapoor et al. 2003).

Germ Cell Tumors Metastatic to the Liver

General Remarks

All malignant gonadal and extragonadal germ cells can metastasize to the liver, albeit with variable preponderances for the diverse types of germ cell tumors, also depending on the efficacy of treatments. Hepatic metastases were described for gonadal and extragonadal seminomas (Stomper et al. 1986; Bokemeyer et al. 2001; Chung et al. 2004; Pectasides et al. 2008; Ng et al. 2010), mature components of immature teratomas (Barwad et al. 2011), yolk sac tumors (Tahara et al. 2008; Zhang et al. 2010; Barman et al. 2013; Littooij et al. 2014), embryonal carcinoma (Yano et al. 1983; Abdel-Dayem et al. 1984; Cunningham et al. 1989; Uekado et al. 1994), choriocarcinoma (Alvarado-Cabrero et al. 2014), and teratoma with malignant transformation (Wang and Kazmi 2011). Also extrahepatic germ cell tumors with somatic-type malignant component can metastasize to the liver (Kobayashi et al. 2010).

Struma Ovarii Metastatic to the Liver

Between 15 % and 20 % of ovarian tumors are germ cell in origin, and approximately 10 % of these contain thyroid cells. A much smaller fraction contain sufficient thyroid tissue (50 %) to be classified as a struma ovarii. Most struma ovarii are benign and it has been estimated that less than 3 % are malignant, although malignancy of struma ovarii, in the absence of metastasis, is more difficult to diagnose than orthotopic thyroid carcinoma. Malignant struma ovarii can metastasize to the peritoneum, produce nonmalignant ascites and hydrothorax (pseudo-Meigs syndrome), and occasionally metastasize to distant organs (metastatic ovarian strumosis; review of the literature: Mattucci et al. 2007). Overall, 5–6 % of malignant struma ovarii metastasize. The targets of dissemination of struma ovarii are different from those of orthotopic thyroid carcinoma. Thyroid carcinomas most commonly spread to regional lymph nodes of the neck and less often via hematogenous dissemination to the lung, bone, and brain. In contrast, malignant struma ovarii can spread by regional lymphatics to pelvic and paraaortic lymph nodes; direct spread to the omentum, the peritoneal surface, and the contralateral ovary; and hematogenous spread to the bone, lung, and liver. Struma ovarii is well known to metastasize to the liver (sometimes with functioning metastases) and has to be distinguished from metastasis of follicular or papillary thyroid carcinoma (Kempers et al. 1970; De Graaff et al. 1983; O'Connell et al. 1990; Thomas and Batty 1992; Balasch et al. 1993; Dardik et al. 1999; Konez et al. 2000; Rotman-Pikielny et al. 2000; DeSimone et al. 2003; Cherng et al. 2005; McDougall 2006; Salvatori et al. 2008; Marcy et al. 2010). In order to increase I131 uptake by hepatic metastases, recombinant human thyrotropin has been employed (Rotman-Pikielny

et al. 2000). Within struma ovarii, follicular or papillary thyroid-type carcinoma can develop (Roth et al. 2008; Zhang and Axiotis 2010), which may metastasize, including to the liver (Garg et al. 2009).

Hepatic Tissue in Germ Cell Tumors

It is well known that a hepatocyte lineage can develop in diverse forms of germ cell tumors. Among 516 germ cell tumors, hepatic tissue was observed in 48 cases (9.3 %). The incidence of hepatic tissue was low in tumors of the ovary (5 %), high in both retroperitoneal (27 %) and sacrococcygeal (24 %) tumors, and low in both mature (0.3 %) and immature teratomas (11 %). The frequency was very high in yolk sac tumors >(48 %) and mixed germ cell tumors (52 %). Many hepatic cell nests were found in polyembryoma. In yolk sac tumors, the hepatocyte-like cells resemble more frequently cells of hepatocellular carcinoma (Nakashima et al. 1987). Teratomas may also contain bile ducts and ductules. In a study of 45 teratomas of different localizations, bile duct-like tubules were found in 24 % of the cases, one tumor being almost entirely composed of such elements (Roma and Humphrey 2010).

Cystic Lesions of the Hepatobiliary Tract Mimicking Teratomas: Epidermoid Cyst of the Liver and the Bile Ducts

Together with dermoid cyst (see below), this is the most uncommon form of a lesion that may be related to teratomas (Schullinger et al. 1983; Lombardi et al. 1995; Fernandez-Castroagudin et al. 2001). The lesion was diagnosed in the pediatric age group, e.g., in a 4-year-old girl who had presented with biliary cirrhosis (Schullinger et al. 1983). Hepatic epidermoid cysts may be large and mimic hydatid disease (Fernandez-Castroagudin et al. 2001). In one case, hepatic epidermoid cyst showed microscopic foci of squamous cell carcinoma (Lombardo et al. 1995).

Epidermoid cyst has been identified in the intrahepatic duct system. In one case, the cyst was located at the confluence of the right and left hepatic ducts and involved all of the common hepatic duct (Chiu et al. 2005).

Extrahepatic Non-germ Cell Neoplasms with Germ Cell Tumor-like Components Metastasizing to the Liver

Extrahepatic carcinomas can contain germ cell tumor or germ cell tumor-like components (Wang et al. 2000; Abe et al. 2008; Satake et al. 2011). These components may metastasize to the liver. In a patient with gastric adenocarcinoma, this tumor showed yolk sac tumor differentiation and liver metastasis of the yolk sac tumor component (Bihari et al. 2013).

Differential Diagnosis

Gonadal germ cell tumors are well known to metastasize to the liver. Post-chemotherapy resection of liver metastases is a successful therapeutic approach (Yokoi et al. 2003; You et al. 2009). The probability of hepatic metastasis of pure immature ovarian teratoma is significantly related to chemotherapy. In one study, the hepatic metastatic rate was 16.7 % in the standard adjuvant chemotherapy group but increased markedly to 31.2 % in the irregular chemotherapy group (Fan et al. 2001). Retroperitoneal teratomas, particularly those which have a close relationship to the inferior vena cava, may mimic a mass lesion in the posterior part of the liver. Retroperitoneal twin fetus in fetu associated with immature teratoma has been described (Pourang et al. 2009).

Abstract

Polycythemia vera (PV; polycythemia rubra vera) is a chronic myeloproliferative neoplasm characterized by increased red blood cell production independent of normal regulatory mechanisms. The majority of patients with PV show the JAK2V617F mutation or another functional similar JAK mutation. In fully developed disease, there is hepatomegaly associated with hyperemia and eventually signs of hepatic infarcts. Histologically, the sinusoids are dilated and filled with erythrocytes which can form stacks or "rouleaus." PV is complicated by hepatic venous outflow disorders, in particular hepatic vein thrombosis with Budd-Chiari syndrome, sometimes associated with factor V Leiden mutation. Portal vein thrombosis is a well-documented complication of PV. These hepatic blood flow disorders are frequently followed by nodular regenerative hyperplasia. PV can also cause perisinusoidal fibrosis with an increase in reticulin and fibrotic changes of the liver related to necrosis and infarction.

Polycythemia Vera

ICD-O Code 9950/3

Introduction

The 2008 WHO classification defines polycythemia vera (polycythemia rubra vera; PV; formerly also termed "plethora vera") as a chronic myeloproliferative neoplasm characterized by increased red blood cell production independent of normal regulatory mechanisms. Practically all patients with PV harbor the JAK2V617F mutation or another functional similar JAK mutation, resulting in proliferation of all hematopoietic cell lineages ("panmyelosis").

PV was first described by Vaquez, and Osler recognized it as a "new clinical entity" characterized by chronic cyanosis and polycythemia, hence using the term still employed today (Vaquez 1892; Osler 1903; review: Means 2008). PV is characterized by the insidious onset of erythroid proliferation (erythrocytosis) and secondary platelet and granulocyte overproduction; it can progress from a proliferative stage to a "metastatic" phase and further develop into a clinically malignant phase (Golden 2003; Gilbert 2003). In 1967, the Polycythemia Vera Study Group (PVSG) was organized to identify the optimal approach to diagnosis of PV (Table 1).

In modern classifications, three phases of PV may be recognized: (1) a prepolycythemic or prodromal phase with borderline to only mild erythrocytosis; (2) an overt polycythemic phase, characterized by a significantly increased red cell mass; and (3) a "spent" or post-polycythemic myelofibrosis phase, in which cytopenias, including anemia, are associated with bone marrow fibrosis, extramedullary hematopoiesis, and hypersplenism. PV can also evolve into myelodysplasia and acute leukemia.

Table 1 PVSG diagnostic criteria for PV

Category A
A1 increased red cell mass
M > = 36 mL/kg
F > = 32 mL/kg
A2 oxygen saturation > = 92 %
A3 splenomegaly
Category B
B1 platelets > = 400 × 10(9)/L
B2 white blood cell count > = 12 × 10(9)/L
B3 LAP score >100[a]
B4 serum B12 > 900 pg/mL (660 pM)
U B12 BC >2,200 pg/mL (1,620 pM)

U B12 BC indicates unbound vitamin B12 binding capacity

[a]In the absence of fever or infection

Epidemiology

The disease is rare, with an estimated incidence of 2.3 per 100,000; it is more frequent in males and usually affects older individuals, although cases in young adults and children have been reported (Tefferi 2001). In a large retrospective study examining all in- and outpatient records of Olmsted County, Minnesota, over a period of 55 years, the incidence rate of PV was 1.9 per 100,000 persons and year, and incidence rates increased with advancing age for men up to 23.5 per 100,000 and year, the median age at presentation being 55–60 years (Ania et al. 1994).

Clinical Features

PV is a chronic myeloproliferative disorder characterized by panmyelosis, splenomegaly, and a predisposition to vascular thrombosis, myelofibrosis, and acute leukemia. Basically, it represents a clonal stem cell disease with persistently increased erythrocyte production and is the only known type of primary acquired polycythemia (reviews: Berlin and Wasserman 1997; Streiff et al. 2002; Golden 2003; Tefferi 2003).

Liver Pathology in Polycythemia Vera

Macroscopy

A part of patients with PV show hepatomegaly. In fully developed disease, the enlarged and engorged liver shows a cut surface which is dark-red or gray-blue, sometimes with small nodular regenerates. In fresh state, cutting through the

organ is followed by copious oozing of blood from the cut surface, sometimes intermingled with small granules of coagulated blood or thrombi (Hirschfeld 1906; Hamilton and Morse 1912; Mosse 1920). The liver capsule can show scarred depressions, probably sequelae of previous infarctions caused by venous thrombosis.

Histopathology

The sinusoids are markedly dilated and filled with erythrocytes which can form stacks or develop rouleau formation. A part of the sinusoids are so densely packed with red blood cells that the endothelial lining is no longer visible, the perisinusoidal space of Disse is effaced or compressed, and hepatocyte plates have undergone atrophy. Erythrocytes may enter the space of Disse, mimicking so-called Disse space hemorrhage. A slight increase of reticulin fibers may occur in the perisinusoidal space. Engorged vessels are also found in the portal tracts. In case of PV with myelofibrosis and myeloid metaplasia, there may be hepatic enlargement with extensive extramedullary hematopoiesis with dilatation of sinusoids, compression of hepatocyte plates, and hepatocyte atrophy and dysfunction, resulting in acute hepatic failure (McBrine et al. 1980).

Hepatic Venous Outflow Disorders in PV

Hepatic venous outflow disorders, and mainly Budd-Chiari syndrome (BCS), occur as a complication of several types of myeloproliferative disorders (Poreddy and DeLeve 2002). As they are specifically well known for patients suffering from PV, these disorders are discussed in this paragraph. The BCS results from thrombogenic conditions and is caused by stenosis or obstruction of the hepatic venous outflow at the level of the hepatic veins and/or of the suprahepatic part of the inferior caval vein (Sherlock and Dooley 1993; Dilawari et al. 1994; Mahmoud et al. 1996; Valla 2002). The level of obstruction is reflected by two chief forms of BCS. The acute syndrome is invariably associated with extensive blockage of the major hepatic veins, and in a small fraction of patients, the caval vein is also occluded. Acute BCS causes a characteristic liver pathology with massive congestion and necrosis. In contrast, the chronic form of BCS is characterized by portal venous hypertension and a variably abnormal vasculature (Dilawari et al. 1994; Tilanus 1995; Iwai et al. 1998). On the other hand, it has been proposed to classify hepatic venous outflow disorders caused by thrombosis into two groups, the first representing "classical" BCS that is more common in the West and the second representing an obliterative disease predominantly affecting the hepatic portion of the inferior vena cava ("obliterative hepatocavopathy"), the latter being predominant in developing countries and being "idiopathic" or then being associated with hepatocellular carcinoma (Okuda et al. 1995, 1998; Okuda 2002). A more recent expert panel classifies BCS on the one hand according to etiology (primary vs. secondary forms) and on the other hand according to the site of obstruction (small hepatic veins, large hepatic veins, inferior vena cava. and combined obstruction) (Janssen et al. 2003).

Pathogenically, BCS probably represents a spectrum of disease caused primarily by a hypercoagulable state and eventually promoted by vascular changes favoring local thrombosis, e.g., malignant tumors in the liver. Membranous obstruction (web) of the caval vein (MOVC) has formerly been regarded as a congenital alteration sometimes causing BCS, but is currently considered to be a sequela to thrombosis (Kage et al. 1992). However, a significant fraction of patients with BCS have no identifiable underlying condition, the percentage ranging from 13 % to 62 % in several studies (Hadengue et al. 1994; Slakey et al. 2001). Apart from PV, BCS developing as a complication of MPD is established for CML (Picardi et al. 2000).

The association of BCS and PV is well established for a long time (Chini 1954; Brown et al. 1955; Caroli and Soulier 1956; Cantwell et al. 1956; Chlumsky and Chlumska 1966; Siguier et al. 1967; Thomas and Caroli 1971; Retzlaff and Monge 1973; Balique 1981;

Fechtner and DelDuca 1994). In one study on BCS, overt PV was the underlying cause in about 10 % of the cases, and essential thrombocythemia and chronic idiopathic myelofibrosis in only a very few (De Stefano et al. 1997). BCS associated with PV has also been observed in children from families with familial PV (Cario et al. 2003). Hepatic venous thrombosis in patients with PV is induced by other disorders with a genetic background, such as the factor V Leiden mutation and other thrombophilic coagulation disorders (Janssen 2000; Mohanty et al. 2001). It was shown that the factor V Leiden mutation is in fact the second most common etiology associated with BCS (Mahmoud et al. 1997; Delarive and Gonvers 1998; Simsek et al. 2000; Janssen et al. 2000; Deltenre et al. 2001), whereas other genetic disorders of thrombophilic factors are rarer causes of BCS (e.g., the G20210A mutation of the prothrombin gene; Poort et al. 1996; Bucciarelli et al. 1998; De Stefano et al. 1998; Oner et al. 1999; Minnema et al. 2000; Brancaccio et al. 2002). It has been observed that fulminant BCS in PV was associated with factor V Leiden mutation (Akyildiz et al. 2006).

Portal Vein and/or Splanchnic Vein Thrombosis in Polycythemia Vera

The etiology of portal vein thrombosis (PVT) is heterogeneous, but important primary risk factors comprise cirrhosis, hepatobiliary malignancies, pancreatitis, and several disorders of the coagulation system (Mahmoud et al. 1997; review: Janssen 2000; Janssen et al. 2000). PVT is a well-documented complication of PV in its overt, masked, or early forms (Lommel 1906; Kratzeisen 1923; Alford et al. 1968; Valla et al. 1988; Drenou et al. 1992; Pati et al. 1998; Escher and Demarmels Biasiutti 1999; Randi et al. 2002). On the other hand, PVT is also known to be itself a complication of BCS that can be caused by PV. PVT, apart from its perfusion disorder of the liver, can cause compression of the bile duct in PV (Löhr et al. 1993). PV T in PV can be complicated by pylothrombophlebitis.

Why Is PV Associated with Thrombosis of Large Veins?

Thrombotic events are present in 20–50 % of patients with PCV at diagnosis and involve both large vessels and the microcirculation. It is estimated that the incidence of thrombosis is higher in PV than in essential thrombocythemia, and significant risk factors are increasing age and previous thrombosis (Orlandi et al. 1989; Pearson 2002). The pathogenic mechanisms underlying the increased incidence of thrombotic events in PV are still somewhat illusive. Prothrombotic factors such as an increased blood viscosity caused by an elevated hematocrit, abnormal platelet functions, and the procoagulative action of the cells involved have been proposed (Fields and Freeman 1993; Fiessinger 1994; Michiels 1997; Barbui and Finazzi 1997; Gumina et al. 2002; Friess et al. 2003). It has been shown that thrombocytes form heterotypic aggregates with leukocytes (platelet-neutrophil complexes; PNC) through platelet CD62P and leukocyte beta2-integrins, resulting in cell features with increased adhesion (Peters et al. 1999). A platelet-leukocyte conjugate formation occurring in myeloproliferative disorders, including PV, seems to indicate platelet activation, associated with platelet microparticle production serving as catalytic surfaces for thrombin generation (Villmow et al. 2002). In BCS or portal vein thrombosis, an increased expression of CD11b on neutrophils was detected, supporting a role for neutrophils in hepatic venous thrombosis (Alvarez-Larran et al. 2004). Increased CD11/CD18 expression on neutrophils is also found in essential thrombocythemia (Burgaleta et al. 2002). In addition, there is an "endothelial factor" in the pathogenic cascade of PV-associated thrombosis. PV seems to cause endothelial dysfunction in the preclinical phase of arterial disease, characterized by impaired flow-mediated vasodilatation (Neunteufl et al. 2001). On the other hand, there are findings indicating that hepatic erythropoietin production occurs in the acute phase of BCS and suggesting that, in some cases of BCS, erythrocytosis which resolves after the acute phase may be secondary to liver disease (Levy et al. 1985). A new line of

thinking in regard to factors promoting thrombogenesis in PV and other myeloproliferative disorders is the pathogenic role of the JAK2V617F mutation in PV (Patel et al. 2006; Sozer et al. 2009; Benedik-Dolnicar et al. 2012; de Grandis et al. 2012; Yonal et al. 2012). This issue is discussed in more detail in the chapter on essential thrombocythemia.

Nodular Regenerative Hyperplasia in PV

Subacute or chronic BCS can result in a distinct hepatocyte response characterized by the production of numerous hepatocyte nodules not encircled by collagen fibers, but compressing the adjacent parenchyma. This is *nodular regenerative hyperplasia* (NRH) of the liver, occurring in several myeloproliferative disorders associated with hepatic venopathies and being a cause of portal hypertension (Al-Mukhaizeem et al. 2004). NRH is characterized by multiple enhancing nodules in CT during the hepatic arterial and portal venous phases and by hyperintense nodules in MR on T1-weighted images and hypointense or isointense nodules on T2-weighted images (Castellano et al. 1989; De Sousa et al. 1991; Wanless 1994; Clouet et al. 1999; Rha et al. 2000; Soler et al. 2000). NRH is discussed in more detail in another chapter. Even though NRH with small regenerative nodules may mimic multiple small metastases in the liver or produce a pseudotumoral presentation (Casillas et al. 1997; Clouet et al. 1999), a more difficult differential diagnostic situation arises in case of larger nodular lesions developing in the liver in chronic BCS. They include large regenerative (macroregenerative) nodules (that are mostly smaller than 4 cm) (Tanaka and Wanless 1998; Vilgrain et al. 1999; Zhou et al. 2000; Brancatelli et al. 2002; Ibarrola et al. 2004), adenomatous hyperplastic nodules (according to the older nomenclature; Soyer et al. 1993), FNH and FNH-like lesions (Schilling et al. 2000; Maetani et al. 2002; Ibarrola et al. 2004), and hepatocellular carcinoma, whereby the latter seems to be more frequent in patients with MOVC (Simson 1982; Nakamura and Takezawa 1982; Kew et al. 1989; Takayasu et al. 1994; Katoh and Shigematsu 1999; Havlioglu et al. 2003; Jang et al. 2003). In BCS, tumorous hepatic lesions may be mimicked by hemorrhagic necroses producing a mass (Shapiro et al. 1993).

Hepatic Fibrosis in PV

Apart from nodular lesions sometimes mimicking neoplastic disease, the liver in PV-associated BCS can undergo marked remodeling associated with fibrosis (Gundling et al. 2004). Severe hepatic fibrosis develops in BCS with a variety of histologic patterns. First, a part of the livers show a pattern of cirrhosis in which there is fibrous bridging between hepatic veins and the portal tracts (the so-called veno-portal cirrhosis); second, some livers in BCS exhibit a pattern of so-called reversed-lobulation cirrhosis (*veno-centric cirrhosis*), in which fibrous bridging between hepatic veins and portal tracts is minimal (Tanaka and Wanless 1998). In one study, all livers with veno-portal cirrhosis had severe portal vein obliteration, not seen to this degree in the other type of cirrhosis or in mixed forms, suggesting that portal vein obliteration in BCS plays a role in the pathogenesis of veno-portal bridging fibrosis (Tanaka and Wanless 1998). In the latter study, 9/15 BCS livers with these types of cirrhosis also showed large regenerative nodules histologically resembling focal nodular hyperplasia, also reported in another study (Schilling et al. 2000). In addition, fibrogenesis in PV may be mediated by activated JAK2-induced expression of galectin-3, known to involved in fibrosis and angiogenesis (Koopmans et al. 2012).

Portal Hypertension in PV and Other Hematological Disorders

As in other myeloproliferative disorders, portal hypertension may occur in PV, and not only due to thrombosis of large hepatic veins. The pathogenic mechanisms have been discussed in detail (Al-Mukhaizeem et al. 2004). These authors

proposed to classify the pathogenic pathways as a function of the anatomical site(s) of the hematologic disorders' manifestations. A first prehepatic (presinusoidal) cause of portal hypertension is, above all, portal vein and other splanchnic vein thrombosis. A second presinusoidal cause includes nodular regenerative hyperplasia of the liver, occurring in myeloproliferative disorders. Intrahepatic or sinusoidal blockage resulting in portal hypertension in myeloproliferative disorders is caused by extramedullary hemopoiesis, infiltration by abnormal hematopoietic cells, perisinusoidal fibrosis induced by hemopoietic cells located to the sinusoidal compartment (particularly fibrogenic megakaryocytes), nodular regenerative hyperplasia, liver cirrhosis, and amyloidosis. Postsinusoidal causes of portal hypertension comprise hepatic venous outflow disorders, as discussed above, and heart failure, e.g., owing to cardiac iron overload or amyloidosis.

PV can be associated with, or cause, acute obliterative endophlebitis of hepatic veins, lesions that can cause sinusoidal blockade and non-cirrhotic portal hypertension (Mandelbaum et al. 1953).

Liver Cancer in Polycythemia Vera

Several reports document the association of erythrocytosis/polyglobulia with hepatocellular carcinoma (HCC). In fact, erythrocytosis is one of the most common of the paraneoplastic syndromes in HCC, with an estimated incidence ranging from 2.2 % to 12 % (McFadzean et al. 1958; Jacobson et al. 1978; Sawabe et al. 1993; Chu et al. 1999; Trotter et al. 2002; Argumanis et al. 2002). From the etiologic point of view, at least four situations of this association have to be considered. The first situation refers to patients having *bona fide* PV and HCC (Toth and Bilodeau 1980; Gensini and Conti 2002). The second situation is characterized by HCCs thought to produce, or have been documented to produce, erythropoietin with secondary erythrocytosis (direct evidence: Funakoshi et al. 1993; Sakisaka et al. 1993; Muta et al. 1994; Matsuyama et al. 2000); (indirect evidence: McFadzean et al. 1958; Kan et al. 1961; Conte et al. 1964; Baume et al. 1965; Brownstein and Ballard 1966; McFadzean et al. 1967; Santer et al. 1967; Ruvidic and Ivaneski 1970; Zlatkina and Shcherbak 1970; Gordon et al. 1970; Nakai et al. 1972; Lizzi et al. 1973; Scott and Theologides 1974; Davidson 1976; Cornet et al. 1978; Jacobson et al. 1978; Okazaki et al. 1979; Kawasaki et al. 1979; Watanobe 1988; Shchekochikhin and Osipova 1991; Sawabe et al. 1993; Huang et al. 1994; Argumanis et al. 2002; Cheng et al. 2002). Of pathophysiologic interest are those situations where both elevated serum erythropoietin and erythrocytosis regressed after HCC resection (Regimbeau et al. 1999). Furthermore, erythropoietin production by HCCs seems to increase in response to hypoxia, for example, hepatic release of erythropoietin increases subsequent to chemoembolization of HCC (Pirisi et al. 1995). It has to be emphasized that elevated erythropoietin levels in patients with HCC may also be due to decreased erythropoietin clearance caused by underlying liver disease (Malaguarnera et al. 1996). An excess synthesis of erythropoietin by tumors was demonstrated in mice with spontaneous HCCs (Horiouchi et al. 1997). The third situation are patients developing HCC in the context of a hepatic venous outflow disorder, including BCS induced by PV (Havlioglu et al. 2003). Overall, HCC is rare in cases of hepatic venous outflow obstruction without concurrent thrombosis of the vena cava (Valla 2002). In fact, it is well known that HCC is a sequela of MOVC, but the incidence of HCC in MOVC varies according to geography (Simson 1982; Okuda 1982; Nakamura and Takezawa 1982; Rector et al. 1985; Kew et al. 1989; Hautekeete et al. 1990; Kage et al. 1992; Shrestha et al. 1996; Seo et al. 1998; Okuda et al. 1998; Karia et al. 2000). The fourth situation is represented by patients with PV exhibiting HCC after treatment, e.g., with radioactive phosphorus (Chudecki 1972), although a causal relationship has not been proven. The clinical triad of *erythrocytosis*, *hemochromatosis*, and *hepatocellular carcinoma* has been reported several times, this combination principally being

found in elderly males (Lizzi et al. 1973; Scott and Theologides 1974; Raphael et al. 1979). Erythrocytosis in this situation has again been proposed to be caused by the action of erythropoietin derived from HCC. As HCC is a frequent complication of hemochromatosis, such a constellation might be expected to occur.

Cytogenetic and Molecular Features

About 20 % of patients show karyotypic abnormalities, including +8, +9, del(20q), del(13q), and del(9p). The most frequent molecular abnormality in PV is the gain-of-function mutation JAK2V617F, occurring in more than 95 % of PV patients (Scott et al. 2007; Scott 2011). This mutation is not specific for PV but also occurs in other myeloproliferative disorders, including idiopathic myelofibrosis and essential thrombocythemia. The reason for this is that the mutation is manifest in a hematopoietic stem cell and is therefore transmitted to all cell lineages derived thereof. The remaining few % of patients show other mutations of JAK with the same functional consequences. Activation of JAK2 (Janus kinase 2), which phosphorylates signal transducer activator of transcription (STAT), promotes overexpression of the cell cycle regulator CDC25A (Gautier et al. 2012) and upregulates a broad array of growth factors, including VEGF, which may be responsible for angiogenesis in PV and other myeloproliferative disorders.

Pathogenic Pathways

The pathogenic mechanisms of PV are not fully understood, but the defect seems to involve hyperresponsiveness of PV progenitor cells to several cytokines (Prchal 2001). Diagnostic criteria and aspects of classification and molecular biology have been reviewed (Michiels and Juvonen 1997; Pearson 1998; Messinezy and Pearson 1999; Prchal and Prchal 1999; Golden 2003; Prchal 2003). It is known that patients with PV exhibit higher levels of a hemopoietic receptor, polycythemia rubra vera-1 (PRV-1), in granulocytes/neutrophils, and it was proposed that this phenomenon provides a rapid, highly specific, and sensitive marker for the diagnosis of PV in comparison with nonneoplastic erythrocytoses (Klippel et al. 2003). However, another group found that the PRV-1 gene is constitutively expressed by bone marrow cells and does not discriminate PV from reactive and other chronic myeloproliferative disorders (Bock et al. 2003), whereas a more recent investigation confirmed that neutrophil PRV-1 upregulation is a characteristic feature of PV, although in itself not sufficient for the diagnosis of PV (Tefferi et al. 2004). One reason for this is that overexpression of the PRV-1 receptor is also found in other myeloproliferative disorders, e.g., essential thrombocythemia (Teofili et al. 2002). The PRV-1 gene encodes an open reading frame of 437 amino acids, containing a signal peptide and two cysteine-rich domains homologous to those found in the uPAR/Ly6/CD59/snake toxin-receptor superfamily, linked to the cell surface via a glycosylphosphatidylinositol (GPI) link (Temerinac et al. 2000; Klippel et al. 2002).

So-called Chronic Erythroid Leukemia

Introduction

This is a rare and heterogeneous group of intriguing disorders that have not yet been classified in a satisfactory way but has already been described by Di Guglielmo and a coworker (Di Guglielmo and Quattrin 1942). In fact, the term does not appear in modern classifications of leukemias and myeloproliferative disorders. The disorder is briefly discussed because the term appears in literature referring to liver involvement, and at least some of these leukemias seem to have a link to the respective acute leukemia forms. Based on the stem cell nature of the disorders, the beginning and evolution of this subset of leukemias are variable. For example, patients may first present with chronic erythroleukemia with refractory anemia, to later switch to acute erythroid leukemia (M6), and then to acute myeloid leukemia of the M0 type, also involving dysplastic features of

other hemopoietic lineages, and therefore suggesting a stage-by-stage trilineage continuum (Michiels et al. 1997). There are several synonyms to denote disorders that are, or have been, interpreted to be chronic neoplastic erythroproliferative diseases. They include chronic erythroleukemia, chronic erythremia, chronic erythremic myelosis, chronic erythremic disease, chronic erythromyelosis, chronic Di Guglielmo syndrome, Di Guglielmo's erythremia with prolonged course, primary chronic erythroblastosis, and Heilmeyer-Schöner disease (Heilmeyer and Schöner 1961; Starcich et al. 1963; Introzzi and Buscarini 1966; Thurm et al. 1967; Spremolla et al. 1970; Stewart 1971; Marsan et al. 1973; Kass 1975; Nunnensiek et al. 1976; Sroczynski and Hrycek 1976; Pivnik et al. 1987; Bindi et al. 1999). Heilmeyer and Schöner described the disorder having their eponyms under the term chronic pure erythroblastosis of the adult as a leukemic process going in parallel to the erythrocytic system (Heilmeyer and Schöner 1961). All or most of these manifestations of hematologic neoplasias seem to have in common a chronically persistent malignant proliferation of cell populations dominated by an erythroid lineage, although it has not been specified as to what percentage of erythroid cells must be involved and what exactly "chronic" means.

In chronic erythroid leukemia, the morphology of blast cells has been studied in detail, particularly in regard to the erythroblastic components. Erythroblasts can show several anomalies, including deviations between cytoplasmic baso- or eosinophilia and the nuclear chromatin features, and binucleated or trinucleated cells (Introzzi and Buscarini 1966). Ultrastructurally, the cells of interest may show cytoplasmic vacuolation and vesicular bodies and may display significant numbers of membrane-bound ferritin particles and also isolated ferritin crystals in the cytoplasm (Introzzi and Buscarini 1966).

Liver Involvement

There are only sparse data available in regard to liver involvement in chronic erythroid leukemia(s). In one patient, tumorous lesions containing erythroid cells ("erythrosarcomas") were found in several organs, including the liver (Pivnik et al. 1987). Another case was characterized by the development of, as it was called, "malignant erythroblastomas" (Goreczky and Toth 1967). The autopsy of a patient with acute erythroid leukemia transforming in chronic erythremia revealed hepatomegaly (2,700 g) with increased consistency of the organ and grayish or hemorrhagic areas. Histologically, the portal tracts and the sinusoids were densely infiltrated by abnormal blastic cells, causing atrophy and dissolution of the liver cell plates. In the portal tracts, blast also occupied alterations looking like interface lesions/piecemeal necroses. The hepatocytes showed iron overload (Starcich et al. 1963; with a histologic figure of the liver changes).

Abstract

Several types of myeloproliferative syndrome (MPS) can involve the hepatobiliary tract, with a wide array of pathologic conditions. In MPSs with infiltration of liver parenchyma, hepatomegaly is a general feature and may be massive, often in conjunction with marked splenomegaly. Primary myelofibrosis (agnogenic myeloid metaplasia) is a clonal myeloproliferative neoplasm characterized by a growth of predominantly granulocyte precursors and megakaryocytes. Involvement of the liver shows accumulation of these cells mainly within sinusoids. This intrahepatic proliferation is frequently associated with liver fibrosis, mainly perisinusoidal fibrosis. The neoplastic cells can also form myeloid tumors or granulocytic sarcomas in the liver. Chronic myelogenous leukemia can also cause proliferation of immature myeloid cells in the liver, with massive hepatomegaly, together with signs of extramedullary hepatic hematopoiesis. In chronic neutrophilic leukemia, maturing and mature neutrophils can accumulate in the liver. In essential thrombocythemia, a myeloproliferative neoplasm involves primarily the megakaryocyte lineage; abnormal megakaryocytes accumulate in hepatic sinusoids. In this MPS, thrombotic complications of liver veins are a well-known phenomenon.

Primary Myelofibrosis

ICD-O code 9961/3

Introduction

According to the 2008 WHO classification, primary myelofibrosis (PMF; synonym: chronic idiopathic myelofibrosis, CIMF; agnogenic myeloid metaplasia, AMM; idiopathic myelofibrosis; myelofibrosis with myeloid metaplasia, osteomyelosclerosis) is defined as clonal myeloproliferative neoplasm (MPN) characterized by a proliferation of predominantly megakaryocytes and granulocyte precursors in the bone marrow that is in a fully developed state, associated with reactive bone marrow fibrosis and extramedullary hematopoiesis. In bone marrow, PMF shows a stepwise evolution, starting with a hypercellular marrow without fibrosis (the prefibrotic stage) and progressing to reticulin deposition, reticulin and collagen deposition, and often osteosclerosis in the final stage. The fibrotic stage is characterized by leukoerythroblastosis in the blood with teardrop-shaped erythrocytes, and patients in this stage usually show marked hepatosplenomegaly (Michiels et al. 2007; Tefferi 2012b). PMF can undergo leukemic transformation. The main causes of morbidity and mortality in PMF are bone marrow failure, thromboembolic events, portal hypertension, cardiac failure, and acute leukemia.

PMF as a clonal hemopoietic stem cell disease has first been described in 1879 (Heuck 1879), 13 years before Vasquez described polycythemia vera rubra, followed by reports in 1905 and 1908 (Hirschield 1905; Donhauser 1908) (historical review: Weinstein 1991; more recent reviews: Tefferi et al. 1995a; Spivak et al. 2003, 2011; Tefferi and Silverstein 1996, 1997; Tefferi 2003, 2012b, 2013). The primary or idiopathic form accounts for roughly 90 %, whereas secondary forms, following another chronic myeloproliferative disorder, account for 10 % of all cases. Criteria for the diagnosis of PMF were first proposed by the Polycythemia Vera Study Group (PVSG; Laszlo 1975), but a host of terms has been proposed for this disorder. A consensus conference had proposed to employ the term myelofibrosis with myeloid metaplasia, MMM (Barosi et al. 1999), but the official term of the WHO classification now generally is PMF. Together with polycythemia vera and essential thrombocythemia, PMF makes part of the Philadelphia chromosome-negative chronic myeloproliferative disorders (CMPD).

The primary pathogenic feature of PMF is a clonal expansion of stem cells resulting in chronic myeloproliferation and atypical megakaryocyte hyperplasia (review: Lataillade et al. 2008). Clonal studies have clearly shown that the trilineage proliferation (granulocytic, erythroid, and megakaryocytic) in PMF is monoclonal and has a stem cell origin, whereas the fibroblastoid/stromal cells producing fibrosis are polyclonal (reviews: Barosi et al. 1999). However, spontaneous growth of *megakaryocytes* and their progenitors is one of the biologic hallmarks of PMF, and, therefore, interest is focused at the mechanisms inducing such a growth response. Pertinent aspects of megakaryocyte development, expansion, and differentiation pathways, involving an intricate network of gene products, are briefly addressed, also in the context with what will be discussed in the paragraphs on polycythemia vera, essential thrombocythemia, acute megakaryoblastic leukemia, and TMD in Down syndrome.

Epidemiology

PMF most often affects individuals in their sixth or seventh decade of life, both sexes being equally involved. The overt fibrotic phase of PMF is estimated to occur at 0.5–1.5 per 100,000 persons per year. Pediatric PMF also occurs, but is a very rare condition. PMF which develops in children is different from adult PMF in that malignant transformation is not a feature, and mutations of JAK2V617F or MPLW515L were not found (DeLario et al. 2012). A subset of PMF shows, similar to other myeloproliferative disorders, hereditary features (review: Ranjan et al. 2013).

Clinical Features

Blood and bone marrow are always involved. In early-stage disease, up to 30 % of patients are asymptomatic, and the disease is suspected because of indolent splenomegaly. Leukoerythroblastosis in the peripheral blood is an important diagnostic element. Patients may first present with marked thrombocytosis, raising the suspicion of essential thrombocythemia. The main features of the disease comprise ineffective erythropoiesis, dysplastic megakaryocyte hyperplasia, an increase in the ratio of immature granulocytes to total granulocytes, substantial bone marrow fibrosis, extramedullary hemopoiesis, anemia, and hepatosplenomegaly (Tefferi et al. 2000). Myelofibrosis is frequently associated with osteosclerosis (Diamond et al. 2002; with a review of the literature). In later stages, extramedullary hematopoiesis becomes a prominent feature, the main cause of hepatosplenomegaly. The most common site of extramedullary hematopoiesis is the spleen, followed by the liver, and in both organs, megakaryocyte accumulation is often the most striking alteration. The prognosis of PMF depends on the stage in which PMF is firstly diagnosed and on leukemic transformation.

Involvement of the Liver

Extramedullary Hematopoiesis

In PMF, extramedullary hemopoiesis (EMH) occurs in several organs, particularly the spleen, the liver, and the lymph nodes, less frequently the kidney and adrenal, and others. Involvement of the liver can result in fatal outcome (Ruebner 1960). It is still a matter of debate as to what the features of the extramedullary hemopoietic tissue are. One view holds it that they represent a compensatory mechanism by which blood cells are formed outside the bone marrow when bone marrow cell production is insufficient to meet the body's demands, and this is underlined by observations of EMH occurring in nonneoplastic situations such as congenital hemolytic anemias (e.g., thalassemias) and severe hemolytic and ineffective erythropoietic states (hypochromic anemia, pernicious anemia, erythroblastosis fetalis, and others). Is, however, EMH occurring in CMPD, including PMF, reactive, or is it a manifestation of abnormal stem cells having homed to remote organs?

Non-tumorous Involvement of the Liver in PMF

The accumulation of hemopoietic cells in the liver (*hepatic EMH*), and particularly within the sinusoidal channels, is a frequent finding in PMF and is associated with hepatomegaly (Figs. 1, 2, and 3; Scheimberg et al. 1995). A clinicopathologic correlation was found between the sinusoidal

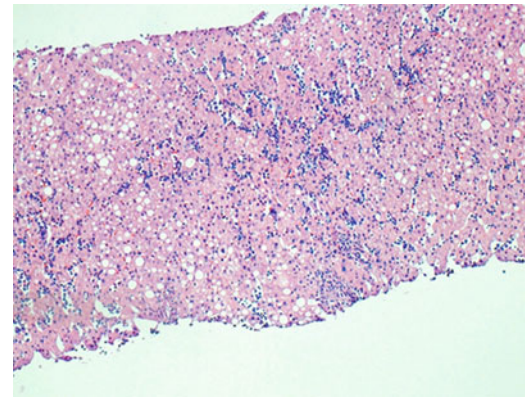

Fig. 1 Involvement of the liver in myeloproliferative syndrome. Immature myeloid cells focally infiltrate hepatic sinusoids (hematoxylin and eosin stain)

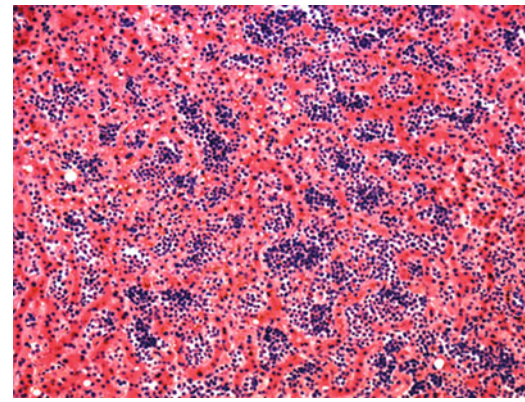

Fig. 2 Myeloproliferative syndrome, liver involvement. In this case, marked accumulation of neoplastic myeloid cells is observed in the sinusoids, causing atrophy of hepatocyte plates (hematoxylin and eosin stain)

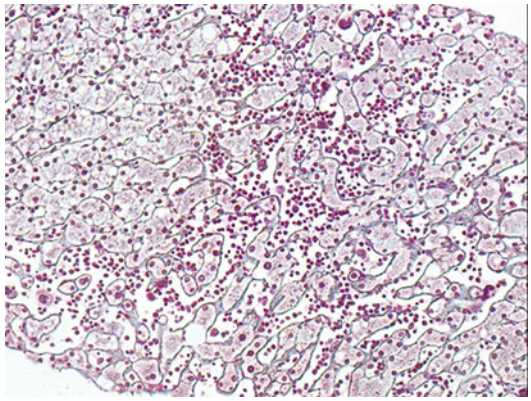

Fig. 3 Myeloproliferative syndrome, liver involvement. This reticulin stain illustrates that most myeloid cells are located within the intrasinusoidal compartment, only few cells being inside hepatocyte plates or in Disse's space. Few megakaryocytes are present (Gomori silver stain)

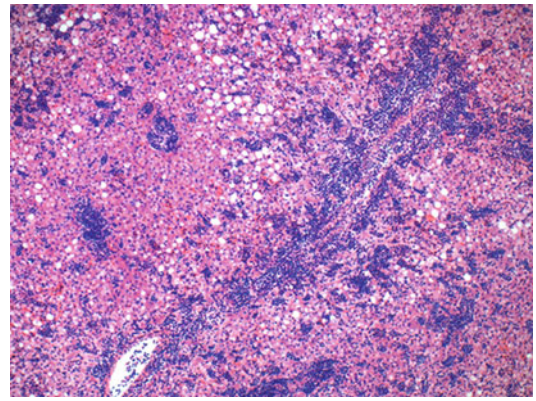

Fig. 4 Myeloproliferative syndrome in the blastic phase. Numerous immature myeloid elements (blasts) occupy both sinusoids and portal tracts (hematoxylin and eosin stain)

hemopoiesis and the number of white blood cell precursors in the peripheral blood, and erythroid hyperplasia in the bone marrow correlated negatively with white blood cell precursors and spleen and liver size (Ozen et al. 1997). In some situations, hepatomegaly is caused by a marked contribution of megakaryocytes (Nalbandian et al. 1968). EMH in PMF has also been reported to involve the wall of the gallbladder, mimicking cholecystitis (Thorns et al. 2002; Sahasrabudhe and Davenport 2005).

Liver Fibrosis

The growth of extramedullary hemopoietic elements in the liver is frequently associated with complex patterns of hepatic fibrosis (Fig. 4; Ruebner 1960; Glew et al. 1973; Degott et al. 1985; review: Le Bousse-Kerdilès 2012). Accumulation of hemopoietic cells and associated stromal elements in the sinusoidal compartment can lead to perisinusoidal fibrosis (Bioulac-Sage et al. 1986; Roux et al. 1987; Tsao 1989), which in turn may cause nodular regenerative hyperplasia of the liver and portal hypertension (Degott et al. 1985). In addition to PMF, perisinusoidal fibrosis can also be encountered in chronic myeloid leukemia, polycythemia vera, and essential thrombocythemia (see the respective paragraphs). Early-stage perisinusoidal fibrosis is revealed by the presence of collagen fiber bundles localized to Disse's space and surrounding liver cell plates, usually in areas where sinusoids are occupied by dense accumulations of hemopoietic elements (Tsao 1989), this distinct spatial relationship suggesting that there might be a pathogenic link between extramedullary hemopoiesis and fibrogenesis. In later stages, collagen deposition in the space of Disse is extensive, sometimes resulting in chicken-fence fibrosis, and associated with atrophy of hepatic plates. This perisinusoidal fibrosis is already visualized in the hematoxylin and eosin stain in the form of an eosinophilic fibrillar material, but is better seen in collagen stains. A variable contribution of reticulin fibers is in evidence. At the ultrastructural level, it has been observed that perisinusoidal fibrosis in CIMF is associated with a differentiation of quiescent stellate cells into myofibroblast-like, matrix-producing cells, i.e., as in other fibrogenic pathways in liver disease (Bioulac-Sage et al. 1986; Roux et al. 1987). Typically, these activated myofibroblasts are immunoreactive for alpha-smooth muscle actin (alphaSMA). Marked perisinusoidal fibrosis may cause a distortion of the lobular architecture, but nodular regenerative hyperplasia and even cirrhosis are rarely seen. In liver areas involved, Kupffer cells may show iron overload. Whether this iron accumulation

contributes to fibrogenesis in PMF is unknown. Perisinusoidal fibrosis with or without capillarization of the sinusoids causes portal hypertension through the establishment of a sinusoidal block and other mechanisms (see below).

