Abstract

B-cell non-Hodgkin's lymphomas (B-cell NHLs) showing a proliferation of small- to medium-sized neoplastic cells have a strong tendency to infiltrate the liver. In particular, small lymphoma cells are capable to circulate and recirculate in the body and to leave the microcirculation in several organs. The most common B-cell NHL is chronic lymphocytic leukemia of the B-cell type. In this slowly progressing neoplasia, the liver is almost always involved. Accumulation of neoplastic cells causes hepatomegaly, a typical and frequent finding, with liver weights slowly increasing over time to sometimes reaching several kilograms. The exterior aspect of the liver may become grayish white, and the cut surface shows numerous small whitish nodules. The histologic substrate is markedly enlarged portal tracts which are densely infiltrated by small neoplastic lymphocytes. In long-standing disease, larger nodular lesions can develop, mimicking metastatic disease. A similar type of liver involvement is seen in the rare B-cell prolymphocytic leukemia. Focal and nodular hepatic infiltration is also observed in follicular NHL, mantle cell lymphoma, and extranodal marginal zone B-cell NHL of mucosa-associated lymphoid tissue/MALT.

Chronic B-Cell Lymphocytic Leukemia (Small B-Cell Lymphocytic Lymphoma; B-CLL/SLL)

ICD-O code 9823/3

Introduction

Based on the 2008 WHO classification, chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) is defined as a neoplasm composed of monomorphic small, round to slightly irregular B lymphocytes in the peripheral blood, bone marrow, spleen, lymph nodes, and other organs and tissues. CLL/SLL is often admixed with prolymphocytes and paraimmunoblasts and can form proliferation centers in tissue infiltrates. The general cytologic and histologic features of CLL are briefly discussed at the end of this chapter.

Chronic B-cell lymphocytic leukemia (B-CLL) and the underlying lymphoma, small B-cell lymphocytic lymphoma (SLL), belong to the group of so-called mature B-cell lymphoproliferative disorders (MBCLDs). SLL and its leukemic manifestation, B-CLL, are classified as one disorder, but in fact this apparent entity consists of several different B-cell diseases that are represented under this name. This phenotypic heterogeneity is reflected by a variability of chromosomal/genetic abnormalities, alterations in the expression of apoptosis-related proteins and other effectors, and mutations of growth factors (Caligaris-Cappio and Hamblin 1999; Wierda and Kipps 1999; Bannerji and Byrd 2000; Guipaud et al. 2003; Messmer et al. 2004).

Epidemiology

In Western countries, CLL is the most common leukemia of adults, with an incidence rate of approximately two to six cases per 100,000 persons per year, to reach 12.8 cases per 100,000 persons per year in the age group 65 years and more. CLL has a gender distribution of M/F = 1.5–2.0:1 (androtropy). The disease is much less common in Eastern countries, likely to be based on genetic factors, as the low incidence persists in migrants from such countries.

Clinical Features

CLL leads to a progressive expansion of small B lymphocytes in blood, bone marrow, and peripheral tissues. As the neoplastic cells, similar to their normal counterparts, circulate and recirculate in the organism, almost any tissue can be involved with time. Clinically relevant manifestations are mainly caused by bone marrow replacement and structural and functional disorders of inner organs such as the spleen. In the first and usually long

period of disease development, most patients are asymptomatic. Rare patients present with aleukemic tissue involvement.

Liver Pathology in Chronic B-Cell Lymphocytic Leukemia/Small B-Cell Lymphocytic Lymphoma

Macroscopy

Hepatomegaly is a typical and frequent finding, with liver weights caused by marked cellular infiltration range from little more than normal in early disease to several kilograms in advanced disease. In most patients, marked hepatomegaly is associated with splenomegaly, but splenic weight in B-CLL is usually less elevated than in myeloproliferative disorders. Due to sometimes massive infiltration, the liver capsule may be tense and the liver margins effaced. The exterior aspect of the unfixed liver may be grayish red or even grayish white. In a minority of cases, the liver capsule is mottled owing to multiple small hemorrhages. Moreover, the capsule may be turbid due to a serosal fibrinous reaction. The consistency of the tissue varies from firm to highly friable or flabby, depending on the density of lymphoma infiltration and the degree of tissue decay. The fresh cut surface typically shows numerous and mostly small whitish nodules reflecting the spacing of the densely infiltrated portal tracts. This location of the spots or dots to the lobular periphery has been recognized for a long time as being characteristic for CLL (Naegeli 1923). In the most typical situation, the lesions are miliar, i.e., one to about 3 or 4 mm in diameter, and may thus be confounded with granulomas. However, granulomas are never so regularly spaced all over the organ as are the lesions in CLL. In case of massive infiltration, these areas may show confluence or "lymphomatous bridging," resulting in a distinct network of grayish-white color. In other patients, and specifically in longer-standing disease and/or in case of blastic transformation, larger lesions can ensue, sometimes forming nodules of one or more cm diameter or even forming massive tumors occupying one or more segments of the liver. These patterns may mimic metastatic disease. Larger lesions are known to obstruct intrahepatic bile ducts, causing cholestasis with greenish discoloration of the entire organ or part of the organ, depending on the level of obstruction. Bile may leak from damaged bile ducts and then stain the lymphoma nodules yellow or greenish yellow. Liver organ changes in CLL not directly related to lymphoma cell infiltration include hemorrhages, abscesses, hepatic infarctions, and other rarer lesions.

The locoregional lymph nodes of the hepatic hilar/perihilar region are frequently enlarged. In most cases, this lymphadenomegaly is caused by lymph node infiltration, but other causes can contribute to node enlargement, including a cellular reaction to tissue breakdown in the liver, accumulation of iron-laden macrophages and of foamy cells subsequent to hepatic hemorrhage, granuloma formation, and immune reactions associated with accompanying liver inflammations (e.g., viral hepatitis).

Histopathology

B-CLL shares the patterns of liver infiltrations with other small cell non-Hodgkin's lymphomas (Barcos et al. 1987; Baumhoer et al. 2008). In the liver, B-CLL/SLL chiefly involves the portal tract spaces and, less so, the lumina of the sinusoids (Prinz 1951). The dense and often well-delineated portal tract infiltrates are typically monomorphic and already visualized at low magnification in the form of blue foci. In advanced disease, the entire portal tract space is occupied by the neoplastic cells, which cause expansion and rounding-up of the tracts, with or without spillover of cells into hepatic parenchyma (Figs. 1, 2, 3, and 4). In most cases, interface lesions are not prominent, and therefore, the boundary between portal tracts and parenchyma is rather sharp, in contrast to chronic active viral hepatitis. Due to dense infiltration, preexisting portal tract structures (blood vessels and bile ducts) are almost effaced, as the small round cells encircle these structures. More than 95 % of infiltrate cells are small B cells, and only a minor contribution of macrophages, plasma cells, and granulocytes is seen. The infiltrate is

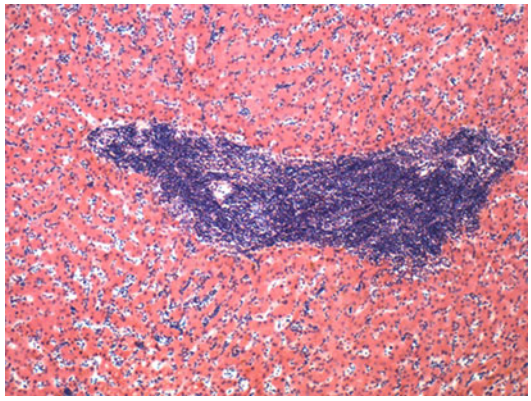

Fig. 1 Involvement of the liver in chronic B-cell lymphocytic leukemia. Small lymphoid cells are present within sinusoids (reflecting leukemia) and form a dense infiltrate in portal tracts. In contrast to infiltrates in chronic hepatitis, the portal tract infiltrate is highly monotonous (hematoxylin and eosin stain)

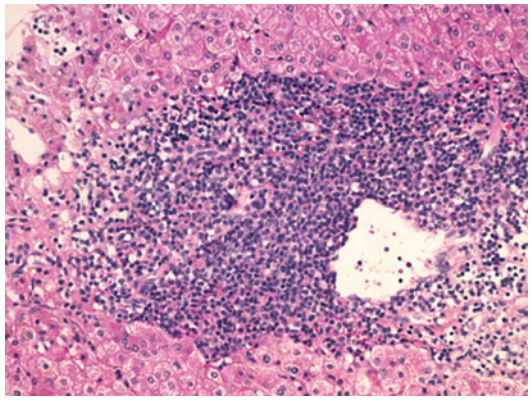

Fig. 2 Liver involvement in B-CLL. The monotonous dense portal tract infiltrate has led to destruction of the hepatic limiting plate ("leukemic/lymphomatous interface lesions or piecemeal necrosis"). The endothelium of the small portal vein branch is damaged by the lymphoma cells (hematoxylin and eosin stain)

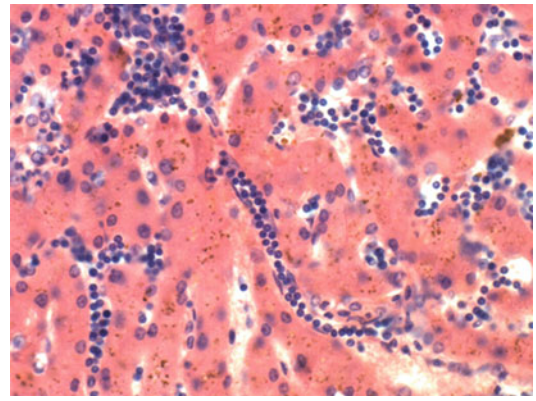

Fig. 3 Sinusoidal accumulation of cells in B-CLL. Tumor cells form rows and "Indian files" and are in close contact with the endothelial surface (hematoxylin and eosin stain)

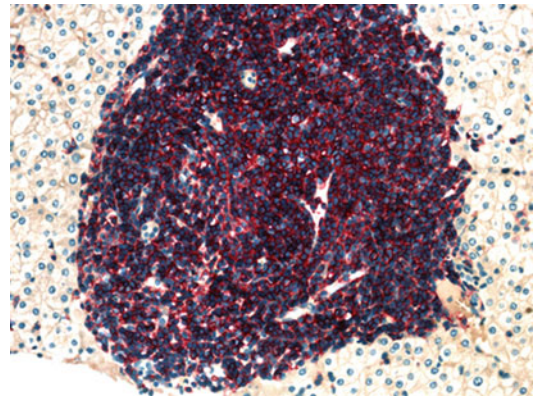

Fig. 4 Portal tract infiltrate in B-CLL. The neoplastic cells are strongly CD79a positive (CD79a immunostain)

dominated by small lymphocytes which are, however, somewhat larger than normal lymphocytes and are also larger than the leukemic lymphocytes circulating in blood. As in involved lymph nodes, so-called paraimmunoblasts or lymphoblasts are always seen, characterized as cells with a larger size, readily visible cytoplasm, oval nuclei with fine chromatin, and a single, centrally placed basophilic nucleolus. The neoplastic infiltrates also always contains few prolymphocytes, which are larger than small lymphocytes and have a nucleus with an open chromatin. The nucleus of prolymphocytes may be oval or irregular, resembling centrocyte nuclei. Paraimmunoblasts and prolymphocytes are the cell components showing mitotic figures. In situations where greater numbers of paraimmunoblasts are present, these cells are mostly clustered as proliferating aggregates, causing a pseudofollicular phenotype (so-called proliferation centers).

Immunohistochemically, a small component of T cells may be noted. Portal tract infiltrates may show a nodular configuration, but true lymph follicles or germinal centers are not found. An interesting phenomenon in some involved livers is parenchymal atrophy of lobular zone 1 and sometimes also 2, zone 3 being spared. The fact that the pericentral zone 3 is not or much less involved speaks against ischemia caused by blockage of sinusoidal entry sites, but effects of cytokines/chemokines may be considered. An increased number of small lymphocytes is seen in the sinusoids, but this feature is less prominent than portal tract infiltrates. The density of intrasinusoidal small B cells reflects leukemia, i.e., the number of neoplastic cells circulating in blood. A subset of patients will develop, usually in later phases of disease, tumorous nodules in the liver substance, mostly composed of prolymphocytes (intrahepatic small B-cell lymphoma; tumor-forming CLL). In tumor-forming CLL, the preexisting reticulin fiber network is effaced, and the cells have a tendency to infiltrate and destroy small- to medium-sized veins and to invade the adventitia of arteries, with splitting of the adventitia. The liver can also show tumorous hepatomegaly in patients with Richter syndrome (Tadmor et al. 2011).

Hepatic Failure in CLL

Marked hepatic infiltration leads to a variety of functional derangements of the organ. In rare instances, hepatic involvement in CLL results in severe hepatocyte injury and acute liver failure (Shehab et al. 1997; Costa et al. 1998; Hasuike et al. 2004; Esfahani et al. 2011). In one patient, this complication occurred in the setting of chronic hepatitis B, but autopsy revealed nodular and massive invasion of the liver by neoplastic lymphocytes associated with hepatocyte necrosis (Hasuike et al. 2004). Hepatocyte injury is probably not only caused by direct physical effects of infiltrating cells and ischemia due to sinusoidal obstruction but also by cytokines and chemokines delivered from immune and tumor cells.

Chronic Lymphocytic Leukemia-Associated Cholangiopathy

CLL-associated cholangiopathy is a recently described disorder (Mann et al. 2011). The index patient was a 41-year-old female with untreated CLL and with elevated liver enzymes in serum, including elevated alkaline phosphatase and gamma-glutamyl transferase. Autoimmune antibodies were negative. A liver biopsy showed that small bile ducts were pushed toward the periphery of infiltrated portal tracts. Some of these bile ducts displayed intraepithelial lymphocyte infiltration, resulting in significant narrowing of the duct lumen (cholangiopathy). The infiltrating lymphocytes had the same immunophenotype as leukemia cells.

Chronic Lymphocytic Leukemia and Portal Hypertension

Non-cirrhotic portal hypertension complicating CLL has been reported several times (Papadakis et al. 1986; Lindor et al. 1987; Rozman et al. 1989; Nakamura et al. 1989; Mouly et al. 1996; Pauwels et al. 2000). In part of the cases, hepatic infiltration was found to be the likely cause of intrahepatic block of blood flow (Rozman et al. 1989; Pauwels et al. 2000), in particular lymphocytic infiltration of the portal tracts that might impair blood flow from small portal venous branches into the sinusoidal vascular bed (Nakamura et al. 1989; Mouly et al. 1996), thus representing a pre-sinusoidal intrahepatic block. Another pathogenic mechanism is nodular regenerative hyperplasia induced by leukemic infiltration (Rozman et al. 1989). Portal hypertension in CLL can develop in the absence of liver infiltration and has been suggested to be caused by an increased spleno-portal flow (Wilputte et al. 2003). This view is supported by the observation of reversal of portal hypertension upon

resection of an involved spleen (Lindor et al. 1987).

Differential Diagnosis

Without immunohistochemistry, the morphologic presentation of B-CLL may be similar to four other lymphoproliferative diseases, i.e., lymphoplasmacytic lymphoma, lymphomas with a high proportion of centrocytes, prolymphocytic leukemia, and lymphocyte-rich forms of Hodgkin's lymphoma.

General Histopathology of Chronic B-Cell Lymphocytic Leukemia/Small B-Cell Lymphocytic Lymphoma)

The cellular and tissue features of B-CLL/SLL have recently been reviewed (Pileri et al. 2004). On a cellular level, the disorder is characterized by a distinct set of neoplastic lymphoid elements that can be classified into small lymphocytes (about 6 μm diameter), prolymphocytes, and paraimmunoblasts. It is of importance to note that the small lymphocyte component consists of cells that are slightly larger than small nonneoplastic lymphocytes. The basophilic cytoplasm is scant; the nuclei are usually spheroid, with a chromatin structure that is slightly more coarse than that of normal small lymphocytes. Cleaved nuclei resembling the nuclei of centrocytes may occur. Prolymphocytes exhibit an amphophilic or acidophilic cytoplasm and are clearly larger than small lymphocytes, and their nuclei display a small but easily evident nucleolus. Paraimmunoblasts have a diameter more than three times larger than small lymphocytes, a gray cytoplasm in the Giemsa stain, and a frequently ovoid nucleus with a prominent nucleolus.

Immunohistochemically, the cells of interest in B-CLL are reactive for CD19, CD45, CD79a, CD5, and CD23 but less consistently for CD20. CD20 is weakly or not expressed in the small cell component and is markedly expressed in prolymphocytes and paraimmunoblasts. The B-CLL cells are typically reactive for CD5 and CD23, usually more so in prolymphocytes and paraimmunoblasts. Furthermore, the neoplastic B cells usually express Bcl-2, being involved in the apoptosis protection in this long-lived cell population (see above). The cells are also positive for CD27, a typical memory B-cell marker: Small cells express the B-cell-specific activator protein (BSAP) encoded by the PAX-5 gene, while prolymphocytes and paraimmunoblasts gathering in proliferation centers/pseudofollicles express interferon-regulating factor 4 (IRF4) encoded by the MUM-1 gene (under normal conditions typically expressed in cells of the late germinal center cell pathway; cells leaving the germinal centers upon somatic hypermutation to become memory B cells or plasma cells; Pileri et al. 2004). B-CLL cells do not express CD27.

B-Cell Prolymphocytic Leukemia

ICD-O code 9833/3

Introduction

Prolymphocytic leukemia of B-cell subtype (B-PLL) is a very rare, highly aggressive disease with characteristic morphologic, immunocytochemical, cytogenetic, and molecular genetic features. About 1 % of all lymphocytic leukemias are B-PLL (reviews: Melo et al. 1987; Bolding and Jacobs 1988; Krishnan et al. 2006; Dungarwalla et al. 2008). The WHO classification of tumors defines B-PLL as a neoplasm of B prolymphocytes affecting the peripheral blood, bone marrow, and spleen. For diagnosis, prolymphocytes must exceed 55 % of lymphoid cells in the peripheral blood. According to WHO, cases of transformed chronic lymphocytic leukemia (CLL), with increased prolymphocytes, and lymphoid proliferations with relatively similar morphology but carrying the t(11;14)(q13;q32) translocation are excluded. CLL and B-PLL can occur as two concurrent lesions derived from two separate clones (Cao et al. 2011). Recently, B-PLL was considered as a specific subgroup of

leukemic mantle cell lymphoma (van der Velden et al. 2014).

Clinical Features

Clinically, patients with B-PLL experience rapid increase of B prolymphocytes in the peripheral blood and commonly show marked or even massive splenomegaly, with spleen weights sometimes exceeding 2000 g, while lymph node enlargement is not a prominent feature or even lacking (Bearman et al. 1978). In contrast to T-PLL, patients with B-PLL can have a prolonged progression-free survival under adequate therapy (review: Absi et al. 2005), and there is a subset of B-PLL patients who have a more indolent course (Shvidel et al. 1999). In a study of 41 patients with B-PLL, the median age at diagnosis was 67 years, with a male-female sex ratio of 2.4. A high level of surface IgM and/or IgD expression was found in all cases, FMC7+ in 76 %, and CD5+ in 67 %. The median overall survival time was 5 years and the event-free survival time was 37 months. No difference in outcome was found between primary BCPLL and secondary B-PLL derived from CLL (Hercher et al. 2001). Lymphocytic leukemia and B-PLL with MYC translocations are rare entities which seem to be associated with adverse prognostic features and unfavorable outcome (Put et al. 2012).

Morphology

The majority (more than 55 % per definition and often more than 90 %) of circulating cells are prolymphocytes. These are medium-sized cells, about twice the size of normal unstimulated lymphocytes, with a small amount of basophilic cytoplasm, round nuclei with condensed chromatin, and a prominent central nucleolus. Ultrastructurally, B-PLL is characterized by the predominance of a relatively large lymphoid cell with a prominent nucleolus, well-condensed peripheral nuclear chromatin, and a variable amount of heterochromatin in intranuclear clumps (Costello et al. 1980). The immunophenotype is characterized by strong expression of surface IgM and usually also IgD, the cells being positive for B-cell markers (CD19, CD20, CD22, CD79a and b, and FMC7). Twenty to thirty percent of cases show positivity for CD5 and 10–20 % for CD23.

Liver Involvement

Similar to the spleen, B-PLL can cause infiltration of the liver with prolymphocytes in a CLL-like distribution pattern (Lampert et al. 1980). These cells are present in the lumina of hepatic sinusoids, depending on the leukemic cell count in the peripheral blood. More impressive are often dense leukemic cell infiltrates occupying the expanded portal tracts, in a pattern often closely resembling that seen in B-CLL . The neoplastic cells first fill the portal tract space, encroaching upon small bile ducts and blood vessels. In the course of the disease, the cells leave the filled portal tract compartment and start to invade the periportal lobular zone 1, causing an ill-defined "blue" and highly cellular infiltrate effacing the portal tract structure. In case of massive hepatic infiltration, acute hepatic failure may ensue (Steidl et al. 1994).

Cytogenetic and Molecular Genetic Features

Complex karyotypes are common in B-PLL. Among these, del(17p) is detectable in 50 % of cases and is associated with p53 mutations. In cells of B-PLL, Ig genes are clonally rearranged with an unmutated heavy chain gene in about half of the cases. CLL and B-PLL have different and distinctive gene expression signatures (review: Del Giudice et al. 2009). B-PLL shows the highest rate of p53 mutations in B-cell malignancies and may be a major factor responsible for the aggressive course with frequent resistance to therapy (Lens et al. 1997). In a subset of B-PLL, BRAF V600E mutation has been detected (Langabeer et al. 2012). B-PLL and CLL with MYC gene

translocations form a subgroup with an aggressive disease course (Put et al. 2012).

Follicular Lymphoma of the Hepatobiliary Tract

ICD-O codes:

Follicular lymphoma	9690/3
Grade 1	9695.3
Grade 2	9691/3
Grade 3A	9698/3
Grade 3B	9698/3

Introduction

According to the definition of the WHO classification, follicular lymphoma (FL) is a neoplasm composed of follicle center (germinal center) B cells, typically both centrocytes and centroblasts/large transformed cells. This lymphoma typically produces a follicular pattern (at least partially). In case of complete formation of large follicular structures resembling giant follicles with germinal centers, the lesion is what has previously been termed Brill-Symmers disease (synonyms: giant follicular lymphoblastoma; giant follicular lymphoma, germinoblastoma; Brill et al. 1925; Symmers 1927). If diffuse areas of any size comprised predominantly or entirely of blastic lymphoid cells are present in any case of follicular lymphoma, a diagnosis of diffuse large B-cell lymphoma is also made (reviews: Klapper 2011; Roulland et al. 2011; Stevenson and Stevenson 2012).

Follicular lymphoma is a rather common lesion in the non-Hodgkin's lymphoma group, with about 20 % of all lymphomas. This high figure is, however, only valid for the USA and Western Europe; in Eastern Europe and Asia, FH is less common. FL is mainly a neoplasm of adults, most patients being diagnosed with FL in the sixth decade, with a slight female preponderance. In the pediatric age group, which is rarely involved, males clearly predominate. FL is mainly a disease of lymph nodes, but also the extranodal lymphatic tissues, including the spleen, are regularly involved. Infiltration of solid organs usually occurs in patients with extensive nodal disease, but (apparently) primary involvement of deep organs also occurs. Similar to other lymphomas, FL can transform to an aggressive lymphoma (Wong and Dickinson 2012).

Clinical Features

Patients commonly show widespread nodal involvement at diagnosis, often with splenomegaly, but the majority of patients are asymptomatic at diagnosis (Freedman 2012). Bone marrow involvement is found in 40–70 % of patients. Patients with FL are classified in regard to risk by use of the international prognostic index (FLIUPI) in the National LymphoCare Study (NLCS). FL in the pediatric age group differs in several respects from adult-type FL (Louissaint et al. 2012).

Morphology and Grading

The hallmark of FL is the presence of lesion mimicking lymphoid follicles that efface the preexisting lymphoid tissue or form a tumorous lesion in non-lymphoid tissues and organs. The follicles usually lack a well-defined mantle zone and typically lack macrophages with tingible bodies. In case of large follicular structures (Brill-Symmers pattern), a distinction between hyperplastic normal follicles and neoplastic lesions may be difficult, but immunostaining for follicular dendritic cells (Cd21/Cd23) will deliver the correct answer. Cytologically, FL is composed of two cell types of the B-cell lineage, i.e., small- to medium-sized cells with angulated or cleaved nuclei and scant cytoplasm (the centrocytes) and large cells, with round to oval nuclei and a thin rim of cytoplasm (the centroblasts). Centroblasts are always present, but usually form the minority. In part of the cases, FL cells may contain prominent Dutcher body formation (Wang et al. 2012a). Dutcher bodies (Dutcher and Fahey 1959) are intranuclear and intracytoplasmic, PAS-positive, Ig chain-related glycoprotein inclusions that were first recognized in patients with Waldenström's disease. The nuclear inclusions are in fact invaginations of cytoplasmic inclusions.

Table 1 Grading of follicular lymphoma (WHO classification 2008)

Grading	
Grade 1–2: Low grade	
Grade 1: 0–5 centroblasts per HPF	
Grade 2: 6–15 centroblasts per HPF	
Grade 3: High grade, >15 centroblasts per HPF	
Grade 3A: Centrocytes present	
Grade 3B: Solid sheets of centroblasts	
Reporting of pattern	***Proportion follicular***
Follicular	>75 %
Follicular and diffuse	25–75 %
Focally follicular	<25 %
Diffuse	0 %
Diffuse areas containing >15 centroblasts per HPF are diagnosed as diffuse large B-cell lymphoma with follicular lymphoma	

Grading of FL (Table 1), based on the proportion of centroblasts, has been advocated as a prognosticator, but the significance of FL grading is still debated. In principle, FL grading is based on counting or estimating the proportion or absolute number of centroblasts in ten neoplastic follicles at 40× magnification (high-power field, HPF), whereby at least ten HPFs within different follicles are evaluated.

Grade 3B is currently identified as a distinct entity by molecular analysis. Transformation to diffuse follicular lymphoma, characterized by a neoplastic proliferation of cells resembling centrocytes in the absence of a follicular pattern, occurs in about 30–40 % of patients, at a rate of around 3 % each year. Diffuse (or high-grade) transformations confer a more aggressive course (review: Takata et al. 2014). The cells must display immunohistochemical features of germinal center cells, and the diagnosis should only be made with an adequate tissue sample, as diagnosis is prone to considerable sampling error.

Immunohistochemically, the tumor cells express B-cell markers (CD19, CD20, CD22, CD79a). They are also reactive for BCL2, BCL6, and CD10, but negative for CD5, CD43, and IRF4/MUM1. The follicular areas may show sparse networks or meshworks of CD21-positive follicular dendritic cells. The tumor cells are usually positive for surface Igs. At least part of neoplastic cells express centerin (SERPINA9/GCEt1), a germinal center serpin variant (Frazer et al. 2000; Pan et al. 2003; Montes-Moreno et al. 2008). In part of FL, centerin is strongly expressed (Paterson et al. 2008).

Primary Follicular Lymphoma of the Hepatobiliary Tract

Primary follicular lymphoma of the liver has only been reported few times (Torres 1969; Michetti et al. 1978; Ryan et al. 1988; Ohsawa et al. 1992; Lei 1998; Yeshurun et al. 2001; Bronowicki et al 2003; Gomyo et al. 2007; Raimondo et al. 2012). It is estimated that only about 1–4 % of primary hepatic lymphomas are FL (Ohsawa et al. 1992). Primary FL of the liver may present as a solitary nodule or multiple nodules, sometimes mimicking a primary epithelial hepatic tumor. In a compilation of nine cases from the literature, five cases were solitary and four were multiple tumors (Gomyo et al. 2007). In case of multiple lesions, FL can cause marked hepatomegaly. In an autopsy case, the liver weighed 2240 g, and both the external and cut surfaces were studded by in part confluent nodules of tumor, some having a shallow central dimpling and measuring from 1.0 to 2.0 cm in diameter. Microscopically, the nodules consisted of lymphocytic NHL forming numerous and sometimes very large follicular aggregates that had effaced the liver structure, with some remaining small bile ducts reflecting previous portal tracts (Torres 1969). In case of marked hepatic infiltration, acute liver failure may be the initial manifestation of low-grade hepatic FL (Yeshurun et al. 2001). The follicular pattern may vary from one part of the hepatic tumors to the other, the more diffuse growth pattern of the lymphoma irregularly blending into the partly atrophic liver substance. The portal tract infiltrate can encroach upon damaged interlobular bile ducts, thus inducing a "lymphomatous bile duct lesion."

Primary FL has also been identified in extrahepatic bile ducts, in one patient mimicking a hilar cholangiocarcinoma (Sugawara et al. 2008; Christophides et al. 2009).

Secondary FL Involvement of the Liver

The liver can be involved in widespread FL (Fig. 5). Several cases have been described as liver involvement in Brill-Symmers disease or not otherwise specified lymphomas with formation of follicle-like structures (Terplan 1929; Symmers 1942; Cohen and Bergstrom 1946; Wells 1954; Wissmer et al. 1955; Fresen 1956; Baessler 1959). In the early report of Terpan (1929), the disorder is described as a "granuloma-like systemic disease," the giant follicles interpreted as granulomatous lesions. Symmers' patient (1942) showed, at autopsy, a markedly enlarged liver with tumor-like infiltrates measuring up to 1 cm in diameter. The patient of Cohen and Bergstrom (1946) showed white focal lesions of 1–2 mm size in the liver at autopsy. Among 31 patients with stage II–IV disease, 2 had liver involvement (Takagi et al. 1989).

Differential Diagnosis

An important histopathologic differential diagnosis of FL of the truly follicular type is nodular lymphoid hyperplasia of the liver (Jimenez et al. 2007). The much rarer diffuse variety may be confounded with other diffusely growing hepatic lymphomas.

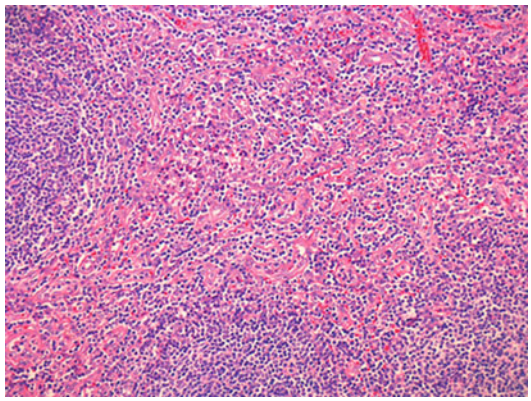

Fig. 5 Follicular non-Hodgkin's lymphoma of the liver. Abnormal follicular structures are found to the *left* and at the *bottom* of the figure (hematoxylin and eosin stain)

Cytogenetic and Molecular Features

Approximately 80 % of FL exhibit the translocation t(14;18)(q32;q21) and BCL2 gene rearrangements, mainly in low-grade lesions. This translocation is therefore a genetic hallmark of FL (review: Kishimoto and Nishikori 2014). BCL2 rearrangements are much less common in grade 3B FL. Five to fifteen percent of FL show abnormalities in 3q27-28 and/or BCL6 rearrangements, predominantly in low-grade lesions (grade 3B). Various other chromosomal and molecular abnormalities have been identified in FL (Oricchio et al. 2011; Kridel et al. 2012). Most patients with FL variably express BAFF (B-cell activation factor) and BAFF-RE, high expression of BAFF-R being an independent risk factor for overall survival (Li et al. 2012). Epigenetic inactivation of p16, p15, MGMT, and DAPK genes can take place in FL, concurrent hypermethylation of MGMT and DAPK genes being markers of chemoresistance and disease recurrence (Krajnovic et al. 2013). FL is characterized by a unique microRNA signature, whereby miR-20a/b and miR-194 targeting CDKN1A and SOCS2 potentially contribute to tumor cell proliferation and survival (Wang et al. 2012b). Apart from the neoplastic lymphoid B cells, the lymphoma's microenvironment is an important factor for tumor progression (Wahlin et al. 2012), and stromal cells associated with FL lymphoma cells play a significant pathogenic role (Mourcin et al. 2012). Furthermore, follicular helper T cells play a role for the survival of follicular neoplastic B cells (Amé-Thomas et al. 2012).

Mantle Cell Lymphoma of the Liver

ICD-O 9673/3

Introduction

According to the 2008 WHO classification, mantle cell lymphoma (MCL) is defined as a B-cell neoplasm composed of monomorphic small- to medium-sized lymphoid cells with irregular

nuclear contours and a CCND1 translocation. MCL is a rare lymphoma which account for about 3–10 % of all non-Hodgkin's lymphomas. The average age at diagnosis is 60 years, with a variable male predominance. The most common site of involvement is the lymph nodes, but the spleen and bone marrow also often participate, and the peripheral blood may be involved. A typical manifestation in the gastrointestinal tract is multiple lymphomatous polyposis. Clinically, many patients present with advanced stage at diagnosis, with lymphadenopathy, hepatosplenomegaly, and bone marrow and peripheral blood involvement (Weisenburger et al. 1982; Swerdlow et al. 1983; Decaudin et al. 1997; Lai and Medeiros 2000; Sander 2011; Kiel and Smith 2012; Shah et al. 2012; Vose 2013; Dreyling and European Mantle Cell Lymphoma Network 2014; Gordon et al. 2014).

Morphology

MCL is characterized by a monomorphic proliferation of small- to medium-sized lymphoid round cells with irregularly shaped nuclei, resembling centrocytes. Centroblast-like cells are absent. In nodes, these cells reveal a growth pattern with diffuse, vaguely nodular, mantle zone or rarely follicular areas. MCL often shows hyalinized small vessels. Large infiltrates may have interspersed pale histiocytes/macrophages, sometimes with a "starry sky" effect. MCL has few variants of prognostic significance, including blastoid and pleomorphic variants. Immunocytochemically, the cells express surface IgM/IgD, more often with a lambda than kappa light chain restriction. Cells are reactive for CD5, CD43, FMC-7, cyclinD1, and BCL2, but negative for CD10 and BCL6.

Liver Involvement

Primary Hepatic Mantle Cell Lymphoma

In rare instances, MCL was observed to develop as a primary liver lymphoma (Itoh et al. 1995; Lei et al. 1995; Zhang et al. 2010).

Secondary Involvement of the Liver

Involvement of the liver has been documented several times (Swerdlow et al. 1983; Franchi et al. 1995; Sousa et al. 1997). In a study of 102 patients, the liver was infiltrated in 22.64 % of cases (Ji et al. 2007). Also the blastic variant can involve the liver substance (Rodler et al. 2004). As in other small to intermediate cell lymphomas, the portal tract space is the preferential compartment for tumor cell proliferation and homing, with variable extension into the periportal lobular zone 1 ("lymphomatous piecemeal necrosis"; lymphomatous interface lesions). MCL can undergo peritoneal seeding (Bahat et al. 2010) and may thus involve the liver capsule.

Differential Diagnosis

As cyclinD1 is normally not expressed in B lymphocytes, cyclinD1 immunostaining is the key diagnostic marker for MCL and a chief discriminator in differential diagnoses of liver lymphomas.

Cytogenetic and Molecular Features

There is clonal rearrangement of Ig genes. Almost all cases show the translocation t(11;14)(q13;q32) juxtaposing IGH and cyclinD1/CCND1, considered as the primary genetic event in MCL lymphomagenesis (Jares et al. 2012; Royo et al. 2011; Dreyling and European Mantle Cell Lymphoma Network 2014). The translocation causes a reregulated overexpression of cyclinD1. In a simplified pathogenetic scheme, the cyclinD1/cyclin-dependent kinase 4/6 complex promotes phosphorylation of the retinoblastoma protein, Rb, leading to the release of the E2F transcription factors inducing progression through the cell cycle into S phase. The 4/6 complex is inhibited by p16INK4a. There are several molecular/cytogenetic variants of MCL, including cyclinD1-negative MCL, cases with trisomy 12, MYC translocation, and BCL6/3q27 translocation. In cyclinD1/CCND1-negative MCL,

CCDN2 rearrangements were the most frequent genetic events (Salaverria et al. 2013). Recently, several recurrent mutations were identified in MCL, including ATM, CCND1, MLL2, TP53, RB1, WHSC1, POT1, and SMARCA4 genes (Zhang et al. 2014). In addition, MCL shows a high number of nonrandom secondary chromosomal aberrations. Among molecular subsets of MCL, those defined by the IGHV mutational status and SOX11 expression have distinct biologic and clinical features (Navarro et al. 2012). In MCL biology and progression, the composition and features of the microenvironment play a significant role, e.g., the production of IL-6, which is an MCL survival factor (Zhang et al. 2012).

Extranodal Marginal Zone B-Cell Lymphoma of Mucosa-Associated Lymphoid Tissue (MALT Lymphoma)

ICD-O: 9699/3

Introduction

Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT; MALT lymphoma) is a low-grade extranodal NHL developing in several extranodal sites, including the gastrointestinal tract, thyroid gland, salivary glands, ocular adnexa, lung, breast, and liver. This type of lymphoma accounts for about 8 % of NHLs and 50 % of primary gastric lymphomas. Most cases develop in adults, with a median age at diagnosis of 61 years, with a slight female preponderance. MALT lymphomas belong to the group of marginal zone B-cell lymphomas (MZBL). Several features suggest that the three different clinicopathologic types of MZBL (nodal, extranodal, and splenic MZBL) are in fact three different diseases. Clinically, most patients present with stage I or stage II disease. Only a minority of patients show bone marrow involvement. Multiple extranodal sites may be affected in up to 25 % of patients with gastric MALT lymphoma and up to 45 % in those with extragastric disease (Isaacson and Du 2004; Zinzani 2012).

Morphology

In lymph nodes, the tumor cells of MALT lymphoma grow in a marginal zone distribution and spread out to form diffuse confluent areas. The cells are small to medium sized, with slightly irregular nuclei and inconspicuous nucleoli, part of the cells closely resembling centrocytes. The cytoplasm is rather abundant and pale, resulting in a monocytoid morphology. In gastric MALT lymphoma, up to a third of cases reveal plasmacytoid differentiation. A minority of cells exhibit a centroblast-like morphology. Where the tumor cells are in contact with epithelial surfaces or glandular structures, lymphoepithelial lesions develop. Small groups of lymphoma cells are in close association with epithelial cells, associated with epithelial disarray and signs of epithelial damage, such as eosinophilic degeneration. Immunocytochemically, the cells express IgM and less often IgA and IgG and are reactive for CD20, CD79a, CD21, CD35, and, rarely, CD5, negative for CD10 and CD23, and variably positive for CD43. A novel selectively expressed marker for MALT lymphoma is immunoglobulin superfamily receptor translocation-associated 1/IRTA1 (Falini et al. 2012).

Liver Involvement

Primary Hepatic Low-Grade MALT Lymphoma

Primary low-grade marginal zone B-cell lymphoma of MALT of the liver is very rare, less than 50 cases having been reported (Isaacson et al. 1995; Ueda et al. 1996; Maes et al. 1997; Prabhu et al. 1998; Ascoli et al. 1998; Kirk et al. 1999; Ye et al. 2000; Chen et al. 2000; Charton-Bain et al. 2000; Murakami et al. 2002; Yago et al. 2002; Golli et al. 2003; Mehrain et al. 2003; Takeshima et al. 2004; Gockel et al. 2005; Nart et al. 2005; Hamada et al. 2006; Shin et al 2006; Doi et al. 2008; Koubaa Mahjoub et al. 2008; Nakayama et al. 2010; Kiesewetter et al. 2012; Kikuma et al. 2012; Yu et al. 2013; Zhong et al. 2014). In most cases reported so far,

the hepatic NHL was identified incidentally, usually by imaging investigations for liver dysfunction or other diseases, including metastases (Chatelain et al. 2006). Nodules of MALT lymphoma can in fact closely mimic liver metastases. Among the 14 patients reviewed in a recent study (Murakami et al. 2002), nine patients were female, and this NHL involved elderly patients (median age: 64 years). Seven of the patients had preceding but variable liver disease. The lymphoma can be associated with HCV infection (Yago et al. 2002; Bronowicki et al. 2003; Orrego et al. 2005; Viswanatha and Dogan 2007; Arcaini et al. 2012), gastric *Helicobacter pylori* infection (Iida et al. 2007), or primary biliary cirrhosis (Prabhu et al. 1998; Ye et al. 2000; Nakayama et al. 2010). Primary hepatic MALT lymphoma c12/14 lesions were solitary. The dimensions of the hepatic masses ranged from less than 2 to 7.5 cm. Three of the patients reported so far suffered from primary biliary cirrhosis (Prabhu et al. 1998; Ye et al. 2000; Golli et al. 2003). This association had been suggested to eventually be related to an effect of chronic antigenic stimulation favoring the development of MALT-type NHL (Prabhu et al. 1998; Ye et al. 2000). Exceptionally, MALT lymphoma in the liver presents as high-grade lymphoma. In one patient, this lymphoma was diagnosed several years after complete remission of a gastric low-grade MALT lymphoma and was thought to have probably transformed from this gastric lymphoma (Chung et al. 2006).

Macroscopy

In the few cases that have been described, MALT NHL of the liver presented as ill-defined solid and firm masses of grayish-red color, sometimes in close relationship with vessels of bile ducts and with signs of necrosis and hemorrhage (Yu et al. 2013).

Histopathology

In more detail, the nodular hepatic growths in MALT lymphoma of the liver consist of small- to medium-sized cells that are slightly larger than normal small lymphocytes and that show centrocyte-like nuclei . In the Giemsa preparation, the moderate cytoplasm stains light or even clear. In addition to this main cell population, other cell types may occur, including elements with monocytoid features (with kidney-shaped nuclei) and cells resembling lymphoplasmacytoid cells. Similar to MALT NHL in the gastrointestinal tract, where about a third of the cases show cells with a plasma cell differentiation, plasma cells are also seen in hepatic lesions. The diffuse or nodular/follicular growth of NHL of the MALT type is intermingled with usually rather few large basophilic blasts of the immunoblast phenotype. Of particular interest for hepatic MALT lymphoma is the observation that the typical lymphoepithelial lesions are also found, but involving the epithelial lining of bile ducts. These *biliary lymphoepithelial lesions* have been reported in the literature (Maes et al. 1997; Charton-Bain et al. 2000; Ye et al. 2000; Iida et al. 2007; Baumhoer et al. 2008). This type of lesion is characterized by a disarray of involved small- to medium-sized bile ducts, with crowding of nuclei, loss of cholangiocytes, and intraepithelial infiltrates consisting of both tumor cells and normal-looking small lymphocytes. The lesions somewhat resemble the bile duct lesions seen in primary biliary cirrhosis and autoimmune cholangiopathy, and the epithelial damage is best visualized by use of biliary cytokeratin immunohistochemistry.

Immunohistochemistry

Immunohistochemically, the tumor cells express surface immunoglobulins (usually IgM), CD20, and CD79a, but not CD43 or CD45RO (Iida et al. 2007; Doi et al. 2008), the latter in cell subsets displaying varying degrees of plasmacytic differentiation, where also CD38 is positive. There is typically no immunoreactivity for CD23 and cyclin D1, but, in contrast to gastrointestinal NHL of the MALT type, extra-GIT lesions may express CD5. The nodular/follicular components

contain CD23- and CD35-positive follicular dendritic cells, however with variable colonization densities.

Nonparenchymal Involvement of the Hepatobiliary Tract

Extranodal marginal zone B-cell lymphoma of the MALT also occurs in the gallbladder and along the extrahepatic bile ducts to the papilla of Vater (Pelstring et al. 1991; Mosnier et al. 1992; McCluggage et al. 1996; Ventrucci et al. 1998; Bickel et al. 1999; Tsuchiya et al. 2001; Kang et al. 2001; Chim et al. 2002; Isomoto et al. 2003). This issue is further discussed in the part on biliary tumors.

Differential Diagnosis

MALT lymphoma of the liver has to be distinguished from other small B-cell lymphomas, either primary or secondary. Furthermore, hepatic pseudolymphomas may sometimes closely resemble MLAT lymphoma in conventional tissue sections (Willenbrock et al. 2006; Hayashi et al. 2011).

Pathogenic Pathways

The development of MALT lymphoma depends on antigen-driven T-cell-mediated stimulation, whereby, in gastric lymphomas, immune stimulation by *Helicobacter pylori* plays a significant role. MALT lymphoma bears specific translocations (reviews: Müller-Hermelink 2003; Bertoni and Zucca 2006). In the primary and most frequent t(11;18)(q21;q21) translocation, an inhibitor of apoptosis, API2 (apoptosis inhibitor-2), assigned to chromosome 11, and MALT1 are involved in this type of translocation, forming fusion transcripts of different lengths due to several breakpoints in the MALT1 gene and a rather constant breakpoint in the API2 gene. The second translocation, t(14;18)(q32;q21), fuses the immunoglobulin heavy chain gene (IGH) with MALT1. The latter translocation was detected most frequently in MALT lymphomas of the conjunctiva, liver, skin, parotid gland, and other salivary glands. It has furthermore observed that the t(14;18)(q32;q21) transcription can also involve fusion of IGH with bcl-2 in a subset of MALT lymphomas in patients with HCV infection (Libra et al. 2004). There are other translocations in MALT lymphoma, including the recently reported translocation t(X;14)(p11;q32), which deregulates expression of an orphan G-protein-coupled receptor, GPR34 (Ansell et al. 2012), and t(11;14)(q23;q32), involving IGh and DDX6 (Stary et al. 2013).

MALT1/paracaspase is a caspase-like protein making part of an evolutionarily conserved superfamily of caspase-like proteins, the paracaspases and metacaspases (Uren et al. 2000; Yu and Lenardo 2003; Hachmann et al. 2012; Kirchhofer and Vucic 2012; Wiesmann et al. 2012), that holds a central role in lymphocyte activation. This has been demonstrated by the use of paracaspase-deficient mice that are defective in antigen receptor-induced NF-kappaB activation and cytokine production (Ruefli-Brasse et al. 2003). MALT1 contains an N-terminal death domain, two immunoglobulin (Ig)-like domains, and a C-terminal caspase-like domain. MALT1 binds to bcl10 through its Ig-like domains and cooperates with bcl10 to activate NF-kappaB. Chimeric API2/MALT1 proteins are thought to function as oncogenes that bilaterally confer a proliferative advantage to the clone by activating the NF-kappaB signaling pathway and also inhibiting p53 protein-mediated apoptosis (Stoffel et al. 2004; Stoffel and Levine 2004). In fact, the chimeric protein binds to several protein partners that regulate apoptotic pathways, including Smac, HtrA2, and TRAF2 (Hosokawa et al. 2004). The NF-kappaB pathway is affected by a series of adaptor proteins, including MALT1/paracaspase (Hailfinger et al. 2011; Rosebeck et al. 2011), CARMA3 (a member of the membrane-associated guanylate kinase {MAGUK} family of scaffold proteins; Sun 2010; Jiang et al. 2011), BCAP, the E3 ubiquitin ligase mind bomb-2 (Stempin et al. 2011), and BCL10 (B-cell lymphoma 10) (Thome 2004), forming a protein

complex (the CARMA3-BCL10-MALT1 signalosome; Delekta et al. 2010; McAllister-Lucas et al. 2010), depending in its assembly on neuroepithelial transforming gene 1/Net1 (Vessichelli et al. 2012), in which BCL10 is thought to facilitate the oligomerization of MALT1 monomers (Simeoni et al. 2004). By this, the paracaspase MALT1 can potently activate NF-kappaB, suggesting that MALT1 might stimulate the kinase complex (IKK, inhibitor of NF-kappaB kinase) responsible for activating cytoplasmic NF-kappaB for translocation into the nucleus. The tripartite protein complex is also responsible for the ubiquitination of NEMO critical for NF-kappaB activation (Lynch and Gadina 2004). Specifically, BCL10 activates NF-kappaB through ubiquitination of NEMO (Zhou et al. 2004). On the other hand, the CARD domain of BCL10 can also activate NF-kappaB by its own, and both MALT1 and bcl10 seem to do so by a mediating action of TRAF6 ubiquitin ligase and TAK1.

The MALT1/paracaspase oligomers bind to TRAF6, induce TRAF6 oligomerization, and activate the ligase activity of TRAF6 to polyubiquitinate NEMO (Sun et al. 2004). The MALT1/paracaspase is also involved in T-cell receptor-induced NF-kappaB activation. MALT1 is required into the lipid rafts of the immunological synapse following activation of the T-cell receptor (TCR) and the CD28 coreceptor (CD3/CD28 costimulation). This recruitment of MALT1 is dependent on CARMA1, and MALT1 associates with CARMA1 in a bcl10-dependent manner (the tripartite/trimolecular complex; Che et al. 2004). It has recently been shown that expression of MALT1 in hematopoietic stem cells in mice recapitulates the pathogenesis of human lymphoma (Vicente-Duenas et al. 2012).

B-Cell Non-Hodgkin's Lymphomas with a Small Cell to Intermediate Cell Phenotype: Special Phenotypes

90

Contents

Abstract

The liver can be involved by several types of rare B-cell lymphoproliferative disorders. Hairy cell leukemia (HCL) is a rather indolent, rare chronic lymphoproliferative disorder that involves a distinct type of small B lymphocytes with oval nuclei and abundant cytoplasm with hairy projections. HCL accounts for 2–3 % of all adult-type leukemias. These neoplastic cells, arrested in a late stage of maturation, accumulate in peripheral blood and diffusely infiltrate bone marrow and inner organs, in particular the spleen. HCL can be associated with autoimmune disorders, such as rheumatoid arthritis and connective tissue diseases. The liver is frequently involved, but hepatomegaly is less common than in chronic lymphocytic leukemia. Histologically, hepatic infiltration ranges from focal cellular infiltrates, mainly in portal tracts, to massive diffuse parenchymal infiltration that may cause liver dysfunction. Rarely, HCL can cause tumoral nodular masses in the liver. The liver can be infiltrated in the setting of the rare disorder, T-cell/histiocyte-rich large B-cell lymphoma, in which scattered large B cells are embedded in a background of abundant T cells. Also, the rare lymphomatoid granulomatosis, defined as an angiocentric B-cell lymphoproliferative disorder associated with EBV infection, can extensively involve the liver.

Hairy Cell Leukemia

ICD-O code 9940/3

Introduction

Hairy cell leukemia (HCL; earlier terms, leukemic reticuloendotheliosis, tricholeukocyte leukemia, trichocellular leukemia, lymphoid myelofibrosis, histio-lymphoctosis; Gosselin et al. 1956; Bouroncle et al. 1958; Duhamel and Guerra 1966; Flandrin et al. 1967; Plenderleith 1970; Ghadially and Skinnider 1972) is an unusual, rather indolent, chronic lymphoproliferative disorders involving a distinct type of small, mature B lymphocytes characterized by oval nuclei and abundant cytoplasm with "hairy" projections. No normal counterpart of this cell has been identified in the maturing B-cell lineage. These cells, which are arrested at a late stage of maturation, involve the peripheral blood and diffusely infiltrate the bone marrow, the spleen, and other inner organs. It is one of the rare NHL disorders, accounting for 2–3 % of all adult-type leukemias (Katayama and Finkel 1974; Staines and Cartwright 1993; Pettitt et al. 1999; Polliack 2002; Goodman et al. 2003; Hockley et al. 2012). Pathogenetically, BRAF V600E mutations are involved in part of the cases.

The term, HCL, refers to a unique morphologic feature of the cells involved, characterized by cytoplasmic projections seen in smears and, less so or not, in tissue sections. A second extraordinary feature of this B-cell neoplasm is the unusual sensitiveness of the disorder to therapy with the agents, interferon alpha and nucleosides. In principle, HCL is a variant of a chronic B-cell lymphoproliferative disorder with a variable propensity for blood involvement and bone marrow suppression. Similar to other chronic B-cell neoplasms, expansion of the abnormal cell population is related to the cells' longevity rather than to increased proliferation (Pettitt et al. 1999).

Clinical Features

The HCL cells have a distinct type of tissue distribution. In contrast to other chronic B-cell lymphoproliferative disease, HCL cells have little or no propensity to populate lymph nodes, whereas the spleen is more frequently, and more severely, involved (Forconi 2011; Galani et al. 2012; review by Cawley 2009). The disease mainly affects middle-aged and old males, with an overall male-to-female ratio of approximately 4:1. The median age of onset is 52 years (Cannon et al. 2008). Most patients show splenomegaly at presentation (mean spleen weight in a study of 16 patients is 1,700 g; Franssila 1983). Common hematological complications, i.e., anemia, neutropenia, monocytopenia, and thrombocytopenia, are mostly due to suppression of bone marrow hemopoiesis by the infiltrating, cytokine-producing HCL cells, to splenomegaly, and to the effects of the frequent infections (Kraut 2003). Infections are still a major cause of morbidity and mortality in HCL patients, possibly related to neutropenia and monocytopenia; a disordered defense is also indicated by the presence of unusual pathogens such as mycobacteria and *Listeria* (Thaker et al. 2001). Very rarely, HCL can undergo blastic transformation associated with the loss of TRAP expression (Nazeer et al. 1997). On the other hand, a nationwide investigation of the Italian Cooperative Group for the Study of HCL did not support the suspicion that patients with HCL are at increased risk for additional second malignancies, although the incidence of lymphoid neoplasms was significantly higher than expected (Federico et al. 2002). For example, it is known that HCL can transform into high-grade lymphomas (Adler et al. 1979; Franssila 1979; Downing et al. 1986; Arnalich et al. 1987; Huang et al. 1987; Sun et al. 2004).