Tumorous Hepatic Lesions in PMF

The extramedullary hemopoiesis in PMF occasionally forms tumorous masses in several organs, called *extramedullary myeloid tumors*. Focal intrahepatic extramedullary hemopoiesis (FIEH) occurring in PMF has repeatedly been documented, and also the imaging features have been described (Wiener et al. 1987; Abbitt and Teates 1989; Kobayashi et al. 1989; Warshauer and Schiebler 1991; Siniluoto et al. 1992; Aytaç et al. 1999; Kwak and Lee 2000; Navarro et al. 2000; Gupta et al. 2004; Cardoso et al. 2011). FIEH can manifest as solitary or multiple lesions (Abbitt and Teates 1989; Warshauer and Schiebler 1991). Reported masses had a diameter of 2.5–15 cm; in rare instances, these myeloid hepatic tumors may grow to giant masses (Navarro et al. 2000; Gil-Fernandez et al. 2001). Sonographically, FIEH presents in the form of two distinct patterns, i.e., (a) a well-defined homogeneously hypoechoic lesion or (b) a well-defined homogeneously hyperechoic mass encircling the portal vein and its main branches (Siniluoto et al. 1992).

The gross presentation of FIEH is characterized by rather sharply delineated tumorous masses with an either spheroid or lobulated contour, reflecting what is seen at imaging (Aytaç et al. 1999; Gupta et al. 2004). The lesion can grow to a size of 15 cm (Navarro et al. 2000). The cut surface of these either friable or firm masses (the consistency depending on the relation between cellularity and stromagenesis) is highly variable, ranging from whitish to tan or even dark-red. Histologically, the masses consist of usually mixed hemopoietic tissue that however typically contains a large proportion of megakaryoblasts and megakaryocytes, but lesions with predominance of erythroid elements are also recognized. It is of interest to note that megakaryocytes also prevail in hepatic manifestations of the transient myeloproliferative disorder occurring in patients with Down syndrome (see below). The hemopoietic cells in FIEH are chiefly localized to dilated hepatic sinusoids, but sometimes the cells also locate to Disse's space and to tissue spaces occupied by hepatocyte cords. The latter finding is intriguing, because hemopoietic cells do not usually home to extrasinusoidal spaces in the liver, owing to the homing and relocation mechanisms required. A distinct array of stromal cells accompanies the hemopoietic elements in FIEH. The density of these mesenchymal cells is, however, markedly variable, ranging from only a few and not easily detectable stromal cells to lesions presenting a sclerosing phenotype (see below). Similar to findings in myelofibrotic bone marrow, extramedullary hemopoiesis in the abdominal cavity may lead to the accumulation of pseudo-Gaucher cells in the peritoneal fluid (Lang and Uthman 1999). FIEH may be associated with nodular regenerative hyperplasia of the liver, a lesion known to also occur in patients with myeloproliferative disorders.

Fibrosing/sclerosing variants of hemopoietic tumors in PMF (sclerosing extramedullary hematopoietic tumor; SEMHT).

Part of the tumor-forming lesions in PMF and other chronic myeloproliferative disorders are characterized by a sometimes marked fibrogenesis, resulting in sclerosed masses. Previously, such lesions were also termed fibrous hematopoietic tumors (Beckman and Oehrle 1982). The term now currently employed is *sclerosing extramedullary hematopoietic tumor* (*SEMHT*; Remstein et al. 2000; Lane et al. 2000). SEMHT are solitary or multiple lesions that mostly form retroperitoneal or serosal-based masses, but they also develop in the breast, the lung, and the skin. The tumors may be mistaken for sarcomas, particularly sclerosing liposarcomas, other solid neoplasms, or lymphocyte-poor Hodgkin's lymphoma.

The anatomical compartment of the liver and associated structures can be involved by SEMHT. The lesion has been found in the liver (Waitz et al. 1978) and in the ligamentum teres hepatis (Kwon et al. 2004). Multiple sclerosing

hemopoietic tumors have been observed throughout the peritoneal surfaces (Tzankov et al. 2002). At gross examination, the tumor nodules are well circumscribed, up to several cm in diameter, firm, with a fibrous texture, and whitish. Histologically, SEMHT reveal a fibrosclerotic and myxoid background with usually thick collagen bundles, sometimes with interspersed groups of mature adipocytes. Within this matrix, there are clusters of trilineage hemopoiesis, with in part atypical megakaryocytes, granulocytes and their precursors, erythroid precursors, and only very few or no blasts.

Myeloid/Granulocytic Sarcoma of the Liver

Myeloid sarcomas are neoplasms of immature granulocytes, monocytes, or both involving extramedullary sites and occur in both leukemic and nonleukemic patients (Hang et al. 2011), also in PMF (Yoshiki et al. 2011; Morita et al. 2012). In rare instances, myeloid metaplasia of the liver may be followed by hepatic granulocytic sarcoma (Gangane et al. 2008), suggesting the focal outgrowth of transformed hematopoietic stem cells.

Portal Hypertension in PMF Patients with Hepatic Involvement

Portal hypertension occurs in 4–10 % of the patients with PMF (Shaldon and Sherlock 1962), and in at least 50 % of these patients, liver biopsies have uncovered extramedullary hemopoiesis as the only abnormality (Wyatt and Sommers 1950), while others show variable degrees of perisinusoidal fibrosis/capillarization or combined lesion patterns. The pathogenesis of portal hypertension arising in PMF has been difficult to understand because liver biopsy findings have often shown only minimal changes (Wanless et al. 1990). In a study of 97 patients with polycythemia vera and 48 patients with PMF (then termed agnogenic myeloid metaplasia), 10 patients without cirrhosis showed portal venous hypertension. All of these patients exhibited lesions in small- or medium-sized portal vein branches, and four had stenosis of the extrahepatic portion of the portal vein reflecting organized thrombi. Portal vein lesions were associated with nodular regenerative hyperplasia. In this autopsy study, there was no correlation between hepatic hemopoietic infiltration and signs of portal hypertension, and it was concluded that portal vein anomalies and subsequent nodular regenerative changes may play a pathogenic role for portal hypertension (Wanless et al. 1990).

Liver Changes Following Splenectomy in Patients with PMF

The risks and benefits of splenectomy in PMF have been studied in detail (Barosi et al. 1998; Tefferi et al. 2000). The postsplenectomy occurrence of extreme thrombocytosis, hepatomegaly, and leukemic transformation is of major concern (Mesa et al. 2000), even though the development of blast transformation after splenectomy may not affect overall survival and does not undermined the palliative role of the procedure for the other indications (Tefferi et al. 2000). In a large study, blast transformation was noted in 14.2 % of the patients, and substantial postsplenectomy hepatomegaly occurred in 16 % (Barosi et al. 1998). Subsequent to splenectomy, patients with CIMF may develop acute or chronic liver changes and rarely acute liver failure. In a recent analysis of numerous patients, liver failure was the direct cause of 7 % of the deaths (Barosi et al. 1998). Liver biopsies revealed extramedullary hepatic hemopoiesis, consisting of dysmorphic megakaryocytes primarily localized to the sinusoidal blood space, often accompanied by erythroid cells (Lopez-Guillermo et al. 1991). Subsequent to splenectomy, hepatomegaly (sometimes massive) can emerge (Grieco et al. 1988; Barosi et al. 1998). The secondary increase of hemopoietic elements in the liver after loss of the splenic compartment may be one of the reasons why the degree of hepatomegaly can increase, or hepatomegaly develop, after splenectomy in CIMF. In the rare complication characterized by acute liver failure with hepatic enlargement after splenectomy (McBrine et al. 1980; Perez-Villa et al. 1988), extensive extramedullary hemopoiesis dilating hepatic sinusoids and apparently compressing liver cells were the main pathologic findings (McBrine et al. 1980).

Differential Diagnosis

Mass-Forming Extramedullary Hematopoiesis

The biopsy differential diagnosis of mass-forming FIEH in CIMF includes focal hemopoiesis in benign hematologic disorders. FIEH can sometimes form large lesions (e.g., in thalassemia; Dewar et al. 1990; Wong et al. 1999) and hepatic myelolipoma (see ▶ Chap. 65, "Lipomatous Tumors, Liposarcoma, Benign Adipocyte-Containing Nonneoplastic Lesions, and Focal Fatty Changes of the Liver"). Rarely, multiple manifestations of FIEH of several cm diameter occur in patients without overt hematologic disease (Gupta et al. 2004). Liver involvement in CIMF may be associated with, or being complicated by, other hepatic tumors, e.g., hepatocellular carcinoma (Mitsuhashi et al. 1977).

Reactive Myelofibrotic Disorders Mimicking PMF

Myelofibrosis develops in one variant of hereditary primary hypertrophic osteoarthropathy (PHO), i.e., in PHO caused by mutations of the prostaglandin transporter SLCO2A1 (Diggle et al. 2012). Interestingly, gray platelet syndrome (GPS; alpha granule storage defect/deficiency) is sometimes associated with myelofibrosis, however usually with formation of increased reticulin fibers (Levy-Toledano et al. 1981). GPS is a rare bleeding disorder with thrombocytopenia, agranular gray platelets, and almost total absence of platelet alpha granules and their constituents (Raccuglia 1971). More than half of the reported cases are from a large family in Japan, and an autosomal dominant trait has been proposed (Mori et al. 1984). A hereditary platelet defect in the rat (Wistar Furth hereditary macrothrombocytopenic rat) resembles GPS of man. GPS belongs to a whole group of platelet disorders with abnormal alpha granule composition and function, also including factor V Quebec disorder (which leads to a degradation of most proteins continued within the alpha granules) and the Paris-Trousseau/Jacobsen-type dysmegakaryopoietic thrombocytopenia (associated with a chromosome 11q23.3 deletion, Fli-1 gene deletion, alpha granule deficiency, and abnormal, giant platelet alpha granules). Platelets in GPS display a markedly reduced concentration of the majority of alpha granule proteins that include platelet factor-4, beta-thromboglobulin, thrombospondin, fibrinogen, von Willebrand factor together with factor VIII, plasminogen activator inhibitor-1, TLT-1 (a TREM family member), PDGF C, glycoprotein (GP) VI, osteonectin, and fibronectin. Under normal conditions, these molecules are stored in alpha granules, and their secretion is mediated by or dependent on SNAP receptor (SNARE) complex formation between syntaxin, SNAP-25, and vesicle-associated membrane proteins.

Cytogenetic and Molecular Features

Cytogenetic abnormalities are detected in up to 30 % of patients (review: Hussein et al. 2009). The most common karyotypic features are del (20q) and partial trisomy 1q. No karyotype abnormality is proving the presence of PMF, but either del(13)(q12-22) or der (6)(1;6) is strongly suggestive (Hussein et al. 2009). Approximately half of patients with PMF show the JAK3V617F tyrosine kinase mutation, also found in other myeloproliferative disorders (Zhang and Li 2008; Kiladijan 2012; Tibes et al. 2012; Xia et al. 2012; Milosevic and Kralovics 2013; Nielsen et al. 2013). Among 30 patients with PMF, 50 % carried a JAK2V617F mutation (Xia et al. 2012). The presence of the JAK2V617F mutation does not seem to have an impact on leukemic transformation in PMF (Helbig et al. 2012). PMF patients can also show MPL/thrombopoietin receptor mutations (Tefferi 2008), but much less commonly than JAK2V617F mutations (Xia et al. 2012). The presence of MPL mutations has narrow and inconsistent phenotypic effects in PMF (Pardanani et al. 2011). The A3669G polymorphism of the glucocorticoid receptor is a susceptibility allele for PMF and contributes to phenotypic diversity and blast transformation (Poletto et al. 2012). Mutations in the isocitrate dehydrogenase (IDH) gene can occur in PMF and predict leukemic transformation and shortened survival (Tefferi et al. 2012b). Another mutational change that predicts poor survival in PMF is mutation in the EZH2 gene (Guglielmelli et al. 2011). EZH2 is

the PcG enhancer of zeste homolog 2, the catalytic component of the polycomb repressive complex 2, which serves to trimethylate histone H3 lysine 27. In PMF, mutations of the spliceosome components SF3B1 and SRSF2 occur, similar to other disorders with leukemogenesis (Malcovati et al. 2011; Makishima et al. 2012). Among 187 patients with PMF screened, 17 % harbored SRSF2 monoallelic mutations affecting residue P95, and mutations were associated with advanced age and shorter overall and leukemia-free survival (Lasho et al. 2012). TP53 mutation is rare in PMF (Greaves et al. 2013). PMF reveals a distinct methylome profile with both aberrant hyper- and hypomethylation gene patterns. Aberrant hypomethylation in PMF was seen to occur in non-CpG island loci, a pattern different from other myeloproliferative disorders (Nischal et al. 2013). Megakaryocytes in PMF show a decrease expression of proapoptotic genes such as BNIP3 (review: Kreipe et al. 2012).

Chronic Myelogenous Leukemia (CML, BCR/ABL1 Positive)

ICD-O code 9875/3

Introduction

In the WHO classification, chronic myelogenous leukemia (CML) is defined specifically as a myeloproliferative disorder that originates in an abnormal pluripotent bone marrow stem cell and is characterized by the invariable presence of the Ph chromosome or the *BCR*/*ABL* fusion gene. BCR/ABL1 is detectable in all myeloid lineages as well as in some lymphoid cells and endothelial cells in CML, although the initial presenting alteration as pathological neutrocytosis. Following an initial indolent chronic phase, CML can progress to accelerated and blast phases (CML accelerated phase (CML-AP) and CML blast phase (CML-BP)). The minimally invasive neoplastic cells in CML largely occupy the hemopoietic compartments and tissues, in particular the blood, bone marrow, and spleen, although the liver may be infiltrated as well.

Clinical Features

CML has an insidious onset, resulting in a largely asymptomatic onset in up to 40 % of patients. Diagnosis in these patients is done when an abnormal leukocyte count is detected in routine blood smears. Later symptoms and signs include fatigue, night sweats, weight loss, and splenomegaly. This phenotype is termed CML in chronic phase (CML-CP). Patients with the accelerated phase or blastic phases of CML, which may develop suddenly or after a transition phase, show the signs and sequelae of cytopenia and sometimes massive splenomegaly.

Morphology and Immunocytochemistry of the Leukemic Cells

In the chronic phase of CML, leukemic cells circulating in blood are neutrophils in different stages of maturation, always associated with absolute basophilia and often with monocytosis, with blasts accounting for less than 2 % of the cells. In the p190 BCR/ABL1 isoform, monocytosis is always present, resembling chronic myelomonocytic leukemia. The increased cell turnover causes the production of pseudo-Gaucher cells and sea-blue histiocytes in the bone marrow, cells derived from the neoplastic clone. The blast phase is characterized by the presence of 20 % or more of blast cells in the peripheral blood of nucleated cells in the bone marrow or by an extramedullary blast proliferation. A myeloid blast population (neutrophilic, eosinophilic, basophilic, monocytic, megakaryocytic, or erythroid blasts) is found around 70 % of patients, while 20–30 % of patients reveal a lymphoid blast lineage (precursor B cells or T lymphoblastic, with co-expression of myeloid antigens). Neutrophils in CML exhibit a markedly decreased neutrophil alkaline phosphatase. The blasts in myeloid blast phase may have strong,

weak, or no myeloperoxidase activity, but often express antigens associated with granulocytic, monocytic, megakaryoblastic, and/or erythroid differentiation.

Liver Involvement

Introduction

In part of patients with CML, the liver is infiltrated by the neoplastic cell populations (Hopps and Rucks 1948; Schwarze et al. 1975; Walz-Mattmüller et al. 1998). In addition, patients with CML may show "normal-looking" extramedullary hematopoiesis (Kajigaya et al. 1987). However, this type of extramedullary hematopoiesis seems to be more abnormal than marrow hematopoiesis (Baccarani et al. 1978).

Pathology

Macroscopy

In part of the patients, hepatomegaly is present, sometimes massive, with liver weights reaching 10 kg (Gruber 1930). The liver capsule is generally smooth, but circumscribed thickening was also noted. On cut surfaces of the liver, the lobular architecture may be blurred due to sinusoidal infiltration. These infiltrates can show confluence, resulting in a whitish network. A subset of patients display focal tumor-like lesions termed leukomas caused by marked focal accumulation of neoplastic cells. In case of strong expression of myeloperoxidase, a green enzyme, leukomas can turn to a greenish color, i.e., chloromas (the "leukemia with green tumors" or myeloid chloroleukemia of Fabian; Fabian 1908).

Histopathology

Histologically, in patients with neoplastic hepatic infiltration, the partially dilated sinusoids contain blood with an increased neutrophil cellularity and/or contain clusters of neutrophil precursors in different stages of maturation and erythroblasts. The neoplastic elements form clusters or are arranged within the sinusoids in the form of "Indian files." Part of the cells, mainly the myeloid cells, are in close relationship with sinusoidal endothelial cells, or seem to adhere to them. In part of the cases, the process infiltrates the portal tracts to variable degrees, however with predominance of immature cell forms with decreased cytoplasmic granularity (Butterfield 1908). Leukomas and chloromas consist of dense tumor-like accumulations of myeloid cells in various stages of differentiations, associated with expansive growth and perifocal atrophy of the hepatic parenchyma (Kchinologuer 1915). Liver biopsies from 15 untreated patients with CML showed that the proportion of erythroblasts was higher than in the bone marrow, and an increased frequency of basophilic leukocytes was recorded in the extramedullary sites. The mitotic indices of the granulocytopoietic and erythrocytopoietic precursor cells were lower in the spleen and liver than in bone marrow, suggesting marked differences in the biologic features of hepatic blood-forming cells in CML in comparison with the marrow. In the liver, also a considerable admixture of lymphoid cells was found (Sjögren and Brandt 1976). Intrasinusoidal normal-looking or abnormal CD61-positive megakaryocytes may also be in evidence. Part of the involved livers show perisinusoidal reticulin fibrosis, similar to that found in the bone marrow (Mikel et al. 1990). In the chronic phase of CML, extramedullary hemopoiesis can result in the emergence of multiple and in part hemorrhagic nodules of extramedullary hemopoiesis ("pseudochloromas") in the absence of blastic transformation (Barton et al. 1979). In the course of blastic transformation, the sinusoids and portal tract spaces are progressively infiltrated by large numbers of lysozyme- and CD34-positive myeloid or lymphoid blasts cells. In the parenchyma, these blasts may cause hepatocyte plate atrophy and effacement of the lobular architecture. Massive hepatic involvement has been observed CML showing monoblastic transformation (Ondreyco et al. 1981). Liver involvement in CML can be associated with hepatic vascular complications, specifically Budd-Chiari syndrome (Anger et al. 1989; Picardi et al. 2000).

Pathogenic Pathways

Ninety to ninety-five percent of CML have the t (9;22)(q34;q11.2) translocation at diagnosis, resulting in the Philadelphia (Ph) chromosome. This translocation fuses sequences of the BCR gene on chromosome 22 with regions of the ABL1 on chromosome 9 (reviews: Ernst and Hochhaus 2012; Gianfelici et al. 2012). The breakpoint in BCR is found in the major breakpoint cluster region M-BCR in the majority of cases. The fusion results in an abnormal fusion protein, p210, a kinase with increased tyrosine kinase activity and responsible for the constitutive activation of several signal transduction pathways. The BCR/ABL fusion directly downregulates the expression of c-Jun, a monopoiesis-promoting transcription factor, by activating the PI3-Akt pathway, thereby promoting neutrophil differentiation in chronic phase CML (Kobayashi et al. 2009). Much less commonly, the breakpoint involves exons 17–20, resulting in a larger fusion protein called p230. Patients with p230 have pronounced neutrophil maturation and/or marked thrombocytosis. CML is regarded as a stem cell disorder derived from a pluripotent bone marrow stem cell (review: Crews and Jamieson 2012). The clonal population of neoplastic cells exhibits marked heterogeneity in regard to proliferation and differentiation. The population contains stem cells with a high proliferative activity and marked self-renewal capacity not found in leukemic cells, and these cells maintain the leukemic process. In the course of CML in chronic phase (CML-CP), leukemia stem cells or their progeny may at some stage acquire additional genetic alterations that cause CML to transform further, from CML-CP to a more advanced phase, which is classified as either accelerated phase CMl (CML-AP) or blastic phase CML (CML-BP). CML-BP is characterized by a massive expansion of immature blasts or progenitor cells with myeloid or lymphoid features (review: Skorski 2012).

Apart from hematopoietic stem cells, other CML-initiating cells have been postulated, including fetal liver kinase-1-ppositive, BCR/ABL1 fusion gene-positive mesenchymal stem cells (Xishan et al. 2011). These findings are of interest in the light of the significant roles played by the stromal microenvironment and its signaling pathways in CML leukemogenesis (review: Seke Etet et al. 2012).

Chronic Neutrophilic Leukemia (CNL)

ICD-O code 9963/3

Introduction

Chronic neutrophilic leukemia (CNL) is a rare BCR/ABL/Ph1-negative chronic myeloproliferative disease mostly occurring in elderly patients of both sexes, characterized by persistent neutrophilia (mature neutrophilic leukocytosis), bone marrow granulocytic hypercellularity without evidence of myelodysplasia, splenomegaly/hepatosplenomegaly, and bearing a poor prognosis (Yam 1982; Zittoun et al. 1994; Elliot et al. 2001; Böhm and Schaefer 2002; Elliott 2004, 2006; Haferlach et al. 2008; Thiele 2009). In addition to the absence of BCR/ABl rearrangement, CNL has no rearrangement of PDGFRA, PDGFRB, or FGFR1.

The exact incidence of CNL is not known, but probably less than 200 cases have been reported in the literature, and of these, only 40 have been found to meet the WHO criteria in a detailed review (Elliott 2006). CNL can be distinguished from CML, neutrophilic-chronic myelogenous leukemia, and myelodysplastic syndromes, although a transition from polycythemia vera (Foa et al. 1991; Higuchi et al. 1999), or from a myelodysplastic syndrome (including CMMoL) (Zoumbos et al. 1989; Cervantes et al. 1990; Pascucci et al. 1997), to CNL has been reported. The criteria for CNL diagnosis have been worked out (You and Weisbrot 1979), but CNL is still in the process for improved definition, having led to the concept of "true" CNL (Reilly 2002). In fact, cases with CNL were not included in the FAB system (Bennett et al. 1994). The disorder has the potential for blastic transformation and progressive refractory neutrophilia (Elliott 2004; Amato et al. 2008).

Clinical Features

The most common reported clinical feature is splenomegaly, sometimes symptomatic. Patients with CNL often show hepatomegaly as well (You and Weisbrot 1979; Zittoun et al. 1994). CNL can be associated with elevated serum vitamin B12 levels and can present with Sweet's syndrome (Gan et al. 2007). As CML, CNL can undergo blastic transformation (Elliott 2004; Amato et al. 2008).

Morphology

Patients with CNL have a marked peripheral leukocytosis (WBC $\geq 25 \times 10(9)/L$), with segmented neutrophils and band forms accounting for more than 80 % of the WBCs, immature granulocytes being less than 10 % of WBCs, and myeloblasts less than 1 %. In the bone marrow, the neutrophil maturation pattern is normal, and myeloblasts amount less than 5 % of nucleated BM cells.

Liver Involvement in Chronic Neutrophilic Leukemia

Liver Infiltration by Leukemic Cells

Similar to CML, maturing and mature neutrophils have the capability to home to the hepatic vascular bed (You and Weisbrot 1979; Zittoun et al. 1994) and are chiefly found within sinusoids (Yamaya et al. 1982; Hayashi et al. 1983; Takenaka et al. 1986), where they are seen either in central parts of the vascular channels or then close to the endothelial lining, sometimes forming small clusters of cells. Similar to other hematologic neoplastic disorders, CNL may show Gaucher-like cells in the infiltrate (Tang et al. 1987).

Other Hepatic Lesions Associated with CNL

CNL has been described to be associated with nonalcoholic steatohepatitis (NASH), and it has been assumed that the hepatic infiltration in CNL may contribute to the pathogenesis of NASH (Yoshida et al. 2004).

Leukocytosis and Leukemoid Reactions in Hepatocellular Carcinoma: Alterations Mimicking CNL

Some patients with hepatocellular carcinoma (HCC) exhibit marked neutrophilic leukocytosis/neutrophilia with or without pyrexia, eventually leading to a hematologic presentation mimicking leukemia ("leukemoid reactions "; "pseudoleukemic hyperleukocytosis"; Ochoa 1981; Rosenfeld et al. 1982; Sylvain et al. 1985; Okuda et al. 1991; Manas Garcia et al. 2004). HCC cells can express and secrete colony-stimulating factor(s), in particular granulocyte CSF (G-CSF), suggested to cause the leukocytosis (Toyoda et al. 1989; Yamamoto et al. 1999). In addition to HCC, other tumors in the liver are capable to synthesize G-CSF inducing leukocytosis, including primary adenosquamous carcinoma of the liver (Hayashi et al. 2001) and primary liver squamous carcinoma (Koyama et al. 1990).

Pathogenic Pathways

Usually, none of the common cytogenetic anomalies characteristic of myeloid disorders are detectable. The clonal nature of CNL has been established (Kwong and Cheng 1993), and monosomy at 11q23 has been interpreted to be a marker for clonality in CNL (Froberg et al. 1998).

The exact cause of CNL is not known so far. Interestingly, several reports illustrate the association of CNL with monoclonal gammopathies/monoclonal gammopathy of uncertain significance (MGUS) and with plasmacytic proliferative disorders, including myeloma, which may even precede the onset of overt CNL (Tursz et al. 1974; Vorobiof et al. 1978; Watanabe et al. 1984; Zoumbos et al. 1987; Rovira et al. 1990; Standen et al. 1990; Masini et al. 1992; Cehreli et al. 1994; Ito et al. 1996; Tanaka et al. 1998; Nitta et al. 1999; Dincol et al. 2002; Hartley et al. 2010). An association with myeloma has also been noted for other types of leukemia and related disorders, such as myelomonocytic leukemia (Raz and Polliack 1984; Akashi et al. 1991), acute monocytic leukemia (Luca and Almanaseer 2003), myelodysplastic syndrome (Sato et al. 1992), and erythroleukemia (Barcos et al. 1979). The pathogenesis of these

associations is not clear. It was suggested that the two groups of disorders may go back to a common stem cell followed by an abnormal development in the sense of "lineage infidelity" (Akashi et al. 1991; Nitta et al. 1999), or that myeloma might induce a leukemoid reaction mimicking a myeloproliferative disorder (Ito et al. 1996). In fact, molecular studies have shown that, in at least part of these associations, the neutrophils were not clonal (Standen et al. 1993). On the other hand, myeloma may produce granulocyte colony-stimulating factor and induce a clinical situation mimicking CNL (Usuda et al. 1997; Kusaba et al. 2004).

Essential Thrombocythemia

ICD-O code 9962/3

Introduction

According to the 2008 WHO classification, essential thrombocythemia (ET) is defined as a chronic myeloproliferative neoplasm that involves primarily the megakaryocytic cell lineage. Synonyms of ET comprise primary thrombocytosis, idiopathic thrombocytosis, and hemorrhagic thrombocythemia. ET is also termed thrombocythemia vera. ET is hematologically characterized by persistent thrombocytosis $\geq 450 \times 10(9)/L$ in the peripheral blood, increased numbers of large, mature megakaryocytes in bone marrow, and clinically by episodes of thrombosis and/or hemorrhage (reviews: Michiels et al. 2007; Levine and Heaney 2008; Harrison 2010; Beer 2011; Tefferi 2012a).

ET was regarded as a "benign" myeloproliferative disorder with an, as such, normal life expectancy. However, the population-based Olmsted County Study suggested that survival among patients with ET was significantly worse than that among age- and sex-matched healthy control subjects (Mesa et al. 1999), and the reduced survival is chiefly caused by thrombotic and vascular complications and in fewer patients by the emergence of myelodysplasia, myelofibrosis, or acute leukemia (Harrison 2002; Cervantes et al. 2002; Bernasconi et al. 2002). As polycythemia vera, ET originates in the clonal expansion of a transformed pluripotential hemopoietic progenitor cell ("clonal thrombocytosis"; Tefferi et al. 1995b; Michiels 1996; Gilbert 2001; review: Schafer 2004). ET is, therefore, one of the chronic myeloproliferative disorders. The relationship of chronic hemopoietic stem cell disorders is underlined by the rare finding of ET following polycythemia vera (Randi et al. 1996) and by thrombocytosis occurring in the context of polycythemia vera. Moreover, thrombocytosis may also be associated with the myelodysplastic 5q- syndrome, a mixed myelodysplastic and myeloproliferative syndrome. The clonality of ET has been investigated by several methods (Schafer 2001; Liu et al. 2003); however, ET may not always be clonal, and these forms may be at lower risk of thrombotic complications (Harrison et al. 1999), suggesting that a non-clonal disease can progress to clonal disease and that ET may be a heterogeneous disorder (Schafer 2004).

Epidemiology

ET has an estimated incidence of 0.6–2.5 per 100,000 persons per year, according to the Polycythemia Vera Study Group (PVSG). Most patients are 50–60 years old at diagnosis, males and females being equally affected. A second age peak, mainly in women, is at about 30 years of age, and also children can develop ET (Michiels and Juvonen 1997; Michiels and Thiele 2002). More than half of patients are asymptomatic when markedly elevated thrombocyte numbers are detected in peripheral blood, the remaining patients usually presenting with thrombosis and signs of vascular occlusion.

Clinical Features

More than half of patients are asymptomatic at diagnosis. Symptomatic patients show signs and complications of vascular occlusion and/or hemorrhage (Falanga and Marchetti 2012).

Hemorrhages are common from mucosal surfaces. Thrombosis of medium-sized to large arteries may occur. About 50 % of patients show splenomegaly, and 15–20 % hepatomegaly. However, the prevalence of splenomegaly depends on the diagnostic criteria for ET used, in that splenomegaly more often occurs in patients who have thrombocytosis in the prefibrotic stage of myeloproliferative syndrome.

Morphology

The major alterations in ET are marked thrombocytosis in peripheral blood, with an abnormal platelet morphology and a prominent proliferation of megakaryocytes in the bone marrow. Large and even giant megakaryocytes predominate, usually with deeply lobulated and hyperlobulated nuclei (the so-called stag hornlike nuclei). ET usually shows an early-stage myeloproliferative bone marrow disorder, characterized by a proliferation of mature-looking enlarged megakaryocytes in the bone marrow with no or only slightly increased cellularity, and there is no progression of the myeloproliferative activity. Granulopoiesis and erythropoiesis are mostly normal in marrow, and no marrow fibrosis is in evidence in 99 % of the patients at the time of diagnosis. ET may pose differential diagnostic problems in comparison with CIMF, because also ET can be associated with an increase in bone marrow reticulin fibers, albeit in a minority of the patients. Initial and early idiopathic myelofibrosis (CIMF) mimicking ET is characterized by a reduction of life expectancy different from that of ET (Thiele and Kvasnicka 2003). The bone marrow in ET reveals an isolated (monolinear) proliferation of megakaryocytes without gross abnormalities of this cell lineage (Thiele et al. 1987), but with a marked expansion of megakaryocyte precursors (Thiele et al. 1990).

At EM examination, bone marrow megakaryocytes in ET were found to be in part large or even giant and characterized by a highly lobulated nucleus containing several nucleoli and an extensive intermediate zone of the cytoplasm with many Golgi fields, numerous profiles of the demarcation membrane system, and an abundance of alpha granules and some dense bodies, findings suggesting not a marked structural abnormality, but rather reflecting a state of markedly increased thrombocytopenic activity (Thiele et al. 1988).

Liver Involvement in Essential Thrombocythemia

Hepatic Infiltration

In ET, liver sinusoids may show an accumulation of megakaryocytes, either as single elements or in clusters, and/or of other hemopoietic elements (Fig. 5). It is not yet known how frequent megakaryocyte homing to the hepatic sinusoidal compartment is in ET. In the case of dense accumulations, sinusoidal plugging by megakaryocytes may ensue, similar to other organs, e.g., the lung (Hill et al. 1996).

Megakaryocytes located to the hepatic sinusoidal channels can contain entire other cells, mainly hematologic cells or fragments thereof in their cytoplasm, a phenomenon termed emperipolesis (Thiele et al. 1984; Tavassoli 1986). The homing, and eventual proliferation, of megakaryocytes and their progenitors to the hepatic sinusoidal vascular bed can induce fibrosis and in particular perisinusoidal fibrosis; this phenomenon is further discussed in the paragraphs on CIMF and TMD in Down

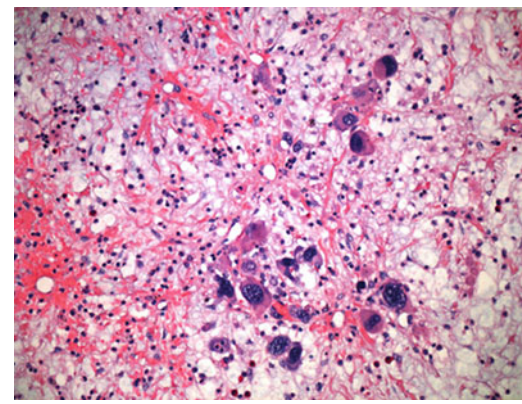

Fig. 5 Liver involvement in essential thrombocythemia. The parenchyma is destroyed and replaced by a tissue containing clusters of atypical megakaryocytes (hematoxylin and eosin stain)

syndrome. Furthermore, sinusoids harboring megakaryocytes may be dilated and distorted, which may be caused not only by a mass effect and/or stasis but also be distinctive effects of megakaryocytes on sinusoidal endothelial cells (see below). Extramedullary hemopoiesis in the liver was found in ET complicated by blastic transformation and acute myelofibrosis (Chen et al. 1987).

Thrombotic Complications of Liver Veins in Essential Thrombocythemia

ET is well known to be associated with diverse thrombotic and hemorrhagic manifestations, including platelet-mediated erythromelalgia, microvascular disturbances, (aspirin-responsive) arterial thrombophilia, coronary artery disease, atypical cerebral ischemic attacks, paradoxical thrombosis and bleeding, and thrombosis of visceral veins (Michiels et al. 1996, 2004). Hemorrhagic thrombocythemia is a clinical syndrome of recurrent spontaneous mucocutaneous and secondary hemorrhages associated with extremely high platelet counts far in excess of 1000 × 10 (9)/L; at increasing platelet counts in excess of 2000 × 10(9)/L, arterial thrombophilia of ET changes into a spontaneous bleeding tendency as a consequence of platelet-mediated increased proteolysis of the large von Willebrand factor multimers leading to a type 2 acquired von Willebrand syndrome (Michiels 2003; Michiels et al. 2004). Venous thromboses, including those of large visceral veins, are related to platelet effects, increased hematocrit, blood cell mass, and increased concomitant blood viscosity. Budd-Chiari syndrome (BCS; see above) occurs as a complication of ET, similar to other myeloproliferative disorders (Garza Trasobares et al. 1988; Corredoira et al. 1989; Brunerova et al. 2004; Karakulska-Prystupiuk et al. 2012). Furthermore, portal vein thrombosis with or without associated splenic vein thrombosis occurs in ET and other forms of thrombocytosis (Chiti et al. 1992; Teofili et al. 1992; Randi et al. 1993, 2002; Jimenez Saenz et al. 1998; Berk and Ahmed 2006). A latent form of ET has presented as portal cavernoma (Cai et al. 2009), and cavernous transformation of the portal vein was also noted in hemorrhagic thrombocythemia (Macpherson et al. 1957). Occlusive thrombotic lesions may also involve microvessels of the liver (Singh and Wetherley-Mein 1977).

In ET, multiple venous and arterial thrombosis of the gallbladder causing acute cholecystitis have been observed (Picon-Coronel et al. 2011). The pathogenesis of thrombotic events in ET and other myeloproliferative disorders has not yet been clarified. It was hypothesized that endothelial cell abnormalities associated with the hematological malignancy might contribute to the prothrombotic state. Budd-Chiari syndrome, splanchnic vein thrombosis, and portal vein thrombosis have been associated with JAK2V617F mutations (Patel et al. 2006; Xavier et al. 2010; Qi et al. 2011; Sozer and Hoffman 2011) and JAK2V617F-positive hematopoiesis, in particular latent myeloproliferative disorders and ET (Allegra et al. 2009; Smalberg et al. 2012; Yonal et al. 2012). In liver endothelial cells of patients with Budd-Chiari syndrome, JAK2V617F mutation has been demonstrated (Sozer et al. 2009). Expression of JAK2V617F may promote cell adhesion. It was demonstrated that it activates Lu/BCAM-mediated erythrocyte adhesion in polycythemia vera through an EpoR-independent Rap1/Akt pathway (De Grandis et al. 2013).

Essential Thrombocythemia and Liver Tumors or Tumor-like Lesions

Relatively few reports document the association of ET with hepatic tumors. Hepatic angiosarcoma has been observed in a patient with ET complicated by Budd-Chiari syndrome (Marichy et al. 1995). On the other hand, hepatocellular carcinomas can be associated with thrombocytosis (Yoshida et al. 2003) and can produce thrombopoietin (TPO) resulting in marked thrombocytosis (Ryu et al. 2003). The thrombocytosis observed in some patients with hepatoblastoma (Forouhar et al. 1984; Shafford and Pritchard 1993) seems to be caused by the same or a similar mechanism (Nickerson et al. 1980; Yamaguchi et al. 1996; Komura et al. 1998). Similar to what has been discussed in BCS occurring in polycythemia vera, hepatic venous disorders in ET may be followed by nodular regenerative hyperplasia of the liver, e.g., in

obliterative portal venopathy (Wanless et al. 1980; Fukai et al. 1992; Al-Mukhaizeem et al. 2004).

These findings are to be interpreted in the light of the role played by the liver for production of several hemopoietic hormones. The liver acts as the primary site of synthesis of erythropoietin (EPO) in the fetal stage, and it is the predominant TPO-producing organ for life (Jelkmann 2001). TPO is synthesized and expressed in hepatocytes in a constitutive way, and serum TPO levels reflect the total mass of functional liver (Sungaran et al. 1997; Okubo et al. 2000). In contrast to EPO and other hepatic export proteins, the hepatic synthesis of TPO is little influenced by external signals (with the exception of IL-6 that enhances hepatic TPO mRNA expression; Kaser et al. 2001), and the kinetics of serum TPO is mainly determined by megakaryocytes and platelets that remove TPO from blood by means of their high-affinity TPO receptors (Jelkmann 2001).

Pathogenic Mechanisms of Organ Infiltration in Essential Thrombocythemia

In the bone marrow, megakaryocytes hold a distinct, nonrandom position, in that they reside at a characteristic distance from the abluminal surface of the sinusal endothelium (Lichtman et al. 1978). There is structural evidence that megakaryocytes are motile (Leven 1987) and that entire megakaryocytes traverse the marrow-blood barrier and then enter the circulation (Thiele et al. 1994), and this passage occurs through apertures of 6 μm in diameter, located in the parajunctional areas of the bone marrow sinus endothelium (Tavassoli and Aoki 1981). In situations of matrix increase, e.g., myeloproliferative disorders with marrow fibrosis, transmural migration of megakaryocytes reveals a mole-like tunneling through the thickened sinusal wall (Thiele et al. 1997). It is not yet known whether megakaryocytes located to hepatic sinusoids in ET and other situation can traverse from the intrasinusoidal compartment into the perisinusoidal space.

The interactions between megakaryocytes and endothelial cells of sinus and sinus-like vascular channels are complex. In an ultrastructural study of the bone marrow in ET, it was found that two different kinds of megakaryocyte cytoplasmic processes are penetrating the marrow sinus wall. Megakaryocytes develop multiple, pseudopod-like projections derived from their peripheral zone and devoid of organelles, probably serving as anchors to keep the cells in a subendothelial position. The second type of cytoplasmic processes reaching into the vascular lumen consists of tentacle-like elongated protrusions rich in organelles, thought to represent either the beginning of megakaryocytes' egress into circulation or putative early platelets ("protruding platelet territories"; platelet fields; proplatelets) (Thiele et al. 1991). It has been suggested that megakaryocyte projections may, in addition to their proposed anchoring function, serve to monitor the circulation and to receive information as to the requirement of the body for platelet formation (Tavassoli and Aoki 1981). It has also been suggested that the distinct marrow position of megakaryocytes reflects their status as components of the barrier, in that megakaryocytes may offer a transmegakaryocytic route for other cells to enter circulation, via emperipolesis (Tavassoli 1986). Upon contact with subendothelial extracellular matrix, megakaryocytes adhere to proteins, spread, and undergo fragmentation, thus exhibiting a platelet-like behavior (Caine et al. 1986).

Megakaryocytes and the Hepatic Sinusoid

Megakaryocytes circulate in the peripheral blood and can home to the non-marrow microvascular bed, including hepatic sinusoids. This is accomplished by the expression and action of distinct adhesion molecules (Hagiwara et al. 1996). Circulating megakaryocytes, although >75 % positive for CD41, have, however, unlike platelets and bone marrow megakaryocytes, a reduced and remarkably heterogeneous labeling with antibodies against the alpha subunits of VLA2, VLA5, and VLA6 (Van Pampus et al. 1992). The lining of the liver sinusoids is different from that of bone marrow sinuses, and this will have an effect of the interaction with megakaryocytes. The endothelium of bone marrow sinuses is a

continuous, structurally polarized layer (the bone marrow microvascular endothelium, BMEC) with segmental surface differentiation and which is selective in cellular transport and can accomplish selective retention/homing of progenitor cells (Tavassoli 1981; Shirota and Tavassoli 1992; Papayannopoulou and Craddock 1997). Cell homing factors for this specialized surface comprise VEGF, vascular endothelial cadherin, VCAM-1, endothelial selectins, and the chemokine, stromal cell-derived factor-1alpha (SDF-1alpha), the latter being produced by bone marrow stromal cells and representing a chemotactic factor for hemopoietic cells (Jacobsen et al. 1996; Kim and Broxmeyer 1998; Frenette et al. 1998; Mohle et al. 1998; Jo et al. 2000; Van Buul et al. 2002). In contrast to normal hepatic sinusoids, bone marrow sinuses have a basement membrane and an endothelial fenestration mode that is different from that of sinusoidal endothelia, with only few fenestrations (Muto 1976). Liver sinusoids are also very distinct vascular channels with respect to their ontogenesis, as they partially derive from liver mesothelial cells and cells of the proepicardium, a mesothelial tissue anatomically continuous with liver mesothelium, in avian embryos (Perez-Pomares et al. 2004). Hepatic sinusoidal endothelial porosities and fenestrations are dynamical structures/phenomena that seem to affect transendothelial trafficking, also during regeneration (Wack et al. 2001).

The traffic of megakaryocytes between extravascular and intravascular compartments in the liver seems to be bidirectional, in that megakaryocytes in fetal hepatic megakaryocytopoiesis are partially located outside vascular channels of the liver and can then enter circulation (Enzan et al. 1980). The accumulation of megakaryocytes in the liver, and their local growth, may be modulated by the local availability of thrombopoietin that is chiefly produced in the liver and changes in function of liver mass and disease (Wolber and Jelkmann 2002; Freni et al. 2002). It has been demonstrated that sinusoidal endothelial cells constitutively co-express thrombopoietin and the thrombopoietin receptor, c-mpl (Cardier and Dempsey 1998). Stimulation of these cells with thrombopoietin in vitro induces the secretion of proinflammatory cytokines and promotes endothelial cell proliferation (Cardier 1999). Thrombopoietin, via its receptor, c-mpl, drives the expansion of megakaryocytes, while the priming, the early developmental steps, and the differentiation of these cells are controlled by several other genes and gene products, including Gfi-1b (Saleque et al. 2002), jumonji (Kitajima et al. 2001), interferon regulatory factor-2 (Stellacci et al. 2004), GATA-1 (Iwasaki et al. 2003), BUBR1 (Wang et al. 2004a), and the glutamate signaling/NMDA glutamate receptor pathways (Hitchcock et al. 2003). Furthermore, megakaryocyte maturation is associated with the expression of the CXC chemokine, connective tissue-activating peptide CTAP III, a chemokine that can support stem cell-derived hemopoiesis, but inhibits the proliferation of committed megakaryocyte progenitors (Deutsch et al. 2000). Platelet formation in turn depends on apoptotic processes, with caspase activation within megakaryocytes (Li and Kuter 2001; De Botton et al. 2002; Testa 2002).

It is not yet known whether sinusoidal and/or perisinusoidal hepatic cells, and in particular hepatic stellate cells, produce factors chemotactic for hemopoietic cells, e.g., stromal cell-derived factor-1, although hepatic stellate cells can secrete several cytokines and chemokines, including CCL2/monocyte chemoattractant protein-1 (Marra et al. 2004), and CCR5 and RANTES, probably allowing a cross talk between stellate cells and leukocytes (Schwabe et al. 2003). Platelet-activating factor (PAF) is predominantly produced in the liver and is released in an increased fashion in cirrhosis (Yang et al. 2004), but PAF plays a major role as a potent hepatic vasoconstrictor and systemic vasodilator. Cells of the megakaryocyte lineage and their platelet products can store and release vascular endothelial growth factor (VEGF; Mohle et al. 1997; Salgado et al. 2001), and megakaryocytes in myeloproliferative disorders can express the Tie-2 receptor (Zetterberg et al. 2003). The

autocrine-paracrine VEGF loops potentiate the maturation of megakaryocyte precursors through the Flt1 receptor (Casella et al. 2003). On the other hand, activated hepatic stellate cells produce cyclooxygenase-2 (COX-2) protein to induced VEGF production, and this response is regulated by vHL/HIF-1 alpha (Wang et al. 2004b). The network is further complicated by the observation that bone marrow cells can give rise to hepatic stellate cells in the mouse (Baba et al. 2004).

Cytogenetic and Molecular Features

Five to ten percent of ET patients reveal an abnormal karyotype, but no cytogenetic alterations specific for ET are known. Forty to fifty percent of the patients carry the Janus kinase 2 (JAK2) V617F or a functionally similar mutation, but these mutations are not specific for ET, because they are found in polycythemia vera and primary myelofibrosis as well (Cho et al. 2009; Deepak et al. 2011; Kiladjian 2012; Martinez-Avilez et al. 2012; Pich et al. 2012). One percent of ET patients show a gain of function mutation of MPL, MPL W515K/L. In patients with JAK2 V617F-positive ET with del(20q), haploinsufficiency of the nuclear factor of activated T-cells, cytoplasmic, calcineurin-dependent 2/NFATC2 seems to cooperate with activation of the JAK-STAT signaling pathway (Vieira et al. 2012). Mutations of TET2 (tet oncogene family member 2) were detected in both JAK-positive and JAK-negative ET, but only in a minority of cases and more often in older patients (Tefferi et al. 2009; Martinez-Aviles et al. 2012). Patients with ET have an increased incidence of acute myeloid leukemia. A predisposition to this evolution is related to a polymorphism in the XPD gene (Hernandez-Boluda et al. 2012). Hereditary thrombocythemia is an autosomal dominant disorder with clinical features resembling those of sporadic ET and caused by germline mutations in the genes for Thrombopoietin and its receptor, MPL (Rumi 2008; Ding et al. 2009).

Myeloid Neoplasms with Eosinophil Lineage

82

Contents

Abstract

The liver can be involved by several neoplastic and reactive disorders characterized by eosinophilia/hypereosinophilia. The common pathogenic pathway of liver damage induced by these conditions is the toxic action of eosinophil granulocyte proteins and eosinophil-associated immune reactions. The liver parenchyma and portal tracts can be infiltrated in the setting of the myeloproliferative neoplasia, chronic eosinophilic leukemia associated with FIP1L1-PDGFRA fusion. Other neoplastic eosinophil processes that may invade and damage the liver are disorders with PDGFRB rearrangement and the 8p11 myeloproliferative syndrome with FGFR1 rearrangement. There are also cases of idiopathic hypereosinophilia, characterized by peripheral eosinophilia with tissue damage in the absence of known cause of eosinophilia. Phenotypically, all these disorders may be associated with various hepatic pathologies, including mass-forming hepatic eosinophilic infiltrations, diffuse hepatic infiltration, eosinophilic granulocytoma/sarcoma, focal hepatic eosinophilic necrosis, eosinophilic hepatitis, eosinophilic cholangiopathy, eosinophilic sclerosing cholangitis, eosinophilic abscesses, eosinophilic hepatic vasculitis, hypereosinophilic hepatic venous thrombosis, and eosinophilic ascites.

DOI 10.1007/978-3-319-26956-6_82

Introduction and Classification

Generally, hypereosinophilic states are classified into three major groups, namely, (1) *reactive* (*or non-clonal*) *eosinophilias* (e.g., *allergic reactions*, *infestations*, *infections*, *side effects of drugs*), (2) *clonal disorders of the hemopoietic system associated with eosinophilia*, and (3) *idiopathic hypereosinophilic syndrome* (*HES*) (review: Brito-Babapulle 2003). The clonal disorders with variable degrees of eosinophilia chiefly comprise acute and chronic eosinophilic leukemia (AEL and CEL, respectively), AML and CML with eosinophilia, polycythemia rubra vera with eosinophilia, essential thrombocythemia with eosinophilia, myelodysplastic disorders (MDS) with eosinophilia, eosinophilias in chromosome 16 variant disorders and in the 8p11 myeloproliferative syndrome (EMS), eosinophilic variants of systemic mast cell disease, and several lymphoproliferative disorders with eosinophilia (Brito-Babapulle 2003).

In regard to clonal disorders, the WHO classification distinguishes two major subgroups: (1) myeloid and lymphoid neoplasms with eosinophilia and abnormalities of PDGFRA, PDGFRB, or fibroblast growth factor receptor 1 (FGFR1), and (2) chronic eosinophilic leukemia (CEL), not otherwise specified (reviews : Gotlib 2010, 2011; Klion et al. 2010; Klion 2011; Noel 2012; Noel and Mesa 2013).

Chronic Eosinophilic Leukemia, Not Otherwise Specified (NOS)

ICD-O Code 9964/3

According to the WHO classification, chronic eosinophilic leukemia (CEL) is defined as a myeloproliferative neoplasia in which autonomous clonal proliferation of eosinophil precursors results in persistently increased numbers of eosinophils in bone marrow, peripheral blood, and peripheral tissues. CEL, not otherwise specified (CEL, NOS) excludes cases with a Philadelphia chromosome, BCR-ABL1 fusion gene, or rearrangement of PDGFRA, PDGFRB, or FGFR1 (reviews: Gotlib 2011, 2012). In CEL, NOS, the eosinophil count in peripheral blood is $=> 1.5 \times 10(9)/L$, and there are less than 20 % blasts in bone marrow or peripheral blood. The proper diagnosis required the proof that the cell lineage is clonal. In case this proof is not available, the disorder should be termed idiopathic hypereosinophilic syndrome (HES). CEL, NOS is a multisystem disorder characterized by eosinophil tissue infiltrations in many organs, including the liver, and cytokine-mediated tissue damage. Evidence of splenic and hepatic involvement is found in 30–50 % of patients. CEL, NOS has a poor prognosis with a high risk of acute transformation (Helbig et al. 2012).

The main feature of morphology is the predominance of mature eosinophils in peripheral blood, with only few eosinophilic myelocytes or promyelocytes. Cytologic abnormalities of eosinophils may be encountered, such as cell enlargement, hyper- or hyposegmentation of nuclei, sparse cytoplasmic granulation, or cytoplasmic vacuolation. Eosinophilia may be accompanied by neutrophilia (a common finding), monocytosis, and mild basophilia. A similar morphologic presentation is found in bone marrow and peripheral infiltrated tissues, often with formation of Charcot-Leyden crystals.

Cytogenetic analyses are important for diagnosis of CEL; the most frequent aberrations have been reviewed (Oliver et al. 1998; Bain 2003). Typical cytogenetic abnormalities include trisomy 8, isochromosome 17, monosomy 7, and several translocations. A breakthrough for the understanding of both CEL and HES was achieved by the identification of a constitutively activated fusion tyrosine kinase assigned to chromosome 4q12, derived from an interstitial deletion, fusing the PDGFR alpha gene (PDGFRA) to an uncharacterized human gene, FIP1-like-1 (FIP1L1) (Cools et al. 2003a). The result of the fusion is called FIP1L1-PDGFRA, encoding a constitutively active receptor tyrosine kinase that is capable of transforming hemopoietic cells; the alteration causes responsiveness to the tyrosine kinase inhibitor, imatinib (Cools et al. 2003a, 2004; Gotlib et al. 2004; Stone et al. 2004; Vandenberghe et al. 2004; Cortes and Kantarjian

2004), and also in a murine model of FIP1L1-PDGFRA-induced CMPD (Cools et al. 2003b). As not all patients responding to imatinib exhibit this characteristic fusion, genetic heterogeneity of HES/CEL is suggested (Gotlib et al. 2004). The fusion of the two genes has also been detected in systemic mast cell disease with eosinophilia (Pardanani et al. 2003; Gilliland et al. 2004; Tefferi and Pardanani 2004; Tefferi et al. 2004), supporting a pathogenic role of the hybrid receptor kinase in eosinophil production (see below; mast cell disorders).

Myeloid and Lymphoid Neoplasms with Eosinophilia Associated with Abnormalities of PDGFRA, PDGFRB, or FGFR1 (ICD-O Codes 9965/3, 9966/3, and 9967/3, Respectively)

In the WHO classification, these three myeloproliferative and lymphoid neoplasms (MPNs) form a rare group of disorders with characteristic gene rearrangements and a distinct morphologic and clinical phenotype. Hypereosinophilia is a characteristic feature, but is not invariable.

MPN with PDGFRA rearrangement (synonym: chronic eosinophilic leukemia with FIP1L1-PDGFRA) is the most common form. The prevailing lesion is FIP1L1-PDGFRA resulting from a cryptic deletion at 4q12. The disorder, which is much more common in males than females (17:1), most often manifests as CEL, but AML, T-LBL, or both simultaneously also occur. The leukemia occurs in patients with a broad age range (7–77 years). Respiratory (interstitial fibrosis), cardiac (endomyocardial fibrosis), and/or gastrointestinal signs are common. The majority of patients have splenomegaly, while hepatomegaly is less common. In the course of CEL, acute transformation may ensue.

MPN with PDGFRB rearrangement (synonym: chronic myelomonocytic leukemia with eosinophilia associated with t(5;12)) is characterized by fusion of PDGFRB with ETV6, usually caused by t(5;12)(q31-33;p12). The hematologic presentation is mostly that of CMML, usually with eosinophilia. However, there are also patients presenting with atypical chronic myeloid leukemia, AML, or juvenile myelomonocytic leukemia. Males are slightly more often involved, and the disease prevails in middle-aged individuals. Splenomegaly is a common finding, whereas liver enlargement is rare. Cardiac involvement can develop. Acute transformation after a relatively short time period can occur.

MPN with FGFR1 rearrangement (synonyms: 8p11 myeloproliferative syndrome, 8p11 stem cell leukemia/lymphoma syndrome) is a heterogeneous group of disorders considered to be derived from a pluripotent hematopoietic stem cell. Several fusion partners of FGFR1 have been identified, all resulting in an abnormal tyrosine kinase. Most patients are young, with a medium onset age of 32 years. Clinically, the disorder presents as CEL, AML, T or B lymphoblastic lymphoma/leukemia, or mixed phenotype acute leukemia. In CEL, blastic transformation may take place. Depending on the type of lineage, there is involvement of the spleen, liver, lymph nodes, or other tissues.

Idiopathic Hypereosinophilic Syndrome (HES)

Introduction

Hypereosinophilia has been defined as a peripheral blood eosinophil count greater than 1,500/mm(3) that persists for at least 6 months, and may be associated with tissue damage, in the absence of other causes of eosinophilia (reviews: Gleich and Leiferman 2009; Gotlib 2012). Idiopathic hypereosinophilic syndromes represent a complex and heterogeneous group of disorders having in common that eosinophil granulocytes are persistently elevated in blood and tissues, eventually causing marked tissue injury with end-organ damage (HES; Hardy and Anderson 1968; reviews: Lin and Boyce 2003; Brito-Babapulle 2003; Bain 2004; Tefferi 2005; Tefferi et al. 2006; Pardanani and Verstovsek 2007; Gotlib 2008; Gleich and Leiferman 2009). Chronic eosinophilic leukemia, not otherwise specified (CEL, NOS) and myeloid and lymphoid

neoplasms with eosinophilia and distinct chromosomal rearrangements make part of this group. Classification criteria for the two disorders have been worked out (Oliver et al. 1998), and according to the new WHO classification, CEL is listed among the chronic myeloproliferative diseases (CMPDs; Haferlach et al. 2004).

In principle, HES and its proved clonal neoplasms comprise a spectrum of indolent to aggressive diseases characterized by persistent hypereosinophilia and that are BCR-ABL negative. Aggressiveness is causally linked to the damaging effects of eosinophils to the tissues that are infiltrated. However, production and release of potentially injurious eosinophil granule products may not suffice for aggressiveness of a given disease process. This is underlined by the observation that eosinophil-derived neurotoxin and major basic protein are elevated in patients with autosomal-dominant familial eosinophilia, but this disorder has a more benign course than typical HES (Klion et al. 2004). Chusid and coworkers have defined three criteria for the diagnosis of HES; they include: (1) eosinophilia of at least 1,500 eosinophils/mm^3 for longer than 6 months, or death before 6 months associated with signs and symptoms of hypereosinophilic disease; (2) lack of evidence for other causes of eosinophilia; and (3) presumptive signs and symptoms of organ involvement (Chusid et al. 1975). In the WHO classification, a diagnosis of HES or chronic eosinophilic leukemia (CEL) requires the exclusion of reactive causes of eosinophilia. However, the classification of HES remained confusing for a longer time period; in particular, "cases referred to an eosinophilic leukemia by many authors overlap with cases termed hypereosinophilic syndrome by others, and generally both fulfill the . . .criteria for HES" (Oliver et al. 1998). A common feature of all the disorders belonging to the large spectrum of diseases is of course the continuing eosinophilia, and, per definition, involvement of tissues and organs is a key alteration, albeit this is highly variable. The patients with these disorders are preferentially male (male-female ratio, 9:1), and HES is usually diagnosed between the ages of 20 and 50 years.

Classification

According to a classification proposal (Oliver et al. 1998), *four subgroups* of patients with HES can be distinguished (Table 1).

A further group of HES is characterized by the expansion of a clonal CD3(−)CD4(+) T-cell population. This is termed the lymphocytic variant of HES, a condition often associated with a pruritic

Table 1 Classification of hypereosinophilic syndromes

Subgroup 1 **patients** exhibit very mild clinical disease, frequently with urticaria and/or angioedema. Some of these patients may, in fact, not have an idiopathic form of HES, but rather a secondary eosinophilia that had not been identified as such
Subgroup 2 **patients** show more severe organ involvement, in particular of the heart, including Loeffler's endocarditis, the lung, the skin, and the CNS, but gastrointestinal, renal, and soft tissue involvement has also been reported
Subgroup 3 **patients** display a prominent hematologic syndrome associated with an unfavorable outcome, with anemia, thrombocytopenia, susceptibility to infections, and splenomegaly. Immature eosinophils are detectable, as is myelofibrosis, with a presentation typical for other chronic myeloproliferative disorders. Patients with this constellation are recommended to be diagnosed as *chronic eosinophilic leukemia* (CEL). Diagnostic for leukemia is the presence of a clonal cytogenetic anomaly, but also the detection of naphthol chloroacetate esterase in eosinophils seems to be specific for neoplastic eosinophils. Morphologic criteria for the diagnosis of CEL have been worked out (Oliver et al. 1998) and comprise the criteria of HES plus either a clonal cytogenetic abnormality or two of the following: immature eosinophil precursors accounting for >25 % of the differential count, myeloblasts accounting for >5 % of the differential count, and naphthol chloroacetate esterase-positive eosinophils. As cellular morphologic anomalies, including dysplasia, may be seen in HES in the absence of neoplastic lineage, these features are not regarded as reliable for the diagnosis of CEL
Subgroup 4 **patients** are those with CEL undergoing blastic transformation. Progression to blastic transformation is well known in patients that had stable disease for several years. This category is defined as CEL with the presence of >30 % of myeloblasts in the differential marrow or peripheral blood count (Oliver et al. 1998). This disease can be rapidly fatal

rash (Zaheri et al. 2010). The involved T-cells secrete IL-5 which is considered to be the cause of the accompanying eosinophilia (Gleich and Leiferman 2009). In some cases, chronic active EBV infection was identified as the driving mechanism of the disorder (Klion et al. 2013). Lymphocyte variant of HES can finally transform into a T-cell lymphoma (Ravoet et al. 2009; d'Elbée et al. 2013).

Liver Changes in HES and Chronic Eosinophilic Leukemia

Phenotypes

HES/CEL typically causes a broad spectrum of organ and tissue damage (Fauci et al. 1982; Weller and Bubley 1994), involving a multistep pathogenic cascade well studied in eosinophilic heart disease. Specific proteins released from eosinophils (e.g., major basic protein and eosinophilic cationic protein) can exert direct cellular damage resulting in necrosis, but some of the injuries are induced by vascular (endothelial) damage followed by local thrombosis and ischemia. Some forms of HES are associated with elevated numbers of T lymphocytes that may harm target tissues. Cell injury, necrosis, and vascular damage may be followed by progressive fibrosis, in particular in patients with myeloproliferative variants of HES and elevated serum tryptase levels (Klion et al. 2003).

A broad spectrum of causes induce eosinophil infiltration of the liver. One group is, similar to other organs, characterized by single-organ eosinophil infiltration without eosinophilia. The other group, discussed in this paragraph, consists of lesions developing in underlying clonal disorders of the hemopoietic system, viz., HES/CEL.

Several lesions are caused in the liver by HES/CEL (Table 2).

Table 2 Phenotypes of liver disease and associated alteration in HES/CEL

Eosinophilic infiltrations of the liver
Diffuse hepatic infiltration by eosinophils and/or their precursors
Focal eosinophilic infiltration of the liver (in part mass forming)
Eosinophilic granulocytoma/myelocytoma/myeloblastoma/granulocytic sarcoma
Focal hepatic eosinophil-related necrosis (FHERN; focal eosinophilic necrosis, FEN)
Eosinophilic hepatic inflammatory changes
Eosinophilic chronic active hepatitis
Eosinophilic lobular hepatitis
Eosinophilic hepatic abscess
Bile duct disease caused by eosinophils
Eosinophilic cholangiopathy
Eosinophilic sclerosing cholangitis
Hepatic vascular disorders in HES/CEL
Budd-Chiari syndrome and hepatic veno-occlusive disease
Hypereosinophilic thrombi in veins and/or arteries
Eosinophilic hepatic vasculitis
Other hepatic changes and associated alterations
Cholestatic hepatopathy
Eosinophilic ascites
Hepatocellular carcinoma in hypereosinophilia

Diffuse Eosinophilic Hepatic Infiltration

Hepatomegaly is a common feature in patients with HES/CEL (Chusid et al. 1975; Kim et al. 1993). At least part of this increase in liver mass is caused by eosinophilic infiltration of this organ, which may occur in up to 32 % of the patients with HES/CEL (Fauci et al. 1982) or, in one study, in all patients (Kim et al. 1993). Blast cells and eosinophils in all stages of maturation, including unusual atypical eosinophil precursors, have been reported to be located to the liver (Bianco et al. 1984; Yu et al. 1989; Take et al. 1990; Bartolomei et al. 1994; Valente et al. 1997; Kim et al. 2002; Reyes et al. 2005; Sun et al. 2005; Lai et al. 2008). In one reported patient, liver infiltration in HES was associated with sinus histiocytosis with massive lymphadenopathy of the Rosai-Dorfman type (Hernandez et al. 1987). The cells occupy both the portal tracts and the parenchyma, and at least part of the eosinophils may be reactive for chloroacetate esterase (Bianco et al. 1984), suggesting the contribution of a neoplastic eosinophil lineage.

Focal Eosinophilic Infiltration of the Liver and Eosinophilic Granulocytic Tumors

Focal eosinophilic infiltration of the liver (FEIL) occurs in both HES/CEL and benign causes of hypereosinophilia, such as parasitic infestations. FEIL should not be called eosinophilic abscess, because the latter almost exclusively occurs in secondary forms of tissue eosinophilia, mainly in parasitic disease. FEIL developing in the setting of HES/CEL has been described several times (Won et al. 1999; Oh et al. 2004; Kim et al. 2005; Lai et al. 2008; Park et al. 2009; Shatery and Sayyah 2011). FEIL may present as single mass of the liver, histologically characterized by marked eosinophilic infiltration of the area involved and centrilobular necrosis (Oh et al. 2004).

Aggressive forms of HES with formation of osteodestructive eosinophilic tumors ("eosinophilic myelocytomas," "myeloblastomas," "eosinophilic chloromas," " eosinophilic granulocytic sarcomas") have been described (Benvenisti and DeBellis 1969; Pardo-Peret et al. 1979; Ellman et al. 1979; Lynott et al. 2000; Adler and Schaefer 2001). Similar lesions may develop in the liver, although no biopsy data are available so far. However, liver sonography in 13 HES patients with liver involvement showed multiple round or oval hypoechoic or variably echogenic lesions in seven patients, and these lesions measured 1–2 cm with poorly defined margins. Four of these patients had one or two hypoechoic lesions 3–4 cm in size. The number of the lesions and the extent of diffuse lesions seemed to be proportional to the degree of eosinophilia (Nam et al. 1999). Similar changes have been described by the use of CT and other imaging techniques (White et al. 1981; Shiomi et al. 1991; Kim et al. 1993; Lim et al. 2000; Yoo et al. 2003).

Focal Eosinophilic Necrosis (FEN) of the Liver (Focal Hepatic Eosinophil-Related Necrosis, FHERN)

Focal eosinophilic necrosis (FEN) of the liver associated with HES is a unique alteration characterized by geographic, multiacinar areas of hepatic necrosis with eosinophilic inflammation, with other liver regions showing features of chronic hepatitis (Ung et al. 2000). In CT and MR images, FEN presents as focal hypoattenuating lesions and as focal hypoechoic lesions on sonography: Sometimes, numerous low-attenuation lesions disseminated throughout the entire liver are seen in CT scans (Yoo et al. 2003; Yu et al. 2005; Choi et al. 2009; Cho et al. 2010). The foci vary in size and are round or oval, and they tend to regress as peripheral blood eosinophil counts decrease (Lee et al. 1999). In contrast to metastases, FEN associated with visceral cancer and analyzed by CT imaging far more frequently showed a fuzzy margin, subtle hypoattenuation, and a nonspherical shape, and rim enhance is seldom encountered (Jang et al. 2002). Histologically, confluent parenchymal necrosis is in evidence, accompanied by a dense perifocal infiltrate rich in eosinophils (Ung et al. 2000). Smaller eosinophilic necroinflammatory foci may occur as well. FEN may be grossly visible, because the lesions can grow to 2 cm in diameter (Ung et al. 2000). Adjacent liver tissue reveals an eosinophil-predominant lobular hepatitis and signs of chronic active periportal hepatitis with accumulation of eosinophils in the interface lesions. The pathogenesis of FEN in HES has not yet been clarified, but cytotoxic effects of densely infiltrating eosinophils and their products have been suggested (Lee et al. 1999; Ung et al. 2000; Yoo et al. 2003).

Eosinophilic Hepatitis

A portal tract/periportal infiltration is regarded as typical for HES/CEL (Fauci et al. 1982; Croffy et al. 1988; Foong et al. 1991; Cha et al. 1998; Minola and Sonzogni 2005; Morgan-Rowe et al. 2011), resulting in the histologic phenotype of *eosinophilic chronic active hepatitis*. The eosinophils located to the widened portal tracts are variably intermingled with lymphocytes, plasma cells, and macrophages. Interface lesions/piecemeal necroses may also contain significant numbers of

eosinophils. Within the lobular parenchyma, eosinophils are mostly seen within the sinusoidal compartment, but some of the cells seem to stick to the endothelia, with endothelial damage and formation of microthrombi, and few eosinophils or eosinophil precursors are found between hepatocytes of damaged and in part even destructed liver cell plates (Cha et al. 1998), suggesting parenchymal injury. In case numerous eosinophils infiltrate the parenchyma, the descriptive histologic features are those of *eosinophilic lobular hepatitis*.

Bile Duct Disease Caused by Eosinophils

Eosinophilic cholangiopathy is a unique disorder of large bile duct characterized by a self-limited eosinophil infiltration of ducts. In eosinophilic cholangiopathy, eosinophils display a ductocentric distribution associated with biliary epithelial damage (Butler et al. 1985; Tenner et al. 1997; Valente et al. 1997; Abdalla and Vauthey 2002; Jimenez-Sanz et al. 2003; Duseja et al. 2005; Jeyamani et al. 2007; Sussman et al. 2008; Oh et al. 2012). Eosinophilic cholangiopathy can develop in conjunction with other eosinophilic gastrointestinal disorders, e.g., eosinophilic colitis (Schoonbrodt et al. 1995; Sussman et al. 2008). The eosinophils are accumulated in the connective tissue around the ducts and ductules, often with a transmural distribution and sometimes more prominently at the sites of the peribiliary plexus, and occasionally forming so-called microabscesses (Cha et al. 1998). The latter is a misnomer, because histology is characterized by dense accumulations of eosinophils not induced by an infectious process. Some of the cells are engaged with the biliary epithelium, with signs of epithelial infiltration and/or dislocation into the lumina. Cholangiocyte damage apparently caused by eosinophils is evident in the form of irregular epithelial lining, cholangiocyte vacuolation, karyopyknosis, and apoptosis. A similar process can develop in the gallbladder (eosinophilic cholecystitis; Jimenez-Sanz et al. 2003; Shakov et al. 2007). What is the biology of disease in eosinophilic cholangiopathy? In a review of 23 reported cases of eosinophilic cholangiopathy, 82.6 % remained disease-free, while among the remaining there may be patients requiring therapy because of biliary stenosis (Nashed et al. 2010). In some patients with eosinophilic infiltration of bile ducts, duct wall sclerosis ensues causing stenosis and mimicking bile duct cancer (Rodgers et al. 2001; Matsumoto et al. 2007; Chen et al. 2009). This lesion has been termed HES-associated *eosinophilic sclerosing cholangitis* (synonym: hypereosinophilic sclerosing cholangitis) (Kagawa et al. 1988; Neeman and Kadish 1987; Rosengart et al. 1990; Grauer et al. 1993; Ichikawa et al. 1997; Al-Abdulla et al. 2000; Pometta et al. 2000; Delevaux et al. 2002; Miura et al. 2009). In part of the patients with HES, sclerosing cholangitis is associated with chronic inflammatory bowel disease (Scheurlen et al. 1992). It is currently not clear, whether eosinophilic cholangiopathy without fibrosis/sclerosis and the sclerosing variant are the same disease in different stages of evolution or whether we deal with two diseases.

Histologically, involved bile ducts disclose a dense ductocentric eosinophil infiltration associated with fibrosclerosis as seen in primary sclerosing cholangitis (Miura et al. 2009). In PSC, eosinophils may occur in the periductal tissue compartment to variable degrees, and it has been suggested that eosinophils are related to the pathogenesis of PSC (Watanabe et al. 1995; Shimomura et al. 1996), similar to primary biliary cirrhosis. The bile duct inflammation with marked contribution of eosinophils may be accompanied by eosinophil infiltration of adjacent parenchyma, as specified above (*eosinophilic cholangiohepatitis*).

Pathogenetically, effects of eosinophil granule products, inducing cell damage and fibrogenesis, have been proposed. In a case of eosinophilic cholecystitis, deposition of secreted eosinophil cationic protein (ECP) and of major basic protein (MBP) has been detected (Noguchi et al. 1992; Tajima and Katagiri 1996).

Hepatic Vascular Disorders in HES/CEL

Veno-occlusive Disease and Budd-Chiari Syndrome in HES

Patients with HES/CEL can develop acute hepatic veno-occlusive disease (VOD Kojima and Sasaki 1995) or Budd-Chiari syndrome (Elouaer-Blanc et al. 1985; Walker 1987; Suenaga et al. 1991; Vargas et al. 1993; Zylberberg et al. 1996; Becker et al. 2006; Inoue et al. 2007; Mishchenko et al. 2012), sometimes followed by liver failure. Pathogenetically, local damaging effects of eosinophils on venous endothelial cells and/or a pro-coagulative action of eosinophils have been proposed, supported by regression of VOD subsequent to corticosteroid therapy (Kojima and Sasaki 1995). As in other forms of hepatic venous outflow disorders, nodular regenerative hyperplasia (NRH) of the liver may develop in HES (Baker et al. 1991; Nakamura et al. 1997).

Eosinophilic Hepatic Vasculitis

HES and CEL are known to be associated with necrotizing vasculitis (Jang et al. 2000; Gotlib et al. 2003). In one patient with HES, liver rupture occurred and was associated with eosinophilic necrotizing arteritis of the hepatic artery with fibrinoid necrosis (Cheung et al. 2009).

Other Hepatic Changes and Associated Alterations

Cholestatic Hepatopathy

HES is known to rarely be associated with cholestasis, sometimes with recurrent episodes of abdominal pain (Valente et al. 1997). In part of these instances, intrahepatic bile duct damage caused by toxic actions of eosinophils may be involved. On the other hand, cholestasis may be caused by stenosis of extrahepatic bile duct in case of pancreatic involvement in HES (eosinophilic pancreatitis; Eugene et al. 1984; Euscher et al. 2000).

Eosinophilic Ascites

HES with or without involvement of the liver can be associated with eosinophilic ascites, sometimes massive (Adams and Mainz 1977; Vandewiele et al. 1991; Rimbrot et al. 2001; de Carpi et al. 2007), but it also occurs in other situations of secondary eosinophilia, e.g., eosinophilic gastroenteritis (Leveque et al. 1998) or toxocariasis (Cruz et al. 2008). As such, eosinophilic ascites is a rare alteration and should therefore raise the suspicion of HES and related disorders.

Hepatocellular Carcinoma Associated with Eosinophilia/Hypereosinophilia

Hepatocellular carcinoma is known to sometimes be associated with paraneoplastic hypereosinophilia, occasionally of severe degree (Komai et al. 1984; Salame et al. 1988; Ranke 1965; Yuen et al. 1995; Chang et al. 1996; Balian et al. 2001; Bonaventure et al. 2003; Villas et al. 2003). Pathogenetically, the production of pro-eosinophilic cytokines, e.g., IL-5 (the most specific cytokine for the eosinophil lineage), by CD4+ T lymphocytes infiltrating the hepatic tumor has been proposed (Balian et al. 2001).

Charcot-Leyden Crystals in HES and Other Hypereosinophilic States

In several of these eosinophilic lesions described above, Charcot-Leyden crystals (CLC) are observed in histologic preparations, e.g., in eosinophilic hepatitis, in eosinophilic cholangiopathy, and in eosinophilic sclerosing cholangitis. In case of marked eosinophilia (e.g., severe HES), CLC can also circulate in the blood and then enter thrombotic material (Dincsoy et al. 1981). Apart from a cytoplasmic localization, CLC have been detected within nuclei, e.g., in refractory anemia with dysplastic eosinophils (Ma et al. 1995).

The crystals have a characteristic ultrastructural morphology (Carson et al. 1992). CLC are mainly composed of a lineage-specific protein

(the eosinophil/basophil Charcot-Leyden crystal protein, galectin-10) with human eosinophil lysophospholipase activity (the CLC protein; Weller et al. 1980, 1984; Calafat et al. 1997; Dyer and Rosenberg 2000). However, eosinophil lysophospholipase has no sequence similarities to any known lysophospholipases; rather, it has a moderate sequence similarity to members of the galectin superfamily of carbohydrate-binding proteins and has thus been termed galectin-10. The CLC protein interacts with (true) eosinophil lysophospholipases and known inhibitors of this lipolytic activity (Leonidas et al. 1995; Dyer et al. 1997; Swaminathan et al. 1999; Ackerman et al. 2002). In eosinophils, the CLC protein is confined to a distinct crystalloid-free granule population in mature cells (Dvorak et al. 1988).

CLC and their component are not exclusively found in eosinophils. CLC are formed by basophils (Ackerman et al. 1982), and lysophospholipase has been localized to human basophil granules (Dvorak and Ackerman 1989; Golightly et al. 1990; Calafat et al. 1997). This phenomenon is probably related to a common basophil-eosinophil progenitor (Denburg et al. 1985). CLC and CLC protein are furthermore detectable in the phagosomes of certain macrophage populations, indicating phagocytosis of crystals and their constituents (Dvorak et al. 1990b). The protein has been localized to intracytoplasmic crystals in neoplastic cells of pancreatic solid and papillary tumors (Dvorak et al. 1990a).

Systemic Mast Cell Disease with Eosinophilia

A subset of systemic mast cell disease (SMCD) is associated with marked eosinophilia. In particular, SMCD may be associated with HES more frequently than previously anticipated (McElroy et al. 1998; Gotlib and Akin 2012). It has recently been found that an early stem cell origin of the FIP1L1-PDGFRA mutation (see above) may be involved in the pathogenesis of hypereosinophilia in SMCD (Pardanani et al. 2003; Gilliland et al. 2004; Tefferi et al. 2004; Florian et al. 2006). These findings serve for a partial molecular classification of SMCD (Tefferi and Pardanani 2004). The liver alterations in the hypereosinophilic form of SMCD can be expected to be a mixture of the findings in HES and those in SMCD that are discussed in more detail in a separate chapter.

Systemic Mastocytosis and Mast Cell Tumors

83

Contents

Abstract

Mastocytosis or mast cell disease is a clonal neoplastic proliferation of mast cells that accumulate in one or more organ systems. Depending on the predominant organ and tissue involvement, mastocytosis can present in the form of various clinic-pathologic conditions, including cutaneous mastocytosis, solitary mastocytoma, systemic mastocytosis, mast cell leukemia, and mast cell sarcoma. The hepatobiliary tract can be involved by several of these disorders. In systemic mastocytosis, focal, mass-forming, and diffuse infiltrations of neoplastic mast cells are observed in the liver. In this disorder, rare hepatic manifestations further include mast cell-induced hepatic fibrosis, obliterative venous disorders, mast cell cholangiopathy, solitary mastocytoma and mast cell sarcoma, intrahepatic cholestasis, and non-cirrhotic portal hypertension. Neoplastic hepatic mast cell infiltrates in systemic mastocytosis are mainly located within sinusoids and portal tracts but may also predominate around intrahepatic bile ducts. Dense portal tract infiltration sometimes causes extensive interface lesions (aggressive mastocytosis), one possible cause of fibrosis and hepatic remodeling. The liver is also involved in mast cell leukemia, an extremely rare disorder characterized by immature mast cells, inner organ damage, and a rapidly malignant course.

Mast cell sarcoma	9740/3

Introduction

According the WHO classification (2008), mastocytosis (synonym: mast cell disease) is due to a clonal, neoplastic proliferation of mast cells that accumulate in one or more organ systems. The disorder is heterogeneous, ranging from skin lesions (cutaneous mastocytosis) that may spontaneously regress to highly aggressive neoplasms associated with short survival. Systemic mast cell disease (SM) is a neoplastic process of multilineage, myelomastocytic, or mast cell-committed hematopoietic progenitor cells (Hartmann et al. 2001; Escribano et al. 2002; Sperr et al. 2002).

The mast cell has been identified by Paul Ehrlich in 1879 (Mastzellen; Ehrlich 1878; Beaven MA 2009; Ribatti and Crivellato 2014; Ghably et al. 2015), the term relating to the German word for "overfed" (Sagher and Even-Paz 1967). However, cutaneous mast cell disease had been discovered 10 years earlier and reported using the term, urticaria pigmentosa (Nettleship and Tay 1869).

Traditionally, mast cell proliferative disorders (MCPD) are divided into *cutaneous mastocytosis* (affecting only the skin) and *systemic mastocytosis* (SM; => organs; Horny et al. 1997; Valent et al. 1999; Pardanani 2011). Mastocytosis may occur in any age, whereby cutaneous mastocytosis (urticarial pigmentosa) is predominantly a disease of children and may be present at birth, while systemic mastocytosis is generally diagnosed after the second decade of life.

One of the most important histologic features of SM is the dense infiltrate of spindle-shaped or round mast cells in the bone marrow, whereas a slight increase in diffusely scattered ("polyclonal") bone marrow mast cells (BMMC) is a reactive process not to be termed, mastocytosis. It can, e.g., also occur in multilineage myeloid malignancies, such as myeloid leukemia, myelodysplastic syndromes, and myeloproliferative syndromes. However, a variable focal infiltration of BMMC without systemic involvement (mastocytosis of bone marrow) has also been reported (reviews: Valent et al. 1999; Pardanani 2012). In a significant subgroup of patients (10–35 %), an associated clonal hematologic non-mast cell lineage disorder (AHNMD) occurs; AHNMDs have been classified according to WHO criteria (see below). Most AHNMDs resemble myeloid malignancies such as AML, myeloproliferative disorders, or myelodysplastic syndromes, and patients with SM-AHNMD have a less favorable prognosis concerning survival when compared with indolent SM (Sperr et al. 2002; Stoecker and Wang 2012). SM has also been observed together with primary thrombocythemia (Le Tourneau et al. 1991). In most instances, SM is a disease of adults, but pediatric cases have been reported (Hartmann and Metcalfe 2000; Chemli et al. 2003), and SM can present as a congenital disorder (Date et al. 1989).

Classification of Mastocytosis

Several systems to classify mastocytosis have been proposed (Travis et al. 1988; Metcalfe 1991; Horny et al. 1993; Valent et al. 2001a; Arock and Valent 2010; Valent and Horny 2011; Chiu and Orazi 2012). Part of the classifications are listed in Table 1.

In addition to these clinical-morphologic classifications, attempts are undertaken to classify SM and related disorders according to mutational patterns of key genes. In fact, a partial molecular classification is now emerging, i.e., Asp816Val c-kit+, FIP1L1-PDGFRA +, and molecularly

Table 1 Classification of mastocytosis/mast cell diseases

(A) 2008 WHO classification of mast cell diseases (modified; comment: Sanchez-Muñoz et al. 2011)	
Cutaneous mastocytosis (including urticarial pigmentosa)	ICD-O code 9740/1
Diffuse cutaneous mastocytosis	ICD-O code 9740/1
Indolent systemic mastocytosis (ISM)	ICO-O code 9741/1
Systemic mast cell disease with associated clonal hematological non-mast cell lineage disease (SM-AHNMD)	ICD-O code 9741/3
Aggressive systemic mastocytosis (ASM)	ICD-O code 9741/3
Mast cell leukemia	ICD-O code 9742/3
Mast cell sarcoma	ICD-O code 9742/3
Extracutaneous mastocytoma	ICD-O code 9740/1
(B) Classification of mastocytosis as proposed by Travis et al. (1988) **and modified by Metcalfe (1991)**	
I. Indolent mastocytosis	
A. Skin only	
Urticaria pigmentosa (UP)	
Diffuse cutaneous mastocytosis	
B. Systemic	
Marrow	
Gastrointestinal tract with/without urticaria pigmentosa	
II. Mastocytosis with an associated hematologic disorder (± *UP*)	
III. Mast cell leukemia	
IV. Lymphadenopathic mastocytosis with eosinophilia (= *aggressive mastocytosis*; ± *UP*)	
(C) Classification of mastocytosis as proposed by et al. (1993)	
I. Cutaneous mastocytosis	
A. Urticaria pigmentosa (UP)	
B. Diffuse cutaneous "erythrodermic" mastocytosis	
C. Telangiectasia macularis eruptiva perstans	
D. Solitary mastocytoma	
II. Systemic (*benign or indolent*) *mastocytosis*; *usually with skin lesions of UP but no associated malignant hematologic disorder* (*bone marrow involvement very common*)	
III. Malignant (*aggressive*) *mastocytosis*; *usually without skin lesions of UP but associated with malignant hematologic disorders*	
IV. Mast cell leukemia	
V. Mast cell sarcoma	
(*continued*)	

Table 1 (continued)

(D) Classification of mastocytosis as proposed by Valent et al. (2001a)
Cutaneous mastocytosis
Urticaria pigmentosa (UP; maculopapular cutaneous mastocytosis; MPCM)
Subvariants:
Typical UP
Plaque form
Nodular
Telangiectasia macularis eruptiva perstans (TMEP)
Diffuse cutaneous mastocytosis (DCM)
Mastocytoma of the skin
Indolent systemic mastocytosis (*ISM*)
Provisional subvariants
(Isolated) bone marrow mastocytosis (BMM)
Smoldering systemic mastocytosis
Systemic mastocytosis with an AHNMD (*SM-AHNMD*)
Subvariants
SM-MDS
SM-MPS
SM-AML
SM-NHL
Aggressive systemic mastocytosis (*ASM*)
Subvariant
Lymphadenopathic mastocytosis with eosinophilia
Mast cell leukemia (*MCL*)
Aleukemic subvariant
Mast cell sarcoma
Extracutaneous mastocytoma

undefined cases, and it is expected that such molecular classifications are therapeutically relevant (Tefferi and Pardanani 2004).

Systemic Mastocytosis and Its Variants: A Brief Overview

Systemic mastocytosis (*SM*) and its variants can induce a common clinical syndrome called *systemic mast cell activation syndrome* (*SMCAS*), a spectrum of organ and tissue manifestations caused by activated mast cells and their released products. In principle, SMCAS comprises disorders characterized by the accumulation of genetically altered mast cells and/or abnormal release of

these cells' mediators, potentially affecting the function of numerous cells and tissues (review: Molderings et al. 2011). *Indolent systemic mastocytosis* (ISM) is a disorder characterized by fulfilled SM criteria, with a modestly elevated burden of mast cells, an indolent clinical course, and a good prognosis, in the absence of mast cell leukemia and AHNMD. Organ function impairment with C signs is lacking, although mast cell infiltration in several organs, including the liver, occurs. Circulating KIT D816V mutation-positive non-mast cells in peripheral blood are a characteristic feature of indolent systemic mastocytosis (Kristensen et al. 2012). In contrast, *aggressive systemic mastocytosis* shows C-findings as a sign of organ function impairment, due to infiltration by neoplastic mast cells and secretion of their products (reviews: Horny and Valent 2001; Patnaik et al. 2007; Pagano et al. 2008; Arock and Valent 2010; Ozdemir et al. 2011; Quintas-Cardama et al. 2011; Andersen et al. 2012; Pardanani 2012; Gotlib et al. 2013). In particular, patients exhibit one of the following: (1) abnormal myelopoiesis with significant blood count abnormalities; (2) hepatomegaly with impairment of liver function (often with ascites), (3) large osteolyses; (4) malabsorption due to GIT infiltration; (5) splenomegaly with hypersplenism; or (6) life-threatening impairment of organ function in other organ systems (Valent et al. 2001a, 2003). Aggressive systemic mastocytosis can be associated crystal-storing histiocytosis storing Charcot-Leyden crystals (Alayed et al. 2010). *Smoldering mastocytosis* is a novel subtype of systemic mastocytosis, characterized by the lack of aggressive disease, absence of associated hemopoietic neoplasias, and slow progression of disease. These patients show a high burden of mast cells, a hypercellular bone marrow, and organomegaly (Valent et al. 2002a). In some patients with smoldering systemic mastocytosis, cryptic life-threatening crises may occur (Shah et al. 2012). *Occult mastocytosis* has, e.g., been observed in AML with a t(8;21) translocation, the neoplastic mast cells being in part spindle shaped and showing an aberrant phenotype, including co-expression of tryptase, chymase, c-kit, and CD25 (Bernd et al. 2004).

Systemic mastocytosis with an AHNMD (SM with an *a*ssociated clonal *h*ematologic *n*on-*m*ast cell lineage *d*isease; SM-AHNMD; Stoecker and Wang 2012) denotes SM disorders associated with several types of hemopoietic or lymphoid neoplastic diseases. Thus, AHNMD are categorized as MDS (myelodysplasia), MPS (myeloproliferative syndrome), AML (acute myeloid leukemia), NHL (Hauswirth et al. 2008a), or malignant histiocytosis (Rudski et al. 2011). Most of the cases involve a myeloid progenitor cell, and SM is usually diagnosed concurrently with the myeloid malignancies. Part of the patients with SM-AHNMD exhibit activating c-kit mutations (Pullarkat et al. 2003).