HCL is sometimes associated with autoimmune disorders, including rheumatoid arthritis (Crofts et al. 1979; Zervas et al. 1991), connective tissue disease (Hasselbalch 1984), sclerodermapolymyositis overlap (Blanche et al. 1995), leukoclastic vasculitis (mainly of the skin, occasionally with cryoglobulinemia), systemic vasculitis, periarteritis nodosa, anticardiolipin syndrome, arthritis, rheumatism-like skin nodules, and chronic active hepatitis (Goedert et al. 1981; Dorsey and Penick 1982; Westbrook and Golde 1985; Begley et al. 1985; Farcet

et al. 1987; Salvarani et al. 1989; Shpilberg et al. 1989; Hasler et al. 1995). The recognition of such associations is also important in regard to eventual manifestations of visceral vasculitis in the liver. Less frequently, HCL is associated with sarcoidosis, the development of which may be favored by abnormal immunologic effector cell functions in HCL (Myers et al. 1979; Berthiot 1993; Schiller et al. 2003). However, granulomas can occur in both the liver and spleen in HCL in the apparent absence of sarcoidosis (Yam et al. 1983; Bendix-Hansen and Bayer Kristensen 1984).

Morphology of Leukemic Cells

The distinct features of the HCL cell have been reviewed (Domagala 1975). The unusual "hairy" surface of HCL cells is best recognized by phase microscopy and confirmed by transmission and scanning electron microscopy (Katayama et al. 1972; Fabre et al. 1974; Golomb et al. 1975). Both ruffles and microvilli have been detected in the HCL cells; cells with ruffled areas next to clumps of microvilli have been termed type A cells, while those cells displaying microvilli interspersed among ruffles are called type B cells (Gamliel and Golomb 1986). At EM examination, and sometimes also in light microscopy, the cytoplasm of HCL cells frequently contains so-called ribosome-lamella complexes (Katayama et al. 1972, 1973; Deegan et al. 1976). The production of the characteristic "hairs" or cytoplasmic projections is caused by an abnormal organization of the actin-containing cytoskeleton (Caligaris-Cappio et al. 1986). In HCL, the neoplastic cells circulate in the blood and infiltrate the bone marrow, but also several extramedullary organs, mainly the spleen and also the lymph nodes and the liver. In the marrow, early changes are sometimes characterized by a so-called spongy lymphoid myelofibrosis (Hasselbalch 1984).

Traditionally, expression of tartrate-resistant acid phosphatase (TRAP) is regarded as a characteristic marker of HCL cells. However, TRAP (Acp 5) is not restricted to HCL cells, but is detectable by immunohistochemistry and mRNA Northern blotting in diverse human tissues, particularly epithelial cells and dendritic cells (Hayman et al. 2001). TRAP isoenzyme 5 is detectable in paraffin sections by use of immunohistochemistry. Using a TRAP antibody, it has been shown that less than 50 % of the hairy cells were stained, whereas reactivity for CD20 and DBA.44 was 90 % and 50–60 %, respectively, suggesting that TRAP immunohistochemistry should be used in conjunction with other markers (Hoyer et al. 1997). As TRAP is not specific for the reliable identification of the neoplastic cell lineage in HCL, other markers are currently sought. It has been demonstrated that annexin A1 (ANXA1) is a gene that is upregulated in HCL and that immunocytochemistry using a monoclonal anti-ANX1 antibody is a specific tool for the diagnosis of HCL (Falini et al. 2004; Sherman et al. 2011). In contrast to classical HCL, variant HCL/HCLv cells do not express annexin A1 (Shao et al. 2013). HCL cells strongly express CD103 (Dong et al. 2009; Morgan et al. 2013), CD22, and CD11c and express the p55 chain of the IL-2 receptor (IL-2R) system recognized by anti-CD25 monoclonal antibodies (de Totero et al. 1994), binding IL-2 with low affinity, and p75 IL-2R chain that binds IL-2 with intermediate affinity. The presence of IL-2R on HCL cells confers a proliferative response to IL-15 (Trentin et al. 1997). There is a minority of HCL that does not express CD25 on the cell surface, but IL-2R receptor is detectable in the cytoplasm of the cells involved (Tison et al. 1995). Furthermore, HCL cells express CD52 in the majority of the neoplastic cells, providing a rationale for the use of anti-CD52 (alemtuzumab) in refractory HCL (Quigley et al. 2003). HCL cells express synaptojanin 2, a phosphatidylinositol 4,5-biphosphatase involved in cell growth and rearrangement of actin filaments; it was suggested that overexpression of this protein may correlate with the morphologic features of HCL (Spaenij-Dekking et al. 2003). A further surface marker that characterizes B-cell disorders with circulating hairy or villous cells is CD123 which identifies the alpha chain of the human IL-3 receptor (Del Giudice et al. 2004). A subset of HCL cells is reactive for T-cell

intracellular antigen-1 (TIA-1) in a small, dot-like, granular expression pattern, whereas other B-cell neoplasms are not (Mori et al. 2004).

Liver Changes in Hairy Cell Leukemia

General Features

In HCL, the liver is frequently involved, but the frequence of hepatomegaly is variably reported, either as a common or an uncommon finding. Participation of the liver in the disease process can occasionally cause liver dysfunction (Kraut 2003). In an autopsy study from 21 patients with HCL, liver involvement was present in 19 patients (Dedic 2003). Among 19 HCL patients, eight had hepatomegaly, although all of the 19 had evidence of liver infiltration in the biopsies (Yam et al. 1983).

Hepatic Infiltration with HCL Cells

Infiltration of the liver by the leukemic cells reveals diverse distribution patterns and variable degrees (Burke et al. 1974; Yam et al. 1983; Vardiman and Golomb 1984; Roquet et al. 1985; Zafrani et al. 1987; Itoh et al. 1989; Evans et al. 1992; Andrade et al. 1998; Dedic 2003). The infiltration ranges from focal cellular infiltrates, mainly in the portal tract spaces and cell accumulations within the lumina of sinusoids, to massive diffuse infiltration of almost the entire liver in advanced cases (Fig. 1; Dedic 2003). Massive hepatic infiltration can result in acute liver failure (Valero et al. 2007). Even in asymptomatic chronic liver disease associated with HCL, an extensive mononuclear accumulation in sinusoids was found (Andrade et al. 1998), a feature already emphasized in early reports (Fabre et al. 1974; Burke et al. 1974). It has been proposed that, in liver biopsies, a sinusoidal pattern of involvement is strongly in favor of HCL, in contrast to other types of NHL that preferentially infiltrate the portal tract spaces (Verdi et al. 1986). The accumulation of HCL cells in the sinusoids may be marked, leading to the effacement of the sinusoidal profiles and the perisinusoidal spaces

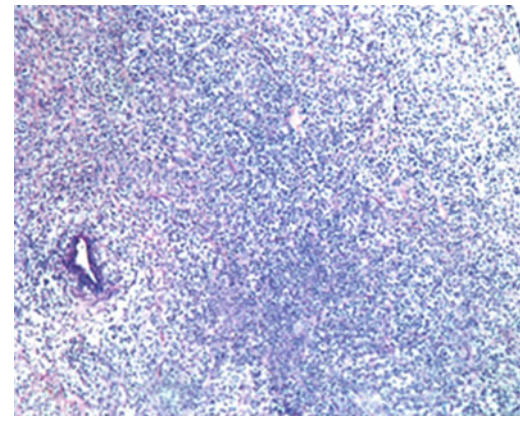

Fig. 1 Nodular infiltration of the liver in hairy cell leukemia (hematoxylin and eosin stain)

(Yam et al. 1983). The cellular features are usually those of a "mononuclear" infiltrate, typically with a so-called clear cell pattern, characterized by a "halo" appearance consisting of a clear rim of abundant cytoplasm surrounding uniform round or slightly indented nuclei. This phenomenon results in a peculiar pattern in case of sinusoidal accumulation of cells, characterized by variably sized, roundish, and clear areas containing the nuclei of the leukemic cells, the latter frequently in a marginal position of the clear areas (Yam et al. 1983; Roquet et al. 1985). The clear aspect of the cells is related to the shaggy cytoplasm which stains poorly with eosin and probably to the loose structures at the cells' periphery caused by the hairy projections (Yam et al. 1983). Interestingly, a hairy phenotype of the cells is more frequently in evidence within sinusoids, while cells forming a portal tract infiltrate more rarely exhibit cytoplasmic projections (Fabre et al. 1974).

The mechanisms of sinusoidal homing are not yet clear. Hairy cell homing seems to depend on CD44-hyaluronan interactions, but this is not relevant to hepatic sinusoids because in sinusoids, hyaluronan is largely absent (Aziz et al. 2000). The HCL cell features may be missed in paraffin sections (or may even not be suggestive of a neoplastic process; Yam et al. 1983), further cell typing requiring immunohistochemistry. The enzyme histochemical detection of HCL cell-related tartrate-resistant acid phosphatase in tissue

is possible in formalin-fixed and paraffin-embedded liver biopsy specimens (Grouls and Stiens 1984). TRAP immunohistochemistry also works in methacrylate-embedded sections (Yam et al. 1983). What is the clinical-biological significance of hepatic infiltration in HCL? In a study on 19 patients, the severity of HCL cell infiltration of the liver correlated poorly with the size of the liver or the spleen, the biochemical changes, or the number of hairy cells in the blood (Yam et al. 1983), confirmed in a later study on 22 patients (Vardiman and Golomb 1984). Very rarely, hepatic infiltration in HCL was associated with signs of fulminant hepatitis, probably caused by a damaging effect of HCL cells on the liver tissue (Evans et al. 1992).

Hepatic Masses Due To Focal HCL Infiltration

Hepatic infiltration in HCL can result in the formation of grossly visible, nodular lesions, ranging in size from 0.2 to 2.5 cm and mimicking a solid primary liver tumor (Katayama and Finkel 1974; Al-Za'abi et al. 2008; Sahar et al. 2009). In the 61-year-old male patient reported by Sahar and coworkers (2009), abdominal imaging and ultrasound first revealed two focal liver lesions presumed to be hemangiomas. Four years later, abdominal CT showed ten hepatic lesions of different sizes. On CT, the lesions had increased in size 3 years later, and two of the multiple lesions were verified to be hemangiomas by red blood cell scans. A tumor biopsy revealed a small-cell neoplasm consisting of cells that were identical to cells of HCL diagnosed in a bone marrow biopsy during the same period of investigation.

Hepatic Vascular Changes

Based on 14 cases of HCL, unique vascular lesions have been observed in splenectomy preparations and wedge biopsies of the liver. The splenic lesions were characterized by markedly distended and dilated sinusal vascular channels filled with erythrocytes (splenic pseudosinuses; Nanba et al. 1977). Interestingly, these channels were lined by HCL cells rather than endothelial cells. Similar changes were detected in the liver in the form of angiomatoid lesions mimicking peliosis hepatis in multifocal aggregates (Nanba et al. 1977; Berard and Nanba 1978). In the study of Nanba and coworkers (Nanba et al. 1977), three of five hepatic biopsies of HCL patients revealed portal tracts that were expanded by angiomatous lesions consisting of numerous dilated blood spaces resembling vascular channels in part extending into lobular zone 1 and thus causing a geographic picture at low magnification. Occasionally, these lesions connected with adjacent portal tracts in a linear fashion, conferring grossly a resemblance to a nutmeg liver (Nanba et al. 1977). Similar lesions were detectable within the lobular parenchyma. It was suggested that these distinct changes were caused by adherence of HCL cells to fibers of the ECM (Berard and Nanba 1978). Angiomatoid changes of sinusoids or sinusoid-like channels consist of intralobular cavities without zonal preference, and the cavities have marginated tumor cells or tumor cells filling the lumina. This angiomatoid lesion, which is apparently only found in HCL, was confirmed in later reports and was found in one study in 9 of 14 patients (Roquet et al. 1985).

The distinct relationship between HCL cells and the walls of sinusoids was investigated by electron microscopy. It was found that HCL cells adhere to the wall of the cavities that exhibited wide areas of communication between the sinusoidal lumen and Disse's space. These disruptions opened the way for HCL cells that were then sometimes in direct contact with hepatocytes. In a detailed ultrastructural investigation, three types of interactions between HCL cells and sinusoidal walls were described. In type I lesions, cytoplasmic processes of the leukemic cells traverse the endothelial lining through gaps ("bouton de chemise"), bifurcate outside, and extend into Disse's space; in type II, numerous projections (en "radicelles") seem to penetrate the endothelium through its fenestrations; and in type III, numerous but short projections slightly indent the endothelial cells (en "chenille," i.e., like a "caterpillar"). These findings illustrate the complexity of the cellular interactions,

suggesting a distinct series of highly ordered events (Fabre et al. 1974). It was suggested that sinusoidal vascular changes are directly caused by the tumor cells themselves (Zafrani et al. 1987). Novel approaches to the interaction of HCL cells with vessel walls are based on the tissue-homing features of all lymphoid cells. Using a human umbilical vein endothelial cell (HUVEC) model, it was found that the receptor-ligand pair, alpha4beta1/VCAM-1, is important for the adhesion of HCL cells to endothelia and accessory cells in tissues (Vincent et al. 1996). In one patient, a unique and large vascular tumorous lesion developed in HCL, causing marked hepatomegaly (Raz et al. 1984). In this patient, the diagnosis of cavernous hemangioma of the liver was done during splenectomy, but afterward, the large hepatic lesion was thought to be caused by the presence of large angiomatous lakes in the liver. Rarely, vasculitis-like lesions known to develop in HCL (see above), but of unknown pathogenesis, also involve hepatic blood vessels. In one report, arteries in the hepatic hilum formed gross nodular structures, causing compression of large bile ducts and hence obstructive jaundice. However, the histopathology of these vascular lesions was clearly different from polyarteritis nodosa: vascular walls exhibited marked edema and intimal fibrosis, but no necrosis, and the involved segments of the vessels were surrounded by leukemic infiltrates that penetrated the walls but infiltrated the entire thickness of the walls only rarely (Klima and Waddell 1984). A similar lesion was described in another report (Elkon et al. 1979).

Chronic Active Hepatitis

Chronic active hepatitis has been observed in HCL and proposed to belong to the spectrum of autoimmune disorders known to occur in this NHL (Begley et al. 1985).

Hepatic Granulomas

Manifestation of HCL in the liver seems to be rather frequently associated with formation of granulomas. In a study of 19 patients, 6 patients had histologically proven hepatic granulomas. These alterations were primarily located in the hepatic lobules, but were also detected within portal tracts in four patients (Yam et al. 1983). It was suggested that the elevation of serum alkaline phosphatase in HCL patients with liver involvement may be related to the presence of granulomas (Yam et al. 1983). In another study of 15 patients, hepatic granulomas were identified in 20 % (Bendix-Hansen and Bayer Kristensen 1984). HCL is known to sometimes be associated with sarcoidosis, another cause of granulomatous organ disease.

Hepatic Fibrosis in HCL

In case of hepatic infiltration in HCL, portal tract fibrosis was often present, but in one study, no patient had evidence of cirrhosis (Yam et al. 1983). Micronodular cirrhosis with "hemochromatosis" was noted in one patient in the series of Burke and coworkers (1974), but the authors did not specify whether the patient really had hereditary hemochromatosis or secondary hepatic overload.

Classification

The main features of HCL cells are their distinct morphology characterized by complex cytoplasmic projections and their particular activation status. However, there are other B-cell proliferative disorders exhibiting cells with projections, leading to the concept of "hairy cell lymphoproliferative disorders (LPD-HC)" (Yavorkovsky et al. 1990; Table 1). Apart from HCL, LPD-HC include splenic B-cell lymphoma with villous lymphocytes (SLVL; Melo et al. 1987), polyclonal B-cell chronic lymphoproliferative disease/hairy B-cell lymphoproliferative disorder (HBLD) (Matsue et al. 1996; Machii et al. 1997; Yagi et al. 2004), and, rarely, plasma cell leukemias (Tanioka et al. 2003). An immunophenotype scoring system has been proposed to distinguish the two probably related disorders, HCL and

Table 1 B-lymphocyte proliferative disorders with cellular/cytoplasmic projections ("hairy cell lymphoproliferative disorders, LPD-HC")

Hairy cell leukemia (HCL) and its variants (Table 2)
Splenic B-cell lymphoma with villous lymphocytes (SLVL)

Table 2 Working classification of hairy cell leukemia (HCL) and its variants

Classic HCL (European-American-type HCL)
Variant HCL
Japanese variant of HCL
CD10+ HCL

SLVL (Matutes et al. 1994). The further subclassification of HCL is not yet universally recognized, but *three variants* have been described: (1) classic HCL (European-American-type HCL), (2) variant HCL, and (3) Japanese variant of HCL, each with distinct clinical and immunophenotype features. Variant HCL (HCLv) has validated diagnostic criteria (Shao et al. 2013) and has been accepted as a new entity in the WHO 2008 classification (Wang et al. 2011). *Classic HCL* is characterized by cells that are almost always positive for CD11c, CD25, and CD103. In contrast, *variant HCL* and *Japanese variant HCL* are CD11c(+), always CD25(−), and occasionally CD103(+). All three variants are typically CD10negative, with very few exceptions (Wu et al. 2000). There emerges a probable further subset of HCL expressing CD10 (CD10+-HCL; Jasionowski et al. 2003). A working classification of HCL is listed in Table 2.

The activation status of HCL cells is evident by the strong expression of cell surface molecules that are associated with normal B-lymphocyte activation, including CD22, CD25, CD72, and CD40. Furthermore, markers normally lost after B-cell activation, such as CD21 and CD24, are expressed only at low levels (review by Pettitt et al. 1999).

Cytogenetic and Molecular Features

There is no cytogenetic abnormality specific for HCL. More than 85 % of HCL cells reveal VH genes with somatic hypermutation indicating a post-germinal center stage of differentiation. By use of gene expression profiling and comparison of HCL cells with several subsets of normal purified B cells, it surfaced that HCL cells are more related to memory B cells (Basso et al. 2004), although the cells are negative for the germinal center-associated markers, CD27 and CD38 (Forconi et al. 2004). HCL commonly expresses multiple immunoglobulin isotypes, a feature rare in other B-lymphocyte malignancies, and genetic analyses have shown that the cells of origin are heterogeneous in terms of mutational status, but reveal common features of activation-induced cytidine deaminase expression and isotype switch events occurring prior to deletional recombination (Forconi et al. 2004). Possible oncogenic pathways in HCL may be related to the expression, in HCL cells, of a T-cell-associated transcription factor, T-bet, that is not expressed in the vast majority of reactive B cells (Dorfman et al. 2004). A BRAF (BRAF kinase) p.V600E mutation has recently been described as a molecular marker of HCL by whole exome sequencing (Tiacci et al. 2011). This BRAF mutation was found to be universally present in this leukemia (Tiacci et al. 2011; Andrulis et al. 2012; Ewalt et al. 2012; Schnittger et al. 2012; Verma et al. 2012). HCL cells express phosphorylated MEK and ERK as downstream targets of the BRAF kinase, and this activation of the RAF-MEK-ERK pathway is a diagnostic target (Tiacci et al. 2013). However, the BRAF mutation was not detected in cases of variant HCL (Xi et al. 2012; Shao et al. 2013). The "hairy" morphology of HCL cells is thought to be driven by overexpression of Rho family small GTPase members and upregulation of the growth arrest-specific molecule Gas7.

Pathophysiological Effects of HCL Cells

The neoplastic cells of HCL seem to affect bone marrow vascularity and to promote angiogenesis

in this tissue compartment. The generation of bone marrow microvessels in HCL seems to infer an increased risk of progression and INF-alpha treatment failure in HCL (Korkolopoulou et al. 2003). Patients with HCL are known to sometimes develop bone marrow reticulin fibrosis, and this seems to be related to a high expression of the fibrokine, TGF-beta1, in TCL cells (Shehata et al. 2004).

T-Cell/Histiocyte-Rich Large B-Cell Lymphoma

ICD-O code 9688/3

Introduction

In the 2008 WHO classification, T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL; synonyms, T-cell-rich B-cell lymphoma, histiocyte-rich/T-cell-rich large B-cell lymphoma) is defined as a neoplasm characterized by a limited number of scattered, large, atypical B cell embedded in a background of abundant T cells and frequently histiocytes. This NHL mainly involves middle-aged men (75 % are men) and accounts for less than 10 % of all diffuse large B-cell lymphomas. In comparison with large B-cell lymphoma, there is a higher incidence of B symptoms (62 %; Aki et al. 2004). THRLBCL mainly affects lymph nodes, but bone marrow and inner organs such as the spleen and liver are also involved in part of the patients, also as a function of disease progression. The lymphoma often presents with high stage at diagnosis (stage III–IV in 64 %; El-Weshi et al. 2007). There is evidence that the cellular composition of this heterogeneous group of lymphomas exerts an impact on tumor biology. Lesions with a high content of histiocytes behave aggressively and are more often resistant to therapy (Rodriguez et al. 1993; Achten et al. 2002; Lim et al. 2002; Bouabdallah et al. 2003; Abramson 2006; Pittaluga and Jaffe 2010; Tousseyn and De Wolf-Peeters 2011). The etiology and pathogenesis of THRLBCL are not known. Transcriptional features suggest a tolerogenic host immune response (Pittaluga and Jaffe 2010).

Morphology

This lymphoma predominantly grows with a diffuse growth pattern, although vague nodular structures may also be found. The typical histologic features are scattered and large B cells in tissues, and infiltrates of small T cells and non-epithelioid histiocytes/macrophages. The large B cells must represent less than 10 % of the cell population. The normal counterpart of the B cells is the germinal center B cell. A picture closely resembling lymphocyte-rich Hodgkin's lymphoma can develop, sometimes with highly atypical B cells, but bona fide Reed-Sternberg cells and eosinophils are lacking. TCRLBCL can be distinguished from classical Hodgkin's lymphoma by the presence of monoclonal IgH rearrangement and the CD30-CD15-CD45 +EMA+ immunophenotype (Fraga et al. 2002). In a minority of cases, the histiocyte component is poorly developed or almost lacking; these tumors may represent what has been termed T-cell-rich B-cell lymphoma. Immunohistochemically, the large scattered cells are reactive for pan B-cell markers and BCL6, and part of the cells express BCL2 and epithelial membrane antigen/EMA. Importantly, expression of CD15, CD30, and CD 138 is absent (Wang et al. 2005). The small lymphocytes are positive for CD3 and CD5 and the histiocytes for CD68. Part of the B cells in THRLBCL express the germinal center serpin, centerin (Montes-Moreno et al. 2008).

Liver Involvement

Primary Involvement of the Liver

Chambers and coworkers (1976) reported a necropsy case of a 55-year-old male patient who had succumbed to a primary hepatic lymphoma. At autopsy, the liver weighed 2,105 g and showed multiple pale nodules alternating with rather hemorrhagic areas almost throughout the liver substance. No tumor was found in the lymph nodes

or the spleen. Even in the absence of immunohistochemical examinations, the histologic description in the report and a histology figure were suggestive of TCRLBCL. The lymphomatous infiltrates were localized to expanded portal tracts and were characterized by scattered large and in part polymorphous lymphoid cells on a background of small lymphocytes and histiocytes with ovoid or reniform nuclei.

Secondary Involvement of the Liver

The liver is one of the deep-seated organs rather often infiltrated by TCRLBCL. The liver is involved in 13–70 % of the patients (Khan et al. 1993; Tajima et al. 1995; Dargent and De Wolf-Peeters 1998; Vidovic et al. 2001; Aki et al. 2004). In a liver biopsy series of eight cases, the main histologic features were a lymphohistiocytic or granulomatous infiltrate, usually centered on portal tracts, containing numerous small T cells and scattered large B cells with a blast-like morphology. In seven of the cases, liver involvement represented stage IV disease of the lymphoma (Khan et al. 1993). Clinically, TCRLBCL may mimic acute hepatitis, considered to be a nonneoplastic liver disease accompanying the lymphoma (Castroagudin et al. 1999).

Differential Diagnosis

The principal histopathologic differential diagnosis is lymphocyte-rich Hodgkin's lymphoma.

Lymphomatoid Granulomatosis

ICD-O code 9766/3

Introduction

Lymphomatoid granulomatosis (LYG) is defined as an angiocentric and angiodestructive lymphoproliferative disease involving extranodal sites and composed of EBV-positive B cells admixed with reactive T cells. The latter usually dominate the infiltrates. LYG is a rare condition that usually presents in adult life, although children with immunodeficiency disease can also be affected. Males are at least twice as often involved as females. Based on the first 40 cases that had been described, the disorder mainly involved the lung and usually spared the lymph nodes, spleen, and bone marrow. However, the skin is involved in about 45 %, and nodular renal lesions are encountered in 45 %, and central nervous system involvement occurs in at least 20 % (Liebow et al. 1972). Other common sites of involvement comprise the brain, kidney, and liver. Less common manifestation sites are the upper respiratory tract and gastrointestinal tract. Males predominate in a ratio of two to one, and the disorder usually affects patients in early middle age (Katzenstein et al. 2010). Pulmonary LYG or related disorders may occur as familial lymphoproliferative disorders (Rogers et al. 1992).

There is strong evidence that the pathogenesis of B-cell predominant LYG is related to EBV infection, suggesting that the mechanism of disease is based on a clonal population of EBV-infected B cells and that LYG may represent a T-cell-rich EBV-associated B-cell lymphoproliferative disease (Guinee et al. 1994; Myers et al. 1995; Wilson et al. 1996; Haque et al. 1998). EBV-positive forms of LYG seem to behave in an aggressive way (Nicholson et al. 1996). Patients with underlying immunodeficiency are at increased risk of attracting this EBV-driven B-cell lymphoproliferative disorder, mainly patients with allogeneic organ transplantation, HIV infection, and X-linked lymphoproliferative syndrome. LYG can progress to overt EBV-positive lymphoma (Stravodimou et al. 2012, reviews by Dunleavy et al. 2012 and Roschewski and Wilson 2012).

Clinical Features

As the lung is commonly affected, patients often present with symptoms and signs related to bronchopulmonary disease, such as cough, chest pain, and dyspnea. Constitutional signs, including fever, malaise, weight loss, and myalgias, are frequent. Patients with CNS involvement are either asymptomatic or show complex neurological

deficits. Overall, less than 5 % of patients with LYG are asymptomatic at the time point of diagnosis (Prapphal et al. 1991; Lucantoni et al. 2009; Melegh et al. 2009; Chung et al. 2011; Gonzalez-Darder et al. 2011; Bailie et al. 2012; Hare et al. 2012; Karabag et al. 2012).

Morphology

The histology of this unusual process has been reported in detail (Koss et al. 1986; Colby 2012). It seems that the proliferative process underlying LYG is based on a clonal expansion of B cells, which is also the reason why high-grade lymphomas developing from LYG are usually B-cell neoplasms. LYG is characterized by the presence of a usually small number of EBV-positive B cells, and these EBV+ cells usually show some atypia, resembling immunoblasts or, less frequently, pleomorphic Hodgkin-like cells. This B-cell-based lesion is accompanied by a prominent T-cell component, a phenomenon that may render the differential diagnosis to angiocentric T-cell lymphoma and related lesions difficult. This unique histologic presentation led to the identification of LYG as an angiocentric T-cell-rich B-cell lymphoproliferative disorder (McNiff et al. 1996), but LYG may be a heterogeneous process with subsets of different phenotypes. In fact, recent studies performing detailed phenotyping of cells involved have demonstrated that (1) B cells may represent a minor component, while T cells of the cytotoxic type predominate, and (2) that there are cases where B cells are not, or not easily, detectable, but the lesion is dominated by an expansion of CD3+ T cells of the CD8 type. This led the authors to identify a T-cell variant of LYG (T-cell LYG; Morice et al. 2002). In the LYG variant with B-cell predominance, the spectrum of B-cell proliferation roughly correlates with histologic grade (Guinee et al. 1998). The background contains, in addition to T cells, variable numbers of plasma cells, macrophages (without granuloma formation), and neutrophils. Blood vessels in the tumorous lesions reveal marked alterations, in particular lymphocytic vasculitis. This may lead to vascular obstruction, ischemia, and infarct-like necrosis. LYG is subject to malignancy grading, whereby the distinction of grade 3 vs. grades 1 and 2 is the most important feature. Grade 3 lesions are characterized by increased numbers of large atypical B cells identified as CD20+ elements in a cellular background that is generally less cellular than that in grades 1 and 2. Grade 1 shows only occasional large B cells, while in grade 2 they are more readily found and can form clusters (review by Katzenstein et al. 2010).

Liver Involvement in Lymphomatoid Granulomatosis

The liver is one of the organs that is regularly involved in the setting of generalized spread of LYG (Michaud et al. 1983; Bernstein et al. 1986; Pavlovskaia and Aikimbaev 1988; Nair et al. 1989; Donner et al. 1990). In the review of 40 patients by Liebow and coworkers (1972), clinical liver involvement was found in none, while among 22 necropsies, seven patients (31.5 %) revealed variable involvement.

Macroscopy

In the autopsy data published by Liebow et al. (1972), focal infiltration of the liver was observed in five patients. Gross liver changes were described in a later report (Schjolseth and Blom 1978). Autopsy revealed hepatomegaly, and the soft and yellow organ exhibited multiple grayish-white, irregular but well-demarcated infiltrates up to 1.5 cm in diameter. Another report refers to a 54-year-old male patient having died of abdominal manifestations of LYG (Chen 1977). Necropsy revealed ascites and marked hepatomegaly (2.5 kg), and both the external and the cut surfaces of the liver showed slightly bulging, firm, pale gray, irregular areas of up to 3 cm in diameter involving both liver lobes, interspersed with congested and mildly bile-stained parenchyma. In the case reported by Nair et al. (1989), autopsy showed multiple infarct-like lesions with erythematous borders in the liver.

Histopathology

The LYG infiltrates in the liver are sometimes rather massive and consist predominantly of atypical cells with occasional mitoses, sometimes with circumscribed foci of necrosis, but without the pattern of portal tract infiltrations seen in leukemias and lymphomas of other types. The infiltrates consist of elements similar to those seen in the classical pulmonary lesions, i.e., a mixture of atypical lymphoid cells, histiocytoid cells, and plasma cells. In two patients, the liver lesion was a thick encapsulated necrotic mass likely to represent previous tumor infiltration (Liebow et al. 1972). Some of the lesions mainly involve the portal tracts, exhibiting a variable infiltration by mononuclear cells, with a preponderance of large and bizarre forms. The vessels and the bile ducts were infiltrated as well in one study (Schjolseth and Blom 1978). In another autopsy report, the histology was characterized by irregular connecting areas of necrosis associated with focal density, in part angiocentric mononuclear cell infiltration consisting mainly of lymphocytes, scattered atypical large mononuclear cells, plasma cells, and macrophages. Apart from small hepatic vessels, the cellular infiltrate also involved the walls of medium-sized veins of the capsular area (Chen 1977).

Cytogenetic and Molecular Features

Most cases with grades 2 and 3 show clonality of immunoglobulin chains, based on the presence of neoplastic large B cells. Southern blot analysis displays clonality of EBV.

B-Cell Non-Hodgkin's Lymphomas with a Blastic/Large Cell Phenotype

91

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_91

Abstract

Several distinct types of B-cell non-Hodgkin's lymphomas characterized by large or blastic cells can markedly infiltrate the liver. Diffuse large B-cell lymphoma (DLBCL), a neoplasm of large B lymphoid cells with a diffuse growth pattern, develops in the liver either as a primary neoplasm or a hepatic manifestation of a lymphoma located elsewhere. Due to the distinct growth pattern within the body, a diagnosis of primary DLBCL of the liver is, however, difficult to assume. Involvement of the liver can present in the form of voluminous tumors that can mimic primary hepatic carcinoma or other solid neoplasms. Hepatic DLBCL can cause portal vein thrombosis. Rarely, the liver is involved by other large B-cell neoplasms, including pyothorax-associated lymphoma, intravascular large B-cell lymphoma, the latter with predominantly intravascular growth of lymphoma cells, and primary effusion lymphoma. Burkitt lymphoma, of which the endemic variant is associated with EBV infection, can infiltrate the liver in part of patients, usually in the setting of widespread disease.

Diffuse Large B-Cell Lymphoma (DLBCL), NOS

ICD-O code: **9680/3**

Introduction

In the 2008 WHO Classification, diffuse large B-cell lymphoma (DLBCL) is defined as neoplasm of large B lymphoid cells with a diffuse growth pattern, with nuclear size equal to or exceeding normal macrophage nuclei or more than twice the size of a normal lymphocyte.

Morphology

Typical is a diffuse growth of B-cell with varying shapes and sizes, according to the variants listed in the Table. The most common variant is the centroblastic variant, composed of medium- to large-sized cells with oval to round, vesicular nuclei with a fine chromatin pattern and two to four nuclear membrane-bound nucleoli. The cytoplasm is amphophilic to basophilic. In the less common immunoblastic variant, more than 90 % of tumor cells are immunoblasts with a centrally placed nucleolus in the nucleus and basophilic cytoplasm. The anaplastic variant shows large to very large round to pleomorphic cells with bizarre, in part multilobed, nuclei and multinucleated giant cells. These cells may resemble Hodgkin cells or Reed-Sternberg cells. Rare variants include those with myxoid stroma, fibrillary matrix, pseudorosette formation, spindle cells, and signet-ring cells. Immunohistochemically, the cells are reactive for B-cell lineage markers (CD19, CD20, CD79a, and CD22). CD10 is found in 30–60 %, BCL6 in 60–90 %, and MUM1 in 35–65 %. Most of the cells express FOXP1. Surface immunoglobin is present in up to 75 % of cases, mostly IgM, followed by IgG and IgA. In tumor with a germinal center cell lineage, the GC-associated marker Jaw1/LRMP is positive (Tedoldi et al. 2006). The anaplastic variant is associated with CD30 expression, in the absence of ALK expression. Most cases lack EMA reactivity. This phenotype had previously been classified as a variant of anaplastic large-cell lymphoma, but is now recognized as a subtype of DLBCL. Similar to ALCL, this lymphoma can show a sinusoidal growth pattern (*CD30-positive sinusoidal large B-cell lymphoma*). In a study of 11 patients, the mean age was 63.2 years, with female/male ratio of 1.2: 1. The lymphomas tended to undergo extensive necrosis.

Anaplastic DLBCL may be associated with Epstein-Barr virus infection, in one case within a composite B-cell-T-cell lymphoma (Hirose et al. 2004). EBV infection in this lymphoma is in clear contrast to ALCL, where there is no evidence for an EBV association. An anaplastic lymphoma-like lymphoma of the B-cell lineage has been observed to be associated with HHV-8 infection in the absence of EBV (Huang et al. 2004).

Liver Involvement

Primary DLBCL of the liver has been reported several times, albeit it is difficult, from the biology of this disease, to assume that a visceral organ is really a primary site of DLBCL.

Selected References (Chabner et al. 1975; Osborne et al. 1985; Ryoo et al. 1986; Jaffe 1987; Lei et al. 1995; Brugière et al. 1996; Al-Fadda and Fashir 1998; Lei 1998; Sato et al. 1999; Chaib et al. 2002; Santos et al. 2003; Noronha et al. 2005; Balduzzi et al. 2010; Makhdoomi et al. 2010; Yeh et al. 2010; Ma et al. 2011; Zafar et al. 2012).

Fig. 1 Tumorous hepatic manifestation of diffuse large B-cell lymphoma ("lymphosarcoma" of the liver)

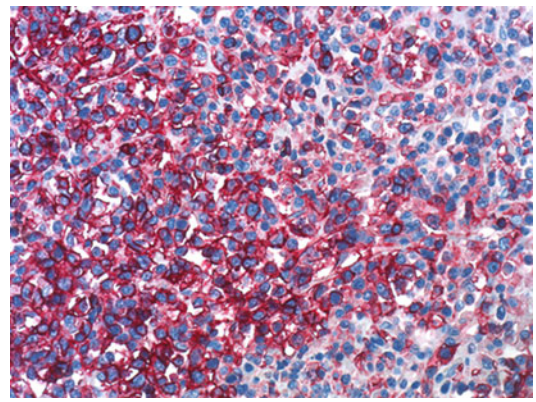

Fig. 2 In diffuse large B-cell lymphoma, neoplastic cells exhibit strong reactivity for CD20 (CD20 immunostain)

In most patients, liver involvement is a secondary phenomenon. In an older study of ten adult patients with large-cell lymphoma, several examinations (laparotomy in eight) revealed that the liver was the sole site of involvement initially, although subsequent staging procedures showed bone marrow involvement in three patients (Osborne et al. 1985). In this study, only one patient had hepatomegaly. Part of hepatic DLBCL are HCV-associated NHLs (Keller et al. 2010; Pellicelli et al. 2011). Primary and secondary DLBCL can form voluminous, whitish to yellowish tumor masses with an expanding growth pattern (Fig. 1). Sometimes, several large tumor nodules are centered around a central area of regression, with tumor collapse in the core area and formation of compressed parenchymal areas between the nodules (Chaib et al. 2002). In case of extensive infiltration, fulminant hepatic failure can ensue (Kheyri et al. 2013). Large tumors can mimic hepatocellular carcinoma radiologically. Tumors of enormous size have been reported, e.g., 18 cm diameter (Pereira et al. 1993). Histologically, cells with a centroblastic, immunoblastic, or anaplastic phenotype form a diffuse and monotonous infiltration, replacing the hepatic parenchyma. In rare variants, a predominantly intrasinusoidal and interstitial lymphomatous infiltration can occur (Kashimura et al. 2013). Immunohistochemistry reveals the immunophenotype found in other localizations of DLBCL, with a very high proliferative activity (Figs. 2 and 3). There is evidence that there is a difference in tumor biology between nodular and diffuse growth patterns, in that a tumor with a diffuse pattern has an unfavorable outcome (Emile et al. 2001). Hepatic DLBCL can cause portal vein thrombosis (Natsuizaka et al. 2009). In exceptional situations, hepatic DLBCL has infiltrated a preexisting other liver tumor, e.g., hepatocellular carcinoma (Utsunomiya et al. 2009). Dense hepatic infiltrates associated with hepatocyte injury, apoptosis, and/or necrosis can cause fulminant hepatic failure (Zafrani et al. 1983; Lettiere and Berg 2003) or biochemically mimic severe hepatitis (Harris and

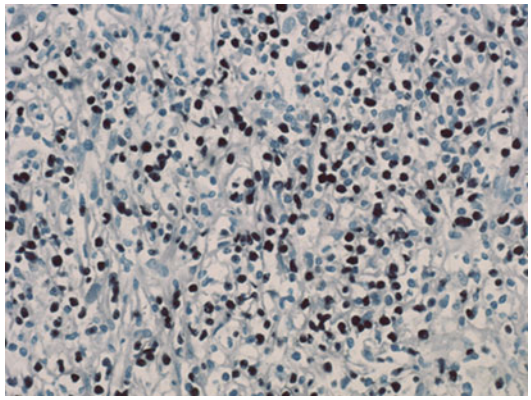

Fig. 3 Diffuse large B-cell lymphoma in the liver. The lymphoma cells reveal a very high proliferative activity (MIB1 immunostain)

Kornstein 1993). In case of large space-occupying lesions, portal hypertension can ensue (Bachmeyer et al. 2001).

Variants of DLBCL can also form primary hepatic neoplasms. De novo CD5-positive DLBCL accounts for about 10 % of DLBCLs, shows an aggressive course, and was found as a primary NHL of the liver and spleen (Zhang et al. 2013). Also EBV-driven DLBCL was diagnosed as a tumor confined to the liver (Dziadzio et al. 2013).

Classification

Several morphological and immunohistochemical variants and subgroups of DLBCL have been described, part of which have an impact on the biology of disease (Table 1; Pileri et al. 2002; Hans et al. 2004; Zinzani et al. 2005, 2010).

DLBCL accounts for 25–30 % of adult non-Hodgkin's lymphomas in western countries, more common in the elderly and median age at diagnosis being situated in the seventh decade, with a slight male preponderance. DLBCL is either a primary lymphoma or develops from a preexisting other B-cell lymphoma through transformation. Clinically, the tumor presents with nodal or extranodal disease, up to 40 % of patients initially having disease confined to extranodal sites, the most common extranodal compartment being the gastrointestinal tract. Other common sites are several visceral organs, including the liver, the bone, and the Waldeyer ring. Patients usually experience rapidly growing tumor masses, because DLBCL has a large proliferative fraction and usually reveals local growths (the former fast-growing tumors termed "lymphosarcomas"). A minority of patients with DLBCL enter a leukemic phase. Patients with DLBCL-associated leukemia present with high tumor burden and frequent involvement of extranodal sites (Muringampurath-John et al. 2012).

Table 1 Variants and subgroups of diffuse large B-cell lymphoma, NOS (According to the 2008 WHO Classification, modified)

Common morphologic variants
Centroblastic
Immunoblastic
Anaplastic
Rare morphologic variants
Myxoid stroma
Fibrillary matrix
Pseudorosette formation
Spindle cells
Signet-ring cells
Molecular subgroups
Germinal center B-cell-like (GCB)
Activated B-cell-like (ABC)
Immunohistochemical subgroups
CD5-positive DLBCL
Germinal center B-cell-like (GCB)
Non-germinal center B-cell-like (non-GCB)

Cytogenetic and Molecular Features

DLBCL shows clonally rearranged heavy- and light-chain genes. Up to a third of cases reveal abnormalities of the 3q27 region harboring the BCL6 gene, the most common translocation in DLBCL. BCL2 gene translocation is less frequently found. Up to 10 % show a MYC gene rearrangement. Aberrant somatic hypermutations involving several genes are seen in half of the cases.

Liver Involvement in DLBCL Associated with Chronic Inflammation (in Particular Pyothorax-Associated Lymphoma/PAL)

ICD-O code: **9680/3**

Introduction

Pyothorax-associated lymphoma (PAL) is a novel B-cell NHL entity that makes part of the rare primary pleural NHL developing in the setting of pyothorax, chronic pleuritis, and pneumopleural tuberculosis (Iuchi et al. 1989; Aozasa et al. 1993; Aozasa 1996; Nakatsuka et al. 2002; Narimatsu et al. 2007; Yamamoto et al. 2007; Sekine et al. 2010; Terada 2012). PAL is the prototypic form of the WHO lymphoma category, diffuse large B-cell lymphoma (DLBCL) associated with chronic inflammation. PAL involves the pleural space and the pleuropulmonary transition zone and, in part of the patients, peripheral parts of the lung and the chest wall. Most patients with this disorder have been reported from Japan. In a study of 37 cases, all patients were admitted after a 22–55 (mean 33)-year history of pyothorax caused by artifical pneumothorax for the treatment of lung tuberculosis or tuberculous pleuritis (Iuchi et al. 1989). In a more recent investigation on 106 cases, the median duration of pyothorax before admission was 37 years, and artificial pneumothorax for therapy of tuberculosis amounted to 80 % (Nakatsuka et al. 2002). In almost all studies, a diffuse proliferation of large B-cells predominated, i.e., the morphology of diffuse large B-cell lymphoma. One exception is Ki-1 (CD30)-positive anaplastic large-cell lymphoma of T-cell phenotype that has also been found to develop in long-standing tuberculous pyothorax (Nakamura et al. 1995). PAL is frequently, but not always, associated with EBV infection, with constant expression of the two latent membrane proteins, latent membrane protein (LMP)-1, and EBV-associated nuclear antigen (EBNA)-2 (Fukayama et al. 1993; Martin et al. 1994; Ohsawa et al. 1995; Takakuwa et al. 2008).

In situ hybridization showed that, in 106 patients, 70 % of the PAL were EBV-positive (Nakatsuka et al. 2002). The EBV load assessed by real-time PCR correlates with tumor mass (Shide et al. 2003). Proposed mechanisms for the pathogenesis of PAL in EBV infection include the production of an immunosuppressive cytokine from PAL cells, HLA class I alleles of patients with PAL, and mutations of cytotoxic lymphocyte epitopes in an EBV-latent antigen (Kanno and Aozasa 1998; Kanno et al. 1999). HHV-8 was not detected in PAL, in contrast to cavity-based high-grade lymphomas/BCBL (Taniere et al. 1998). The neoplasm consists of large lymphoid cells with frequent plasmacytoid differentiation, immunoreactive for CD20, CD79a, and/or CD138 B-cell antigens. Detailed immunophenotyping suggests that the cells derive from late germinal center (GC)/post-GC B-cells (Petitjean et al. 2002). Few cases exhibit aberrant expression of T-cell markers. The B-cell origin of lymphoma cells was confirmed by the demonstration of immunoglobulin light-chain restriction or clonal B-cell population (Petitjean et al. 2002). The differential diagnosis of pyothorax-associated B-cell lymphoma is the very rare T-cell counterpart of this lymphoma (Narimatsu et al. 2007; Santini et al. 2009).

Liver Involvement in Pyothorax-Associated Lymphoma

Involvement of the liver by PAL is exceptional. Extrathoracic dissemination to the liver was detected in a patient with PAL presenting a right basal calcified mass and parietal infiltration (Petitjean et al. 2002).

Intravascular Large B-Cell Lymphoma

ICD-O code: 9712/3

Introduction

In the 2008 WHO Classification, intravascular large B-cell lymphoma (IVLBCL) is defined as a rare type of extranodular large B-cell lymphoma showing selective growth of lymphoma cells within the lumina of blood vessels, in particular capillaries. Definition, diagnosis, and management of IVLBCL have been standardized in an international consensus meeting (Ponzoni et al. 2007).

IVLBCL is a rare and highly aggressive form of NHL that mainly occurs in adults, but pediatric and even congenital cases have been reported as well (median: 67 years at diagnosis), with an almost balanced gender distribution. The lymphoma has previously been described under several terms, including systemic endotheliomatosis, malignant angioendotheliosis, angioendotheliomatosis proliferans systemisata, neoplastic endotheliosis, intravascular lymphomatosis, and angiotropic large-cell lymphoma. The neoplasm was originally described in 1959 under the term systemic endotheliomatosis (Pfleger and Tappeiner 1959). As the term illustrates, this neoplasm was first thought to have an endothelial cell origin, but was about 30 years later identified to be a lymphoid cell growth (Wick et al. 1986; Otrakji et al. 1988). The hallmark of this high-grade B-cell lymphoma is its tendency to proliferate and spread within vascular lumina of several organs, however with predominant manifestations in the skin and in the central nervous system (Demirer et al. 1994; Conlin et al. 2001; Lui et al. 2003). In a clinicopathologic study of 38 HIV-negative patients diagnosed in western countries, two-thirds of the patients had disseminated disease at presentation (Ferreri et al. 2004). IVLBCL may disseminate to the heart, lungs, pancreas, liver, spleen, adrenals, genital tract, and, rarely, bone marrow and lymph nodes. About a fourth of the patients suffer from hepatosplenic involvement (Ferreri et al. 2004). A presence of lymphoma cells in the peripheral blood has only very occasionally been noted.

Clinical Features

Frequently, the first presentations are fever, neurologic symptoms, dementia, skin manifestations such as erythemas, nodules or plaques, and telangiectases, and/or shortness of breath and diffuse infiltrates in chest X-rays in those patients with pulmonary involvement (Hong et al. 2014). Rarely, humoral hypercalcemia associated with elevated serum parathyroid-related protein is a presenting symptom (Knobel et al. 2001). One variant of IVLBCL mainly occurring in Asian patients (the so-called Asian variant of IVLBCL) is characterized by early involvement of bone marrow and associated with hemophagocytic syndrome (IVL-HS; Hsieh et al. 2010; Fung et al. 2012). In addition to East Asian patients, individuals from Caucasian countries and Africa are rarely affected (Fung et al. 2012; Geyer et al. 2012). This variant has also been reported to be characterized by hepatosplenomegaly in the absence of neurologic or skin manifestations (Murase et al. 2002).

Morphology

Histologically, large and discohesive cells with a moderate rim of amphophilic cytoplasm and round to often bizarre nuclei with prominent nucleoli and mitotic figures accumulate in the lumina of capillaries, small veins, arterioles, and small arteries, but the cells may also occupy the perivascular spaces. It has even been observed that the cells of IVLBCL can colonize abnormal vascular compartments such as hemangiomas (Cerroni et al. 2004). The immunophenotype is that of a B-cell lineage (CD 20 and/or CD79a), with negative EMA staining. The cells express CD11a and CD49d (Kanda et al. 1999). A subset of IVLBCL (about 30 %) is reactive for CD5 (Khalidi et al. 1998; Murase et al. 2000), and there seems to be a variant with the same morphologic features but a T-cell phenotype (Au et al. 1997). IVLBCL may express myeloperoxidase, important for the differential diagnosis of granulocytic sarcoma (Conlin

et al. 2001). Furthermore, it has been reported that prostatic acid phosphatase is a possible tumor marker for IVLBCL (Seki et al. 2004; Kishi et al. 2004).

Liver Involvement in IVLBCL

IVLBCL usually undergoes an aggressive and sometimes fulminant course, spreading within vascular structures in numerous organs, including the liver.

Selected References for Liver Involvement (Kayano and Katayama 1990; Demirer et al. 1994; Rubin et al. 1997; Onishi et al. 1998; Tucker et al. 1999; Camidge et al. 2000; Murase et al. 2000; Yamashiro et al. 2001; Knobel et al. 2001; Fiegl et al. 2002; Goh et al. 2002; Lui et al. 2003; Terrier et al. 2005; Shiraki et al. 2007; Roshal et al. 2008; Xu et al. 2008; Higurashi et al. 2009; Szuba et al. 2010; Yasuda et al. 2010; Hishikawa et al. 2011; De Fino et al. 2012; Fung et al. 2012; Geyer et al. 2012; Gual-Tarrada et al. 2012; Yamada et al. 2012; Sekiguchi et al. 2013; Abe et al. 2014; Hoshi et al. 2014).

In a larger study, hepatosplenic involvement occurred in 26 % of the patients (Ferreri et al. 2004). Liver infiltration may cause abnormal liver function tests and jaundice, likely to be induced by direct hepatocyte damage by the lymphoma cells located to the vessels (Zeidman et al. 2004; Sekiguchi et al. 2013). In one patient with an unusual, mixed neurotropic and intravascular large B-cell lymphoma, the neoplasm had produced an ill-defined large and soft tumor mass in the right liver lobe (Yamada et al. 2012).

Liver histology shows large and in part highly atypical lymphoma cells, immunoreactive for CD45 and CD20, in several categories of vascular channels, including small portal venous branches and branches of the hepatic artery (DiGiuseppe et al. 1994; Demirer et al. 1994;). In particular, small portal veins in the portal tracts may be massively engorged with bizarre cells (Demirer et al. 1994). A preferential accumulation of the large cells may be found in the lumina of hepatic sinusoids (DiGiuseppe et al. 1994; Tucker et al. 1999; Camidge et al. 2000; Murase et al. 2000; Yagita et al. 2000; Conlin et al. 2001; Goh et al. 2002; Shimizu et al. 2007; Shiraki et al. 2007; Xu et al. 2008; Higurashi et al. 2009; Hishikawa et al. 2011). The intravascular cells may be enmeshed in fibrin or microthrombi, and associated endothelial proliferations may be seen. It is striking to note that, in IVLBCL, several categories of small blood vessels are involved, i.e., the terminal arterial segments, the capillary bed, and the draining veins, suggesting a distinct mode of neoplastic cell homing. In Asian variant IVLBCL, hepatomegaly is a typical feature, and hepatic infiltration is frequently accompanied by signs of hemophagocytosis (Onishi et al. 1998; Aoki et al. 2011). In addition to intravascular tumor cell accumulations, nodular or tumorous intrahepatic lesions have also been reported, showing that these lymphoma cells can also proliferate in extravascular compartments (Hashizume 2011).

Differential Diagnosis

The main differential diagnosis is sinusoidal accumulation of neoplastic cells in the course of lymphoid cell leukemias, e.g., plasmablastic leukemia.

Cytogenetic and Molecular Features

Few karyotypic abnormalities have been reported, without a specific recurrent pattern. IVLBCL is cytogenetically heterogeneous, but the most frequent alterations seen were -6 or 6q- and +18 or dup (18q) (Khoury et al. 2003). Immunoglobulin genes are clonally rearranged. The distinct intravascular localization of the lymphoma cells may be related to the differential expression of lymphoid homing receptors (Ferry et al. 1988) and/or deficiency or absence of the adhesion molecules

CDIia/CD18 (Jalkanen et al. 1989), CD29 (beta1-integrin), and CD54 (ICAM-1).

Primary Effusion Lymphoma (PEL)

ICD-O code: 9678/3

Introduction

Primary effusion lymphoma (PEL; synonym: body cavity-based lymphoma) is a large B-cell neoplasm usually presenting as serous effusions without detectable tumor masses. PEL is associated with human herpesvirus 8 (HHV8; Kaposi sarcoma-associated herpesvirus, KSHV) and most often develops in the setting of immunodeficiency (WHO 2008 Classification; reviews: Cousins and Nicholas 2014; Giffin and Damania 2014; Kim et al. 2014).

Lymphomatous effusions, often developing in the absence of solid tumor masses, were described since 1989 to occur in homosexual men with or without risk for AIDS (Knowles et al. 1989). The neoplastic cells of these lesions show clonal B-cell derivation and express CD45 and CD138, but lack the expression of other B-cell antigens. Many of the tumors show evidence of clonal EBV infection, and KSHV has been shown to be involved in the pathogenic pathways of most, but not all, cases of PEL (Cesarman et al. 1995; Buonaito et al. 2002; Sunil et al. 2010; Wang et al. 2011). The KSHV-positive lymphoma cells are in most cases coinfected by EBV, and they show mutated rearranged Ig genes, suggesting that the neoplastic cells originate from germinal center or post-germinal center B-cells (Hamoudi et al. 2004). The pathogenic pathways involving HHV8/KSHV in PEL are complex and only partially understood. HHV8 miRNA functions as a hijacking system that targets numerous cellular genes involved in proliferation and apoptosis in PEL (Gottwein et al. 2011; Gottwein 2012; Haecker et al. 2012), including the TGF-beta signaling pathway to promote cell survival (Lei et al. 2012), phosphorylation of PTEN on chromosome (Roy and Dittmer 2011), amplification of SELPLG and CORO1C genes encoding for proteins important for cell migration (Luan et al. 2010), and deletion of the suppressor genes FHIT and WWOX (Roy et al. 2011). PEL displays a highly complex transcriptome (Punj et al. 2012), which is modulated by HHV8 which also affects the immune system of the host (Lee et al. 2012). In cases being HHV8-negative, PAX-5 gene rearrangement has been detected (Ichinohasama et al. 1998). Characteristically, the majority of PELs occur exclusively as malignant neoplastic lymphomatous effusions, but part of the patients with PEL secondarily develop solid-tissue lymphoma masses. Clinically, the most common sites of PEL are the pleural, pericardial, and peritoneal cavities, whereby one body cavity is involved in most cases. However, multicavity involvement is also known (Hsieh et al. 2007), and prognosis is influenced by the number of body cavities involved (Castillo et al. 2012a). Extracavitary PEL involves the gastrointestinal tract, skin, lung, CNS, and lymph nodes. Furthermore, there are patients with this phenotype of neoplasm who initially present with a tissue mass and subsequently develop a malignant neoplastic effusion. There are also extracavitary HHV8-associated large B-cell lymphomas with a primarily solid growth pattern that may eventually represent a subtype of PEL (Giessen et al. 2012; Kim et al. 2012; Pan et al. 2012).

Liver Involvement

As the neoplastic cells in PEL are suspended in body cavity fluids without the formation of tumor masses, the liver is not expected to be involved by this NHL. However, PEL with formation of ascites may result in settling of lymphoma cells on the capsular surface of the liver. Similar to other serosal surfaces, the cells form a cellular layer of variable thickness, eventually associated with fibrinous and/hemorrhagic serositis. Within this epicapsular mass, the neoplastic cells seem to form cohesive structures consisting of large and in part highly polymorphous elements, with rather abundant and amphophilic cytoplasm, and large vesicular, partly deformed or indented nuclei

showing prominent nucleoli. The cells located to serosal surfaces and suspended in free fluid are usually CD138 (syndecan-1) reactive, and this expression may be important for the characteristic homing and location of the tumor cells, as syndecan-1 (normally also expressed in mature B-cells and plasma cells) is involved in adhesion of cells to the extracellular matrix. There seems to exist a relationship between chronic HCV infection and PEL. PEL developing in patients with HCV-related liver cirrhosis is exclusively manifest in the peritoneal cavity, usually with marked ascites, and is more frequently of the B-cell phenotype, in contrast to other PELs that are usually of the null phenotype (Ascoli et al. 1997; Ichinohasama et al. 1998; Hara et al. 2001; Paner et al. 2003; Makis and Stern 2010). PEL in HCV-related cirrhosis is usually HIV- and HHV-8 negative (Hara et al. 2001; Paner et al. 2003). The solid form of HHV8/KSHV-associated large B-cell lymphoma, whose relationship to PEL is not clarified, can also arise from the liver and spleen as multiple nodular lesions (Hasagawa et al. 2004).

There are other lymphomas characterized by serosal spreading consistent with PEL but not associated with KSHV infection (CD138-positive and KSHV-negative B-cell lymphomas with serosal spreading; Kuwabara et al. 2000). In an autopsy case, lymphoma manifestations were, in addition to body cavities and several lymph node stations, also detected in hepatic hilar nodes (Kuwabara et al. 2000).

Burkitt Lymphoma

ICD-O code: 9687/3

Introduction

According to the WHO classification, Burkitt lymphoma (BL) is a rapidly proliferating B-cell neoplasm with extremely short doubling times and a preference for extranodal sites. The tumor is named after Denis Parsons Burkitt, who graduated as a physician in 1935 from Trinity College in Dublin and served as a surgeon and lecturer in Africa during World War II, where he identified the endemic lymphoma (Burkitt and O'Conor 1961; Burkitt 1962; Smith 2012). Three forms of this lymphoma are known: endemic, sporadic, and immunodeficiency-associated BL (reviews: Magrath 2012; Molyneux et al. 2012). The endemic form is mainly known from equatorial Africa and Papua New Guinea. In Africa, the lymphoma chiefly involves children with a peak age between 4 and 7 years of age. In endemic BL, the EBV genome is present in virtually all tumor cells of patients, EBV-infected tumor cells being derived from memory B-cells, and there is a strong link with holoendemic malaria. The sporadic form is found throughout the world, mainly occurs in children and young adults, and is a rare type of NHL, accounting for only about 1–2 % of all lymphomas in western countries. However, BL accounts for 30–50 % of all childhood lymphomas. About 30 % of sporadic BLs show EBV infection, but the infection rate is higher in early EBV infection and in the presence of a low socioeconomic status. Immunodeficiency-associated BL chiefly develops in HIV-infected individuals, and 25–40 % of patients show EBV infection of neoplastic cells.

Morphologically, the neoplastic B-cells are medium sized and grow in a diffuse manner, with cell cohesion but often also cytoplasmic retraction in the sections. The cytoplasm is markedly basophilic; nuclei are round, with several basophilic, paracentrally placed nucleoli. Numerous mitotic figures are noted, and many apoptotic bodies are usually present. Part of BL shows plasmacytoid features or nuclear pleomorphism. A marked nuclear pleomorphism of BL cells is known following chemotherapy (Banks et al. 1975). A typical histologic feature is the "starry sky" pattern, characterized by numerous large and clear macrophages being dispersed in the tumor, these cells having phagocytosed apoptotic cells and/or nuclear fragments (so-called tingible bodies). Immunohistochemically, the tumor cells reveal reactivity for B-cell markers (CD19, CD20, CD22) CD38, BCL6, CD43, and CD77. The cells show expression of membrane IgM with light-chain restriction. More than 90 %

of cells are Ki-67 positive, reflecting the extremely high proliferation fraction.

Primary Burkitt Lymphoma of the Liver

Primary bona fide or probable Burkitt lymphoma of the liver is a very rare lesion; only less than 30 cases having been reported and only few of them with immunohistochemical verification (Siegel and Melson 1981; Miller et al. 1983; Rak et al. 1988; Wan et al. 1988; Adeodu et al. 1990; Scoazec et al. 1991; Ramos et al. 1997; Huang et al. 1997; Chim et al. 2001; Kuroda et al. 2001; Lee et al. 2008; Mantadakis et al. 2008; Mattar et al. 2010; Citak et al. 2011). Primary hepatic BL occurs in both endemic and sporadic forms of BL and was also detected, characterized by a hypervascular lesion, in a patient with HIV infection (Jacobs and Rozenblit 2006). Hepatic BL can develop in children with this type of lymphoma (Vade and Blane 1985; Huang et al. 1997; Hsu et al. 2003; Wammanda et al. 2004; Fikri and Dafiri 2006; Mantadakis et al. 2008). One case has been reported in a 14-year-old child, presenting a large solid mass confined to the right lobe of the liver, without evidence of involvement of other sites. The mass was resected and histologically proven to be Burkitt lymphoma (Huang et al. 1997). In two pediatric patients, hepatic BL manifested as obstructive jaundice (Hsu et al. 2003; Wammanda et al. 2004). In another child aged 8.5 years, primary hepatic BL presented as multifocal liver lesions (Mantadakis et al. 2008). One fully documented lesion of 6 cm diameter, including a detailed immunohistochemical work-up, was identified in an old patient having chronic hepatitis C. At autopsy, the mass was well delineated and showed, on the cut surface, geographical necroses and hemorrhage. The neoplasm was not associated with EBV infection (Kuroda et al. 2001). Primary hepatic BL can present with acute liver failure caused by dense hepatic infiltration associated with hepatocyte damage (Mattar et al. 2010).

Differential Diagnosis

The liver can be involved by BL situated elsewhere in the abdominal cavity (Durodola 1977; Anaissie et al. 1985; Glass et al. 1985; Park et al. 2004; Baumhoer et al. 2008; Kiresi et al. 2008). In a group of 19 pediatric patients with BL, the liver was involved in 12.1 % (Kamona et al. 2007). BL can also extensively involve the peritoneal surface (Wong et al. 2009).

Molecular Features

On the molecular level, around 90 % of cases show MYC oncogene translocation to Ig heavy-chain region (Soldini et al. 2013). In endemic BL, most of these translocations result from hypermutation, while in sporadic cases, the translocation mostly involves the Ig switch regions of the IgH locus at chromosome 14q32 (Greisman et al. 2012). BL can arise from lymphoplasmacytic lymphoma following acquisition of MYC translocation and loss of the ETV6 tumor suppressor gene (Peker et al. 2013). Other mutational events playing a role in BL pathogenesis comprise inactivating mutations of ID3, an inhibitor of the TCF3 transcription factor (Campo 2012; Leventaki et al. 2012; the ICGC MMML-Seq Project et al. 2012), and the GNA13, RET, PIK3R1, E2F4, and SWI/SNF-associated genes (Dave 2012; Giulino-Roth et al. 2012; Love et al. 2012; Molina-Privado et al. 2012). Expression of TCF3 activates the pro-survival PI3K pathway in BL (Schmitz et al. 2012). In fact, a strong survival signal for BL tumor cells is the PI3K signaling pathway, cooperating with MYC (Sander and Rajewski 2012). In childhood BL, EBV expression acts as a risk effect and independent prognosticator (Minnicelli et al. 2012). In memory B-cells, EBV nuclear antigen 1 induces expression of cellular microRNA has-miR-127, impairing B-cell differentiation and considered to play a pathogenic role in BL (Onnis et al. 2012). In BL, the extremely strong proliferative response is in part counteracted by cell loss via apoptosis, reflected not only by the presence of

apoptotic bodies, and karyorrhexis, but also by an increased expression of the apoptosis-associated proteins survivin, livin, and thrombospondin-1 (Kalungi et al. 2013).

Plasmablastic Lymphoma

ICD-O code: 9735/3

Introduction

Plasmablastic lymphoma (PBL) is defined as a diffuse proliferation of large neoplastic cells resembling B immunoblasts but which have the immunophenotype of plasma cells.

PBL is a rare and probably heterogeneous group of lymphomas (Colomo et al. 2004). The neoplasm prefers mostly extranodal sites and has the highest incidence in HIV-infected individuals, predominantly males, manifestations in the oral cavity being most common. It occurs also in other situations of immunosuppression. PBL has developed in the setting of Crohn's disease treated with azathioprine and infliximab (Plaza et al. 2011) and was found to arise in liver allografts. About half of patients with PBL have EBV infection. PBL prevails in elderly adults, but also occurs in the pediatric age group (Pather et al. 2013). A well-known site of PBL is the oral cavity, but it is also found in several other mucosae (including the sinonasal region), skin, bone, gastrointestinal tract, and soft tissues. Lymph node involvement is uncommon. At diagnosis, most patients present with advanced stage of disease (Corti et al. 2011; Hsi et al. 2011; review: Castillo and Reagan 2011). In a study of 50 patients with HIV-associated PBL, 90 % of patients had extranodal involvement at presentation, and 69 % had advanced stage disease (Castillo et al. 2012b). The biology of disease appears to differ as a function of the HIV status. In a series of elderly HIV-negative patients from Japan, the clinical behavior was more indolent than that of age-related EBV-associated lymphoproliferative disorders (Liu et al. 2012).

Morphology

The spectrum of cytomorphologies in PBL ranges from diffuse growths of immunoblast-like cells to cells resembling those in plasmablastic plasma cell myeloma. The nuclei of immunoblast-like cells show prominent nucleoli, whereas the nuclei of plasmacytoid components exhibit round nuclei with coarse chromatin and smaller or even unapparent nucleoli. Tumors with a high proportion of plasmablastic cells prevail in HIV-infected patients and in the oro-sinonasal region, while those with a plasmacytic differentiation tend to more often occur in other extranodal sites, but also in lymph nodes. Immunocytochemically, the cells express a plasmacytic phenotype, with reactivity for CD138, CD38, Vs38c, and MUM1. CD79a is expressed in 50–85 % of the cases. Typically, the tumor cells are negative or only weakly positive for CD20, CD45, and PAX5. Fifty to seventy percent of cases reveal expression of cytoplasmic immunoglobulins, most commonly IgG and either kappa or lambda light chains.

Liver Involvement

Few cases of apparently primary PBL of the liver have been reported (Metta et al. 2009; Tani et al. 2013). The HIV-infected adult patient reported by Metta et al. (2009) presented a nodular tumor lesion in the left lobe of the liver. Diagnosis of PBL was confirmed by liver biopsy. Morphology revealed a dense infiltrate composed of atypical and in part plasmacytoid lymphocytes expressing plasma cell markers (CD138, MUM1), but negative for CD20 and CD45. Immunohistochemistry and FISH showed the presence of EBV infection of tumor cells. There are no informations regarding infiltration pattern in secondary PBL involvement of the liver. The 79-year-old male HIV-negative patient described by Tani and coworkers (2013) presented with a very large liver mass. Autopsy showed a diffuse infiltration of the involved part of the liver with large-cell lymphoma with plasmacytoid features, the

neoplastic cells being reactive for CD30, EBV, Bob-1, and CD38.

Differential Diagnosis

The principal differential diagnoses are plasmablastic and pleomorphic plasma cell myelomas.

Cytogenetic and Molecular Features

There are no recurrent/specific karyotypic abnormalities. The tumor shows clonal IgH gene rearrangement. MYC rearrangement has been found in part of PBL cases (Slack and Gascoyne 2011; Castillo et al. 2012b).

Liver Cyst-Associated Non-Hodgkin's Lymphoma (CANHL)

Introduction

In very rare instances, non-Hodgkin's lymphomas (NHL) develop in preexisting cysts or organs with polycystic disease. We term these neoplasms cyst-associated NHL (CANHL).

CANHL of the Liver

In one old female patient, a hepatic cystic lesion suspicious of hepatobiliary cystadenoma was detected. Hepatic resection revealed a complex, but well-delineated cystic mass within parenchyma, having a diameter of 12 cm. It showed solid components, mural nodularity, and contained friable tissue masses with cystic spaces and clefts. Histology and immunohistochemistry showed primary diffuse large B-cell lymphoma (Valladolid et al. 2013). NHL was detected in a patient with isolated adult polycystic liver disease, forming nodular lesions among cysts (Cirasino et al. 1997). We observed hepatic CANHL in a female patient undergoing liver transplantation of primary hepatic polycystic disease. The massively enlarged organ was diffusely involved by numerous thin-walled cysts containing a clear fluid. On cut surfaces, one of these cysts did not contain fluid, but a soft matter of grayish-brown color which showed cracks after fixation suggesting a highly cellular tissue (Fig. 4). Histologically, most of the tissue was necrotic, with numerous shadow cells, but nucleated large round cells forming a homogeneous population were found at the periphery of the focus. These cells were positive for B-cell markers, were highly proliferative, and represented a monoclonal proliferation at PCR,

Fig. 4 Cyst-associated diffuse large B-cell lymphoma of the liver. In this specimen of adult polycystic liver disease, one of the cysts (*left lower* aspect of specimen) is filled with a yellowish mass representing necrotic tumor

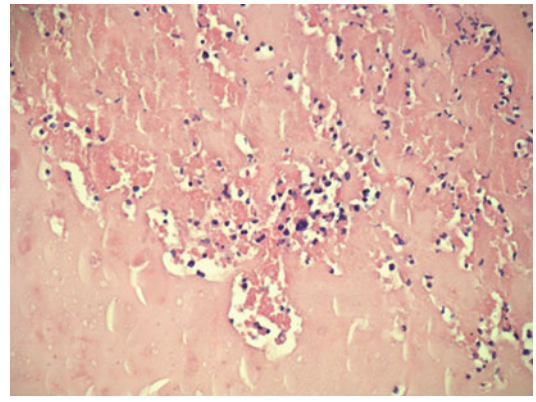

Fig. 5 Cyst-associated diffuse large B-cell lymphoma of the liver. The necrotic tissue, which completely filled the cyst, contains clusters of atypical large lymphoma cells (hematoxylin and eosin stain)

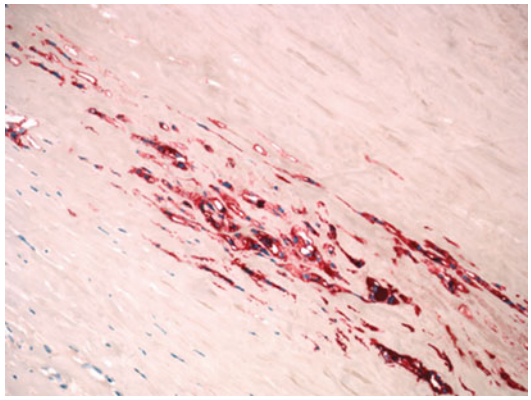

Fig. 6 Cyst-associated diffuse large B-cell lymphoma of the liver. The preserved lymphoma cells are diffusely reactive for CD20 (CD20 immunostain)

compatible with diffuse large B-cell lymphoma (Figs. 5 and 6). No other manifestations of an NHL were present in this patient, who survived without any chemotherapy.

Non-Hodgkin's Lymphoma Associated with Inflammatory Pseudocysts

Diffuse large B-cell lymphoma has been observed in association with pseudocysts probably arisen in the course of inflammation, e.g., in adrenals and in the paratesticular region. It was proposed to classify such NHLs in the WHO category of DLBCL developing in long-standing chronic inflammation, pyothorax-associated NHL being the prototype lesion (Boroumand et al. 2012). This type of lymphoma has not yet been described for the hepatobiliary tract.

Differential Diagnosis

In rare situations, NHLs can present as cystic or multicystic lesions, these cysts probably being secondary phenomena (Noguchi et al. 2013).

B-Cell Non-Hodgkin's Lymphomas with Lymphoplasmacytoid and Plasmacytic Features

92

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_92

Abstract

The liver can be infiltrated in lymphoplasmacytic lymphoma (LPL), a neoplasm of small B lymphocytes, plasmacytoid lymphocytes, and plasma cells, a disease usually involving bone marrow and less commonly lymph nodes and inner organs. LPL is often associated with production of a paraprotein, usually of the IgM type (Waldenström's disease). LPL of the liver may rarely be a primary process, but in most cases liver infiltration is the manifestation of generalized LPL. Hepatic infiltration is usually located to portal tracts, but rarely large tumor masses can develop, and compression of small blood vessels may cause portal hypertension. LPL is sometimes associated with peliosis hepatis. The liver is a known manifestation organ of plasmacytoma. In most cases, the liver participates in cases with systemic neoplastic disease. Diffuse, nodular, and mixed hepatic growth patterns of plasmacytoma are known. The rare disorder, plasma cell leukemia, can involve the liver, more frequently in primary plasma cell leukemia than in the secondary form that develops in the setting of plasmacytoma.

Lymphoplasmacytic Lymphoma and Waldenström's Macroglobulinemia

ICD-O code 9671/3

Introduction

Lymphoplasmacytic lymphoma (LPL) is, according to the 2008 WHO classification, defined as a neoplasm of small B lymphocytes, plasmacytoid lymphocytes, and plasma cells, usually involving bone marrow and sometimes lymph nodes and the spleen and less commonly other tissues and organs. LPL often produces and secretes a paraprotein, usually of the IgM type, but this feature is not required for diagnosis, as there are nonsecretory forms of this disease. A significant fraction of LPL patients show Waldenström's macroglobulinemia, defined as LPL with bone marrow involvement and an IgM monoclonal gammopathy. LPL mostly occurs in adults with a median age in the sixth decade and a slight male predominance (reviews by Owen et al. (2003), Lin and Medeiros (2005), Vijay and Gertz (2007), Morel et al. (2009), Naderi and Yang (2013).

Waldenström's macroglobulinemia (WM, IgM paraproteinemia) is a disease that had been described by the great physician, scientist, and botany lover, Jan Gösta Waldenström (1906–1996), in 1944 under the term *incipient myelomatosis or essential hyperglobulinemia with fibrinogenopenia* (Waldenström 1944). Apart from macroglobulinemia (Waldenström's syndrome I), other eponyms associated with his name include a form of autoimmune hyperglobulinemia (Waldenström's syndrome II, not to be confounded with macroglobulinemia), Waldenström's disease (an acute form of thyrotoxicosis), Waldenström's chronic active hepatitis (a form of the now autoimmune hepatitis), Waldenström's syndrome (a hereditary disorder), and Waldenström's uveoparotitis (a disorder related to Heerfordt's syndrome). He also coined the term monoclonal gammopathy.

WM is characterized by the presence of a lymphoproliferative disorder (usually LPL) and of an elevated serum monoclonal IgM. Common clinical features include anemia, abnormal bleeding, hyperviscosity, lymphadenopathy, and splenomegaly (McDermott and Bell 1999). WM may represent the expression of several IgM-secreting, usually low-grade NHLs of the lymphocyte lineage and may thus not be a homogeneous disorder, but rather a clinicopathological entity (Pangalis et al. 2003; Owen et al. 2003). It is, therefore, important to recognize that WM can also occur in lymphomas different from LPL, including CLL, diffuse large B-cell lymphoma, follicular lymphoma,

mantle cell lymphoma, and extranodal marginal zone B-cell lymphoma (Owen et al. 2000). WM is also one feature of monoclonal gammopathy of undetermined significance (MGUS; Owen et al. 2000). Consensus recommendations for the clinicopathological definition of WM have been prepared in conjunction with the Second International Workshop on WM, referring to symptomatic WM, asymptomatic WM, MGUS, and so-called IGM-related disorders (Owen et al. 2003). LPL with WM is consistently composed of a spectrum or morphologic continuum of small lymphocytes, plasmacytoid lymphocytes, and plasma cells and occurs in at least two histologic variants, i.e., a more frequent lymphoplasmacytic or lymphoplasmacytoid variant and a less frequent group of lesions (monocytoid, signet ring cell, and hairy cell leukemia-like) (Remstein et al. 2003). Part of LPL cells show intranuclear inclusion containing IgM-kappa immunoglobulin, the Dutcher-Fahey intranuclear inclusion bodies (Boyd 1980).

All typical cases of LPL/WM express monoclonal surface immunoglobulin (predominantly kappa; k:l = 5:1) and the pan-B markers, CD19, CD20, CD22, and CD24, and slightly more than half of the neoplasms lack expression of CD5, CD10, and CD23 (San Miguel et al. 2003; Remstein et al. 2003). LPL/WM cells can show nuclear expression of BCL-10 (Merzianu et al. 2006). LPL is characterized by t(9;14)(p13;q32) in 50 % of patients who lack paraproteinemia. WM frequently shows 6q21 deletions (Schop et al. 2002) and is sometimes associated with 14q23 translocations and t(11;18)(q21;q21). Patients with WD can show somatic mutations in MYD88 and CXCR4 that are determinants of disease progression and outcome. These mutations are similar to nonsense and frameshift mutations found in the warts, hypogammaglobulinemia, infections, and myelokathexis/WHIM syndrome (Treon et al. 2012, 2014). MYD88 mutations were found in more than 90 % of WD patients and stimulate nuclear factor kappaB activity (Jimenez et al. 2013; Xu et al. 2013). Abnormal cytogenetic findings in LPL correlate with the polymorphous subtype and poor prognosis (Mansoor et al. 2001). LPL can transform into diffuse large B-cell lymphoma exhibiting plasmablastic/plasmacytoid features (Lin et al. 2003b; Simonitsch-Klupp et al. 2004).

Hepatic Manifestations of LPL/WM

Primary Lymphoplasmacytic Lymphoma of the Liver

Occasionally LPL has been reported as primary hepatic lymphoma, albeit such a primary organ manifestation is, similar to other NHLs with circulating lymphoma cells, difficult or even impossible to prove (Borgonovo et al. 1995). In two patients with primary hepatic LPL, a serum monoclonal peak of IgG kappa was identified (Borgonovo et al. 1995; Sekikawa et al. 1999).

Liver Infiltration in Extramedullary LPL/WM

Extramedullary involvement by Waldenström's macroglobulinemia occurs in a subset of patients. In a study on 44 patients, extramedullary involvements were, in decreasing order of frequency, the lymph nodes, the soft tissues, the spleen, the skin or lung, and rarely, each situation occurring only once, the tonsils, colon, liver, and gallbladder (Fig. 1). The lymphoplasmacytoid NHL phenotype was observed in 78 % (Lin et al. 2003a). On the other hand, another study on 45 patients found hepatomegaly in 44 % of patients, without specifying the cause of liver enlargement (Krajny and Pruzanski 1976). Rarely, infiltration of the liver in LPL is marked, resulting in tumorous lesions of the liver (Blatrix et al. 1973) or in massive sarcomatous infiltration that starts in sinusoids and portal tracts (Beau et al. 1984). Portal tract infiltration with compression of small portal venous branches may cause portal hypertension in LPL (Brooks 1976). Liver infiltration was detected in a patient with LPL associated with IgA

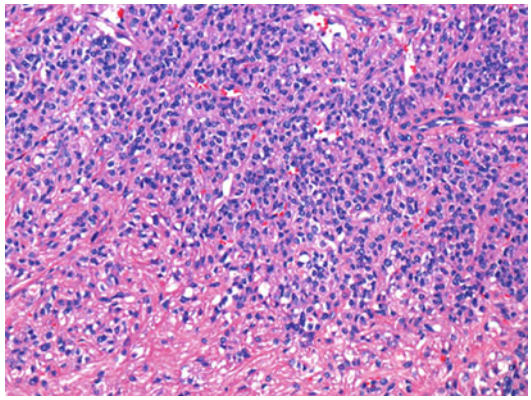

Fig. 1 Lymphoplasmacytoid infiltration of the liver in Waldenström's disease (hematoxylin and eosin stain)

hypergammaglobulinemia (Polprasert et al. 2009). Rarely, the liver is affected by high-grade immunoblastic lymphoma developing subsequent to WM, sometimes with jaundice and liver failure (Beau et al. 1984).

Peliosis Hepatis and Regenerative Changes of the Liver in WM

Peliosis hepatis has repeatedly detected in patients with WM (Ginestal-Cruz et al. 1979; Voinchet et al. 1988; Corpa et al. 2004). The peliotic foci may grow to a size rendering them grossly visible at autopsy (Corpa et al. 2004). In the patient of Corpa et al. (2004), the peliotic cavities were also irregularly filled with a monotonous population of CD20-positive neoplastic small lymphocytes, most with lymphoplasmacytic features (IgG/kappa). In contrast, the case reported by Ginestal-Cruz and coworkers (1979) showed a portal tract infiltrate by lymphoma cells, surrounded by typical peliotic cavities, which did not contain neoplastic cells. In this patient, peliosis might have been caused by oxymetholone therapy, a steroid known to induce peliosis hepatis (McDonald and Speicher 1978; Pavlatos et al. 2001), possibly via endothelial damage (Kosek and Smith 1980). Similarly, another patient with WM-associated peliosis hepatis did not display lymphoma cells within the peliotic lesions (Voinchet et al. 1988).

Nodular regenerative hyperplasia (NRH) of the liver in WM has been reported as a distinct association (Wanless et al. 1981). Pathogenetically, peliosis and nodular regenerative hyperplasia have been related to a disorder of hepatic microcirculation caused by light chain deposits in the sinusoidal walls (Voinchet et al. 1988). A similar or the same pathogenic pathway may be operational in liver peliosis rarely observed in multiple myeloma with production of Bence-Jones proteins (Kaise et al. 1982).

Amyloidosis and Light Chain Disease in LPL/WM

Primary systemic amyloidosis is a rare complication of immunoglobulin M monoclonal gammopathies and WM (Bedossa et al. 1988; Gertz et al. 1993, 2004; Gertz and Kyle 1988).

LPL/WM and Hepatocellular Carcinoma

There are few cases in the literature where WM was associated with hepatocellular carcinoma (Shimizu et al. 1982; Lotz et al. 1985; Lee et al. 1986; Yamamoto et al. 1990; Izumi et al. 1996; Hasegawa et al. 2000). This association may be related to chronic liver disease occurring in WM (Izumi et al. 1996), in particular the frequent infection of WM patients with HCV (Santini et al. 1993; Mussini et al. 1995; Mangia et al. 1996; Silvestri et al. 1998).

Differential Diagnosis

Monoclonal IgM gammopathy and hepatomegaly can occur in the absence of LPL/WM. Schnitzler's syndrome is a rare condition characterized by chronic urticarial, monoclonal IgM gammopathy,

intermittent fever, joint and/or bone pain with osteosclerosis, lymphadenopathy, hepatomegaly, splenomegaly, and leukocytosis. The etiology of this syndrome remains obscure (Lipsker et al. 2001; Kastritis et al. 2008). Schnitzler's syndrome can, similar to WD, be associated with nodular regenerative hyperplasia of the liver (Lauwers et al. 1999).

IgA-Type Lymphoplasmacytic Lymphoma with Liver Involvement

Introduction

Lymphoplasmacytic lymphoma with IgA hypergammaglobulinemia is a very rare variant of this type of lymphoma, which may clinically mimic Waldenström's disease (Hijmans 1975; Tursz et al. 1977; Hishitani et al. 1982; Askari et al. 1985; Basu et al. 2004). Histologically, a relatively high proportion of pleomorphic tumor cells is a feature in at least part of cases. The lymphoma is sometimes associated with autoimmune disorders (Askari et al. 1985) and can cause extranodal tumorous manifestations, involving the breast (Tsuji et al. 2009) and liver (see below).

Liver Involvement

Ig4-type lymphoplasmacytic lymphoma has been shown to involve the liver, clinically manifesting as abnormal liver function tests. This entity was first recognized in a 48-year-old female patient presenting with anemia and renal failure. Liver biopsy showed an infiltrate of small, atypical clonal cells with signs of plasmacytoid differentiation, associated with Ig4 hypergammaglobulinemia in serum (Polprasert et al. 2009).

Plasmacytoma of the Hepatobiliary Tract

ICD-O codes 9732/3 and 9734/3

Introduction

Both osseous plasmacytoma (plasmacytic multiple myeloma, PCM) and extraosseous plasmacytoma can manifest in the liver and biliary tract. In most cases, liver involvement occurs in the setting of myeloma, whereas primary hepatic plasmacytoma is very rare. In the 2008 WHO classification, extraosseous (extramedullary) plasmacytomas (EOPCs) are localized plasma cell neoplasms arising in tissues other than bone marrow. EOPCs account for about 3–5 % of all plasma cell neoplasms, with a medium age of patients at diagnosis of 55 years (Wiltshaw 1976; Knowling et al. 1983; Holland et al. 1992; Kremer et al. 2005). Two thirds are males. EOPC has a distinct frequency distribution pattern: About 80 % of the neoplasms arise in the upper respiratory tract, including the pharynx and larynx, but almost any other organ can be involved. Clinically, manifestations of EOPC depend on localization of the lesion and the tumor mass. Typically, the bone marrow is not involved. Approximately 20 % of patients show a small M-protein gradient, most often IgA (Shaheen et al. 2008; Lorsbach et al. 2011).

Liver Involvement in Plasmacytoma

Primary and Secondary EOPC of the Liver

In most cases of nodular hepatic manifestations of PCM, liver involvement makes part of extramedullary disease in systemic plasmacytoma (Fig. 2). In contrast, *primary hepatic nodular plasmacytoma* is exceedingly rare and usually presents as solitary plasmacytoma situated within the liver substance (Dohy et al. 1979; Abe et al. 1980; Weichhold et al. 1995; Loze et al. 1995; Demirhan et al. 1997; Petrucci et al. 2003; Lee et al. 2007; El Maaroufi et al. 2012). In one case, primary plasmacytoma of the liver had grown to the impressive size of 12 cm (Demirhan et al. 1997). Apart from the liver substance proper, PCM can develop at the hepatic hilus (Oyama et al. 2009) or in the gallbladder fossa (Majerovic et al. 2012).

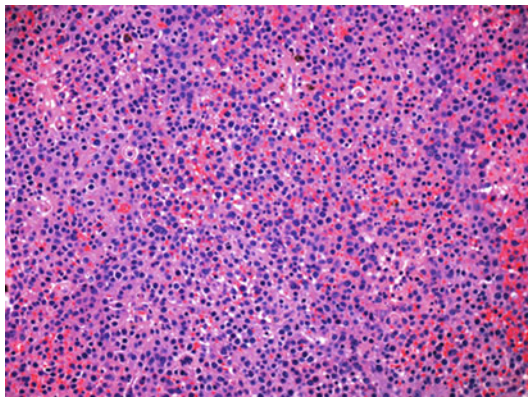

Fig. 2 Plasmacytoma in the liver. There is marked infiltration of the parenchyma with basophilic atypical plasma cells (hematoxylin and eosin stain)

Liver Involvement in Osseous/Medullary ("Classical") PCM

Extramedullary involvement of the liver of any form in PCM is seen at autopsy in 28–50 % of the patients (Walz-Mattmuller et al. 1998; Sucker et al. 2002), but diagnosis antemortem is chiefly based on presumptive clinical and laboratory findings and on imaging studies (Thomas et al. 1973; Kapadia 1980; Perez-Soler et al. 1985; Walz-Mattmuller et al. 1998; Oshima et al. 2001; Sucker et al. 2002; Malhotra et al. 2005; Bhandari et al. 2007; Poudel et al. 2012; Saboo et al. 2012). In a study of 869 cases, a palpable liver was detected in 21 % (Kyle 1975). In fact, hepatomegaly, sometimes massive (Jain et al. 2003), is the most frequent clinical sign of hepatic manifestations in some reported series of PCM and may cause compression signs and abdominal pain and sometimes portal hypertension (Solves et al. 1999). Hepatic involvement may also manifest as jaundice, with or without biliary obstruction (Pastor et al. 1996; Taarit et al. 2007) or caused by cholestatic hepatitis (Barth et al. 2005), or as liver failure (Rahhal et al. 2009; Coffey et al. 2012). Plasmacytoma nodules can rupture and mimic hepatocellular carcinoma (Ueda et al. 2010). Liver disease can rarely represent the primary manifestation of PCM (Solves et al. 1999). Biclonal multiple myeloma has also been observed in conjunction with preexisting liver disease, e.g., HCV-induced liver disease (Montella et al. 2000; Tashiro et al. 2003), which is of interest in the light of the pathogenic relationship between HCV infection and lymphomagenesis (see the respective paragraph).

Hepatic involvement mainly occurs in a *diffuse pattern*, a *nodular pattern*, and a *mixed pattern*. In the *diffuse pattern* of liver involvement, variable areas of the liver substance are more or less diffusely infiltrated by the abnormal plasma cells (Pasmantier and Azar 1969; Perez-Soler et al. 1985; Yoon et al. 1993; Sucker et al. 2002; Lopes da Silva et al. 2011), and nodular hepatic lesions are not visualized at imaging (Simmons et al. 1997). Among 21 histologically studied patients with liver involvement, diffuse infiltration of the liver was observed in ten patients (Perez-Soler et al. 1985). Diffuse liver infiltration can result in massive hepatomegaly (Jain et al. 2003) and, rarely, in hepatic failure (Fujii et al. 1998), but in a study of 21 patients, plasma cell infiltration of the liver did not appear to have a major prognostic significance (Perez-Soler et al. 1985). A reduced liver function thought to be caused by hepatic infiltration was detected in 13–58 % of the patients involved (Kyle 1975; Perez-Soler et al. 1985). Apart from the standard plasmacytic phenotype in PCM, liver infiltration has also been identified in the rarer signet ring-like light chain myeloma (Haidar et al. 2003). Plasmacellular neoplasms may also contain plasma cells with several to numerous variably PAS-positive intracytoplasmic globules or inclusions (Russell bodies) containing immunoglobulins stored in the smooth endoplasmic reticulum. Such cells have previously been termed morular cells by F.W. Mott in 1901 (from Latin morus, mulberry). Nowadays, these cells are often called Mott cells (Bavle 2013; McCormick et al. 2013). Histologically, large parts of liver tissue may be replaced by dense accumulations of plasma cells (producing low-attenuation areas at CT; Solves et al. 1999), sometimes only leaving partially atrophic bile ducts indicating the previous portal tracts (Simmons et al. 1997). The plasma cells are in close spatial contact with cholangiocytes, with

or without signs of plasma cell decay and occasionally with cholangiocyte apoptosis. Dense infiltration of portal tracts can induce cholestasis and jaundice (Thomas et al. 1973). In early phases of hepatic involvement, liver biopsies revealed a preferential infiltration of portal tracts by atypical plasma cells, with focal invasion of the adjacent zone 1 parenchyma (Kaur et al. 2000). However, there are also situations where monotypic light chain-expressing neoplastic cells preferentially accumulate in the sinusoids, associated with hepatocyte damage (Kapadia 1980; Kawano et al. 1991; Solves et al. 1999; Jain et al. 2003). Hepatocyte failure in these situations may lead to hyperammonemia and encephalopathy as the first signs of PCM (Kawano et al. 1991; Caminal et al. 1993).

In the *nodular pattern* of hepatic manifestation ("myelomatous nodules"), few to numerous, gray to white nodules resembling metastatic foci and consisting of dense accumulations of neoplastic plasma cells are observed at autopsy (Sucker et al. 2002). The lesions can reach a diameter of 2–3 cm. Ultrasound scans may reveal target lesions, with a hyperechoic center and peripheral hypoechoic haloes, whereas the lesions were reported to be slightly hypodense to the liver on non-contrast CT and slightly hyperdense during the arterial phase of contrast enhancement. On MRI the lesions were slightly hypointense to the liver on T1-weighted images and hyperintense on T2-weighted images, and they enhanced minimally with intravenous gadolinium (Mathieu et al. 1986; Caturelli et al. 1993; Curtis et al. 1995; Simmons et al. 1997; Ng et al. 1999). In case of abnormal angioarchitecture of the nodules, the lesions may mimic hypervascular hepatocellular carcinoma (Park et al. 2002). The histology is characterized by nodules composed of densely packed atypical plasmacytoid and plasma cells replacing the parenchyma and sometimes encroaching upon damaged bile ducts (Simmons et al. 1997). A rare manifestation of hepatic PCM is hepatic failure due to CD3+ plasma cell infiltration of the liver associated with light chain deposits (Yagci et al. 2002). Overall, involvement of the liver by PCM in the form of space-occupying lesions is less common than the diffuse form (Fernandez-Flores et al. 2003).

Selected References (Voet et al. 1983; Garfinkel et al. 1985; Mathieu et al. 1986; Thiruvengadam et al. 1990; Musto et al. 1992; Nguyen et al. 1992; Wajima 1992; Caturelli et al. 1993; Fautrel et al. 1993; Ganjoo et al. 1993; Curtis et al. 1995; Kelekis et al. 1997; Simmons et al. 1997; Chemlal et al. 1999; Hyun et al. 1999; Ng et al. 1999; Bangerter et al. 2000; Fernandez-Flores et al. 2003; Poggi et al. 2003; Galani et al. 2007; Invernizzi et al. 2007; Carneros et al. 2009; Wu et al. 2009; Gonzalez et al. 2010; Vazquez et al. 2010; Tan et al. 2011; de Vos et al. 2012; Husaric et al. 2013; Pal et al. 2014).

In a subset of cases with PCM, altered immunoglobulins and/or chains thereof are stored in histiocytic cells/macrophages in the form of crystalloid structures that can be detected by light microscopic examination (Takahashi et al. 1987; Jones et al. 1999; Lebeau et al. 2002; Papla et al. 2004). This condition is termed crystal-storing histiocytosis (CSH) and may also occur in other lymphomas, including those of the MALT type, and in transient polyclonal plasma cell hyperplasia following bone marrow transplantation. In CSH, large macrophages filled with oblong crystalline particles are found in ample quantities in several organs (mainly in the bone marrow), and the exact nature of the crystals may be unclear until immunohistochemical examinations are performed. Some of the macrophages resemble Gaucher cells or the pseudo-Gaucher cells seen in myelogenous leukemia, leading to the term "pseudo-pseudo-Gaucher cells" (Schaefer 1996). It has been suggested that Ig crystal accumulation in histiocytes/macrophages may be related to a possible pro-aggregation defect in Ig heavy chains (Papla et al. 2004). The liver may be involved by CSH developing in PCM, with accumulation of crystal-containing macrophages in the portal tracts and within liver lobules (Zioni et al. 2004; Papla et al. 2004). In one study, Ig heavy chain-derived crystals were not only identified in hepatic macrophages but, ultrastructurally, also within hepatocytes, the

crystals more frequently forming clusters in these parenchymal cells (Papla et al. 2004). The presence of Ig chain crystals in hepatocytes is most probably related to the expression of receptors for the Fc portion of Ig molecules on hepatocytes, also capable for binding immunoglobulin complexes or immunoglobulin aggregates, followed by endocytosis. Apart from crystalloid inclusions, immunoglobulin chains may, similar to normal plasma cells, accumulate in tumor cells in the form of numerous Russell bodies. Such lesions have been called Mott cell tumors (Brink et al. 1999; Fujiyoshi et al. 2001), in analogy to Mott cells that are plasma cells with abundant Russell bodies rendering the cell morula-like. We are not aware of such a lesion occurring in the liver.

Other Hepatic Manifestations of Plasmacytoma

Cholestasis

Cholestasis occurs in few patients that have extrahepatic large bile duct stenosis/obstruction due to plasmacytic tumor formation in perihilar lymph nodes, lymph nodes of the hepatoduodenal ligament, involvement of the bile ducts, or PCM manifestations in the pancreatic head area (Coban et al. 2004). However, few patients with extramedullary PCM develop jaundice in the absence of bile duct obstruction, in part associated with fever of unknown origin/FUO (Pastor et al. 1996; Vella et al. 2003; Mumoli et al. 2004). In part of the patients, this is related to the development of hepatic amyloidosis in plasmacytoma (Licht et al. 1999).

Hepatomegaly and Increased Hepatocyte Proliferation in POEMS Syndrome/Crow-Fukase Syndrome

POEMS is an acronym for polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes and denotes a distinct syndrome associated with neoplasms of the plasma cell lineage. Alternative terms to denote this syndrome are Crow-Fukase syndrome, Shimpo's syndrome, Takatsuki's syndrome, and PEP syndrome (Nakanishi et al. 1984; Rolon et al. 1989; Bisail et al. 1990; Soubrier et al. 1994; Koike and Sobue 2000; Takakura et al. 2003). The syndrome is sometimes associated with another group of lesions occurring in conjunction with plasmacytoma, namely, the AESOP (adenopathy and extensive skin patch overlying a plasmacytoma) syndrome (Lipsker et al. 2003). The minimal criteria to establish the diagnosis of POEMS syndrome are the presence of a demyelinating and axonal polyneuropathy associated with an IgA or IgG monoclonal gammopathy, the light chain being almost always lambda, and at least two of the following eight features: sclerosing plasmacytoma, endocrinopathy, skin changes, organomegaly, Castleman disease, anasarca, papillary edema, and thrombocytosis. Among these features, cutaneous glomeruloid angiomas are regarded as specific (Lagueny et al. 2004). Microvascular changes have also been described in the glomeruli of kidneys in patients with POEMS syndrome (Fukatsu et al. 1991). The cellular sources of M-proteins (i.e., lambda light chains and almost always alpha or gamma heavy chains) are typically osteosclerotic or, less frequently, mixed osteosclerotic and lytic myelomas or gammopathies of undetermined significance, while purely lytic multiple myeloma is rarely found (Nakasnishi et al. 1984; Soubrier et al. 1994). Crow-Fukase syndrome can develop with a long delay after plasmacytoma, in one case 18 years after the first manifestation of plasmacytoma (Sakemi and Okada 1992). The syndrome is, in addition to plasmacytoma, also associated with multicentric Castleman disease (Rolon et al. 1989). Pathogenetically, the syndrome is thought to be caused by increased levels of vascular endothelial growth factor (VEGF) produced by megakaryocytes and released from the increased thrombocytes, but independent of M-protein (Soubrier et al. 1997; Watanabe et al. 1998; Hashiguchi et al. 2000; Tokashiki et al. 2003; Lewerenz et al. 2003). However, several reports described a decrease of serum VEGF subsequent to the treatment of plasmacytoma

(Shinde et al. 2001; Yoritaka et al. 2004). Increased availability of VEGF may be related to the glomeruloid skin angiomas and other angiomatoid lesions occurring in POEMS syndrome, including arteriovenous fistulas and plexogenic pulmonary arteriopathy causing pulmonary arterial hypertension (Lewerenz et al. 2003). What are the pathogenic pathways causing hepatomegaly in POEMS syndrome? Liver biopsies suggest that hepatic enlargement is due to increased hepatocyte proliferation (Fushimi et al. 1995). Serum from patients with POEMS syndrome induced sustained proliferation of cultured murine hepatocyte by factors apparently different from hepatocyte growth factor (Fushimi et al. 1995, 1996). Increased serum levels of IL-6, a priming cytokine for hepatocyte proliferation, may play a role (Nakazawa et al. 1992; Hitoshi et al. 1992).

Liver Changes Related to PCM-Associated Hyperlipidemia

PCM and monoclonal gammopathies are sometimes associated with hyperlipidemia/type III hyperlipoproteinemia (Ansari 1992; Fukudome et al. 1996. The pathogenesis involves an autoimmune-like reaction mediated by inhibitory monoclonal immunoglobulin (frequently of the IgA class) directed against low-density lipoprotein binding to cellular receptors (Baudet et al. 1978; Cortese et al. 1982; Nozaki et al. 1997) or the formation of paraprotein-lipoprotein complexes (Taylor et al. 1978; Kilgore et al. 1985). The hyperlipidemia in plasmacytoma/myeloma is known to induce the development of xanthomatosis, with xanthomas consisting of lipid-laden, foamy macrophages (Moschella 1970; Marien and Smeenk 1975; Chelazzi and Uccella 1974; Roberts-Thomson et al. 1975; Wilson et al. 1975; Taylor et al. 1978). However, cutaneous xanthomas in association with paraproteinemia can also occur in the absence of hyperlipidemia (Feingold et al. 1989; Piccinno et al. 1990). In the liver, multiple xanthomatous collections of foamy macrophages as well as a sinusoidal accumulation of foam cells have been observed, resulting in xanthomas of the liver (Yim et al. 1995).

Vascular Complications in the Liver

Plasmacytoma can in rare instances involve small hepatic veins (Lazure et al. 2007). Rarely, PCM is associated with thrombotic venous complications in the liver, including Budd-Chiari syndrome (Tsuji et al. 1986, 1990).

Hepatic Tumors

An association of PCM with hepatocellular carcinoma (HCC) has rarely been reported (Inoue et al. 1986; Christou et al. 1998; Nakanishi et al. 2003). In a consecutive series of 317 patients with HCC, 32 (10.1 %) had 35 extrahepatic primary malignant neoplasms. Among these, ten were B-cell lymphoid neoplasms, these disorders therefore representing the most frequent associated malignancies (Di Stasi et al. 1994).

Differential Diagnosis

Several reactive disorders are associated with marked peripheral plasmacytosis, and some of them may lead to accumulation of increased numbers of plasma cells in organs and tissues, including the liver and the biliary tract. They include sickle cell anemia, certain infections (rubella, dengue, mononucleosis, parvovirus B19), serum sickness, drug therapy (e.g., sulfisoxazole or azathioprine), alcoholic liver disease, and hyperimmunization (review by Gawoski and Ooi 2003).

An unusual and etiologically unclarified plasma cell proliferative disorder of the upper aerodigestive tract has been reported, with plasma cell lesions typically producing a cobblestone or warty appearance of the upper aerodigestive tract mucosa including the larynx, pharynx, palate, lips, mouth, tongue, and trachea. Histologically,

all lesions were characterized by psoriasiform epithelial hyperplasia with dyskeratosis and dense subepithelial plasmacytosis (Ferreiro et al. 1994; Imbing et al. 1996; Khan et al. 1997; review by Bharti and Smith 2003).

Cytogenetic and Molecular Features

Cytogenetically, many cases of PCM and monoclonal gammopathy of undetermined significance (MGUS) are normal, but several chromosomal anomalies have been described for part of the lesions. A high frequency of chromosomal aberrations has in particular been detected by the use of direct chromosome preparations and with FISH (Nilsson et al. 2004). A subset of PCM exhibits a recurrent translocation t(14;20)(q32; q12) resulting in the aberrant expression of the transcription factor, MAFB, and there is evidence that this translocation has an adverse biologic effect (Boersma-Vreugdenhil et al. 2004). In the molecular level, primary chromosomal lesions cooperate with secondary genetic events, including gene mutations and epigenetic mechanisms (review by Boyd et al. 2012).

Plasma Cell Leukemia

Introduction

Plasma cell leukemia (PCL) is defined as a variant of plasma cell neoplasms with increased numbers of neoplastic plasma cells circulating in peripheral blood (synonyms, leukemic myelomatosis and myeloma cell leukemia). In case PCL is present at the time point of diagnosis of plasmacytic neoplasm, the diagnosis is that of primary PCL. Secondary PCL is the form that evolves as a late feature of plasma cell myeloma. Primary PCL is a rare disorder, accounting for only 2–5 % of cases of plasma cell neoplasms. It presents about one decade earlier than secondary PCL (Tiedemann et al. 2008). In PCL, the number of clonal plasma cells in peripheral blood exceeds $2 \times 10(9)/L$ or represents 20 % of the leukocyte differential count. Plasma cells infiltrate the bone marrow and are often also present in extramedullary tissues, including the spleen and liver. In contrast to plasma cell myeloma of IgD or IgA types, those with IgD, IgE, or light chains only are more often complicated by PCL.

Clinical Features

The clinical features are dominated by the sequelae of extensive bone marrow infiltration (bone marrow failure, anemia, thrombocytopenia), signs of osteolysis, and deep organ infiltration, sometimes with impaired renal function. Patients often show significant hepatosplenomegaly. Hyperviscosity syndrome has been observed. Patients with primary PCL show an aggressive course, with often abrupt onset of disease, with poor response to therapy, and with shorter median overall survival, progression-free survival, and complete response duration.

Liver Involvement

As both primary and secondary PCL tend to show extramedullary organ and tissue infiltration, the liver is expected to be involved, but hepatic infiltration is more frequent in primary PCL than in its secondary counterpart (Badhe et al. 2003; Majumdar et al. 2009; Islam and Anoop 2011). In a study of 64 patients with primary PCL, hepatomegaly was detected in 23 % of patients (Pagano et al. 2011). Atypical plasma cells mainly infiltrate the liver sinusoids (Sandri et al. 1976; Noguchi et al. 1985; Kawano et al. 1991), but portal tract infiltrates are seen in massive hepatic infiltrations, and part of patients develop tumorous plasmacellular masses in the liver substance in late phases of disease. Liver insufficiency is a rare complication (Lopez Guillermo et al. 1989).

Differential Diagnosis

The main differential diagnosis is infiltration of the liver in the setting of plasma cell myeloma.

Cytogenetic and Molecular Features

In primary PCL, IGH translocations were identified in 87 % of cases, with prevalence of t(11;14) (40 %) and t(14;16) (30.5 %), the translocations being more frequent than in plasma cell myeloma (Cho et al. 2011). The most frequent numerical alterations involved chromosomes 14q, 16q, 1p, 1q, 8p, 13q, and 17p (Chang et al. 2009, 2010; Peijing et al. 2009; Mosca et al. 2013). Among the genes activated and overexpressed in primary PCL are genes involved in hepatic stellate cell activation and hepatic fibrosis (Usmanl et al. 2012).

Immunoproliferative Small Intestinal Disease (IPSID)

Introduction

Immunoproliferative small intestinal disease (IPSID) is a variant of extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT), in which alpha immunoglobulin heavy chains are secreted. Owing to the latter phenomenon, the disorder is and was often called alpha heavy chain disease, but the 2008 WHO classification proposes the use of the term IPSID (reviews by Rappaport (1976), Nassar et al. (1978), Haghighi and Wolf (1986), Al-Saleem and Al-Mondhiry (2005), Salem and Estephan (2005).

The recognition of IPSID as an entity goes back to observations in the early to mid-1960s, when several reports appeared from Israel specifying a distinct primary small intestinal lymphoma associated with malabsorption in young adults (Frand and Ramot 1963; Ramot et al. 1965; Eidelman et al. 1966). This lesion is the previous so-called Mediterranean lymphoma that has now been recommended by the WHO to be termed IPSID. It is a variant of the B-cell lymphoma of MALT and a further member of infection-associated lymphoproliferative disorders. IPSID demonstrates an association with *Campylobacter jejuni*, is prevalent in the Middle and Far East and in Africa (and in immigrants thereof), and involves mainly the proximal small intestine resulting in malabsorption, diarrhea, and abdominal pain, with a remarkably uniform clinical presentation. In advanced disease, intestinal obstruction, abdominal masses, and ascites may be common (Doe 1975; WHO Report 1976; Kharazmi et al. 1976; Lewin et al. 1976; Tabbane et al. 1976; Seligman 1979; Kojasteh et al. 1983; Isaacson 1985; Salem et al. 1987; Takahashi et al. 1988; Kojasteh and Haghighi 1990; Price 1990; Martin and Aldoori 1994; Fine and Stone 1999; Swaroop 2000; Lecuit et al. 2004; Peek 2004; Peterson 2004; Economidou et al. 2006; Mrabti et al. 2011; Pervez et al. 2011; Huang and Sheu 2012; Mesnard et al. 2012). IPSID affects mainly older children and young adults, of low socioeconomic status in developing countries.