Recently, a further group of mast cell disorders has been described under the term, *myelomastocytic overlap syndromes* (Valent et al. 2001b). These patients show large numbers of very immature mast cell lineage cells (metachromatically granulated blast-like cells), but the criteria to diagnose mastocytosis are not met. The patients have advanced myeloid neoplasms (myelodysplastic syndromes or myeloproliferative syndromes with blast cell increase, or AML) and variably suffer from mediator-related symptoms. These disorders may mimic mast cell leukemia or basophilic leukemia, but in contrast to basophilic leukemia, the cells involved are markedly Kit positive and tryptase positive, and in contrast to mast cell leukemia, CD25 expression and the c-kit Asp-816-Val mutation are lacking (Valent et al. 2001b). A further novel entity is myelomastocytic leukemia, a myeloid neoplasm characterized by partial differentiation of mast cell lineage cells (Valent et al. 2002b).

Mast cell leukemia is a manifestation of high-grade (malignant) mast cell disease with a significant number of leukemic mast cells circulating in the peripheral blood (Valent et al. 2001a; Georgin-Lavialle et al. 2013). Mast cell leukemia accounts for less than 1 % of all mastocytoses (review: Georgin-Lavialle et al. 2013). Mast cell leukemia is a rapidly fatal disease in contrast to non-leukemic variants; it is characterized by a substantial increase of atypical mast cells in the

peripheral blood, diffuse infiltration with atypical mast cells in the bone marrow, a strong association with peptic ulcer disease, marked constitutional symptoms, and hepatosplenomegaly (Travis et al. 1986). Systemic mastocytosis can undergo progressive evolution into fatal mast cell leukemia (Gülen et al. 2012). Aleukemic mast cell leukemia has replaced the former "malignant mastocytosis" and is an extremely rare form of leukemia (Horny et al. 2002). The relationship between mast cell leukemia and bone marrow progenitor cells is complex and not yet fully clarified. It has, e.g., been shown that mast cell leukemia can evolve from refractory anemia with excess of blasts in transformation (RAEB-T/5q syndrome), showing blast cells of the mast cell lineage (Sugita et al. 1996). Recently, a variant of mast cell leukemia with more mature neoplastic cells and a more favorable course has been defined as chronic mast cell leukemia (Cehreli et al. 2014; Valent et al. 2014). Chronic mast cell leukemia can exhibit KIT S476I and lacks inner organ damage. A rare transition form of immature mast cell leukemia is myelomonocytic leukemia (Horny et al. 2014).

It is known that up to one third of the patients with SM have some degree of peripheral blood and/or bone marrow eosinophilia, but SM is sometimes associated with an hypereosinophilia syndrome (HES) in its proper sense (*eosinophilic disorders and SM*/*SMCD*; Miranda et al. 1994; McElroy et al. 1998). Based on the detection of the index c-kit gene mutation (Asp816Val), it has been found that, in the SM/HS combination, eosinophils are derived from the neoplastic clone in some patients (Pardanani et al. 2003c). Therefore, the term *SM*/*SMCD-eos* has been proposed to denote this spectrum of lesions. An interesting group of lesions is formed by a subset of patients who have a myeloproliferative variant of idiopathic hyper-eosinophilic syndrome associated with increased bone marrow mast cells, tissue fibrosis, poor prognosis, and imatinib responsiveness. In these patients, serum tryptase levels are elevated, and this phenomenon is a sensitive marker of this myeloproliferative variant of HS, in addition showing the presence of the recently described fusion of the Fip1-like 1 (FIP1L1) gene to the platelet-derived growth factor receptor alpha (PDGFRA) gene (Klion et al. 2003). The fusion of the two genes results from an approximately 800-kb interstitial chromosomal deletion that includes the cysteine-rich hydrophobic domain 2/CHIc2 locus. FIP1L1-PDGFRA is a constitutively activated tyrosine kinase that transforms hematopoietic cells and is a therapeutic target for imatinib mesylate. The deletion of CHIC2, located to chromosome 4q12, is a surrogate marker of the FIP1L1-PDGFRA fusion, and this deletion has been found in HES/SM (Pardadani et al. 2003b). More recently, FIP1L1-PDGFRalpha has been directly detected in SMCD associated with HES (Gilliland et al. 2004; Tefferi et al. 2004), and, together with c-kit mutations, this fusion gene has been proposed for a partial molecular classification of SMCD (Tefferi and Pardanani 2004).

Tumorous growth of neoplastic mast cells (*mastocytoma*) is almost exclusively found in the skin and is very rare in other organ sites (Valent et al. 2001a).

Mast cell sarcoma is a very rare disorder. It is defined by a locally destructive (sarcoma-like) growth of a tumor consisting of highly atypical mast cells without systemic involvement, but secondary generalization can occur (Ryan et al. 2013). Bone marrow mastocytosis can be associated with immature extramedullary mast cell sarcoma (Sotlar et al. 1997).

Liver Involvement in Mastocytosis

Introduction

In SM, diffuse involvement of many organs and tissue occurs, including the skin, bone, lymph nodes, respiratory tract, gastrointestinal tract, spleen, and liver. Gastrointestinal manifestations are observed in at least 20 % of patients with SM (Mutter et al. 1963; Webb et al. 1982; Tharp 1985; Debeuckelaere et al. 1991; Metcalfe 1991; Karnam and Rogers 1999; Jensen 2000; Tharp and Chan 2003; Akin and Metcalfe 2004; Kirsch et al. 2008). Involvement of the alimentary canal may result in abdominal pain, diarrhea, peptic

Table 2 Spectrum/phenotypes of liver involvement in systemic mastocytosis

Hepatic mast cell infiltration as single change (slight, moderate, severe; severe with interface lesions = histologically "aggressive mastocytosis")
Hepatic mast cell infiltration with chronic fibrosing liver disease or cirrhosis
Mast cell-induced hepatic obliterative venous disorders with/without NRH (obliterative portal venopathy and hepatic venopathy)
Mast cell cholangiopathy
Mastocytoma of the liver
Mast cell sarcoma of the liver
Intrahepatic cholestasis
Non-cirrhotic portal hypertension

ulcer disease, and, in severe cases, malabsorption. GIT and other organ manifestations can be associated with hemorrhagic diathesis, which may complicate liver biopsy in SM (Adler et al. 1985). The manifestations of SM in the liver comprise several more or less defined pathologic and pathophysiologic constellations (Table 2). In addition to alterations caused by the mere presence of a tumorous infiltrate, the liver may also be involved in systemic mast cell activation syndrome (SMCAS). Patients with SMCAS have shown an elevation of plasma cholesterin in 75 %, elevations of serum transaminases and bilirubin in 40 % and 36 %, respectively, and elevation of hepatomegaly in 34 % (Alfter et al. 2009).

Clinical and Imaging Features

Clinically and radiologically, SM causes hepatomegaly (sometimes massive) with or without ascites in up to 77 % of the patients (Rohner and Rodermund 1981; Webb et al. 1982; Yam et al. 1986; Travis et al. 1988; Biersack 1988; Horny et al. 1989; Chemli et al. 2003; Kupfer et al. 2007), and liver involvement is sometimes evidenced by elevated serum alkaline phosphatase and, interestingly, in signs of portal hypertension in a subset of patients. Massive diffuse mast cell infiltration of the liver can cause cholestasis (Kupfer et al. 2007) or even hepatic failure (Wendum et al. 2004). Focal involvement of the liver presents as ill-defined areas of low attenuation in imaging (Kennedy et al. 1999). What is the prevalence of liver disease in SM ? In a large study involving 41 patients, a combination of clinical, radiologic, and serum biochemical criteria resulted in 61 % of the patients with SM having liver involvement. This included hepatomegaly in 24.4 %, ascites in 7 %, and elevated serum enzymes in 54 % (Mican et al. 1995).

SM rarely presents non-cirrhotic portal venous hypertension, complicated by esophageal variceal bleeding (NCPH; Capron et al. 1978; Grundfest et al. 1980; Sawers et al. 1982; Le Jeunne et al. 1986; Bonnet et al. 1987; Narayanan et al. 1989; Vincenzi et al. 1992; Fonga-Djimi et al. 1995; Kyriakou et al. 1998). This may result in shunting of mast cell-rich splenic blood into the systemic circulation (Sumpio et al. 1988). It is thought that a hepatic sinusoidal block caused by perisinusoidal fibrosis is the main pathogenic mechanism, but an impairment of microvascular liver blood flow owing to mast cell infiltration has also been considered (Grundfest et al. 1980). Furthermore, it has been proposed that the development of portal and/or hepatic venopathy with or without associated nodular regenerative hyperplasia of the liver can cause NCPH (Mican et al. 1995), because such changes have been observed in other disorders accompanied by NCPH, including myeloproliferative disorders (Wanless et al. 1980). NCPH in SM has been reported to simulate autoimmune cholangiopathy (Kyriakou et al. 1998).

Liver Pathology in Systemic Mastocytosis

Within the normal liver, mast cells are relatively scarce, with a density of about 1–2 to 3.9 mast cells per square millimeter in humans (Farrell et al. 1995; Armbrust et al. 1997). It has been reported that normal liver mast cells are mainly from the MC-TC type (Gulubova 2003). The morphology of liver involvement in SM as assessed by liver biopsy or after OLT has been reported several times (Hissard et al. 1950; Ende

and Chernis 1953; Mutter et al. 1963; Bureau et al. 1965; Burgoon et al. 1968; Campbell et al. 1979; Fishman et al. 1979; Hirschowitz and Groarke 1979; Bredfeldt et al. 1980; Grundfest et al. 1980; Abraham et al. 1992; Safyan et al. 1997; Mican et al. 1995; Maruyama et al. 1998; Pauls et al. 1999). Liver involvement in SM is dominated by mast cell infiltrations of variable densities.

Histologically, one pattern of involvement in SM presents as a diffuse infiltration of hepatic tissue, but predominantly the portal tracts, by abnormal mast cells, with or without associated changes (Demis 1963; Sawers et al. 1982; Ghandur-Mnyamneh and Gould 1985; Yam et al. 1986; Horny et al. 1989; Mican et al. 1995). The mast cells are frequently spindle shaped and hypogranular, thus requiring special stains as discussed above (Maruyama et al. 1998). In part of the patients, the mast cell infiltrate forms clusters of cells (Kyriakou et al. 1998). Mast cell numbers in liver involvement have been quantified and shown to be clearly higher than in normal livers or those with fibrotic changes or cirrhosis (Horny et al. 1989), even though a marked increase in mast cell numbers may very occasionally occur in some other liver disorders (Murata et al. 1973; Bardadin and Schuer 1986). The infiltrate is sometimes mixed, but there are situations where mast cells are the predominant infiltrating cell. In a mixed infiltration, toluidine blue staining will easily identify the cell of interest and has been shown to be crucial to detect mast cells otherwise masked by other cells (Mican et al. 1995). The mast cell nature of spindle cells localized to the portal tract in SM has been proved by the use of electron microscopy (Ghandur-Mnyamneh and Gould 1985). In some of the patients, mast cells hug bile ducts (ductocentric mast cell infiltrates). Although a portal tract infiltration may be impressive, intralobular infiltrates of mast cells are also frequently discernible, chiefly involving the sinusoids (more so in the periportal zone 1), amounting to 96 % of the cases in one study (Mican et al. 1995). Within portal tract spaces, an angiocentric localization of mast cells may be in evidence. Severe degrees of portal tract mast cell infiltration cause sometimes extensive interface lesions ("aggressive mastocytosis"). In regard to accompanying inflammatory changes, chronic portal inflammation was observed in all cases, and 60 % of biopsies showed accompanying eosinophilia of portal tracts (Mican et al. 1995). A usually low-grade eosinophil component in the infiltrates is recognized, but this may be expected to be more significant in those cases of SM associated with hypereosinophilia (see above). Marked infiltration of the liver by abnormal cells of the mast cell lineage have also been reported for mast cell leukemia (Yoshida et al. 2009) and aleukemic mast cell leukemia/malignant mastocytosis (Horny et al. 2002). In mast cell leukemia, extramedullary leukemic infiltrates are most commonly found in the spleen, liver and lymph nodes (Valentini et al. 2008).

Immunohistochemically, infiltrating mast cells can be detected by immunoreactivity for c-KIT (Wendum et al. 2004). Detection of aberrant expression of CD25 and CD2 on the surface of neoplastic mast cells but not their normal counterparts is an important diagnostic element (Sanchez-Munoz et al. 2011). CD203c is overexpressed in neoplastic mast cells in SM and is upregulated upon IgE receptor cross-linking (Hauswirth et al. 2008b). Immunoreactivity for CD25 in mast cells of the GIT is regarded as specific for SM (Hahn and Hornick 2007).

Liver Involvement in Mast Cell Leukemia

Mast cell leukemia is an extremely rare disorder characterized by immature mast cell forms, inner organ damage, and a rapidly malignant course (Lu et al. 2014). A variant, chronic mast cell leukemia has a more favorable biology and lacks inner organ damage (see above). In the setting of mast cell leukemia, neoplastic mast cells involve the liver circulation and may settle within sinusoids and portal tracts. Liver infiltration with abnormal cells can be massive and is then associated with marked infiltration of the bone marrow, spleen, and lymph nodes. At autopsy, the liver sinusoids, mainly in lobular zone 3, and central veins are clogged with mast cell tryptase-positive

cells, causing rapidly progressive non-cirrhotic portal hypertension (Yoshida et al. 2009). As in other organs, liver cells undergo damage induced by the neoplastic cells.

Mastocytoma of the Liver

Exceptionally, mast cell accumulation in the liver can result in a tumorous lesion, i.e., mastocytoma of the liver. In one report, a mass located to the quadrate liver lobe and isodense with liver substance on native CT imaging had a diameter of up to 3 cm. Needle biopsy of the lesion induced an anaphylactoid reaction (Klose and Skora 1990).

Liver Fibrosis in Systemic Mast Cell Disease

Mast cell infiltration in SM can be associated with liver fibrosis (Sawers et al. 1982; Brunning et al. 1983; Ghandur-Mnyamneh and Gould 1985; Yam et al. 1986; Horny et al. 1989; Mican et al. 1995) and has been reported to cause liver cirrhosis (Ghandur-Mnyamneh and Gould 1985; Horny et al. 1989), but no patient with cirrhosis has been detected in a large study of 41 patients (Mican et al. 1995). In the latter study, increased portal fibrosis was seen in 64 % of the biopsy specimens and correlated with mast cell infiltration and portal infiltration, whereas extensive bridging fibrosis was seen in 12 % (Mican et al. 1995). The pathogenesis of liver fibrosis in mastocytosis has not yet been clarified, but fibrokines such as TGF-beta and basic fibroblast growth factor secreted by mast cells may play a role (Choi and Claman 1987; Levi-Schaffer and Weg 1997; Marone et al. 1997; Li and Baek 2002; Baek et al. 2002). Mast cells can interact with myofibroblasts thought to play a role in the production of extracellular matrix (Akiyoshi and Terada 1998; Jeong et al. 2002), and it has also been shown that murine mast cells directly synthesize basement membrane components involved in early fibrosis responses (Thompson et al. 1991). For the pathogenesis of hepatic fibrosis, it is also of interest to note that human and rat hepatic stellate cells (HSC) can produce stem cell factor, a possible mechanism for fibrogenic mast cell recruitment (Gaca et al. 1999). On the other hand, mast cells and histamine did not appear to exert an important role in the induction of fibrosis under experimental conditions using mast cell-deficient Ws/Ws rates (Okazaki et al. 1998). What may furthermore influence the development of a fibrotic response is the capability of mast cells to induce angiogenesis; this has, e.g., been demonstrated in the bone marrow of patients with SM (Wimazal et al. 2002).

Mast Cell-Induced Obliterative Hepatic Venous Disorders

Mast cell hepatopathy is rarely associated with in part obliterative hepatic venous changes (*portal obliterative venopathy and/or veno-occlusive-like disease/hepatic venopathy*), possibly causing nodular regenerative hyperplasia (NRH) of the liver in a minority of patients (Mican et al. 1995). Histologically, portal venopathy in SM shows prominent hypertrophy of smooth muscle around markedly narrowed portal venous branches, whereas hepatic venopathy is visualized in the form of terminal veins showing almost complete occlusion by loose connective tissue infiltrated by mast cells, eosinophils, and lymphocytes (Mican et al. 1995).

Cholangiopathy and Chronic Cholangitis in SM ("Mast Cell Cholangiopathy")

Liver involvement in SM can result in a presentation indistinguishable from primary sclerosing cholangitis, associated with periductal/ductocentric mast cell infiltration. This lesion has been proposed to be termed *mast cell cholangiopathy* (Baron et al.1995). In SM cases presenting with *intrahepatic cholestasis*, mast cell infiltration of portal tracts, periductal portal tract edema, epithelial irregularities of the interlobular bile ducts, and centrizonal cholestasis have been noted (Safyan et al. 1997), suggesting an obstructive mechanism at the level of small intrahepatic bile ducts. It may be assumed that abnormal mast cells forming a

ductocentric infiltrate can damage cholangiocytes by secreted cytokines and other mast cell-derived components. Mast cell cholangiopathy can lead to bile duct fibrosis and show ductal changes compatible with those found in primary sclerosing cholangitis (Baron et al. 1995; Marbello et al. 2004; Papachristou et al. 2004).

Non-cirrhotic Portal Hypertension in SM

Few informations are still available for liver pathology in case of *SM-induced NCPH*. NCPH can be caused by dense hepatic infiltrates in systemic mastocytosis (Capron et al. 1978) or in mast cell leukemia (Yoshida et al. 2009). In one case, liver biopsy disclosed dense fibrosis of hepatic arterial and portal venule walls, resulting in complete obstruction of some portal radicles, and focal fibrosis of outflow venules and peliosis were also present (Bonnet et al. 1987).

The Liver in Mast Cell Activation Syndrome

Mast cell activation syndrome (MCAS) occurs in a number of different clinical conditions, such as IgE-dependent allergies, other forms of inflammatory reactions, and neoplastic mastocytosis (reviews: Haenisch et al. 2012; Valent 2013). The clinical presentation spectrum of MCAS is broad and ranges from mild symptoms and signs to a life-threatening disorder induced by mast cell products and depending on the number of degranulating mast cells and genetic predisposition factors. MCAS is classified into (1) primary MCAS in which KIT-mutated clonal mast cells are detectable, (2) secondary MCAS based on inflammatory and in particular IgE-mediated disorders, and (3) idiopathic MCAS. The liver may be involved in MCAS. In one study, an elevation of plasma cholesterol was found in 75 % of the patients, and elevations of transaminases and bilirubin were present in 40 % and 36 % of the patients, respectively. Thirty four percent had hepatomegaly (Alfter et al. 2009).

Differential Diagnosis: Mast Cells in the Liver in Disorders Other Than Systemic Mastocytosis

Mast cells form an important hepatic cell population involved in liver homeostasis and in several hepatic disorders (Benyon 1999). Mast cells have been shown to play a role in fibrotic and stromal reactions for several hepatic lesions, including acute inflammation (Grizzi et al. 2002), chronic inflammatory hepatobiliary diseases (Tsuneyama et al. 1999; Matsunaga and Terada 2000), hepatic fibrosis and cirrhosis (Kim 1971; Murata et al. 1973; Farrell et al. 1995; Armbrust et al. 1997; Yamashiro et al. 1998; Matsunaga et al. 1999; Sugihara et al. 1999), primary biliary cirrhosis (Nakamura et al. 1997), secondary biliary cirrhosis in rats (Rioux et al. 1996), granulomatous hepatitis (Celasun et al. 1992), hepatic radiation damage (Peng et al. 1994), the regulation of the peribiliary vascular plexus (Koda et al. 2000), perimetastatic reactions (Gulubova 2003), stroma and capillarization of HCC and intrahepatic CCC (Terada and Matsunaga 2000; Grizzi et al. 2003), sclerosing hepatic hemangiomas (Makhlouf and Ishak 2002), biliary atresia (Uddin Ahmed et al. 2000), and chronic liver graft rejection (O'Keeffe et al. 2002). Mast cell increase was more pronounced in primary biliary cirrhosis than in other forms of chronic liver disease (Farrell et al. 1995). Mast cells can also constitute a major cellular component of the infiltrate in inflammatory pseudotumors of the liver, hence the previous and now obsolete term, "solitary mast cell tumor" (Krech et al. 1995).

Differential diagnostically, most of these lesions will not be confounded with liver involvement in SM. However, difficulties may arose in chronic and in particular sclerosing cholangitis with mast cell infiltrates, because this may histologically mimic mast cell cholangiopathy.

The Phenotype of Normal Mast Cells and of Mast Cells in Systemic Mastocytosis

Mature normal mast cells are easily identifiable in hematoxylin and eosin-stained sections, but the reliable detection of immature forms requires

special staining techniques, such as Wright-Giemsa stain, toluidine blue stain, alcian blue/safranin stains, Unna's method (polychrome methylene blue with differentiation in glycerol ether), and other stains (Graham et al. 1994; Tomasi et al. 2003). It has also been emphasized that mast cells form a heterogeneous group of cells in regard to their formalin sensitivity (Marshall et al. 1987). Mast cells are identifiable by the use of cyto-/histochemistry (naphthol-AS-D chloroacetate esterase reaction; Horny et al. 1997) and immunohistochemistry with monoclonal antibodies directed against tryptase (Walls et al. 1990; Yamashiro et al. 1998). Human mast cells are categorized into mast cells positive for tryptase (MC-T) and those positive for both tryptase and chymase (MC-TC). MC-T are mainly mucosal-type mast cells, whereas connective tissue-type mast cells are chiefly MC-TC. Ultrastructurally, MC-T have granules with discrete scrolls and particulate and beaded pattern, while MC-TC have granules with finely granular or particulate material (Gulubova 2003). Normal mast cells express CD117 (c-kit/KIT; the receptor for stem cell factor) and CD68 (a marker for activated macrophages) but not CD25 or CD2 (Horny et al. 1990; Li et al. 1996; Escribano et al. 1999; Jordan et al. 2001; review: Tefferi and Pardanani 2004).

Mast cells from patients with SM display unique morphologic properties and aberrant immunophenotypic characteristics as compared with normal mast cells (Li et al. 1996; Horny and Valent 2001; Li 2001). Based on cytomorphologic features, four distinct cell types have been recorded, i.e., (1) typical tissue mast cells; (2) atypical mast cells exhibiting elongated cytoplasmic extensions, oval nuclei, and a hypogranular cytoplasm (atypical mast cells type I); (3) atypical mast cells with bi-or multilobed nuclei (atypical mast cells type II); and (4) metachromatically granulated blast-like cells ("metachromatic blasts"). Patients having more than 5 % atypical mast cells type II and/or "metachromatic blasts" showed a significantly shorter survival, suggesting that mast cell typing is a prognosticator in SM (Sperr et al. 2001). In contrast to normal mast cells, neoplastic mast cells in mastocytosis express the T-cell-associated antigen CD2 (Horny and Valent 2002), and they also express CD117/Kit and bcl-x(L) (Jordan et al. 2001). SM mast cells show aberrant expression of CD30 (Sotlar et al. 2011) and of CD25 (IL-2 receptor alpha chain) and abnormally high levels of the CD11c and CD35 complement receptors, the CD59 complement regulatory molecule, the CD63 lysosomal membrane antigen, and the CD69 early-activation antigen. In addition, SM mast cells express abnormally low levels of CD117 (Escribano et al. 2004; Lim et al. 2008). Of relevance for the tissual distribution of mast cells is the finding that neoplastic mast cells express the homing-associated cell adhesion molecule, CD44/HCAM (Horny et al. 1996). These distinct features are of relevance for the assessment of tissue involvement in SM, and strategies for immunophenotyping/quantitative multiparametric flow cytometry have recently been proposed by the Spanish Network on Mastocytosis (REMA; Escribano et al. 2004). In addition, soluble stem cell factor receptor (CD117) and CD25 levels in the plasma have been demonstrated to be surrogate markers of disease severity in mastocytosis (Akin et al. 2000). The complex function of normal and neoplastic mast cells is regulated by distinct transcriptional networks (Takemoto et al. 2008).

Molecular Features in Mastocytosis

A series of laboratory investigations has revealed that mast cell disease is a clonal stem cell disorder, with pathogenetically relevant mutations of the c-KIT being in the center of pathogenic pathways (Tefferi and Pardanani 2004; Sadrzadeh et al. 2011). Malignant variants of SM are therefore considered to be c-kit-driven disorders (Furitsu et al. 1993).

Most mastocytosis cases are associated with somatically acquired activating mutations of the tyrosine kinase domain of the KIT receptor for stem cell factor/SCF (reviews: Fuller 2012; Verstivsek 2013). Most of the patients with SM display the c-kit AL (Asp816Val; KITD816V) mutation, and this mutation is associated with advanced age, an aggressive clinical course,

increased bone marrow mast cell content, and sometimes CML (Valent et al. 2001a; Sotlar et al. 2002; Pardanani et al. 2003a, b; Laine et al. 2011). The somatic D816V KIT mutation has also been found in adult-onset familial mastocytosis (Zanotti et al. 2013). The KITD816V mutation results in ligand-independent activation of KIT tyrosine kinase and provides relative resistance to the tyrosine kinase inhibitor imatinib. The KITD816V mutation accounts for about 95 % or more of adults with SM. Rare other mutations include D816Y, D816H, and D816F. In children with mast cell disorders, the KITD816V mutation accounts for only about one third of cases of cutaneous mastocytosis. The mechanism leading from KIT mutations to mast cell disease involves a pathway where constitutively active mutant D816Vkit, even though not a transformant, induced increased differentiation of cells along cell lineages in the absence of factors and increased differentiation along the mast cell lineage in the presence of stem cell factor (SCF) (Ferrao et al. 2003). KIT regulation of mast cell proliferation has been linked to the activation of phosphatidylinositol 3-OH kinase/PI3K, in that the activating D816V mutation causes a robust activation of PI3K signaling. The proliferative mast cell response induced by the activation of this pathway is linked to PTEN downregulation (Furumoto et al. 2011). Oncogenic KIT signals are operational on endolysosomes and endoplasmic reticulum in order to promote neoplastic mast cell proliferation (Obata et al. 2014).

KIT gene mutations are a major driving force for common forms of SM, but the mechanisms involved in other phenotypes of mast cell disease are less clear. TET2, DNMT3A, and ASXL1 mutations are also present in mastocytosis and may have an impact on the biology of disease (Traina et al. 2012). It has been shown that TET2 mutations associate with aggressive forms of the disease. In murine mast cells, TET2 loss cooperates with c-KITD816V to transform mast cells (Soucie et al. 2012). In patients with SM-AHNMD, mutations other than those found in classical SM have been identified. SM associated with AML showed the RUNX1-RUNX1T fusion gene, while SM associated with myeloproliferative neoplasms revealed JAK2V617F. In patients with mast cell proliferation and eosinophilia, the FIP1L1-PDGFRA fusion gene has been found.

Abstract

In several types of acute leukemia, neoplastic cells infiltrate the liver parenchyma, portal tracts, and tissues accompanying bile ducts and blood vessels. Acute myeloid leukemia (AML), defined as a clonal expansion of myeloid blasts, frequently results in hepatic infiltrates that sometimes cause hepatomegaly. In massive infiltration, leukemic blasts induce liver damage and eventually hepatic failure. Dense bile duct infiltrates can cause obstructive jaundice. In AML, mass-forming hepatic lesions termed granulocytic sarcoma can develop. In contrast to AML, neoplastic cells in acute erythroid leukemia tend to accumulate in the lumens of hepatic blood vessels, but marked blastic infiltration of parenchyma also occurs. Acute megakaryoblastic leukemia is a neoplasia in which at least 50 % of cells are of the megakaryocyte lineage. Infiltration of the liver by cells of this leukemia is often associated with hepatic fibrosis. This neoplasm overlaps with the rapidly progressive disorder, acute panmyelosis with myelofibrosis. Blastic infiltration of the liver associated with fibrosis is also a feature of transient abnormal myelopoiesis in Down syndrome.

Acute Myeloid Leukemia (AML) and Related Precursor Neoplasms

Introduction

Acute myeloid leukemia (AML) is defined as a clonal expansion of myeloid blasts in the bone marrow, blood, or other tissues (reviews: Jaffe et al. 2001; Betz and Hess 2010; Estey 2013; Ferrara and Schiffer 2013; Puumala et al. 2013; Walter et al. 2013). AML exists in numerous variants, a part of which display recurrent genetic abnormalities.

Liver Involvement in Acute Myeloid Leukemia

Introduction

The findings of liver infiltration in AML are known from both biopsy and autopsy studies (Krishbaum and Preuss 1943; Ito 1970; Bross et al. 1975; Chi et al. 1976; Viadana et al. 1978; Ondreyco et al. 1981; Aviles Miranda et al. 1981; Ito et al. 1985; Barcos et al. 1987; Scheimberg et al. 1995; Walz-Mattmuller et al. 1998). In fact, the recognition of extramedullary dissemination by leukemia, also in the absence of overt marrow involvement, is documented in the old literature referring to this issue (Gruber 1930; Nies et al. 1965; Mathé et al. 1966). Infiltration of the liver by blasts may be clinically silent, may induce marked hepatomegaly and liver function abnormalities (Sharma Poudel and Karki 2007), or may cause jaundice and/or fulminant hepatic failure in case of massive blastic infiltration (Zafrani et al. 1983; Eisen et al. 2008). The majority of patients with AML-induced liver abnormalities display jaundice, a cholestatic picture, or obstructive jaundice at presentation (Mathews et al. 2008). In a large autopsy study on 585 patients with AML, 41 % exhibited organ involvement of the liver (the liver, spleen, and lymph nodes being the organs with the highest incidence of leukemic involvement), and the mean liver weight in these autopsied patients was 2253 g (Barcos et al. 1987). In another study of 127 liver specimens (2 biopsies and 125 autopsies), 60–70 % of the specimens showed liver infiltration in acute myeloid leukemia (Walz-Mattmüller et al. 1998). The hepatic infiltration pattern seen in AML may also be present in cases where chronic leukemia is followed by massive production of blasts, e.g., monoblasts (Ondreyco et al. 1981). Massive blastic infiltration of the liver can result in fulminant hepatic failure (Ondreyco et al. 1981; Zafrani et al. 1983).

Pathology

Patients with various forms of AML can show hepatomegaly, but in most cases, enlargement of the liver is slight to moderate, but can become marked in certain situations of blast crisis. Hepatomegaly can also be caused by disorders complicating AML, including generalized infection/septicemia, portal vein thrombosis, fatty change, and therapy-induced parenchymal damage. At

autopsy, the liver may show rounded margins, dilated subcapsular blood vessels, a grayish-red discoloration, and a flabby consistency. In cases of marked liver infiltration, mostly in blast crisis, the lobular architecture is effaced. In AML, myeloid cells infiltrate both the portal tracts and the parenchyma, with permeation of the sinusoids (Fig. 1; Scheimberg et al. 1995; Wandroo et al. 2004; Mathews et al. 2008; Nishihori et al. 2011), sometimes with a diffuse and marked infiltration pattern associated with the signs of cholestatic hepatitis (Sevinc et al. 2004; Wandroo et al. 2004). A diffuse accumulation of neutrophil precursors, maturing forms with more cytoplasmic granules, and blast cells can occur within the hepatic sinusoids (Wandroo et al. 2004), but there are situations where either the portal tract spaces or the parenchyma are almost exclusively involved. In some patients, a predominance of micromyeloblasts was noted. In the portal tracts, the leukemia cells appear to be randomly distributed, but sometimes an angiocentric or a ductocentric pattern is in evidence. That part of the leukemia cells that may be attracted by, or home to, distinct tissue components is further illustrated by a sometimes preferential localization of these cells to the periductular space or to interface lesions. The hepatic infiltrates in AML consist of cells displaying several size classes ranging from small- to medium-sized cells: The cytoplasmic features and the nuclear morphology vary from one type/variant of AML to the other (Ito 1970), therefore requiring immunohistochemical techniques. Hepatic infiltrates in AML with predominance of a neutrophil lineage exhibits cells expressing MPO, CD13, CD15, and/or CD33, while AML with monocytoid differentiation, or AMML and acute monoblastic/monocytic leukemias, display numerous cells, or a majority of cells, expressing monocyte lineage markers (Cd14, CD4, CD11b, CD11c, CD64, CD36, and lysozyme). Diagnostic difficulties arise in immature forms of AML (see above), where the cellular infiltrates may resemble non-Hodgkin's lymphoma, but immunohistochemical stains will usually solve these questions.

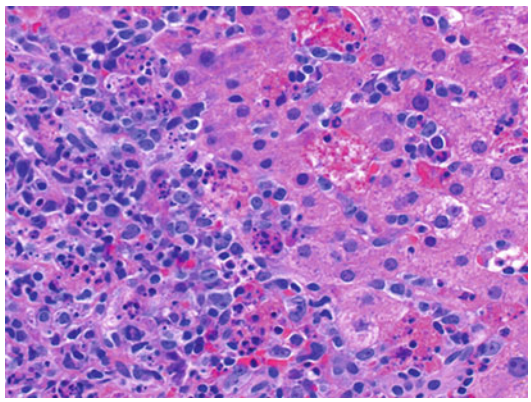

Fig. 1 Acute myeloid leukemia, infiltration of the liver. Basophilic and amphophilic blasts invade the sinusoids. Numerous nuclear debris are seen (hematoxylin and eosin stain)

Obstructive Jaundice in AML

Leukemic cells in AML can infiltrate the walls of large bile ducts, cause stenosis, and hence induce obstructive jaundice (Rajesh et al. 2006). In part of patients, large and dense infiltrates of immature myeloid cells have been observed in the hilar/perihilar area, with formation of thick sheaths engulfing hilar bile ducts and blood vessels (review: Gruber 1930). However, there are also patients with AML associated with signs of obstructive jaundice without bile duct infiltration at imaging (Goor et al. 2002; Mathews et al. 2008).

Granulocytic Sarcomas in AML

In AML or variants thereof, initial organ manifestation may be in the form of granulocytic sarcomas (GS; Liu et al. 1973; Alama Zaragoza et al. 2003; Best-Aguilera et al. 2005; Lee et al. 2007). Overall. GS was detected at autopsy in 8 % of patients with AML and in 4 % of those with CML (Liu et al. 1973). Involvement of the gastrointestinal tract is relatively rare, being reported in 7 % of 61 tumors (Neiman et al. 1981). GS in the liver, the hepatic ducts, at the porta hepatis, the common bile duct, or the pancreatic head are known to cause cholestasis

and obstructive jaundice, sometimes as the presenting feature of AML (McCord et al. 1973; Lillicrap et al. 1982; King et al. 1987; Gutierrez de Guzman et al. 1987; Case Records of the Massachusetts General Hospital 1988, 1990; Matsueda et al. 1998; Abe et al. 1999; Jaing et al. 2001; Alama Zaragoza et al. 2003; Mano et al. 2004). Lesions developing in the perihilar region have been reported to be as large as 2.5 cm (Matsueda et al. 1998) and may thus mimic a perihilar stenosing carcinoma/Klatskin tumor. In part of cases, chloroma-like nodular lesions can develop. AML cases with such features have previously been termed "chloroleukemic myeloblastosis" or "acute chloroleukemia."

Hepatic Extramedullary Hematopoiesis in AML

Extramedullary hemopoiesis can occur in both treated and untreated patients, but is rarer than in myeloproliferative disorders.

Hepatic Vascular Alterations in AML

AML cells can accumulate within microvascular lumina, thus forming aggregates and so-called leukocyte thrombi (McKee and Collins 1974). In the liver, this is sometimes in evidence within the sinusoidal channels, but is also found in the small vessels forming the peribiliary plexus. Targeting of leukemia cells to the sinusoidal compartment has been found to be induced by treatment with gemtuzumab ozogamicin (an immunoconjugate composed of recombinant humanized murine anti-CD33 antibody linked to calicheamicin) that targets CD33-positive cells (Rajvanshi et al. 2002). AML can cause thrombotic obstruction of hepatic veins, leading to Budd-Chiari syndrome and eventually liver failure (Amitrano et al. 2006).

Hepatic Fibrosis in AML

Hepatic fibrosis is known to develop in AML (Niedobietk 1968) and presents in several patterns, but it is more frequent or more severe in the chemotherapy and chemo-/radiotherapy groups (Scheimberg et al. 1995). In a minority of cases, hepatic fibrosis is associated with liver lobule remodeling, resulting in cirrhosis (Danopoulos and Angelopoulos 1953; "leukemic liver cirrhosis").

Other liver Alterations in AML

In rare instances, AML can cause bridging necrosis and reticulin bridging fibrosis, with distortion of liver lobules and associated with activation of hepatic stellate cells (Kuroda et al. 2006). Involvement of the liver in AML can be associated with macrovesicular or microvesicular steatosis, and/or with visible cholestasis (Scheimberg et al. 1995), however at least in part caused by chemotherapeutic measures. In particular, L-asparaginase is known to induce diffuse hepatic steatosis (due to asparagine deficiency) in 50–90 % of the treated patients and to increase in severity with increased duration of the treatment (Kitmacher et al. 1991; Halton et al. 1998; Sahoo and Hart 2003). L-asparaginase induces hypertriglyceridemia (Tozuka et al. 1997), eventually via a derangement of glutamine metabolism (Ollenschlager et al. 1988) which, apart from a direct toxic effect on hepatocytes, may be involved in the pathogenesis of liver steatosis. Necrosis of liver parenchyma was reported in patients with AML with or without therapy and has been proposed to be a consequence of leukemic infiltration and/or infection in the latter group (Scheimberg et al. 1995). Focal necrosis is sometimes associated with steatosis (Scheimberg et al. 1995). Hepatic iron overload is a frequent finding and is most marked in the bone marrow transplant group (Armand et al. 2011). AML cells are involved in an angiogenic phenotype (Schuch et al. 2002), and native human AML blasts have a pro-angiogenic phenotype involving the action of VEGF and IL-8 that are released at relatively high levels (Glenjen et al. 2003). Involvement of visceral organs in AML may result in release of leukemia cells into the abdominal cavity, with formation of so-called leukemic ascites (Simel and Weinberg 1985).

Therapy of AML can, as in other situations, cause alterations of hepatic veins. For example, probable veno-occlusive disease has been observed in AML treated with gemtuzumab ozogamicin (O'Boyle et al. 2003). There is an increased incidence of AML after liver transplantation (Camos et al. 2004; with a review of the literature). Veno-occlusive disease in patients with AML can be caused by treatment with gemtuzumab ozogamicin (Stadtmauer 2002; Giles 2002), in up to 2 % of the treated patients (Leopold et al. 2002), and even in the absence of previous stem cell transplantation (Giles et al. 2001). Apart from the accumulation of leukemic cells in the microvascular bed, AML may also be complicated by disseminated intravascular coagulation (Genova and Georgief 1974). This is mainly observed in patients with APL (acute promyelocytic leukemia).

A further group of hepatic lesions in acute non-lymphoblastic leukemia is directly or indirectly caused by therapy, sometimes with signs of chronic liver disease, including diverse forms of viral hepatitis (Aviles Miranda et al. 1981; Locasciulli et al. 1983) and direct sequelae of chemotherapy (Iqbal et al. 1996). Massive hepatic infarction caused by the almost complete obstruction of both the hepatic artery and portal vein by thrombi was observed as a complication developing after salvage chemotherapy such as FLAGM inducing marked myelosuppression (Saito et al. 2010). In addition, a significant proportion of patients with AML in remission display persisting liver function abnormalities of unknown pathogenesis, liver biopsies showing non-characteristic inflammatory changes of varying degrees (Armitage et al. 1978). The liver may also be involved in infections developing under, or subsequent to, therapy of acute leukemia, including septicemia (Chi et al. 1976).

Classification

Based on the numerous cytogenetic and molecular features of AML, classification of this disorder has become complex. The classification of AML comprises four major categories: (1) AML with recurrent genetic abnormalities; (2) AML with multilineage dysplasia; (3) AML, therapy-related; and (4) AML, not otherwise categorized/specified (NOS). AML NOS also contains rare acute myeloid leukemias including myelomonocytic, monoblastic/monocytic, erythroid, megakaryoblastic, and basophilic leukemias. These uncommon disorders are treated in separate paragraphs.

Morphology

The morphologic features of "classical" AML cells have been studied in detail, including electron microscopy (Schumacher et al. 1973). The cells of interest are best stained with Wright-Giemsa or May-Grünwald-Giemsa stains. By use of these stains, myeloblasts vary in their size from enlarged lymphocytes to monocytes (or even larger). The cytoplasm is usually basophilic to blue-gray, and the nuclei are mostly round to oval, with several nucleoli. The cells may disclose few azurophilic granules; Auer rods are lineage specific for myeloid cells (Jaffe et al. 2001). A further myeloid lineage-specific marker is myeloperoxidase (MPO) that can be detected by use of cytochemistry. The immunophenotype of myeloid leukemia cells is characterized by reactivity for CD13, CD33, CD15, MPO, and CD117 (Ball and Fanger 1983; Jaffe et al. 2001). The morphology exhibits some particularities in regard to the subtypes of AML. AML1/ETO (ICD-O code: 9896/3; AML1 = RUNX1 gene), which is an AML generally showing maturation in the neutrophil granulocyte lineage (Jaffe et al. 2001), consists of cells with the features of large blasts with more abundant cytoplasm, often numerous azurophilic granules, frequent Auer rods, and few cells with very large granules (pseudo-Chediak-Higashi granules). Smaller blasts in this variant occur mainly in the streaming blood. In addition to the lineage-specific immunophenotype, the cells typically express CD34, often express CD56, and a subset displays the lymphoid marker, CD19. The AML1/ETO translocation t(8;21)(q22;q22) involves the AML1/RUNX1 gene encoding CBFalpha and the ETO (8;21) gene. AML (CBFbeta/MYH11)

(ICD-O code: 9871/3) is an AML that mostly displays granulocytic and monocytic differentiation and a characteristically abnormal eosinophil component in the marrow (Jaffe et al. 2001). Acute myelomonocytic leukemia with abnormal eosinophils is also termed AMML Eo.

Acute Erythroid Leukemias

ICD-O code 9840/3

Introduction

In the 2008 WHO classification, acute erythroid leukemias (synonyms: erythremic myelosis; Di Guglielmo's disease; Di Guglielmo 1917, 1962) are acute leukemias characterized by a predominantly erythroid lineage. Today, two subtypes are recognized based on the presence or absence of a significant myeloid/granulocyte component: erythroleukemia (erythroid/myeloid) and pure erythroid leukemia (acute erythremic myelosis; true erythroleukemia; Hasserjian et al. 2001). Erythroleukemia (erythroid/myeloid) may present as a de novo neoplasm or evolve from MDS or chronic myeloproliferative disorder. The features of acute erythroid leukemias have been described and reviewed in detail (Domingo-Claros et al. 2002; Srinivas et al. 2007; Santos et al. 2009; Hasserjian et al. 2010; Kasyan et al. 2010; Zuo et al. 2010; Liu et al. 2011, 2012), as well as the issue of erythroid proliferations in myeloid neoplasms (Wang and Hasserjian 2012). Classifications of acute erythroid leukemia are briefly discussed at the end of this chapter.

Clinical Features and Morphology

Several reports document the hematologic presentation of erythroid leukemias, both in children and adults (Scott et al. 1964; Sondergaard-Petersen 1975; Roggli and Saleem 1982; Ruvidic et al. 1986; Griesser and Horny 1987; Atkinson et al. 1992; Day et al. 1997; Hasserjian et al. 2001). The most common presenting symptoms and signs are related to the moderate or profound anemia which is always present. Pure erythroid leukemia can be associated with hemophagocytosis (Kitagawa et al. 2009). Hemophagocytic lymphohistiocytosis is a recurrent and specific complication of acute erythroid leukemia (Yamazaki et al. 2011).

Morphology

In erythroleukemia (erythroid/myeloid), all maturation stages may be found, erythroid precursors being dysplastic, often with megaloblastoid nuclei, binucleated, and multinucleated forms. Myeloblasts are commonly of intermediate size, contain relatively few granules, and may show Auer rods. Dysplastic features also involve neutrophils and megakaryocytes. In pure erythroid leukemia, erythroblasts of medium to large size prevail, commonly with a deeply basophilic cytoplasm and round nuclei with a fine chromatin structure (proerythroblasts). Red cell maturation is blocked in acute erythroid leukemia (Blum and Angelillo-Scherrer 2012). In contrast to immature fetal erythroid cells that can undergo enucleation to produce pyrenocytes (McGrath et al. 2008), maturation with enucleation dependent on erythroblast macrophage protein/Emp (Soni et al. 2006) does not take place in acute erythroid leukemias.