Many patients with IPSID were found to exhibit variable levels of abnormal immunoglobulin in serum or other body fluids, later identified to be truncated alpha heavy chains. Historically, a partial immunoglobulin heavy chain of the IgA class devoid of light chains in serum and other body fluids of some patients was reported in the late 1960s already (Seligmann et al. 1968, 1969; Rambaud et al. 1968). IPSID may, therefore, be regarded as an enteric form of alpha heavy chain disease (alpha HCD; WHO Report 1976; Seligmann 1979; Altuntas and Ensari 2000). Secretory forms (secreting IPSID/secretory alpha chain disease) and nonsecretory forms (nonsecreting IPSID/NS-IPSID/extensive small intestinal lymphomas without gammopathy) are recognized (Matuchansyk et al. 1989; Pai et al. 2005). There are also cases of IPSID that are alpha chain negative (Gilinsky et al. 1983; Cammoun et al. 1989).

Clinical Features

The natural history of the disease appears to be one of evolution from extensive lymphoid cell and plasma cell infiltration to overt malignant lymphoma. In stage A disease, the intestinal mucosa is diffusely and densely infiltrated by normal-looking lymphocytes and plasma cells, with

similar involvement of locoregional lymph nodes. Stage B is characterized by the emergence of atypical plasma cells and immunoblasts, and the infiltrate extends into the submucosa and the muscle layer. In stage C, an overt NHL involves the small intestine and locoregional lymph nodes (Galian et al. 1977). Apart from the Galian et al. staging system (1977), other staging systems are employed, including the WHO scheme (WHO Report 1976) and the Salem scheme (Salem et al. 1977). This evolution, which may take many years, apparently reflects a progression from the so-called "low-grade" IPSID to "high-grade" IPSID (Galian et al. 1977; Seligman and Rambaud 1983; Rogers et al. 1988; Kojasteh and Haghighi 1990; Androulaki et al. 2003). In Western patients with IPSID, the gross and histologic presentation may deviate from the pattern typically seen in Eastern patients, e.g., with the development of polypoid gastrointestinal lymphoma (Cohen et al. 1978).

Histopathology

In fully established IPSID, the intestinal mucosa is densely and diffusely infiltrated by lymphoid cells with a centrocyte-like morphology, by lymphoplasmacytoid cells, and by plasma cells, the entire mixed cell population forming a band-like and compact infiltrate in the mucosa, causing a grossly visible diffuse or sometimes nodular thickening of mucosal folds. Usually, long segments of the proximal small intestine are preferentially involved (Rappaport 1976; Galian et al. 1977; Haghighi et al. 1978; Nassar et al. 1978; Rambaud et al. 1990). This is the so-called "low-grade" IPSID. The dense infiltration leads to separation, infiltration, and partial or complete destruction of the crypts that look then sparse and splayed, whereas the surface enterocyte lining is mostly intact or only minimally altered, with intraepithelial lymphoid infiltration. Similar to MALT lymphomas, lymphoepithelial lesions are a typical morphologic feature of IPSID (Price 1990). In situations of heavy infiltration, the intestinal villi are shortened or even completely flattened. In some patients, micronodular aggregates are formed deep in the mucosa (so-called lympho-histiocytoid nodules; Nassar et al. 1978). In case of progression to lymphoplasmacytic and immunoblastic lymphoma of higher grade (Rogers et al. 1988; the so-called "high-grade" IPSID), lymphoid and plasmacytoid cells with increased atypia and pleomorphism emerge, and these cells may then leave the mucosal compartment to invade the submucosa and the muscularis propria.

Immunohistochemically, the centrocyte-like neoplastic cells forming the lymphoepithelial lesions show alpha 1 heavy chain, but no light chain, in the perinuclear space and cytoplasm. The plasma cells are reactive for alpha heavy chain and the J chain, but no light chains (Isaacson 1979; Isaacson et al. 1989). There is also a form of IPSID rich in reactive T cells (T-cell-rich alpha chain disease), mimicking T-cell lymphoma (Lavergne et al. 1997).

Liver Involvement in IPSID

Apart from the intestinal wall, locoregional lymph nodes and, rarely, other abdominal organs are involved (Galian et al. 1977; Nassar et al. 1978; Tabbane et al. 1988). Generalized lymphadenopathy and slight splenomegaly caused by lymphomatous infiltration have been reported (Takahashi et al. 1988). An involvement of the liver in IPSID occurs, but its prevalence is difficult to judge (Doe 1975; Plesnicar et al. 1975; Galian et al. 1977; Kahn and Novis 1977; Haghighi et al. 1978; Nassar et al. 1978; Asselah et al. 1983). Sparse informations on gross pathology of the liver are available. Among seven patients with either laparoscopy or necropsy findings, one patient showed miliary lesions throughout the liver, histologically corresponding to hepatic portal tract spaces uniformly expanded by a cell infiltrate identical to that noted in the involved small intestine and in locoregional lymph nodes, although a variable admixture with small lymphocytes was found. In addition, some of the plasmacytoid cells were seen in the sinusoids adjacent to the infiltrated portal tracts, i.e., within zone 1 (Haghighi et al. 1978). Among 16 patients having a liver

biopsy, none of the biopsies revealed malignant changes, but focal lymphocytic infiltrations were frequently observed in the portal tracts, and non-caseating granulomas were detected in two patients (Salem et al. 1977; Nassar et al. 1978). In contrast, liver localization of the lymphomatous infiltration was observed in other investigations. Liver infiltration was observed in four of six patients studied (Galian et al. 1977). In one patient having stage A intestinal and mesenteric lymph node disease, portal tract spaces were densely infiltrated by mature or sometimes atypical plasma cells and by some lymphocytes, and small foci of plasma cells were also scattered within the liver lobules. In another patient with intestinal and mesenteric lymph node stage B, surgical liver biopsies showed a portal space infiltrate made of lymphocytes, mature plasma cells, and regular immunoblast-like cells, and in a third patient, the infiltrate was seen to produce portal tract nodules formed by immunoblast-like cells and very rare mature plasma cells. A postmortem examination of a further patient revealed that portal tracts and the periportal tissue were occupied by a massive infiltration of large neoplastic cells identical to those found in the small intestine and mesenteric lymph nodes (Galian et al. 1977). In a large analysis of 22 patients, the liver histology was usually normal, but a slight or moderate lymphoplasmacytic infiltrate without evidence of atypia was found occasionally in the portal tracts. Portal and intralobular accumulations of atypical mononuclear cells were detected in three patients, while cells accumulating in the hepatic sinusoids were not found (Asselah et al. 1983). Among 17 patients with IPSID of the alpha chain disease type that had macroscopic and/or microscopic data, five showed neoplastic liver involvement, all with stage C disease according to Galian et al. (1977). Among 21 patients with nonsecreting IPSID, neoplastic liver involvement was identified in four patients, and four more patients had nonspecific portal tract infiltration (Tabbane et al. 1988).

Hepatic infiltration in progressive/advanced stage IPSID starts in the form of a sparse and mixed portal tract infiltration containing various numbers of plasma cells, requiring immunophenotyping for correct diagnosis, to then progress to dense infiltrates occupying the entire portal tract spaces, to nodular lesions, and finally to parenchymal involvement, mainly of periportal zone 1. A sparse lymphoid cell infiltrate may involve intrahepatic bile ducts (minimal biliary mucosal infiltration, MBMI).

Etiological and Pathogenetic Factors

The prevalence in certain geographic areas led to the supposition that an environmental infectious factor is responsible for initiating disease onset, previously supported by the observation that IPSID can occasionally respond to antimicrobial agents. Based on this phenomenon, a molecular strategy employing universal bacterial PCR primers in affected tissues resulted in the identification of *Campylobacter jejuni* as the likely factor (Lecuit et al. 2004). FISH signals for *C. jejuni* were most prominent within the mucosal lamina propria, in close apposition to capillaries. These observations supported the contention that *C. jejuni* may represent a hitherto undefined causative agent for IPSID (Puri et al. 1992; Lecuit et al. 2004; Peek 2004; Peterson 2004; Sellin 2004; Lecuit and Lortholary 2005). In addition, infection with *Helicobacter pylori* has been considered an etiological factor, as IPSID regressed in one patient upon *Helicobacter* eradication (Dutta et al. 2010).

Amyloidogenic Immunoglobulin Chain and Non-amyloidogenic Immunoglobulin Chain Diseases

Contents

Abstract

B-cell non-Hodgkin's lymphomas (NHL) can be associated with amyloidogenic immunoglobulin chain and non-amyloidogenic immunoglobulin chain disease. In both groups of disorders, the hepatobiliary tract can be involved in form of various patterns. Hepatic amyloidosis caused by NHL is termed amyloid light-chain or AL amyloidosis (primary amyloidosis) and develops in the setting of various B-cell neoplasms, most commonly with plasmacytoma. This form of amyloidosis induces an enlarged liver with increased transparency and elevated consistency. The predominant histological localization of amyloid is perisinusoidal and in portal tracts, associated with marked atrophy of hepatocyte plates. In a minority of cases of AL amyloidosis, tumor-like amyloid masses can develop (amyloidoma or amyloid tumor). This tumefactive hepatic amyloidosis is a very rare disorder. Amyloidosis can rarely involve intrahepatic and extrahepatic bile ducts. Among non-amyloidogenic immunoglobulin chain diseases, light-chain deposit disease can involve the liver. The liver is in fact the most frequent extrarenal localization of this disorder and is characterized by the deposition of granular or ribbonlike non-congophilic material along sinusoids.

Hepatic Amyloidosis Caused by Non-Hodgkin's Lymphomas

Introduction

Amyloid light-chain (AL) amyloidosis (synonyms: primary systemic amyloidosis, primary amyloidosis, ICD-1o E85) is a form of amyloidosis caused by the deposition of abnormal monoclonal immunoglobulin light chains or light-chain fragments transformed into amyloid fibers with a beta-pleated structure (Husby 1983). AL is the most common form of amyloidosis in western countries and is typically associated with plasmacytoma/multiple myeloma, but also develops in other B-cell-derived malignancies, including lymphoplasmacytic lymphoma/Waldenström's disease (Gertz et al. 1993; Simmonds et al. 1997), diffuse and follicular B-cell lymphomas (Tschang 1976; Cohen et al. 2004), MALT lymphomas (Satani et al. 2007), and marginal zone lymphoma (Ryan et al. 2012), and in other monoclonal gammopathies. It is estimated that about 10–15 % of patients with multiple myeloma will develop overt AL amyloidosis. AL affects a wide range of organs and tissues and is therefore associated with highly variable clinical manifestations, but the kidney is the most commonly affected organ in AL amyloidosis.

Amyloidosis was and still is a very complex group of disorders. The unique gross and later histologic features of amyloidosis are known for a long time period. A sago spleen of amyloidosis has probably first been noted in 1639 by Nicolaus Fontanus, and lardaceous organ changes were reported in 1789 by Antoine Portal and later, in 1818, by Merat. A liver infiltration by a gelatinous substance in patients with tuberculosis or syphilis was described in 1842 by Rokitansky, the first description of the present secondary or AA amyloidosis (review: Kyle 2001). The term amyloid for these depositions goes back to "amyloid" used by Schleiden, a botanist, in 1838 to denote normal starch-containing material in plants. Rudolf Virchow first employed this term to describe the iodine-positive hyaline material characterizing amyloidosis. The characteristic apple-green birefringence when sections are stained with Congo red when viewed under polarized light was reported in 1927 (Divry and Florkin 1927). Electron microscopically, the non-branching fibrillar structure of amyloid was published in 1959 (Cohen and Calkins 1959). Apart from immunoglobulin light chains, up to 30 other proteins have been identified to cause diverse forms of amyloidosis. The pathogenesis of AL amyloidosis is not yet fully elucidated (Maniatis 1998; Merlini and Bellotti 2003; Pinney and Hawkins 2012; Ramirez-Alvarado 2012). A central step in the process is the partial lysosomal proteolysis of monoclonal light chains in macrophages, followed by tissue deposition of these altered chains or N-terminal chain fragments in the form of beta-pleated amyloid fibrils attached to a polysaccharide (so-called beta-fibrillosis; Glenner 1980). There are 40 kappa and 33 lambda germline genes that form a light-chain variable domain. In AL amyloidosis, there exists an overrepresentation of the germline light-chain genes, kappaI, lambda1, lambda2, lambda3, and lambda6. Each patient with AL amyloidosis reveals a unique amyloidogenic protein, because the phenomenon of somatic Ig hyper-mutation contributes to the complexity of AL amyloidosis.

Liver Involvement in AL Amyloidosis

Hepatic AL amyloidosis has most commonly been observed in the setting of multiple myeloma (Gertz and Kyle 1988; Yamamoto et al. 1995; Cross et al. 2006; Son et al. 2011b). Deposition of AL amyloid in the liver may induce significant functional derangements of this organ. AL amyloidosis of the liver can cause jaundice (Macias Robles et al. 1994) or cholestasis (Rubinow et al. 1978; Konikoff et al. 1987; Hoffman et al. 1988; Mohr et al. 1999; Ferreira et al. 2008). In part of patients with AL amyloidosis, cholestasis developed in the absence of visible hepatic amyloid involvement. In these cases, a toxic effect of abnormal light chains has been proposed

(Paudice et al. 2011). AL amyloidosis of the liver can cause hepatic failure (Dohmen et al. 1991; Yamamoto et al. 1995; Linardaki et al. 1997; Mainenti et al. 1997; Okabe et al. 1998; Berrios et al. 2003; Varela et al. 2003; Cross et al. 2006; Hydes and Aspinall 2012) and massive amyloid deposits resulting in atrophy and loss of hepatocytes, almost the entire liver substance being replaced by amyloid in some cases (Tabata et al. 2012). Livers occupied by amyloid may show increased tissue fragility and tend to hemorrhage and/or rupture (Naito et al. 2008; Tam et al. 2009; Szturz et al. 2013).

Marked hepatic amyloidosis is macroscopically characterized by either an enlarged liver with an increased transparency and elevated consistency (the "lardaceous liver"; Reuben 2004) or the presence of transparent deposits. In some cases, only a markedly atrophic liver with hyperemia is found. The histologic presentation of hepatic AL amyloidosis is different from that in AA amyloidosis (secondary amyloidosis). The predominant localization pattern in AA amyloidosis is vascular, whereas AL amyloidosis shows a perisinusoidal pattern in addition to portal tract and blood vessel involvement (Chopra et al. 1984; Smith and Malcolm 1986; Looi and Sumithran 1988; Iwata et al. 1995; Econimo et al. 2011; Sarsik et al. 2012). However, other studies arrived at different results (Chopra et al. 1984), e.g., showing that a sinusoidal deposition pattern also occurred in 29/78 cases of secondary (AA) amyloidosis (Buck and Koss 1991), suggesting that the hepatic amyloid distribution pattern will not help much in distinguishing the two forms of amyloidosis. Parenchymal involvement in AL amyloidosis often leads to atrophy of hepatocyte plates, sometimes associated with fatty change of liver cells. Perisinusoidal amyloid accumulation can narrow sinusoidal lumina and may cause complete effacement of the sinusoidal vascular channels.

Hepatic AL amyloid deposits more often show reactivity for lambda-type amyloid fibrils (Kuçi et al. 2007; Gioeva et al. 2009), but the inverse situation has also been reported in AL amyloidosis (Kebbel and Röcken 2006). In hepatic AL amyloidosis, the identification of amyloid deposits with anti-light-chain antibodies depends on the light-chain fragment regions to which antibodies had been raised. Amyloid deposits in the space of Disse tended to react weakly or partially with anti-lambda (118–134), but well with anti-lambda (159–175), while amyloid deposits in the portal vein wall reacted relatively well with both antibodies (Kiyama et al. 2007). Whether hepatic AL amyloidosis is reversible is currently unknown. Amyloid deposits can induce a macrophage reaction, sometimes with the formation of multinucleated giant cells of the foreign body type (amyloid granulomas), and small fragments of congophilic phagocytosed material may be seen within macrophages. Hepatic sinusoidal endothelial cells can store and metabolize serum immunoglobulin (Iwamura et al. 1995), but it is not established whether these cells can also metabolize AL amyloid fibrils.

Primary Hepatic Amyloidosis

Primary hepatic amyloidosis (PHA; synonym: hepatic AL amyloidosis) is a very rare disorder characterized by the abnormal deposition of monoclonal Ig light chains in the liver in the absence of overt myeloma or other B-cell neoplasms (Schmid et al. 1992; Park et al. 2003; Wang et al. 2012). The rarity of this disorder is illustrated by the observation that, in a study of 805 patients with clinically suspected or biopsy proven systemic amyloidosis, amyloidosis was never confined to the liver (Lovate et al. 1998), suggesting that at least part of cases with apparently primary hepatic AL amyloidosis are cases in the pre-gammopathy phase of disease. In PHA, AL amyloid deposition is predominantly found in the perisinusoidal space of Disse, but also occurs in portal tracts and in the walls of portal vein branches and central veins (Park et al. 2003; Wang et al. 2012). The pathogenesis of this unusual process is unknown. Patients with PHA often show marked hepatomegaly and elevated serum levels of alkaline phosphatase.

Mass-Forming Hepatic Amyloidosis (Amyloidoma, Amyloid Tumor)

In a minority of cases, AL amyloid presents in the form of tumor-like masses (amyloidoma, amyloid tumor, tumefactive liver infiltration in amyloidosis; Fig. 1). Amyloidomas have mostly been observed in the soft tissues, breast, urinary tract, muscles, lung, kidney, CNS, and lymph nodes (review: Westermark 2012). Amyloidomas were also observed following eradication of amyloid-containing lymphoma tissue by means of radiotherapy (Levitan et al. 1985). Amyloid tumors are very rare in the liver. Tumefactive hepatic amyloidosis was first described in detail based on a patient who had 15 × 8-cm-sized amyloid mass in the right liver lobe (Tötterman and Manninen 1982). In a 73-year-old female patient with multiple myeloma, dynamic CT of the abdomen revealed three high-density lobulating masses with central calcification in the dome and segment 3 of the liver, measuring up to 3 cm in diameter. Needle biopsy of a mass lesion showed diffuse, Congo red-positive amyloid deposits without viable hepatocytes (Son et al. 2011a). Localized pulmonary nodular amyloidosis can rarely extend through the diaphragm and reach the liver (Rosen et al. 2008).

Globular Hepatic Amyloid

A very rare form of hepatic amyloid that is sometimes associated with B-cell neoplasms is globular amyloid, a lesion mostly found in male patients. Histologically, round- to oval-shaped and sometimes laminated congophilic globules of 1–40 μm in diameter are found, sometimes with a transition to linear amyloid. The globules show the typical apple-green birefringence under polarized light. Most globules are found in portal tracts and within the hepatic parenchyma (French et al. 1981; Kanel et al. 1981; Pilgaard et al. 1993; Makhlouf and Goodman 2007). In rare forms of B-cell neoplasms, globular hepatic amyloid is an indicator of systemic AL amyloidosis (Agaram et al. 2005). Globular amyloid has also been detected in other tissues, e.g., the small bowel (Hemmer et al. 2007).

Biliary Tract Amyloidosis

A distinct and unique form of amyloidosis in the liver is the localization of amyloid around extra- and/or intrahepatic bile ducts (Fig. 2). Relatively few such situations have been reported (Sasaki et al. 1990; Terada et al. 1994). In one patient with multiple myeloma and obstructive jaundice, autopsy revealed the presence of amyloid

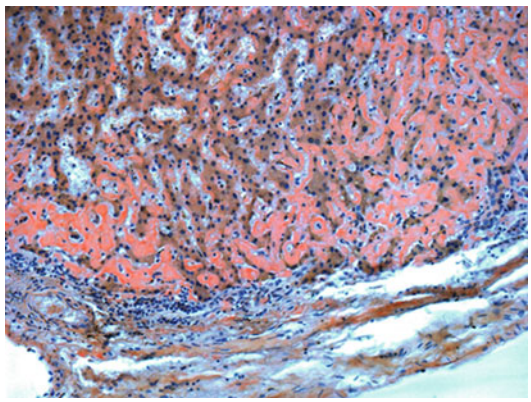

Fig. 1 Mass-forming amyloidosis (amyloidoma, amyloid tumor) of the liver in a patient with plasmacytoma. There is marked deposition of congophilic material in Disse's space, associated with atrophy of hepatocyte plates (Congo red stain)

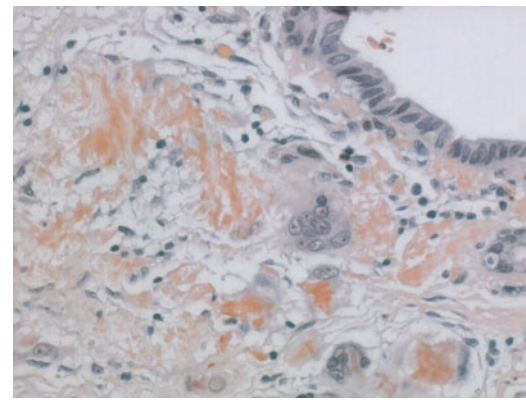

Fig. 2 Amyloidosis of the bile duct. The mucosa shows interstitial deposition of congophilic material, associated with a foreign body reaction mediated by giant cells (Congo red stain)

(ultrastructurally proven) in the walls of extra- and large intrahepatic bile ducts, associated with narrowing of the ducts involved (Terada et al. 1994). Amyloidosis was also diagnosed in the gallbladder (Remy et al. 1995; Kwon et al. 2007). In one patient, it presented as elevated nodular lesions mimicking gallbladder cancer and was histologically characterized by deposition of congophilic material in the walls of vessels within the gallbladder wall (Kwon et al. 2007).

Liver Involvement in Heavy-Chain Amyloidosis (AH)

Heavy-chain amyloidosis (AH) is a very unusual disease with few reported informations (Eulitz et al. 1990; Copeland et al. 2003; Mai et al. 2003; Gono et al. 2006). Whether amyloidosis that had been noted clinically in several patients with gamma heavy-chain disease (Frangione and Franklin 1973; Dickson et al. 1989) resulted from light – or heavy-chain deposition – has not been established (Eulitz et al. 1990). Based on the rarity of AH, only sparse data on liver involvement are available. In a first report of this disease, an enlarged, cirrhotic-appearing liver was detected at cholecystectomy, and a liver wedge biopsy revealed typically congophilic and birefringent amyloid diffusely involving the perisinusoidal spaces. At autopsy, additional amyloid deposits were found in the patient's kidney, heart, and spleen. Both serum and urine protein electrophoresis showed the presence of a whole and one fragment of IgG heavy chain, and both of these IgG heavy chains were associated with a kappa1-type light chain. In addition, urine analysis exhibited a further monoclonal gamma heavy-chain fragment that was also present in splenic amyloid showing an internally deleted IgG1 heavy chain (Eulitz et al. 1990).

Differential Diagnosis

The main histologic differential diagnosis of AL amyloidosis is AA amyloidosis. Hepatic amyloidosis is sometimes seen in hereditary amyloidosis (Harrison et al. 1996) and in the setting of amyloid-inducing hepatic tumors. AA amyloidosis has been reported to be associated with, or induced/caused by, liver cell adenoma several times (Thysell et al. 1986; Fievet et al. 1990; Melin et al. 1993; Cosme et al. 1995; Shibasaki et al. 1997). This is further discussed in the chapter of hepatocellular adenoma. An association between systemic amyloidosis and hepatocellular carcinoma has also been described (Delgado et al. 1999). The pathogenic mechanisms involved in these associations, which may not be coincidental in the case of liver cell adenoma, have not been clarified. It is, nevertheless, interesting to note that, in one reported patient, remission of nephrotic syndrome related to AA amyloidosis was achieved after hepatic adenomectomy (Melin et al. 1993). Furthermore, a patient with generalized amyloidosis and liver cell adenoma exhibited a decrease of highly elevated C-reactive serum protein and a complete normalization of the SAA level after resection of the adenoma. In this adenoma, amyloid deposition was detectable, and the tumor showed significantly elevated levels of tumor necrosis factor-alpha (TNF-alpha). It was suggested that this phenomenon, owing to the known SAA-inducing effect of TNF-alpha, might be linked to the pathogenesis of AA amyloidosis (Shibasaki et al. 1997).

Non-amyloid (Non-amyloidogenic) Immunoglobulin Chain Deposition Diseases

Introduction

Non-amyloidogenic monoclonal immunoglobulin-related diseases mainly include light-chain deposit (deposition) disease (LCDD, Randall disease), light- and heavy-chain deposition disease (LHCDD), and heavy-chain deposition disease (HCDD) (Buxbaum and Gallo 1999; Buxbaum et al. 1990). These disorders are plasma cell or, less commonly, lymphoplasmacytic neoplasias synthesizing and secreting abnormal clonal immunoglobulin light chains, heavy chains (less often), or both types of chains. These Ig chains are

deposited in the extracellular space of diverse tissues, where they cause tissue damage in the absence of amyloid formation or tumoral deposits ("aggregomas"). Immunoglobulin chain deposition diseases are rare disorders of adults, with a median age at presentation 56 years. Sixty-five percent of patients suffer from plasmacytoma/multiple myeloma.

Light-Chain Deposit Disease (Light-Chain Deposition Disease, LCDD)

Introduction

Light-chain deposit disease (LCDD; Randall et al. 1976; reviews: Buxbaum et al. 1990; Ronco et al. 2011; Jimenez-Zepeda 2012) is a rare monoclonal systemic gammopathy characterized by the presence of non-amyloidogenic monoclonal light chains in the serum and/or urine and deposition of kappa or lambda light chains in organs and tissues compromising organ function. The underlying diseases comprise plasmacytoma/myeloma; macroglobulinemia (lymphoplasmacytic lymphoma); several types of NHLs, including B-CLL; and monoclonal gammopathy of undetermined significance/MGUS (Okura et al. 2009). Only 5 % of patients with multiple myeloma will develop LLDD (Buxbaum et al. 1990). In patients without evident lymphoplasmacytic disorder (up to 40 % for periods of 2–17 years; Pozzi et al. 1995), LCDD is a frequent cause of diagnostic difficulty (Hall and Peat 2001).

Although light-chain amyloidosis (AL) is also a monoclonal immunoglobulin deposition disease, LCDD and AL differ in several ways, in that the *fibrillar* deposits in AL are congophilic, representing amyloid, and are more frequently derived from lambda than kappa light chains, whereas the *granular* deposits in LCDD are non-congophilic, are more frequently kappa than lambda, and exhibit a striking preference to be deposited along basement membranes in many organs (Randall et al. 1976; Ganeval et al. 1982). Light-chain deposition in LCDD is frequently present in the heart, kidneys, gastrointestinal tract, and liver. Renal manifestations include proteinuria, nephrotic syndrome, and progressive renal failure. End-stage kidney disease requiring dialysis is found in about 70 % of the patients with LCDD. The mean survival time is 34 months, i.e., significantly longer than in AL amyloidosis. But heart involvement can reduce survival to only 6 months, severe cardiac involvement thus being the most important prognostic factor. The deposits consist of an amorphous to granular, slightly eosinophilic material that is PAS positive and diastase resistant, but is typically negative for amyloid stains, including Congo red and thioflavin-T, and immunohistochemically stain for kappa or lambda light chains, but not for IgA, IgG, IgM, IgD, AA, or AL proteins, or amyloid P component (Michopoulos et al. 2002), and the deposits to not colocalize with apolipoprotein E. In contrast to light-chain amyloidosis (AL), where the deposits are ultrastructurally fibrillar, the deposits in LCDD exhibit a dense granular material usually located close to epithelial cells and/or the basal lamina of vascular walls (Hoffman-Guilaine et al. 1984). There is limited knowledge of the primary structure of light chains in LCDD, important for the deposition mechanisms, but amino acid substitutions caused by somatic mutations of the L12a gene have been detected, likely to cause increased hydrophobility with the potential for protein destabilization and disordered conformation (Vidal et al. 1999; including a review of the literature).

Liver Involvement in Light-Chain Deposit Disease

The liver is the most frequent extrarenal localization of LCDD, but has received less attention than the kidneys. The main manifestations of LCDD in the liver comprise hepatomegaly, abnormalities of liver function, portal hypertension, ascites, intrahepatic cholestatic jaundice, and eventually hepatic failure. Exceptionally, hepatic LCDD is associated with hepatic amyloidosis (Smith and Malcolm 1986; Casiraghi et al. 2000). LCDD can cause massive hepatomegaly, similar to amyloidosis (Pelletier et al. 1988; Nath et al. 2010). Mild or moderate abnormalities of liver function tests

are reported in approximately 20 % of patients; they most often accompany overt renal disease (Droz et al. 1984; Le Verger et al. 1985; Bedossa et al. 1988). Significant liver involvement is known to reduce the mean survival (Klinkenberg et al. 1991; Pozzi and Locatelli 2002). In a study of seven patients with liver involvement in LCDD, clinical renal involvement antedated liver light-chain deposits in all patients (Droz et al. 1984). LCDD of the liver sometimes results in cholestatic jaundice (Kumar et al. 2012), liver rupture (Croitoru et al. 2006), or liver failure (Faa et al. 1991; Casiraghi et al. 2000; Michopoulos et al. 2002; Mena-Duran et al. 2012), the latter probably due to marked impairment of hepatocyte function caused by obstruction of Disse's space by the protein deposits.

Selected References Mignon et al. 1980; Preud'homme et al. 1980; Case Records of the Massachusetts General Hospital 1981; Ganeval et al. 1981; Linder et al. 1983; Le Verger et al. 1985; Kirkpatrick et al. 1986; Bedossa et al. 1988; Pelletier et al. 1988; Toyoda et al. 1988; Faa et al. 1991; Girelli et al. 1998; Michopoulos et al. 2002; Croitoru et al. 2006; Samanez et al. 2006; Nath et al. 2010; Kwon et al. 2011; Kumar et al. 2012; Mena-Duran et al. 2012.

Macroscopic liver examination was obtained in two patients, with liver weights of 2,000 and 2,100 g, respectively, without other gross alterations. But hepatic light-chain deposition is also known to occur in LCDD without renal involvement (Michopoulos et al. 2002). Rarely, hepatic amyloidosis is associated with light-chain deposition disease (Smith and Malcolm 1986; Kirkpatrick et al. 1986; Pelletier et al. 1988; Faa et al. 1991; Girelli et al. 1998; Casiraghi et al. 2000), suggesting that LCDD and amyloidosis could be two expressions of the same disease. In a patient with multiple myeloma, the liver substance was involved by light-chain depositions, whereas amyloid was found in the wall of portal vein branches (Kirkpatrick et al. 1986).

Histologically, light-chain deposits are observed as a granular or compact, ribbonlike eosinophilic, variably PAS-positive, non-congophilic, and not birefringent material in the interstitial tissues spaces and in the space of Disse. This material is chromophilic on trichrome preparations and faintly red after picrosirius, but does not stain with Congo red, and is not metachromatic after crystal violet staining (Droz et al. 1984). The deposits are immunoreactive for light chains (kappa or lambda; Mignon et al. 1980; Droz et al. 1984; Le Verger et al. 1985; Faa et al. 1991; Girelli et al. 1998), and both portal tracts and the perisinusoidal space of Disse can be occupied (Droz et al. 1984; Michopoulos et al. 2002). It has been demonstrated that 15–20 % of LCDD have lambda light-chain deposits and a combination of light- and heavy-chain deposition is seen in less than 10 % of cases (Buxbaum et al. 1990). In the enlarged portal tracts, an increase of reticulin fibers and of collagen can be noted, together with light-chain deposition, and portal tract blood vessel walls may contain the deposits as well (Droz et al. 1984). Furthermore, the basement membranes of small bile ducts may be thickened owing to light-chain deposition (Droz et al. 1984). In the case of marked light-chain deposition, adjacent liver cell plates become atrophic. Electron microscopically, the light-chain deposits in the perisinusoidal space are visualized in the form of large and irregular mottles of granule dense material, spatially associated with a discontinuous or continuous basement membrane. Occasionally, the basement membrane material forms a double layer enclosing mottles of granular light-chain material. The adjacent hepatocytes reveal a lack of microvilli (Le Verger et al. 1985). In one study it has been demonstrated by an extraction procedure that the histologically visualized deposits in fact correspond to a deposition of kappa light chain, with a molecular weight of approximately 14–17 kDa (Toyoda et al. 1988). In lymph nodes and the lung, light-chain deposition may occur in the form of tumoral masses, termed "aggregomas" (Kijner and Yousem 1988; Stokes et al. 1997; Piard et al. 1998; Rostagno et al. 2002). So far, lesions of this type have not yet been described to occur in the liver.

Light-chain deposition along the sinusoidal profiles can also result in sinusoidal damage and the formation of peliosis or peliosis-like lesions

(Mignon et al. 1980; Droz et al. 1984; Le Verger et al. 1985). Moreover, perisinusoidal fibrosis (collagenization of Disse's space), and sometimes extensive liver fibrosis can develop (Droz et al. 1984; Bedossa et al. 1988), with an increase of immunoreactive collagens type I, III, and IV, laminin, and fibronectin in the space of Disse (Le Verger et al. 1985; Bedossa et al. 1988; Faa et al. 1991). Double immunostaining showed the co-deposition of large and thick deposits of light chain with thin and linear deposits of type IV collagen in the perisinusoidal space (Le Verger et al. 1985). Apart from the parenchymatous form of hepatic LCDD, a rare variant is characterized by light-chain deposits restricted to the hepatic artery tree, clinically associated with ischemic cholangitis due to stenosis of arteries feeding the bile ducts (Weisel et al. 2009).

Heavy-Chain Disease

Heavy chains or their fragments can be amyloidogenic, and the resulting amyloidosis shares the same morphologic features with other types of amyloidosis (Mai et al. 2003). In rare instances, monoclonal Ig heavy chains are deposited in tissues in the absence of formation of amyloidogenic beta-pleated sheets (heavy-chain deposition disease, HCDD; Katz et al. 1994; review: Kambham et al. 1999). HCDDs are caused by B-cell neoplasms that produce truncated monoclonal immunoglobulin heavy chains. In accordance with the diverse Ig heavy chain types, four types of HCDD are recognized, viz., alpha heavy-chain disease b (Seligmann's disease; mostly a digestive tract disorder), gamma heavy-chain disease (Franklin disease), mu heavy-chain disease, and delta heavy-chain disease. Gamma-type HCDD is chiefly characterized by lymphadenopathy, fever, anemia, hepatosplenomegaly, and renal glomerular and peritubular depositions of heavy chains without associated light chains (Oe et al. 2010). The gamma3 heavy chain seems to prevail (immunoglobulin gamma3 heavy-chain deposition disease; Kambham et al. 1999; Soma et al. 2004; Masai et al. 2009). Liver gamma heavy-chain deposits have not yet been reported.

B-Cell Non-Hodgkin's Lymphomas Associated with Viral Infections

94

Contents

Abstract

A complex spectrum of lymphoproliferative disorders is associated with, or caused by, distinct viral infections. These infections include Epstein-Barr virus (EBV), human herpesvirus 8 (Kaposi's sarcoma-associated herpesvirus), human T-cell lymphotropic virus 1 (HTLV-1), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) infections. EBV is long known to have associations with special forms of B-cell neoplasms, endemic Burkitt lymphoma being the most prominent example. But EBV infection is also involved in the pathogenesis of classical Hodgkin's lymphoma and plays a central role in posttransplant lymphoproliferative disorders. HHV-8 infection is, apart from Kaposi's sarcoma, associated with a broad array of rare lymphomas which in part develop in the setting of immunodeficiencies. HTLV-1 is involved in adult T-cell leukemia/lymphoma. HCV infection is a major worldwide cause of chronic liver disease, but is also associated with numerous extrahepatic manifestations, including B-cell neoplasms, suggested to be caused by chronic antigenic stimulation of the immune system. Lymphomas arising in patients with HIV infection are mostly related to the immunosuppression and concomitant infections known to promote lymphomagenesis, in particular EBV and HHV-8.

DOI 10.1007/978-3-319-26956-6_94

Introduction

Several types of lymphoproliferative disorders are associated with, or caused by, distinct types of viral infections. Viruses involved include Epstein-Barr virus (EBV), human herpesvirus 8 (HHV-8; Kaposi's sarcoma-associated herpesvirus), human T-cell lymphotropic virus 1 (HTLV-1), hepatitis C virus (HCV), and human immunodeficiency virus (HIV). These viruses are directly involved in the pathogenesis of lymphoproliferative disease or lymphomas, or cause conditions that favor the development of such disorders, mainly via generation of immunosuppression (Table 1).

Epstein-Barr Virus (EBV) Infections

As listed in Table 1, Epstein-Barr virus (EBV) infection is associated with a distinct group of lymphoproliferative diseases. The classification of these disorders was recently reviewed (Carbone et al. 2008). Part of these disorders can involve the hepatobiliary tract, either as a primary manifestation or as a secondary involvement in the setting of generalized disease. Apart from a direct action on lymphoid target cells, EBV is also capable to modulate cells of tumor microenvironments (Dolcetti 2015). It does so by hijacking the exosome pathway to excrete viral and cellular components, including Fas ligand to induce apoptosis in recipient cells (Ahmed et al. 2015).

Table 1 Viral infections associated with lymphoproliferative disorders

Virus	Lymphoproliferative disorder
Epstein-Barr virus (EBV)	Endemic Burkitt lymphoma
	EBV-positive large B-cell lymphoma (immunoblastic)
	EBV-associated primary CNS lymphoma
	EBV-associated polymorphic B-cell lymphoma with leukemia and congenital immunodeficiencies
	Lymphomatoid granulomatosis
	Senile EBV-associated B-cell lymphoproliferative disorder
	Classical Hodgkin's lymphoma
	Posttransplant lymphoproliferative disorder/PTLD
Human herpesvirus 8 (KSHV)	Primary effusion lymphoma (PEL)
	Multicentric Castleman disease (MCD)
	MCD-associated large B-cell lymphoma
	MCD-associated plasmablastic lymphoma
	MCD-associated PEL
	KSHV-associated solid lymphomas
	KSHV-associated plasmablastic lymphoma
	KSHV- and EBV-associated germinotropic lymphoproliferative disorder
	KSHV-associated anaplastic large cell lymphoma-like lymphoma
	KSHV- and EBV-associated anorectal lymphoma
	KSHV-related posttransplantation plasmacytic proliferation
EBV-HHV-8 co-positive lymphoproliferations	Various B-cell lymphomas
HTLV-1	Adult T-cell leukemia/lymphoma
Hepatitis C virus	Various B-cell non-Hodgkin's lymphomas
HIV	HIV-associated B-cell lymphoid malignancies
	EBV- and HHV-8-associated lymphomas in HIV infection

Abbreviations: *KSHV* Kaposi's sarcoma-associated herpesvirus, *HTLV-1* human T-cell lymphotropic virus 1, *HIV* human immunodeficiency virus

Endemic Burkitt Lymphoma

As specified in the respective chapter, endemic Burkitt lymphoma is primarily diagnosed in children in equatorial regions and is strongly associated with EBV infection and MYC gene translocations (review: Brady et al. 2007). A part of the patients also show molecular evidence for the participation of other infectious agents, in particular human herpesvirus 5 and HHV-8 (review: Abate et al. 2015).

B-Cell Lymphomas Other Than Burkitt Lymphoma

EBV infection is rarely associated with other B-cell lymphomas, including EBV-positive large B-cell lymphoma in young patients (Nicolae et al. 2015). Other B-cell neoplasms associated with EBV are primary central nervous system lymphomas and polymorphous lymphomas associated with leukemia and congenital immunodeficiencies.

EBV-Positive T-Cell Lymphoproliferative Diseases of Childhood

ICD-O codes (provisional) 9724/3 and 9725/3

In the 2008 WHO tumor classification, T-cell lymphoproliferative disorders of childhood that are associated with EBV are known as two distinct variants, both mainly occurring in Asians and in natives from Central and South America. The first form is Hydroa vacciniforme-like lymphoma, a cutaneous T-cell neoplasm with an indolent course over longer time periods. The second form is systemic EBV-positive T-cell lymphoproliferative disease (STLPD) of childhood, with a fulminant course (review: Hong et al. 2013). The latter is discussed here in some more detail, due to its prominent hepatic manifestations.

Hydroa vacciniforme-like lymphoma (ICD-O 9725/3) develops in children and adolescents in Asia and Central/South America and is related to sensitivity to insect (mosquito) bites and sunlight sensitivity. A defective immune response directed against EBV plays a pathogenetic role. Patients present with a papulovesicular eruption that proceeds to ulceration and scarring. Late in disease, systemic signs may develop, including hepatosplenomegaly and lymphadenopathy. The tumor cells are cytotoxic T-cells that reveal T-cell receptor rearrangement (Yachie et al. 2003; Wada et al. 2012).

Systemic EBV-positive T-cell lymphoproliferative disease of childhood (STLPD; ICD-O code 9724/3; synonyms: sporadic fatal infectious mononucleosis; severe chronic active EBV infection/CAEBV; Kimura 2006) is a severe and life-threatening systemic disease of children and young adults, predominantly males, characterized by an aggressive neoplastic proliferation of cytotoxic T-cells and EBV infection of B-cells. Most patients are from Japan and Taiwan, but few patients are from Western countries. Exceptionally, adult patients are affected (Abdul-Ghafar et al. 2011). Clinically, the patients show a rapidly progressive illness with multiorgan involvement and failure, often with sepsis, death occurring within days to weeks. One particularly aggressive variant reveals high fever, pancytopenia, marked lymphadenopathy, and hepatosplenomegaly. In contrast to the standard variant, EBV in this dangerous variant infects T-cells and NK cells, T-cells stimulated to become a monoclonal population and then a frankly malignant neoplastic cell population (Craig et al. 1992; Dolezal et al. 1995; Ohshima et al. 2008; Ohga et al. 2011; Rodriguez-Pinilla et al. 2011; Wang et al. 2012).

Infiltrating cells are small T-cells without relevant atypia. Few patients show larger and pleomorphic cell forms. The characteristic immunophenotype is a positive reaction for CD2, CD3, and, in forms secondary to acute primary EBV infection, CD8, whereas T-cells in patients with severe CAEBV are CD4 positive. The cells show T-cell receptor rearrangement. All cells contain EBV in a clonal episomal form.

Liver Involvement

In EBV-positive STLPD of childhood, the liver is the most commonly involved inner organ (review:

Yoshii et al. 2012). Prominent hepatomegaly, liver dysfunction, and eventually liver failure are typical features (Chan et al. 1992; Quintanilla-Martinez et al. 2000; Hauptmann et al. 2001; Liu et al. 2008; Salama et al. 2008; Rodriguez-Pinilla et al. 2011; Sevilla et al. 2011), followed by the spleen, lymph nodes, bone marrow, skin, and lung. Liver biopsies show CD3+ CD8+ lymphoid T-cells in sinusoids, sometimes in high numbers (Abdul-Ghafar et al. 2011). These sinusoidal lymphocytes are almost invariably EBER positive. Marked hemophagocytosis may be observed (Quintaneilla-Martinez et al. 2000).

Human T-Cell Lymphotropic Virus 1 (HTLV-1)

HTLV-1 is a central etiologic agent for adult T-cell leukemia/lymphoma (ATLL), as further discussed in the chapter on T-cell Non-Hodgkin's lymphomas, but does not suffice for neoplastic transformation of target T-cells to take place. HTLV-1 is a retrovirus of the *Retroviridae* family. In humans, HTLV-1 can infect several cell types, including T-lymphocytes, B-lymphocytes, dendritic cells, and fibroblasts. Persons with ATLL are exposed to HTLV-1 early in life, and the development of the lymphoproliferative process requires a long time period (reviews: Bangham and Ratner 2015; Utsch Gonçalves et al. 2010). Apart from its direct effects on gene expression in target cells, the virus affects epigenetic mechanisms, whereby its Tax and HBZ oncoproteins can both activate and silence cellular promoters by interaction with enzymes involved in histone modifications (Minarovits et al. 2016).

Lymphomas Associated with Kaposi's Sarcoma-Associated Herpesvirus (KHV)/Human Herpesvirus 8

Introduction

The Kaposi's sarcoma-associated herpesvirus (KSHV; human herpesvirus 8, HHV-8), detected in 1994 (Chang et al. 1994), belongs to the gamma human herpesvirus group, containing members of oncogenic viruses, specifically EBV and KSHV in man (Roizmann et al. 1992; Damania 2004). Gamma-herpesviruses, which have been identified in many animal species, are lymphotropic and can establish a lifelong period of latency in their host, with intermediate periods of lytic replication. The genome of KSHV is complex; apart from open reading frames (ROF) encoding enzymes and viral structural proteins, it contains several ORF that have been pirated during viral evolution from cellular genes. The gene products affect a host of cellular functions, including growth (Bcl-2 and cyclin homologs), signaling pathways, immune regulation (cytokine homologs), and angiogenesis (Boshoff and Weiss 1998; Sarid et al. 2002; Damania 2004; Schulz and Cesarman 2015). KSHV is found invariably in Kaposi's sarcoma (KS; Chang et al. 1994; Huang et al. 1995), and compelling evidence suggests that it is an etiologic agent of KS (Boshoff and Weiss 1998). This aspect is addressed in a separate chapter.

KSHV is lymphotropic (Mesri et al. 1996), and several lymphoproliferative disorders are known to be associated with KSHV infection (Ascoli et al. 1999, 2001; Matsushima et al. 1999; Du et al. 2001, 2002; Schulz 2001; Hengge et al. 2002; Navarro et al. 2003; Huang et al. 2004; Chadburn et al. 2004; Colomo et al. 2004; Cioc et al. 2004; Carbone et al. 2004; Carbone and Gloghini 2008; Bhutani et al. 2015; Elyamany et al. 2015; Huang and Low 2015). They are listed in Table 1. KSHV also induces a distinct pattern of inflammations, termed the KSHV inflammatory cytokine syndrome/KICS (Polizzotto et al. 2016).

KSHV (HHV-8) is common in sub-Saharan Africa and around the Mediterranean Sea, but is rare in most other countries. It is known to be transmitted in childhood within families in endemic regions and through sexual contacts among high-risk groups in Western countries. However, evidence is growing that transmission also occurs through heterosexual contact or injection drug use (Henke-Gendo and Schulz 2004). In contrast to PEL that is listed in the WHO classification, solid lymphomas developing in

association with KSHV infection have not yet been well characterized and classified. KSHV-associated solid lymphomas have been found to occur following resolution of PEL (Huang et al. 2002).

KSHV-Associated Lymphoma of the Liver

Few reports have described KSHV-associated lymphoproliferative disorders that were apparently primary to the liver. An AIDS patient showed BCL-6-positive B-cell lymphoma associated with KSHV, exclusively localized to the liver and spleen. The tumor cells were medium sized to large and were reactive for CD20, CD45, and BCL-6, but negative for CD30 and EMA, suggesting a neoplasm of germinal center cell origin (Hasegawa et al. 2004). Ferry and coworkers (2009) reported on a 59-year-old HIV-positive man who died after several weeks of fever, anemia, thrombocytopenia, hepatosplenomegaly, and multiorgan failure. Autopsy showed intravascular large B-cell lymphoma that had also involved the liver. The tumor cells were KSHV positive.

B-Cell Non-Hodgkin's Lymphomas Associated with Hepatitis C Virus Infection

Chronic infection with the hepatitis C virus (HCV) is not only responsible for a frequent liver disease worldwide, but is also associated with growing spectrum of extrahepatic manifestations (EHMs) involving the skin, kidneys, salivary glands, eyes, central nervous system, thyroid, and the immune system. Clinically, the most prominent EHMs of HCV infection include mixed cryoglobulinemia, cryoglobulinemic vasculitis, nephropathies, thyreopathies, cardiovascular diseases, type 2 diabetes mellitus, and neurocognitive and neuropsychiatric disorders. The term "HCV syndrome" has been coined to include both hepatic and extrahepatic manifestations of HCV infection (reviews: Ferri et al. 2007, 2015; Zignego et al. 2007; Monaco et al. 2015; Vigano and Colombo 2015). Furthermore, an increasing number of investigations have associated infection with HCV with the emergence of autoimmune disorders and NHL, mainly B-cell lymphomas.

Selected references: Ferri et al. 1994; De Rosa et al. 1997; Zuckerman et al. 1997; Luppi et al. 1998; Silvestri et al. 1998; Ohsawa et al. 1999; Kim et al. 2000; Mizorogi et al. 2000; Chindamo et al. 2002; Gasparotto et al. 2002; Fiorilli et al. 2003; Mele et al. 2003; Paydas et al. 2003; Tomita et al. 2003; Weng and Levy 2003; de Sanjose et al. 2004; Gisbert et al. 2004; Kitabayashi et al. 2004; Morton et al. 2004; Negri et al. 2004; Talamini et al. 2004; Viswanatha and Dogan 2007; Ito et al. 2011; Pellicelli et al. 2011; Tsutsumi et al. 2011; Arcaini et al. 2012; De Re et al. 2012; Hartridge-Lambert et al. 2012; Kikuma et al. 2012; Kedia et al. 2014; Carrier et al. 2015; Fiorino et al. 2015; Tasleem and Sood 2015.

In a study of 529 consecutive patients newly diagnosed with a lymphoid malignancy in Spain, a prevalence of 5.9 % HCV infection was found versus 3.8 % among controls, after exclusion of HIV-infected subjects and organ recipients (de Sanjose et al. 2004). Overall, the reported prevalence of HCV infection in patients with B-cell NHL is between 9 % and 32 %. In the DANVIR cohort study covering 11,975 HCV-infected patients, these patients had a 29.97-fold increased risk of NHL during the first year of follow-up and a 1.26-fold increased risk after the first year (Omland et al. 2012). In a recent population-based cohort study, chronic HCV infection was temporally associated with a twofold increased risk of lymphoid neoplasms, especially NHL in Asian patients (Su et al. 2015). But there are also reports not confirming such an association (King et al. 1998; Collier et al. 1999; Pioltelli et al. 2000; Hausfater et al. 2001; Aviles et al. 2003; Abe et al. 2015). It was suggested that these controversial data may reflect regional differences in the prevalence of HCV infection

(McColl et al. 1997). There is evidence that B-cell NHLs related to HCV infection exhibit certain types more frequently than others. For example, a study on 157 patients with de novo B-NHL showed that those with HCV infection had more frequently follicular, marginal zone, and diffuse large B-cell NHL (Luppi et al. 1998). On the other hand, there is evidence that the spectrum of B-cell NHL types is different in HCV-infected individuals in comparison with a noninfected population. In one investigation, B-cell NHLs in HCV-infected patients frequently presented at onset an extranodal localization with peculiar target organs of HCV infection (i.e., the liver and major salivary glands) being overrepresented, a diffuse large B-cell phenotype without prior history of low-grade B-cell NHL, and a weak association with a full-blown predisposing autoimmune disease (De Vita et al. 1997). Chronic HCV infection also seems to favor the evolution of plasma cell tumors/myelomas (Montella et al. 2000; Gharagozloo et al. 2001; Tashiro et al. 2003). In addition, HCV seems to be related to a subset of NHL primarily originating from the liver (Bronowicki et al. 2003), an issue discussed in more detail below.

What are the potential mechanisms involved in HCV-associated lymphomagenesis, provided that an association is accepted? So far, the molecular basis for HCV-induced lymphomagenesis is still unknown, but several findings may shed light on putative pathogenic pathways. One line of thinking is that the presence of HCV and/or the HCV genome (or parts of it) in target cells may be involved in lymphomagenic pathways. B-lymphocytes seem to have an important role in viral propagation of HCV (Muller et al. 1994). It was shown that HCV infects B-cells in vivo and in vitro, and cell lines can be derived from B-cell NHL that are persistently infected with HCV and display enhanced apoptosis (Sung et al. 2003). Few investigations suggest that the HCV genotype plays a role for the development of NHL, e.g., genotype 2ac might be more involved in the pathogenesis of lymphoproliferative disorders than others (Silvestri et al. 1997). In one study, the presence of components of the HCV genome has been detected in lymphoma cells of primary hepatic lymphoma (Ohsawa et al. 1998). Both positive-strand and negative-strand HCV RNA was detected in B-cell lymphomas, indicating viral replication (Karavattathayyil et al. 2000; Paydas et al. 2004). On the other hand, there is persistence of HCV in peripheral blood mononuclear cells in mixed cryoglobulinemia, a disorder thought to evolve into NHL in at least part of the cases (Zignego et al. 1997). The potential causal relationship between HCV and NHL is supported by observations from animal experimentation. Transgenic mice expressing the HCV core transgene develop malignant lymphoma of the follicular center cell type, and the livers of these animals express HCV core protein and mRNA (Ishikawa et al. 2003). Epigenetic mechanisms involving distinct patterns of microRNA expression in HCV-related malignancies have been discussed (review: Gragnani et al. 2015; Grewal et al. 2015).

A second pathogenic pathway that may play a significant role is HCV-mediated chronic immune stimulation promoting lymphomagenesis, a mechanism also discussed for NHLs arising in the setting of Helicobacter pylori infection (review: Suarez and Lecuit 2015).

Human Immunodeficiency Virus (HIV)

HIV infection is associated with an increased risk of B-cell lymphoid malignancies. Lymphomas occurring in patients with HIV infection are often EBV- or HHV-8-associated lesions (Mylona et al. 2008; Krishnan and Zaia 2014; Arvey et al. 2015; Carroll and Garzino-Demo 2015; Pinzone et al. 2015; Silverberg et al. 2015) or develop from EBV-HHV-8 co-positive cell systems. HIV-associated proteins, in particular tat and vpu, affect cell cooperation between lymphoid cells and cells of the microenvironment, including endothelial cells (De Paoli and Carbone 2015). On the other hand, microenvironments favoring the development of lymphomas exhibit EBV and/or HHV-8 coinfection (Pantanowitz et al. 2015).