In regard to the immunophenotype, erythroid cells in erythroleukemia (FAB M6a) usually lack myeloid markers and MPO, but are reactive for glycophorin A and hemoglobin A (Keifer et al. 1984; Jaffe et al. 2001). The expression of Hb A and the aberrant expression of Hb F in cells of acute erythroid leukemia have been described, in particular fetal hemoglobin-containing erythroblasts or "F blasts" (Omine et al. 1983; Markham et al. 1983; Sumitra et al. 1988; Choi et al. 2002), and these erythroid lineage markers can be detected by use of immunohistochemistry in tissues (Pinkus and Said 1981; Forni et al. 1983).

Liver Involvement in Acute Erythroid Leukemia

The immature erythroid cells in acute erythroid leukemias have a marked tendency to accumulate and grow within vascular lumina, i.e., showing an intravascular growth pattern (Hasserjian et al. 2001). Therefore, immature erythroid cells in these leukemias are capable to spread and to locate in the liver, resulting in hepatomegaly (Lazzaro 1933; Stodtmeister 1941; Mirchandani et al. 1983; Reiffers et al. 1985; Kowal-Vern et al. 1992; Tsuji et al. 1995; Mazzella et al. 1998; Hasserjian et al. 2001; Funakoshi et al. 2011). There is, however, marked variability in the reported incidence of hepatomegaly (0–18 %; review: Roggli and Saleem 1982). Infiltration of the liver had already been noted by Di Guglielmo in his first description of the disorder (Di Guglielmo 1926). Marked blastic infiltration of the liver in acute erythroid leukemia has been described in autopsy liver samples (Roggli and Saleem 1982; Iida et al. 1991; Tsuji et al. 1995). In the autopsy study of Roggli and Saleem, the organs involved in order of decreasing frequency were the bone marrow, spleen liver, lymph nodes, kidneys, dura, stomach, urinary bladder, skin, and choroid plexus (Roggli and Saleem 1982). In liver biopsy, a patchy intrasinusoidal and focal portal infiltrate of large, beta-sialoglycoprotein-positive, immature erythroid lineage cells were reported (Hasserjian et al. 2001). Rarely, erythroblastic islands are seen within sinusoids, similar to findings in the bone marrow (Taher et al. 1981). It is surmised that the cells involved express distinct adhesion molecules that mediate the homing mechanisms (Hasserjian et al. 2001). The erythroblasts may show erythrophagocytosis (Sondergaard-Petersen 1974). In a patient with the anerythremic variant of acute erythroid leukemia (described in the title as Di Guglielmo's syndrome), autopsy showed hepatomegaly (1800 g) and a diffuse infiltration of both the portal tracts and the sinusoids with blast cells that were immunohistochemically reactive for hemoglobin (Tsuji et al. 1995).

Erythroleukemia can present as a congenital disorder, both with erythremic and anerythremic manifestation. Congenital anerythremic erythroleukemia, is a very rare disorder (Bjure et al. 1960; Lasson and Goos 1981; Allan et al. 1989; Hadjiyannakis et al. 1998). Per definition, congenital leukemias originate in utero, and manifestations are present at birth or in the first four postnatal weeks. The disorder has been reported to present with connatal hepatosplenomegaly and abnormal liver tests, later resulting in death due to hepatic failure (Lazure et al. 2003). A premortem biopsy and the autopsy in this patient showed a blastic infiltration of organs, in the liver mainly within portal tracts, and these cells expressed only the erythroid markers, glycophorin A and C. In addition, the biopsy revealed extensive portal and perisinusoidal fibrosis without atrophic hepatocytes. At autopsy, the liver was enlarged (225 g; expected: 133 g) and grossly cholestatic and multinodular (numerous millimetric pink nodules), with hilar and portal lymph node swelling (Lazure et al. 2003). Histologic examination showed a diffuse and nodular blastic infiltration consisting of basophilic cells with round or multilobated nuclei; in addition, binuclear and giant blasts were noted. In an another report, congenital erythroleukemia was associated with liver failure of unknown pathogenesis (Allan et al. 1989).

Erythroblastomas and Erythroblastic Sarcomas

A distinct variant of acute erythroid leukemia is characterized by the formation of tumorous lesions rich in abnormal erythroblasts, described in the literature under several terms, including *erythroblastic sarcoma*, *erythroblastomatosis*, *erythroblastoma malignum*, and *erythroblastoma diffusum*. The recognition of these lesions goes back to 1934, based on the observation of a patient with abnormal erythropoietic foci (erythroblastoma; Limarzi and Levinson 1943), followed by several reports afterward (Birkle 1950; Siede and Rotter 1950; Harwerth 1952; Dubois-Ferrière et al. 1955; Böttiger and Hellström 1956; Rohr 1960; Goreczky and Toth 1967; Wang et al. 2011; Cornfield 2012; Riddle

and Olsen 2012). Morphologically, this disorder is characterized by a growth dominated by abnormal erythroblasts, including large or even giant, markedly basophilic forms, frequently with vacuolization of the cytoplasm ("paraerythroblasts"). Proerythroblasts and other maturing cells with denser nuclei and amphophilic or slightly eosinophilic cytoplasms occur in variable numbers.

Few data relate to manifestations of malignant erythroblastoma in the liver (Corwin and Nettleship 1959; Goreczky and Toth 1967). In a 66-year-old female patient, autopsy of the liver (2500 g) revealed a tumor-like growth ("erythroid metastases") of the cells described above, predominantly of the immature types (Goreczky and Toth 1967).

Differential Diagnosis

The differential diagnosis comprises AML with maturation and shift into a population of increased erythroid precursors and AML with multilineage dysplasia. Rarely, CML, idiopathic myelofibrosis, or polycythemia vera undergo erythroblastic transformation and may then mimic (or represent?) acute erythroid leukemia (Dammert and Kaipainen 1960; Bank et al. 1966; Garcia et al. 1989). On the other hand, acute erythroid leukemia may dedifferentiate and end up with a disorder compatible with AML-MO (Michiels et al. 1997). Pure erythroid acute leukemia may have poor erythroid maturation and is then difficult to distinguish from other types of AML, in particular acute megakaryoblastic leukemia. Most cases of acute erythroid leukemia are sporadic, but familial occurrence has also been reported (Siebert et al. 1995). Erythroleukemia has been identified following erythropoietin therapy in a patient with CIMF (Coleman et al. 2001). Of particular interest is the association of acute erythroid leukemia with the stem cell disorder, paroxysmal nocturnal hemoglobinuria (PNH; Carmel et al. 1970; Cowall et al. 1979; Luzzatto et al. 1979; Kiga et al. 1980; Shimano et al. 1983; Meletis and Terpos 2003).

Classifications of Acute Erythroid Leukemia

The 2008 WHO classification distinguishes erythroleukemia from pure erythroid leukemia. In the FAB classification system, these leukemias were classified as AML-M6 (AML6), with three subtypes, i.e., M6a, erythroid/myeloid; M6b, pure erythroid leukemia; and M6c, mixed (Table 1).

Acute and Chronic Basophilic Leukemia

Acute Basophilic Leukemia (ABL; ICD-O 9870/3)

Acute basophilic leukemia (ABL) is a very rare disorder (about 4–5 % of all acute nonlymphocytic leukemias; Chevallier and Marinone 1951; Shah et al. 1984; Peterson et al. 1991). Usually, ABL presents as a mixture of blasts from different lineages with a considerable but highly variable participation of mature or immature basophilic cells (Liso et al. 1978). Complete diagnostic criteria of ABL, therefore, remain to be worked out. Essential thrombocythemia can transform into ABL (Shah et al. 1984), and basophilic crisis has been observed in chronic myeloid leukemia (Ozaki et al. 1989). Furthermore, basophilic differentiation occurs in

Table 1 Classifications of acute erythroid leukemias

WHO classification (2008)
Erythroleukemia (erythroid/myeloid)
Defined by the presence in the bone marrow of =>50 % erythroid precursors in the entire nucleated population and =>20 % myeloblasts in the entire non-erythroid population
Pure erythroid leukemia
Defined as a neoplasia of immature cells (undifferentiated or proerythroblastic in appearance) exclusively committed to the erythroid lineage, accounting for =>80 % of bone marrow cells
FAB classification
M6a, erythroid/myeloid
M6b, pure erythroid leukemia
M6c, mixed

some patients with acute promyelocytic leukemia (Tallman et al. 1993).

Four ABL types have been recognized, i.e., (a) the basophilic terminal phase (basophilic blastic crisis) of chronic myeloid leukemia, (b) the mixed basophilic-eosinophilic types, (c) the promyelocytic basophilic type, and (d) the so-called histio-basoblastic type (Quattrin 1978). However, ABL does now no longer include the basophilic proliferation seen frequently in patients with chronic myeloid leukemia or other myeloproliferative disorders in either the chronic or the blastic stage (Dick 1991). Most frequently, the blast cells are morphologically undifferentiated, and the recognition of the presence of coarse basophilic granules may be the first step in diagnosis, although the number of blast cells with deep purple granules in May-Grünwald-Giemsa preparations is variable from case to case. These granules are metachromatic and MPO negative, although the results of the peroxidase reactivity are controversial and the typical toluidine blue metachromatic reaction is frequently equivocal (Shvidel et al. 2003).

Chronic Basophilic Leukemia

Evidence has accumulated that chronic basophilic leukemia represents a distinct clinicopathologic entity and a variant form of a chronic myeloproliferative neoplasm (Barlas 1954; Nasi et al. 1960; Anikin 1963; Rosenthal et al. 1977; Pardanani et al. 2003; Tang et al. 2009). Basophilia is recognized as a feature of chronic myeloid leukemia and is considered a prognosticator for poor outcome (Denburg and Browman 1988). The emergence of a basophil cell lineage is also known for the blastic phase of CML (Nissenblatt 1980; Li and Yam 1987; Peterson et al. 1991), and prominent basophilia is associated with blast crisis with the i(17q) anomaly (Alimena et al. 1987). In CML, basophilia is mostly found in the Ph+/bcr+ and Ph−/bcr+ configurations. Chronic basophilic leukemia, an aggressive disorder with a potential to transform into acute leukemia, is Ph negative and shows marked bone marrow hypercellularity with trilineage overgrowth, prominent basophilia, dysmegakaryopoiesis, and abnormal mast cells in part of the patients (Pardanani et al. 2003). Chronic myeloproliferative disorders with production of numerous basophils can present in an aleukemic form, with infiltration of internal organs, including the liver (Lertprasertsuke and Tsutsumi 1991).

Liver Involvement in Basophilic Leukemia

In basophilic leukemia, immature leukemic cells with variable signs of basophilic differentiation can infiltrate portal tracts or the liver and/or accumulate within hepatic sinusoids. A part of the cells correspond to immature blasts. In the Giemsa stain, purple metachromatic cytoplasmic granules are in evidence. Leukemic cells with coarse basophilic granules may represent a minority of infiltrate cells and can be missed without special staining or immunohistochemistry (CD9 and CD25). A disorder of liver function has been observed in acute basophilic leukemia in the absence of leukemic liver infiltration (Scolyer et al. 2000). In chronic myeloproliferative disorders with marked basophilia, immature basophils infiltrate, among other internal organs, the liver, associated with liver fibrosis and sometimes accumulation of abnormal mast cells (Lertprasertsuke and Tsutsumi 1991). Thus, the hepatic changes in part resemble those observed in systemic mastocytosis (see below).

Acute Megakaryocytic Leukemias: Acute Megakaryoblastic Leukemia and Acute Myeloid Leukemia (Megakaryoblastic) with t(1;22)(p13;q13)

ICD-O code 9910/3

Introduction

In the WHO classification of tumors, acute megakaryoblastic leukemia (AMKL; FAB: M7; ICD-O code 9910/3; "acute megakaryocytic leukemia"; "acute panmyelosis with myelofibrosis") is an acute leukemia with 20 % or more blasts of which at least 50 % are of the megakaryocyte lineage. The category excludes cases of AML with myelodysplasia-related changes, Down syndrome-related cases, AML with t(1;22)(p13;q13), AML with inv(3)(q21q26.2), and AMl with t(3;3)(q21;q26.2).

Acute Megakaryoblastic Leukemia (AMKL)

AMKL is an uncommon disease that was included in the FAB classification in 1985 (Bennett et al. 1985; Gassmann and Loffler 1995). The disorder occurs in both children and adults and accounts for 3–5 % of acute leukemias. Hematologically, the patients usually present with cytopenia, including thrombocytopenia, although thrombocytosis may also occur. Circulating leukemic blasts are usually rare or lacking, but there are patients with organomegaly and significant numbers of circulating blasts as well. The frequent finding of bone marrow fibrosis has led to the term "acute myelofibrosis" in some reports relating to AMKL, leading to some confusion. AMKL evolves de novo or, less frequently, in the context of a preexisting myeloproliferative disease, e.g., essential thrombocythemia (Radaelli et al. 2002) or chronic myeloid leukemia (Wu et al. 1996). The striking relationship with myeloproliferative disorders occurring in Down syndrome is discussed in a later paragraph (see below). The prognosis of AMKL is usually poor in adults when compared to other types of AML, but the outcome of AMKL in children with or without Down syndrome is more favorable (Hama et al. 2008).

Morphologically, megakaryoblasts are medium-sized or large elements with a round or slightly irregular nucleus and a basophilic, often agranular cytoplasm. In some patients, small cells reminiscent of lymphoid cells or lymphoblasts develop. The cells of interest are mostly reactive for one or more of the thrombocyte glycoproteins, CD41 and/or CD61, while CD42, characterizing more mature thrombocytes, is less frequently present. Typically, CD 36 is positive. In contrast, expression of CD13, CD33, and CD34 is rare or lacking, and MPO is, in most cases, not detectable (Koike 1984; Choate et al. 1988; Jaffe et al. 2001).

Liver Involvement in Acute Megakaryoblastic Leukemia

Hepatic leukemic infiltration in the setting of AMKL (Sato et al. 1990; Vargas et al. 2011) makes part of a distinct clinicopathologic entity, extramedullary AMKL (Chitragar et al. 2011). Similar to CIMF and other myeloproliferative disorders, AMKL can, probably through the action of its cells, induce fibrotic changes in the liver in case of hepatic involvement (Garel et al. 1991; Shibata et al. 1998). This leukemia is well known to exhibit bone marrow fibrosis ("acute myelofibrosis"), and this may be followed by progressive fibrosis in the liver (Shibata et al. 1998). In infantile AMKL (not associated with trisomy 21), hepatomegaly with hepatic fibrosis surrounding intrahepatic blast accumulations has been observed (Garel et al. 1991). It seems that cells of the megakaryocyte lineage play a key role in fibrogenic pathways in these disorders, further discussed in the paragraphs on CIMF and ET. This is exemplified by the observation of frequent and marked myelofibrosis in patients with Ph-positive CML undergoing megakaryoblastic transformation (Van Slyck et al. 1970) and the distinct position of the megakaryoblast in pediatric transitional myeloproliferative disorders (TMD). The megakaryocyte-mediated fibrotic reactions in the liver of children with Down syndrome (DS) is discussed in the paragraph on DS-TMD. The fibrotic liver reaction in the early phases is chiefly characterized by perisinusoidal fibrosis, apparently more pronounced in places where megakaryoblasts/

megakaryocytes have accumulated. There seems to be an intricate spatial relationship between megakaryoblasts and the sinusoidal wall, mature-looking megakaryocytes seemingly extending through the endothelium into the perisinusoidal space of Disse, where they may achieve contact with hepatic stellate cells. These putative biologic contact sites are of interest insofar as factors released by megakaryocytes and cells of AMKL comprise TGF-beta (mainly the isoforms 2 and 3) and PDGF-B (Terui et al. 1990; Reilly et al. 1993; Kitagawa et al. 1994; Wickenhauser et al. 1995; Hassan et al. 1995; Yoon et al. 2000). Furthermore, megakaryocytes express PDGFRbeta (Yoon et al. 2000). These findings suggest a fibrogenic action of megakaryocytes, as further discussed in the paragraphs on CIMF and TMD. It will be interesting to study whether megakaryoblasts/megakaryocytes can engage into distinct contacts with hepatic stellate cells, because HSC are able to form specific aggregates with partner cells of their vicinity, such as hepatocytes during certain phases of liver regeneration (Mabuchi et al. 2004).

Tumor Formation

The cells of AMKL can sometimes develop tumorous lesions as a result of their cohesive nature, and these masses may simulate metastatic disease (Pui et al. 1985; Dharmasena et al. 1986; Penchansky et al. 1989; Ashfaq et al. 1992; Kitagawa et al. 1994; Bozkurt et al. 2008). Such lesions also occur in AMKL developing in Down syndrome (see below; Nito et al. 1983; Hoshikawa et al. 1988). It has to be emphasized, however, that extramedullary megakaryoblastic tumors also occur in other stem cell disorders, e.g., chronic idiopathic myelofibrosis (CIMF) (Chubachi et al. 1995; Chan et al. 1996), probably reflecting a switch in priming of neoplastic progenitor cells. Conversely, megakaryoblastic sarcoma in CIMF can terminate as acute megakaryoblastic leukemia (Hirose et al. 2001). Histologically, the tumorous lesions are composed of a mixture of megakaryoblasts and spindle cells, sometimes with a significant desmoplastic reaction (Ashfaq et al. 1992).

Liver Involvement in Acute Myeloid Leukemia (Megakaryoblastic) with t(1;22)(p13;q13)

This type of acute leukemia seems to be more often associated with liver infiltration, sometimes massive and tumor forming. In a 4-week-old infant with this type of leukemia who had presented with ascites, massive infiltration of hepatic sinusoids by leukemic cells were found. Bone marrow fibrosis appeared after infiltrative disease in the liver and liver fibrosis (Lewis et al. 2008). Tumoral leukemic infiltration of the liver found at autopsy was reported in a neonate with congenital megakaryoblastic leukemia associated with t(1;22)(p13;q13). There was a massive, predominantly periportal leukemic infiltration extending into larger bile ducts and encasing the portal vein (Gong et al. 1999). A large tumor developing in the course of acute megakaryoblastic leukemia and consisting of leukemic cells associated with fibrosis was observed in the liver of a child who presented with a hepatic mass lesion that resembled hepatoblastoma. The child was later shown to have t(1;22)(p13;q13) (Amemiya et al. 2008). Severe liver dysfunction probably related to hepatic leukemic infiltration was observed in a child with putative variant of t(1;22)(p13;q13), i.e., acute megakaryoblastic leukemia with t(17;22)(q21;q13) (Chitlur et al. 2004).

Cytogenetic and Molecular Genetic Features of AMKL

There is no unique chromosomal abnormality associated with AMKL in adults. However, an AML with contribution of megakaryoblasts but not included among AMKL in the WHO classification is associated with at least two distinct cytogenetic abnormalities, i.e., trisomy of chromosome 21 and the reciprocal t(1;22)(p13;q13) chromosomal translocation. AMKL in adults frequently exhibits the cytogenetic abnormalities of secondary leukemia (Duchayne et al. 2003), while the genetic features are more restricted in children

(review: Hama et al. 2012). Rare chromosomal aberrations in AMKL comprise t(10;11)(p13;q14-21), resulting in the fusion of the gene CALM, encoding a clathrin assembly protein, to the gene AF10, a putative transcription factor (Jones et al. 2001); MNX1-ETV6 fusion (Taketani et al. 2008). Gene mutations identified in AMKL include mutations in the thrombopoietin receptor gene (Hussein et al. 2009) and a novel Janus kinase 3 P132A mutation (Riera et al. 2011).

Acute Panmyelosis with Myelofibrosis (APMF)

ICD-O code 9931/3

Introduction

Acute panmyelosis with myelofibrosis (APMF) is a rapidly progressing entity showing partial morphologic overlap with acute megakaryoblastic leukemia. The concept of APMF (acute or malignant myelofibrosis/myelosclerosis) originated from observations showing that part of patients with myeloproliferative disorders associated with myelofibrosis were characterized, in contrast to the usually chronic course, by a rapidly fatal outcome. It is still difficult to judge whether all cases previously assigned to so-called acute myelofibrosis are the same as APMF. The WHO classification defines APMF as an acute panmyeloid proliferation with increased blasts and accompanying fibrosis of the bone marrow that does not meet criteria for AML with myelodysplasia-related changes.

APMF is a disorder characterized by a multilineage myeloid proliferation with a less numerous population of blasts than acute megakaryoblastic leukemia, blasts always being CD34 positive, in contrast to the latter, where only part of the blasts are positive, and the blasts in APMF rarely express megakaryocytic antigens (Orazi et al. 2005). Most cases of APMF show a fibrotic bone marrow with an increased number of immature trilineage hematopoietic elements and dysplastic megakaryocytes predominantly of small size showing hypolobulated or non-lobulated nuclei. Foci of blasts are found in bone marrow, but the overall marrow blast content in APMF is difficult to assess. The cytogenetic patterns seem to be nonspecific (Suvajdzic et al. 2004).

Clinical Features

Patients with APMF often present acutely with symptoms and signs of severe illness, including fatigue and weakness, fever, and bone pain. Splenomegaly is not a feature. The patients always show pancytopenia and the course is characterized by the rapid development of bone marrow insufficiency and the transition to acute myelogenous leukemia in a high proportion of patients (Thiele et al. 2004).

Liver Involvement

In extramedullary disease, APMF can cause considerable diagnostic difficulties (Orazi 2007). In one patient with this disorder, autopsy revealed an infiltration of the liver (sinusoidal cell accumulation) by myeloid and erythroid cell and in part atypical megakaryocytes (Hayashi et al. 1989). This infiltration pattern can also occur in other myeloproliferative disorders and is therefore not specific for APMF. APMF can cause peritoneal hematopoiesis (Metzgeroth et al. 2005) which may involve the liver surface.

Myeloid Proliferations Related to Down Syndrome (Transient Abnormal Myelopoiesis/ Myeloproliferative Disorders in Trisomy 21): High Risk for Acute Megakaryoblastic Leukemia

Introduction

Down (or Down's) syndrome (trisomy 21) is a frequent condition associated with a variety of signs and symptoms. A major gene product that is overexpressed by chromosome 21 polysomy is

the dual-specificity tyrosine-(Y)-phosphorylation regulated kinase 1A (Dyrk1A), which participates in the mechanisms underlying the mental and other physical signs of Down syndrome (Park et al. 2009). In addition, overexpression of Dyrk1A is thought to be involved in leukemogenesis and in the reduced risk of epithelial cancers in these patients (Birger and Izraeli 2012).

A transient myelopoiesis/myeloproliferative disorder (TMD) can develop in newborns and infants with Down syndrome, characterized by a hematologic disorder resembling acute megakaryoblastic leukemia (Engel et al. 1964; Okada et al. 1972; Evans 1975; Weinstein 1978; Lewis et al. 1983; Wong et al. 1988; Homans et al. 1993; Zubizarretta et al. 1995; D'Angelo and Merlo 2003; Zipursky 2003; reviews: Brink 2006; Wiseman et al. 2009). TMD is characterized by an abundance of blasts within the peripheral blood and the liver. These blasts share expression megakaryocytic and erythroid phenotypes (Ito et al. 1995; Bozner 2002). A part of the patients with TMD will develop acute megakaryoblastic leukemia within 1–3 years. There is a complex causal relationship between chromosome 21, GATA1, and megakaryocytopoiesis, briefly discussed later.

Epidemiology and Clinical Presentation

TMD develops in approximately 10 % of Down syndrome newborns. It rarely occurs in newborns with trisomy 21 mosaicism. Newborns and infants with TMD usually present with thrombocytopenia, often associated with excess blasts in peripheral blood. Other cytopenias are less common. Hepatosplenomegaly may be found. Most patients show healing within a few months, but in around 20 % TMD is life-threatening or fatal. In the patient group with low-risk and hence solely observed, peripheral blasts and all other TMD signs cleared at a median of 36 and 49 days from diagnosis, respectively (Gamis et al. 2011). A fraction of the TMD patients undergoes progression (or transformation) to acute megakaryoblastic leukemia (Down syndrome-associated acute megakaryoblastic leukemia; DS-AMKL), with an estimated 30 % of TMD patients developing DS-AMKL within 1–3 years (Cosson et al. 1974; Lewis et al. 1983; Nito et al. 1983; Stoll et al. 1985; Suarez et al. 1985). Children with Down syndrome are 500 times more likely to develop AMKL, but also 20 times more likely to develop acute lymphoblastic leukemia (reviews: Bruwier and Chantrain 2012; Seewald et al. 2012). DS-AMKL post-TMD can be preceded by refractory anemia with excess of blasts (RAEB; Yokoyama et al. 1984), indicating the relation between MDS and TMD. Approximately 20 % of patients with TMD die at an early age due to failure of several organs, specifically also liver disease (Park et al. 2014).

Liver Involvement in TMD

Introduction

TMD is associated with a complex liver disorder mainly caused by blast infiltration and a distinct type of hepatic fibrosis. The disorder presents as hepatomegaly, cholestasis, and hyperbilirubinemia (predominantly conjugated) with minimal elevation of serum transaminases. Neonatal cholestasis develops in a significant percentage of patients with Down syndrome and is always associated with involvement of other organs (Arnell and Fischler 2012). Down syndrome with or without TMD can lead to severe perinatal liver disease with fatal outcome (Ruchelli et al. 1991). Early death is significantly correlated with the degree of transaminase elevation during the course of illness. TMD-associated hepatic fibrosis together with sinusoidal colonization by blasts and megakaryocytes can develop already during the fetal period (Vimercati et al. 2003). There is indirect evidence that liver involvement may develop between the 11th and 13th week of gestation already, in that liver volume determined by 3D ultrasound was increased in Down fetuses in comparison with euploid fetuses (Gielchinsky et al. 2011).

Liver Infiltration with Blastic Cells

In TMD, the liver may be infiltrated by numerous blasts with bilineage features and, sometimes, by a large number of megakaryocytes and their

precursors localized to the sinusoidal compartment (Ruchelli et al. 1991), causing hepatomegaly (Becroft 1993), sometimes already in the fetal period (Macones et al. 1995). Rarely, cells of the megakaryoblast/megakaryocyte lineage may grow in the form of tumors localized to several organs, including the liver (Nito et al. 1983), but megakaryoblastic/megakaryocytic tumor formation in the liver also occurs in those DS patients developing leukemia. In a 2-year-old DS patient with acute megakaryoblastic leukemia, autopsy showed an enlarged liver studded with numerous miliary yellowish nodules, histologically characterized by dense nodular infiltrates consisting of large immature megakaryoblasts. Many of these cells were detectable within sinusoidal lumina as well (Hoshikawa et al. 1988).

Liver Fibrosis

TMD is associated with a distinct type of infantile liver fibrosis in approximately 15–20 % of the patients (Becroft and Zwi 1990; Miyauchi et al. 1992; Yagihashi et al. 1995; Inoue et al. 1996; Villamour Zambrano et al. 1997; Schwab et al. 1998; Hongeng et al. 2000; Brink 2006; Tokairin et al. 2008; Hirabayshi et al. 2011). A diffuse pattern of a sometimes severe perisinusoidal fibrosis is a main alteration. The fibrosis can result in marked disarray of hepatocyte plates and in ductular proliferation with or without cholestasis (Schwab et al. 1998). In an autopsy study of four patients, diffuse intralobular fibrosis was a striking change in all patients (Miyauchi et al. 1992). Hepatic fibrosis in TMD can rarely result in liver cirrhosis (Urano et al. 1983). In one report, moderate iron deposits in hepatocytes were described (Schwab et al. 1998), whereas a heavy iron overload reflecting perinatal hemochromatosis syndrome was detected in the majority of patients with Down syndrome-associated severe perinatal liver disease (Ruchelli et al. 1991). In addition to the liver, the pancreas can also undergo fibrosis in TMD ("perinatal visceral fibrosis"; Becroft and Zwi 1990; Becroft 1993).

Molecular Features

TMD is initiated before birth when fetal liver hematopoietic cells trisomic for chromosome 21 acquire mutations in GATA1 (Roy et al. 2012). Mutations in the gene of the transcription factor GATA1 are associated with both TMD and DS-AMKL (Ito et al. 1995; Mundschau et al. 2003; Xu et al. 2003; Greene et al. 2003; reviews: Izraeli et al. 2007; Ciovacco et al. 2008; Shimizu et al. 2008; Gamis and Smith 2012; Toki et al. 2013). GATA1 is a member of a transcription factor family that affects growth and maturation of several cell systems, but is expressed primarily in hematopoietic cells, and is essential for the development of erythroid cells, megakaryocytes, eosinophils, and mast cells. Absence of GATA1 leads to differentiation arrest and apoptosis of erythroid progenitor cells and promotes the accumulation of immature megakaryocytes. GATA1 mutations are an early event in the pathway leading from latent TMD clones to AMKL (Hitzler et al. 2003; Rainis et al. 2003; Gurbuxani et al. 2004), but abnormal telomerase expression may also play a role in the malignant conversion of TMD cell lineages (Holt et al. 2002). Recently, GATA1 mutations have been identified in TMD blasts from every infant examined, supporting the view that GATA1 plays a crucial role in Down syndrome leukemogenesis (Mundschau et al. 2003). GATA1 mutations occur in utero in most DS-TMD and DS-AMKL; multiple separate GATA1 mutant clones can develop in an individual, and these mutations may occur without clinical signs of disease (Ahmed et al. 2004; Yoshida et al. 2013). A fetal origin of the GATA1 mutations has been verified in identical twins with TMD and DS-AMKL (Shimada et al. 2004). There are, however, also situations where polysomy of chromosome 21 is associated with AMKL in the absence of GATA1 mutations. For example, tetrasomy 21 as a sole acquired abnormality was found in pediatric AMKL without GATA1 mutations (Shin et al. 2008). In the pathways leading to megakaryocyte differentiation, GATA1 interacts with components of the transcriptional elongation factor, P-TEFb, a complex containing cyclin T1 and the cyclin-dependent kinase 9/Cdk9 (Elagib et al. 2008). GATA1 mutations in Down syndrome

may act in a genetic network also involving PML and SUMO3, as found by the detection of a 15q24 microdeletion in patients with TMD (Haemmerling et al. 2012). A part of Down patients with TMD and AMKL have acquired gain- or loss-of-function mutations of JAK3/Janus kinase 3 gene mutations (De Vita et al. 2007). Recent studies have also shown that the critical gene on chromosome 21, DYRK1A, is involved in leukemogenesis of AMKL (Malinge et al. 2012). Furthermore, Down syndrome critical region 1 (DSCR1), a member of the calcipressin family of calcineurin inhibitors, is overexpressed in Down syndrome. Overexpression of DSCR1 causes destabilization of the calcineurin/nuclear factor of activated T cells (NFAT) pathway, a mechanism that drives the proliferation of megakaryocyte precursors and may act in AMKL leukemogenesis (Kyttälä et al. 2009).

Myeloid Neoplasms with a Monocytoid Lineage

85

Contents

Abstract

Myeloid neoplasms with a monocytoid lineage can involve the hepatobiliary tract. In acute myelomonocytic leukemia, characterized by the proliferation of both neutrophil and monocyte precursors, the liver can show an increased number of monocytoid cells and neutrophils in sinusoids, but usually without blasts. Similar cells infiltrate portal tracts, often with monocytoid cells with nuclei of promonocytes. In juvenile myelomonocytic leukemia, hepatomegaly can develop due to infiltration of the liver with monocytoid cells and immature granulocytes, mainly in sinusoids. Hepatic involvement in acute monoblastic and monocytic leukemia is characterized by sometimes massive blastic infiltration of parenchyma, monoblasts occupying sinusoids and portal tracts, causing hepatomegaly and a whitish discoloration of the organ. The liver is often involved in chronic myelomonocytic leukemia, with myelomonocytic cells, erythroid precursors, and less commonly megakaryocytes mainly within sinusoids. Dense sinusoidal infiltration may result in sinusoidal obstruction and portal hypertension. This leukemia can be associated with hepatobiliary myeloid tumors.

Acute Myelomonocytic Leukemia

ICD-O code 9867/3

Introduction

In the WHO classification of tumors, acute myelomonocytic leukemia (AMML; AML-M4) is defined as an acute leukemia characterized by the proliferation of both neutrophil and monocyte precursors. In peripheral blood and bone marrow, = >20 % blasts, including promonocytes, are found, and neutrophils and monocytes plus their respective precursors each comprise at least 20 % of bone marrow cells. AMML accounts for about 5–10 % of acute myeloid leukemias. It is slightly more common in males and is predominantly a disease of the elderly. Clinically, patients with AMML usually present with fatigue, fever, anemia, and thrombocytopenia.

Morphology

The morphology of AMML is characterized by monoblasts, large cells with abundant basophilic cytoplasm, which may contain vacuoles and scattered fine azurophilic granules. Monoblasts usually have roundish nuclei with prominent nuclei. Immunocytochemically, in contrast, promonocytes have a less basophilic and more granulated cytoplasm, sometimes with large azurophilic granules, and more irregular and slightly convoluted nuclei. Cells of AMML may show the pseudo-Chediak-Higashi anomaly (Rao et al. 2009). Immunocytochemically, AMML blasts variable express CD13, CD33, CD65, and CD15. Some of the blasts are immature precursor cells expressing CD34 and CD117. Subpopulations of blasts express monocyte lineage markers, including CD14, CD4, CD11b, CD11c, CD64, CD36, macrophage-restricted CD68 (PGM1), CD163, and lysozyme. Monocyte lineage differentiation is typically characterized by coexpression of CD15 and CD64. Cells of AMMl can undergo differentiation which was shown to be induced by thrombomodulin via JNK signaling (Yang et al. 2012). Posttranscriptional modulation of C/EBPalpha (CCAAT/enhancer-binding protein alpha), which induces monocyte differentiation in normal leukocytes, also prompts monocytic differentiation and apoptosis in AMML cells (Yoshida et al. 2012).

Liver Involvement

The liver of patients with AMML shows an increased number of neutrophils and monocytoid cells in the sinusoids, usually without blasts. The monocytoid elements have reniform or oval nuclei with a rather fine chromatin pattern. Similar cells infiltrate the portal tracts, sometimes with expansion of these structures. The infiltrate contains monocytoid cells with nuclei of the type found in promonocytes seen in blood and bone marrow smears. Inflammatory pseudotumor of the liver has been found in association with AMML (Isobe et al. 1991).

Cytogenetic and Molecular Genetic Features

Cytogenetically, an abnormal but nonspecific karyotype, in particular +8, is found in the majority of cases. Double supernumerary isochromosome 4p was detected in AMML (Soriani et al. 2010). Inversion of chromosome 16 in AMML was found to be associated with basophilia and bone marrow eosinophilia (Matsuura et al. 1987). CD7-positive AMML with trisomy 21 as a sole acquired chromosomal abnormality was observed in two adolescents (Kudo et al. 2011). The t(8;16)(p11;p13) translocation is a rare alteration involved in de novo and therapy-related AMML and acute monocytic leukemia. It fuses two genes encoding histone acetyltransferases MYST3 (MOZ) located at 8p11 to CREBBP (CBP) located at 16p13. Leukemias with 8p11 (MYST3) rearrangement were AMML in 7 % and monocytic (93 %), and the abnormality was associated with poor prognosis (Gervais et al. 2008). Genome profiling revealed that MYST3-linked cases of AMML (MYST3 located

at 8p11) show alteration of the MYB locus (Murati et al. 2009).

Juvenile Myelomonocytic Leukemia

ICD-O code 9946/3

Introduction

The WHO classification of tumors defines juvenile myelomonocytic leukemia (JMML; formerly juvenile chronic myeloid leukemia) as a clonal hematopoietic disorder characterized by the proliferation principally of the granulocytic and monocytic lineages. Blasts plus promonocytes account for less than 20 % of cells in the peripheral blood and bone marrow. Erythroid and megakaryocytic abnormalities are often present. The BCR-ABL1 fusion is absent, while gene mutations of the RAS/MAPK signaling pathway are characteristic (reviews: Emanuel 2008; Urs et al. 2009).

JMML is a rare disorder of infants and children, with about 1.3 cases per million children 0–14 years of age. It is expressed as a clonal, mixed panmyelopathy responding poorly to most standard chemotherapy regimens and showing an elevated relapse rate after stem cell transplantation, although this procedure can cure the disease (Shannon et al. 1994; Busque et al. 1995; Hess et al. 1996; Arico et al. 1997; Chang et al. 2004; Emanuel 2004). Together with pediatric myelodysplastic syndrome, JMML is classified as a pediatric myeloproliferative disorder (PMPD; Cotter 1998). JMML usually presents with leukocytosis with the presence of early myeloid and monocytic forms, thrombocytopenia, a skin rash, and hepatosplenomegaly. During the frequently rapid progression of disease, infiltration of organs and tissues other than the bone marrow ensues. About half the patients have lymphadenopathy, and leukemic infiltration can cause markedly enlarged tonsils. A distinct feature of JMML is that the majority of young individuals exhibit elevated levels of fetal hemoglobin (HbF), especially in those with an abnormal karyotype, sometimes producing an acquired Cooley's anemia-like phenotype, suggesting that cell systems in JMML may undergo a reversion to a fetal pattern (Weatherall et al. 1968; Maurer et al. 1972; Weinberg et al. 1990; Honig et al. 1998). The most common cytogenetic alteration is that of monosomy or deletion of the long arm of chromosome 7 occurring in up to 25 % of the individuals (Cotter 1998; Chang et al. 2004). Other abnormalities are found in 10 % of patients and a normal karyotype in 65 %.

Morphology

The peripheral blood generally exhibits leukocytosis, thrombocytopenia, and often anemia. The leukocytosis is dominated by neutrophils, with some promyelocytes and myelocytes as well as monocytes. Blasts are usually less than 5 % and always less than 20 %. Red cell macrocytosis may be seen, especially in patients with monosomy 7. In the bone marrow, which shows hypercellularity with granulocyte proliferation, monocytes are less impressive than in peripheral blood, usually accounting for 5–10 % of nucleated cells. Blasts are less than 20 % of bone marrow cells. Auer rods are never seen, and dysplasia is minimal in most cases.

Liver Involvement

Relatively few reports refer to liver changes in JMML. Patients with JMML typically show splenomegaly, whereas hepatomegaly is less common, occurring in about a third of patients in one series (Niemeyer et al. 1994). Enlargement of the liver is mainly due to infiltration of hepatic tissue by leukemic cells, as based on liver biopsy findings. The blood in the liver sinusoids show increased numbers of circulating cells, whereby granulocytes, including hyposegmented forms, predominate. Monocytoid cells may be noted in histologic sections mostly diagnosed based on the characteristic nuclear morphology. Few nests of erythroblasts may be found, and megakaryocytes are often found. The portal tracts may show dense

infiltrates mainly of mature granulocytes and their precursors, with a variable admixture of partly CD68-positive monocytoid cells. The infiltrate sometimes encroaches upon small intralobular bile ducts, and increased myeloid cells are also noted in the lumens of small portal vein branches (Honig et al. 1998). Hepatic fibrosis has been detected in patients with juvenile chronic granulocytic leukemia/JMML (Takanashi 1972; Kajigaya et al. 1987; Mikel et al. 1990). The liver histology is characterized by several features, including extramedullary hemopoiesis, both portal and bridging fibrosis, with fibrosis around terminal/central veins, and these alterations were proposed to be caused by leukemic infiltration.

Pathogenesis

The pathogenic pathways involved in JMML leukemogenesis have been elucidated in the course of the last years. Patients with JMML reveal characteristic alterations in several signaling pathways, whereby the RAS, NF1, and PTPN11 pathways have a central role (reviews: Koike and Matsuda 2008; Niemeyer and Kratz 2008; Loh 2010). There is a striking relationship between JMML and a dysregulation of factors involved in the Ras and neurofibromatosis 1/NF1 signaling pathways. Up to 75 % of cases of JMML have a disorder in the GM-CSF/Ras signal transduction pathway (Emanuel 2004). In fact, the most common myeloid malignancy in children with NF type 1 is JMML, which seems to develop in a stepwise fashion (Clark and Hutter 1982; Miles et al. 1996; Leung et al. 2003).

A further factor involved in the Ras pathway and altered in JMML is PTPN11 (Liu et al. 2009). The PTPN11 gene encodes a non-receptor protein tyrosine phosphatase, SHP-2 (Src homology 2 domain-containing protein tyrosine phosphatase), that acts as an upstream regulator of Ras via relaying signals from activated growth factor receptors to p21 ras and other signaling molecules. PTPN11 is mutated in approximately 35 % of patients with JMML. Compared with patients with RAS mutations or without any aberrations, patients with PTPN11 mutation were significantly older at diagnosis and had higher fetal Hb levels, both of which have been identified as poor prognosis factors.

Missense mutations of CBL, an E3 ubiquitin ligase and multi-adaptor protein that control proliferative signaling networks by downregulating growth factor receptor signaling cascades, have been detected in JMML (Loh et al. 2009; Makishima et al. 2009). Germ line mutations of the CBL gene cause a new genetic syndrome with predisposition to JMML (Pérez et al. 2010). This dominant disorder is characterized by impaired growth, developmental delay, cryptorchidism and a predisposition to JMML (Niemeyer et al. 2010).

A distinct translocation (t(5;17) (q33;p11.2)) causing the fusion of the PDGF B receptor and HCMOGT-1 has been detected in JMML (Morerio et al. 2004). The chromosome rearrangement site 5q31–33 harbors the PDGFRB gene, encoding a tyrosine kinase receptor, and this gene is known to fuse with at least six partner genes, i.e., ETV6, CEV14, HIP1, H4/D10S170, RAB5, and PDE4DIP (Morerio et al. 2004). Spliceosomal gene aberrations are rare in JMML (Hirabayashi et al. 2012).

Acute Monoblastic and Monocytic Leukemia

ICD-O code 9891/3

Introduction

Acute monoblastic leukemia and acute monocytic leukemia are defined as myeloid leukemias in which 80 % or more of the neoplastic cells are members of the monocyte lineage, including monoblasts, promonocytes, and monocytes. These two forms of leukemia are distinguished by the relative proportions of monoblasts and promonocytes, monoblasts accounting for 80 % or more of the cells in acute monoblastic leukemia, whereas the majority of cells in acute monocytic leukemia are promonocytes

Epidemiology

Among AMLs, acute monoblastic leukemia and acute monocytic leukemia are rare subsets, both accounting for less than 5 % of AMLs. The disorder is more common in younger individuals, although it may develop in any age group and can also occur as a congenital leukemia. Acute monocytic leukemia is more common in adults and is slightly more frequent in males than in females (M:F = 1.8:1).

Clinical Features and Morphology

Acute monoblastic leukemia and acute monocytic leukemia are clinically characterized by lymphadenopathy, gingival hypertrophy, coagulation disorders, and lysozymuria (Shaw 1978).

Monoblasts are large cells with abundant cytoplasm that is moderately to markedly basophilic, the cytoplasm containing scattered and discrete azurophilic granules and some clear vacuoles. Normal monoblasts usually show round nuclei with a delicate chromatin structure and one or more prominent nucleoli. In contrast, promonocytes have a less basophilic and more granulated cytoplasm and a more irregular and convoluted nuclear shape. The cytoplasm contains large azurophilic granules and vacuoles. Both of these cell types exhibit intense reactivity for nonspecific esterase, but 10–20 % of acute monoblastic leukemia lack nonspecific esterase activity or show only weak positivity. Monoblasts lack activity of myeloperoxidase, while promonocytes may show a weak activity in part of the cells. The immunophenotype of these cells is characterized by reactivity for the myeloid antigens CD13, CD33 (bright), CD15, and CD65. There is reactivity for at least two markers of the monocytoid lineage, i.e., CD14, CD4, CD11b, CD11c, CD64, CD68, CD36, lysozyme, and, in part, CD163.

Hepatobiliary Involvement

Massive blastic infiltration of the liver by monoblastic/monocytic cells in acute leukemia can cause hepatomegaly (Ondreyco et al. 1981). Macroscopically, dense and diffuse infiltrates lead to a whitish discoloration of the organ (Park et al. 2001).