T-Cell Non-Hodgkin's Lymphomas 95

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_95

Abstract

Several types of T-cell non-Hodgkin's lymphomas are characterized by liver involvement, usually in the context of generalized lymphoma disease. The aggressive neoplasm, T-cell prolymphocytic leukemia, showing a proliferation of small- to medium-sized T cells, results in massive bone marrow infiltration and marrow failure but also infiltrates the lymph nodes, liver, and spleen. Hepatic infiltrates mostly involve portal tracts, causing hepatomegaly. Hepatic involvement is a common feature of T-cell large granular lymphocytic leukemia. Liver infiltration is also known for aggressive NK cell leukemia, a systemic proliferation of NK cells almost always associated with EBV infection. The liver may be densely infiltrated by large granular lymphocytes with azurophilic granules. The generalized neoplastic T-lymphocyte process, adult T-cell leukemia/lymphoma, is frequently complicated by focal t diffuse parenchymal or portal tract infiltration of the liver. Other T-cell neoplasms variably involving the liver comprise nasal-type extranodal NK/T-cell lymphoma, hepatosplenic T-cell lymphoma, mycosis fungoides, Sézary syndrome, and peripheral T-cell lymphomas.

T-Cell Prolymphocytic Leukemia

ICD-O Code 9834/3

Introduction

T-cell prolymphocytic leukemia (T-PLL) is an aggressive T-cell leukemia composed of small to medium-sized prolymphocytes having a mature post-thymic T-cell phenotype. The T-PLL cell population is mainly located in the bone marrow and peripheral blood, but other frequent sites are the lymph nodes, liver, and spleen. T-PLL is a rare lymphoproliferative disorder (about 2 %) that involves persons older than 30, with a median age of 65 years at diagnosis. It was first described in 1973 (Catovsky et al 1973). Clinically, most patients present with signs of bone marrow failure (anemia, thrombocytopenia), lymphadenopathy, and splenomegaly, and 20 % of patients have skin involvement. T-PLL rapidly progresses and is clearly more aggressive than B-PLL (Dearden 2009; Lim et al. 2009; Delgado et al. 2012; Tirado et al. 2012).

The tumor cells is a small- to medium-sized lymphoid round cell with a nongranular basophilic cytoplasm and round to ovoid (sometimes irregular) nuclei (Matutes et al. 1986). In 25 % of cases, the small lymphoid cells with nuclei without detectable nucleoli prevail (small cell variant of T-PLL). A small minority of cases (around 5 %) have highly irregular and even cerebriform nuclei. Cytoplasmic protrusions or blebs are characteristic alterations. The cells stain strongly for alpha-naphthyl acetate esterase and acid phosphatase with a dot-like reaction product in the region of the Golgi apparatus. Immunocytochemically, tumor cells express markers of mature peripheral T cells (CD2, CD3, CD7, CD52). In 60 % of patients, the cells are $CD4^+$, and 25 % of patients have $CD4^+/CD8^+$ cells. The oncogene TCL1 is overexpressed.

Liver Involvement

As in other leukemic forms of T-cell neoplasms, the liver can be infiltrated in patients with T-PLL, causing hepatomegaly (Valbuena et al. 2005). The pattern of infiltration in liver biopsies was mostly portal/periportal, with portal tract expansion and sometimes disruption of the limiting plate, while sinusoidal accumulations of leukemic cells were less prominent. In portal tracts, small portal venous branches may be distended with T-PLL cells, and interlobular bile ducts were buried in the dense leukemic infiltrate (Valbuena et al. 2005). In case of massive liver involvement and associated hepatocyte injury, acute hepatic failure can develop (McElreath et al. 2006).

Differential Diagnosis

The main histopathological differential diagnoses comprise hepatic infiltrates of other lymphomas

and leukemias with small- to intermediate-sized cells, such as B-CLL, and reactive lymphocytic lesions (pseudolymphomas; chronic active hepatitis).

Cytogenetic and Molecular Features

The cells of T-PLL belong to a mature post-thymic T-cell phenotype. T-cell receptor genes are clonally rearranged. The most common karyotypic abnormality is inversion of chromosome 14 with breakpoints in the long arm of q11 and q32. A minority of patients (10 %) show a reciprocal tandem translocation t(14;14)(q11;q32), juxtaposing the TRA locus with the oncogenes TCL1A and TCL1B at 14q32.1, associated with activation. TCL is an oncogene that can induce T-cell leukemia in murine models. A part of patients show mutations in ATM (ataxia telangiectasia mutated) on 11q23. In fact, T-PLL is a leukemia that occurs in ataxia telangiectasia. Patients with TCL1A-TCRAD juxtaposition have recurrent loss of the SMARCB1 tumor suppressor gene (Bug et al. 2009). Primary T-PLL exhibits recurrent JAK1 and JAK2 somatic mutations (Bellanger et al. 2014) and showed constitutive activation of the IL2RG-JAK1-JAK3-STAT5B axis promoting deregulation of DNA repair (Kiel et al. 2014).

T-Cell Large Granular Lymphocytic Leukemia

ICD-O Code 9831/3

Introduction

According to the 2008 WHO classification, T-cell large granular lymphocytic leukemia (T-LGL) represents a heterogeneous disorder that reveals persistent (>6 months) increase in the number of peripheral blood large granular lymphocytes (Brouet et al. 1975; McKenna et al. 1977). T-LGL accounts for 2–3 % of mature lymphocytic leukemias. There is no defined age peak, and genders are equally affected, but the disorder is rare before the age of 25 years. T-LGL mainly involves the bone marrow, peripheral blood, liver, and spleen. Conversely, lymph nodes are rarely affected. Most patients with T-LGL display an indolent clinical course, but sequelae may emerge due to the common signs of bone marrow failure, with severe neutropenia with or without anemia, while thrombocytopenia is uncommon. Neutropenia can cause severe infections. Splenomegaly is a frequent physical finding. A part of the patients develop autoimmune disorders such as rheumatoid arthritis (Sheridan et al. 1988; Nichols et al. 1994; Noguchi et al. 1997; Lamy and Loughran 2003; Osuji et al. 2005; Shah et al. 2009; Dearden 2011; Liu and Loughran 2011; Watters et al. 2011; Zhang and Loughran 2012).

Morphology

Normal natural killer cells (NK) are larger granular lymphocytes of the innate immune system and are widely distributed in lymphoid and nonlymphoid organs. Their precursors originate from the bone marrow and go through a complex differentiation process. From bone marrow and lymph nodes, they traffic to the blood, spleen, liver, lung, and other organs (Grégoire et al. 2007). The typical neoplastic cell in T-LGL is a cell with moderate to abundant cytoplasm which shows fine or coarse azurophilic cytoplasmic granules containing perforin and granzyme B. Ultrastructurally, these granules show parallel tubular arrays. Immunocytochemically, the cells are reactive for mature T-cell markers (CD3, CD8; seldom CD4). Over 80 % of cases express CD57 and CD16, and at least 50 % express members of the KIR family. Abnormally diminished or lost expression of CD5 and/or CD7 is common in T-LGL.

Liver Involvement

Involvement of the liver is a common feature of T-LGL and is characterized by infiltration with small- to intermediate-sized granular lymphocytes, which can expand portal tracts but mainly

accumulate in the sinusoidal lumina (Aisenberg et al 1981; Hooks et al. 1981; Kruskall et al. 1982; Pross et al 1982; Thien et al. 1982; Semenzato et al. 1984; Wallis et al. 1985; Vahancik et al. 1988; Agnarsson et al. 1989; Mizuki et al. 1996; Lamy and Loughran 2003). The combination of granular T-cell leukemia/lymphoma and hepatic sinusoidal infiltration was so typical that it was even classified as a "syndrome" (Kruskall et al. 1982). In a study of six liver biopsies (Agnarsson et al. 1989), all samples showed essentially similar features. A prominent intrasinusoidal accumulation of mononuclear cells with scant cytoplasm was identified. In case of dense infiltration, also the portal tracts were involved. The hepatocytes were not altered and not show signs of injury.

Molecular Features

T-LGL shows clonal rearrangement of the alpha/beta T-cell receptor, while gamma/delta T-cell receptor rearrangement is rare. There are no specific karyotypic abnormalities, but several activating pathways for the neoplastic cells have been identified, including pathways utilizing PDGF and IL-15 signaling (Leblanc et al. 2012). STAT3 mutations are highly specific for large granular lymphocytic leukemia (Fasan et al. 2012; Koskela et al. 2012; Jerez et al. 2012), whereby the SH2 dimerization ad activation of STAT3 is mutated. These mutational events lead to deregulation of STAT3 target genes (IFNGR2, BCL2L1, and JAK2), thought to be important elements in the pathogenic cascade of events (Koskela et al. 2012).

Aggressive NK Cell Leukemia

ICD-O Code 9948/3

Introduction

Aggressive natural killer (NK) cell leukemia (ANKL, aggressive NK cell leukemia/lymphoma) is a systemic neoplastic proliferation of NK cells almost always associated with EBV infection and clinically characterized by an aggressive course. It has been discussed whether ANKCL is the leukemic variant of extranodal NK/T-cell lymphoma.

The neoplasm chiefly involves young to middle-aged individuals, mainly in Asia and neotropical countries. The disease invariable involves the bone marrow and the peripheral blood, and the liver and spleen are the inner organs most commonly infiltrated. In part of the patients, the leukemic cell count in blood is low, and lymphomatous manifestations may predominate. Clinically, fever, a leukemic blood picture, signs of bone marrow failure, hepatosplenomegaly, and constitutional symptoms prevail. Coagulopathy, hemophagocytic syndromes, or multiorgan failure can develop (Chan et al. 1997; Cheung et al. 2003; Tse and Liang 2004; Nava and Jaffe 2005; Oshimi 2007; Ryder et al. 2007; Liang and Graham 2008; Semenzato et al. 2012; Lima 2013; Zhang et al. 2013). Etiology and pathogenesis of ANKL are unknown, but a significant role of EBV infection is considered in part of cases (Gogia et al. 2010; Okuno et al. 2012).

Bone marrow and inner organs are densely infiltrated by cells varying in morphology from typical large granular lymphocytes with fine or coarse azurophilic granules to highly atypical elements with irregularly folded nuclei. In the Wright-Giemsa stain, the cytoplasmic granules are prominent organelles. The cytoplasm ranges from pale to lightly basophilic. In bone marrow and inner organs, the tumor cells can form monotonous, cohesive infiltrates that destroy the background tissue. Apoptotic bodies and zonal necrosis are often found. Immunocytochemically, the neoplastic elements are positive for CD2, CD3epsilon, and CD56, and often CD16, but are CD3-negative. The cytoplasm expresses perforin, granzyme B, and granulysin, the latter being detectable in serum owing to elevated levels characterizing ANKL (Sekiguchi et al. 2012). and the majority of cells express Fas ligand. EBV virus can be detected in the tumor cells by various methods, whereby EBV early region protein is usually positive.

Liver Involvement

Focal to diffuse parenchymal infiltration or portal tract infiltration by neoplastic NK cells is a common finding in ANKL, associated with hepatomegaly, liver dysfunction, and jaundice (Boysen et al. 2011; Gao et al. 2013; Zhang et al. 2013; Park 2014). The cellular infiltrates are associated with numerous mitotic figures, apoptotic bodies, and necroses (Chan et al. 1997; Dunkley et al. 1998; Mori et al. 2000; Takai and Sanada 2001; Gao et al. 2013). The infiltrating cells express the typical immunophenotype and show marked apoptosis. Mainly in dense and large infiltrates, necroses develop, often with a zonal morphology. The infiltrates may contain macrophages with signs of erythrophagocytosis (hemophagocytic syndrome). Hemophagocytosis seems to be more frequent in ANKL patients with hepatic involvement. In part of the cases, an angiocentric growth pattern is seen. Multifocal to diffuse liver involvement is often associated with hepatocyte dysfunction and jaundice, the latter being a risk factor for early death (Zhang et al. 2013). In massive liver infiltration, acute liver failure due to hepatocyte loss can develop (Dellon et al. 2006). Apart from the effects of tissue infiltration, liver dysfunction in patients with ANKL is also supposed to be caused by interaction between Fas and Fas ligand (Makishima et al. 2007).

Cytogenetic and Molecular Features

T-cell receptor genes are in germline configuration and, therefore cannot be employed for clonality assessment. A part of the cases reveal clonal del (6)(q21q25) and 11q deletion.

Adult T-Cell Leukemia/Lymphoma

ICD-O Code 9827/3

Introduction

In the 2008 WHO classification, adult T-cell leukemia/lymphoma (ATLL) is defined as a peripheral T-cell neoplasm most frequently consisting of highly pleomorphic T lymphoid cells. ATLL, first described in 1977, is in part caused by the human T-cell leukemia virus type1 (official designation in viral taxonomy: human T-lymphotropic virus 1; HTLV-1), a retrovirus (Ohshima 2007). At diagnosis, ATLL is usually widely disseminated (high stage), with extensive nodal and organ involvement and leukemic presentation (review: Tsukasaki 2012). HTLV-1 (human T-cell lymphotropic virus 1) plays an important etiologic role in ATLL (see below).

Epidemiology and Clinical Features

Epidemiologically, ATLL prevails in certain endemic regions, above all Southwestern Japan, the Caribbean Basin, and Central Africa (Gessain and Cassar 2012). A nonendemic variant is known from Europe and North America (Foucar et al. 1985). The neoplastic cells infiltrate a wide range of tissues and organs, albeit lymph nodes and skin are the most commonly affected structures. Frequent additional sites are the bone marrow, spleen, liver, gastrointestinal tract, and central nervous system. Males are slightly more often affected, the age range at diagnosis being 20 to more than 80 years, with an average of 58 years. ATLL occurs in several clinical variants, i.e., acute, lymphomatous, chronic, and smoldering ATLL (Shimoyama 1991). In the acute phase of the disease, leukemia is frequent, associated with a skin rash, lymphadenomegaly, hepatosplenomegaly, and constitutional signs of disease.

In the acute variant of ATLL, hypercalcemia with or without lytic bone lesions is a common complication. A part of the patients display T-cell immunodeficiency with typical infections and infestations, such as *Pneumocystis carinii* and *Strongyloides stercoralis*. Lymphomatous ATLL is characterized by marked lymph node disease in the absence of leukemia. Ulcerated skin lesions are typical. The chronic form of ATLL is often accompanied by an exfoliative skin rash, and leukemia is rare. Patients with smoldering ATLL have an elevated percentage of peripheral blood T lymphocytes, but the WBC count is normal.

Skin and pulmonary lesions occur, but hypercalcemia is lacking.

ATLL is characterized by a broad range of neoplastic cell morphologies, comprising pleomorphic small, medium and large cell types, anaplastic morphology, and an uncommon form resembling angioimmunoblastic T-cell lymphoma. In most cases, neoplastic cells are medium-sized to large, frequently with marked nuclear pleomorphism, coarse chromatin structure, and prominent nucleoli. In part of the cases, highly atypical giant cells with polylobulated nuclei develop. These cells may resemble Reed-Sternberg cells with "kissing nuclei" (the Hodgkin-like ATLL), mostly seen in lymph nodes. Multilobated (polylobulated) tumor may circulate as leukemic cells (so-called flower cells). Immunohistochemically, the neoplastic cells express T-cell lineage markers (CD2, CD3, CD5) and often FOXP3 and CCR4, the latter two being markers of regulatory T cells. Most cases are $CD4^+/CD8^-$, but a minority show $CD8^+/CD4^-$ or $CD4^+/CD8^+$ phenotypes. Large transformed T cells may be CD30 positive, but they consistently lack ALK expression. ATLL cells show T-cell receptor rearrangement. Neoplastic cells display integration of HTLV-1, lacking in healthy carriers.

Liver Involvement

As ATLL is a generalized neoplastic disease, the liver is often involved (Hoshi et al. 1988; Taniguchi et al. 1993; Yamada et al. 1997; Tong et al. 2004; Kawamura et al. 2006; Powell et al. 2006; Takasaki et al. 2007). In ATLL, hepatic involvement is more frequent than in other lymphomas. There was a more frequent palpable hepatomegaly, higher total bilirubin, GOT, GPT, LDH, and alkaline phosphatase values, and among 36 autopsied cases out of 111, invasion of the liver was confirmed in 22 patients (Yamada et al. 1997). Concomitant involvement of bone marrow and visceral organs, including the liver, worsens prognosis (Takasaki et al. 2007). Hepatic infiltration is usually diffuse or multifocal, but a metastatic pattern also occurs (Tong et al. 2004). ATLL with blast crisis can be associated with acute liver failure (Kawamura et al. 2006; Powell et al. 2006). In this severe clinical situation, liver biopsy revealed massive infiltration with atypical T cells characteristic of ATLL and hepatic necrosis (Powell et al. 2006). It can be surmised that, similar to other situations with massive leukemic liver infiltration, dense accumulation of tumor cells in sinusoids and portal tracts can critically compromise portal venous inflow and hepatic sinusoidal microcirculation. In case of marked humoral hypercalcemia characterizing ATLL, extensive metastatic calcification of several organs may ensue, the liver being involved in 25 % (Senba and Kawai 1991). Multiorgan failure due to calcification may develop, including massive calcifications in the liver (Kumamoto et al. 1998). ATLL-associated hypercalcemia is related to upregulation and activation of several factors involved in bone demineralization, specifically the osteoclast differentiation factor receptor activator of nuclear factor-kB ligand (RANKL), its receptor RANK, and its decoy receptor osteoprotegerin/OPG. In very rare situations, adult T-cell lymphoma with anaplastic features can develop as an apparently primary tumor in the liver, forming nodular lesions mimicking metastatic disease (Cerban et al. 2012).

Etiology and Pathogenesis

Human T-cell lymphotropic virus 1 (HTLV-1) is a central etiologic agent for ATLL (Yamagishi and Watanabe 2012), but does not suffice for neoplastic transformation of target T cell to take place. HTLV-1 is a member of the viral genus *Deltaretrovirus*, subfamily *Orthoretrovirinae*, and family *Retroviridae*. Other members of *Deltaretrovirus* comprise HTLV-2, HTLV-3, and HTLV-4; the simian counterparts STLV-1,STLV-2, and STLV-3; and bovine leukemia virus (BLV). HTLV-1 and STLV-1, the latter causing disease in Old World monkeys and great apes, seem to have originated from a common ancestor. HTLV-1 contains an enveloped virion that is spherical to pleomorphic and is about 80–100 nm in diameter. HTLV-1 has a complex genome that contains,

apart from retroviral structural genes gag, pol, and env, several regulatory genes (Tax and Rex) and accessory genes (p12, p13, p30, and HBZ). HTLV-1 naturally infects humans, but experimental infections showed that also several rodents and New World monkeys can be infected. In tissue culture, HTLV-1 can infect several cell types, including T- and B-lymphocytes, dendritic cells, and fibroblasts, but only T cells can be transformed by this virus, mainly $CD4^+$ helper cells and much less efficiently $CD8^+$ cells. HTLV-1 exists in two subgroups in endemic Japan, i.e., the transcontinental and the Japanese subgroups (Otani et al. 2012). Persons with ATLL are exposed to HTLV-1 early in life, and lymphomagenesis requires a long time period. HTLV-1 is transmitted by breast milk, sexual transmission, and through contact with infected blood and blood products. It is estimated that about 20 million persons are infected by HTLV-1 worldwide. The lymphoma yield following viral infection is relatively low, in that ATLL is estimated to develop in 2.5 % of HTLV-1 carriers in Japan. Sporadic cases of ATLL often seem to refer to patients originally stemming from an endemic area.

Extranodal NK/T-Cell Lymphoma, Nasal Type

ICD-O Code 9719/3

Introduction

Extranodal NK/T-cell lymphoma of the nasal type (ENNKT-NT) is a predominantly extranodal neoplasm composed of either classical NK cells or cells with a cytotoxic T-cell phenotype. ENNKT-NT tends to induce vascular damage associated with often extensive necroses and is associated with EBV. Previously, the lymphoma had been termed ulceronecrotic proliferative lesion of the upper airways, progressive lethal granulomatous ulceration of the nose, granuloma gangraenescens, Stewart's granuloma, necrotizing granulomatous process of the midface, polymorphic reticulosis, non-healing midline granuloma, idiopathic midline destructive disease, malignant midline reticulosis, malignant medio-facial pseudogranuloma, lethal midline granuloma, centrofacial malignant granuloma, centrofacial reticulosarcoma with necrotic gangrenous evolution, and angiocentric immunoproliferative lesion. Stewart (1933) described ten such cases in detail, still the classical source on the subject. The lesion was suggested to lymphoma in 1966 (Eichel et al. 1966), confirmed in 1977 (Michaels and Gregory 1977).

The lymphoma predominantly occurs in Asian countries and in Meso- and South America, and males predominate. The most commonly involved tissues are those of the upper aerodigestive tract, particularly paranasal sinuses, nasal cavity, and nasopharynx. In addition, the skin, gastrointestinal tract, and testis are well-documented sites. In the nasal/midface region, the neoplasm can cause massive destruction followed by rapid spread to other tissues (extranasal NK/T-cell lymphomas). Patients usually have high-stage disease at diagnosis, with involvement of multiple sites.

Morphology

Typically, the neoplastic cells grow with an angiocentric and angiodestructive growth pattern, associated with fibrinoid vascular changes, apoptosis, and coagulative (infarctoid) necrosis caused by vascular obstruction/ischemia and cytokine/chemokine effects. In a series of 73 patients, an angiocentric and angiodestructive pattern was found in 69 % of patients (Li et al. 2013). The morphology of cells ranges from small cells to large and anaplastic cells. Tumors with intermediate cells and those with a mixture of small and large cells prevail. The cytoplasm is typically pale. Many tumor cells have irregularly shaped, folded, or elongated nuclei, with numerous mitotic figures. Nucleoli are usually small.

Immunohistochemically, the leading cell is positive for CD2, CD56, and cytoplasmic CD3 epsilon and negative for surface CD3. Many cells

express perforin and granzyme B. Few cases are positive for CD30 and CD7. The tumor typically express EBV.

Liver Involvement

In the course of the often rapid multiorgan spread, the liver can be involved (Michaels and Gregory 1977; Chappel and Powell 1981; Hatta et al. 1993; Ullrich et al. 1999; Chang et al. 2002; Ng et al. 2004; Kim et al. 2008). In a study of 18 patients, liver involvement was found in 92.8 % (Hatta et al 1993). Hepatic involvement may cause liver dysfunction (Monma et al. 2009). As far as it is known, the cells types infiltrating the liver are the same as those encountered in midfacial tumors, but it is unknown whether the angiodestructive phenotype is also seen in the liver. In one case reported by Michaels and Gregory (1977), the liver sinusoids showed infiltration by atypical lymphoid cells, some of them multinucleated. In a second case, the authors observed infiltration of portal tracts and parenchyma by groups of cells similar to those seen in lymph nodes and spleen.

Cytogenetic and Molecular Features

T-cell receptor gene is in germline configuration, but in a minority of cases, there is clonal T-cell receptor rearrangement, representing the cases with cytotoxic T-lymphocyte phenotype. A variety of nonspecific cytogenetic aberrations are known. By means of array-based comparative genomic hybridization, numerous chromosomal gains and losses were detected, with several critical candidate genes (Sun et al. 2014). Genes deregulated in this lymphoma include PRDM1/positive regulatory domain containing 1, ATG5, AIM1, FOXO3, and HACE1 (Huang et al. 2013; Liang et al. 2014).

Hepatosplenic T-Cell Lymphoma

ICD-O Code 9716/3

Introduction

In the 2008 WHO classification, hepatosplenic T-cell lymphoma (HSTL) is defined as an extranodal and systemic lymphoid neoplasm derived from cytotoxic T cells, most often of the gamma/delta T-cell receptor type. The leading neoplastic cell is a medium-sized element that tends to populate vascular sinusoids in the bone marrow, spleen, and liver. The skin is rarely affected. Overall, HSTL is a rare lymphoma that accounts for less than 1 % of all non-Hodgkin's lymphomas. Adolescents and young adults are most often affected (median: 35 years of age), with a male predominance. Up to 20 % of cases develop in the setting of chronic immune suppression, specifically long-term immunosuppressive therapy for solid organ transplantation. In children, HSTL has been reported following azathioprine therapy and infliximab therapy for Crohn's disease. Two main variants of HSTL can be distinguished, i.e., gamma/delta and the rarer alpha/beta HSTL (Wei et al. 2005; Vega et al. 2007; Shale et al. 2008; Falchook et al. 2009; Roelandt et al. 2009; Schmidt and Lim 2009; Thai and Prindiville 2010; Hocker et al. 2011; Kotlyar et al. 2011; Travert et al. 2012).

Hepatosplenic Gamma/Delta T-Cell Lymphoma

HSTL gamma/delta is recognized as a distinct subset of post-thymic peripheral T-cell lymphoma, characterized by the involvement of the spleen, liver, and often the bone marrow, but with no or little lymphadenopathy, usually following an aggressive course. Hepatosplenomegaly may be massive, due to dense tumor cell infiltration (Gaulard et al. 1986, 1990; Farcet et al. 1990; Wong et al. 1995; Cooke et al. 1996; Salhany et al. 1997a; Weidmann et al. 2000; Rossbach et al. 2002;; Ferreri et al. 2012; Qi et al. 2012; reviews: Sallah et al. 1997; Belhadj et al. 2003; Gaulard et al. 2003). Only few patients under 15 years of age have been reported (Weidmann et al. 2000; Rossbach et al. 2002; Gassas et al. 2004;). Bone marrow involvement is found

in approximately two thirds of the patients at diagnosis (Weidmann et al. 2000), but may be more frequent or even a constant feature as based on newer studies (Belhadj et al. 2003). The improvement of bone marrow diagnostics by use of efficient immunotyping has led to a decrease of splenectomies for diagnostic purposes (Belhadj et al. 2003). In a small number of patients, malignant cells are detectable in the peripheral blood either at presentation or later in the course of disease (Mastovich et al. 1994; Sallah et al. 1997). In contrast to other gamma/delta T-cell lymphomas, HSTL gamma/delta seems to be less heterogeneous (de Wolf-Peeters and Achten 2000). HSTL gamma/delta can occur as a complication of immunosuppression, e.g., subsequent to solid organ transplantation (Ross et al. 1994; Hanson et al. 1996; François et al. 1997; Salhany et al 1997b; Kraus et al. 1998; Roncella et al. 2000; Khan et al. 2001; Steurer et al. 2002; Belhadj et al. 2003). In part of these patients, HSTL gamma/delta manifests as late-onset posttransplant lymphoproliferative disorder (Wu et al. 2000). Very rarely, gamma/delta HSTL develops as a pregnancy-associated lymphoma (Niitsu et al. 2004); development of lymphoma during a pregnancy is as such rare, occurring in only 1 of 1,000–6,000 deliveries, the majority of these lesions being Hodgkin's lymphoma or B-cell lymphomas (Gelb et al. 1996; Pohlman and Macklis 2000; Glaser et al. 2012). Clinically, hepatosplenomegaly, sometimes marked, is a constant feature. Thrombocytopenia is frequent, and a part of the patients develop hemophagocytic syndrome (Kadin et al. 1981; Jaffe et al. 1983; Sun et al. 1990; Nosari et al. 1999; Côté-Daigneault and Bernard 2011). Thrombocytopenia may be associated with hemolytic anemia (Evans' syndrome; Motta et al. 2002). In a minority of patients, lymphoma-associated coagulopathy developed (Jahangiri and Mahesh 2010; Perini and Pro 2010). Apart from the now well-recognized, typical presentation, HSTL gamma/delta may come in variants with a different tissue expression or different evolution. Thus, this NHL may show an angiocentric growth pattern (Zabernigg et al. 1996) HSTL gamma/delta can undergo a blast-like terminal transformation (Mastovich et al. 1994), exhibit transformation into a prolymphocytic lineage (Sohn et al. 1997), or undergo a leukemic course after renal transplantation (Steurer et al. 2002).

Hepatosplenic Alpha/Beta T-Cell Lymphoma

In addition to the gamma/delta variant, there is a group of hepatosplenic T-cell lymphomas exhibiting an *alpha/beta lineage* (Lai et al. 2000; Suarez et al. 2000; Kumar et al. 2001; Macon et al. 2001; Dong et al. 2003; Nagai et al. 2010). The relative frequency and the prognostic relevance of the gamma/delta versus the alpha/beta phenotype in HSTL remain unknown, but the alpha/beta variant is thought to be rarer than its gamma/delta counterpart. This NHL may be associated with thrombocytopenia (similar to the gamma/delta variant) and with hemolytic anemia (Lai et al. 2000). In a study of 14 patients, 11 were female and 3 were male, with a median age of 36 years (HSTL gamma/delta: 34 years in one study). The clinical presentation was similar to that described previously for the gamma/delta variant of HSTL, except for the female preponderance and the different age distribution (5 patients younger than 13 years and 5 patients older than 50 years of age). The neoplastic cells in all these 14 NHLs were cytotoxic alpha/beta T cells. Three cases were associated with EBV, and alpha/beta HSTL has been observed following azathioprine therapy (Rashidi et al. 2012).

Liver Involvement in Hepatosplenic T-Cell Lymphomas

In liver biopsies, atypical small- to medium-sized cells occupy the sinusoids in variable density, mostly with sparing of the portal tract spaces (Farcet et al. 1990; Belhadj et al. 2003; Taguchi et al. 2004). The preferentially sinusoidal accumulation of the neoplastic cells has been highlighted in the original description of HSTL

gamma/delta already ("sinusal/sinusoidal localization of malignant cells"; Farcet et al. 1990), but sometimes this sinusoidal infiltration is sparse (Coventry et al. 1999). A sinusoidal pattern of infiltration also prevails in the alpha/beta variant of HSTL (Dong et al. 2003), but liver infiltration was largely periportal in four cases (Macon et al. 2001). In case of portal tract infiltration, a part of the neoplastic cells also infiltrate the periportal zone 1 of the liver lobule (Khan et al. 2001). The morphology of the cells is characterized by monomorphy and the presence of round or slightly irregular small- to medium-sized nuclei containing rather prominent nucleoli. A moderate amount of slightly basophilic or amphophilic cytoplasm is observed. In some of the patients, medium to large cells are found with signs of increased cellular pleomorphism, and predominantly large cell variants of HSTL gamma/delta have been reported (Khan et al. 2001). Probably caused by the cells' contact with the endothelia of the sinusoids, a part of the neoplastic cells display an elongated shape and dendritic projections. The density of neoplastic cells accumulating in the sinusoids is sometimes striking and leads to morphologic signs of a sinusoidal block. Small clusters of lymphoma cells sometimes seem to penetrate the perisinusoidal space and appear to locate within the suprajunctional space between two hepatocytes. Furthermore, tumor cells apparently situated in the perisinusoidal space are in close physical contact with hepatic stellate cells. As hepatic infiltration can be associated with a slight degree of perisinusoidal matrix increase, one may surmise that a signaling interaction might take place between the two cell systems involved.

The typical phenotype of the target cells is reactivity for CD2, CD3/CD3 epsilon, CD5, CD7, CD56, absence or presence of CD4 and/or CD8, absence of CD16 and CD57, and positivity for the gamma/delta TCR, mostly in the absence of an activated cytotoxic cell phenotype (Wong et al. 1995; Sadahira et al. 2003; Belhadj et al. 2003), although cases with a cytotoxic phenotype (expression of perforin, granzyme B, TIA-1) are known as well (Salhany et al. 1997). It has been shown that the cells in HSTL can express epithelial membrane antigen (EMA; Ohno et al. 1993) and CD26, the transmembrane serine aminopeptidase, dipeptidyl peptidase IV (Ruiz et al. 1998). This is of interest for the pathogenesis of lymphoma spread, because CD26 participates in ECM protein, and specifically collagen, interactions. Furthermore, the serine protease, granzyme M, is preferentially expressed in gamma/delta T-cell lymphomas (Krenacs et al. 2003).

The sinusoidal infiltration is sometimes associated with pericentral parenchymal necrosis (Khan et al. 2001). This may be caused by decreased sinusoidal blood flow owing to obstruction by lymphoma cells, i.e., an ischemic pericentral hepatocyte damage. HSTL gamma/delta can result in hepatic failure, eventually requiring liver transplantation (Blakolmer et al. 2000; Petersen-Benz et al. 2003). In one case of HSTL alpha/beta, biopsy revealed necrotizing hepatitis and the presence of a low-density infiltrate of atypical lymphocytes (Petersen-Benz et al. 2003). A similar situation has been reported by another group, again with extensive liver necrosis (Schwartz et al. 1998). Rarely, HSTL clinically mimics acute hepatitis, with markedly elevated serum aminotransferases and reduced prothrombin activity (Perfetto et al. 2003).

Cytogenetic Features, EBV Expression, and Molecular Mechanism

Cytogenetically, many patients reveal an isochromosome 7q as a primary and consistent aberration (Wang et al. 1995; Yao et al. 1996; Jonveaux et al. 1996; François et al. 1997; Alonsozana et al. 1997; Rossbach et al. 2002; Wlodarska et al. 2002), sometimes in association with trisomy 8 (Coventry et al. 1999; Chin et al. 2004). EBV infection is rarely encountered and may, if present, indicate a late event in posttransplant HSTL gamma/delta (Roncella et al. 2000). In a study of 21 patients, the median age at presentation was 34 years; 21/21 had splenomegaly, 15/21 hepatomegaly, and 20/21 showed thrombocytopenia. 18/21 of the patients were negative for EBV. 9/21 showed isochromosome arm 7q. Of these

21 patients, eight patients had previously undergone kidney transplantation or had a history of systemic lupus erythematodes, Hodgkin's disease, or malaria. The prognosis was poor; median survival time was 16 months, and all but two patients ultimately died despite consolidative or salvage high-dose therapy (Belhadj et al. 2003). The relationship between HSTL and EBV infection has been studied in detail (Ohshima et al. 2000).

Of four cases of alpha/beta HSTL analyzed cytogenetically, two revealed an isochromosome 7q (Macon et al. 2001). Isochromosome 7q in the alpha/beta variant has been detected in other reported patients (Lai et al. 2000; Suarez et al. 2000). The cells of alpha/beta HSTL may be immunoreactive for S100 protein (Dong et al. 2003).

Subcutaneous Panniculitis-Like T-Cell Lymphoma

ICD-O Code 9708/3

Introduction

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) is defined as a T-cell lymphoma with a cytotoxic T-cell phenotype, predominantly infiltrating the subcutis of diverse body regions. Typically, the subcutaneous infiltrates are associated with adipose tissue necrosis (fat necrosis) with associated inflammatory reactions (panniculitis-like lesions; Gonzalez et al. 1991; Kumar et al. 1998). The neoplastic cells show T-cell receptor rearrangement, but lesions with rearrangement of the gamma/delta T-cell receptor are excluded from the SPTCL group and are now classified as cutaneous gamma/delta T-cell lymphoma (Go and Wester 2004; Hoque et al. 2003; Ghobrial et al. 2005; Willemze et al. 2008; Huang et al. 2009; Lü et al. 2010; Bakhshi et al. 2011).

SPTCL is rare and accounts for less than 1 % of all non-Hodgkin's lymphomas. 20 % of the patients are younger than 20 years at diagnosis, and females are slightly more often affected. Extremities and trunk are most frequently involved. The skin lesions are papules or nodules of up to several cm diameter, sometimes painful, usually without ulceration, as the lesions are deep-seated, but in case of large necrosis, upper parts of the skin undergo damage as well and become ulcerated. In addition to subcutaneous lesions, 20 % of the patients present with autoimmune features, most often system lupus erythematodes. Systemic signs of disease are common, as are abnormal liver function tests (Takeshita et al. 2004; Zhang et al. 2007). Among 21 patients with SPTCL, liver dysfunction with elevated serum enzymes was detectable in 52 % of patients (Ghobrial et al. 2005). Fifteen to 20 % of patients were reported to have hemophagocytic syndromes, which is an adverse prognosticator. A minority of patients show hepatosplenomegaly. Extranodal disease may involve the lung (Ma et al. 2005) and the liver (see below).

Morphology

The neoplastic T cells are of intermediate to large size and form an infiltrate within adipose lobules, without epidermotropism. The tumor cells are intermingled with histiocytes/macrophages containing apoptotic debris and lipid droplets, the latter from necrotic adipocytes. Nuclei are irregularly shaped and hyperchromatic, and the cytoplasm is usually pale. The tumor cells form typically rims around large adipocytes. Immunohistochemically, the cells are usually CD8-positive and contain perforin and granzyme B. They have a mature T-cell phenotype with expression of alpha/beta T-cell receptor.

Liver Involvement

From its subcutaneous sites, SPTCL can spread to lymph nodes and remote organs, including the liver. Extranodular organ involvement was identified in 7 out of 19 patients with SPTCL (Huang et al. 2009). In patients with advanced disease and extracutaneous and extranodal disease, the liver can be infiltrated (Huang et al. 2009; Babb

et al. 2011; Bakhshi et al. 2011). Tumor-associated hepatomegaly was observed part of patients with SPTCL (Yi et al. 2013). Liver involvement can present as small and multiple focal infiltrates or a diffuse infiltrate of atypical T cells, but it was also noted in the form of discrete nodules within the liver substance (Bakhshi et al. 2011).

Mycosis Fungoides

ICD-O Code 9700/3

Introduction

In the 2008 WHO classification, mycosis fungoides (MF; formerly also termed, "granuloma fungoides") is defined as an epidermotropic, primary cutaneous T-cell lymphoma composed of a neoplastic lineage of small- to medium-sized T cells with cerebriform nuclei. The postulated cell of origin is a mature skin-homing $CD4^+$ T-cell. MF accounts for about 50 % of all cutaneous lymphomas and mainly affects adults but also occurs in the pediatric age group and in adolescents. Males are twice as often affected than females. In the first stages of the disease, diverse cutaneous regions are involved, but in advanced stage disease, MF tends to spread to lymph nodes and inner organs, including the lung, spleen, and liver (Toro et al. 1997; Girardi et al. 2004; Zinzani et al. 2008; Beyer et al. 2011; Wong et al. 2011; Quaglino et al. 2012; Talpur et al. 2012; Vora et al. 2012). Stage-specific involvement of the blood occurs in high-stage disease. Mainly in the tumor stage, so-called transformation may ensue, defined as the presence of more than 25 % of large lymphoid cells in the dermal infiltrates. Large-cell transformation is associated with an aggressive course and shorter survival (Benner et al. 2012; Herrmann and Hughey 2012).

The classical form of MF is also termed Alibert-Bazin type of MF. Apart from this type, various other forms of MF or disorders related to MF are known. A rare variant of MF is pagetoid reticulosis with two distinct distribution patterns and clinical courses. One variant shows a localized patch or plaque, usually solitary on the extremities, containing intraepidermal proliferations of neoplastic T cells in a pagetoid distribution, typically affecting middle-aged and elderly men. This form of pagetoid reticulosis has a bland course and is called Woringer-Kolopp disease (Woringer and Kolopp 1939; Degreef et al. 1976; Braun-Falco et al. 1979; Oliver and Winkelmann 1989; Haghighi et al. 2000; Lee et al. 2008; Lichte et al. 2009; Matsuzaki et al. 2009; Martin et al. 2010; Koga et al. 2011; Mendese et al. 2012; review: Cribier 2005). The second variant reveals a more generalized presentation with diffuse cutaneous involvement and a more aggressive clinical course. This is Ketron-Goodman disease, which typically involves the trunk and extremities and probably represents an aggressive cutaneous T-cell lymphoma (Sullivan 1958; Mielke et al. 1989; Nakada et al. 2002; Carlesimo et al. 2009; review: Steffen 2005).

The pathogenetic pathways leading to MF are only partially elucidated. Malignant T cells forming the neoplastic population in MF have the capacity to home to the skin, a process facilitated by the expression of chemokines, cytokines, adhesion molecules, and defective apoptosis. The skin microenvironment with its epidermal-mesenchymal interactome and the presence of skin-associated immune cells, including cutaneous T cells, follicular helper T cells, and dendritic cells, play a supportive role for the development of MF (review: Jawed et al. 2014).

Clinical Features

Early disease if characterized by the development of cutaneous patches, papules, and plaques, later followed by tumor formation (the tumorous stage). In some patients, distinct exophytic tumor lesions develop (fungiform mycosis). This evolution, which may take years, had led to a clinical staging system.

In the stage of patches, papules, and plaques, layers of the epidermis show a band-like infiltrate of lymphocytes and histiocytes. In this stage, few lymphocytes typically display irregular, indented

(cerebriform) nuclei. In plaques, the epidermotropism is more pronounced, and in a minority of cases, small clusters of atypical T cells are situated within the epidermis (Pautrier microabscesses; in fact, these are not true abscesses, because the lesions consist of atypical T cells and not neutrophils). As the process continues, more and more infiltrates also occupy deeper layers of the skin, causing tumorous swellings (the tumorous stage). In this stage, greater numbers of highly atypical large tumor cells with cerebriform nuclei and blast cells with prominent nuclei are present (Berman 1940; Sausville et al. 1988). Clinically and histomorphologically, several subtypes or variants of MF have been defined, in addition to Woringer-Kolopp disease and Ketron-Goodman disease. They include hypopigmented MF, hyperpigmented MF, annular hypopigmented MF, erythrodermic MF, papular MF, erysipelas-like MF, interstitial MF, ichthyosis-like MF, poikilodermatous MF, purpuric MF, syringotropic MF, erythema annulare centrifugum-like MF, cutis laxa-like MF, invisible MF, granulomatous MF, pityriasis lichenoides-like MF, solitary (unilesional) MF, bullous MF, vesicular MF, and vesiculobullous MF(Abeldaño et al. 2011). These different presentations may be associated with patterns of biology of disease. For example, bullous MF (mycosis fungoides bullosa) represents a particularly aggressive form of MF and is associated with poor prognosis (Kneitz et al. 2010). Conversely, solitary MF (Ally et al. 2012) and annular hypopigmented MF (Uhlenhake and Mehregan 2012) appear to have a good prognosis. Folliculotropic MF can be combined with granulomatous slack skin. A part of the variants have demonstrated an abnormal immune phenotype of the neoplastic cells. Hyperpigmented MF is an unusual variant with a frequent $CD8^+$ phenotype (Pavlovsky et al. 2012). Folliculotropic MF was rarely found to undergo large-cell transformation with $CD30^+$ cells associated with eosinophilia and unfavorable course (Ishibashi et al. 2010). MF has been found in combination with lymphomatoid papulosis, and this associated seems to confer a more favorable outcome (Gallardo et al. 2004).

Liver Involvement

Generally, 75 % of patients with diverse types of cutaneous T-cell lymphomas, including MF, have extracutaneous disease, the most frequently infiltrated organs being the liver, spleen, and lung, which contain lymphoma in 38–66 % of autopsied patients (review: Huberman et al. 1980). In MF, visceral involvement is almost always associated with lymph node involvement and involvement of the spleen (Rappaport and Thomas 1974). In MF there was hepatic infiltration in an average of 45 % of these patients (Farber 1939; Epstein et al. 1972; Long and Mihm 1974; Rappaport and Thomas 1974; Variakojis et al. 1974; Griem et al. 1975; Levi and Wiernik 1975; Rodin et al. 1976; Rappaport 1977; Huberman et al. 1980; Doyle and Winkelmann 1981; Trope et al. 1985; Thomsen and Wantzin 1987; Liu et al. 2012). In part of the studies, the rate of liver involvement was higher (53 %; Rappaport and Thomas 1974). In a series of 49 consecutive cases of MF and Sézary syndrome, 18 % of the patients had visceral involvement (Bunn et al. 1980). Infiltration of the liver can cause hepatic failure (Albukerk and Duffy 1973; Shibata et al. 2009).

In an analysis of 17 MF patients who had microscopic evidence of MF infiltrates in the liver, 11 showed gross involvement. Seven of these had multiple nodules ranging from 0.1 to 5.5 cm, two patients had solitary nodules measuring 2 cm and 5 cm, and two were described as having tumor infiltrates. In 11 cases with gross liver involvement, the mean weight of the liver was 2004 g (range: 1,200–3,030 g), but liver weights exceeding 3 kg were also noted in cases with only microscopic involvement (Rappaport and Thomas 1974). MF of the liver presents in the form of whitish nodules with a size of dew mm to pea size. Sometimes, lentil-shaped nodules are noted close to the liver surface, often with a red, hyperemic rim. Peripheral nodules with radiating capsular folds have also been described (review of the old literature: Gruber 1930).

The liver is involved by circulating abnormal T cells in stages III and IV and parenchymal infiltration in stage IV (Table 1). The liver is characterized by a highly variable mode of tumor cell

Table 1 Patterns of liver involvement in mycosis fungoides

Accumulation of neoplastic circulating T cells in sinusoids and other hepatic vessels
Portal tract infiltrates with or without involvement of periportal zone 1
Tumorous nodular involvement
Diffuse hepatic infiltration

infiltration, more so than other involved visceral organs (Rappaport and Thomas 1974).

In part of patients, histology of the liver in MF involvement showed an infiltration of portal tracts, with encroachment upon the parenchyma of zone 1, with small atypical lymphocytes, sometimes admixed with neutrophils. Some of the lymphoid cells are larger and exhibit indented or cerebriform nuclei, as in the cutaneous/epidermal infiltrates (Rappaport 1977). In other patients, involvement is seen in the form of tumorous nodules that have no relation to portal tracts or other anatomical structures, and there are also patients who show a diffuse hepatic infiltration, similar to infiltrations seen in myeloproliferative disorders (Rappaport and Thomas 1974). Atypical T cells are also found in sinusoids and within hepatocyte plates (Albukerk and Duffy 1973). In several instances, only very rare tumor cells were found between liver cell plates, associated with sparse portal tract infiltrates containing few large cells with atypical dense nuclei (Variakojis et al. 1974). Diagnosis is difficult in such cases and requires detailed immunohistochemistry, even in the presence of rare atypical cells with indented or cerebriform nuclei. Microvascular changes of the liver have been observed in MF, including fibrinoid necrosis of central veins (Albukerk and Duffy 1973). MF can also infiltrate the walls of the extrahepatic bile ducts. In one case, mucosal infiltration of extrahepatic bile ducts caused biliary obstruction (Madsen et al. 1999).

Immunocytochemically, the tumor cells are $CD5^+$, $CD4^+$, and $CD8^-$. Only few cases are $CD8^+$ (Cho et al. 2012; Kasugai et al. 2012; Yamashita et al. 2012). Subsets of cells express clusterin, and this expression pattern correlates with stage and presence of large cells in MF (Chandra et al. 2009). A part of the cells have the features of follicular center helper T cells (Meyerson et al. 2013) and are reactive for PD-1 (Park et al. 2014). CD4/CD8 double-negative MF with CD279 expression has been suggested as disease of follicular helper cells (Kempf et al. 2012). Large cells in the transformation phase (see above) are $CD30^+$. In the Woringer-Kolopp variant of MF, T cells may be $CD4^+$ and $CD8^+$ (Zengin et al. 2008).

Cytogenetic and Molecular Features

Many cases show complex karyotypic aberrations, but above all in advanced stages, probably linked to increasing genomic instability of the neoplasm. Most abnormalities are, therefore, nonspecific. T-cell receptor genes are clonally rearranged. It was reported that constitutive activation of STAT3 and inactivation of PTEN and CDKN2A/p16INK4a are associated with disease progression. Tumor-stage MF has a characteristic molecular signature (van Kester et al. 2012). MF cells have a complex constellation of proliferative activity vs. cell loss through apoptosis. Almost all MF lesions were Fas ligand-negative, and in two thirds of lesions, Fas expression is low. Twenty five percent showed the phenotype, Fas high, and FLICE/Fas pathway inhibitor high, suggesting defective apoptotic pathways in MF (Stutz et al. 2012). Part of MF showed mutations in PLCG1 (phospholipase C gamma 1), associated with increased downstream signaling toward nuclear factor of activated T cells (NFAT) and nuclear NFAT immunostaining (Vaqué et al. 2014).

Sézary Syndrome

ICD-O Code 9701/3

Introduction

In the 2008 WHO classification, Sézary syndrome (SS) is defined by the triad of erythroderma,

generalized lymphadenopathy, and the presence of a neoplastic T-cell neoplasia with cerebriform nuclei (the Sézary cells) in the skin, lymph nodes, peripheral blood, and rarely inner organs. Additional diagnostic criteria are a Sézary cell count of at least 1,000 cells/mm^3, an expanded CD4$^+$ T-cell population with CD4/CD8 ratio of more than 10, and/or loss of one or more T-cell antigens. SS is rare, representing less than 5 % of all cutaneous T-cell lymphomas and is typically a disease of aged persons, usually over 60 years. Apart from erythroderma and lymphadenopathy, patients may show alopecia, palmar or plantar hyperkeratosis, and onychodystrophy. The loss of normal circulating CD4$^+$ cells causes an immunodeficiency state, with an increase of infections and secondary malignancies. SS is a progressive disease with a 5-year-survival rate of 10–20 %. Massively erythrodermic forms and cutaneous tumor load correlate with survival (Vonderheid and Bernengo 2003; Ogilvie et al. 2012; Yamashita et al. 2012; Booken et al. 2013).

Morphology

The neoplastic cells are small- to medium-sized and in part large lymphoid cells with a hyperconvoluted and deeply indented (cerebriform) nucleus, the Sézary cell. The histopathologic presentation is similar to that of mycosis fungoides, but infiltrates in SS are more often monotonous and less epidermotropic. In fact, epidermotropism is often absent. The architecture of enlarged lymph nodes is effaced by a dense infiltrate of Sézary cells. In contrast to lymph nodes, bone marrow usually displays only a sparse infiltration. Immunocytochemically, the tumor cells are reactive for CD2, CD3, and CD5, and most cases have a CD4$^+$ helper cell phenotype, CD8$^+$ Sézary syndrome being rare. Typically, SS shows heterogeneity of T-cell phenotypes, with differential antigen losses, e.g., regarding CD7 and CD26 (Steinhoff et al. 2009). T cells in Sézary syndrome are highly reactive for CD164 (a sialomucin) and FCRL3, a molecule present on a subset of human natural T regulatory cells (Wysocka et al. 2014).

Liver Involvement

In the terminal phase of the disease, almost all visceral organs can be involved by this lymphoma (Cohen et al. 1977; Hoppe et al. 1990), including the liver. Patients with generalized erythroderma had a higher frequency of visceral involvement (Bunn et al. 1980). Liver infiltration has been found in classical SS and is the most common extranodal site (Huberman et al. 1980), but also in variants presenting as T-cell leukemia (Dawkins et al. 1975). Sézary cells with the typical immunophenotype are mainly found in portal tracts, sometimes in high density, but in leukemic forms, also the sinusoids contain typical T cells with cerebriform nuclei. Circulating tumor cells appearing in the liver have a distinct phenotype, with co-expression of CD158k and vimentin (Ortonne et al. 2006). The mechanisms of hepatic homing of Sézary cells are not known, but homing to liver has been observed in a mouse model of SS (injection of Sézary cells into immunodeficient RAG2(–/–)yc(–/–) mice; van der Fits et al. 2012). Skin homing of Sézary cells involves SDF-1-CXCR4 signaling and downregulation of CD26/dipeptidyl peptidase IV (Narducci et al. 2006) and is related to expression of CCR4 and CCR10, while lymph node homing depends on CCR7 expression (Sokolowska-Wojdylo et al. 2005). Sézary cells migrate in response to stimulation by the chemokine, stromal cell-derived factor 1 alpha, but not the NT1 receptor (Magazin et al. 2004).

Cytogenetic and Molecular Features

SS shows several complex cytogenetic abnormalities, mainly of chromosomes 1p, 6q, 10q, 17p, and 19, reflecting marked progressive genomic instability, but there is no specific alteration known. Sézary cells show clonal T-cell receptor rearrangement. A part of cases show inactivation of TP53 and p16INK4a. As the Sézary cell transcriptome is studied in detail (Lee et al. 2012), more and more specific alterations are expected to be identified. Novel somatic missense mutations have been found in TBL1XR1,

EPHA7, and SLFN12 genes (Andersson et al. 2014). Furthermore, cutaneous T-cell lymphomas, including Sézary syndrome, showed PLCG1 mutations, eliciting increased downstream signaling toward NFAT/nuclear factor of activated T-cell activation (Vaqué et al. 2014).

Peripheral T-Cell Lymphoma (PTCL), NOS

ICD-O Code 9702/3

Introduction

According to the 2008 WHO classification, peripheral T-cell lymphoma (PTCL) forms a heterogeneous group of nodal or extranodal mature T-cell lymphomas which do not correspond to other, distinct categories of T-cell lymphomas. One variant of PTCL-NOS is characterized by epithelioid histiocytes and corresponds to Lennert's lymphoma (lymphoepithelioid variant). PTCL accounts for about 30 % of all peripheral T-cell lymphomas and is chiefly a disease of adults, with a male predominance. Patients usually show nodal involvement, but almost any tissue can be infiltrated. The typical patient shows generalized disease, with infiltration of the lymph nodes, bone marrow, spleen, liver, and other organs and tissues. Extranodal sites most often involved are gastrointestinal tract and skin. Leukemic presentation is uncommon, although the mature T cells can circulate and recirculate in blood and lymph. The cell of origin is an activated mature T lymphocyte, mostly of the $CD4^+$ central memory type of the immune system (Haioun et al. 1992; Foss et al. 2011; Piccaluga et al. 2011; Armitage 2012; Jaffe et al. 2013).

Morphology

Typically, neoplastic T cells in PTCL-NOS exhibit a highly variable phenotype, ranging from monomorphous medium-sized cells to large cells and highly polymorphic cells. Nuclei are often large, with prominent nuclei and numerous mitotic figures. A part of cases display large cells with a clear cytoplasm and/or cells resembling Reed-Sternberg cells. The neoplastic cells are situated in a tissue background that may contain significant numbers of nonneoplastic cells, including small T cells, plasma cells, B cells of variable size classes, and eosinophils. PTCL has been proposed to be divided into several categories or subtypes, viz., T-zone; pleomorphic, small; pleomorphic, medium; pleomorphic large; angiocentric; immunoblastic; and Lennert type (Shimizu et al. 1989). Lennert's lymphoma is a variant that has numerous epithelioid lymphohistiocytoid cells (the lymphoepithelioid cell variant). As Lennert's lymphoma appeared in numerous reports under this term, this variant of PTCL will be discussed in a separate paragraph for comparison reasons. One variant of PTCL is characterized by the presence of Reed-Sternberg-like cells of B-cell phenotype and genotype associated with EBV infection (Quintanilla-Martinez et al. 1999). Immunohistochemically, PTCL is characterized by an aberrant T-cell phenotype with common downregulation of CD5 and CD7. $CD4^+$ cells usually predominate. Some of the cases exhibit positivity for CD8, CD56, and mixed CD4/CD8 patterns.

Liver Involvement

Primary Liver Involvement

Peripheral T-cell lymphoma (PTCL) primarily manifesting in the liver is considered to be rather uncommon (Andreola et al. 1988; Sutton et al. 1989; Anthony et al. 1990; Shibata et al. 1991; Harris and Kornstein 1993; Bowman et al. 1994; Lei 1998; Kim et al. 2000; Schweiger et al. 2000; Levy 2002; Stancu et al. 2002; Leung et al. 2009; Miyashita et al. 2011; Hu et al. 2014). The tumor can present as a liver mass in the absence of lymphadenopathy, splenomegaly, or bone marrow disease (Hu et al. 2014). The hepatic manifestation may be a solitary lesion, multiple nodules, or

a diffuse infiltration (Levy 2002). Among three elderly men with this entity, two showed hepatomegaly and one jaundice. Imaging studies revealed marked hepatomegaly without focal lesions on one patient and multiple discrete tumor masses in two patients. Histology showed PTCL, with neoplastic cells situated in an inflammatory background and showing a monoclonal T-cell receptor gamma chain gene rearrangement, what is unusual (Stancu et al. 2002). These authors compiled eleven previous patients with apparently primary PTCL arising in the liver. Together with their 3 patients, 14 patients were evaluated, 11 being male and most patients older than 50. Eleven patients showed hepatomegaly, and seven were jaundiced. In the patient reported by Miyashita and coworkers (2011), liver biopsy showed portal tract infiltration of small- and intermediate-sized T cells with irregular nuclear contours. The cells were positive for CD3, CD8, and TIA-1, but negative for CD4, and showed T-cell receptor rearrangement. Portal tract infiltration may be massive and led to extensive lymphomatous infiltration of the entire liver (Harris and Kornstein 1993). Primary hepatic PTCL is sometimes associated with autoimmune disorders, including systemic lupus erythematodes (Sutton et al. 1989) and Felty's syndrome (Bowman et al. 1994).

Secondary Liver Involvement

The liver is one of the organs regularly infiltrated in generalized PTCL (Figs. 1 and 2; Shimizu et al. 1989; Tsutsumi et al. 1991; Lee et al. 2003; Mitarnun et al. 2004; Huang et al. 2012). In a study of 25 patients with PTCL, liver involvement was detected in 56 % (Shimizu et al. 1989). In one investigation, the morphology of T-cell infiltrates varied from mature small lymphocytes to larger, malignant-looking cells (Mitarnun et al. 2004). Peripheral T-cell lymphoma may cause hepatic failure (Schwartz et al. 1998). In one patient with acute liver failure requiring liver transplantation, the T-cell lymphoma recurred in the graft (Blakolmer et al. 2000).

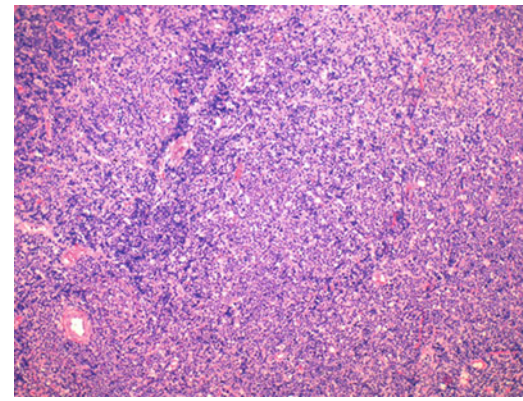

Fig. 1 T-cell lymphoma of the liver. The neoplastic lymphoid cells form vaguely nodular structure with intervening areas of smaller lymphocytes (hematoxylin and eosin stain)

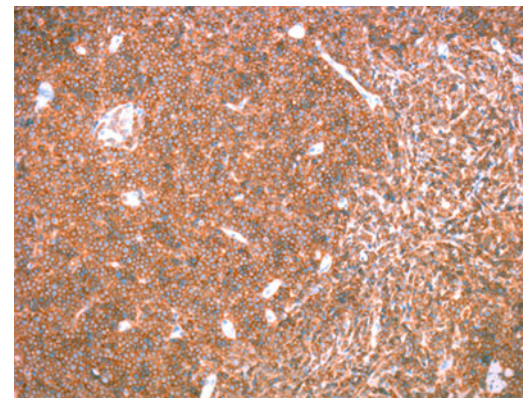

Fig. 2 T-cell lymphoma of the liver. The neoplastic cells are strongly CD3-positive (CD3 immunostain)

Other Liver Lesions Associated with PTCL-NOS

In a patient with PTCL, hemophagocytic syndrome presenting as hepatic failure has been observed (Hino et al. 1997).

Molecular Features

PTCL often show complex karyotypes. This is associated with alterations in gene expression of

numerous genes involved in proliferation, apoptosis, cell adhesion, and cell-matrix interactions. The molecular etiology of mature T-cell NHL has been studied in detail (Evens and Gartenhaus, 2003). T-cell receptor beta chain is usually expressed, in contrast to other T-cell lymphomas. PTCL show recurrent structural abnormalities of TP63 and other p53-related genes, involved in the disruption of p53-associated tumor suppressor functions (Vasmatzis et al. 2012). Similar to other T-cell lymphomas, the RHOA G17V gene mutation occurs frequently in PTCL (Manso et al. 2014; Palomero et al. 2014). Expression of small nucleolar RNAs (snoRNA) in PTCL cells was found to have diagnostic and prognostic significance (Valleron et al. 2012).

T-Cell Non-Hodgkin's Lymphomas: Variant Forms

96

Contents

Abstract

There are several variant forms of T-cell non-Hodgkin's lymphomas that can involve the hepatobiliary tract. A distinct and highly aggressive variety of T-cell NHL is the lymphoepithelioid cell variant of peripheral T-cell lymphoma, also termed Lennert's lymphoma (LECL). LECL is characterized by a proliferation of CD4-positive T cells associated with high content of epithelioid macrophages/histiocytes. LECL exhibits a high incidence of generalized lymphadenopathy but rare extranodal disease. Liver involvement may occur, with variable degrees of hepatomegaly. A variant of peripheral T-cell NHL with a polymorphous T-cell lymphoproliferation and association with EBV infection and systemic disease is angioimmunoblastic T-cell lymphoma. This neoplasm accounts for 15–20 % of T-cell NHL. Hepatosplenomegaly is a frequent feature, and the liver shows infiltration by polymorphous lymphoid cells of the T-cell class associated with angiogenesis.

Lennert's Lymphoma (WHO Classification: Lymphoepithelioid Cell Variant of Peripheral T-Cell Lymphoma, Not Otherwise Specified)

ICD-O Code 9702/3

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_96

Introduction

A distinct and highly aggressive variety of ATL is lymphoepithelioid cell lymphoma (LECL; synonym: lymphohistiocytic lymphoma according to the Kiel classification) or Lennert's lymphoma. LECL is characterized by a T-cell NHL (CD4+ phenotype) with a high content of epithelioid histiocytes/macrophages (Lennert and Mestdagh 1968; Feller et al. 1986). Several cases with this NHL phenotype have since been reported, although the question as to whether LECL is a true entity has not been settled (Burke and Butler 1976; Klapper et al. 2008; Chihara et al. 2010; Savage et al. 2011). Lennert's lymphoma is characterized by a high incidence of generalized lymphadenopathy, but rare extranodal disease (Patsouris et al. 1993). A fraction of the patients with LECL show an aggressive course (Kitamura et al. 2005) and may exhibit transformation into a large-cell T-cell lymphoma without the prominent epithelioid cell component (Patsouris et al. 1988). Today, Lennert's lymphoma is classified as the lymphoepithelioid cell variant of PTCL-NOS (2008 WHO Classification). The reason for treating this lymphoma in a separate paragraph is, on the one hand, that several older reports of liver involvement employed the term, Lennert's lymphoma, instead of the now accepted term, lymphoepithelioid cell variant of PTCL. On the other hand, there is evidence that Lennert's lymphoma forms a rare but distinctive entity among epithelioid cell-rich lymphomas, differing from other PTCL subtypes (Hartmann et al. 2011). Lennert's lymphoma can show chromosomal abnormalities not found in other T-cell lymphomas, such as translocation t(14;19)(q11.2;q13.3) (Shin et al. 2012).

Morphology

Histologically and cytologically, LELC is characterized by a dense T-cell-dominated infiltrate, the usually CD4-positive T cells (Feller et al. 1986) ranging in morphology from small cells to large or even pleomorphic cells. The diagnostic feature of LELC is the presence of numerous histiocytes/macrophages, many of them having epithelioid features. Epithelioid cells may, in some cases, dominate the picture and even form small aggregates resembling microgranulomas (Lennert and Mestdagh 1968; Patsouris et al. 1988).

Liver Involvement

Relatively few data are available in regard to hepatic changes in patients with LECL, although liver involvement may occur, presenting as hepatomegaly (Staples and Getaz 1977). In an autopsy study of an old patient succumbing to LECL, liver weight was not increased, but histology sowed extensive infiltration of the portal tracts of the liver by a lymphoid cell population that, in contrast to lymph node biopsies, lacked the typical epithelioid cell component (MacGillivray and Macintosh 1978). Another patient revealed multiple low-density liver nodules, and biopsies thereof displayed an infiltration of neoplastic lymphoid cells with a CD3+, CD4−, CD8+ immunophenotype (Kojima et al. 2003). There are few reports describing hepatic failure in rapidly progressive LECL, likely due to massive hepatic infiltration (Kojima et al. 2003).

Angioimmunoblastic T-Cell Lymphoma

ICD-O Code 9705/3

Introduction

Angioimmunoblastic T-cell lymphoma (AITL) is defined as a peripheral T-cell lymphoma which is characterized by signs of systemic disease and a polymorphous T-cell lymphoproliferations mainly involving lymph nodes, but also several extranodal organs. AITL shows a nearly constant association with EBV infection; however, the neoplastic T cell themselves are EBV negative. The postulated cell of origin is the CD4+ follicular helper T cell. This lymphoma, which accounts for about 15–20 % of T-cell lymphomas, mainly

occurs in middle-aged and elderly individuals, males and females being equally affected. Apart from lymph nodes, the bone marrow, spleen, liver, and other organs and tissues can be involved (Ferry 2002).

AITL was formerly designated as angioimmunoblastic lymphadenopathy with dysproteinemia (AILD), a rare clinical and pathologic entity defined as a malignant lymphoproliferative disorder, originally described under various terms, such as lymphogranulomatosis X, diffuse plasmacytic sarcomatosis, immunologic aberrations in idiopathic reticulosis, and immunoblastic lymphadenopathy (Lennert 1973; Lennert and Mohri 1974; Frizzera et al. 1974, 1975; Lukes and Tindle 1975; Radaszkiewicz and Lennert 1975). The original concept of AIDL was that of an atypical reactive process having an increased risk of progression to lymphoma. It is now evident that 80 % of cases of AIDL follow an aggressive course with short median survival and that the majority of cases are T-cell clonal disorders of still unknown etiology (Sallah and Gagnon 1998; Dogan et al. 2003). Therefore, most authors now accept that the disorder arises as a de novo peripheral T-cell lymphoma. In the WHO lymphoma classification, it is listed as a peripheral T-cell NHL, i.e., angioimmunoblastic T-cell lymphoma (AILT; ICD-O 9705/3), this term corresponding to AILD-TL, or angioimmunoblastic lymphadenopathy with dysproteinemia [AILD]-type T-cell lymphoma. AILT accounts for only 1–2 % of all NHL. The classification as a malignant T-cell NHL is also based on earlier reports showing malignant evolution of the disorder (Rubinstein and Dauber 1983). For example, about 10 years after the original description of AILD, a study on 172 patients (then with the diagnosis, "lymphogranulomatosis X") showed transformation into overtly malignant lymphoma proven at autopsy in 13.2 % of the cases (Knecht et al. 1985).

Clinical Features

Patients with this disorder present with frequently acute-onset fever, fatigue, rash (usually with pruritus), weight loss, generalized lymphadenopathy, hepatosplenomegaly, pleural effusion, ascites, arthritis, anemia (including anemia with positive Coombs test), quantitative changes in serum protein levels (polyclonal hypergammaglobulinemia), diverse immunologic disorders with signs of immunodeficiency, and sometimes hypocomplementemia (Frizzera et al. 1975; Pangalis et al. 1978; Cullen et al. 1979; Schauer et al. 1981; Ganesan et al. 1987; Higuchi et al. 1996; Ferry 2002; Dogan et al. 2003). In the setting of the International Peripheral T-Cell Lymphoma Project, it was found that, at presentation, generalized lymphadenopathy was present in 76 %, and 98 % of patients had stages III to IV disease (Federico et al. 2013). Immunodeficiency in patients with AILT is thought to be secondary to the malignant neoplastic process. Cells reactive for EBV antigen(s) are observed in the majority of cases and usually involve B cells (rarely in T cells as well); it is not yet known whether EBV plays a causal role in this lymphoma, or whether this infection follows the immunologic disorders associated with AITL.

Liver Involvement in AILT

As AILT is a generalized disorder, liver involvement is to be expected and in fact occurs in a significant proportion of the patients. However, exact quantitative data referring to prevalence are still sparse. Among 24 patients studied in an early report, hepatomegaly was present in 20 patients (Frizzera et al. 1975). Histologically, the liver is infiltrated by abnormal cells, but the morphology is usually less specific than that found in lymph nodes. In principle, the histologic appearance in extranodal sites are more unspecific but mimic some of the features seen in involved lymph nodes, including a polymorphous lymphoid cell infiltrate and, in particular, increased vascularity (Seehafer et al. 1980; Ghani and Krause 1985; Brown et al. 2001). The infiltrate may be difficult to interpret in some instances, diagnosis of involvement thus requiring specific methods including molecular clonality analysis (Murakami et al. 2001).

Infiltration of the liver tissue with atypical lymphoid cells with a T-cell immunophenotype is seen in part of the advanced cases (Knecht et al. 1985; Takai and Sanada 2000). As in lymph nodes, Reed-Sternberg-like cells representing large transformed blasts may occur in variable amounts. Based on 38 autopsy cases, liver involvement was found in 36.8 %. In addition to infiltrates of lymphocytes and plasma cells in a preferentially portal/periportal location, fibrosis and necrosis of liver tissue was occasionally seen. According to the previously employed subtyping, most of the liver lesions were either type II or type III (plasma cell predominant or mixed, respectively), while types I and IV (immunoblast predominant or epithelioid cell predominant, respectively) were rarer, and no case of type V infiltration (lymphocyte predominant) was found (Knecht et al. 1985).

The neoplastic cells are CD3+ and mostly phenotypically mature CD4+ T cells (Caulet et al. 1988; Lee et al. 2003b), usually admixed with normal CD4+ and CD8+ cells. The sometimes prominent plasmacytic component of the infiltrate is polytypic/polyclonal. A part of the neoplastic T cells are reactive for CD10 (Attygalle et al. 2004). Reactivity for CD10 (neutral endopeptidase, NEP; a cell surface metalloproteinase structurally related to CD26 and CD13) is very helpful in diagnosis, particularly in cases with low density of the neoplastic infiltrates, and in situations where the target cells are intermingled with numerous other cells, because CD10 is normally expressed in B cells with a typically high rate of apoptosis (Chu et al. 2000), but not by normal peripheral T cells or nodal peripheral T-cell lymphomas, whereas it is induced in T cells undergoing apoptosis, e.g., during HIV infection (Cutrona et al. 1999). Physiologically, CD10/NEP reduces the peptide concentration available for receptor binding and regulates a number of cell functions. In AILT, it seems that most, if not all, neoplastic T cells express CD10, but these CD10-reactive cells usually account for only a fraction of the infiltrate cells, ranging from about 5 % to about 30 %, depending on the infiltrate pattern type. The cells have an intricate spatial relation to CD21-positive dendritic cells, suggesting that the follicular dendritic cell network is important for lymphoma growth and expansion. However, in contrast to the lymph nodal lesions, CD21-reactive follicular dendritic cells are not easily detectable in hepatic infiltrates. If present, they prevail in infiltrated portal tract spaces. It may be added that the CD21+ cells occurring in AILT showing a dendritic morphology may not be "true" follicular dendritic cells, but rather fibroblastic reticulum cells expressing CD21 (Jones et al. 1998). This is, for the liver, of interest insofar as the cells sometimes found in portal tracts in AILT and showing a dendritic phenotype also express alpha SMA and/or desmin (myofibroblast-like cells), with or without cytokeratin expression. The lineage of these cells is not clear. Cytokeratin-positive reticulum cells, but of the extrafollicular interstitial type (CIRCs), have been described as a subset of fibroblastic reticulum cells (FBRCs) normally found in lymph nodes, and these cells co-express alpha SMA and desmin (Franke and Moll 1987; Gould et al. 1995). The relationship between these nodal cells and the hepatic cells has to be further studied.

As AILD-TL can be complicated by lymphoma-associated hemophagocytic syndrome (LAHS), hepatic macrophages having phagocytosed erythrocytes have been observed in this lymphoma (Takai and Sanada 2000). AILT is rarely associated with synchronous or metachronous Kaposi's sarcoma, with involvement of the liver (Diebold et al. 1980; Friedman-Birnbaum et al. 1985; Suster et al. 1987). Several other hepatic changes are known to be associated with AILT, including peliosis hepatis (Cadranel et al. 1990), nodular regenerative hyperplasia (NRH; Cadranel et al. 1990), perisinusoidal fibrosis (Sato et al. 1990; Cadranel et al. 1990), and sclerosing cholangitis (Wegerle et al. 1994). The pathogenesis of these associations is unknown. However, it has to emphasized that several agents that may be or have previously been administered in patients with AILT and other NHL are known to have peliosis and/or NRH as side effects, such as azathioprine (Lorcerie et al. 1990; Duvoux et al. 1991; Knudsen 2002), 6-thioguanine (Larrey et al. 1988). Peliosis hepatis also occurs in patients

with marasmus (Simon et al. 1988). AILT is, furthermore, sometimes associated with small- or large-vessel vasculitis with or without cryoglobulinemia (Simon et al. 1983; Molina Boix et al. 1984; Warlow et al. 1984; Sugaya et al. 2001). It is not yet known whether the liver may participate in these types of disorders.

Morphology of AILT

The term, angioimmunoblastic, is related to a specific lymph node histology generally characterized by a polymorphous T-cell infiltrate effacing the structure, prominent branching high-endothelial venules (so-called neovascularization), and a coarse network of CD21-reactive follicular dendritic cells (see below for more details) (Frizzera et al. 1974; Knecht et al. 1985; Feller et al. 1988; Leung et al. 1993; Jones et al. 1998). The origin of the neoplastic T-cell population seems to be a mature T-helper cell with variable expression of CD4 (Lee et al. 2003b). Typically, lymph node germinal centers can undergo regressive changes (burnt out germinal centers; Frizzera et al. 1974). Neoplastic T cells in AILT in most cases can be identified by the aberrant expression of CD10, also in cases with extranodal dissemination (Lee et al. 2003a; Attygalle et al. 2002; Attygalle et al. 2004). As in other types of NHL, a subset of cases show cells expressing the ZAP-70 protein (Admirand et al. 2004). Expression of CXCL13, a chemokine highly upregulated in germinal center T-helper cells, distinguishes AITL from other peripheral T-cell lymphomas (Grogg et al. 2006; Ortonne et al. 2007). Expression of nm23-H1, a gene involved in the regulation of tumor spread and metastasis, is detectable in part of AILT, and this expression is associated with poorer prognosis (Niitsu et al. 2003). It is important to recognize that AILT frequently harbors an expanded "monoclonal" B-cell population. Current evidence suggests that this phenomenon relates to B-cell clones that are driven by EBV infections that is found in over 95 % of all patients with AILT, i.e., representing a secondary change. In more detail, lymph node histology in AILT is characterized by the partial or complete effacement of architecture by a lymphoid infiltrate chiefly occupying the paracortical area. The sinuses are mostly spared, but an extranodal infiltrate component is frequently seen. Histology reflects a dynamic process leading from nodal lesions originally described as AILD, with diverse infiltrate components in addition to malignant T cells, to fully established T-cell lymphoma consisting of an almost pure cellular infiltrate. Depending on the time point of examination, several morphologic features can therefore be encountered. Based on histologic presentation, five subtypes had previously been distinguished, i.e., type I (immunoblastic predominance), type II (plasma cell predominance), type III (mixed cell type), type IV (epithelioid cell predominance), and type V (lymphocytic predominance) (Lennert et al. 1979). The histology of the lymph nodal lesions has been described in detail (Knecht et al. 1985). However, these categories may reflect some sort of observation windows in an ongoing evolution process of disease modified by secondary phenomena (such as recruitment of plasma cells and activated macrophages) and may therefore be rather artificial. In regard to the presence or absence of hyperplastic B-cell follicles/germinal centers previously emphasized to be important within a diagnostic setting, it is now recognized that the architectural changes in AILT seem to fall into three main patterns, i.e., *pattern I* (20 % of cases) with preservation of the lymph node architecture, hyperplastic B-cell follicles/germinal centers and an expanded paracortex harboring the abnormal T-cell population, a prominent vascular network, and increased numbers of macrophages, eosinophils, and plasma cells; *pattern II* (30 % of cases) with loss of nodal architecture, few depleted remnant follicles with concentrically arranged follicular dendritic cells, and a polymorphous nodal infiltrate; and *pattern III* (50 % of cases) with complete effacement of node architecture, lack of follicles, irregular proliferations of follicular dendritic cells, extensive neovascularization, and a polymorphous infiltrate (Ree et al. 1998, 1999; Attygalle et al. 2002; review: Dogan et al. 2003). These patterns again seem to represent dynamic

features of AILT, and phases with hyperplastic germinal centers may, therefore, indicate an earlier phase of disease rather than an unusual feature (Kojima et al. 2001). The marked vascular proliferative reaction seen in AILT, increasing over time, seems to be related to increased expression of vascular endothelial growth factor A both in lymphoma cells and endothelial cells (Zhao et al. 2004). Some cases of AITL show hyperplastic germinal centers (Ree et al. 1998). It has been suggested that this variant is a neoplasia with origin in the outer zone of the germinal center (Rodriguez-Justo et al. 2009).

Molecular Features

The neoplastic T cells in AITL show T-cell receptor rearrangement (Ren et al. 2008). AITL is associated with EBV infection, which may play a role in lymphomagenesis, although the neoplastic T cell does not express EBV. Histological progression of AITL has been shown to be associated with EBV and HHV6B viral load (Zhou et al. 2007). One subset of AITL apparently forming a distinct entity has been found to show clonal immunoglobulin gene rearrangement, associated with a component rich in large B cells and EBV infection (Abruzzo et al. 1993; composite AILD-TL and diffuse large B-cell lymphoma; AILD-TL rich in large B cells; Lome-Maldonado et al. 2002; Zettl et al. 2002; Battegay et al. 2004; Attygalle et al. 2007b). It has been proposed that EBV-associated large B-cell lymphoma may be a secondary event in AILD-TL via EBV infection or reactivation followed by clonal expansion of an immortalized EBV-infected B-cell clone (Willenbrock et al. 2007). AITL with a proliferation of large B cells shows CD10 expression (Attygalle et al. 2002, 2004, 2007a; Reichard et al. 2006). Recently, a recurrent inactivating mutation in RHOA GTPase, encoding p. Gly17Val, was detected in more than two thirds of AITL. The RHOA Gly17Val protein is thought to interfere with RHOA GTPase signaling (Palomero et al. 2014; Sakata-Yanagimoto et al. 2014; Yoo et al. 2014).

Posttransplant Lymphoproliferative Disorders (PTLDs)

97

Contents

Abstract

Posttransplant lymphoproliferative disorders (PTLDs) are lymphoid or plasmacytic proliferations that develop as a consequence of immunosuppression in recipients of a solid organ, a bone marrow, or stem cell allografts. PTLDs include a broad spectrum of lesions that include early lesions (plasmacytic hyperplasia, infectious mononucleosis-like lesion), polymorphic PTLD, monomorphic PTLD (B-cell and T-cell variants), plasmacytoma-like lesions, and classical Hodgkin lymphoma-type PTLD. PTLD usually presents between 6 and 17 months posttransplantation, in most cases with signs of systemic illness. Following liver transplantation, PTLD may develop in the liver, but overall this is a rare complication. The spectrum of hepatic PTLD after hepatic transplantation ranges from polymorphic PTLD to high-grade lymphomas and is most often related to EBV-infected lymphoid cells. Growth patterns comprise discrete nodules to diffuse patterns involving the entire organ.

Introduction

Posttransplant lymphoproliferative disorders (PTLDs) are, as defined in the 2008 WHO classification, lymphoid or plasmacytic proliferations that develop as a consequence of immunosuppression in recipients of a solid organ, a bone marrow, or stem cell allografts. PTLDs comprise a broad

Classical Hodgkin lymphoma-type PTLD (including Hodgkin lymphoma-like PTLD)

spectrum of lesions that are listed in Table 1 (Knowles et al. 1995; Swerdlow 1997; Chadburn et al. 1998).

PTLD typically presents between 6 and 17 months posttransplantation, usually with the signs of a systemic illness. The epidemiology of PTLD depends on several factors, including the immunosuppression modalities, the EBV infection status, and genetic factors. In the group of adult solid organ recipients, the prevalence of PTLD in part corresponds with the intensity of immunosuppression required. This depends on the type of graft, in that recipients of renal grafts, bone marrow grafts, and stem cell grafts have a low frequency of PTLD (1 % or less) and those with heart-lung/lung grafts or intestinal grafts the highest. Generally, PTLD is more common in children, most cases being related to posttransplantation primary EBV infection (Chadburn et al. 1997; Cesarman et al. 1998; Knowles 1998; Hauke et al. 2001; Capello et al. 2004; Dhillon et al. 2007; Choi et al. 2010; Jagadeesh et al. 2012; Khedmat and Taheri 2012; Michonneau et al. 2013). In solid organ recipients, more than 90 % of PTLD are of host cell origin, but PTLD derived from donor cells is also well-documented (Cherqui et al. 1993; Armes et al. 1994; Strazzabosco et al. 1997; Capello et al. 2009). The majority of PTLDs are associated with EBV infection and are therefore through to represent EBV-driven monoclonal or polyclonal B-cell or monoclonal T-cell proliferations (Jones et al. 2010). Up to 30 % or more of PTLDs are EBV negative, with a tendency to increase. Relatively few EBV-negative PTLDs are caused by KSHV/HHV8 (e.g., primary effusion lymphoma), although expression of KSHV was not always confirmed (Chen et al. 2009). PTLDs developing after solid organ transplantation usually involve the lymph nodes, gastrointestinal tract, lungs, and liver, and the allograft itself is often involved, particularly in early EBV-associated lesions.

Liver Involvement

Following liver transplantation, PTLD may develop in the liver, but overall this is a rare complication (Barkholt et al. 1991; Mulvihill et al. 1994; Pickhardt and Siegel 1999; Nuckols et al. 2000; Wu et al. 2001; Jain et al. 2002; Gouya et al. 2006; Avolio et al. 2007; Ulu et al. 2007). Hepatic PTLD in a grafted liver may be of donor origin (Spiro et al. 1993). The spectrum of PTLD after liver transplantation ranges from polymorphic PTLD to high-grade lymphomas and is most often related to EBV-infected lymphoid cells (Chapchap et al. 1991; Kamdar et al. 2011). In a follow-up of 32 patients with PTLD, hepatic involvement was detected in 69 % (Pickhardt and Siegel 1998). In this study, hepatic involvement appeared as discrete nodules or a diffuse infiltration of the liver substance. The discrete lesions were well circumscribed solitary or multiple masses that were hypoechoic with variable through transmission on sonography and low attenuation on CT images. In diffuse hepatic infiltration, the process appeared as low-attenuation regions against a background of enhancing parenchyma and vessels. Among 51 patients with PTLD after solid organ transplantation, the liver involvement amounted to 53 % (Pickhardt and Siegel 1999). In a study of 18 cases of PTLD post-liver transplantation, the average time interval between transplant and diagnosis of PTLD was 50 months. Seven patients developed solitary or multiple liver/liver hilar masses, measuring in diameter from 5 to 9 cm (Dhillon et al. 2007). An

analysis of 17 consecutive cases of PTLD following adult liver transplantation revealed that the grafted liver was involved in 41 % of patients (Patel et al. 2007). The intrahepatic PTLD masses may become large tumors (Strouse et al. 1996), sometimes reaching a diameter of 12 cm (Wu et al. 2001). Burkitt lymphoma-like PTLD of the monomorphous type was observed in the grafted liver following OLT (Ulu et al. 2007). In child with liver transplantation, liver nodules of PTLD underwent primary calcification (Lecouvet et al. 1996). Plasmacytoma-like PTLD has also been observed to develop in the liver graft following liver transplantation (Vishnu et al. 2011).

Histologically, PTLD may be difficult to distinguish from marked acute rejection, the morphologic presentations sometimes being similar (Howard et al. 1992). In PTLD developing in the grafted liver, EBV expression and a high mitotic count were significantly more often found than in samples of acute rejection (Rizkalla et al. 1997).

Types of PTLD

Early Lesions (Plasmacytic Hyperplasia/PH and Infectious Mononucleosis/IM-Like PTLD)

Early lesions are lymphoid cell proliferations that preserve the architecture of involved tissues, mainly in the lymph nodes, and produce mass lesions. Both PH and IM-like lesions prevail in younger individuals, often in children and adult solid organ recipients who had no prior EBV infection. Morphologically, PH is characterized by an infiltrate that has abundant plasma cells, few bland immunoblasts, and numerous small lymphocytes. The IM-like variety has the typical histologic features of infectious mononucleosis, with numerous immunoblasts intermingled with T cells and plasma cells. Immunohistochemically and molecularly, the population of B cells is polytypic/polyclonal. EBV is expressed in many, but all cases. PL-PTLD may be followed by plasmacytic malignancy (Dunphy et al. 2002).

Polymorphic PTLD (P-PTLD)

P-PTLD is a more common type among all PTLD variants, frequency ranging from 20 % to over 80 % of the cases. In the pediatric age group, this is the most common form of PTLD, frequently following primary EBV infection. In contrast to early lesions, infiltrates in P-PTLD efface the structure of the involved tissues. The infiltrates consist of immunoblasts, plasma cells, and small- to medium-sized lymphocytes, with the full maturation program of B cells. In extranodal compartments, P-PTLD forms destructive masses. B cells show clonal rearrangement of Ig genes, but less prominently in monomorphic PTLD.

Monomorphic PTLD (M-PTLD)

This group of PTLD contains the cases which fulfill the criteria of B-cell or T-cell/NK-cell neoplasms and are subclassified as such.

Plasmacytoma-Like Lesion (Posttransplant Plasma Cell Proliferative Disorders (PT-PCPDs)

A recently described form of PTLD is PT-PCPD (Richendollar et al. 2009), in part associated with HCV infection, which is known to be related to essential mixed cryoglobulinemia and some non-Hodgkin lymphomas. In two patients having undergone liver transplantation, PCPDs developing in the grafted livers were associated with actively replicating HCV in neoplastic plasma cells. Liver biopsies showed a predominantly portal tract infiltration by plasma cells that were CD138 positive with kappa light chain restriction indicating the neoplastic feature of the target cells. ISH for EBV-encoded RNA in liver tissues was negative, while ISH for HCV RNA demonstrated a positive signal in hepatocytes and a stronger signal in the plasma cells. This post-OLT primary hepatic PCPD is different from other forms of posttransplant lymphoproliferative diseases and is associated with a high level of monoclonal proteins in the peripheral blood, negativity for EBV,

and replicating HCV in the proliferating plasma cells, suggesting that HCV was pathogenically involved (Tun et al. 2004; Vishnu et al. 2011).

Classical Hodgkin Lymphoma-Type PTLD (CHL-PTLD)

This is the least common of the major PTLD forms. It most commonly develops in renal graft recipients and is almost always EBV positive. Histologically, CHL-PTLD must fulfill the known criteria for classical Hodgkin disease, including the confirmation by immunohistochemistry (both CD15 and CD30 expression) (Nalesnik et al. 1993; Pitman et al. 2006; Semakula et al. 2006; Rohr et al. 2008; Krishnamurty et al. 2010). A part of these conditions are termed Hodgkin lymphoma-like PTLD (HL-like PTLD), due to cellular and immunohistochemical features different from those in classical Hodgkin lymphoma. HL-like PTLD is almost always EBV associated, similar to Hodgkin lymphoma developing in patients with HIV infection or immunosuppressed patients following chronic low-dose methotrexate administration. HL-like PTLD has been grouped together with CHL-PTLD, but there is still controversy as to whether it is truly a form of HL or whether it should rather be classified as a form B-cell PTLD (Ranganathan et al. 2004; Pitman et al. 2006). There is, in fact, recent evidence that HL-like PTLD represents a distinct clinicopathologic entity with an aggressive clinical course (Krishnamurthy et al. 2010).

EBV-Positive T-Cell Lymphoproliferative Diseases of Childhood

ICD-O codes (provisional) 9724/3 and 9725/3

Introduction

In the 2008 WHO tumor classification, T-cell lymphoproliferative disorders of childhood that are associated with EBV are known as two distinct variants, both mainly occurring in Asians and in natives from Central and South America. The first form is Hydroa vacciniforme-like lymphoma, a cutaneous T-cell neoplasm with an indolent course over longer time periods. The second form is systemic EBV-positive T-cell lymphoproliferative disease (STLPD) of childhood, with a fulminant course (review: Hong et al. 2013).

Hydroa vacciniforme-like lymphoma (ICD-O 9725/3) develops in children and adolescents in Asia and Central/South America and is related to sensitivity to insect (mosquito) bites and sunlight sensitivity. A defective immune response directed against EBV plays a pathogenetic role. Patients present with a papulovesicular eruption that proceeds to ulceration and scarring. Late in disease, systemic signs may develop, including hepatosplenomegaly and lymphadenopathy. The tumor cells are cytotoxic T cells that reveal T-cell receptor rearrangement (Yachie et al. 2003; Wada et al. 2012).

Systemic EBV-positive T-cell lymphoproliferative disease of childhood (STLPD; ICD-O code 9724/3; synonyms: sporadic fatal infectious mononucleosis; severe chronic active EBV infection/CAEBV; Kimura 2006) is a severe and life-threatening systemic disease of children and young adults, predominantly males, characterized by an aggressive neoplastic proliferation of cytotoxic T cells and EBV infection of B cells. Most patients are from Japan and Taiwan, but few patients are from Western countries. Exceptionally, adult patients are affected (Abdul-Ghafar et al. 2011). Clinically, the patients show a rapidly progressive illness with multiorgan involvement and failure, often with sepsis, death occurring within days to weeks. One particularly aggressive variant reveals high fever, pancytopenia, marked lymphadenopathy, and hepatosplenomegaly. In contrast to the standard variant, EBV in this dangerous variant infects T cells and NK cells, T cells stimulated to become a monoclonal population and then a frankly malignant neoplastic cell population (Craig et al. 1992; Dolezal et al. 1995; Ohshima et al. 2008; Ohga et al. 2011; Rodriguez-Pinilla et al. 2011; Wang et al. 2012).

Morphology

Infiltrating cells are small T cells without relevant atypia. Few patients show larger and pleomorphic cell forms. The characteristic immunophenotype is a positive reaction for CD2, CD3, and, in forms secondary to acute primary EBV infection, CD8, whereas T cells in patients with severe CAEBV are CD4 positive. The cells show T-cell receptor rearrangement. All cells contain EBV in a clonal episomal form.

Liver Involvement

In EBV-positive STLPD of childhood, the liver is the most commonly involved inner organ (review: Yoshii et al. 2012). Prominent hepatomegaly, liver dysfunction, and eventually liver failure are typical features (Chan et al. 1992; Quintanilla-Martinez et al. 2000; Hauptmann et al. 2001; Liu et al. 2008; Salama et al. 2008; Rodriguez-Pinilla et al. 2011; Sevilla et al. 2011), followed by the spleen, lymph nodes, bone marrow, skin, and lung. Liver biopsies show CD3+ CD8+ lymphoid T cells in sinusoids, sometimes in high numbers (Abdul-Ghafar et al. 2011). These sinusoidal lymphocytes are almost invariably EBER positive. Marked hemophagocytosis may be observed (Quintanilla-Martinez et al. 2000).

Hepatobiliary Castleman Disease

98

Contents

Abstract

Castleman disease (CD), which can involve the hepatobiliary tract, is a complex spectrum of lymphoid proliferations that is divided into two clinical subtypes, i.e., localized CD (LCD) and multicentric CD (MCD). Both LCD and MCD can occur in one of several clinical and histological types or patterns. The main histologic presentations include the hyaline-vascular type of CD (a standard subtype and stroma-rich or angiomyoid subtype), a plasmacellular type of CD, and mixed patterns. MCD can also occur as an aggressive plasmablastic variant. Hepatomegaly is a common feature in patients with CD, but the histologic substratum is unknown in many cases. MCD produces atypical, mixed cellular infiltrates in the liver, consisting of lymphoid cells, macrophages, and plasma cells mainly located in portal tracts. Lymph follicles with germinal centers can develop. Localized CD can develop deeply in the liver substance or the porta hepatis. A very rare manifestation of hepatobiliary CD is a plasma cell-rich variant confined to the liver.

Localized and Multicentric Castleman Disease (LCD and MCD)

Introduction

Lymph node disorders characterized by both follicular hyperplasia and increased vascularity were originally termed hypervascular follicular hyperplasia (HFH; Rywlin et al. 1966). In the fully developed form, this histologic pattern has received the eponymic designation Castleman disease. Castleman disease (CD) is a rare and still poorly understood, heterogeneous, so-called atypical proliferative disorder of the lymphatic system, first described in 1954 (Castleman and Towne 1954). Synonyms for at least part of the cases of CD comprise angiofollicular lymph node hyperplasia (ALNH), giant lymph node hyperplasia, follicular lymphoreticuloma, and giant lymphoid hamartoma (reviews: Frizzera 1988; Shahidi et al. 1995; McCarthy et al. 1995; Bowne et al. 1999; Palestro et al. 1999; Maslovsky et al. 2000; Van den Berge et al. 2002; Martino et al. 2004; McClain et al. 2004; reviews: Dham and Peterson 2007; Roca 2009). The lesions described in the early literature are now known as the hyaline-vascular type of CD, but later, a much rarer variant, the plasma cell type of CD, was identified that is also localized but bears very different clinical features. Later, it was recognized that CD can occur in a multicentric pattern, and more recently, an aggressive "plasmablastic" variant of multicentric CD was recognized.

CD has no predilection for either sex, and most patients are in the second and third decades of life, with rare occurrence in children younger than 15 years of age. CD is usually manifested as an asymptomatic, solitary mediastinal tumor (40–70 % of cases), but clinical manifestations of CD can vary from a localized mass (unicentric CD; see below) to a systemic disorder (multicentric CD; see below) with widespread lymphadenopathy, fever, autoimmune manifestations, and recurring infections (Herrada et al. 1998; Maslovsky et al. 2000; Talat and Schulte 2011; Dispenzieri et al. 2012). Meta-analytic data showed that peripheral lymphadenopathy is present in 100 %, abdominal lymphadenopathy in 53 %, mediastinal lymphadenopathy in 47 %, splenomegaly in 79 %, hepatomegaly in 63 %, edema or pleural effusions in 48 %, and skin rash in 37 % (Greiner et al. 2000). CD may, depending on the variant or form, remit, be chronic and nonprogressive, or may rapidly progress and be fatal, indicating the marked clinical heterogeneity of this group of disorders. Localized childhood CD may be associated with iron deficiency anemia, probably involving the IL-6/hepcidin pathway (Arlet et al. 2010).

Classification of CD

CD is divided into two clinical subtypes, i.e., *localized CD* (*LCD*) and *multicentric CD* (*MCD*) (McCarthy et al. 1995; McClain et al. 2004). LCD is also termed unicentric CD, and MCD, generalized CD. In some reports, MCD is listed under the term multicentric angiofollicular lymph node hyperplasia (MAFH). Both LCD and MCD can occur in one of several clinical and histologic types or patterns (Table 1). As the etiology and pathogenesis of these forms and variants differ considerably, this classification is not final and may undergo marked changes in the future. In particular, localized and multicentric forms may represent two different diseases. The histologic patterns of the subtypes are described in more detail below.

Table 1 Clinical and histologic subtypes of Castleman disease (CD)

Clinical subtypes
Localized (unicentric) CD (LCD)
Multicentric CD (MCD)
Not otherwise specified
Plasmablastic variant of MCD
Histologic subtypes
Hyaline-vascular type CD (HVCD)
"standard" subtype
Stroma-rich subtype (in part with angiomyoid proliferative lesion)
Plasma cellular type CD
Mixed histopathologic pattern

Hepatobiliary Pathology in Castleman Disease

Hepatomegaly and Diffuse Infiltration of the Liver

Hepatomegaly sometimes associated with hepatalgia is a frequent feature of CD, found in about two thirds of the cases (Bowne et al. 1999; Greiner et al. 2000; Maloisel et al. 2003; Mura et al. 2011), but the histologic substratum is unknown in most cases. MCD has been demonstrated to produce atypical, mixed infiltrates of the liver (Rais et al. 1990). They consist of accumulations of lymphocytes, macrophages (sometimes epithelioid cells) and plasma cells chiefly in the portal tracts (Fig. 1), with or without associated lymph follicles with large germinal centers.

Focal Hepatic Infiltration and Hepatic Tumors in CD

Localized CD may develop deeply in the liver substance or the porta hepatis as localized space-occupying and sometimes hypervascular lesions (Rahmouni et al. 1992; Mosnier et al. 1996; Peck and Lum 1996; Cirillo et al. 1998; Uzunlar et al. 2000; Meador and McLarney 2000; Maloisel et al. 2003; Przkora et al. 2003; Erkan et al. 2004; Jang et al. 2012; Miyoshi et al. 2013) that may mimic other tumorous hepatic lesions. Localized CD can develop in a hilar/perihilar location (Peck and Lum 1996; Karami et al. 2010; User et al. 2011) and can cause biliary obstruction (Przkora et al. 2003). In one patient, a hyaline-vascular CD of the liver produced a mass that mimicked hepatocellular carcinoma (Jang et al. 2012). CD can involve lymph nodes around the porta hepatis and along the common bile duct, causing biliary obstruction (Al-Salamah et al. 2005).

The plasma cell variant of CD confined to the liver has rarely been reported (Mosnier et al. 1996). In one young female patient with slight polyclonal hypergammaglobulinemia, ultrasonography and CT revealed a 2 cm diameter nodule in the liver. The resection specimen showed a gray-white, nodular, ill-defined lesion histologically composed of a stellate fibrous scar, which delimited small hepatocyte nodules without lobular organization. Numerous hyperplastic lymph follicles with large germinal centers were observed in the fibrotic areas. The interfollicular area was characterized by increased vascularity with short, closely spaced venules containing high endothelial cells and by a moderate to dense polytypic plasmacytic infiltration, some of the plasma cells exhibiting Russel bodies (Mosnier et al. 1996). Lesions of the liver in MCD may present in the form of multiple nodules visualized by ultrasound and CT. In an MCD patient with this pattern undergoing hepatic transplantation, the explant showed large fibrotic masses resembling the hyaline-vascular germinal centers that have previously been found in a lymph node involved with hyaline-vascular CD (Maloisel et al. 2003). In another female patient, a tumorous and partly calcified lesion of up to 13 cm diameter was detected in the porta hepatis, abutting the left lobe of the liver. Histology showed a mixed histologic pattern of CD (Cirillo et al. 1998). In a further case of tumorous CD localized to the porta hepatis, the histologic pattern was that of hyaline-vascular CD. The resected specimen revealed a partly nodular mass measuring up to 3.5 cm with a characteristic histology (Uzunlar et al. 2000). Localized

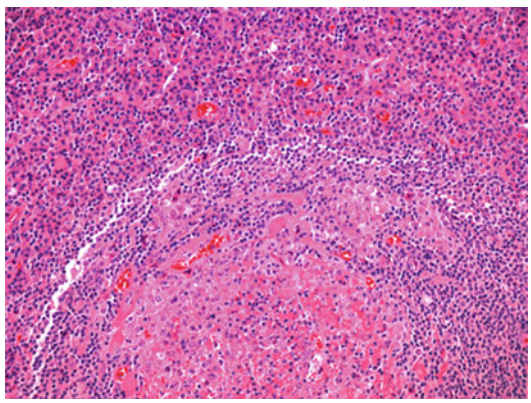

Fig. 1 Castleman disease of the liver. This case shows a focal epithelioid cell reaction (hematoxylin and eosin stain)

hyaline-vascular CD was also found as a nodule in the liver parenchyma (Miyoshi et al. 2013) and in the hepatoduodenal ligament (Sato et al. 2006).

Castleman Disease of the Bile Duct System

In very rare cases, CD manifests in the biliary tract. A case of hyaline-vascular CD of the extrahepatic bile duct, causing obstructive jaundice, was described. There was no evidence of disease elsewhere (Kalimuthu et al. 2013).

Vascular Neoplasia (VN) Complicating HVCD

The features of this unique tumor, which is different from Kaposi sarcoma (Gerald et al. 1990) have been described above. Among the seven patients described by the authors in 1990, two patients developed metastatic disease, in both instances involving the liver, with numerous nodules involving large areas of the liver (see Fig. 4 in the work of Gerald et al. 1990).

Microvascular and Regenerative Lesions of the Liver in CD

CD can be associated with marked hepatic sinusoidal dilatation causing hepatocyte plate atrophy (Featherstone et al. 1990; Curciarello et al. 1998; Kakar et al. 2004), with peliosis hepatis (Sherman et al. 1992) or peliosis hepatis combined with perisinusoidal fibrosis and nodular regenerative hyperplasia of the liver (Molina et al. 1995), a combination of lesions known to occur in several NHL (see the respective paragraphs). Interestingly, part of these changes may regress upon resection of the tumor, suggesting a humoral factor produced by CD lesions (Curciarello et al. 1998). In fact, it was shown that nodular regenerative hyperplasia of the liver in CD may be mediated by interleukin-6 (Kiyuna et al. 2005).

Amyloidosis in CD

The liver may be involved in those patients developing generalized amyloidosis in Castleman disease, causing hepatomegaly (Yamagata et al. 2006). By use of 123I-SAP scintigraphy and liver biopsy, hepatic accumulation of AA amyloid has been detected in such patients (Lachmann et al. 2002). A perihepatic manifestation of amyloidosis in Castleman disease has also been described (Ikeda et al. 1997).

Amyloidosis as a complication of CD is now well established and has been reported several times, but the pathogenic relationship has not yet been elucidated (West et al. 1989; Ordi et al. 1993; Tanaka et al. 1995; Ikeda et al. 1997; Curioni et al. 2001; Derici et al. 2002; Lachmann et al. 2002; review of the literature: Altiparmak et al. 2002; Gholam et al. 2003). Amyloidosis can develop in the localized form of CD and was found to regress following tumor removal (Androukali et al. 2007). One of the acute phase protein components of AA amyloid, SAA, has been shown to be elevated in Castleman disease (Ikeda et al. 1997) and to decrease after resection of the primary lesion (Perfetti al. 1994; Lachmann et al. 2002). In AA amyloidosis, a sustained high plasma concentration of SAA is a prerequisite for the development of amyloid accumulation, but it is not sufficient, because amyloid affects less than 10 % of those individuals with chronic inflammatory disease. One factor thought to modify amyloidogenic responses is IL-6, which is one of the major stimulants of acute phase protein synthesis by hepatocytes. The germinal centers of hyperplastic lymphoid follicles in the plasma cell variant of Castleman disease secrete large amounts of IL-6, and this response may affect pathways resulting in AA amyloidosis in this disorder.

Differential Diagnosis

Differential diagnosis includes lymphoid hyperplastic lesions other than CD, lymphocyte-predominant forms of Hodgkin disease, and several types of non-Hodgkin lymphomas.

Subtypes of CD and Their Histopathology

Localized (Unicentric) CD/LCD

LCD, the more common variant, manifests as a solitary mass that may be circumscribed or infiltrative, with associated lymphadenopathy confined to one lymph node or involving an entire nodal group/area. LCD of the hyaline-vascular type (HVCD) chiefly occurs in children and young adults (median age in the 30s), usually with manifestations in the mediastinum or the mesenteric area, sometimes with markedly enlarged peripheral or abdominal lymph nodes. More than 90 % of these patients do not have constitutional symptoms at presentation It usually follows a benign course after surgery (Bowne et al. 1999). LCD of the plasma cell type (PCCD) also preferentially occurs in children and young adults but overall in a younger age group (median age in the 20s). In contrast to HVCD, the mass usually consists of an aggregate of enlarged lymph nodes, most frequently in the mediastinum or the abdomen. Unlike HVCD, patients with PCCD often show constitutional symptoms and signs, and up to 90 % exhibit hematologic disorders, such as anemia and leukocytosis, and many develop hypergammaglobulinemia and hypoalbuminemia. It is the plasma cell variant of CD that, in contrast to HVCD, shows abnormal IL-6 expression by cells in the germinal centers and elsewhere in nodes, thought to hold an important position in pathogenic pathways.

Multicentric CD/MCD

MCD is rarer, and patients are older (median age in the 50s) and have multicentric manifestations. MCD is clinically characterized by cyclic episodes of lymphadenopathy, hepatosplenomegaly, fever, anemia, leukocytosis, hypergammaglobulinemia, hypoalbuminemia, skin rash, and rarely tumor lysis syndrome (Frizzera et al. 1983; Kessler 1985; Weisenburger et al. 1985; Peterson and Frizzera 1993; Lee et al. 2004). HIV-associated MCD is a rare lymphoproliferative disorder, the incidence of which seems to be increasing in the highly active antiretroviral therapy era (Bower et al. 2011; Reddy and Mitsuyasu 2011). It appears to occur more frequently in older HIV-positive individuals and well-preserved immune function (Powles et al. 2009). A significant fraction, or even most cases, of MCD are caused by KSHV/HHV8 (Polizzotto et al. 2012; Uldrick et al. 2012). It is a disease requiring chemotherapy and carries a worse prognosis, as subsequent infection of malignancy may lead to death (Herrada et al. 1998). Whereas LCD mainly presents with a mass effect, MCD is well known to manifest with constitutional symptoms and signs, multicentric lymphadenopathy, hepatosplenomegaly in many cases, and abnormal laboratory findings, including anemia and polyclonal hypergammaglobulinemia (Weisenburger et al. 1985). MCD follows one of four courses: relapse and remission, rapidly fatal disease, development of malignant lymphoma and/or Kaposi sarcoma, or stable and persistent disease (Weisenburger et al. 1985; Peterson and Frizzera 1993; Abdel-Reheim et al. 1996; Advani et al. 1999; Larroche et al. 2002 (with review of the literature); Oksenhendler et al. 2002). One subset of MCD is characterized by a "plasmablastic" cell population (plasmablastic-type MCD; PB-MCD) distinguished by the expression of HHV-8 latent nuclear antigen.

A disease occurring in Japan related to multicentric CD is characterized by thrombocytopenia, anasarca, fever, reticulin fibrosis, and organomegaly. The disorder shows myelofibrosis, microcytic anemia, signs of generalized inflammation, and renal dysfunction. Lymph nodes exhibited mixed or hyaline-vascular CD. This condition is termed TAFRO syndrome or Castleman-Kojima disease (Kawabata et al. 2013; Masaki et al. 2013).

Histologic Patterns of CD

Histologically, CD can be divided into three major patterns, i.e., the more common *hyaline-vascular type CD* (70–90 %), the less common *plasma*

cellular or plasma cell type CD, and a *mixed histopathologic pattern*. There is an association between these histologic patterns and the biology of disease. The histologic patterns can, in principle, occur both in localized and multicentric CD, however with some differences in prevalence.