In acute monoblastic leukemia with liver involvement, portal tracts and sinusoids are densely populated with monocytoid cells (Peterson et al. 1981; Ondreyco et al. 1981; Hayashida et al. 1992; Kontny et al. 1995; Park et al. 2001). These are characterized as small- to medium-sized cells with an amphophilic, finely granulated cytoplasm (azurophilic granules) and irregularly shaped, ovoid, and sometimes slightly indented nuclei with multiple nucleoli, features characteristic for acute monoblastic/monocytic leukemias (McKenna et al. 1975). The cytoplasm may show few clear vacuoles. The sinusoids can become markedly distended by massively proliferating intrasinusoidal leukemia cells. Adjacent hepatocytes are sometimes atrophic or are destroyed by invading leukemia cells. The cells may also accumulate in hepatic venules (Park et al. 2001). At the border between portal tracts and the lobular parenchyma, the leukemic cells may induce piecemeal-like lesions ("leukemic piecemeal necrosis"). The cytoplasm of the neoplastic cells is markedly positive for nonspecific esterase, a reaction inhibited after fluoride incubation (Ondreyco et al. 1981). In liver infiltrates, the monoblastic character of leukemia cells was confirmed by electron microscopy. The cells display a cluster of mitochondria at one side of the nucleus, slightly dilated ER profiles, characteristic lysosomal granules, and nuclei with course and peripheralized chromatin and some indentations of the nuclear contour (Ondreyco et al. 1981). These ultrastructural features have also been observed in other extramedullary manifestations of acute monoblastic/monocytic leukemias (Sultan et al. 1977; Peterson et al. 1981).

Monoblastic/Monocytoid Mass Lesions in the Liver ("Monocytomas"; Monoblastic Sarcomas; Monoblastic Tumors; Monoblastic Type of Myeloid Sarcoma)

In some patients with acute monoblastic or monocytic leukemia, extramedullary masses consisting

of leukemic cells can develop (Peterson et al. 1981). These mass lesions (monocytomas; monoblastic sarcomas; monoblastic tumors) may involve the skin and several visceral organs, including the gastrointestinal tract, liver, kidneys, and heart (Rappoport and Kugel 1947; Feichter et al. 1974; Miliauskas 1986; Sepp et al. 1993; Orts et al. 1996; Iwaka and Saikawa 2007; Zuo et al. 2008; Holloman et al. 2009). Several reports document nodular "monocytomas" of the liver (Rappoport and Kugel 1947; Bonnin 1951; Feichter et al. 1974; Wu et al. 2011). In the 64-year-old patient described by Feichter and coworkers (1974), necropsy revealed several cherry-sized whitish nodules in the liver histologically composed of monocytoid infiltrated in the setting of monoblastic leukemia. In a neonate with congenital monoblastic leukemia presenting as jaundice and ascites, CT showed several hypodense liver lesions (Wu et al. 2011).

Immunohistochemistry

The monocytoid leukemic cells are partly reactive for CD68, lysozyme, and CD31 (Park et al. 2001). Subsets of monocytoid leukemia cells are reactive for CD163. CD163 (hemoglobin scavenger receptor/HbSR) is a specific marker of the macrophage cell lineage (Lau et al. 2004). CD163 serves to identify the monocytoid character of cells in acute myeloid leukemia with monocytic differentiation (Walter et al. 2003; Garcia et al. 2008). The most specific monocyte lineage marker after CD68 and CD163 is Krüppel-like factor 4, while CD68 is the most sensitive monocyte marker (Klco et al. 2011).

Differential Diagnosis

The main differential diagnosis refers to other leukemias with mononuclear cells, including poorly differentiated forms of acute myeloid leukemia and acute lymphoblastic leukemias.

Pathogenic Pathways

Parts of leukemias show the involvement of the mixed lineage leukemia/MLL gene. MLL (MLL1, HRX, ALL1; the human homologue of the Drosophila gene trithorax) is frequently rearranged in leukemia, particularly in infantile leukemia and therapy-related leukemia. MLL-induced acute leukemias are often highly aggressive, frequently refractory to therapy, and markedly driven by epigenetic dysregulation (Bernt and Armstrong 2011; Muntean and Hess 2012). The MLL gene is localized at chromosome 11q23 and encodes a large histone methyltransferase that directly binds DNA and positively regulated gene transcription, including homeobox (HOX) genes. MLL regulates HOX gene expression through direct promoter binding and histone H3 Lys 4 methylation mediated by the intrinsic methyltransferase activity of the MLL SET domain (Hess 2004). Translocations involving chromosome band 11q23 and hence MLL are found in more than 70 % of infant leukemias, 5.2 % of acute myeloblastic leukemia, and 22 % of acute lymphoblastic leukemia (De Braekeleer et al. 2005). More than 25 fusion partners of MLL have been identified. The MLL-human gephyrin fusion gene was often found in leukemias with a chromosome 11 band q23 (11q23). Gephyrin (GPHN) is a rat glycine receptor-associated protein which forms submembranous complexes and anchor glycine or gamma-aminobutyric acid A receptors to microtubules. It is an organizer at GABAergic synapses where it forms oligomeric superstructures (Tretter et al. 2012). The small tubulin-binding oligomerization domain of gephyrin is sufficient to convert MLL to an oncogene (Eguchi et al. 2004). Patients with acute monoblastic leukemia or acute undifferentiated leukemia showed t(11;14)(q23;q24) translocation and revealed that a human homologue of gephyrin (human gephyrin) had fused with MLL (Eguchi et al. 2001; Kuwada et al. 2001). Other fusion partners for MLL comprise SEPTIN6 (associated with inv ins (X;11)(q24;q23q13; Kim et al. 2003); SEPTIN9 associated with t(11;17)(q23q25;

Kurosu et al. 2008); MYO1F, an unconventional myosin type 1F (Taki et al. 2005); AF3p21, a nuclear protein with SH3- and proline-rich domains (Sano 2001); AF9 (Li et al. 2008); MLLT10 (de Figueiredo et al. 2012); and ELL (De Braekeleer et al. 2012). In MLL-fused leukemia cells, the CCAAT/enhancer-binding proteins (C/EBPs), C/EBPalpha and C/EBPepsilon, induce monocytic differentiation of myelomonocytic cells through downregulation of Myc (Matsushita et al. 2008). It is known that C/EBPalpha also directs monocytic commitment of primary myeloid progenitor cells (Wang et al. 2006). MLL family proteins interact with menin, a nuclear protein mutated in the MEN1 multiple endocrine neoplasia syndrome and that interacts with many proteins and is involved in a variety of cellular processes. Menin acts as a hub recruiting both wild-type MLL and MLL-fusion proteins to target genes (Thiel et al. 2012). Menin is an essential oncogenic cofactor for MLL-associated leukemogenesis (Yokoyama et al. 2005). Menin binds to the N terminus of MLL and in cooperation with MLL regulates the expression of the cyclin-dependent kinase inhibitors, p27Kip1 and p18Ink4c, via a mechanism involving recruitment of MLL to the p27Kip1 and p18Ink4c promoters and coding regions (Milne et al. 2005). MLL also forms a SET1-like histone methyltransferase complex with menin to regulate HOX gene expression (Yokoyama et al. 2004). Menin also acts as an adaptor that physically links MLL with LEDGF (lens epithelium-derived growth factor), a chromatin-associated protein that is required for MLL-dependent transcription and leukemogenesis (Yokoyama and Cleary 2008). Menin binds the JUN family transcription factor JUND and inhibits its transcriptional activity. The menin molecule contains a deep pocket that binds short peptides of MLL or JUND in the same manner, but with opposite effects on transcription. The menin-JUND interaction blocks the JUN N-terminal kinase (JNK)-mediated JUND phosphorylation and suppresses JUND-induced transcription, while menin promotes gene transcription by binding the transcription activator MLL (Huang et al. 2012). Another DNA methyltransferase gene mutated in acute monocytic leukemia is DNMT3A, encoding the DNA methyltransferase 3A (Yan et al. 2011; Fried et al. 2012).

Other Antigens/Proteins Associated with Acute Monocytoid Leukemias

MLAA-34, a splice variant of the CAB39L gene, is an antigen characterizing acute monocytic leukemia. MLAA-34 is an anti-apoptotic protein closely related to monocytoid leukemogenesis (Zhang et al. 2009).

Chronic Myelomonocytic Leukemia

ICD-O code 9945/3

Introduction

The WHO classification defines chronic myelomonocytic leukemia (CMML) as a clonal hematopoietic malignancy derived from a hematopoietic stem cell that is characterized by features of both a myeloproliferative neoplasm and a myelodysplastic syndrome. The diagnostic criteria for CMML include persistent monocytosis $>1 \times 10(9)/L$ in peripheral blood, absence of a Philadelphia chromosome and BCR-ABL 1 fusion gene, no arrangement of PDGFRA or PDGFRB, fewer than 20 % in peripheral blood and bone marrow (promonocytes are considered to be blast equivalents), and dysplasia involving one or more myeloid lineages. In the absence of myelodysplasia, a diagnosis of CMML can be done if the other requirements are met, and an acquired clonal cytogenetic or molecular genetic abnormality is present in bone marrow cells, or if the monocytosis has persisted for at least 3 months, and all other causes of chronic monocytosis are excluded.

CMML is divided into two subsets, CMML-1 and CMML-2, in dependence of the number of blasts plus promonocytes in the bone marrow and the peripheral blood. CMML-1 has <5 % blasts in peripheral blood and <10 % blasts in bone marrow. CMML-2 has 5–19 % blasts in peripheral blood or 10–19 % blasts in bone marrow. The International Prognostic Scoring System for myelodysplastic syndrome cannot be used to risk stratify patients with CMML because this model excluded patients with a leukocyte count >12 × 10(9)/L (review: Parikh and Tefferi 2012).

Clinical Features

Clinically, the disorder presents as an atypical myeloproliferative disorder with usually elevated peripheral white blood cell counts. Nonspecific clinical features comprise fatigue, fever, night sweats, and weight loss. CMML often involves extramedullary sites, specifically the spleen, liver, skin, and lymph nodes. CMML can cause myeloid sarcomas in various organs (Taillan et al. 1990; Hancock et al. 1997; Suh and Shin 2000; Akiyama et al. 2002).

Morphology

The hallmark of CMML is peripheral blood monocytosis, with almost always monocytes representing more than 10 % of leukocytes. Monocytes in blood smears are mostly mature, but abnormal granulation, abnormal nuclear lobulation, and/or abnormal chromatin patterns may occur. Neutrophil precursors account for less than 10 % in typical cases. In most patients, dysgranulopoiesis is noted. The bone marrow is hypercellular in three quarters of patients, with prominent granulocytic proliferation an invariable monocytic proliferation. In up to 80 % of patients, microkaryocytes and megakaryocytes with abnormally lobulated nuclei are found. Up to 30 % of cases reveal an increase in reticulin fibers.

Involvement of the Liver and Biliary Tract

The liver is often involved in CMML and shows myelomonocytic infiltrates and sometimes erythroid precursor cells and few megakaryocytes mostly in the sinusoids and portal tracts (Thomas et al. 1981; Pamplona et al. 1996). Infiltration of myelomonocytic cells of the wall of a liver cyst has been described (Akai et al. 2007). Dense sinusoidal infiltration may result in a sinusoidal blockage and portal hypertension (Pamplona et al. 1996). Massive infiltration of the spleen and liver may cause death (Thomas et al. 1981). Involvement of the liver by pyoderma gangrenosum developing in the setting of CMML was reported (Vadillo et al. 1999). CMML was found to be associated with myeloid tumor of the gallbladder (Bartley et al. 2007).

Cytogenetic Features and Molecular Genetic Features

Nonspecific clonal cytogenetic abnormalities were previously found in 20–40 % of patients with CMML, mostly +8, −7/del(7q) and structural abnormalities of 12p. Up to 40 % reveal point mutations of RAS genes at diagnosis or during disease evolution, and an alteration of the RUNX1 gene has been detected (Gelsi-Boyer et al. 2008). Recently, characteristic molecular genetic changes have been identified in patients with CMML (review: Muramatsu et al. 2012), including TET2 mutations (Grossmann et al. 2011; Euba et al. 2012; Pérez et al. 2012) and recurrent spliceosomal gene mutations (SRSF2, U2AF1, SF3B1; Abu Kar et al. 2012; Makishima et al. 2012), and mutations of genes associated with epigenetic regulation (Jankowska et al. 2011). The ASXL1 mutation correlated with an evolution toward an acutely transformed state in patients with CMML (Gelsi-Boyer et al. 2010). Part of CMML patients show novel chimaeric fusion genes involving the RET gene, enhancing monocytic differentiation (BCR-RET and FGFR1OP-RET).

Malignant and Benign Extramedullary Tumor-Forming Myeloid Proliferations

86

Contents

Abstract

Myeloid neoplasms can form extramedullary myeloid tumors or masses, also in the hepatobiliary tract. Granulocytic sarcoma (extramedullary myeloid tumor (EMMT)) is an uncommon extramedullary manifestation of myelogenous leukemias and other forms of myeloproliferation. The gastrointestinal tract is rarely involved, and most patients are under 18 years of age. EMMT is mainly associated with acute myeloid leukemia, the blastic phase of chronic myeloid leukemia, and several types of myeloproliferative syndromes. In the liver, EMMT produces solitary nodular masses or, less commonly, multiple nodular lesions. In tumors composed of neoplastic cells rich in myeloperoxidase, the nodules have a greenish color (chloroma). Histologically, the tumors are composed of a mixture of myeloid cells with diverse degrees of differentiation, including lesions that consist of myeloid blasts. EMMT can also present as neoplasms with predominance of eosinophilic precursors or megakaryoblasts/megakaryocytes. EMMT has to be distinguished from benign extramedullary myeloid proliferations (BEMMPs) that also occur in the hepatobiliary tract. These reactive lesions can grow to important size (tumefactive BEMMP). Rare BEMMPs are characterized by a prominent fibrous matrix (sclerosing variants).

Granulocytic Sarcoma (WHO: Myeloid Sarcoma; Extramedullary Myeloid Tumor (EMMT))

ICD-O code 9930/3

Introduction

Granulocytic sarcoma ((GS); extramedullary myeloid tumor (EMMT); chloroma) is an uncommon extramedullary manifestation of myelogenous leukemias and other forms of myeloproliferation (3–8 %) in which tumorous masses of immature cells of the myeloid lineage develop. The concept was subsequently expanded to include all forms of extramedullary myeloid leukemic infiltrates, and the more comprehensive term extramedullary myeloid tumor (EMMT) is more and more in use, although the term proposed in 1988 was "extramedullary myeloid *cell* tumor" (Davey et al. 1988). In what follows, however, the original term, granulocytic sarcoma (GS) (Rappaport 1966), will be employed throughout. A short history of definitions and terminology is found at the end of this chapter.

Epidemiology and Clinical Features

GS is most commonly situated in the bones, skull, orbit, soft tissues, skin, breast, serosal surfaces, and paranasal sinuses (Huber 1878; Muss and Moloney 1973; Libson et al. 1986; Binder et al. 2000). The gastrointestinal tract is rarely involved, being reported in 4/61 (7 %) lesions (Neiman et al. 1981). GS occurs typically in children (Reinhard and Creutzig 2002; Porto et al. 2004); in fact, 75 % of the reported cases were patients under 18 years of age. GS may present at any time during the course of disease and can even precede the clinical onset of leukemia (Mason et al. 1973; McCarty et al. 1980). However, GS arising in non-leukemic patients does not necessarily progress to AML; in one study, 7 of 16 patients presenting with GS without manifesting leukemia did not develop acute leukemia after 3.5–16 years of follow-up (Meis et al. 1986). The disorders where GS has been observed include AML (the major association), CML (in particular its blastic phase), myeloproliferative syndromes (chronic idiopathic myelofibrosis), essential thrombocythemia, myelodysplastic syndromes, and polycythemia vera. GS may be seen as a de novo lesion without marrow involvement, or as a neoplasm associated with overt leukemia in the marrow, or as a site of leukemia relapse. AML and MDS can relapse as GS/chloroma after bone marrow transplantation (Bekassy et al. 1996; Szomor et al. 1997). In the retrospective EBMT cohort study, 0.7 %, 0.3 %, and 0.2 % of patients transplanted, respectively, for AML, MDS, or CML relapsed with GS/chloroma after allogeneic bone marrow transplantation (Bekassy et al. 1996). It seems that the incidence of GS is rising, and this may be due to prolonged survival of patients with myeloid malignancies. Based on an autopsy series, GS was found in 8 % of patients with AML and in 4 % of those with CML (Liu et al. 1973). It has been proposed that certain features of the abnormal stem cell-derived lineages (e.g., t(8;21); morphology of FAB M2, M4, and M5; expression of CD56, CD2, CD4, CD 7) may be associated with a higher incidence of extramedullary myeloid tumors (Binder et al. 2000).

Granulocytic Sarcoma (GS) of the Liver

GS/chloroma of the liver has been documented in the early literature already (Gade 1884; Fabian 1908; Kchinowloguer 1915; Askanazy 1916), and few reports are available in the more recent literature (Suh and Shin 2000; Alama Zaragoza et al. 2003; Sedinc et al. 2004; Best-Aguilera et al. 2005; Gangane et al. 2008; Hang et al. 2011). In a historical study of 96 observed and reported cases of chloroma, the liver was the site of "chloromatous nodules" in 19 instances (Kchinowloguer 1915). GS of the liver may develop on the background of myeloid metaplasia, with formation of multiple nodules of variable size (Gangane et al. 2008). Clinically, hepatic GS may be silent, present as a space-occupying mass with sequelae as in other larger tumors, or is

seldom associated with important acute jaundice (Alama Zaragoza et al. 2003).

GSs of the liver are solitary nodular masses or develop in the form of multiple nodules. The gross features may vary, the green or greenish color not always being clearly in evidence. Apart from the techniques used to examine the tumors, heterogeneity of differentiation and expression of myeloperoxidase may play a role for such differences. For example, a case of myeloid leukemia has been reported where hepatic perihilar, enlarged lymph nodes were yellow to greenish, whereas numerous GS nodules within the liver substance were gray to yellow, with a "dry" inner zone, resembling caseous necrosis (Fabian 1908). In typical hepatic chloroma, the green color may already be seen in biopsy specimens (Alama Zaragoza et al. 2003).

Histologically, GS are composed of a mixture of myeloid cells exhibiting diverse degrees of differentiation. The lesions may be subdivided into well differentiated, poorly differentiated, and blastic, according to the cytologic criteria reported (Menasce et al. 1999). The myeloid cells may be admixed with stromal cells and cells of the macrophage lineage, sometimes resulting in a starry-sky-like picture due to the presence of phagocytes with tingible bodies. The cells of GS may contain crystalline inclusions that, ultrastructurally, are indistinguishable from Charcot-Leyden crystals (Strauchen and Gordon 2002).

Variant Patterns of GS: Eosinophil (Eosinophilic Granulocytic Sarcoma) and Megakaryocytic Lineages

There are variants of GS/chloroma with a distinct cellular differentiation pattern. One variant is characterized by a high content in eosinophils and their precursors, a lesion termed eosinophilic granulocytic sarcoma or "eosinophilic chloroma" (Benvenisti and DeBellis 1969; Adler and Schaefer 2001). These lesions show dense accumulations of eosinophilic granulocytes (Muller et al. 1987), myelocytes, and few promyelocytes combined with a background of nongranular blasts, accompanied by the presence of Charcot-Leyden crystals, in part phagocytosed by macrophages. Contrary to GS with a predominantly or exclusively neutrophil lineage, myeloperoxidase (MPO) and naphthol-AS-D-chloroacetate esterase (NACE) are absent from eosinophils. Instead, eosinophils contain a peroxidase different from MPO/verdoperoxidase; this eosinophil peroxidase fails to contribute any green color to the macroscopic aspect. Therefore, GS with predominance of eosinophils must not be called "eosinophilic chloroma," because they cannot be green cancers. In addition, the cells in GS can enter a megakaryoblast/megakaryocyte differentiation pathway (extramedullary megakaryoblastic tumors), eventually terminating as acute megakaryoblastic leukemia (Kobayashi et al. 1992; Chubachi et al. 1995; Chan et al. 1996; Hirose et al. 2001). GS in the liver may, similar to non-tumorous involvement in myeloid disorders, be associated with hepatic iron overload/hemosiderosis (Fabian, Butterfield, Fabian).

Table 1 Predominant immunohistochemical phenotype in granulocytic sarcoma

Positivity in high percentage for:
Myeloperoxidase (MPO)
CD 43
Lysozyme
CD117/c-Kit
CD45
CD56
CD13

The histologic identification of GS may be difficult, thus requiring immunohistochemical examinations (Table 1; Davey et al. 1988, 1990; Roth et al. 1995). Reliable markers for a differentiating myeloid cell lineage comprise myeloperoxidase (MPO), lysozyme, and CD13 (Roth et al. 1995; Quintanilla-Martinez et al. 1995; Eelnitoba-Johnson et al. 1996; Audouin et al. 2003). MPO is detectable by use of the monoclonal antibody, MPO-7 (Lepelley et al. 1993). GS cells are variably positive for CD45 (Hudock et al. 1994; Quintanilla-Martinez et al. 1995). Expression of CD56 is frequent in

GS, especially when the marrow blasts have monocytoid differentiation, and immature myeloid cells in GS are frequently reactive for HLA-DR, whereas CD34 positivity of immature myeloid cells is relatively uncommon in GS, except in cases with underlying myelodysplastic syndrome or CML (Chang et al. 2000). Myeloid progenitor cell antigens, CD31 and CD34, can be expressed in GS, and CD43 is expressed in the majority of cases (Hudock et al. 1994). Lysozyme and CD43 together seem to be potent markers for GS (Menasce et al. 1999), and the use of the combination of CD34, MPO, and Leder's chloroacetate esterase stain can help to reach a definitive diagnosis (Mourad et al. 2001). It has been shown that CD99 (MIC2) is commonly expressed in blasts in M1-, M3-, and HLA-DR-negative AML (Zhang et al. 2000) and may therefore show reactivity in a subset of GS cells. Other markers that are variable positive in the GS target cells include elastase, CD15, CD68, and c-Kit (Traweek et al. 1993; Chen et al. 2001). A study of 30 cases showed CD117/c-Kit reactivity in 87 %, MPO 97 %, lysozyme 93 %, CD34 47 %, CD45 84 %, CD43 97 %, TdT 37 %, CD79a 20 %, CD20 10 %, CD3 10 %, and CD10 1 % (Chen et al. 2001).

Granulocytic Sarcoma of the Biliary Tract

Stenosing lesions of intrahepatic bile ducts caused by GS (see below) have to be distinguished from those situations, where neoplastic myeloid cells locate to the tissues surrounding the bile ducts, including the large ducts and causing extrahepatic obstructive jaundice (Gutierret de Guzman et al. 1987; Nakamoto et al. 1987; Case Records of the Massachusetts General Hospital 1988; Mano et al. 2004; Gonzalez-Vela et al. 2006; Hourseau et al. 2006; Sung et al. 2006; Lee et al. 2007; Abid et al. 2010; Bartels et al. 2010; Hachicha et al. 2010; Hwang et al. 2010; Kawamura et al. 2010; Rajeswari et al. 2012). Obstructive jaundice caused by GS has been observed in a child with FLT3-internal tandem duplication with t(8;21) AML (Kawamura et al. 2010). GS of the bile ducts may be followed by AML with multilineage dysplasia and chromosomal abnormalities (Sung et al. 2006).

GS can develop in the main biliary ducts, both in AML and in CML, but obstructive jaundice caused by such lesions had only rarely been reported, and in several patients, GS causing biliary obstruction was related to AML (Lillicrap et al. 1982; King et al. 1987; Gutierret de Guzman et al. 1987; Case records 1988, 1990; Rotter et al. 1992; Fleming and Slone 1997; Matsueda et al. 1998; Jaing et al. 2001; Piccalunga et al. 2007; Table). However, obstructive jaundice in AML can also develop in the absence of a mass in the sense of GS (Goor et al. 2002). One patient developed overt AML 16 months after the onset of jaundice and 11 months after the diagnosis of GS (King et al. 1987). In part of the cases, GS involved the hilar/perihilar region and caused bile duct stenosis, sometimes mimicking Klatskin tumor (Pomeranz et al. 1985; Matsueda et al. 1998; Ascani et al. 2003; Kim et al. 2006). Obstruction of extrahepatic bile ducts with subsequent cholestasis can be caused by GS located to the pancreas (King et al. 1987; Ravandi-Kashani et al. 1999; Servin-Abad et al. 2003).

Histologically, biliary tract GS presents as a tumor-like stenosing mass or as a lesion with transmural infiltration of the duct by myeloid cells with medium-sized round nuclei with central nucleoli and an eosinophilic cytoplasm. Immunohistochemically, the cells are reactive for MPO, CD68, lysozyme, CD45, CD117, and CD43 (Gonzalez-Vela et al. 2006). In some instances, numerous myeloid cells infiltrate the periductal tissue and may form macroscopically greenish sheaths of up to 0.5 cm in diameter ("Glisson tract chlorosis"; Müller 1926). Histologically, the dense myeloid infiltrate fills the Glisson's spaces and can extend into the tissues adjacent to liver lobules, suggesting cirrhotic remodeling at low magnification (Figs. 26 and 27 in Gruber 1930). The myeloid cells may encroach upon intrahepatic bile ducts, associated with bile duct damage ("myeloid leukemic cholangiopathy"). An intricate spatial relationship between leukemia cells and the biliary epithelium has been shown by use of myeloperoxidase

immunohistochemistry, the leukemia cells also encircling the vessels of the peribiliary plexus (Fleming and Slone 1997).

Why Are Bona Fide Chloromas Green?

Myeloperoxidase (MPO; hydrogen peroxide oxidoreductase; EC 1.11.1.7) is a neutrophil lysosomal heme protein essential for optimal oxygen-dependent microbicidal activity of these phagocytes (Arnhold 2004). The importance of MPO is illustrated by an individual with a neutrophil function defect caused by hereditary MPO deficiency (Romano et al. 1997; Petrides 1998; Marchetti et al. 2004). The gene encoding MPO is assigned to human chromosome 17q21.3-q23 (van Tuinen et al. 1987; Inazawa et al. 1989), where it forms a gene cluster together with the lactoperoxidase and eosinophil peroxidase genes (Sakamaki et al. 2000). The three genes are also clustered in the mouse (on the murine chromosome 11; Sakamaki et al. 2002). MPO, itself subject to genetic promoter polymorphisms (Ritgers et al. 2003), is the most abundant neutrophil granule enzyme and catalyzes the two-electron oxidation of ubiquitous chloride to generate the potent bleaching oxidant, hypochlorous acid (HOCl), a halogenation cycle that is important in microbial killing (reviews: Jantschko et al. 2004; Arnhold et al. 2003). The enzyme is a unique peroxidase in having a globin-like standard reduction potential of the ferric/ferrous couple, and the kinetics of the reactivity of ferrous MPO with molecular oxygen has been studied in detail (Jantschko et al. 2004).

During biosynthesis of MPO, the luminal endoplasmic reticulum proteins, calreticulin and calnexin, act as molecular chaperones, associating reversibly with the heme-free glycosylated precursor, apo-Pro-MPO (Nauseef et al. 1998). Neutrophil *primary* granule release (neutrophil degranulation) is dependent on the Rho GTPase, Rac2, as based on studies employing rac2 (−/−) knockout mice, whereas secondary specific and tertiary granule release does not seem to depend on Rac2 (Abdel-Latif et al. 2004). For the identification of cell lineage features, MPO is an early-appearing and very reliable myeloid lineage marker. The protein is detectable in a subset of hemopoietic bone marrow progenitors as well as in granulo-/monocytopoietic cells, whereas other myeloid-related cells including epidermal Langerhans cells lack MPO expression. There is evidence that early myeloid progenitors lack MPO and then enter two pathways, one representing the origin of MPO-positive myeloid cells and the other remaining MPO-negative and delivering non-granulocytic/non-monocytic cells such as Langerhans cells (Scholz et al. 2004). MPO can be purified from freshly isolated blood cells, resulting in a protein preparation which is *green* and has an A430/A280 nm of 0.68 (Xu et al. 1990). This typical color, having led to the term verdoperoxidase (from Latin viridis, green), depends on the porphyrin moiety of MPO's heme component (Newton et al. 1965; Lee et al. 1967; Nichol et al. 1969; Mitsuoka 1969). Crystalline protoporphyrin has been isolated from cells of experimental chloroma (Schultz and Schwartz 1956).

The Concept of Granulocytic Sarcoma: Brief Historical Outline

The lesion has probably first been described in 1811 (Burns 1811). The association of GS and acute leukemia was established in 1893 (Dock 1893), while the term GS was first employed in 1966 (Rappaport 1966). Synonyms include chloroma, chloromyeloma, chloromyelosarcoma, granulocytic leukosarcoma, chloroleukemia, myeloblastoma, chloromyeloblastoma, myelocytoma, myelosarcoma, and leukoma. The 2001 tumor classification of the WHO employs the term myelosarcoma.

The term chloroma (from Greek chloros, green) was coined already in 1853 (King 1853). This author used this term based on the observation that the cut surface of the tumor appears temporarily green under light, owing to the tumor's high content in myeloperoxidase. Chloroma is the "green cancer of Aran" (Aran 1854; see also Turk 1903; Brannan 1926; Edgerton 1947; Ross 1955; Anonymous 1961; Reardon and Moloney 1961; Tran et al. 1962;

Kojima 1963; Wiernik and Serpick 1970; Mason et al. 1973) and is also known as Balfour's disease (Balfour 1835). Both Balfour and, later, Aran (who coined the term "cancer vert" ("green cancer")) described chloroma in the skull and dura. François-Amilcar Aran, born 1817 in Bordeaux (France), was a physician with widespread interests; in 1858, he published an influential book, entitled *Leçons cliniques sur les maladies de l'uterus et de ses annexes*. A major work, his planned *Dictionnaire de Thérapeutique*, remained unfinished owing to his untimely death in 1861 at the age of 44. John Hutton Balfour, born 1808 in Edinburgh, made his MD in 1831, but in 1840 he began giving lectures in botany and became botany professor already in 1841. In fact, he is much more known for his botanical studies, becoming head of the Royal Botanical Garden and Queen's botanist in Scotland. For 30 years, he was dean of the medical faculty in Edinburgh where he first introduced teaching in microscopy. The description of GS represents one of his relatively few medical articles, his opus being clearly dominated by botany, but his description of GS earned him the eponym Balfour's disease. Owing to his strong encouragement of the Palliser expedition, his name was also given to Balfour Pass and Mount Balfour (3,272 m/10,735 ft) in Canada. In 1916, Askanazy used, in addition to chloroma, the term "leukemia with green tumors" (Askanazy 1916).

Benign Extramedullary Myeloid Proliferations

Introduction

Extramedullary hematopoiesis (EMH) refers to the production of blood cells outside the bone marrow and is often a compensatory response to cope with bone marrow failure associated with marrow infiltration, marrow depletion, or marrow hyperactivity in certain chronic anemias (Kumar et al. 1995; review by O'Malley 2007). Benign extramedullary myeloid proliferations (BEMMPs; the so-called myeloid metaplasia) are reactive lesions occurring in diverse extramedullary compartments, consisting of reactive EMH. BEMPP can present as diffuse tissue infiltrations, microfocal alterations, or macronodular tumor-like lesions, the latter sometimes mimicking a neoplastic process. BEMMPs forming tumor-like masses are also termed tumefactive extramedullary hematopoiesis. Tumor-forming BEMMPs are rare lesions that were described in 1945 based on autopsy findings showing intrathoracic tumor-like lesions (Ask-Upmark 1945). A preference of intrathoracic BEMMP lesions was later confirmed by Verani et al. (1980) who collected 55 cases from the literature up to 1980, most cases seen in patients with thalassemia and spherocytosis, while sickle cell anemia as a cause of intrathoracic BEMMP was less often noted in comparison with other hemolytic disorders. Typical localizations of BEMMP include the intrathoracic/paravertebral compartment, skin, salivary and lacrimal glands, lung, spleen, kidney, and liver (see below). In part of tumor-forming BEMMP, the hematopoietic tissue undergoes marked production of extracellular matrix (ECM), with deposition of collagen and other ECM proteins (sclerosing extramedullary hematopoietic tumor (SEMHT)). The proliferations develop as a response to high demands for production of blood elements and are usually caused by hematologic disorders occupying bone marrow spaces, by increased destruction of blood cells, or by hematopoietic growth factors (reviews by Nappi et al. 2003; O'Malley 2007).

Benign Extramedullary Myeloid Proliferations in the Liver

The liver is a central site for early hematopoiesis and possesses a distinct stromal cell microenvironment for stem cell homing and priming for hematopoietic cell lineages. This stromal compartment is maintained in adult livers, and it is therefore not astonishing that the liver is a relatively common site for EMH. In infants, the presence of hepatic hemopoiesis is considered normal up to about 5 weeks of age. The stromal microenvironment is maintained in adult livers which are therefore a relatively common site for EMH. In

the adult liver, BEMMP usually presents as accumulations of hematopoietic cells within sinusoids. In fact, the hepatic parenchyma is one of the most common sites of diffuse BEMMP in patients with hemolytic anemias or myeloproliferative disorders (Ward and Block 1971). The cellular composition of these accumulations varies markedly and ranges from tiny erythropoietic foci with normoblasts to foci containing a mixture of immature and mature erythroid and granulocytopoietic cells, with or without associated megakaryocytes, the latter being rare findings. Apart from diffuse sinusoidal infiltrates, BEMMP can also present as microfocal lesions that are not macroscopically visible.

Nodular Extramedullary Hematopoiesis of the Liver (Tumefactive BEMMP)

Less commonly, BEMMP develops into larger focal lesions or even tumefactive lesions. These lesions, which are also termed nodular extramedullary hematopoiesis of the liver (NEMH-L), occur in the form of solitary or multiple lesions of variable size, involving one or both liver lobes (Kopecky et al. 1986; Wiener et al. 1987; Kopecky 1988; Dardi et al. 1990; Tamm et al. 1995; Lemos et al. 1997; Wong et al. 1999; Priola et al. 2012). Among eight cases with sufficient data compiled from the literature, five were multiple and three solitary lesions (Wong et al. 1999). NEMH-L can present as a solitary space-occupying lesion mimicking a primary liver neoplasm, mainly HCC (Lee et al. 2008), metastatic disease, FNH, or an atypical hemangioma (Wiener et al. 1987; Bradley and Metreweli 1990; Gil-Fernandez et al. 2001; Tamiolakis et al. 2004), thus promoting diagnostic fine needle aspiration (Dardi et al. 1990; Lemos et al. 1997). Metastatic disease may in particular be suspected in case NEMH-L produces several lesions with nodular hepatomegaly (Hervé et al. 2001).

Macroscopically, NEMH-Ls are generally described as nodular and sometimes bulky and rather well-defined lesions that are of medium consistency and show a cut surface that varies from red-brown or tan (in case of high vascularity and/or iron deposition) to grayish white. Sizes of the nodules range from tiny lesions mimicking microabscesses (Kopecky et al. 1986) to 1.5 cm (Hervé et al. 2001), 3 cm (Wong et al. 1999), or even 8 cm (Ma and Au 1999). Massive solitary NEMH-L has been observed in thalassemia (Dewar et al. 1990) and in myelofibrosis (Navarro et al. 2000). The masses may grow rather rapidly, particularly postsplenectomy; in one observation, the first hepatic manifestation was a 3 cm lesion, growing to 6 cm within 3 months (Wong et al. 1999). On the other hand, even very large lesions have been reported to remain unchanged for 4 years (Ma and Au 1999).

Histologically, NEMH-L is composed of normal-looking hematopoietic tissue consisting of all three lineages. Few small cells with a lymphoid morphology may be present. It is not yet known whether such cells may, in addition to a lymphocyte population, represent hematopoietic stem cells. Similar to bone marrow, the hematopoietic tissue contains scattered macrophages with or without stainable iron. In addition, cells with a spindle-shaped morphology are detectable in small numbers (an analogue to marrow stromal cells?). In larger lesions, extracellular matrix may be increased, sometimes with focal fibrosis or sclerosis. In fact, NEMH-L can produce stellate scars visible in MRI and CT (Wong et al. 1999). The adjacent liver substance is compressed in large lesions, and perifocal hepatocytes may show iron overload (Ma and Au 1999). Hematopoietic tissue in BEMMP lesions may undergo adipose transformation ("fatty marrow change"; "fatty replacement"; Yamato and Fuhrman 1987), similar to what can take place in bone marrow. This alteration was also noted in intrahepatic BEMMP (Gupta et al. 2004).

Sclerosing Extramedullary Hematopoietic Tumor of the Liver

Sclerosing extramedullary hematopoietic tumor (SEMHT) is a rare lesion that typically arises in patients with chronic myeloproliferative disorders

(Remstein et al. 2000; Sukov et al. 2009). It can develop in the abdominal cavity, where it can form large solitary masses or multiple nodular tumors (Yang et al. 2002). In one patient, SEMHT involved the lesser omentum and the ligamentum teres of the liver (Kwon et al. 2004). Histologically, elements of the myeloid lineage, including blasts, are embedded in a dense matrix rich in collagen fiber bundles and reticulin fibers. In some cases, the cells situated in the matrix are predominantly bizarre-looking giant cells with lobated nuclei, cells that mimic malignancy but representing megakaryocytes and megakaryoblasts morphologically altered by the sclerosed matrix.

Differential Diagnosis

The most important, and at the same time the most difficult, differential diagnosis of hepatic BEMMP is differentiated hemopoietic elements with a neoplastic character. On exclusively morphological grounds, it is not, or barely, possible to distinguish reactive myeloid proliferations and neoplastic ones in the setting of a malignant myeloproliferative disorder. Neoplastic myeloid disorders morphologically mimicking BEMPP may also develop in the biliary tract. A disseminated myeloproliferative lesion of the gallbladder has been observed in a 63-year-old female in the absence of bone marrow involvement. The patient subsequently developed a neoplastic myeloid disorder that was disseminated throughout inner organs at autopsy, but again with sparing of the bone marrow (Bartley et al. 2007).

Blastic Plasmacytoid Dendritic Cell Neoplasm

87

ICD-O 9727/3

Contents

Abstract

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is an aggressive tumor derived from precursors of plasmacytoid dendritic cells. Novel findings showed that BPDCN originate from myeloid-derived dendritic cells or are related to subtypes of acute myeloid leukemia. The neoplastic cells display a complex immunophenotype, with expression of natural killer cell markers, CD68, CD123, CD303, TCL1, cutaneous lymphocyte-associated antigen, and granzyme B. This is a rare malignancy that mainly occurs in elderly males and has a tendency to involve multiple sites, but almost all patients show skin involvement. The tumor can spread to internal organs and shows early liver metastasis. Hepatic involvement often causes significant hepatomegaly. Histologically, the medium-sized lymphoid-looking neoplastic cells form infiltrates that chiefly occupy portal tracts. The cells typically exhibit cytoplasmic microvacuoles that localized along the cell membrane.

Introduction

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a clinically aggressive tumor which is derived from precursors of plasmacytoid dendritic cells, with a high frequency of cutaneous

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_87

and bone marrow involvement and leukemic dissemination. Synonyms of BPDCN include blastic NK-cell lymphoma, agranular CD4+ natural killer cell leukemia, blastic natural killer leukemia/lymphoma, and agranular CD4+CD56+ hematodermic neoplasm/tumor. Novel findings suggest that cells of BPDCN originate from myeloid-derived dendritic cells or are related to subtypes of acute myeloid leukemia (Menezes et al. 2014). BPDCN is a rare neoplasm that more often occurs in males, mostly in elderly patients, with a mean age at diagnosis of 61–67 years, but the tumor can also develop in children. The malignancy tends to involve multiple sites, but almost all patients show skin involvement, followed by bone marrow, lymph nodes, and overt leukemia (Petrella and Facchetti 2010; Pagano et al. 2013; Riaz et al. 2014; Shi and Wang 2014).

The patients commonly have asymptomatic solitary or multiple skin plaques or nodules, measuring from a few millimeters to up to 10 cm, often associated with locoregional lymphadenopathy. Low-level bone marrow and peripheral blood involvement are observed in up to 90 % of cases, and may dominate the clinical picture, sometimes in the absence of skin manifestations. Cytopenia is a common finding, sometimes associated with megaloblastic erythroid maturation and tumor-induced monocytosis. Systemic B symptoms are rare at presentation. After an initial phase of minor involvement, the bone marrow and peripheral blood are invariably affected in the course of the disease. In advanced disease, inner organs and the central nervous system are infiltrated. In most cases, a fulminant leukemic phase develops in the final segment of disease.

Morphology and Immunocytochemistry

The neoplasm is composed of a diffuse, monomorphous infiltrate of medium-sized blast cells, usually with a rather scant neoplasm that is agranular and gray blue on the Giemsa stain. The neoplastic cells display a lineage-negative CD4+/CD56+/CD43+/HLA-DR+ immunophenotype, initially suggesting an NK-cell derivation. Reactivity for the plasmacytoid dendritic cell-associated antigens CD123 (IL 3-alpha-chain receptor), BDCA-2/CD303, TCL1, CLA (cutaneous lymphocyte-associated antigen), and the interferon-dependent MxA (myxovirus A) protein is observed (Pilichowska et al. 2007; Hama et al. 2009; Cota et al. 2010). CD68 is expressed in about 50 % of cases, with a discrete dot-like reaction product, and at least part of the cells express granzyme B. Part of BPDCN cells are reactive for CD31/PECAM-1 (platelet endothelial cell adhesion molecule 1; Salva et al. 2014). In a systematic study, simultaneous expression of five markers, CD4, CD56, CD123, CD303, and TCL1, was found in only 46 % of patients (Julia et al. 2014). A novel marker for BPDCN cells is the protein, SPIB (Montes-Moreno et al. 2013).

What Are Plasmacytoid Dendritic Cells?

Immature dendritic cells (DCs) include plasmacytoid DCs, or so-called lymphoid DCs, and myeloid DCs and represent early-committed progenitor cells capable of differentiating into antigen-presenting DCs central to the initiation of primary T-cell-based immune responses.

Plasmacytoid DCs (pDCs; previously called, plasmacytoid T cells and plasmacytoid monocytes) are an immune cell type that forms the bridge between innate and adaptive immunity (Dzionek et al. 2002; Cao and Liu 2007; Cao 2009; Jegalian et al. 2009). These unique cells were observed initially in 1958 and called plasmacytoid T cells (Lennert and Remmele 1958). In 1997 it was shown that pDCs are able to differentiate into DCs and were given the additional name pre-DC2 cells (Grouard et al. 1997). DC2 differentiate from CD34+ progenitors and then plasmacytoid precursors which circulate in the blood as veiled cells and enter lymph nodes and mucosal tissues in response to immune activation (Brière et al. 2002). Less than 0.1 % of peripheral blood mononuclear cells are pDCs. They express BDCA-2, CD123 (but not the

markers of myeloid DCs, CD13, and CD33), and the adaptor protein CD2AP (Marafioti et al. 2008). In a recent study, CD56(+) dendritic-like cells were suggested to be the normal counterpart of cells characterizing blastic plasmacytoid dendritic cell tumors (Osaki et al. 2013). Analysis of a congenital BPDCN suggested that CLTC-ALK fusion is a primary event in a multipotent hematopoietic progenitor cells giving rise to plasmacytoid dendritic cells (Tokuda et al. 2014).

Liver Involvement

BPDCN can spread to internal organs and show early liver metastasis. Liver involvement may clinically present as hepatomegaly (Cui et al. 2014). In one patient, a liver scan revealed a 10 cm heterogeneous hypoechoic mass in the left liver lobe, and ultrasound-guided needle biopsy showed a well-demarcated, discrete infiltrate, mainly in portal tracts, of atypical lymphoid cells with an immunophenotype typical for BPDCN (Choi et al. 2010).

The infiltrate consists of medium-sized lymphoid-appearing cells that display a slightly irregular-shaped nucleus with smooth chromatin. The cytoplasm is mostly scant and never shows granulation. A minority of the cells are either small or large. Typically, the neoplastic cells show microvacuoles in the cytoplasm that localize along the cell membrane, resembling a string of pearls, and cytoplasmic pseudopodia.

Differential Diagnosis

Unusual forms of myeloid leukemia may mimic plasmacytoid dendritic cell leukemia (Sano et al. 2008). In fact, acute myeloid leukemia carrying cytoplasmic mutated nucleophosmin [NPMc (+) AML] shows considerable clinical and morphological overlap with CD4+/CD56+ neoplasms. However, cytoplasmic nucleophosmin is not detectable in blastic plasmacytoid dendritic cell neoplasias (Facchetti et al. 2009).