Hyaline-Vascular CD

The hyaline-vascular type is commonly found in localized CD but has also been found in multicentric CD (Erkurt et al. 2009). This form of CD has been regarded as a reactive hyperplastic lesion, but recent studies have found monoclonality and cytogenetic abnormalities in part of these cases (Chang et al. 2014). In the hyaline-vascular type of CD (HVCD; synonym: Castleman disease of hyaline-vascular type, CDHV), the histologic hallmark consists of dense and in part venous vascular channels located to the interfollicular area and small, hyalinized follicles, in lymph nodes without distinction between cortical and medullary nodal architecture. The follicles are surrounded by circumferentially arranged layers of small lymphocytes, resulting in an "onion-skin" aspect in the mantle zone with radially arranged capillaries often penetrating the germinal centers. Frequently, the germinal centers contain deposits of hyaline connective tissue with a characteristic whorled appearance (Weisenburger et al. 1985; Carbone et al. 1986; Shahidi et al. 1995; Ghosh et al. 2010). A central stellate fibrosis visible in three-phase dynamic CT can occur in HVCD (Ota et al. 1997). In addition, this variant displays either an expanded, disrupted follicular dendritic cell network or multiple tight collections of follicular dendritic cells, whereas the arrangement and distribution of follicular dendritic cells in the plasma cell variant resemble those in normal follicles (Nguyen et al. 1994). The distinct features of follicular dendritic cells may be related to differential epidermal growth factor receptor expression in these cells, a shared feature of CD and follicular dendritic cell sarcoma (Sun et al. 2003). Whether the abnormally arranged follicular dendritic cells in CD express estrogen receptor alpha, as these cells do in lymph nodes (Sapino et al. 2003), is not yet known. Based on the distinct cellular composition of the interfollicular area in HVCD, resulting in considerable morphologic diversity of this tissue compartment (Danon et al. 1993), cells other than lymphocytes, plasma cells, and vascular cells have been studied in more detail. Specifically, a proliferation of dendritic-shaped or spindle cells was detected, a cell population divided into two types according to the immunostaining phenotype: CD68-reactive histiocytoid cells and smooth muscle actin-reactive myoid cells. Cases of HVCD with abundance of such cells were termed stroma-rich variants of HVCD (Danon et al. 1993). Similar proliferative lesions in the interfollicular area with either angiomyoid features or involving follicular dendritic cells were reported somewhat later and were predominantly found in female patients, and only in adults, frequently in an abdominal location (Lin and Frizzera 1997). Subsequently, cases of stroma-rich HVCD with marked and probably hyperplastic angiomyoid proliferative lesions consisting of SMA-positive but CD34- and desmin-negative spindle cells were reported (Izumi et al. 2002). HVCD is frequently associated with intra-lesion calcification, sometimes with a ramification or arborizing pattern (Sadamoto et al. 1998; Meador and McLarney 2000). In cases with marked fibrosis, a calcifying lesion (calcifying fibrous pseudotumor) may develop (Dargent et al. 1999). Most hyaline-vascular lesions are intrathoracic (Keller et al. 1972), with the anterior mediastinum as the most common site of occurrence. Although more than 90 % of the patients with hyaline-vascular CD are asymptomatic, symptoms caused by tracheobronchial compression may arise.

Plasma Cell Type CD

The plasma cell type of CD (PCCD) was first described in lymph nodes (Flendrig and Schillings 1969). It is characterized by normal to large germinal centers, no marked vascularization and hyalinization, occasional remnants of sinuses

between follicles, and a dense infiltration by plasma cells lying in sheets in the interfollicular areas (Keller et al. 1972). In PCCD associated with HHV8 infection, a distinct pattern of lymphoid follicle/germinal center dissolution, resulting from blurring of the mantle zone boundary where HHV8-infected lymphocytes are located, had been observed (Amin et al. 2003). The plasma cell type of CD is clinically more aggressive, commonly with involvement of multiple enlarged lymph nodes (Keller et al. 1972). Patients with the multicentric plasma cell variant of CD are generally older than those with plasma cellular LCD. In the localized plasma cell variant of CD, clonal cytogenetic abnormalities were detected, the clonal cells being non-lymphoid but rather stromal, dendritic, or endothelial in origin (Reichard et al. 2011).

A recently described clinicopathologic entity is the "plasmablastic" type of MCD (PB-MCD; Dupin et al. 2000). There is a clear association between PB-MCD and KSHV/HHV-8 infection. An increased pathogenicity of HHV-8 as well as an exacerbation of MCD have specifically been described in HIV-infected individuals and in the setting of AIDS (Suda et al. 2001; Schultz 2001; Aaron et al. 2002). The virally encoded production of IL-6 (vIL-6) in HHV-8 infection is regarded as an important driving force in the pathogenesis of this variant of MCD. vIL-6 not only contributes to plasmacytosis but can also induce VEGF and thus enhance angiogenesis (Aoki et al. 1999). In part of the patients, elevated levels of human IL-6 have been identified, apparently linked to increased IL-6 production in the interfollicular area in MCD and by dendritic cells located inside the enlarged follicular germinal centers (Yoshizaki et al. 1989; Leger-Ravet et al. 1991). Many of the HHV-8-infected cells also express the human IL-6 receptor, further supporting the significance of an IL-6-mediated pathway (Du et al. 2001). The expansion of target cell populations may also be affected by the function of HHV-8 K15 protein that can form a homodimer with an antiapoptotic protein, HAX-1 (Sharp et al. 2002). One variant of MCD is immunohistochemically characterized by numerous IgG4-positive plasma cells, resulting in a phenotype having overlapping features with IgG4-associated systemic sclerosing disease (Sato et al. 2010).

Neoplastic Lesions Associated with Castleman Disease

Lymphoproliferative Disorders

LCD and MCD are associated with the synchronous or metachronous development of a whole spectrum of tumorous lesions. LCD, including the plasma cell variant, can be complicated by NHL, albeit less commonly than the MCD counterpart, and a part of the NHL are plasma cell-rich marginal zone B-cell NHL resembling plasmacytoma (Kojima et al. 2002). Hypervascular follicular hyperplasia (HFH) associated with LCD can evolve into sometimes large angioproliferative and mass-producing lesions that may later behave aggressively (Gerald et al. 1990). It has been proposed that this vascular proliferative response in lymph nodes and in extranodal areas is related to increased production of vascular endothelial growth factor by cell systems of CD (VEGF; Nishi and Maruyama 2000).

MCD is more frequently associated with malignancy, especially Kaposi sarcoma (Dickson et al. 1985; De Rosa et al. 1989) and several types of NHL (Dickson et al. 1985; Vasef et al. 1992; Abdel-Reheim et al. 1996; Orcioni et al. 1998; Advani et al. 1999; Ascoli et al. 2001; Larroche et al. 2002 (with review of the literature); Oksenhendler et al. 2002; Nozawa et al. 2002; Theate et al. 2003; Vanizelos et al. 2004), including plasmacytoma (Schlosnagle et al. 1982; Kurihara and Hashimoto 1983; Wilkinson and Forrester-Wood 2003). NHL is clearly more often associated with MCD, its diagnosis being concurrent with CD diagnosis or occurring within 2 years. B-NHL is predominant (about 70 %), and mantle cell NHL represents about 40 % of the B-NHL. Hodgkin disease (HD) chiefly occurs in LCD of the plasma cell type, usually in the same nodal areas (Zarate-Osorno et al. 1994; Drut 1996). HD is of interfollicular or nodular sclerosis types, and its clinical course seems to be better than NHL (Larroche et al. 2002). Interestingly,

MCD can result in a population of immunoblastic/plasmablastic neoplastic cells (MCD-associated plasmablastic lymphoma) that localize to the body cavities, thus inducing the PEL phenotype (Ascoli et al. 2001). This observation suggests a link between MCD and PEL and suggests that MCD is a prelymphoma state. Further neoplastic lesions known to complicate CD, and more commonly the hyaline-vascular variant, are angiomyoid and follicular dendritic cell proliferative lesions, in particular follicular dendritic cell tumor, which is of specific interest in the light of the pathogenic involvement of follicular dendritic cells and other stromal cells in CD lesions (Chan et al. 1994, 2001; Saiz et al. 1997; Katano et al. 1997; Lin and Frizzera 1997; Fornelli et al. 1998; Perez-Ordonez and Rosai 1998; Desai et al. 2000; Yamamoto et al. 2004). A disorder sometimes regarded as identical to MCD is idiopathic plasmacytic lymphadenopathy with polyclonal hypergammaglobulinemia (IPL). However, IPL has a significantly better 5-year survival rate than MCD, and none of 16 reported patients developed Kaposi sarcoma or a B-cell NHL or were KSHV positive, suggesting that IPL is distinct from MCD reported in Western countries (Kojima et al. 2004).

Vascular and Spindle Cell Tumors in Castleman Disease

The most well-established vascular tumor associated with CD is Kaposi sarcoma. Its histologic differential diagnosis comprises fibrovascular lymph node lesions mimicking hypervascular forms of CD, including angioproliferative lymphadenopathy developing in Epstein-Barr virus infection (Kojima et al. 2003). In addition to Kaposi sarcoma, the most intriguing vascular tumorous lesion evolving in CD is the so-called vascular neoplasia (VN; spindle cell sarcoma complicating Castleman disease; Gerald et al. 1990; Kakiuchi et al. 2002). It is characterized by a vascular neoplastic phenotype that is clearly different from Kaposi sarcoma. Based on seven cases (Gerald et al. 1990), the following features are characteristic of this distinct lesion: (1) combined features of HVCD/HFH and vascular neoplasia; (2) predominant location in the retroperitoneal space; (3) the vascular neoplastic component seems to arise from the interfollicular hypervascular regions of HVCD and is characterized by swirling fascicles of spindle, oval, and epithelioid cells, sometimes forming well-defined lumina with or without red blood cells, the lesions in part forming nodular structures; (4) constant presence of significant nuclear atypicality and pleomorphism in the absence of markedly elevated mitotic activity; (5) hemorrhage, fibrosis, and necrosis in most cases; and (6) recurrence of disease with metastases in the minority of the cases. Furthermore, lymphonodal spindle cell tumors occur in conjunction with mycobacterial infection in HIV-positive patients ("mycobacterial pseudotumors"; Logani et al. 1999), lesions not to be confounded with Kaposi sarcoma with mycobacteria. The abnormal vascular proliferative response in some of the lesions developing in HHV8-associated CD may be directly related to HHV-8 infection of target cells. It has been demonstrated that HHV-8 is localized to lymphonodal subcapsular spindle cell proliferations (where early intranodal Kaposi sarcoma initiates) and endothelial cells in CD (O'Leary et al. 2000). On the other hand, Kaposi sarcoma-associated herpesvirus-encoded interleukin-6 (vIL-6), a multifunctional cytokine that is elevated in HHV-8-associated CD, and IL-6 that may be increased in CD (Yoshizaki et al. 1989; Hsu et al. 1993; Foss et al. 1997) seem to exert a pro-angiogenic activity (Aoki et al. 1999) and are therefore thought to play an important role in the pathogenesis of certain HHV-8-associated disorders, including CD with hypervascular features and associated fibrovascular lesions. Furthermore, vascular endothelial growth factor (VEGF) is elevated in CD (Nishi and Maruyama 2000), and is mainly expressed in spindle cells, most likely myofibroblasts, located to follicular structures in CD, suggesting that vascularization of germinal centers in CD may be a consequence of abnormal local VEGF production (Foss et al. 1997). Secretion of VEGF and IL-6 was also observed in a distinct CD-associated vascular tumor, spindle cell sarcoma complicating Castleman disease, and so-called vascular neoplasia (Kakiuchi et al. 2002).

Apart from endothelial cells, distinct mesenchymal and/or myoid cell types are involved in a growing spectrum of fibrous, myoid, and vascular tumors and tumor-like lesions in several organs and tissues, and some of them may occur in the context of Castleman disease. They include (1) the so-called vascular neoplasia developing in CD (VN; spindle cell sarcoma complicating CD; Gerald et al. 1990); (2) pericyte-rich vascular neoplasms (Chan et al. 1994); (3) a group of lymphonodal myofibroblastic nodular lesions, comprising palisaded myofibroblastoma/intranodal hemorrhagic spindle cell tumor with amianthoid fibers/features (Michal et al. 1992; Padberg et al. 1994; Rossi et al. 1995; Rahimi et al. 1995; Creager and Garwacki 1999); (4) angiomyomatous lymphonodal hamartoma (Sakurai et al. 2000); (5) fibrohistiocytic nodular lesions developing in Castleman disease (Kurotaki et al. 1993); (6) angiomyoid proliferative lesions in stroma-rich HVCD (Izumi et al. 2002); (7) cutaneous glomeruloid hemangioma in Castleman disease associated with POEMS syndrome (Chan et al. 1990); (8) sclerosing angiomatoid nodular transformation (SANT) of the spleen (Martel et al. 2004), previously termed "cord capillary hemangioma" (Krishnan et al. 1993); and (9) a growing group of lesions consisting of cells probably belonging to a myofibroblast lineage, including pseudoangiomatous stromal hyperplasia (PASH) of the breast (Powell et al. 1995).

At least one cellular component involved in the pathogenesis of nodular spindle cell lesions of lymph nodes consists of a nodal stromal cell with myoid features, probably representing a subset of reticular cells in lymph nodes and the spleen. The true nature of such myoid cells still awaits characterization. One form of myoid cells is reactive for smooth muscle myosin and occurs mainly in lymph follicles and especially in germinal centers but is not present in the interfollicular area (Pinkus et al. 1986). Desmin negativity of interfollicular myoid cells has later been confirmed (Izumi et al. 2002). However, another study reported that the myoid cells in the interfollicular area and deep lymphonodal cortex were positive for both alpha-SMA and desmin, while myoid cells in the medulla were only positive for desmin (Toccanier-Pelte et al. 1987). A further lymphonodal spindle cell type originally termed "fibroblastic reticulum cell" and being reactive for smooth muscle actin and myosin (Müller-Hermelinck et al. 1981) most likely represents a myofibroblast or a myofibroblast-like cell. Therefore, at least some of the myoid and in part nodular lesions occurring in CD may in fact represent lesions consistent with myofibroblastic inflammatory pseudotumor (Izumi et al. 2002).

Pathogenesis

The pathogenesis of CD is still controversial and complex (reviews: Al-Maghrabi 2011; El-Osta and Kurzrock 2011). Overall, etiopathogenic pathways discussed include infections, autoimmune mechanisms, and dysregulated cytokine production. In particular, overproduction of interleukin-6 (IL-6), either by cells of the hyperplastic follicles or virally encoded (KSHV-induced, vIL-6) seems to be important for the progression of both. LCD and MCD, but predominantly in histologic variants characterized by high plasma cell density, i.e., the plasma cell types (Van den Berg et al. 2002; Day et al. 2003; Abe et al. 2006). There is increasing evidence that an abnormal proliferative response of mesenchymal/stromal cells, including follicular dendritic cells, may play a pathogenic role in CD and in particular its hyaline-vascular variant. It has, e.g., been shown that a rearrangement of a target gene located to 12q13–15 and encoding a member of the high mobility group protein family (HMGIC) is exclusively present in anti-CD21-reactive follicular dendritic cells in hyaline-vascular CD, suggesting a distinct molecular pathway promoting stromal cell overgrowth (Cokelaere et al. 2002). An abnormal vascular proliferative response in some of the lesions (see below) is thought to be mediated by increased release of VEGF (Nishi and Maruyama 2000).

The pathogenetic mechanisms involved in KSHV-induced CD are only partially elucidated. KSHV-encoded proteins determine or modulate cell proliferation, apoptosis, and differentiation,

acting on several types of target cells, including lymphoid cells, fibroblastoid spindle cells, and endothelial cells (review: Giffin and Damania 2014). In order to induce long-lasting effects on surviving host cells, lifelong latency of KSHV is important, but the mechanisms causing this latency are not well known. Latently infected cells have multiple extrachromosomal copies of covalently closed circular KSHV genomes (episomes) that are stably maintained in proliferating cells. The principle latency-associated factor is the latency-associated nuclear antigen, LANA, a protein which mediates episome persistence. It does so by promoting episome replication with each cell division (review: Ballestas and Kaye 2011). One regulatory loop is based on a feedback mechanism in which the viral replication and transcription activator (RTA) induces the expression of the latency-associated nuclear antigen (LANA) during early infection. LANA is expressed also in KSHV-induced tumor cells. LANA represses transcription and the function of RTA, thus establishing latency. For RTA repression, LANA interacts with the recombination signal sequence-binding protein Jk (RBP-Jk), a repressor of the Notch signaling pathway (Jin et al. 2012). For proliferation of KSHV-associated tumor cells, viral-encoded interleukin-6 (vIL-6) plays an important role (review: Nicholas 2010), regulated by a microRNA pathway (Kang et al. 2011). In addition, there is increasing evidence that not only factors produced during latent infection but also lytic phase viral gene products are involved in the regulation of host cell proliferation (review: Gantt and Casper 2011). The KSHV-encoded viral FLICE inhibitory protein (vFLIP) K13 protects against antibody-induced growth arrest and apoptosis in B lymphocytes in an NF-kB-dependent manner (Graham et al. 2013). KSHV is associated with angioproliferation as seen in Kaposi sarcoma. Several pathways seem to be involved in this angiogenic cascade. In Kaposi sarcoma, both hypoxia-inducible factor (HIF)-1alpha and HIF-2alpha were detected, suggesting a role of these oxygen sensors in tumoral angiogenesis. It appears that this oxygen-mediated influence on the actions of KSHV is regulated by a signaling network. The KSHV-associated ORF34 protein, a lytic gene product, is activated by hypoxia, and its transcription is upregulated by both HIFs. RF34 binds to HIF-1alpha and causes its degradation through the proteasome pathway (Haque and Kousoulas 2013). In MCD caused by KSHV/HHV8, the angiogenic response may be induced by the two KSHV-encoded factors, vMIP-I and vMIP-II. These proteins can be identified in MCD by use of monoclonal antibodies (Nakano et al. 2012). KSHV exerts profound effects on the host's immune system and alters the proliferation and differentiation of immunologic effector cells, important mechanisms in the pathogenesis of both CD and KSHV-associated lymphomas. Immune cells latently infected by KSHV downregulate genes involved in the host immune response, including genes for CD80, CD86, and the cytokines TNFalpha and IL-1beta, leading to a minimization of the viral immunological signature and evasion from host detection (Gregory et al. 2012).

Multicentric Giant Lymph Node Hyperplasia

Multicentric giant lymph node hyperplasia is a rare disorder of unknown etiology, characterized by the presence of lymphoid hyperplasia of lymph nodes at different sites, including cervical, axillary, and inguinal lymph nodes. Liver and bone marrow showed a moderate lymphocytic and plasmacellular infiltration. The patient has fever, skin rashes, and a polyclonal gammopathy and shows a rapidly progressive course (Bartoli et al. 1980).

Multicentric Abdominal Angiofollicular Hyperplasia

Multicentric abdominal angiofollicular hyperplasia is a very uncommon nonmalignant lymphoproliferative disorder of unknown etiology, characterized by fever, arthralgia, polyclonal gammopathy, presence of several autoantibodies, exclusively abdominal lymphadenopathy, and liver infiltration. Abdominal lymph nodes showed

reactive angiofollicular hyperplasia. Polyclonal lymphocytosis persisted in spate of steroid therapy (Montalban et al. 1989). The liver showed a portal tract infiltrate composed of small lymphocytes, plasma cells, and centrofollicular cells forming portal tract nodules, sometimes with intraepithelial lymphocytic infiltrates of small bile ducts, with lymphoepithelial lesions.

Lymphoid Hyperplasia and Pseudolymphomas of the Hepatobiliary Tract

99

Contents

Abstract

The hepatobiliary tract can show several types of lymphoid hyperplasia and so-called pseudolymphomas, reactive lesions that have to be distinguished from neoplastic lymphoproliferative processes. Reactive lymphoid hyperplasia of the liver is an unusual, benign hepatic mass lesion characterized by a dense circumscribed, expansively growing lymphocyte infiltrate with lymph follicles and sometimes germinal centers. These masses are usually incidental lesions and are symptomless. Etiology and pathogenesis are not clarified, but a long-standing local and uncontrolled immune reaction may play a role. This is underlined by an association of lymphoid hyperplasia with hepatitis C virus infection. Several cases of reactive lymphoid hyperplasia were observed to accompany malignant tumors situated elsewhere, including gastrointestinal tract cancers. Lesions can grow to several cm in size and may be confounded with primary hepatic cancers. The nodules are well circumscribed and nonencapsulated. Apart from the most common lymphocytic B-cell-predominant lesions, a rare histiocyte-rich variant is known. Reactive lymphoproliferations of the liver also develop in autoimmune lymphoproliferative syndromes.

Reactive Lymphoid Hyperplasia

Introduction

Reactive lymphoid hyperplasia of the liver (synonyms: pseudolymphoma of the liver, nodular lymphoid lesion of the liver) is an unusual, benign hepatic mass lesion chiefly characterized by the presence of a reactive lymphocyte infiltrate with lymph follicles and an expanding growth pattern. Similar to reactive lymphoid hyperplasias in other organs, the etiology and pathogenesis have not been clarified, but an excessive local immune reaction to unknown antigen(s) may be involved.

Pseudolymphoma was first described in 1963 as a reactive lymphoproliferative lesion in the lung (Saltzstein 1963). The lesion can be found in various organs, including the gastrointestinal tract, orbit, thyroid gland, skin, and lung, but its occurrence in the liver is rare. Definitions available so far specify the lesion as propagation of lymph follicles constructed of lymphoid cells without cytological atypia, accompanied by conspicuous and sometimes hyperplastic germinal centers (Saltzstein 1963). Other authors have also proposed reactive lymphoid hyperplasia as a localized lesion well demarcated from surrounding tissue and characterized by the presence of hyperplastic lymphoid follicles with associated polyclonal population of small lymphocytes, mature plasma cells, macrophages, and stromal fibrosis (Katayanagi et al. 1994; Tanizawa et al. 1996).

Epidemiology

The first report of hepatic reactive lymphoid hyperplasia dates from 1981 (Snover et al. 1981), and less than 50 cases of reactive lymphoid hyperplasia of the liver have been reported so far, with most reports known from Japan. In most patients the lesion was symptomless and detected owing to routine examinations for other reasons. Incidental reactive lymphoid hyperplasia was found during back table examination of a donor liver (Sibulesky et al. 2010). In a review of 14 cases, the age range was 15–85 years (average 58 years; Zen et al. 2010); there is an impressive gynecotropy: among these 14 patients, 12 were female (Takahashi et al. 2006). 60 % of the lesions were located to the right liver lobe.

Selected References Grouls 1987; Fukuo et al. 1987; Tanabe et al. 1991; Isobe et al. 1993; Katayanagi et al. 1994; Ohtsu et al. 1994; Hiroshige and Tanabe 1995; Endou et al. 1996; Tanizawa et al. 1996; Fujinaga et al. 1997; Kim et al. 1997; Nishijima et al. 1998; Nagano et al. 1999; Sharifi et al. 1999; Okubo et al. 2001; Pantanowitz et al. 2001; Mori et al. 2002; Okuhama et al. 2003; Shiozawa et al. 2004; Maehara et al. 2006; Ota et al. 2006; Sato et al. 2006; Takahashi et al. 2006; Willenbrock et al. 2006; Jimenez et al. 2007, 2008; Machida et al. 2007; Matsumoto et al. 2007; Lin 2008; Park et al. 2008; Okada et al. 2009; Dominguez-Pérez and Castell-Monsalve 2010; Fukuo et al. 2010; Sibulesky et al. 2010; Watanabe et al. 2010; Zen et al. 2010; Hayashi et al. 2011; Kobayashi et al. 2011; Marchetti et al. 2011; Osame et al. 2011; Yoshikawa et al. 2011.

Several cases of hepatic reactive lymphoid hyperplasia accompanying malignant tumors have been reported, including colorectal carcinoma, gastric cancer, renal cell carcinoma, ovarian cancer, and multiple carcinomas in the same patient (Grouls 1987; Kim et al. 1997; Osame et al. 2011; Yoshikawa et al. 2011). Reactive lymphoid hyperplasia of the liver may be associated synchronously with other hepatic tumors, such as hemangioma and focal nodular hyperplasia (Willenbrock et al. 2006).

Imaging Features

Abdominal ultrasonography shows a homogeneous and hypoechoic lesion, sometimes with a hyperechoic rim (Tanabe et al. 1991; Nagano et al. 1999; Mori et al. 2002; Matsumoto et al. 2007; Hayashi et al. 2011). In CT images, a low-density area is detectable, which is not strongly enhancing in the arterial phase and

exhibits a vague low-density mass in the parenchymal and portal phases (Maehara et al. 2006). In one case, abdominal CT revealed a low-density area before contrast material injection, which was enhanced in the early arterial phase and subsequently washed out in the late phase (Hayashi et al. 2011). In case of extrahepatic malignancy, the CT features of reactive lymphoid hyperplasia can suggest metastatic disease (Marchetti et al. 2011). MR imaging showed a hyperintense T2 signaling nodular lesion and arterial phase enhancement with gadolinium injection (Matsumoto et al. 2007; Jimenez et al. 2008; Okada et al. 2009; Dominguez-Pérez and Castell-Monsalve 2010; Kobayashi et al. 2011). In a multinodular lesion, the masses showed slight T1 and T2 prolongation and restricted diffusion (Osame et al. 2011). In one case, a perfusion defect was seen during CT arterial portography (Maehara et al. 2006). The lesion has also been identified by use of FDG-PET (Lin 2008). Owing to expansive growth, the mass may cause narrowing of adjacent intrahepatic bile ducts.

Nodular Lymphoid Hyperplasia of the Liver

There are situations where large numbers of lymphoid follicles, also with prominent germinal centers, develop in the liver in the absence of hepatitis virus infection, sometimes forming macroscopically visible lesions. This is called *nodular lymphoid lesion of the liver* or *reactive lymphoid hyperplasia of the* liver and is thought to emerge via an immune-mediated process directed against so far unknown antigens. Clinically and radiologically, the lesions can closely mimic primary hepatic neoplasms or metastatic disease. The lesions have been observed in the setting of autoimmune disorders, including primary biliary cirrhosis (Okada et al. 2009; Fukuo et al. 2010; Ishida et al. 2010) and Sjögren's syndrome (Okubo et al. 2001). Rarely, nodular lymphoid lesion was associated with other tumorous lesions in the liver, i.e., focal nodular hyperplasia and hemangioma (Willenbrock et al. 2006).

Selected References Snover et al. 1981; Isobe et al. 1993; Katayanagi et al. 1994; Ohtsu et al. 1994; Tanizawa et al. 1996; Nagano et al. 1999; Sharifi et al. 1999; Okubo et al. 2001; Pantanowitz et al. 2001; Maehara et al. 2006; Sato et al. 2006; Takahashi et al. 2006; Willenbrock et al. 2006; Jimenez et al. 2007; Machida et al. 2007; Lin 2008; Okada et al. 2009; Dominguez-Pérez and Castell-Monsalve 2010; Fukuo et al. 2010; Ishida et al. 2010; Zen et al. 2010; Hayashi et al. 2011; Kobayashi et al. 2011; Marchetti et al. 2011; Tuckett et al. 2011; Yoshikawa et al. 2011; Amer et al. 2012; Yuan et al. 2012; Moon and Choi 2013.

In lesions that have been resected, the gross features were characterized by a well-circumscribed, nonencapsulated, mostly solitary nodule with a firm to rubbery consistency and a smooth or coarsely granular, whitish to yellowish or tan cut surface (Maehara et al. 2006; Jimenez et al. 2008; Zen et al. 2010). Some of the lesions may bulge from the fresh cut surface (Fig. 3 in Takahashi et al. 2006). The diameter of the reported lesions ranged from 0.9 to 5.5 cm (average: 1.7 cm; Zen et al. 2010). In another study of seven cases, the average size of the lesions was 45 mm (range: 15–105 mm; Yuan et al. 2012). Among eight reviewed lesions, six had a diameter between 15 and 20 mm (Maehara et al. 2006). The largest reported lesion (5.5 cm diameter) was observed in an 81-year-old male patient without preexisting liver disease (Zen et al. 2010). The macroscopic growth pattern is expanding causing perifocal atrophy of the liver substance, sometimes associated with perifocal nodular change and angiectases.

Histologically, reactive nodular lymphoid hyperplasia exists in two patterns, a lymphocyte-rich variant (Fig. 1) and a histiocyte-rich variant. In the lymphocyte-rich variant, the circumscribed nodules exhibit a dense lymphocytic infiltrate with formation of numerous lymph follicles, many of them with fully developed, normal-looking germinal centers containing the typical macrophages with tingible bodies/nuclear fragments. The infiltrate is also occupied by macrophages (mainly in

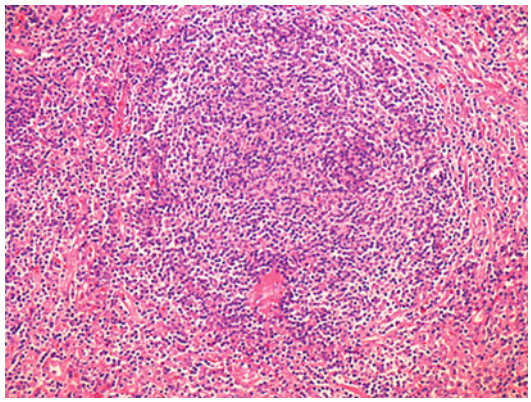

Fig. 1 Lymphoid hyperplasia of the liver with follicular structures (hematoxylin and eosin stain)

the interfollicular compartment; sometimes with an epithelioid morphology; Zen et al. 2010), immunoblasts, plasma cells, and other leukocytes, but these cells usually form a minority. Variable degrees of interfollicular hyalinosis have been noted (Tanizawa et al. 1996; Nagano et al. 1999; Sharifi et al. 1999; Pantanowitz et al. 2001; Sato et al. 2006; Machida et al. 2007). This sclerohyalinosis may rarely form fibrous nodular structures of various sizes (Machida et al. 2007). The edge of the lesions shows ductular proliferations which are CK7+ (Zen et al. 2010). Portal tracts in the vicinity of the lesion may show an increased lymphocytic infiltration (see below). Multinucleated giant cells in a granulomatous reaction containing cholesterol clefts have been noted (Zen et al. 2010). One lesion showed small calcifications (Zen et al. 2010).

Immunohistochemically, the lesion demonstrated B lymphocytes in the follicles (CD20+, CD79a+ and Bcl-6+, and Bcl-2 negative) along with CD3+ T lymphocytes (Matsumoto et al. 2007). Lymph follicles were found to be positive for CD10 (Hayashi et al. 2011). The plasma cells were polytypic, positive for both kappa and lambda light chains at a 3:1 ratio (Takahashi et al. 2006; Jimenez et al. 2008). Polyclonality of B cells/plasma cells was also confirmed by the use of in situ hybridization (Sato et al. 2006; Zen et al. 2010) and of Ig heavy chain analysis via PCR (Machida et al. 2007; Zen et al. 2010). IgG4+ cells were scarce in all lesions (Zen et al. 2010). Flow cytometric analysis of tumor cell suspensions disclosed a B:T cell ratio of 53.4 % CD3+ cells and 35.0 % CD20+ cells (Maehara et al. 2006). The lymphocyte population is immunohistochemically polytypic (Machida et al. 2007) and shows a polyclonal phenotype by the use of in situ hybridization for light chain restriction (Zen et al. 2010).

The histiocyte-rich variant its characterized by a high content of histiocytes, in addition to lymphoid cells. Park and coworkers (Park et al. 2008) reported a case of hepatic reactive lymphoid hyperplasia exhibiting unusual histiocyte-rich histologic features in a 47-year-old female patient in conjunction with a renal cell carcinoma. The well-circumscribed, yellowish-white, solitary nodule measured 1 cm in diameter. Histologically, two components were in evidence, the first being characterized by an infiltrate of CD68+ histiocytes, many of them epithelioid and sometimes forming granuloma-like structures, and the second by lymphocytes, lymph follicles, and germinal centers. The amount of histiocytes was the dominant feature, although few epithelioid macrophages and even sparse giant cells had been reported previously (Sharifi et al. 1999; Willenbrock et al. 2006). Most of the lymphoid follicles were present at the edge of the nodule, whereas ductular proliferations were noted. The mass also showed a focally marked hyalinosis. In the surrounding liver tissue, a prominent periductal lymphocyte infiltration with fibrosis was observed, but these changes were not found in more remote liver areas.

Another variant of nodular lymphoid lesion was characterized by epithelioid cell granulomas and Schaumann bodies in giant cells within the lesion (Nonomura et al. 1998). Rarely, the lesions may display an angiofollicular pattern, thus resembling Castleman's disease (Tanizawa et al. 1996).

Hepatic Pseudolymphoma

In case of large lesions that produce masses mimicking malignancy, the alterations have sometimes been allocated to the clinicopathologic category of *hepatic pseudolymphomas* (Grouls 1987; Katayanagi et al. 1994; Hiroshige

et al. 1995; Kim et al. 1997; Shiozawa et al. 2004; Ota et al. 2006; Matsumoto et al. 2007; Osame et al. 2011; Yang et al. 2013; Yoshida et al. 2013). Pseudolymphomas are mass lesions that may show the same or similar histologic pattern as nodular lymphoid lesion and may thus represent excessive forms of nodular lesions. Sometimes, complex multinodular lesions develop that can involve both liver lobes (Osame et al. 2011). It is, therefore, difficult to distinguish between the lesions in published reports, as the terminologies were sometimes not employed in a comparable manner. They are sometimes associated with conditions known to stimulate a lymphocyte-mediated immune reactions, e.g., chronic hepatitis C (Kim et al. 1997). But part of pseudolymphomas deviate from this lymphoid hyperplastic pattern and contain, e.g., increased numbers of plasma cells and histiocytes/macrophages. Such lesions show a histologic overlap with inflammatory pseudotumors, which are treated in separate chapters.

Non-nodular Lymphoid Hyperplasia of the Hepatobiliary Tract

Lymphoid Hyperplasia in Viral Hepatitis

One of the best known situations where lymph follicles emerge in the liver, and specifically in the portal tract spaces, is chronic hepatitis C (Hino et al. 1992; Mosnier et al. 1993; Freni et al. 1995; Murakami et al. 1999).

Portal Tract and Small Bile Duct Changes in Reactive Lymphoid Hyperplasia of the Liver

In the majority of the cases, the portal of the adjacent liver substance revealed a sometimes dense lymphocytic infiltration, which also involved the periductal tissue compartment (Isobe et al. 1993; Katayanagi et al. 1994; Sharifi et al. 1999; Pantanowitz et al. 2001; Maehara et al. 2006; Sato et al. 2006; Takahashi et al. 2006; Machida et al. 2007; Park et al. 2008; Zen et al. 2010). In at least two instances, these alterations were associated with lymphoepithelial lesions of small bile ducts (Sharifi et al. 1999; Willenbrock et al. 2006), and the periductal lymphocytic infiltration may be correlated with periductal fibrosis.

Lymphonodular Hyperplasia of Large Extra- and/or Intrahepatic Bile Ducts

The presence of numerous lymph follicles in the bile duct mucosa, resulting in bile duct stenosis, has rarely been observed and termed *follicular cholangitis* (Aoki et al. 2003). In the patient described by these authors, the mucosa of the common bile duct of a resection specimen showed a moderate stenosis by soft granular nodules with a "cobblestone-like" appearance, whereas the confluence of the hepatic ducts was whitish and firm upon palpation, and the right hepatic duct was completely obstructed. Histologically, the thickened duct wall contained numerous lymph follicles with richly formed germinal centers located to the outer layers, and, at the hepatic hilum, significant fibrosis and hyalinization in the interfollicular spaces were found.

Biology of Disease

Reactive lymphoid hyperplasia of the liver has a favorable outcome. Among five patients with a longer follow-up, the lesions did not recur after resection, and some nodules may regress spontaneously (Zen et al. 2010).

Differential Diagnosis

The main differential diagnosis is low-grade malignant follicular non-Hodgkin's lymphoma (NHL; Sharifi et al. 1999), in particular B-cell lymphoma of the MALT type (Sharifi et al. 1999; Willenbrock et al. 2006; Hayashi et al. 2011). In the presence of germinal centers, macrophages with tangible bodies are diagnostically helpful, because this feature is lacking in malignant lymphoma. In case of doubt and

particularly in needle biopsies, immunohistochemistry and molecular methods should be added to exclude NHL, which also occurs as a primary malignancy in the liver (see the respective chapter). Reactive lymphoid hyperplasia of the liver was found in at least two patients with colorectal cancer and first suspected to be metastases (Takahashi et al. 2006).

Etiology and Pathogenesis

An association between the development of hepatic reactive lymphoid hyperplasia and systemic or local pathologic immune reactions has been suggested. The lymphoid reaction has been observed in conjunction with chronic hepatitis C (Kim et al. 1997), a disorder known to be associated with autoimmune reactions and lymphoma; in conjunction with autoimmune thyroiditis (Nagano et al. 1999), primary biliary cirrhosis (Sharifi et al. 1999; Okada et al. 2009; Fukuo et al. 2010; Zen et al. 2010), Takayasu arteritis (Zen et al. 2010), or Sjögren's syndrome (Okubo et al. 2001); following interferon-alpha therapy for chronic hepatitis B (Ohtsu et all. 1994); and in a patient with primary immunodeficiency and polyglandular failure syndrome (Snover et al. 1981). In one patient, the histology of the lesion resembled an angiofollicular pattern as seen in Castleman's disease (Tanizawa et al. 1996).

Part of the lesions described were associated with a malignancy (see above). It may be hypothesized that the partly nodular reactive lymphoid lesions in the livers of these patients are local (and successful) immune reactions directed against small liver metastases of extrahepatic carcinomas.

Reactive Lymphoproliferative Disorders: Human Autoimmune Lymphoproliferative Syndrome

Introduction

Autoimmune lymphoproliferative syndrome (ALPS) denotes a disorder characterized by generalized reactive (non-neoplastic) lymphadenopathy, hypergammaglobulinemia, lymphocytosis, splenomegaly, sometimes hepatomegaly, and autoimmune features (Oliveira and Fleisher 2004; Deutsch et al. 2004). ALPS has originally been described as a chronic lymphadenopathy simulating malignant lymphoma in children (Canale and Smith 1967), resulting in the eponymic designation, Canale-Smith syndrome (Kellerer and Mutz 1976). A central feature of ALPS and its variants is a chronic reactive expansion of a distinct lymphocyte population, related to deranged lymphocyte apoptosis (reviews: Campagnoli et al. 2006; Rieux-Laucat and Magerus-Chatinet 2010; Madkaikar et al. 2011; Teachey 2010, 2011, 2012; Teachey et al. 2010). The involved lymphocyte population is dominated by T-cell receptor alphabeta CD4-CD8- (double-negative) T cells in the blood and in tissues (Sneller et al. 1992; Fisher et al. 1995; Lim et al. 1998; Price 2013). Apart from the TCR alphabeta phenotype typical for ALPS, TCR gammadelta has also been identified in double-negative T cells in ALPS (van den Berg et al. 2003). An increased risk for neoplasias of the lymphoid cell system has clearly been established but particularly so in patients having Fas gene mutations (see below; Straus et al. 2001; Oliveira and Fleisher 2004).

Liver Pathology in ALPS and Related Disorders

ALPS seems to be often associated with hepatomegaly (Koo et al. 1984; Le Deist et al. 1996; Avila et al. 1999). Hepatomegaly in ALPS seems to be caused by infiltration of the liver by lymphoid cells. One patient showed, in the liver biopsy, an infiltration of portal tracts and sinusoids by large lymphocytes and marked hemophagocytosis in the hepatic sinusoids (Le Deist et al. 1996). A pathologic study of ten patients with ALPS revealed marked paracortical hyperplasia of lymph nodes, the expanded interfollicular areas being dominated by T-cell receptor alphabeta CD3+, CD4-CD8- (double-negative) T cells and characterized by decreased apoptosis. The spleens were markedly enlarged, more than ten times normal size, with cellular expansion of both the red and white pulps.

Liver biopsies from two patients showed a lymphocytic infiltration of portal tracts ("triaditis") consisting again of predominantly double-negative T cells (more than 50 % of the cells). One of these patients developed chronic active hepatitis consistent with a form of autoimmune hepatitis (Lim et al. 1998). Type 2 autoimmune hepatitis developing in ALPS has been observed in another study (Pensati et al. 1997). The pathogenesis of hepatitis in apoptosis-deficient patients with ALPS is of particular interest, because there is evidence that Fas-mediated apoptosis is a critical step in the genesis of hepatitis (Kondo et al. 1997). It has been suggested that hepatitis emerging in failure of Fas-mediated lymphocyte pathways may be mediated by a hyperactivation of granzyme B counterbalancing Fas deficiency (André et al. 2004).

MRL/MP mice bearing the lymphoproliferative gene lpr (MRL/MP-lpr/lpr or MRL/lpr mice) are known to spontaneously develop severe autoimmune disease, including a form of chronic suppurative destructive cholangitis and antimitochondrial autoantibodies, mimicking human primary biliary cirrhosis (Tsuneyama et al. 2001). It is not yet known whether patients with ALPS or related disorders also tend to develop autoimmune disorders of the biliary tract.

Classification

There is now evidence that ALPS is not a single entity but makes part of a growing spectrum of disorders with overlapping phenotypes and different etiopathogenic pathways. A spectrum of symptoms and signs similar to ALPS may be seen in some patients with Evans syndrome, a hematologic disorder defined by autoimmune destruction of at least two hematologic cell types, associated with elevated double-negative T cells as in ALPS (Teachey et al. 2005). An ALPS-like clinical pattern in patients with decreased Fas function, but no Fas gene mutations, has been described under the terms autoimmune lymphoproliferative disease (ALD) and Dianzani autoimmune/lymphoproliferative disease (DALD) (Dianzani et al. 1997; Ramenghi et al. 2000; Chiocchetti et al. 2004). A further novel disorder of lymphocyte apoptosis is characterized by a combination of autoimmunity, infectious lymphadenopathy, double-negative T cells, and impaired activation-induced cell death in the absence of Fas or FasL gene mutations (Hundt et al. 2002).

ALPS bears striking similarities to respective diseases in the MRL and C3H/Hej strains of mice, showing mutations of the lpr and gld loci, respectively (Sneller et al. 1992). These gene loci encode for two proteins involved in the regulation of apoptosis, in humans representing CD95 (Fas/Apo-1) and CD95L (FasL; Fas ligand), respectively (Nagata 1996). Fas and its ligand have a central role in immune cell homeostasis and autoimmunity (Siegel et al. 2000), and Fas and FasL mutations are involved in several disorders of the immune system (Weintraub et al. 1998; Siegel and Fleisher 1999; Mullauer et al. 2001). In patients with ALPS, mutations of the CD95/Fas gene were identified (Fisher et al. 1995; Rieux-Laucat et al. 1995; Drappa et al. 1996; Bettinardi et al. 1997; Infante et al. 1998; Fleisher et al. 2001; Dowdell et al. 2010; Boggio et al. 2012; Fleisher and Oliveira 2012; Hsu et al. 2012; Lambotte et al. 2013; Magerus-Chatinet et al. 2013; Simesen de Bielke et al. 2012), indicating that ALPS is a group of mostly genetic disorders characterized by germline defects of apoptotic pathways in lymphoid cells (Puck and Sneller 1997; Dianzani et al. 2003), although sporadic somatic mutations of Fas gene have also been described (Holzelova et al. 2004). Variations in perforin expression are a susceptibility factor for ALPS development in subjects with defective Fas function (Clementi et al. 2006). There is a relation between the type of Fas mutations and the clinical phenotype (Rieux-Laucat et al. 1999). The pathogenic role of abnormal Fas expression in the pathogenesis of ALPS has also been studied in a transgenic mouse model of this disorder (Choi et al. 1999). Interestingly, targeted mutation of the Fas gene with loss of function in the mouse does not only promote massive lymphocyte expansion but also substantial liver hyperplasia (Adachi et al. 1995). The genetic basis of ALPS has since continued to expand with the identification of the much rarer Fas ligand gene mutations and defects in caspase-8 and caspase-10 (Grzela et al. 2004; review: Oliveira and Fleisher

Table 1 Proposed classifications of autoimmune lymphoproliferative syndromes (ALPS) and related disorders

Previous classification
ALPS
ALPS type I (Canale-Smith syndrome; OMIM 601859)
ALPS type Ia (ALPS-FAS; germline mutations in Fas)
ALPS type Ib (ALPS-FASLG; germline mutations in FasL)
ALPS type sFas (somatic mutations in Fas)
ALPS type II (mutations of caspase-10)
ALPS caused by mutations of caspase-8
DALD (Dianzani autoimmune/lymphoproliferative disease)
Evans syndrome with ALPS-like features (Teachey et al. 2005; Seif et al. 2010)
Hundt-type of ALPS-like disorder
Revised classification of ALPS proper (Oliveira et al. 2010)
ALPS type 0: germline homozygous mutations in Fas
ALPS type Ia: germline heterozygous mutations in Fas
ALPS type lm: somatic mutations in Fas
ALPS type Ib: germline mutations in Fas ligand
ALPS type IIa: germline mutations in caspase-10
ALPS type III: genetic defect undetermined

2004). In ALPS-like disorders without mutations of the Fas/FasL system, other factors involved in an apoptosis defect may play a role. In Dianzani autoimmune/lymphoproliferative disease (DALD), high levels of osteopontin associated with polymorphisms of its gene were found, suggesting that high osteopontin levels are involved in defective apoptosis (Chiocchetti et al. 2004). The diversity of ALPS and related disorders has led to a comprehensive classification, based on a 2009 NIH International Workshop (Oliveira et al. 2010), shown in Table 1.

Diffuse Infiltrative Lymphocytosis Syndrome

Introduction

Diffuse infiltrative lymphocytosis syndrome (DILS) is a reactive lymphoproliferative disorder that occurs in individuals infected with HIV-1. DILS is characterized by a persistent circulating CD8 lymphocytosis, marked salivary gland, and in particular parotid gland enlargement, sicca signs and symptoms, pulmonary insufficiency, a severe form of peripheral neuropathy, and an apparently antigen-driven CD8(+) T-cell lymphocytic infiltration of various organs and tissues, including a progressive visceral involvement also affecting the liver. The most dense CD8 cell infiltrates are observed in the salivary glands and lung. Specific associations with distinct MHC class I and II gene products suggest a pathogenic role of host immune responses to HIV (Itescu et al. 1989, 1993; Itescu 1991; Itescu and Winchester 1992; Franco-Paredes et al. 2002; Feller et al. 2007). Definitive DILS was found in 3 % of a large group of HIV-1-infected subjects, and patients with DILS had higher CD8 counts compared with those without DILS (Williams et al. 1998). DILS was more common in African Americans than in Caucasians and prevailed in persons with male-to-male transmission of HIV-1 (Kazi et al. 1996).

Liver Involvement

In patients with progressive DILS involvement of abdominal viscera, the liver shows an increasing parenchymal and portal tract infiltration with CD8 (+) T lymphocytes. This infiltration can be evident as hepatitis (Franco-Paredes et al. 2002). The hepatic infiltrative process has been distinguished from cellular infiltrations in the setting of T-cell non-Hodgkin's lymphomas which also tend to markedly involve the liver in part of patients.

Abstract

Langerhans cell histiocytosis (LCH) is a rare proliferative disorder of bone marrow-derived antigen-presenting cells that home to diverse organs and tissues, predominantly the skin. LCH is a rare disease that mainly manifests in the pediatric age group, with several in part overlapping phenotypes. Clinically and morphologically, LCH is divided into unifocal LCH, single-system LCH, multifocal LCH, multiorgan/disseminated LCH, Langerhans cell sarcoma, and Langerhans tumors. All forms and variants are characterized by a progressive and monoclonal proliferation of medium-sized, CD1a-reactive, and langerin-/CD207-reactive cells that often contain Birbeck granules. Langerhans cell infiltrates are regularly accompanied by infiltrates of eosinophils, lymphoid cells, and macrophages. Lesions with a high density of eosinophils were previously termed eosinophilic granuloma. Hepatobiliary involvement in LCH presents with a characteristic spectrum of lesions that include a disseminated form, focal forms (microscopic and macroscopic), and a form associated with bile ducts (LCH cholangiopathy). A small subset of Langerhans cell proliferations present as tumorous lesions or Langerhans cell sarcoma. In addition to LCH, there are a group of so-called self-healing Langerhans cell and related disorders that can involve the hepatobiliary tract.

Langerhans Cell Histiocytosis (LCH)

ICD-O code 9751/3

Introduction

Langerhans cell histiocytosis (LCH) is a rare proliferative disorder of bone marrow-derived antigen-presenting cells that tend to chiefly infiltrate the skin, but also other organs and tissues, including the bone marrow, bone, liver, spleen, lymph nodes, gastrointestinal tract, lungs, and hypophysis (Arico and Egeler 1998; Broadbent et al. 1994; Herzog and Tubbs 1998; Ladisch 1998; Allen and McClain 2007; Windebank and Nanduri 2009; Abla et al. 2010; Minkow 2011; Munir et al. 2012; Xu et al. 2012a; Gadner et al. 2013; Haupt et al. 2013; Collin et al. 2015; El Demellawy et al. 2015). Synonymous terms that are currently regarded as obsolete are histiocytosis X, eosinophilic granuloma, Letterer-Siwe disease, Hand-Schüller-Christian disease, Langerhans cell granulomatosis, type II histiocytosis, and nonlipid reticuloendotheliosis (Komp 1987; Favara et al. 1997). These older terms reflect the first clinical descriptions of LCH and its variants by Hand (1893, 1921), by Schüller (1915), by Christian (1919), and later by Letterer (1924) and Siwe (1933), resulting in considerable confusion in nomenclature until it was recognized that the disease in each of these clinical syndromes was components of a spectrum of disease involving the LC (Lichtenstein 1953; Lieberman et al. 1969; Broadbent et al. 1994).

Epidemiology

The estimated incidence of LCH is approximately five per one million population per year. Most cases are diagnosed in the pediatric age group. LCH has a clear predilection for males (M/F = 3.7:1) and chiefly occurs in whites of northern European descent, being rare in blacks. LCH can be clustered within families, with high concordance in monozygotic twins, but there is no evidence for vertical transmission. LCD occurs in the neonatal period, where it is associated with a poor prognosis (Gee et al. 2013). In very rare instances, LCH can present as congenital disorder, sometimes with placental involvement (Terry et al. 2013).

Clinical Features

The clinical presentation and biology of LCH are highly heterogeneous and range from unifocal manifestations with an apparently self-limited course to multifocal and chronic, complex organ manifestations to rapidly progressing and fatal,

disseminated leukemia-like forms. LCH can be localized to a single site, multiple sites within a single system, or more disseminated and multisystemic. The solitary or unifocal form mainly involves bones and adjacent soft tissues and less commonly the skin, lung, lymph nodes, and other organs. Multifocal LCH is typically a bone disease, with involvement of the periosseous tissue. Preferential involvement sites in multisystemic LCH comprise the bone marrow, spleen, bone, skin, and liver. Interestingly, kidneys and gonads are very uncommonly involved. Clinically, solitary/unifocal lesions prevail in older children and adults and typically present as lytic bone defects. In skull base involvement, diabetes insipidus is common. Multisystem involvement predominantly occurs in infants and small children and is characterized by a febrile illness with skin, bone, and visceral lesions and cytopenia.

Classifications of LCH

What renders histopathologic diagnosis and classification difficult is the fact that the clinical heterogeneity is reflected in a broad spectrum of morphological lesions, heterogeneous themselves in regard to a given patient and her or his age and genetic background, the organ localization, the time point of examination, and the stage of disease, lesions that histologically sometimes do not appear to have something to do with a proliferative LC disorder. The criteria for a definitive diagnosis of LCH have been worked out and published in 1987 (Writing Group of the Histiocyte Society 1987); they are not further discussed here. Differential organ and tissue involvement has led to the definition of several subtypes, e.g., *unifocal LCH* (formerly, eosinophilic granuloma), *single-system LCH* (almost a third in one large study; Arico et al. 2003), and *multisystem/multiorgan/disseminated disease*. Pulmonary LCH (PLCH) is an important member of single-system LCH, being clearly distinct from systemic multiorgan LCH (Yousem et al. 2001; Sundar et al. 2003). A further variant of single-system LCH seems to be soft tissue solitary LCH (al-Abbadi et al. 1997).

Table 1 Working classification of Langerhans cell histiocytosis

Unifocal LCH (with or without marked eosinophilia, in the latter case corresponding to the former "eosinophilic granuloma")
Single-system LCH
Multifocal LCH (including manifestations corresponding to the former Hand-Schüller-Christian disease)
Multiorgan/disseminated LCH (acute, subacute; including manifestations corresponding to the former Letterer-Siwe disease)
Langerhans cell sarcoma
Langerhans cell tumors

Multisystem LCH covers syndromes originally denoted as Hand-Schüller-Christian disease and Letterer-Siwe disease, distinct by the rapidity of disease progression and by the involved organ/tissue spectrum, but an individual patient with multisystem LCH may present with signs intermediate between these apparent entities (Kato et al. 1981; Iupati and Chander 2006; Cugati et al. 2011). In the present chapter, the *working classification of LCH* summarized in Table 1 is used.

Langerhans cell tumors and Langerhans cell sarcomas are discussed in a separate paragraph.

General Morphologic Features of Langerhans Cell Histiocytosis

In principle, LCH is a progressive and apparently monoclonal proliferation of CD1a-positive cells, at least part of them containing Birbeck granules. "Langerhans cell granules" have already been reported for LCH then termed "subacute disseminated histiocytosis of Letterer-Siwe" in 1968 (Gianotti et al. 1968). The cells are medium sized (10–15 μm) of oval shape, lacking dendritic processes, with a slightly eosinophilic cytoplasm and grooved, folded, lobulated, or indented nuclei with fine chromatin and inconspicuous nucleoli. These cells are embedded in a cellular background with variable numbers of macrophages (in part multinucleated forms), eosinophils, neutrophils, and lymphocytes. Plasma cells are sparse. Eosinophils are sometimes very numerous, especially in solitary/unifocal bone lesions (the former

"eosinophilic granuloma"). Such lesions may contain eosinophilic abscesses with Charcot-Leyden crystals. Ultrastructurally, cells of LCH contain Birbeck granules, zipper-like structures with a tennis racquet shape, measuring 200–400 nm in length and 33 nm in width. Birbeck granules originate from subdomains of endosomal recycling compartments that consist of disks of two limiting membranes separated by leaflets with periodic zipper-like striations. Immunohistochemically, cells in LCH are strongly reactive for CD1a, langerin, and S100 protein. Langerin (CD207) is a trimeric C-type lectin that functions as a antigen receptor and in pathogen capture via the recognition of glycan motifs by three carbohydrate recognition domains (CRDs) (Muñoz-Garcia et al. 2015). Langerin recognizes hyaluronic acid on dendritic cells and is involved in the morphogenesis of Langerhans cell Birbeck granules (Chabrol et al. 2015). In addition, the tumor cells are positive for CD68, HLA-DR, and vimentin. LCs in LCH can express matrix metalloproteinase-9 (MMP-9), mostly co-expressed in cells that are also CD68+ and associated with recurrence of lesions (Zyada 2009).