Pathogenesis, Cytogenetic Abnormalities, and Molecular Genetic Features

BPDCN is derived from precursor plasmacytoid dendritic cells (review: Riaz et al. 2014). Molecular profiling indicates that the neoplastic ells of BPDCN originate from the myeloid lineage and, in particular, from testing dendritic cells (Sapienza et al. 2014). About two thirds of patients with BPDCN have an abnormal karyotype, but specific chromosome aberrations are lacking so far. Several recurrent chromosomal abnormalities have been encountered, including 5q21 or 5q34 (the most common), 12p13 and 13q13–21 (both in two thirds of patients), 6q23–qter, 15q, and loss of chromosome 9. Recurrent deletions occurred in chromosomes 4 (4q34), 9 (9p13–p11), and 13 (13q12–q31). TET2 and TP53 mutations have frequently been observed in BPDCN (Jardin et al. 2011). BPDCN cells display aberrant activation of the NF-kappaB signaling pathway (Sapienza et al. 2014). TET2 (ten eleven translocation 2) mutations (Alayed et al. 2013) and EWSR1 gene rearrangement (Cao et al. 2014) have been detected in BPDCN. Recently, deleterious mutations in IKZF3, HOXB9, UBE2G2, and ZEB2 have been identified in BPDCN (Menezes et al. 2014).

Hepatobiliary Hodgkin's Disease

Hodgkin Lymphoma of the Hepatobiliary Tract

88

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_88

Abstract

In most cases of classical Hodgkin lymphoma (HL), the neoplastic cells are derived from mature B lymphocytes at the germinal center stage of differentiation. The WHO classification separates nodular lymphocyte-predominant HL from classical HL, the latter subdivided into nodular sclerosis classical HL, lymphocyte-rich classical HL, mixed cellularity classical HL, and lymphocyte-depleted classical HL. All these forms of HL can occur in the hepatobiliary tract, either as rare primary lesions or as secondary manifestations of HL primarily located elsewhere. HL in the liver presents as one of several phenotypes, including miliary lesions, solitary or multiple nodular lesions, large masses, and rare diffuse patterns of involvement. In addition, HL can involve bile ducts and liver-associated lymph nodes with subsequent biliary obstruction mimicking primary bile duct cancer. The histologic presentation of hepatobiliary HD is the same as that in other organs. HL can be associated with several nonneoplastic hepatic alterations. These include a distinct type of vanishing small bile duct disease, granulomatous hepatitis, sclerosing cholangitis, and sinusoidal ectasias mimicking hepatic peliosis.

Introduction

Hodgkin lymphomas (HL) form a group of malignant lymphoproliferative disorders based on a neoplastic expansion mostly of a distinct type of B cells. In more than 98 % of classical HL, the neoplastic cells are derived from mature B cells at the germinal center stage of differentiation. HL presents in the form of several well-defined phenotypes that have an impact on the biology of disease. The principal clinical histologic features, their impact on the natural history of HL, and etiologic issues of HL have been elucidated and reviewed in detail. An outline referring to the history of the HL concept is added at the end of the chapter.

Table 1 2008 WHO histological classification of Hodgkin lymphoma

		ICD-O code
Nodular lymphocyte-predominant Hodgkin lymphoma	(NLPHL)	9659/3
Classical Hodgkin lymphoma	(CHL)	9650/3
Nodular sclerosis classical Hodgkin lymphoma	(NSHL)	9663/3
Lymphocyte-rich classical Hodgkin lymphoma	(LRCHL)	9651/3
Mixed cellularity classical Hodgkin lymphoma	(MCHL)	9652/3
Lymphocyte-depleted classical Hodgkin lymphoma	(LDHL)	9653/3

Selected References (Ziegler 1911; Favre and Croizat 1933; Jackson and Parker 1947; Harrison 1952; Lukes and Butler 1966; Lukes et al. 1966; Cross 1969; Lukes 1971; Jaffe et al. 2001; Thomas et al. 2004; Küppers and Hansmann 2005; Re et al. 2005; Schmitz et al. 2009; Smith 2010; Hjalgrim 2012; Küppers et al. 2012; Carbone et al. 2013; Gobbi et al. 2013; Ansell 2014).

The *WHO histological classification of HL* is shown in Table 1.

Epidemiology

HL accounts for 25–40 % of all lymphomas developing in Caucasians (much rarer in Orientals and persons from underdeveloped countries), with one peak of occurrence in the second to third decades and another in the sixth decade (Nakatsuka and Aozasa 2006). Involvement of the pediatric age group has been recognized early (von Hüttenbrenner 1871; Hübener 1893) and is an important manifestation of HF. The prevalences of the diverse subtypes of HL differ considerably. NLPHL accounts for approximately 5 % of all HL, patients being predominantly male and in the 30–50 years age group. Classical HL accounts for 95 % of all cases and hence is the

main form of HL. Classical HL shows a bimodal age distribution in Western countries, with a first peak at 15–35 years of age and a second peak in late life. NSCHL, the dominant subtype of classical HL, accounts for about 70 % of classical HL in Europe and North America and is more often encountered in resource-rich areas than in resource-poor areas. The incidence of NSCHL is similar in males and females and has its peak at 15–34 years of age. LRCHL is rare and comprises about 5 % of all classical HL. The majority of patients are male, with a higher age than in other forms of classical HL. MCCHL accounts for 20–25 % of classical HL and is more frequent in HIV-infected individuals and in developing countries. Seventy percent of the patients are male, with a mean age at diagnosis of 38 years. LDCHL forms the rarest subtype of classical HL, accounting for less than 1 % of cases in Western countries. Up to 75 % are male, with a median age at diagnosis of 30–37 years. LDCHL is often associated with HIV and is more often found in developing countries.

Epstein-Barr virus (EBV) infection has been associated with an increased risk of HL chiefly in young adults, based on the growing amount of evidence (Hjalgrim et al. 2003). The presence of EBV had a beneficial effect on the length of failure-free survival of patients with classical HL (Krugmann et al. 2003). Classical HL is a rare complication after solid organ transplantation (Hood et al. 1996). Lymphomas resembling HK developing after posttransplant lymphoproliferative disorder ("Hodgkin-like PTLD") have been reported (Stern et al. 2005). The relationship between bona fide posttransplant HL and the intriguing HL-like posttransplant disorders is not yet clarified.

Liver Involvement in Hodgkin Lymphoma

Introduction

Thomas Hodgkin described liver involvement incidentally (Hodgkin 1832); but in a critical analysis of Hodgkin's original cases, the diagnosis of HL involving the liver was accepted in only two cases (Fox 1936). Wilks noted hepatic involvement in 7 of his 13 cases (Wilks 1865). Manifestations of HL, albeit in a highly variable spectrum of patterns, were later reported and discussed many times.

Selected References (Murchison 1869; Barié 1875; Brauneck 1889; Reed 1902; Longcope 1903; Fabian 1911; Ziegler 1911; Rolleston 1912; Barron 1926; Coronini 1928; Gruber 1930; Chevallier and Bernard 1932; Foulon 1932; Hartfall 1932; Wallhauser 1933; Sternberg 1936; Baker and Mann 1939; Goldman 1940; Symmers 1944; Jackson and Parker 1944a, b; Newman and Pushkin 1951; Beatty 1954; Klein 1955; Levitan et al. 1961; Skovsgaard et al. 1982).

Liver involvement is uncommon in HL in early disease, but the incidence increases in the advanced phases of disease, becoming as high as 70 % in certain series (detailed review of the old literature, Wallhauser 1933; Givler et al. 1971; Bagley et al. 1973). In a study of 74 cases, the duration from diagnosis of HL to clinical evidence of liver abnormalities was 1–6 months in 23 %, 7–12 months in 10.8 %, 13–18 months in 10.8 %, and 19–24 months in 12.2 % and was then slowly decreasing as a function of time (Levitan et al. 1961). These data markedly depend on the clinical features, the patterns of liver involvement, and the choice of techniques for assessing liver involvement (radiology, peritoneoscopy, hepatic needle biopsy, autopsy). Direct hepatic involvement in visceral Hl is a frequent event (Cowan and Trounce 1973; Diebold and Temmim 1980; Urbano-Marquez et al. 1981; Kiewe et al. 2004) and may be the presenting manifestation of HL (Trewby et al. 1979). It seems that there is a correlation between splenic involvement and HL manifestations in the liver: The risk of hepatic involvement correlates closely with splenic involvement (Colby et al. 1981), and generally the liver is not involved when the spleen is not tumoral. In a study of 250 exploratory laparotomies for HL, hepatic tumoral localizations were disclosed by liver biopsies in 16 % of the patients with splenic involvement (Diebold and Temmim

1980). There are, however, exceptions to this "rule" where the liver has shown manifestations of HL in the absence of splenic involvement (Glatstein et al. 1969; Aisenberg 1971; Farrer-Brown et al. 1971; Piro et al. 1972; Michel et al. 1973; Spinelli et al. 1975; Fialk et al. 1979; Sulkes et al. 1979; Gordon et al. 1984). Among 472 liver biopsies performed within a large investigation, 11 biopsies from 10 patients (2.4 %) had infiltrates consisting of Reed-Sternberg cells and abnormal histiocytoid cells against the characteristic background of lymphocytes together with neutrophil and eosinophil granulocytes (Skovsgaard et al. 1982). In an autopsy study of 57 cases of malignant lymphoma, hepatic involvement was demonstrated in 67 % of HL versus 56 % in NHL (Okazaki et al. 1985). In another investigation of 112 consecutive patients with malignant lymphoma, hepatic lymphomatous involvement was found more frequently in NHL (16 %) than in HL (8 %) (Sans et al. 1998).

Involvement of the liver by HL often results in hepatomegaly. Hepatomegaly was observed clinically from 2.3 % to 80 % in a series reported before the modern treatment strategies of HL (Murray 1908; Burnam 1926; Uddströmer 1934; Baker und Mann 1939; Goldman 1940; Levitan et al. 1961; Biemer 1984). In a large study of 875 patients with HL, 32.5 % had hepatomegaly, and out of the 122/875 patients autopsied, hepatomegaly amounted to 79.6 % (Levitan et al. 1961). There are differences of opinion regarding the onset of hepatomegaly, some describing it as a sign of the terminal stages of disease (Ackerman and del Regato 1954), whereas others described hepatomegaly as a presenting feature, using the terms "*. . .forme hépatique et forme hépatosplénomégalique de la maladie de Hodgkin*" ("hepatic form and hepatosplenomegalic forms"; Pène 1952; Pène et al. 1955). Considering all types of HL, hepatomegaly seems to be infrequent in early HL and, when present, may represent a nonspecific reactive phenomenon (Biemer 1984). It is more frequently observed in LDCHL (Neiman et al. 1973). Some authors, basing their judgment on autopsy material primarily, claimed that hepatic involvement with organomegaly is a late manifestation of HL (Pène et al. 1955). In later phases of the disease, hepatomegaly can reflect direct, primary or secondary, organ involvement (Chim et al. 2000). Among 308 patients with HL analyzed in a more recent study, hepatomegaly was registered in 34, was more frequently encountered in stages III and IV versus I/II, and was more frequent in MCCHL and LDCHL than in LPCHL and NSCHL (Brinckmeyer et al. 1982).

Hepatic HL can be associated with jaundice and cholestasis. For example, in a study of 421 patients with HL presenting as a cholestatic febrile illness, 7.4 % of liver involvement was found (Cervantes et al. 1996). A icteric/cholestatic complication of HL has already been described in the end-nineteenth century and then in the 20th century (Brauneck 1889; Peiser 1913; Beatty 1954; Mac-Clure et al. 1959; Levitan et al. 1961; Bouroncle et al. 1962; Casirola and Dionigi 1966; Bombara et al. 1970; Barge and Potet 1971; Matsko and Zhukovets 1971; Perera et al. 1974; Piken et al. 1979; Liebermann 1986; Birrer and Young 1987; Marinone et al. 1989; Jansen and van der Lelie 1994; Warner and Whitcomb 1994; Cervantes et al. 1996; Yalcin et al. 1999; Gupta et al. 2002; Opeskin et al. 2003; Omidvari et al. 2004). Peiser described a patient with jaundice and histologic demonstration of HL infiltration mainly of the portal tracts and suggested to compress the small bile ducts as a mechanism of cholestasis (Peiser 1913). Cholestatic hepatitis may be mimicked in situations of massive hepatic infiltration by HL tissue resulting in hepatic failure (Lefkowitch et al. 1985). Cholestasis in patients with HL is sometimes caused by tumorous obstruction of extrahepatic bile ducts, in part also by enlarged perihilar or retroperitoneal lymph nodes (Michalitschke 1919; Diessner und Heck 1958; Razemon et al. 1961; Juniper 1963; Justin-Besançon et al. 1963; Sanbe and Shirato 1966; McNulty 1971; Pariente et al. 1981; Martin et al. 1992; Abe et al. 1997). Other causes of jaundice and/or cholestasis in HL comprise hemolysis, viral hepatitis, and drug toxicity. In the absence of any direct liver involvement by HL, a paraneoplastic cause of cholestasis has also been

postulated (Jansen and van der Leite 1994). The unique cholestatic syndrome caused by intrahepatic ductopenia in HL is discussed in a separate paragraph. HL can present as, or cause, acute hepatic failure (Gunasekaran et al. 1992; Weiner et al. 1994; Tornero et al. 1998; Rowbotham et al. 1998; Vadillo Serrano et al. 2002; Olnes et al. 2003; Vardarelli et al. 2004; Woolf et al. 2008; Hong et al. 2010). In part of these cases, hepatic insufficiency is caused by massive infiltration of the organ by HL (Tornero et al. 1998; Rowbotham et al. 1998; Karmacharya et al. 2014). Fulminant hepatic failure in HL has been described to be a paraneoplastic manifestation of HL (Dourakis et al. 1999), albeit of unknown mechanism.

What Are the Criteria for Involvement of the Liver in HL?

The involvement of the liver in HL is a key element for the success of abdominal pathologic HL staging for harvesting adequate liver samples, including laparoscopy, laparotomy, and/or hepatic needle biopsy, to date more and more assisted by modern imaging techniques. However, liver biopsy is still a standard in the assessment of hepatic involvement by HL, provided a reliable diagnosis can be done in a biopsy sample of the liver. But, as seen in the data given below, the highly variable figures of prevalence suggest, among true variances of involvement, differing types of criteria used to detect bona fide HL in contrast to nonspecific accompanying lesions (see below). Therefore, the question of suitable criteria has been addressed in the literature. In a now classical work by Lukes (1971), biopsies of the liver obtained at laparotomy have revealed three types of lesions: HL of nodular sclerosis, mixed, diffuse fibrosis, and reticular types (in accordance to the then employed nomenclature); the granulomas of uncertain origin (described in more detail in a later paragraph); and portal lymphocytic infiltration associated with proliferation of ductules, also of uncertain origin. Expectedly, difficulties in diagnosing HL mainly arise in small, microscopically detectable lesions. As emphasized by Lukes, the criteria for involvement in case of small hepatic lesions are the same or similar to those for small foci elsewhere. This author proposed that the evidence of a discrete lesion with features of one of the histologic types is essential as well as conclusive evidence of a Reed-Sternberg cell variant, although a diagnostic Reed-Sternberg cell is not required: a large, abnormal mononuclear cell with a huge nucleolus is an acceptable form. Lukes has it that particular caution must be used in interpreting small portal lymphocytic lesions in which there are a few abnormal mononuclear cells (Lukes 1971). It is advisable to perform numerous sections in order to search for the target cells (Dich et al. 1989). In case the large atypical cells are not evidence even after multiple sections, but the infiltrate and the configuration of the lesion nevertheless suggest HL, we propose to denote such lesions, suspicious of HL, not otherwise specified (NOS).

Primary Hodgkin Lymphoma of the Liver

HL can develop as a primary extranodal disease (Padhi et al. 2012), of which the liver manifestation is an uncommon variant. HL limited to the liver has been rarely reported (Goia 1935; Symmers 1944; Guemes Diaz 1965; Gascard et al. 1970; Khapat'ko and Shestakova 1983; Zaman et al. 1991; Chim et al. 2000; Yokomori et al. 2008; Gota et al. 2009). Based on the biologic nature of HL, it is difficult to distinguish between a putative origin of HL primary to the liver in comparison with a secondary hepatic manifestation of HL originating elsewhere.

Macroscopic Features of the Liver in Hepatic HL Involvement

There have been attempts to classify the hepatic manifestations of HL. Coronini, Gruber, and Foulon distinguished the following types of hepatic involvement by HL: (1) capsular, (2) nodular or granulomatous lesions localized to the portal triad, (3) diffuse, and (4) encroachment upon or invasion of blood vessels (Coronini 1928; Gruber 1930; Foulon 1932).

Hepatic Nodular Manifestations of HL

Nodular involvement is manifest at laparoscopy in the form of white liver spots or nodules (Sans et al. 1998), and the nodular growth pattern is also grossly recognized in larger biopsy specimens (Fialk et al. 1979). In an autopsy study of HL and NHL patients, intrahepatic nodular lesions over 1 cm in diameter were macroscopically identified in 33 % of patients with HL, more frequent than in patients with NHL (22 %; Okazaki et al. 1985). In nodular hepatic HL, hypoechogenic foci have been observed, proved by biopsy to consist of HL tissue (Marjanska-Radziszewska et al. 1996). The macroscopically detectable lesions range in size from miliary foci to large nodules. The miliary pattern is characterized by tiny round lesions of gray to white color (Fraenkel and Much 1910a), easy to be confounded with granulomas. They may be grouped around intrahepatic bile ducts (Peiser 1913). When being cut, they are, however, more consistent than granulomas, and caseification is usually not seen in these small lesions. Similar to the spleen, these small lesions may reveal a characteristic bright color on a darker background, resulting in what has been called a "quartz splinter on granite" pattern (Dietrich 1908). These tiny nodules may grow to numerous, frequently very firm pea-sized lesions, sometimes with ill-defined borders (v. Hüttenbrenner 1871). Larger hepatic nodules may be solitary lesions, reaching up to 5 cm in diameter (Yamasaki 1904), or multiple (Sternberg 1898; Fabian 1911; Meyer 1911; Stahr and Synwoldt 1922; Barge and Potet 1971) and may then resemble metastases of other tumors (Peiser 1913; Russell 1914; Chim et al. 2000), all the more so as, in case they are located in peripheral parts of the liver, they may show a shallow central concavity (Barge and Potet 1971) or, rarely, typical umbilication (Fabian 1911). The coarse nodular manifestations of HL in the liver, resulting in markedly prominent nodular masses, were already recognized by Langhans (Langhans 1872), but intrahepatic tumorous manifestations in HL in progressive, and particularly non- or inadequately treated, disease are highly variegated.

This polymorphous gross picture is illustrated by an autopsy case of non-treated patient with HL, documented by Dr. Greenfield in 1876, showing the complex gross features of liver manifestations in this disease:

> On its (the liver's) surface were seen a number of irregular, somewhat prominent patches, either single or made up of a number of clustered nodules of small size, with surrounding injection. On sections these were found to be irregular infiltrating masses of new growth, which appeared to have become caseous. In addition to these nodules there were very marked thickeling and infiltration of the tela conjunctiva of the portal vein and bile ducts, extending into the liver; and here there were seen small patches or irregularly ramified infiltration of translucent, waxy-yellowish colour, apparently starting at the periphery of the lobules, these, with the caseous masses before described, being the most evident morbid appearances. (Greenfield 1876)

On the cut surface, medium-sized or large nodules are usually well delineated and exhibit a grayish-white, homogeneous, or spotted tissue, sometimes with central necrosis or hemorrhage (Russell 1914) resulting in a grossly visible central concavity (Barge and Potet 1971). Large nodules may be accompanied by much smaller but still grossly detectable foci, a part of which are located to the portal tracts. The large nodules may show a hyperemic and/or hemorrhagic rim of red-blue color (Meyer 1911). In HL lesions of high cellularity, the cut surface is pale gray to gray-red, said to resemble fish meat, and typically bulges (protuberant nodules of Sternberg; Sternberg 1913), whereas sclerosing forms of HL rather reveal a flat and firm cut surface of whitish color.

In case of marked sclerosis, the cut surface has been described to be "dry," and in such situations, the cut surface also reveals furrows and septa dividing the nodule into "acinar-like" compartments (Langhans 1872) or structures resembling "pseudolobules" (so-called secondary tuberculinization; Gilbert and Weil 1900). Intrahepatic septa-like structures have already been described by Masson and thought to follow the geometry of the portal fields ("*on constate que le foie est parcouru par des trainées fibreuses irrégulières qui suivent les bandelettes porte*" ["one notes that the liver is traversed by irregular fibrous tracts following the portal fields"]; Masson 1956). Other reports described that the firm linear lesions, or lesions like beads-on-a-string, seemed to follow the geometry of the intrahepatic bile ducts (Meyer 1911).

Old autopsy reports from the pre-chemotherapy period specify that HL masses in the liver are first smooth and elastic to become more and more firm with time, until the lesions may be very hard (the "hard lymphosarcoma"), producing a screeching sound when being cut with the knife (v. Hüttenbrenner 1871). In case of advanced fibrosclerosis of nodular lesions, these have been reported to resemble syphilitic gummas macroscopically (Jackson and Parker 1944b). This apparent evolution of the lesions, also reported several times in the old literature to occur in lymph nodes and other organs in Hodgkin disease not modified by therapy, is of interest insofar, as sclerosis, now regarded as a subtype of HL, may be part of the natural development of disease ("period of sclerosis"; Masson 1956). Particularly in larger nodules, necrosis may be seen with the naked eye, resulting in yellow-gray or dirty-looking, opaque masses. Dry granular necroses sometimes reminiscent of a caseification necrosis may be encountered and have been reported to form an arborizing network or a geographic pattern (Kaufmann 1909). Rarely, lardous necrotic lesions resembling those in the Hodgkin spleen are seen. The "red porphyry" appearance seen in the spleen involved by HL is not observed in the liver, owing to its different histologic architecture and composition. In lymphocyte-depleted HL, grayish and sometimes numerous nodules are seen scattered throughout the liver (Jackson and Parker 1944b).

Some presentation forms of hepatic HL are characterized by macroscopically yellow lesions caused by a complex mixture of infiltration, necrosis, and accumulation of lipid-laden macrophages (xanthomatous/xanthomatoid reaction). The lesions may present as miliary hepatic micronodules of brown-yellow color (Fraenkel and Much 1910b). One may encounter focal circumscribed cream-colored lesions or yellow streaks along the course of the portal areas (Jackson and Parker 1944b), likely to reflect a distinct pattern of spread of the disease. In case of a xanthomatoid/xanthogranulomatous reaction (accumulation of lipid-laden macrophages), yellow flecks are seen within the nodules or around the nodules in a yellow crescent-like structure, already recognized in other organs in the older literature (Dietrich 1908). This presentation may be modified by hemorrhagic spots or a focal brown discoloration owing to deposition of iron pigment, particularly after treatment. Rarely, the nodules show a greenish hue due to leakage of bile into the lesions. Superficially placed lesions may form confluent beds of coalescing nodules, thus forming plaque-like multinodular tumors that may occupy large areas of the capsular liver surface. The lesions may extend along the lymphatic drainage of the hepatic ligaments in a beads-on-a-string pattern, especially in the region of the round ligament. Although most of nodules have a spheroid shape, lesions with a streak-like or stellate morphology also occur (Hauck 1918; Kaufmann 1922). From the periphery of such nodules, furrows are seen to traverse the adjacent capsule of the liver, probably representing tissue retraction due to scarring. In addition, there may be streaky and in part arborizing lesions seen from the capsular surface of the organ (Sternberg 1913) or inside the organ, where they encircle atrophic parts of the lobular hepatic parenchyma (Langhans 1872). It has been suggested that grossly visible arborizing lesions may take their origin from the connective tissue sheath of portal and/or hepatic venous branches (Langhans 1872).

Diffuse Infiltration of the Liver

In contrast to miliary or macronodular forms, a diffuse pattern of liver infiltration by HL cells is a rare but severe form of disease that can cause fatal hepatic failure (Karmacharya et al. 2014).

Hepatic Capsular Manifestations of HL

These are rare lesions but have already been documented in old autopsy studies (Meyer 1911). In an autopsy study of 112 cases, an exclusively capsular manifestation was found in 2 cases only (Levitan et al. 1961).

Histopathology of Hepatic HL

The reliable diagnosis of HL in a liver biopsy is frequently difficult owing to the small sample size and the scarcity of diagnostic Reed-Sternberg cells and their variants (Gupta et al. 1999). It has, however, been emphasized that a primary diagnosis of HL involving the liver should only be made if diagnostic Reed-Sternberg cells are seen (Jaffe 1987), because nonspecific infiltrates are found in approximately 50 % of liver biopsies from patients with HL (Leslie and Colby 1984). If only a so-called inflammatory component is seen, the liver should not be considered to be involved with HL (Jaffe 1987).

Miliary Lesions

The miliary pattern of HL in the liver is histologically characterized by one of several types of lesions. Frequently, one notes collections consisting of atypical histiocytoid cells with prominent nucleoli, surrounded by small lymphocytes, in the absence of bona fide RS cells. The diagnostic significance of such lesions is questionable but has been proposed as being consistent with HL, provided that diagnostic evidence of the disease is present elsewhere (Kadin et al. 1971). In addition, small hepatic manifestations of HL may frequently defy classification of HL, even in cases where marked fibrosis suggesting nodular sclerosis is present. In a study of 51 *untreated* patients with HL, laparotomy staging revealed small foci of HL in liver biopsies of 9 patients. These lesions were largely confined to portal tracts and only rarely contained typical RS cells; they were registered as "unclassified" Hodgkin lesions (Kadin et al. 1971). Submiliary lesions, usually not detectable with the naked eye, are usually between 100 and 200 mm in size (Skovsgaard et al. 1982). Mixed portal tract infiltrates containing variable numbers of Reed-Sternberg cells and eosinophils are observed (Kiewe et al. 2004).

Portal Tract Infiltration

Portal tract involvement is rather typical for microscopic hepatic manifestations of HL and is characterized by an infiltration of the portal tract spaces by lymphocytes, atypical large mononuclear (nondiagnostic) cells, and diagnostic Reed-Sternberg cells (Chim et al. 2000), the pattern of the diagnostic cells depending on the type of HL. The HL tissue may extend from the portal tracts to the parenchyma of zone 1 (Davey and Doyle 1973). The lesions may then grow to a size to be recognized macroscopically as miliary-like micronodules (Peiser 1913). They can be associated with hepatocyte atrophy or necrosis, hepatocyte necrosis being found in up to 90 % in some studies (Davey and Doyle 1973) and the formation of lesions resembling interface lesions seen in active chronic hepatitis. Reed-Sternberg cells are capable to invade the parenchyma in these destructive lesions. As the lesions progress, the expanding infiltrates in the involved portal tracts may grow to the next portal tract, thus forming what may be called "lymphomatous bridging," and these lesions then become confluent and form larger tumor nodules (Davey and Doyle 1973). The portal tract infiltrate is sometimes accompanied by fibrosis, not only in NSHL lesions. However, a marked fibrosclerotic reaction in the portal triads seems to be more frequent and more prominent in hepatic NSHL. A contribution of eosinophils is regularly seen, also in the interface lesions,

but the density of eosinophil infiltrates is highly variable.

In the absence of diagnostic Reed-Sternberg cells, the combination of lymphocytes, eosinophils, and large atypical nondiagnostic cells in portal tracts should raise the suspicion of involvement by HL. Immunostaining for Reed-Sternberg cell markers may be helpful in these situations in order to uncover cells that are not easily identifiable in H&E sections. In some cases, several foci of HL are arranged in the portal tracts in the form of ductocentric, ringlike, or crescent-like structures that may compress the ducts (Peiser 1913; Coronini 1928). These ductocentric nodules may, in the larger intrahepatic ducts, be associated with fibrosis, resulting in a thick sheath encircling the ducts (Meyer 1911), somewhat resembling advanced primary sclerosing cholangitis. It has been suggested that portal tract infiltrates apparently encroaching upon small, interlobular bile ducts may cause cholestasis/jaundice (Peiser 1913), sometimes even with a clinical presentation simulating acute cholestatic hepatitis (Marinone et al. 1989). Old observation showed that small interlobular bile ducts embedded in HL tissue of portal tracts may resist destruction for longer time periods, epithelial necrosis being rather uncommon (Coronini 1928). Longer-standing involvement of the liver by HL may result in fibrosis of the liver (Mignot et al. 1979).

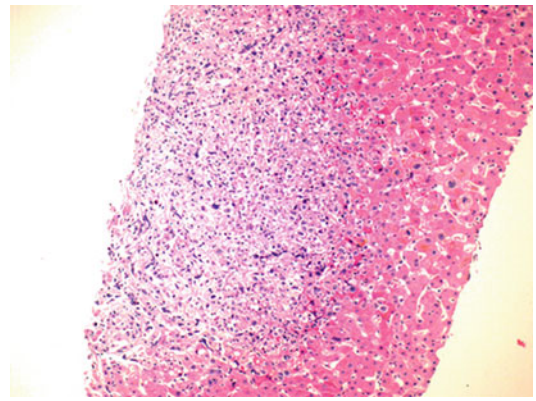

Fig. 1 Liver involvement in Hodgkin disease. A nodule consists of a mixed population of cells, with some large and atypical forms (needle biopsy; hematoxylin and eosin stain)

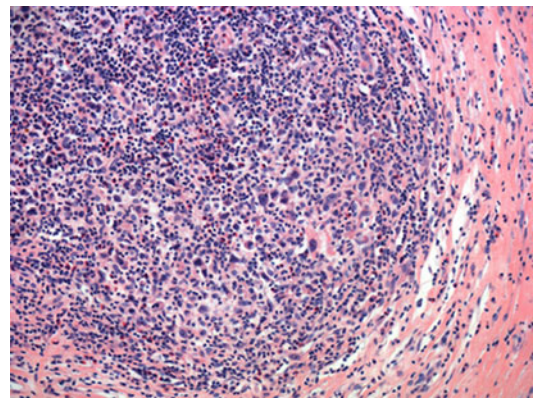

Fig. 2 Hodgkin lymphoma in the liver, mixed cellularity. Within a lymphocytic infiltrate, numerous Hodgkin cells are noted. The nodule is limited by slight fibrosis (hematoxylin and eosin stain)

Nodular Hepatic Lesions of HF

Nodular hepatic lesions histologically consist of dense infiltrates of lymphocytes, macrophages, eosinophils, Hodgkin/Reed-Sternberg cells, and Sternberg giant cells (Figs. 1, 2, 3, 4, and 5). There is recent evidence that giant cells in HL originate from mononucleated progenitors that divide and subsequently re-fuse (Rengstl et al. 2014). Plasma cells and mast cells may also be encountered in the infiltrate. The nodules may coalesce to conglomerates, thus effacing the liver architecture at these places. The cellularity of larger HL nodules is highly variegated, cellular areas and hypocellular, fibrosclerotic areas changing from one place to the other, sometimes interspersed with necroses containing nuclear debris (Russell 1914). Larger nodules are sometimes accompanied by miliary or submiliary foci of HL in their vicinity or may be connected by lymphoma tissue to infiltrated or non-infiltrated portal tracts. In the latter situation, a septal type of fibrosis may ensue, in particular in the nodular sclerosis variant of HL. Large HL nodules sometimes show few lymphocytes in their center, whereas dense lymphocytic infiltrations are seen at their periphery, mainly around small blood vessels (Russell 1914). Large nodules may integrate intrahepatic bile ducts, the contour of the ducts

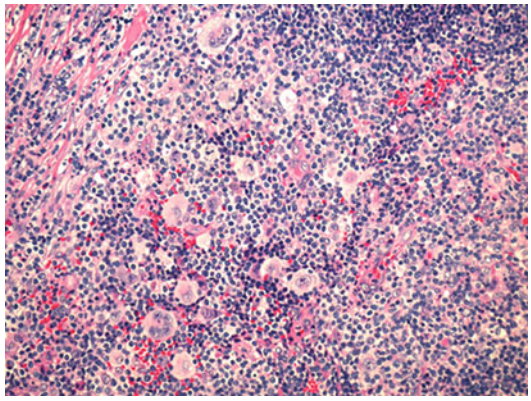

Fig. 3 Hodgkin lymphoma in the liver. Numerous Hodgkin cells and Reed-Sternberg cells are observed (hematoxylin and eosin stain)

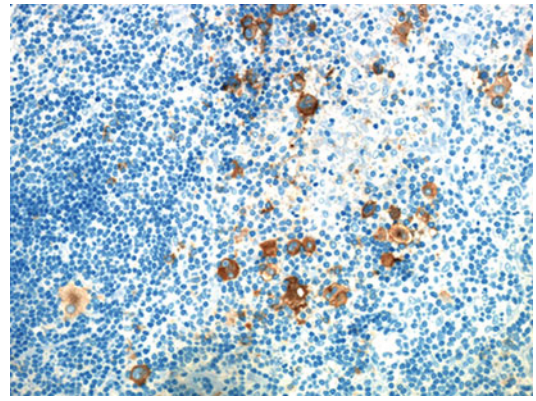

Fig. 5 Hodgkin lymphoma in the liver. Hodgkin cells and Reed-Sternberg cells show positivity for CD15 (CD15 immunostain)

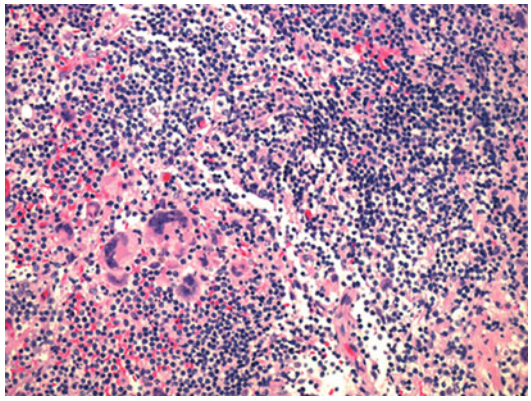

Fig. 4 Hodgkin lymphoma in the liver. In this case, Sternberg giant cells are found (*left half* of figure; hematoxylin and eosin stain)

being visible for some time, ending up with atrophy (with few remnants of cholangiocytes remaining) or even complete duct destruction with substitution by lymphoma tissue. In this situation, bile may leak out of the ducts and stain the HL tissue, particularly in case of lymphoma necrosis (Russell 1914). The neoplastic cell lineage of HL close interacts, within the tumor cell niche, with macrophages and dendritic cells, this interactome regulating a complex immune reaction (review: Tudor et al. 2014).

In addition to intrahepatic bile ducts, intrahepatic portal vein branches may be invaded, sometimes followed by portal vein thrombosis. In an autopsy study, this phenomenon was observed in 23 % of the cases, and this feature tended to occur more frequently with the lymphocyte-depleted type of HL (Davey and Doyle 1973). At the periphery of the nodular lesions, infiltration of hepatic parenchyma may occur, associated with hepatocyte plate atrophy and fatty change of hepatocytes (Russell 1914; Symmers 1944; Sherlock 1955) or even complete destruction of parenchyma. This atrophy has been observed already in old autopsy studies, described, e.g., as hepatocytic "spindle cells" or "spindle-shaped liver cells" (v. Hüttenbrenner 1871). Very rarely, HL may localize to lesions preexisting in the liver, e.g., hepatic angiomas (Toncini and Venzano 1981).

Hilar/Perihilar HL of the Liver and Large Bile Duct Involvement by HL

Involvement of the perihilar hepatic lymph nodes, together with those of the retroperitoneal space and/or the mesentery, causing compression of the large bile duct and thus jaundice, has been described in several reports, sometimes with formation of huge conglomerate masses (Fraenkel and Much 1910a; Meyer 1911; von Jaksch 1913; Weinberg 1917; Michalitschke 1919; Razemon et al. 1961; Martin et al. 1992). Interestingly, these clinical reports describe obstructive

jaundice and in part very large periductal lymphomas, but no prestenotic dilatation of the large hilar bile ducts. On the other hand, Russell described an autopsy case with nodular manifestations of HL in the liver, associated with impressive saccular dilatations of large bile ducts close to the hepatic hilum, these ducts being filled with a dark and viscous bile ("*dilatatio cystica circumscripta ductuum biliferorum*"), whereby some of these cystic structures seemed to follow the larger and infiltrated Glisson's tracts into the liver substance (Russell 1914). Rarely, periductal enlarged lymph nodes involved by HL may bulge into the duct lumen. That enlarged lymph nodes involved by HL exert obstructive effects is exemplified by nonvisualization of the gallbladder in HL of the cystic lymph node (Wee et al. 1970).

Seven patients with direct involvement in the perihilar/hilar tissue compartment were described in detail by Coronini (1928). In two patients, perihilar involvement with biliary obstruction was induced by involvement of hilar/perihilar lymph nodes by HL. In one patient, a perihilar lymphoma had led to kinking of the choledochal duct (Coronini 1928). Direct perihilar tissue involvement was detected in six patients of the extensive analysis of Coronini. Rarely, involvement of the large bile duct close to the hepatic hilum presents in the form of firm and flat nodes developing in the bile duct wall and causing stenosis (Meyer 1911; "Gallengangsgranulomatose"; Coronini 1928), thus clinically mimicking Klatskin's tumor. In other situations, a single bean-sized nodule of HL has been observed in the wall of the choledochal duct (Meyer 1911). Rarely, the entire mucosa of the large bile ducts is seeded by flat tumor nodules, separated from each other by clefts, causing lumenal stenosis (Stahr and Sywolt 1922). Histologically, the latter authors noted that these ductal wall lesions had a transmural extension and were rich in Reed-Sternberg cells, a HL tissue of high cellularity prevailing in the deeper parts of the lesions, while a tissue of lower cellularity was found more close to the mucosal surface. These ductal/periductal nodules may reach 1.5 cm in thickness, encircle the bile ducts, and induce filiform stenosis associated with prestenotic dilatation of the biliary tract (Coronini 1928), sometimes with sacculiform dilatations of the ducts close to the hilum (Russell 1914). Intramural growth of HL tissue in large bile ducts has later been confirmed (Ochoa and Keene 1970; Martin et al. 1992; Abe et al. 1997). In some patients, only duct strictures causing intermittent or persistent obstructive jaundice were found (Diessner and Heck 1958). Fibrotic HL lesions located to the bile ducts may produce imaging features indistinguishable from sclerosing cholangitis (Tartar and Balfe 1990). Biliary and portal vein strictures may also develop following HL therapy (Roberts et al. 2012).

Invasion and Spread of Hodgkin Lymphoma Within the Liver

Invasion of blood vessels and lymphatics by HL has been described by several authors (Reed 1902; Jeanselme and Marchal 1926; Coronini 1928; Callender 1930; Jackson and Parker 1944b; Sayhoun and Eisenberg 1949; Varadi 1960; Rappaport and Strum 1970; Strum et al. 1971; Rappaport et al. 1971; Naeim et al. 1974; Kirschner et al. 1974). But there are also informations in the literature showing the case against (Lamoureux et al. 1973). Rarely, HL reveals a nodal intrasinusoidal invasion pattern mimicking that of anaplastic large cell lymphoma (Lee et al. 2004), suggesting that HL cells can undergo a distinct homing pattern to, and expansion in, specific vascular channels. In the liver, several histopathologic patterns suggest an invasive phenotype of HL. The probably most early phases of involvement, when a specific infiltrate is found to partially occupy the portal tracts, are difficult to judge in regard to invasion, because it is currently still unknown as to how the neoplastic cells of HL reach the liver tissues. It is suggested that the distinct cells circulate in the blood and achieve access to the portal tracts or sinusoidal compartments of the liver by specific homing mechanisms followed by egress of the cells into the extravascular compartments.

In fact, some authors claimed that HL primarily invades the liver within the portal tract spaces

(Schmorl 1922; Sternberg 1936), whereas others proposed that HL extends along the periportal spaces (Fabian 1911; Ziegler 1911) or along the major intrahepatic bile ducts and the portal vein and its branches (Chevallier and Bernard 1932; Sternberg 1936). Spread along the portal tracts is suggested by the typical distribution of xanthomatous yellow streaks that follow the portal course in some cases of hepatic HL (Jackson and Parker 1944b). Dense accumulations of HL infiltrates containing Reed-Sternberg cells may be explained, at least at the beginning of the process, by proliferative expansion of the cells. That the apparently rather dense connective tissues located to the portal tracts allow a rapid infiltration by leukocytes is well known from diverse inflammatory processes (portal hepatitis), illustrating that lymphocytes are potently capable to invade the portal tract space. It may be surmised that the cells of HL can do the same thing, but the mechanisms are not known. On the other hand, expansion of the process beyond the limiting plate and thus into the liver lobules will require invasion rather than proliferative growth alone. Similarly, spread along the intrahepatic bile ducts and blood vessels necessarily involves an invasive phenotype of the neoplastic cells of HL. As described above, Reed-Sternberg cells can be observed within the lumina of hepatic sinusoids, and this will need specific homing and adhesion mechanisms. The fate of such cells in regard to later growth patterns (infiltration of the perisinusoidal space) is not established, but there is some morphologic (and thus indirect) evidence that miliary or submiliary HL growths found within the lobular parenchyma may take their origin from cells primarily settled in the sinusoids.

Invasion of lymph vessels, veins, and arteries by HL has been reported several times (Reed 1902; Jeanselme and Marchal 1926; Coronini 1928; Callender 1930; Jackson and Parker 1944b; Sayhoun and Eisenberg 1949; Varadi 1960). Vascular invasion by HL tissue/cells has been observed in lymph nodes, the incidence of vascular invasion in the original lymph node biopsies being highest in LDHL and decreasing in MCHL, NSHL, and LRCHL (Naeim et al. 1974). It is of importance to note that lymph node vascular invasion is associated more frequently with liver, lung, or bone marrow involvement, either initially or within 1 year in most of the cases analyzed in one study (Strum et al. 1971). Vascular invasion of lymph nodes or the spleen of patients with HL was associated with a high incidence of extranodal organ involvement in other investigations of several hundred tissue samples (Rappaport and Strum 1970; Rappaport et al. 1971). Similarly, HL vascular invasion in the spleen was associated with hepatic and bone marrow involvement, early relapse, and shortened survival (Kirschner et al. 1974). Simonds first noted HL lesions invading the portal vein (Simonds 1926), and this feature was confirmed in later studies (Davey and Doyle 1973). Other types of hepatic vessels have been found to be invaded in an autopsy study (Libansky et al. 1962). The most detailed histopathologic analysis found in the old literature is that of Coronini (Coronini 1928). He described several patterns of vascular lesions occurring in HL, also in the liver. The lesions comprise subendothelial granuloma-like proliferations, associated with endothelial damage, in portal vein branches, a ringlike phlebocentric granulomatosis (granulomatous phlebitis) of portal vein branches resulting in occluding venous thrombosis, and a massively stenosing lymphomatous invasion of large portal vein branches at the liver hilum (lymphomatous phlebopathy), sometimes with accumulation of Reed-Sternberg cells in the markedly thickened portal venous intima. In patients with hilar/perihilar involvement, he also observed an angiodestructive invasion of hepatic artery branches by HL, sometimes with impressive arrosion of the adventitia, a marked granulomatous reaction and/or arterial tissue and tumor necrosis, destruction of the elastica interna, and obliteration of the lumen and with accumulation of Reed-Sternberg cells within the altered media and intima (lymphomatous arteriopathy; Coronini 1928). These hepatic arterial lesions may be associated with necrosis of bile ducts (Coronini 1928), owing to ischemic cholangiopathy/cholangitis.

The neoplastic cells in HL, including cells with the features of Hodgkin and/or Reed-Sternberg cells, can circulate in the peripheral blood (Varadi

1955, 1960; Keiser 1960; Libansky et al. 1962; Hayhoe et al. 1978; Malfitano et al. 1980; Riccardi et al. 1980), sometimes in high numbers leading to what has been termed Reed-Sternberg cell leukemia (Cavalli et al. 1981). The source of these cells is not clear, but it has to be emphasized that peripheral blood mononuclear cells of patients with HL can give rise to permanently growing Hodgkin/Reed-Sternberg cells (Wolf et al. 1996). In regard to the liver, Reed-Sternberg cells have been observed within hepatic sinusoids (Priesel and Winkelbauer 1926; Coronini 1928; Barge and Potet 1971). In his extensive work in hepatic HL involvement, Coronini depicts three large elongated cells located in the sinusoids, most probably representing Sternberg giant cells (Coronini 1928; Fig. 2), a finding which is of interest in the light of target cell homing in HL. A very similar change is depicted in a work published 2 years earlier, again with huge cells with irregular or lobulated nuclei (not representing megakaryocytes) within the sinusoids (Priesel and Winkelbauer 1926). The preparations were from a small child with a generalized lymphomatous disease with numerous hepatic nodules; it is, based on the description, however not certain whether this child had bona fide HL. A convincing figure of Reed-Sternberg cells clearly situated within sinusoids is found in the work of Barge and Potet (Barge and Potet 1971; their Fig. 3).

How Frequent Are HL Infiltrates in the Liver in Extrahepatic HL?

This question has been addressed in rather large number of reports based on autopsies, but using highly variable criteria for identifying HL in the liver, with an incidence range of 10–70 % (Ziegler 1911; Wallhauser 1933; Sternberg 1936; Symmers 1944; Jackson and Parker 1944a; Ackerman and del Regato 1954; Davey and Doyle 1973; Colby et al. 1981). Detailed informations were obtained in a study of 875 patients with HL, 300 (34.3 %) presented with clinical evidence pointing at liver disease such as hepatomegaly and/or abnormal liver function tests. Of this group with clinical signs of liver disease and histologic proof of HL, 112 cases (44 %) were autopsied (Levitan et al. 1961). Of these 122 cases, 74 (66 %) revealed HL involving the liver and 38 (34 %) did not. In the latter group, however, all the livers exhibited some abnormality of major or minor degree. Of the cases with proven hepatic HL involvement, 86.5 % presented with diffuse infiltration, 10.8 % with nodular lesions, and 2.7 % exhibited mixed lesions. Both liver lobes were involved in most cases. Among 59 autopsies of patients with HL, intrahepatic HL was found in 41 or 70 % (Davey and Doyle 1973). In an autopsy study of 80 patients with HL from the time period 1972 to 1977, 54 patients had residual HL, and among 52 of these where the liver was autopsied, 33 had liver involvement (63 %; Colby et al. 1981). Different figures were obtained in liver biopsy studies, likely to be due to an earlier diagnostic approach in comparison with the late stages observed in autopsies. It has been maintained that silent liver involvement can be demonstrated early in the course of the disease by liver biopsy (Pène 1952). In a total of 472 liver biopsies performed in 308 patients with HL, only 2.4 % showed hepatic HL infiltrates consisting of Sternberg-Reed cells and abnormal lymphohistiocytic cells against a background of lymphocytes together with neutrophilic and eosinophilic granulocytes. These infiltrates formed foci of 100–200 mm diameter. This prevalence of bona fide HL involvement is somewhat lower than that in other studies (Rosenberg and Kaplan 1970; Glatstein et al. 1970; Kadin et al. 1971; Abt et al. 1974; Hellman 1974). In a further eight patients of the study of Skovsgaard and coworkers, infiltrates were found that had all the characteristic features of HL except the presence of Sternberg-Reed cells (Skovsgaard et al. 1982). In this large biopsy series, the most frequent finding was lymphocytic infiltration in portal tracts (in 56 % of biopsies), but was of moderate or severe degree in 20 % and 1 % only, respectively. This feature was followed in frequency by focal necrosis (24 %). It has been shown that changes found in liver biopsies taken at the end of staging operations instead at the beginning (a procedure preferred by many surgeons, because no further

manipulations are required) can readily be differentiated from the changes found in HL (Brown et al. 1981).

Is There a Preference of Certain HL Variants to Manifest in the Liver?

This question is difficult to answer due to the fact that the type of lesions found in the liver may or may not correspond to extrahepatic histologic patterns of HL. In an early autopsy study where access to histology was available for 39 cases, it was impossible to classify the intrahepatic HL infiltrates according to then used Lukes classification (Davey and Doyle 1973). This can, at least in part, be due to the phenomenon that extranodal spread, including the liver, is more prevalent in advanced disease and that there is convergence of the morphotypes of HL as a function of progression (Naeim et al. 1974). Nodular lymphocyte-predominant HL (NLPHL; nodular paragranuloma) is different clinically and also in regard to extranodal spread from other variants of HL (Bodis et al. 1997; Diehl et al. 1999). Clinically, most patients present with early stage disease (Ann Arbor I/II; Pappa et al. 1995), but 28 % of patients have presented with advanced stage disease and some of these cases have pursued an aggressive and even fatal clinical course (Hansmann et al. 1984; Trudel et al. 1987). Overall, liver involvement in NLPHL is regarded as rare (Pappa et al. 1995). Of 145 patients with NLPHL, 13 % of the involved sites were extranodal, 4 of them concerning the liver (Hansmann et al. 1984). Among 13 patients with NLPHL (10 with Ann Arbor stage III or IV), four exhibited liver involvement, in two patients with a macroscopic mass; the lesions were focal in two and multifocal in two patients, respectively (Siebert et al. 1995). Among 16 patients with NLPHL, six liver specimens were reviewed (needle or wedge biopsies), four having evidence for NLPHL involvement. None of the involved livers had grossly identifiable lesions. Small to large collections of mature-looking lymphocytes were present in the portal tracts of three of the cases, and varying numbers of LP cells with the immunophenotype typical for NLPHL were also present in this tissue compartment. The fourth case had intralobular and not portal tract involvement, and the numbers of L&H cells and of Reed-Sternberg cells were very low (Chang et al. 1995). The histopathologic differential diagnosis of NLPHL in the liver includes classical HL, T-cell-rich B-cell lymphoma involving the liver (Khan et al. 1993; Fraga et al. 2002), and B-lineage NHL. From a large autopsy study of 122 cases, it turned out that exactly half of the hepatic lesions were what was then termed Hodgkin granuloma (i.e., not LDHL), and of these 82.3 % showed almost exclusive involvement of the portal tracts (Levitan et al. 1961). For LDCHL, liver involvement has been documented by few liver biopsies (Neiman et al. 1973). In the setting of autopsies, liver involvement has been observed in eight out of nine necropsies (Neiman et al. 1973). It seems that portal vein invasion tends to be more frequent in LDCHL (Davey and Doyle 1973).

Hepatic Involvement by Variant Richter's Syndrome

Variant Richter's syndrome can involve the liver (Reddy and Thompson-Arildsen 2010). Hepatomegaly has been described as a feature of this disorder (Brecher and Banks 1990). A progressively enlarged liver has been reported in a patient who developed classical HL 4 years after the diagnosis of Rai stage II (Binet B) chronic lymphocytic leukemia, without liver histology (Nemets et al. 2003). Among nine patients with Richter's syndrome described by Foucar and Rydell, two showed a histology compatible with lymphocyte-depleted HL and were, therefore, likely to be variant Richter's syndrome. At autopsy, one of these two patients exhibited extensive hepatic infiltration with enlarged, confluent portal areas forming actual tumor nodules less than 5 mm in size (Foucar and Rydell 1980).

Differential Diagnosis

Histologically, the main differential diagnoses include lymphomatous lesions that produce cells resembling Hodgkin and Reed-Sternberg cells. These neoplasms mainly include T-cell-rich B-cell lymphoma and so-called Hodgkin-like peripheral T-cell lymphoma/PTCL (Mori et al. 2014). It has been suggested that nodular lymphocyte-predominant HL and T-cell/histiocyte-rich B-cell lymphoma might be endpoints of a spectrum of one disease (Hartmann et al. 2013).

Nonneoplastic Hepatic Manifestations of HL

Vanishing Bile Duct Syndrome in Hodgkin Lymphoma

A syndrome of "idiopathic" intrahepatic cholestasis occurs in some patients with HL, caused by a distinct ductopenic disorder. Secondary intrahepatic ductopenia (vanishing bile duct syndrome; VBDS) usually in the absence of direct HL infiltration of the liver is a rare but critical cause of cholestasis with or without jaundice in patients with HL; the disorder is thought to be a paraneoplastic manifestation of HL and may result in intractable fatal liver damage (review: Nader et al. 2013). Fatal liver failure due to VBDS can ensue despite HD remission (Aleem et al. 2013). The pathogenesis of HL-associated VBDS is not known. That HL as such is in some complex manner involved is supported by the observation that the small bile duct disorder may show resolution following successful therapy of HL (Crosbie et al. 1997). The differential diagnosis of cholestasis in HL due to VBDS/ductopenia comprises nonobstructive HL-associated cholestasis (see above), obstruction due to infiltration of the bile ducts by HL tissue (Ochoa and Keene 1970; Chaudhari et al. 2013), large extrahepatic bile duct obstruction by HL masses (Sanbe and Shirato 1966; McNulty 1971; Pariente et al. 1981; Martin et al. 1992; Abe et al. 1997), and extrahepatic biliary stricture subsequent to radiotherapy of the upper abdomen (Cherqui et al. 1994).

Selected References (Cavalli et al. 1979; Hubscher et al. 1993; Gottrand et al. 1997; de Medeiros et al. 1998; Ludwig 1998; Allory et al. 2000; Rossini et al. 2000; Yusuf et al. 2000; Ozkan et al. 2001; Ripoll et al. 2002; Liangpunsakul et al. 2002; Guliter et al. 2004; Ballonoff et al. 2008; Leeuwenburgh et al. 2008; Pass et al. 2008; Foramiti et al. 2011).

Sclerosing Cholangitis in Hodgkin Lymphoma

Apart from the well-established association with inflammatory bowel disease, primary sclerosing cholangitis (PSC) has been associated with other diseases, which are often cited as single case reports, including HL. Two patterns of bile duct disease resembling sclerosing cholangitis have been described. In the first pattern, fibrosing HL lesions situated in the walls of larger bile ducts produce a radiographic picture mimicking primary sclerosing cholangitis (PSC), with sometimes marked stenosis (Tartar and Balfe 1990; Gupta et al. 2002). The second pattern is characterized by PSC-like larger bile duct alterations in the absence of proven bile duct involvement by malignancy. In the adult age group, a first report concerned three men, of whom one patient had Crohn's disease of the colon. In these three patients, primary sclerosing cholangitis was diagnosed 2, 11, and 17 years before diagnosis of HL, and all three had then advanced biliary cirrhosis prompting referral for liver transplantation (Man et al. 1993). In a pediatric patient with HL involving the liver, biopsy disclosed a morphology compatible with sclerosing cholangitis (Gupta et al. 2002). The pathogenesis of the association of HL and PSC, if this is not a mere coincidence, is unknown. It has been suggested that immune suppression associated with long-standing and advanced liver disease or immunosuppressive drug therapy may predispose PSC patients to HL (Man et al. 1993).

Hepatic Granulomas in Hodgkin Lymphoma

Hodgkin lymphoma (HL) is well known to be associated with a granulomatous reaction in several organs and tissues (Brincker 1970; Kadin et al. 1970, 1971; Goldman 1970; Colby et al. 1981; Brooks 1982; Johnson et al. 1990; Arai et al. 1992), e.g., in the bone marrow, but also in the liver (Atwood et al. 1966; Brinker 1970; Stolzenbach et al. 1976; Sacks et al. 1978; Koene-Bogman 1978; Pak and Friedman 1981; Skovsgaard et al. 1982). In a study of 459 liver biopsies from 308 patients with HL, granulomas were detected in only 2 %, suggesting the rareness of this finding (Skovsgaard et al. 1982). The development of a marked granulomatous reaction can, similar to the situation of NHL, even be a prominent manifestation at the outset of HL (Lerza et al. 2002). In a study of 51 untreated patients, granulomas were detected in otherwise uninvolved tissues in 14 % of the patients (Kadin et al. 1971).

It was at first considered that hepatic granulomas in HL might be an early tissue expression of this neoplasm (Atwood et al. 1966; Brincker 1970); however, there is no evidence for this, with very few exceptions (Goldman 1970). HL, similar to NHL, may masquerade as "idiopathic" liver granulomas (Aderka et al. 1984), so that the presence of hepatic granulomas without clear cause should make one consider HL or NHL. Usually, the granulomas in HL present as noncaseating epithelioid cell nodules with or without a significant lymphocyte seam, but Langhans giant cells are usually sparse or lacking. Central fibrinoid necrosis was occasionally seen, whereas Schaumann and asteroid bodies were not observed (Kadin et al. 1971). A caseating reaction in the granulomas in the absence of mycobacterial infection is exceedingly rare (Johnson et al. 1990). In the liver, HL-associated granulomas are chiefly located to the portal tracts (Kadin et al. 1971). It is established that lymph nodes draining an area harboring malignancy can show epithelioid granulomas, sometimes to a degree histologically mimicking sarcoidosis and reflecting marked macrophage activation in conjunction with a cell-mediated immune reaction directed to tumor antigens (Nadel and Ackerman 1950). There is evidence that at least a part of the granulomas observed in conjunction with HD represent a reaction to oily radiographic contrast media used in lymphangiography (Pak and Friedman 1981), although it has been claimed that the granulomatous lesions in HL do not really resemble reactions to lymphangiography, mainly based on the observation that the heavily lipidized foreign body-type granulomas developing shortly after oily lymphangiography do not occur in HL (Kadin et al. 1970, 1971). But it has been shown that, as a function of time, lipid-rich lipogranulomas with vacuolated cells slowly transform into sarcoid-like granulomas of the type encountered in HL (Pak and Friedman 1981). A sarcoidosis-like granulomatous reaction has been observed following chemotherapy for HL (Merchant et al. 1994). The histiotype of granulomas occurring in HL may rarely deviate from the "standard" granuloma. Very rarely, hepatic granulomas of the liver in HL have been found to be of the caseating type, in the absence of tuberculosis (Johnson et al. 1990). Apart from typical epithelioid granulomas with a variably developed peripheral rim of lymphocytes, the fibrin-ring granuloma-type of lesion has also rarely been encountered in the liver in HL (in 4 % among 23 patients with such granulomas; Marazuela et al. 1991).

Whether the presence of epithelioid granulomas in HL, including granulomas in the liver, is of prognostic significance has been suggested and discussed in few reports, but a conclusive answer to this question requires more and prospective studies (O'Connell et al. 1975; Sacks et al. 1978; Chopra et al. 1995). In a larger analysis of 55 previously untreated patients with HL and associated granulomas, survival and relapse-free survival were significantly different in favor of the granuloma group in comparison with 553 patients without granulomas (Sacks et al. 1978). A later study revisiting the significance of granulomas (with one of the authors of the just mentioned 1978 study), involving 89 HL patients with granulomas and with a longer follow-up, resulted in a different conclusion: after long follow-up, the relapse-free survival advantage was no longer apparent (Abrams et al. 1988).

Lymphoid Hepatic Lobular Infiltration in the Absence of Bona Fide HL Infiltration of the Liver

The presence of lymphoma in the liver at staging may be difficult to confirm histologically when infiltrates are focal and/or nondiagnostic, i.e., without detectable Hodgkin or Reed-Sternberg cells. Focal lymphocytic infiltrations of the liver may, in the otherwise proven presence of HL, suggest hepatic manifestation of this disease. But how frequent are such infiltrates? In a study of wedge and needle liver biopsies from 123 consecutive staging laparotomies for HL, 12 biopsies revealed discrete lobular lymphoid aggregates. In this investigation, there were nine cases of hepatic involvement by HL and one of extensive portal infiltrates by inflammatory cells, but none of these specimens contained the distinctive parenchymal lymphoid aggregates. The lobular aggregates varied from a few lymphocytes clustered within sinusoids to large aggregates entrapping hepatocytes (Leslie and Colby 1984). The nature of these intralobular lymphoid infiltrations has not been clarified so far, but they may represent an immune reaction to unknown, eventually HL-associated antigens.

Nodular Regenerative Hyperplasia of the Liver

Infiltration of the liver substance by HL cells and tissue, associated with complex vascular abnormalities and a deranged blood flow, can result in nodular regenerative hyperplasia/NRH, a recurrent alteration of the liver in HL patients (Lopez et al. 2014).

Hepatic Sinusoidal Changes in Hodgkin Lymphoma

Hepatic sinusoidal dilatation (HSD) is characterized by the widening of sinusoids that may involve the entire liver lobule or predominate in periportal, midzonal, or pericentral areas. Peliosis hepatis, first described in 1916 under this term (Schoenlank 1916), differs from HSD by the formation of intraparenchymal blood-filled spaces ("lakes") without preferential location (Degott and Potet 1984), although there may be transitions or overlaps between the two lesions. Hepatic peliosis is characterized by oval or irregular, multiple blood-filled spaces within the liver parenchyma, the cavities ranging in size from less than 1 mm to several centimeters. In a study of 906 consecutive liver biopsies, sinusoidal dilatation unrelated to passive hepatic congestion was observed in 26 (2.9 %), and in 21 out of 26 the final diagnosis was a neoplastic or granulomatous disease, but in only half of them was there evidence of neoplastic or granulomatous infiltration of the liver (Bruguera et al. 1978). Sinusoidal dilatation (HSD; sinusoidal ectasia) occurring in the context of HL not associated with direct liver involvement has repeatedly been reported (Bain et al. 1982; Bruguera et al. 1987; Kakar et al. 2004). The examination of liver biopsy specimens from 46 patients with HL revealed sinusoidal dilatation with a predominantly centrilobular and mid-lobular localization in 50 %, more frequently in patients with (90 %) than in those without (20 %) systemic symptoms of disease. The prevalence of these alterations was not related to the stage of HL or the existence of hepatic infiltration by HL (Bruguera et al. 1987). From the descriptions, it is difficult to judge whether sinusoidal dilatation fulfilled the criteria of peliosis hepatis, but at least in part of the cases, these lesions may in fact represent, or may evolve to, bona fide peliosis hepatis (Pasquier et al. 1973; Iwai et al. 2002; Kleger et al. 2009), although peliosis in HL has been suggested to be an infrequent association (Bhaskar et al. 1990).

Cytogenetic and Molecular Features

LP cells in NLPHL show clonally rearranged immunoglobulin genes. The variable region of the immunoglobulin heavy chain genes have a high load of somatic mutations. In contrast to other forms of HL, latent EBV infection is consistently absent from LP cells but may be detectable in nonneoplastic lymphocytic bystander cells. In

80 % of NLPHL cases, aberrant somatic gene mutations have been found, involving PAX5, PIM1, RhoH/TTF, and MYC.

In classical HL, HRS cells contain clonal immunoglobulin gene rearrangements in more than 98 % of cases. In rare cases, T-cell receptor gene rearrangements had been detected. HRS cells have lost many of the typical B-cell lineage markers and express a host of aberrant markers. This is in part caused by a downregulation of early B-cell factor 1 (EBF1), a major B-cell transcription factor (Bohle et al. 2013). The transcription factor NF-kappaB is constitutively activated in HRS cells. There is recent evidence that HL is associated with genetic variations at both HLA and non-HLA loci, including loci at 2p16, 5q31, 6p31, 8q24, and 10p14. A susceptibility locus for HL is on chromosome 19p13.3, involving TCF3 (or E2A), a regulator of B- and T-cell lineage commitment (Cozen et al. 2014).

Both proliferation and survival of HL Reed-Sternberg cells require this activity, which is comprised of the p50 and relA subunits. It was shown that EBV-negative Reed-Sternberg cells reveal enhanced expression of NF-kappaB2/p52 and RelB-containing NF-kappaB DNA-binding activity and that CD30 triggers the noncanonical NF-kappaB activation pathway. Hodgkin cells and Reed-Sternberg cells display a disturbed cell cycle regulation with an abnormality short G1 phase (Tzankov et al. 2005). The p18INK4c gene, encoding a cyclin-dependent kinase (CDK) inhibitor interfering with the Rb-kinase activity of CDK6/CDK4, is silenced in HL through epigenetic promoter hypermethylation (Sanchez-Aguilera et al. 2004). Epigenetic inactivation of the putative tumor suppressor with proapoptotic activity, RASSF1 A, has been found in HL (Murray et al. 2004). Mutations of the JAK regulator SOC-1 occur and are associated with nuclear STAT5 accumulation in HRS cells. As discussed above, overexpression of CD30 is a typical feature of neoplastic cells in HL. CD30 is a member of the tumor necrosis factor/nerve growth factor receptor superfamily and is the receptor of the cytokine, CD30 ligand (CD30L; Gruss and Herrmann 1996). CD30 is expressed transiently on activated B and T cells and constitutively on several B- and T-cell NHLs and on HL. The major CD30 functions include participation in negative selection of thymocytes, costimulation of activated T cells, isotype switching of B cells, and regulation of the effector activity of cytotoxic lymphocytes. CD30 is expressed in Reed-Sternberg cells, and increased levels of serum CD30 are observed in HL patients and are a marker for predicting poor prognosis and poor treatment response. In fact, the CD30 antigen has been characterized as a marker for both primary and cultured Reed-Sternberg cells, but this antigen is also expressed in cells of anaplastic large cell lymphoma and of Burkitt lymphoma. Persistent expression of high levels of CD30 in HL cells, and in particular Reed-Sternberg cells, is thought to play a central role in growth regulation of the neoplastic cells involved. Reed-Sternberg cells, in contrast to cells of anaplastic large cell lymphoma, coexpress CD30 and CD30 ligand, suggesting an autocrine CD30L-CD30 cytokine receptor loop (Hsu and Hsu 2000). The differential expression patterns of downstream components of the CD30 signaling pathway, in particular TRAF1 and c-Rel, may prove a useful adjunct in distinguishing cases of classical HL from morphologically and immunophenotypically similar lymphomas (Rodig et al. 2005). CD30-mediated signals are involved in lymphoid cell homing to lymph nodes, and affect, in a complex network, apoptosis in that CD30 on the one hand upregulates Fas, death receptor 3, and TNF-related apoptosis-inducing ligand and on the other hand upregulates TNFR-associated factor 1 and cellular inhibitor of apoptosis 2, protecting cells from certain types of apoptosis (Muta et al. 2000). It has been found that expression of CD30 by neoplastic cells in HL is associated with inhibition of proliferation and activation of T cells (Su et al. 2004). Proteins that function in signaling events downstream of activated CD30 are also expressed in neoplastic cells of classical HL, including TRAF1 and activated c-Rel (Rodig et al. 2005), and CD30 ectodomain shedding affecting its biologic activity is mediated by TNF-alpha converting enzyme (TACE), is dependent on the availability of the

cysteine-rich domains (CRD) 2 and 5 of the CD30 ectodomain (Hansen et al. 2004), and is increased by depletion of cellular cholesterol and of lipid rafts (von Tresckow et al. 2004). TACE is itself a metalloproteinase, and inhibitors of this enzyme therefore affect the turnover of CD30 (Hansen et al. 2002).

Role of EBV Infection

HL is more often seen in patients with EBV infection (Khan 2006; Kapatai and Murray 2007; Martin et al. 2011; review: Mohamed et al. 2014). The highest frequency of EBV gene expression in HRS cells is found in MCCHL (around 75 %) and the lowest incidence in NSCHL (10–40 %). In Western countries, the EBV strain 1 prevails, whereas strain 2 prevails in resource-poor areas. EBV-encoded latent membrane protein 1 (LMP-1) gene exhibiting deletion mutants is highly associated with HIV-related HL, and these mutants accumulate in RS cells (Guidoboni et al. 2005). From a genome-wide association study of 1200 classical HL patients, it resulted that there were associations between EBV-positive classical HL and genetic variants within the class I region and between EBV-negative classical HL and the rs6903608 locus within the class II region, the latter association being confined to NSCHL (Urayama et al. 2012). In pediatric HL, tumor-associated macrophages are associated with EBV, suggesting that the macrophage microenvironment in pediatric classical HL is different from that of HL in adults (Barros et al. 2012). EBV contributes to the growth and survival of HRS cells. Expression of EBNA1 is associated with downregulation of the TGF-beta target gene, protein tyrosine phosphatase receptor kappa (PTPRK), conferring increased growth and survival to HRS cells (Flavell et al. 2008). EBV infection also affects the recruitment of accessory cells of HL tissue. Expression of the EBV-encoded EBV nuclear antigen 1 in HL neoplastic cells mediates the upregulation of the chemokine CCl20 and the migration of regulatory T cells (Baumforth et al. 2008).

Mechanisms Involved in Growth, Apoptosis, Invasion, and Spread of HL Cells

The Mummified Reed-Sternberg and Hodgkin Cells and Mechanisms of Para-apoptosis/Apoptosis in Hodgkin Lymphoma

The presence of degenerative or regressive changes occurring in the large neoplastic cells in HL had already been noted by Reed and by Sternberg, and these features were later specified in more detail (Jackson and Parker 1944b; Cross 1969; Lorenzen et al. 1997), in one instance described under the term "selective apoptotic necrosis (SAN)" (Kodousek et al. 1992). The phenomenon represents distinct stages of a cellular death process including para-apoptosis and apoptosis of Hodgkin/Reed-Sternberg cells, although it is established that the neoplastic cells in HL are characterized by a remarkable resistance to certain apoptotic stimuli. Histologically, the tissues of HL contain Reed-Sternberg cells with a condensed and markedly eosinophilic or amphophilic cytoplasm and basophilic and condensed nuclei lacking chromatin marginalization, termed mummified cells (Lorenzen et al. 1997). In certain stages of this decay process, the cells may be triangular or elongated. Although the nuclear chromatin undergoes condensation, the tortuous nuclear contour is retained for longer time periods. Similarly, immunoreactivity for CD30 and/or CD15 is retained in what has been termed para-apoptosis, while these markers are negative in cells with classical signs of apoptosis (Lorenzen et al. 1997). Para-apoptosis (nonclassical apoptosis) is a specific morphologic type of programmed, non-necrotic cell death, characterized by cytoplasmic vacuolization, condensed chromatin (but not early margination of the chromatin), and swollen mitochondria. In contrast to classical apoptosis, surface blebbing and the formation of typical apoptotic bodies do not occur (Asher et al. 1995). It seems that para-apoptosis is driven by an alternative caspase-9 activity that is Apaf-1-independent (Sperandio et al. 2000). Para-apoptosis, in addition to Hodgkin and Reed-Sternberg cells, has been observed

in several other cell systems, including lymphocytes (Asher et al. 1995) and the megakaryocyte lineage (Houwerzijl et al. 2004). It is sometimes noted that apoptosis and para-apoptosis are seen in classical HL, but in fact they may occur in any type and subtype of HL (Cross 1969). In a detailed study, the lowest incidence of mummified cells was found in NLPHL ("paragranuloma"), significantly different from the mixed cellularity subtype (Lorenzen et al. 1997). Mummified cells ("mummy cells") do not seem to exhibit DNA fragmentation, but the apoptotic cells are strongly reactive by in situ end labeling of DNA fragments (Benharroch et al. 1996, 1998), while abortive mitoses and nuclear DNA fragmentation were observed in CD30-reactive large cells of HL (Leoncini et al. 1996).

What are the mechanisms of apoptosis and para-apoptosis in HL? Several proteins known to regulate apoptosis and protection from apoptosis show an increased expression in HL tissue and/or Reed-Sternberg cells, including CD95/Fas (Vassallo et al. 2003; although the neoplastic cells show a remarkable resistance to Fas), Bcl-2 (Lauritzen et al. 1999; Kanavaros et al. 2000; Van Spronsen et al. 2000; Vassallo et al. 2003; Kim et al. 2003; Garcia et al. 2003; Kim et al. 2004), Bcl-x (Schlaifer et al. 1996; Chu et al. 1999; Lauritzen et al. 1999; Vassallo et al. 2003; Garcia et al. 2003; Kim et al. 2004), Bax (Brousset et al. 1996; Kanavaros et al. 2000; Vassallo et al. 2003), Bak (Brousset et al. 1999), CD40 ligand (Metkar et al. 2001), Mcl-1 (Vassallo et al. 2003), p53 protein and p53-binding protein MDM2 (Chilosi et al. 1994; Lauritzen et al. 1999), survivin (Garcia et al. 2003), and caspases (Smolewski et al. 2000). Bcl-2 protein reactivity is not usually found in NLPHL (Algara et al. 1991), but is observed in other types of HL to variable degrees (Gupta et al. 1994). Less is so far known about key mechanisms driving para-apoptosis which is an important pathway for the generation of typical mummified cells occurring in HL. A recent study has shown that IGFIR (insulin-like growth factor I receptor), as well as the IGFIR intracytoplasmic domain, induces non-apoptotic programmed cell death characterized by cytoplasmic vacuolation and resistance to apoptosis inhibitors, and this process requires transcription and the de novo synthesis of proteins. IGFIR-induced cell death is mediated by caspase-9 which is, as such, an inducer of apoptosis via cleavage and activation of caspase-3 zymogen and possibly other caspase zymogens, but in para-apoptosis, the caspase-9 effects are different from those in apoptosis owing to the effects of the caspase inhibitors, BAF, p53 protein, and XIAP (Sperandio et al. 2000).

What is the potential role of pro- and antiapoptotic mechanisms in the striking resistance of HL neoplastic cells to apoptosis? Deregulation of some of the factors seems to mediate rescue from apoptosis. There are differences in the expression patterns of Bcl-2 mRNA and Bcl-2 protein (Hell et al. 1995). HL-derived cell lines are resistant to Fas-mediated apoptosis and thus behave differently in comparison with normal germinal center B cells that are eliminated via a Fas pathway. The rescue mechanisms are not yet fully known, but Reed-Sternberg cells, although expressing Fas, exhibit a low frequency of Fas gene mutations, and part of these mutations may impair Fas/CD95 function in apoptotic pathways (Muschen et al. 2000; Maggio et al. 2003). Although expressed in HL cells, Fas does not seem to significantly affect apoptosis in these cells, because an inhibitor protein, cellular FLICE (FADD-like IL-1beta-converting enzyme)-inhibitory protein (c-FLIP), is expressed in the cells as well and protects them from autonomous Fas-mediated death (Dutton et al. 2004; Mathas et al. 2004). Inhibition of Fas-mediated apoptosis in Reed-Sternberg cells also seems to be mediated by constitutional expression of the Fas inhibitor operational in germinal B-cell survival, c-FLIP, in HL cells (Thomas et al. 2002). Furthermore, in regard to caspase effectors of apoptosis, one study did not find significant cytoplasmic staining for caspase-3 and caspase-8 in Reed-Sternberg cells (Xerri et al. 2000), whereas others did (Smolewski et al. 2000). The role of caspase activity in the light of the relative apoptosis resistance of at least some populations of neoplastic cells in HL is complex and is modified by other effectors. Cytochrome c fails to stimulate caspase-9 and

caspase-3 activation in HL-derived B cells, which is due to high level expression of the X-linked inhibitor of apoptosis (XIAP), apoptosis protease-activating factor-1, and caspase-3 being complexed (Kashkar et al. 2003). The expression of CD40 ligand in HL cells has been suggested to rescue these cells from apoptosis (Metkar et al. 2001). Soluble stem cell factor which interacts with the c-kit receptor expressed by Reed-Sternberg cells was able to partially rescue these cells from apoptosis (Aldinucci et al. 2002). On the other hand, some mechanisms seem to promote apoptosis of HL cells and therefore to be involved in pathways leading to mummified cells. Apoptosis of the neoplastic cells in HL is related to the expression of the cdk inhibitor, p27KIP1, suggesting that the p27 and possibly also the p21 pathways are involved in protection from apoptosis in HL (Kolar et al. 2000). The frequent expression in Reed-Sternberg cells of the proapoptotic proteins, Bax (Brousset et al. 1996) and Bak (Brousset et al. 1999), may be an important feature in the pathogenesis of mummified cells.

At least some of these factors seem to be correlated with the biology of disease. For example, a high percentage of Reed-Sternberg cells expressing Bcl-2 protein is associated with treatment failure and subsequent poor survival in young patients with nodular sclerosing HL (Van Spronsen et al. 2000). The simultaneous expression of Bcl-2, Mcl-1, and EBV-associated LMP-1 was shown to significantly and independently be correlated with excellent survival in classical HL (Vassallo et al. 2003). High numbers of active caspase 3-positive Reed-Sternberg cells predict a favorable clinical outcome (Dukers et al. 2002), although the action of caspases in these cell systems is complex, as briefly discussed above.

In contrast to pathogenic pathways promoting apoptosis in neoplastic HL lineages, there are mechanisms prolonging survival of these cells. Telomerase expression and telomere lengthening and inhibition of apoptosis by NF-kappaB expression and inhibitor of NF-kappaB mutations have been suggested to play a role in the possible immortalization of Hodgkin and Reed-Sternberg cells (Emmerich et al. 2003; Zheng et al. 2004). Survival of HL cells is also promoted by a Jagged1-activated Notch1 signaling pathway (Jundt et al. 2002).

Invasion and Spread

It may be anticipated that, similar to other malignant neoplasms, invasion and spread of HL cells markedly depend on cell-to-matrix interactions, all the more so as HL is characterized by a complex mixture of neoplastic cell lineages and nonneoplastic reactive tissues. It is well established that hematologic neoplasms derive from cell systems with an innate capacity of the expression of enzymes acting on the extracellular matrix, particularly metalloproteinases and gelatinases. MMP-9 levels are substantially increased in HL (Thorns et al. 2003; Hazar et al. 2004), and in HL, MMP-9 has been shown to be linked to an adverse prognosis (Kuittinen et al. 2002), similar to NHL (Sakata et al. 2004), suggesting a pathogenic effect promoting tumor cell spread in the matrix. It has been found that proteins associated with EBV (being involved in the development of HL) may affect the expression of metalloproteinase-9. This is of interest insofar as EBV, and specifically its LMP-1, seems to induce other invasion and metastasis factors, such as type IV collagenase, cyclooxygenase-2, and VEGF (Wakisaka and Pagano 2003). In fact, several reports have described an upregulating effect of LMP-1 on the expression of metalloproteinase-9 (Yoshizaki et al. 1998, 1999; Takeshita et al. 1999; Horikawa et al. 2000; Yoshizaki 2002; Wang et al. 2002). However, no correlation between the EBV status in HL and the expression of MMP-9 was found in another investigation (Flavell et al. 2000).

HL tissue also expresses proteins counteracting metalloproteinases, in particular tissue inhibitors of metalloproteinases (TIMPs), similar to NHL (Kuittinen et al. 2003). Expression of TIMP-1 has been detected in Reed-Sternberg cells and found to be an autocrine and paracrine survival factor, but also to be immunodepressant via inhibition of T-cell-mediated cytotoxicity (Oelmann et al. 2002). It has been shown that

the expression of TIMP-1 protein is strongly associated with the nodular sclerosis subtype and the existence of a bulky tumor in HL, while the expression of TIMP-2 is correlated with the occurrence of B symptoms, suggesting that TIMP-1 may promote growth of HL and linked to increased connective tissue turnover, whereas TIMP-2 may correlate with systemic effects of the disease (Pennanen et al. 2004). On the other hand, the expression of MMPs is induced by the extracellular MMP inducer (EMMPRIN). It was found that EMMPRIN and TIMP-1 were co-expressed in two thirds of HL (Thorns et al. 2002, 2003) and the interplay of these two factors may modulate the MMP activity in spread of HL. MMPs are also integrated in a complex network of other proteins, including CD30 that is expressed by a set of HL cells. It has been shown that CD signaling affects lymphoid cell trafficking and homing to lymph nodes (Muta et al. 2000). Furthermore, CD30 affects, via mediation of ICAM-1 upregulation, lymphocyte cluster formation in lymphoid tissues (lymphocyte self-aggregation; Nam et al. 2002). Apart from metalloproteinases, distinct components of the extracellular matrix (ECM) itself and cell surface molecules interacting with the ECM seem to affect the spreading mechanisms of HL cells. Syndecan-1 (CD 138) is a cell surface proteoglycan belonging to the syndecan family of cell surface transmembrane heparan sulfate proteoglycans participating in proliferation, cell migration, and cell-matrix interactions and thus is a multifunctional regulator of cell behavior within the microenvironment of normal cells and several tumors (Dhodapkar and Sanderson 1999; Conejo et al. 2000). Specifically, syndecan-1 has anti-invasive properties dependent on an invasion regulatory domain within the core protein (Langford et al. 2005). The cell-matrix relationship by syndecan-1 is also mediated by its ectodomain regulating alpha(v)beta(3) integrin activity (Beauvais et al. 2004), and shed ecodomains exert a proteolytic activity observed in a wound healing model of mice overexpressing syndecan-1 (Elenius et al. 2004). It is also involved in osteoprotegerin-induced chemotaxis in peripheral blood monocytes. The proteoglycan also makes part of mechanisms controlling vascular development, in that ephrinB2 and EphB4, its cognate receptor, upregulate syndecan-1 in inflammatory angiogenesis (Yuan et al. 2004). Syndecan-1 is associated with post-germinal center and terminal B-cell differentiation and is expressed by Reed-Sternberg cells (Carbone et al. 1997), but only in distinct subtypes of HL: it is not expressed by nodular sclerosis HL, but is, together with Bcl-6, expressed in classical mixed HL (Carbone et al. 1998); furthermore, the syndecan-1+MUM1/IRF4+Bcl-6- phenotype characterized HIV-HL (Carbone et al. 2001). In B-cell NHL, the expression of one of the hyaluronidases, HYAL2, acting on the substrate hyaluronan, was related with tumor aggressiveness (Bertrand et al. 2005), and it may be anticipated that this pathway is also active in the spread of HL.

The spread of HL is, furthermore, affected by the composition and amount of stroma and the local vascular geometry and thus by angiogenesis. The stromal response, which is a dominant feature in the NSHL subtype, is at least in part regulated by TGF-beta that is chiefly expressed in the nodular sclerosis variants (Kadin et al. 1990). It has been documented that vascular endothelial growth factor (VEGF) is expressed in HL (Foss et al. 1997) and specifically by neoplastic Hodgkin/Reed-Sternberg cells in HL but also by nonneoplastic cells (in particular macrophages) located to the stroma (Doussis-Anagnostopoulou et al. 2002)

History of the Hodgkin Disease Concept

Several synonyms of this disease were previously recognized, part of them integrating the observation that the progressive lymph node disorder was not associated with leukemia (lymphogranulomatosis maligna, lymphomatosis granulomatosa, malignant lymphogranuloma, pseudoleukemia, fibromyeloid medullary reticulosis, Paltauf-Sternberg disease, Hodgkin-Paltauf-Sternberg disease, Sternberg disease, Bonfils' disease, Bonfils' syndrome, Hodgkin granuloma, Hodgkin

syndrome, Pel-Ebstein fever, anemia sive cachexia lymphatica, cachexie sans leucémie, adénie, lymphadenoma, lymphome ganglionnaire anémique, progressive multiple lymph node hyperplasia, malignant aleukemic lymphadenoma). This goes back on a series of seminal reports describing the disorder (Hodgkin 1832; Bonfils 1857; Wilks 1865; Greenfield 1876; Pel 1885; Ebstein 1887; Paltauf 1897; Sternberg 1898; Fraenkel and Much 1910b). Thomas Hodgkin (1798–1866) was an English physician and pathologist. In 1825 he was elected member of the Royal College of Physicians in London, was appointed to a position as physician to The London Dispensary (comparable to present emergency unit), and became the curator of the pathology Museum at Guy's Hospital Medical School. Here, he started his career as a leading pathologist of his time and in 1827 became the first reader in England lecturing on pathological anatomy. He discovered the biconcavity of erythrocytes and the cross-striation of skeletal myocytes, but is of course best known for the description of the disease now bearing his name (Hodgkin 1832). At Guy's Hospital in London, Hodgkin was a colleague of Richard Bright and Thomas Addison. Unfortunately for him, he was denied professional advancement, and he later devoted most of his time to issues of social medicine, predominantly the medical problems of the poor and unprivileged, specifically American Indians and natives of black Africa. He was one of the founders of the British and Foreign Aborigines Protection Society, the later British and Foreign Anti-Slavery Society. Up to now, the seven original preparations of Hodgkin lymphogranulomatosis are kept in Guy's Hospital in London. The later analysis of these cases confirmed the diagnosis of the now Hodgkin disease in three of the seven, one designated as "cancer cerebriformis."

Carl Sternberg (Carl von Sternberg; 1872–1935) was working as assistant of pathology in the Viennese Rudolfspital, where he was influenced by professor Richard Paltauf (1858–1924). Several years after the first world war, where he earned great reputation for fighting for soldiers' rights, he became full professor in Vienna in 1926. His main research concerned tuberculosis and leukemia. In 1898, he published his work (in a Journal edited in Prague) on what is now known as Hodgkin disease, but regarded by him as a special form of tuberculosis ("*eigenartige Tuberkulose des lymphatischen Apparates*"), and described one of the cellular hallmarks of this disease (review: Sternberg 1936). HL, early thought to be a variant of tuberculosis, was then named, Sternberg disease or Paltauf-Sternberg lymphogranuloma, until Pappenheim coined the term lymphogranulomatosis.

Although Hodgkin and Sternberg are in the center of the recognition of the disease in question, others have contributed much to our understanding of Hodgkin disease. Another British physician, Samuel Wilks, independently described the same disease and with greater precision (Wilks 1856). But he recognized Hodgkin's priority and named the disease for Hodgkin in an article in Guy's Hospital Reports entitled "Cases of enlargement of the lymphatic glands and spleen (or, Hodgkin's disease) with remarks" (Wilks 1865). There is some evidence that a disease possibly representing Hodgkin disease was already described by Malpighi and Morgagni (in Birch-Hirschfeld 1878). Marcello Malpighi (1628–1694) is said to have described lesions corresponding to Hodgkin disease in 1666 (Malpighi 1666). Giovanni Battista Morgagni (1682–1771) presents a description of a disorder likely to be Hodgkin disease in his famous work entitled *De Sedibus et Causis Morborum per Anatomen Indagatis* (On the seats and causes of diseases investigated by anatomy) (Morgagni 1761). The view of Sternberg that HL may represent a unique form of tuberculosis was put into question several years after his descriptions only. Chiari had observed in several patients that the "granulomatous disease" can progress into a sarcomatous growth, with diffuse infiltration of organs adjacent to the lymph nodes initially involved, and already remarked that, in this situation, the cellularity of the lesions may increase (cited in Dietrich 1908), and these observations were confirmed later, leading to the term "granuloma-like sarcoma of lymph nodes" (Dietrich 1908).

An interesting history also relates to the giant cell that is such a typical feature of Hodgkin disease (the Reed-Sternberg cell). These characteristic giant and/or multinuclear cells were already registered by early authors (v. Hüttenbrenner 1871; Langhans 1872; Greenfield 1878; Dreschfeld 1891; Hübener 1893; Gilbert and Weil 1900; Dietrich 1908). Langhans, in his description of what was then termed "hard lymphosarcoma" (i.e., sclerosing forms of Hodgkin disease), noted scattered large cells with 2 or 3, and sometimes many more, nuclei of irregular shape ("*Hie und da finden sich zerstreut grössere dunkelkörnige Zellen, etwa von der Grösse der Schleimkörper, mit 2, 3 auch mehr Kernen, und ferner wahre Riesenzellen, grosse Haufen von dunkelkörniger Zellsubstanz mit 10, 20 Kernen, von länglich unregelmässiger Gesta*lt"). These cells do not represent the reactive multinuclear giant cells also detected by Langhans, but in fact a first description of the later Reed-Sternberg cell (Langhans 1872). Langhans refers, in his work, to a similar observation by v. Hüttenbrenner (1871), who described "multinuclear protoplasmic masses (giant cells)" and "*myeloplaques à plusieurs noyaux*." The striking giant cells were reported again in 1878 (Greenfield 1878). In his autopsy study on HL patients, Greenfield described the cells observed in enlarged lymph nodes as follows: "There were a large number of multinucleated cells adherent to the trabeculae, well seen on washing away the lymph cells. These multinucleated cells, containing from 4 to 8 or 12 nuclei, were often collected in clusters in the parts of the gland especially where the fibrous change was progressing" (Greenfield 1878). In his Fig. 2 (a drawing by the author), the typical large nuclei with the characteristic prominent nucleolus are nicely depicted. It is seen that this author already recognized that the cells in question occur in clusters, what is typical for certain variants of HL. Hübener described, based on the autopsy of a 5-year-old girl with typical HL, large cells in involved lymph nodes, characterized by the presence of two or more nuclei (Hübener 1893). The detailed description of the characteristic cells occurring in HL was performed by Sternberg (Sternberg 1898). Four years later appeared the work of Dorothy Reed Mendenhall (1874–1964) who not only produced more relevant information on the unique cells types but also separated Hodgkin disease from tuberculosis (Reed 1902). The so-called lacunar Reed-Sternberg cells chiefly observed in the nodular sclerosis variant of HL and characterized by cytoplasmic retraction in formalin-fixed samples have probably first been described in 1900 (Gilbert and Weil 1900; "*la très grosse majorité (des cellules) sont constituées par un gros noyau arrondi ou ovalaire, très clair, vésiculeux, que l'hématéine teinte à peine en violet clair et qui présente un ou deux nucléoles; on ne constate presque pas de protoplasme autour de ce noyau*"; the large majority of the cells exhibit a large, roundish, or ovoid nucleus, very clear, vesicular, that the hematein hardly stains violet, and that show one or two nucleoli; one detects almost no cytoplasm around these nuclei). A further characteristic feature in HL is the presence of a distinct type of Hodgkin cell apoptosis, resulting in so-called mummified cells (see below). It seems that this feature was first recognized in 1910 already. In an autopsy case of HL ("Sternberg's so-called peculiar tuberculosis of the lymphatic system") Graetz found large and giant cells in the bone marrow (with indented, reniform, or lobulated nuclei), part of these cells showing "marked pycnosis or other signs indicating cell decay" (Graetz 1910).