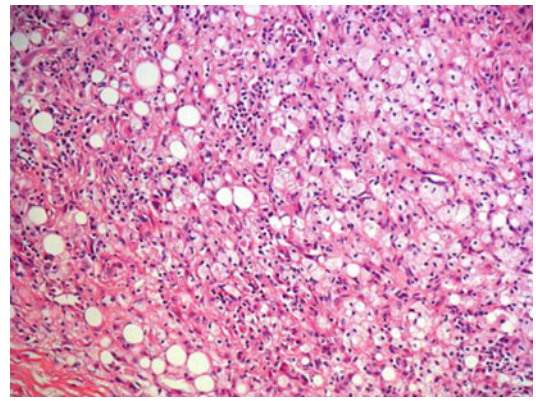

Fig. 1 Langerhans cell histiocytosis of the liver. Medium-sized to large cells have infiltrated the steatotic liver tissue (hematoxylin and eosin stain)

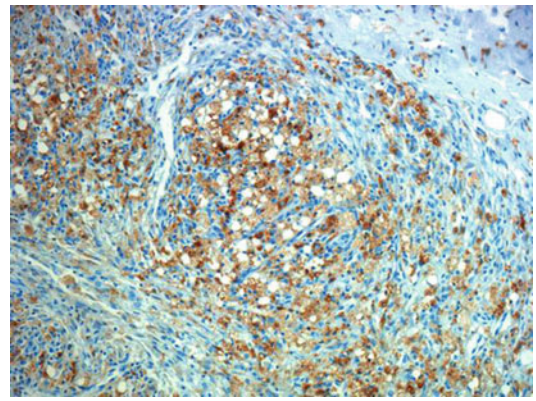

Fig. 2 Langerhans cell histiocytosis of the liver. Most of the neoplastic cells are reactive for CD1a (CD1a immunostain)

Liver Involvement in Langerhans Cell Histiocytosis

Introduction

In LCH, the liver is commonly involved, albeit with a rather broad spectrum of manifestations reflecting the different biologic phenotypes of LCH, including those with marked contribution of eosinophils (Figs. 1, 2, 3, 4, 5, and 6 and Table 2). Liver infiltration can sometimes cause massive hepatomegaly (Trochtenberg and Dessypris 1990). In multisystemic LCH, liver dysfunction may be the first clinical presentation (Liu et al. 2012). The morphology and immunophenotypes of LC in LCH of the liver are, in principle, similar to that of normal LC. For example, cells of LCH contain, albeit to variable degrees, Birbeck granules, a finding known since 1973 (Nezelof et al. 1973). However, LC in LCH expresses a phenotype of an LC apparently "fixed" at an earlier stage of activation, the cells being functionally defective in antigen capture and presentation and being very different in regard to tissue distribution and homing features (Chu and Jaffe 1994).

Classifications of Hepatic LCH

There are several propositions to classify hepatic LCH, based on various criteria (Table 2).

Portal Tract/Bile Duct Involvement

Pretreatment liver biopsies show several lesions, a considerable part of the changes being nonspecific. In a study on 20 patients with LCH, pretreatment evaluation of liver tissues revealed various abnormalities of the portal tracts in 19/20 specimens, including "triaditis," small bile duct proliferation, variable fibrosis with infiltration of "histiocytes," and liver cirrhosis. One patient showed a granulomatous lesion (Heyn et al. 1990). In this study, patients with larger livers and hepatic dysfunction tended to exhibit

Table 2 Classifications of hepatic Langerhans cell histiocytosis

Clinicopathologic classification
I. Disseminated form (with or without sinusoidal spread)
II. Focal forms
1. Focal LC infiltration, microscopic pattern
2. Nodular LCH of the liver
3. Granulomatous hepatopathy
III. LCH cholangiopathy (in particular, sclerosing cholangitis)
IV. Posttransplant manifestations and associations of LCH
V. Paraneoplastic manifestations of LCH
Pathologic/pathogenic classification (Kaplan et al. 1999, modified)
A. Portal area/bile duct infiltration by LC causing:
Cholangionecrosis
Periductal sclerosis with or without LC ("PSC-like")
Ductopenia
Chronic cholestasis
Fibrosis/secondary biliary cirrhosis/atrophy-hypertrophy complex (AHC)
B. Sinusoidal infiltration
C. Disseminated infiltration
D. Multifocal infiltration with tumor-like lesions
E. Focal granulomatoid lesions (including "eosinophilic granuloma")
F. Secondary sclerosing cholangitis
G. Other liver manifestations

more marked histologic anomalies in the portal tracts, however, with considerable overlap. It turned out that patients showing fibrohistiocytic changes or cirrhosis initially were more likely to have continuing or progressive liver disease, although the liver histology was not diagnostic for LCH (Heyn et al. 1990). Triaditis was also observed in the majority of cases in another study (Favara 1996). In case of more advanced involvement of the liver, focal aggregates of LC (microscopic pattern) are observed in a polymorphous background of mature eosinophils, lymphocytes, neutrophils, and plasma cells (Kaplan et al. 1999). Specific LC infiltrates may be cholangiocentric, forming dense collections of cells surrounding damaged bile ducts (Favara 1996), or in the form of apparently random acinar "histiocytic" lesions (Favara 1996). Ductocentric LCH can result in progressive portal tract fibrosis or septal fibrosis (Arakawa et al. 1994). Involvement of the bile ducts with LCH may result in biliary wall calcification (Caruso et al. 2008). LCH may be associated with cholelithiasis and bile duct dilatation (Caruso et al. 2009).

Sinusoidal Infiltration

In part of cases of hepatic LCH, the CD1a-reactive tumor cells are found within the sinusoidal lumina, either as single cells or small clusters or groups of cells. This infiltration pattern can be associated with atrophy of hepatocyte plates.

Disseminated Infiltration

Relatively few data are available on the liver pathology in multisystemic/disseminated LCH, and in some of the published observations, it is difficult to judge as to what form of LCH one really deals with. In contrast to the chronic disseminated form of LCH (the former Hand-Schüller-Christian disease; Fig. 3), disseminated LCH is known to show an acute or subacute course. In the pediatric age group, the most impressive manifestation of disseminated LCH is the disorder characterized by a severe illness, a distinctive and frequently hemorrhagic skin rash, a low-grade fever, a leukemia-like blood change, and a massive hepatosplenomegaly with or without ascites, jaundice, lymphadenomegaly, soft tissue edema, and gingival necrosis, i.e., what has previously been termed Letterer-Siwe disease or "acute nonlipid disseminated reticuloendotheliosis" (see below; Batson et al. 1955; Komp 1987). Liver manifestations have been reported in the literature (Childers and Price 1954; Batson et al. 1955). In an autopsy case (two-and-a-half-year-old child with "classical" presentation of Letterer-Siwe disease), the enlarged liver showed numerous nodular projections on the capsular surface, a greenish-yellow color, and a firm consistency. Microscopy revealed an increased amount of connective tissue in the portal tracts associated with ductular proliferations, portal tract infiltrates of mononuclear

cells and small lymphocytes, and signs of cholestasis (Childers and Price 1954). The disease manifestations depend on the stage of disease, i.e., florid lesions with tissue damage together with highly cellular infiltrates being more prominent in early phase disease, while the portal tract lesions described in the case of Childers and Price reflect longer-standing disease.

Multifocal Infiltration with Tumor-like Lesions

LCH can produce focal infiltrations growing in the form of nodules, termed nodular LCH of the liver, but this type of manifestation is much rarer than the disseminated form (Foschini et al. 1995; Levy et al. 1998; Cavazza et al. 1999; Rice and Wyatt 2000; Yagita et al. 2001). In this situation, the liver substance is partially replaced by a hypercellular tissue forming lobulated, poorly demarcated nodules surrounded by fibrous tissue . The nodular lesions can clinically and radiologically resemble a primary hepatic malignancy and thus be misdiagnosed as liver cancer (Ma et al. 2014). The diameter of the nodules ranges from 1 mm to a few centimeters. In very few instances, only one hepatic nodule had been detected (Rice and Wyatt 2000). The infiltrate nodules may encroach upon small intrahepatic bile ducts (Parker and Lichtenstein 1963), but focal LCH confined to a bile duct has also been found (Finn and Jaffe 1997). Multifocal or disseminated hepatic LCH is mainly seen in patients who also show significant involvement of other organs and tissues and can present similar to multiple hepatic metastases (Hara et al. 1988; Guilarte Lopez-Manas et al. 1997). On the other hand, multiple tumor-like lesions at imaging may also be caused by marked periportal fibrosis in hepatic LCH (Arakawa et al. 1994).

Focal Granulomatoid Lesions (Including "Eosinophilic Granuloma")

Rarely, hepatic lesions in the context of LCH may contain numerous eosinophils, thus reflecting what previously has been termed eosinophilic granuloma, either unifocal or multifocal (the former Hand-Schüller-Christian disease; Parker and Lichtenstein 1963). Hepatic eosinophilic granuloma and other solitary liver lesions in LCH may radiologically be confounded with metastatic cancer (Saito et al. 2008). Hepatic lesions representing unifocal LCH may contain numerous lipid-laden macrophages in addition to eosinophils ("xanthomatous eosinophilic granuloma"; Fione and Rizzo 1959), leading to differential diagnostic problems with respect to other xanthomatous hepatic lesions such as those occurring in some lipidoses and in obstructive cholestasis. In an autopsy of a patient with multifocal LCH of the former Hand-Schüller-Christian type (chronic disseminated form of LCH), the liver was enlarged (1,900 g) and showed yellow flecks scattered about the parenchyma (Parker and Lichtenstein 1963). Histologically, the liver displayed marked cholestasis with formation of bile lakes, rounded portal tracts with fibrosis and ductular proliferations, and histiocyte-containing nodules (sometimes impinging upon bile ducts and producing florid duct lesions), containing in addition to histiocyte-like cells lipid-laden macrophages, but only few eosinophils, whereas a previous biopsy had shown eosinophil-rich nodules. This observation illustrates the transitional or overlapping features of LCH, lesions at one time point looking like the eosinophil-rich variant of focal LCH (eosinophilic granuloma) and showing at a later time point the features of xanthomatous lesions. Hence, an initial histologic diagnosis of eosinophil focal LCH or eosinophilic granuloma may result in the erroneous judgment that one deals with a benign process, what may then not be the case.

Langerhans Cell-Induced Secondary Sclerosing Cholangitis

A distinctive situation is obstructive cholestasis caused by secondary sclerosing cholangitis (SSC) in hepatic LCH (Leblanc et al. 1981; Thompson et al. 1984; Squires et al. 1993; Kaplan et al. 1999; Hadzic et al. 2000; Romao et al. 2002;

Lee et al. 2011). As in other forms of SSC, SSC due to LCH can result in secondary biliary cirrhosis. In a study of nine cases of LCH of the liver, four of the patients had SSC with visible infiltration of the ductal compartment with LC, but in two other patients, SSC was not associated with directly visible involvement of the ducts with LC (Kaplan et al. 1999). In children, LCH is probably a cause of SSC almost as frequent as SSC related to inflammatory bowel disease (Mieli-Vergani and Vergani 2001; Sabib et al. 2011). The pathogenesis of SSC in hepatic manifestations of LCH has not been clarified. In particular, infiltration of the bile ducts walls or the periductal tissues by LCH cells may be sparse. In five explanted livers with marked destructive cholangitis, CD1a staining revealed a small number of LCs in the choledochal wall in only one specimen (Braier et al. 2002). Conversely, there are highly unusual situations where marked infiltration of a hepatic duct in LCH has caused features clinically suggesting biliary atresia (Heitner et al. 1978). Furthermore, LCH of the eosinophilic granuloma type can produce highly cellular and micronodular lesions impinging upon the bile ducts, associated with florid duct lesions and focal-sectorial bile duct destruction (Parker and Lichtenstein 1963). The fibrotic response centered around the bile ducts results in a sonographic pattern characterized by hypoechoic or hyperechoic lesions, the hypoechoic changes probably corresponding to periportal inflammation (Chan et al. 1997).

Histologically, intrahepatic bile ducts show ductocentric fibrosis of varying cellularity, most of the infiltrate cells found in this periductal compartment consisting of lymphocytes, with variable contributions of macrophages (including epithelioid forms), plasma cells, and eosinophil granulocytes. Similar to SSC of other etiologies, lymphocytes and macrophages can reveal an intimate relation to bile ducts (Parker and Lichtenstein 1963), invade the normal-looking or already damaged biliary epithelium, with sectorial bile duct destruction, or infiltrate form micronodules impinging upon small bile ducts. The abnormal infiltration can be associated with portal tract fibrosis, sometimes with ductular proliferation (Parker and Lichtenstein 1963). In most situations, LC is only detectable when using immunohistochemistry (in particular CD1a), LC being recognized as single cells or small groups of cells intermingled with other cell types within the fibrotic areas. Usually, LC is not seen to invade the epithelial duct lining, even though this may occur. The array of these lesions has been put together to form two lesion groups, i.e., (a) small bile duct infiltration and destruction, producing clinicopathologic features of chronic cholestasis reminiscent of primary sclerosing cholangitis, and (b) destructive cholangitis of larger bile ducts, producing cystic dilatation and/or bile extravasation (Kaplan et al. 1999).

Biology of Disease

The clinical course strongly depends on stage of disease at presentation. Patients with solitary/unifocal disease have a 99 % or greater survival, while infants with multisystemic disease have a mortality of more than 60 %. Treatment strategies in LCH are based on the distribution pattern of disease and unifocality versus multifocality versus multisystemic disease. Low-risk organs include the skin, bone, lymph nodes, pituitary gland, and CNS. High-risk organs for unfavorable outcome are the bone marrow, lung, spleen, and liver involvement. The involution of lesions in some forms of LCH is well known, albeit multisystem variants can take a rapidly fatal course (Mosterd et al. 2008). In multisystem LCH (MS-LCH), reactivation is a frequent and early event, but involvement of risk organs at reactivation is rare and mortality is minimal. But reactivations have been shown to increase the risk for permanent consequences by about twofold (Minkow et al. 2008). The incidence of reactivation correlates with the stage of disease at diagnosis (Pollono et al. 2007). The spontaneous regression of lesions in single-system disease (and eventually in infantile self-healing forms) may be caused by apoptosis through the Fas/Fas-L pathway (Peng et al. 1999; Petersen et al. 2003).

On the other hand, LCH occurs in conjunction with, or is sometimes followed by, malignant

neoplasias involving a cell lineage different from LC. Examples of synchronous or metachronous neoplastic disorders comprise B-cell lymphoma (Almanaseer et al. 1986), T-cell lymphoblastic lymphoma (Li and Borowitz 2001; Rodig et al. 2008), splenic lymphomas (Llamas-Velasco et al. 2012), and Hodgkin's disease (Karadeniz et al. 1991; Ibarrola de Andres et al. 1999; Park et al. 2012). LCH has also been observed in conjunction with Erdheim-Chester disease (Pineles et al. 2011).

Cytogenetic and Molecular Features

Monoclonality and, hence, neoplastic features seem to be present in many, but not all, forms of LCH, clonality, i.e., having been identified in solitary lytic bone lesions, in multisystem disease of infancy, and in the intermediate form of the disease that usually has multisystem involvement and chronic course (Willman 1994; Willman et al. 1994; Yu et al. 1994; Badalian-Very et al. 2013), whereas the majority of cases with PLCH have been shown to be nonclonal lesions (Yousem et al. 2001). It has also been proposed that LCH may represent a reactive condition, possibly induced by immune stimulation (Bank et al. 2003). The clonal features of Langerhans cells may be related to elevated expression of p53, c-myc, and H-ras, the p53-p21 pathway and the p16-Rb pathway being activated (Schouten et al. 2002), and distinct deleted chromosomal segments, the highest frequency of LOH being found in chromosomes 1p and 7 (Murakami et al. 2002). As the abnormal dendritic histiocytes in LCH express elevated levels of tumor necrosis factor-alpha (TNF-alpha), IFN-gamma, GM-CSF, IL-1, and leukemia inhibitory factor (LIF), increased cytokine levels may contribute to the expansion of the cells, and polymorphisms of the TNF-alpha promoter in LCH could increase the production of that particular cytokine (Wu and McClain 1997), even though polymorphisms of the TNF-alpha promoter have not been detected in a more recent study (McClain et al. 2003). Tumor cells in LCH differ from normal epidermal LC in their transcription profile, in that they selectively express the Notch ligand Jagged 2, and are the only dendritic cells that express both Notch ligand and its receptor, suggesting the presence of a unique Notch signaling pathway in LCH cells (Hutter et al. 2012).

There is recent evidence that variably differentiated cells in LCH carry the BRAFV600E and BRAF600DLAT gene mutations (Badalian-Very et al. 2010; Sahm et al. 2012; Satoh et al. 2012; reviews: Badalian-Very et al. 2012, 2013), indicating that these mutations are somatic mutants enriched in LCH CD1a + cells. In BRAF V600E-negative LCH, a high prevalence of recurrent, mutually exclusive somatic MAP2K1 mutations was detected (Brown et al. 2014), supporting an important role for ERK (extracellular signal-regulated kinase) activation in pathogenic pathways involved in LCH (Chakraborty et al. 2014). There is evidence that MAPK activation in self-renewing hematopoietic progenitors cells can induce disseminated and high-risk disease, while MAPK activation in a more differentiated committed myeloid lineage promotes low-risk disease, shedding more light on the cells of origin of LCH (Collin et al. 2015).

Liver Manifestations of Eosinophilic Granuloma, Hand-Schüller-Christian Disease, and Abt-Letterer-Siwe Disease: What Is the Relationship with Modern LCH?

As specified above, these terms and the entities behind them are today obsolete; the disorders have been identified as related manifestations of a single nosologic entity, i.e., LCH (Lichtenstein 1953; Lieberman et al. 1969). In the context of the improvement of classification, based on increased knowledge regarding the cell involved, this is on the one hand a progress. On the other hand, the price that had to be paid is a certain loss of valuable information, mainly in regard to the understanding of excellent clinical and pathologic observations found in the older literature, specifically relating to liver involvement. In this paragraph, some informations pertinent to the liver and extractable from "historical" reports are

briefly summarized (historical reviews: Komp 1987; Coppes-Zantinga and Egeler 2002).

Originally, some of the "entities" discussed in this paragraph made part of what was called "nonlipid reticuloendothelioses" and defined to include Hand-Schüller-Christian disease (HSCD), eosinophilic granuloma of the bone, and acute disseminated reticuloendotheliosis (Letterer-Siwe disease, LSD). HSCD is characterized by the triad, diabetes insipidus, exophthalmos, and defects in membranous bones (Smith 1864; Hand 1893; Kay 1905; Schüller 1915; Christian 1919). Later reports put emphasis on the intriguing finding that the cells found in HSCD frequently accumulated considerable amounts of lipid ("lipoid histiocytosis," "lipoid granulomatosis"), resulting in the concept that the disorder might have something to do with a genuine lipid storage disease (Weidman and Freeman 1924). In contrast, acute forms of pediatric LCH do not usually show these features and thus were initially called "acute *nonlipid* disseminated reticuloendotheliosis" (Batson et al. 1955). Schüller, who appears in the eponym HSCD, described peculiar skull defects related to LCH and coined them "geographic skull defects (i.e., 'Landkartenschädel' in German)" (Schüller 1915). Later, he further discussed the lesions employing the term "dysostosis hypophysaria" (Schüller 1926). Henry Asbury Christian (1876–1951) had read the article of Schüller and, based on his own observations, thought that the disease in question was hypophyseal in origin, but apparently failed to recognize Dr. Hand's case of polyuria as being part of the same syndrome (Komp 1987). The cell type involved in these disorders, i.e., the LC, was detected during the same time period by the then 21-year-old medical student, Paul Langerhans (1847–1888), who studied medicine under Haeckel and Virchow and described in his 1869 thesis in the rabbit pancreas the structures that later became the islets of Langerhans, an eponymic term created by Edouard Laguesse (Coppes-Zantinga and Egeler 2002). The identification of skin dendritic cells (LC) was based on Cohnheim's gold chloride staining technique (Langerhans 1868).

The pathway to the concept of "eosinophilic granuloma" is rather complex as well. Two early reports independently documented, in the same year and in the same volume of the American Journal of Pathology patients with solitary bone lesions rich in both histiocytes and eosinophils (Lichtenstein and Jaffe 1940; Otani and Ehrlich 1940). "Unifocal" eosinophilic granuloma (UFEG), which is now classified as unifocal LCH, not only develops in bones but also in visceral organs including the liver. UFEG is its original description denotes the most benign disorder in the spectrum of LCH (review: Duncan et al. 1988). "Multifocal eosinophilic granuloma (MFEG)," proposed as a replacement for the designation formerly known as Hand-Schüller-Christian disease (HSCD) (Krutchkoff and Jones 1984), may also manifest in the liver. In contrast to UFEG/unifocal LCH, MFEG/HSCD is a chronic disorder with a complex manifestation pattern and a highly variable histology, including the participation of eosinophils, markedly depending on the manifestation site (Kaufman et al. 1976). In the liver, MFEG/HSCD presents in the form of multifocal lesions and displays a multifaceted infiltrate with or without numerous eosinophils, with or without easily detectable LC, and with or without lipid-laden macrophages or giant cells (Parker and Lichtenstein 1963). As the terms imply, a dense infiltrate of eosinophils should characterize these lesions. However, there are instances where unifocal LCH (the "new" entity) is poor in eosinophils, suggesting that unifocal LCH is heterogeneous (Papasozomenos 1999). This not only confers difficulties in histopathologic diagnosis but also has an impact on the pathogenesis of the lesion patterns associated with LCH.

The study of older reports on acute or subacute, rapidly progressive or even fulminant forms of LCH is fruitful insofar as one may obtain carefully collected clinical informations and pathology data from a pre-chemotherapy era. What has previously been termed Letter-Siwe disease (Abt-Letterer-Siwe disease; aleukemic reticulosis; Letterer 1924) is a highly impressive and catastrophic disorder mainly occurring in infants and children, fetal and congenital presentations also

being known (Shuangshoti and Seksarn 1987; Yu et al. 1990; Valde et al. 1993). Letterer reported an acute fulminant non-leukemic disorder of the Aschoffian reticuloendothelial system in a 6-month-old child (Letterer 1924). Nine years later, Siwe reported a further case (Siwe 1933) and formulated the diagnostic criteria of the disease. The eponymic term, Letterer-Siwe disease, goes back to Arthur Frederick Abt, an American physician. Together with Denenholz, he discussed the issue of so-called reticuloendothelioses by proposing the term Letterer-Siwe disease (Abt and Denenholz 1936). Hence, the disorder was sometimes called "Abt-Letterer-Siwe disease." A disseminated visceral involvement, including the liver, is a striking feature in many patients ("disseminated visceral histiocytosis X"; Landing 1987). The involvement of bona fide LC has been documented in at least part of the cases (Ruco et al. 1988). Lipid-laden histiocytes can also occur in the Letterer-Siwe type of LCD (Kawai et al. 1978), similar to MFEG/HSCD.

Langerhans Cell Tumors and Langerhans Cell Sarcoma

Introduction

A small subset of Langerhans cell neoplasms present as isolated mass lesions rather than a diffusely growing process. These Langerhans cell tumors (LCTs) have been proposed to be classified into two distinctive groups: (a) typical LCT consisting of cells found in classical Langerhans cell histiocytosis and (b) a sarcomatous form (Langerhans cell sarcoma, LCS) (Warnke et al. 1995; Lieberman et al. 1996; Pileri et al. 2002). The diagnosis of both lesions requires the detection of expression of both CD1a and S-100 protein, but there is frequently also expression of some histiocyte markers, such as CD68 and some focal, weak expression of lysozyme, the latter staining being clearly less than in histiocytic sarcoma and eventually being due to background staining or staining by infiltrating normal histiocytes/macrophages. Staining for CD35 or CNA.42 (Pileri et al. 2002); the transcription factor PU.1 (Muirhead et al. 2009); the phosphatidylserine receptors T-cell immunoglobulin mucin proteins 3 and 4 (Dorfman et al. 2010); langerin, fascin, DEC-205, and DC-SIGN (Orii et al. 2010); and CD163 (hemoglobin scavenger receptor) (Nguyen et al. 2005) has been described.

Langerhans Cell Tumors (LCTs)

Solitary or multiple circumscribed tumors consisting of Langerhans cells have seldom been observed in several organs and tissues, including the skin (Ricciardo et al. 2011) and the hepatobiliary tract. Multiple LCTs of the liver have been observed (Guilarte Lopez-Manas et al. 1997; Cavazza et al. 1999; Yagita et al. 2001) and in part suggested the existence of hepatic metastases of colorectal cancer. LCT has been found as a mass causing extrahepatic biliary obstruction in children, probably originating from periductal lymph nodes or lymph nodes situated near the porta hepatis (Chen et al. 1989). In rare instances, massive periportal fibrosis of the liver caused by hepatic Langerhans cell histiocytosis mimicked multiple liver tumors on CT and MR images (Arakawa et al. 1994).

Langerhans Cell Sarcoma (LCS)

ICD-O code 9756/3

Introduction

Langerhans cell sarcoma (LCS, synonyms: dendritic/histiocytic sarcoma, Langerhans cell type; malignant Langerhans cell tumor, MLCT; true histiocytic neoplasm of Langerhans cell type; malignant histiocytosis X) is a rare malignant dendritic cell neoplasm with a Langerhans cell phenotype and a highly aggressive biology (high grade), tending to disseminate throughout the body and leading to death usually within 1 year. This tumor has to be distinguished from LCH (Imamura et al. 1971; Henderson and Sage 1973; Wood et al. 1984; Delabie et al. 1991;

Tani et al. 1992; Favara et al. 1997; Itoh et al. 2001; Misery et al. 2003). It seems that at least part of the cases of LCS correspond to what has been reported in the literature "Letterer-Siwe disease of the adult" (Vollum 1979; Wells 1979). A particularly aggressive subset of LCS is positive for CD56/N-CAM (Kawase et al. 2005).

Morphology

LCS is composed of pleomorphic neoplastic cells, with nuclei having clumped chromatin and large nucleoli. Part of the cells display the diagnostically important complex grooves of LCH cells. The mitotic rate is usually high, with more than 50 mitotic figures per 10 HPFs. Ultrastructurally, Birbeck granules are present. Typical LCS has an immunohistochemical profile being CD1a/langerin/S100 +. Exceptionally, T-cell markers are expressed, e.g., CD3 (Xu et al. 2012b). LCS cells can express some members of the B7 superfamily, including B7-H1, B7-H3, and B7-H4, co-expressed with signals from the T-cell immunoglobulin and mucin-domain (TIM)-containing molecules, i.e., TIM-1, TIM-3, and TIM-4 (Li et al. 2013).

Epidemiology

LCS is a very uncommon neoplasm that almost exclusively occurs in adults, with a female predominance. The median age at diagnosis is 39 years (range 10–72 years). The most common sites of LCS are the skin and soft tissues, often with multiorgan involvement (lung, lymph nodes, spleen, bone, and liver). Rarely, LCS initially presents as a single-organ disorder, e.g., in the lung (Langfort et al. 2009) or in the thyroid (Kitahama et al. 1996).

Liver Involvement

As LCS may involve the liver, this lesion is discussed here in some more detail. In the patients described so far, the disease usually started in the skin in the form of erythematous nodules of up to a few centimeter diameter, followed by diffuse or nodular spread within the body. LCS exhibits overtly malignant cytologic features and marked, sometimes, extreme cellular pleomorphism (similar to histiocytic sarcoma), but cells with grooved nuclei are generally detected (Pileri et al. 2002). The cell involved exhibits immunohistochemical features typical for abnormal LC (CD1a and S-100 protein), and Birbeck granules have been detected (Wood et al. 1984). The cells of LCS express B7, a member of a group of proteins involved in the immunoescape of cancer cells (Li et al. 2012).

Multisystem involvement in LCS, including jaundice and infiltration of the liver, has been reported (Wood et al. 1984; Itoh et al. 2001; Kawase et al. 2005). In the patient described by Wood and coworkers (1984), autopsy of a patient with rapidly fatal MLCT revealed massive tumor infiltration of the liver; the neoplastic cells were identical to those detected in the earlier skin biopsies, many showing extremely large, multilobulated nuclei, looking like "bunches of grapes." Numerous mitoses were seen, and the eosinophilic cytoplasm was rather scanty. The neoplastic cells in this case exhibited typical Birbeck granules (Wood et al. 1984). LCS can arise in the gallbladder and involve locoregional lymph nodes (Zhao et al. 2009).

Biology of Disease

LCS is a high-grade tumor with rapid progression, still bearing a mortality of more than 50 %. LCS can undergo leukemic transformation (Sumida et al. 2008). The neoplasm may develop in the setting of other neoplasms. It can arise from Langerhans cell histiocytosis (Lee et al. 2006) and sometimes occurs on a background of other hematologic malignancies. LCS has been observed following ALL (Castro et al. 2010). A common clonal origin of an acute B-lymphoblastic leukemia and an LCS has been observed, suggesting evidence for hematopoietic plasticity (Ratei et al. 2010). LCS and dendritic cell tumors can occur in conjunction with chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), suggesting a transdifferentiation of CLL/SLL B cells to a dendritic or

Langerhans tumor cell lineage (Shao et al. 2011). LCS was found to arise from hairy cell leukemia (Muslimani et al. 2012).

Spontaneously Regressing/Involuting "Histiocytic" Disorders (So-Called Autoinvolutive Disorders)

Introduction

Several regressing or self-healing disorders involving an expansion of Langerhans cells or still ill-defined "histiocytic" cells have been identified, mainly in infants and children (Jang et al. 2000). Based on the data in the literature, a classification of these disorders is emerging, but not yet settled (Jang et al. 2000). The reason for the difficulties arising in the attempt at creating reliable categories is based on the fact that older investigations did not yet have access to modern cell typing and that terms such as "histiocytosis X" have been used to identify disorders with some clinical resemblance but quite different cells involved (Ferrando et al. 1982; Coldiron et al. 1988; Oranje et al. 1988; Contreras et al. 1990; Kolde and Bonsmann 1992; Gianotti et al. 1993; Hernandez-Martin et al. 1997; Campourcy et al. 1997; Hashimoto et al. 1999; Wee et al. 2000).

Classification

A preliminary classification is presented in Table 3. What seems to be established is that self-healing, and most frequently congenital or infantile, "histiocytoses" can involve Langerhans cells or cells with a histiocyte phenotype, the latter lacking Birbeck granules (Oranje et al. 1988).

Table 3 Working classification of self-healing Langerhans cell and non-Langerhans cell "histiocytic" disorders

Langerhans cell* "*histiocytic*" *disorders
Congenital self-healing Langerhans cell histiocytosis (CSHLCH), Hashimoto-Pritzker type (including variants with epidermotropism, pagetoid variants)
Solitary congenital self-healing Langerhans cell histiocytosis (SCSHLCH)
Self-healing childhood histiocytosis X of the Illig-Fanconi type (Illig-Fanconi disease)
Benign regressing histiocytosis of the Langerhans cell type
Non-Langerhans cell* "*histiocytic*" *disorders (*non-X histiocytoses*, *non-X histiocytic syndromes*)
Congenital self-healing non-Langerhans cell histiocytosis
Acquired regressive cutaneous non-Langerhans cell histiocytosis of infancy
Generalized eruptive histiocytosis (GEH, possible variants with regressive course: generalized lichenoid juvenile xanthogranuloma, benign cephalic histiocytosis)
Juvenile xanthogranuloma
Xanthoma disseminatum
Scalloped cell xanthogranuloma

Self-Healing Langerhans Cell Histiocytosis: A Complex Spectrum of Diseases

Self-healing Hashimoto-Pritzker LCH (Hashimoto-Pritzker disease; congenital self-healing histiocytosis/reticulohistiocytosis, CSHH/CSHR; congenital self-healing Langerhans cell histiocytosis, CSHLCH) is a rare variant of LCH originally described in 1973 (Hashimoto and Pritzker 1973). Since, several terms have been employed to denote this disorder, including reticulohistiocytosis of benign evolution, autoinvolutive congenital reticulosis, congenital self-healing reticulohistiocytosis, childhood self-healing histiocytosis X, congenital self-healing histiocytosis, and Hashimoto-Pritzker disease (Laugier et al. 1975; Mascaro et al. 1978; Bonifazi et al. 1982; Berger et al. 1986; Hashimoto et al. 1986; Pujol et al. 1988; Cambazard et al. 1988; Larralde et al. 1999). CSHLCH is characterized by neonatal onset, with purple or necrotic nodular lesions, rare visceral manifestations, spontaneous regression within the first 3 months of life, and an overall histology similar or identical to that of LCH, albeit with less Birbeck granules. Apart from multiple lesions, solitary variants have also been observed (Masouye et al. 1990; Shy et al. 1996; Tay et al. 1998; Walia et al. 2004; Kapur et al. 2007; Belhadjali et al. 2008; Sankilampi et al. 2008;

Hatakeyama et al. 2009). Unusual cases showed involvement of monozygotic twins (Ersoy-Evans et al. 2006) or late-onset disease, e.g., in an 8-year-old girl (Nakahigashi et al. 2007). Rarely, CSHLCH presents as a blistering eruption (Higgins et al. 1994), with hemorrhagic bullae (Inuzuka et al. 2003) or with papulovesicular, herpes-like lesions (Morgan and Callen 2001), and a variant with marked epidermotropism of the abnormal Langerhans cells, with a pagetoid growth pattern, has been reported (Hashimoto et al. 1999). As skin lesions of CSHLCH may contain large numbers of mast cells, Darier's sign typical for mastocytosis can ensue (Butler et al. 2001). The infiltrating cells show, at electron microscopic examination, a complex cytoplasmic structure, with myelinoid inclusions, laminated profiles, and so-called vermiform bodies but only few Birbeck granules (Laugier et al. 1975; Bonifazi et al. 1982; Kanitakis et al. 1988; Larralde et al. 1999). It has to be emphasized that not all patients clinically presenting with CSHLCH will follow a favorable course. The disorder may, in its early phases, mimic congenital LCH, and the outcome may then be dismal (Longakter et al. 1994; Larralde et al. 2003).

Solitary Congenital Self-Healing Langerhans Cell Histiocytosis

SCSHLCH is a very rare congenital disorder characterized by single (solitary) cutaneous Langerhans cell lesions that show self-healing (Chun and Song 1992; Dorjsuren et al. 2011; Wheller et al. 2013; Yurkovich et al. 2013). One variant of SCSHLCH revealed a combine immunohistochemical phenotype, cells being both CD1a+ and S100+ (Tardio et al. 2013).

Self-Healing Childhood Histiocytosis X (Illig-Fanconi Disease)

Illig-Fanconi disease is a rare cutaneous self-healing Langerhans cell histiocytosis restricted to the pediatric age group. Clinically, the skin lesions are characterized by few, small, translucent, and confluent papules, sometimes purpuric. This histology is that of LCH, ultrastructurally with the presence of Birbeck granules (Ferrando et al. 1982; Calero et al. 1986).

Self-Healing Non-Langerhans Cell "Histiocytic" Disorders

Self-healing non-Langerhans cell, or non-X, histiocytoses constitute a group of disorders that share clinical manifestations and are characterized by proliferations of histiocyte-like cells or macrophages in the absence of evidence for Langerhans cell histiocytosis (Zelger et al. 1996). The diseases present as in part nodular cutaneous infiltrates consisting of cells with a histiocytic phenotype, being reactive for Leu M3 and HLA-DR, but CD1 – and Leu-6 – negative and lacking Birbeck granules (Oranje et al. 1988; Kodet et al. 1991). The cutaneous forms can occur as congenital lesions or as acquired regressive skin lesions.

Generalized eruptive histiocytosis/histiocytoma (GEH) is a rare and self-healing non-Langerhans cell histiocytosis, clinically characterized by recurrent crops of papules that appear in a symmetrical fashion on the face, trunk, and arms. The disorder occurs both in children and adults. GEH may represent an early undifferentiated stage of various histiocytic disorders (Winkelmann and Müller 1963; Stables and Mackie 1992; Wee et al. 2000; Seward et al. 2004). Benign cephalic histiocytosis is histologically similar to juvenile xanthogranuloma and generalized eruptive histiocytosis (Gianotti et al. 1993), but chiefly involves the head and the neck (Jih et al. 2002).

Liver Involvement in Self-Healing Histiocytosis Syndromes (Except Juvenile Xanthogranuloma and Xanthoma Disseminatum)

Congenital Self-Healing Langerhans Cell Histiocytosis (Hashimoto-Pritzker Disease)

CSHLCH may rarely involve inner organs, e.g., involvement of the lung (Chunharas et al. 2002) or infiltration of the eye (Zaenglein et al. 2001). Hepatomegaly has been encountered in CSHLCH

(Chunharas et al. 2002). In a female newborn with CSHLCH, liver ultrasonography revealed hypoechoic lesions with blurred borders, suggested to represent liver involvement with this form of histiocytosis (Parentin et al. 2011). In one patient with Hashimoto-Pritzker disease and marked cutaneous involvement, multisystem disease with involvement of the liver, bone marrow, lymph nodes, and lung was noted (Mandel et al. 2014).

Benign Regressing Histiocytosis

Benign regressing histiocytosis of the Langerhans cell type has been reported to manifest in the liver. In an adult patient, the disease presented in the form of multiple hepatic nodules varying in size from 0.5 to 1 cm, histologically composed of clusters of polygonal to roundish, S100-protein-positive cells with granular, eosinophilic cytoplasm and vesicular nuclei with central folding, admixed with an infiltrate of eosinophils and lymphocytes. At EM examination, no Birbeck granules were detectable. The liver nodules spontaneously disappeared within a relatively short time period (Foschini et al. 1995).

Juvenile Xanthogranuloma

In normolipemic juvenile xanthogranuloma (JXG, synonym: naevoxantho-endothelioma) and its variants, cutaneous accumulations of histiocytes lacking Birbeck granules and without the immunohistochemical features of Langerhans cells occur. JXG was first described as a clinicopathological entity, in 1905 (Adamson 1905) and 1912 (McDonagh 1912), but Virchow had already described a child with cutaneous xanthomas in 1871. JXG is the only more common non-Langerhans cell histiocytosis (Burgdorf and Zelger 1996; Hernandez-Martin et al. 1997; Dehner 2003; Janssen and Harms 2005; Sivapirabu et al. 2011) and is, in most instances, a benign disorder of infancy and early childhood characterized by yellowish cutaneous nodules that spontaneously regress over months to years.

Very few cases of typical JXG have been observed in the adult age group (Jain et al. 2011; Narvaez-Moreno et al. 2013). The most common skin lesions are classified as either solitary versus multiple or a "small nodular form" versus a "large nodular form," but other manifestations comprise keratotic, lichenoid, pedunculated, subcutaneous, clustered, plaque-like, giant, eruptive, disseminated, or disseminated clustered lesions (Sidwell et al. 2005; Aparicio et al. 2008; Kaur et al. 2008). In the vast majority of children, JXG is usually limited to the skin, but systemic forms occur (Chang 1999; Jain et al. 2011). JXG is currently thought to be a proliferative disorder of dendrocytes, possibly dermal dendrocytes (Kraus et al. 2001), i.e., a "dendritic cell-related histiocytosis." However, the cellular infiltrate is mixed, consisting of monocytoid and macrophage-like forms, epithelioid and foamy macrophages, Touton giant cells, lymphocytes, plasma cells, eosinophils, and spindle cells of two forms (dendritic and fusiform) (Tahan et al. 1989). Although JXG is classified as a non-Langerhans cell histiocytosis, very rare "overlap disorders" have been observed, e.g., LCH preceding the development of JXG, possibly caused by therapy-induced modulation of cell differentiation (Bains and Parham 2011), or LCH accompanying JXG as a deep-seated process (Tran et al. 2008).

Histologically, JXG is characterized by lipid-laden, foamy macrophages (foamy histiocytes) in upper parts of the dermis. These cells have centrally placed, bland nuclei of the macrophage type, usually without visible mitotic activity. These cells are intermingled with Touton giant cells, lymphocytes, and eosinophils. Touton cells ("xanthelasmic giant cells") were described in 1885 by Karl Touton, who was active as a specialist in dermatology and venereal diseases in Wiesbaden, Germany, where he also had duties as physician in a spa ("Badearzt") (Touton 1885; review: Aterman et al. 1988). Apart from this "classical" form, a hypolipidized or nonlipidized form also exists, showing a more diffuse pattern of infiltration, with or without rare Touton cells, and a mitotic activity that is somewhat higher than in the "classic" form. This phenotype has been termed mitotically active xanthogranuloma

(Batista et al. 2012; Ngendahayo and de Sant Aubain 2012).

The etiology and pathogenesis of JXG are not known. As the lesions can regress, a reactive process has been suggested, but at least one study showed a clonal bone marrow proliferation with a distinct abnormal karyotype, in the absence of leukemia (Maly et al. 2012). Clonality in another case has been demonstrated via the HUMARA technique (Janssen et al. 2007). JXG can be associated with certain other disease entities. An association between JXG and juvenile myelomonocytic leukemia, with or without neurofibromatosis type 1, has been recognized in more than 20 cases (Cooper et al. 1984; Shin et al. 2004; Cham et al. 2010; Al Ghamdi and Al Suwaidan 2010; Arachchillage et al. 2010; Raygada et al. 2010). JXG has been found in association with Wiskott-Aldrich syndrome (Jesenak et al. 2013).

JXG rarely presents with systemic involvement (systemic juvenile xanthogranuloma, "deep juvenile xanthogranuloma"), with involvement of diverse inner organs, including the central nervous system (sometimes with multiple cerebral lesions), heart, lung, kidney, bone marrow, and liver (Fig. 7). Involvement of the liver has been reported several times, also in the setting of neonatal systemic xanthogranulomatosis (Diard et al. 1982; de Graaf et al. 1992; Di Blasi et al. 1993; Guthrie and Arthur 1994; Freyer et al. 1996; Favara 1996; Dehner 2003; Chantranuwat 2004; Nakatani et al. 2004; Cabrera et al. 2005; Janssen and Harms 2005; Unuvar et al. 2007; Yeh et al. 2007; Azorin et al. 2009; Patel et al. 2010; Fan and Sun 2011). Among 34 children with various forms of systemic JXG, the median age was 0.3 years; 8/34 had involvement of the liver/spleen (Freyer et al. 1996). In a large study on 174 patients, visceral manifestations were identified in 5 % of the patients (Dehner 2003). Neonates with systemic JXG can develop severe and sometimes fatal liver disease associated with fever, jaundice, hepatomegaly, ascites, and giant cell neonatal hepatitis in addition to xanthogranulomas in the liver and other visceral sites (Hu et al. 2004; Chantorn et al. 2008; Azorin et al. 2009; Papadakis et al. 2012). Severe congenital systemic JXG with liver failure has been observed in monozygotic twins (Chantorn et al. 2008). Massive liver involvement in neonatal disseminated JXG with progressive cholestasis, marked hepatic infiltration, and portal hypertension may require liver transplantation (Haughton et al. 2008). Hepatic manifestation of JXG may be associated with hypergammaglobulinemia (de Graaf et al. 1992). Indirect liver changes consist of obstructive jaundice, e.g., in case the manifestations of JXG develop in the pancreatic head (Prasil et al. 1999).

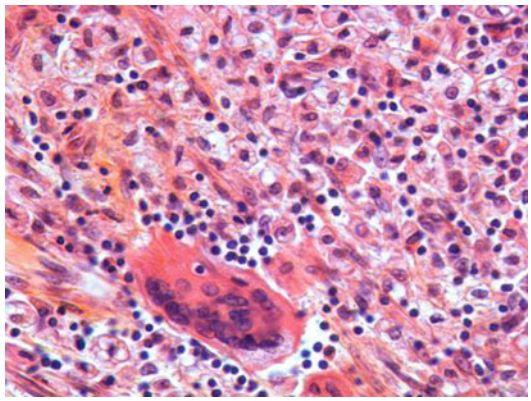

Fig. 7 Juvenile xanthoma in the liver. The lesion is characterized by foamy xanthomatous cells, but can also contain Touton-type giant cells (hematoxylin and eosin stain)

In severe liver involvement, hepatomegaly develops, and yellow nodules are seen on the liver surface at laparoscopy (Di Blasi et al. 1993). The cell types prevailing in extracutaneous sites consist of mononuclear (monocytoid) cells and spindle cells (arranged in fascicles or in a storiform pattern), whereas Touton giant cells are less common or even lacking. The portal tracts may be crowded with lipid-laden foamy macrophage-like cells or spindled nonlipidized cells (Dehner 2003; Haughton et al. 2008), and focal granulomatous lesions may be present (Favara 1996). The immunophenotype of these cells is characterized by uniform positivity for vimentin, CD68, and factor XIIIa, while S-100 protein and CD1a are consistently negative (Dehner 2003; Janssen and Harms 2005). The hepatic manifestations of JXG may be accompanied by syncytial giant cell hepatitis in neonates

and infants (Dehner 2003). In case of JXG-induced fulminant infantile hepatic failure, autopsy showed marked hepatomegaly, the organ containing extensive irregular nodular tumor infiltrates centered around blood vessels and portal tracts. Histologically, interlobular bile ducts were encircled by JXG tissue, but biliary epithelium was not infiltrated. The tumor cells consisted of a population of plump histiocytoid and spindle-shaped forms. Touton cells were present but rare. The process had infiltrated the lumen of hepatic vein, the veins sometimes being nearly completely occluded by tumor. There were signs of infantile syncytial giant cell hepatitis (Hu et al. 2004).

Xanthoma Disseminatum

Xanthoma disseminatum (XD, disseminated xanthoma, Montgomery syndrome) is a rare benign non-Langerhans cell histiocytic disorder in older children and adults of unknown etiology and pathogenesis. In 60 % of cases of XD, the age of onset has been between 5 and 25 years, men being affected twice as common as females (Altman and Winkelmann 1962). XD was first described in 1938 (Montgomery and Osterberg 1938), is characterized by the development of cutaneous xanthomas, and typically involves the skin of the flexor skinfolds and eyelids or a mucocutaneous disorder but may also affect inner organs, including the eye, CNS, pituitary gland, peripheral nerves, skeletal system, respiratory tract, kidney, pancreas, uterus, and gastrointestinal tract.

Involvement of the respiratory tract, complicated by dyspnea, life-threatening obstruction, and eventually asphyxiation, is the most recognized cause of morbidity in XD (Altman and Winkelmann 1962; Caputo et al. 1995; Ferrando et al. 1998; Davies et al. 2000). XD is usually not associated with hyperlipidemia. The biology of disease of XD is commonly benign, but visceral manifestations can cause morbidity and mortality (reviews: Ringel and Moschella 1962; Weiss and Keller 1993; Alexander et al. 2005). Caputo and coworkers (1995) identified three clinical patterns of XD. In the first pattern, skin lesions are persistent and continue unabated in patients who are otherwise in good health. The second form is characterized by spontaneous regression of lesions after many years (self-healing form). The third form, the rarest variant, exhibits systemic involvement, including the CNS and other organs. Involvement of the hypothalamo-pituitary region often causes diabetes insipidus. In a minority of patients with XD, malignant lymphoma has developed as a late complication (Battaglini and Olsen 1984; Shoo et al. 2008). Histologically, the foamy histiocytes/macrophages (xanthoma cells) form clusters and then develop into plaques or nodular lesions, the infiltrate being mostly situated in the upper and mid dermis. These cells are CD68+, but are negative for S-100 protein and CD1a, and lack Birbeck granules (Zelger et al. 1992; Weiss and Keller 1993; Ferrando et al. 1998; Caputo et al. 2003). The histiocytic infiltrate may contain Touton giant cells. Non-foamy histiocytes and lymphocytes may also occur (Caputo et al. 2003).

In a minority of patients, XD can involve the liver, with formation of nodular lesions of fatlike low density on CT images, consisting of xanthoma cells (Woollons and Darley 1998). A 32-year-old female patient with XD associated with diabetes insipidus and progressive CNS and ocular involvement revealed an echo-dense liver and gallbladder polyposis. A liver biopsy showed steatosis and foamy histiocytes in portal tracts (Knobler et al. 1990). Liver involvement was suspected in a child having XD with systemic manifestations in the skeleton and marrow cavities (Calverly et al. 1995). Hepatic steatosis has been observed in XD (Celic et al. 2004).

Neoplasms of Histiocyte/Macrophage Lineage: Histiocytic Sarcoma and Similar Neoplasms

101

Contents

Abstract

Malignant neoplasms of the histiocyte/macrophage lineage can develop as primary lesions in the hepatobiliary tract, but more frequently involve the liver as metastatic lesions. Histiocytic sarcoma is a very rare and highly malignant neoplasm of cells with features of mature tissue histiocytes. The diagnosis of histiocytic sarcoma was previously more frequently formulated, but many of the former so-called malignant histiocytic neoplasms have later turned out to be poorly differentiated tumors of B and T lymphocytes and dendritic cells. True histiocytic sarcomas amount to less than 1 % of all lymphomas that occur in lymph nodes. Extranodal histiocytic sarcoma can very rarely involve the liver and/or biliary tract. Here the cancer presents in the form of a nodular or diffuse proliferation of oval to spindle-shaped abnormal histiocytes. Apart from mononuclear tumor cells, multinucleated giant cells also develop. The cells are immunoreactive for histiocyte-associated markers, specifically CD68 and CD163, but are consistently negative for CD1a and markers of the B- and T-cell lineages.

Histiocytic Sarcoma

ICD-O code: **9755/3**

Introduction

According to the WHO classification of tumors, histiocytic sarcoma is a very rare, highly malignant neoplasm of cells with the features of mature tissue histiocytes. Neoplasms associated with acute monocytic leukemia are excluded (review: Grogan et al. 2008).

Terminology, Cell of Origin, and Classification

Most of malignancies formerly classified as so-called malignant "histiocytic" neoplasms have later turned out to be poorly differentiated B-cell, T-cell, or anaplastic lymphomas, and only a very small fraction of the lesions are histiocytic lymphomas of monocyte/macrophage or dendritic cell origin. Conditions previously termed "histiocytic medullary reticulosis" are now regarded as a heterogeneous group of lesions, but often belonging to the hemophagocytic syndromes. Histiocytic sarcoma is derived from macrophages/histiocytes, which in turn originate from bone marrow-derived monocytes. Macrophages and the phagocyte concept in general go back to Metchnikoff (review: Tauber 2003). Neoplasms with a histiocytic lineage are closely related to monocytic tumors, but are separated from tumors that arise in the setting of monoblastic/monocytic leukemias (review: Jaffe et al. 2008).

In order to separate lymphomas with a clear histiocyte lineage from other lymphomas that may morphologically resemble them, the term "true histiocytic lymphoma" has previously been proposed and employed (Isaacson et al. 1983; Pileri et al. 1985; Hsu et al. 1991; Levine et al. 1991; Kamel et al. 1995; Elghetany 1997; Copie-Bergman et al. 1998). Also the designation, monocytic sarcoma, was in use (Soria et al. 1992). These terms have now been replaced by histiocytic sarcoma as used in the most recent WHO classification. Histiocytic sarcoma was already employed as a term in the older literature (van der Valk et al. 1981; Lauritzen et al. 1994). In the 2001 WHO definition of histiocytic sarcoma, the absence of clonal immunoglobulin heavy chain (IgH) or TCR gene rearrangements were required for diagnosis. The 2008 version of the WHO classification no longer strictly requires the absence of these rearrangements, as histiocytic sarcomas that have developed concurrent with or subsequent to B- or T-cell non-Hodgkin's lymphomas, or mature B-cell neoplasms, can show IgH or TCR rearrangements (review: Takahashi and Nakamura 2013).

Epidemiology

Malignant neoplasms of the histiocyte lineage represent very rare lymphoid tissue tumors and amount to less than 1 % of all lymphomas occurring in lymph nodes. Most histiocytic sarcomas are diagnosed in adult patients (median age: 52 years), but the neoplasm also occurs in the pediatric age group (Brito et al. 2014). Whether a sex predilection is present is still a matter of controversy, but probably the neoplasm occurs equally between men and women.

Clinical and Imaging Features

Most histiocytic sarcomas were detected in extranodal compartments, specifically the skin, soft tissues, and the gastrointestinal tract. Less common organs include the CNS, mediastinum, kidney, breast, salivary glands, liver, and biliary tract. Apart from signs and symptoms related to tumor-induced alterations at the primary site (mass effects, pain, hemorrhage), many patients experience systemic signs and symptoms, such as fever, weight loss, fatigue, and anemia. Hepatosplenomegaly is a common finding. In

the GI tract, histiocytic sarcoma can cause hollow organ obstruction and bleeding. In a minority of patients, the neoplasm manifests as a systemic disorder with multiple nodules in many organs and tissues, a condition termed, "malignant histiocytosis." In advanced disease, the bone marrow can be extensively infiltrated, followed by pancytopenia and lytic bone lesions (Pileri et al. 1985; Ralfkiaer et al. 1990; Kamel et al. 1995; Copie-Bergman et al. 1998; Sun et al. 2003; Hornick et al. 2004; Gill-Samra et al. 2012; Guan et al. 2012; Sundersingh et al. 2012; Wang et al. 2012; Shen et al. 2013; Wu et al. 2013). In most patients, histiocytic sarcoma is a high-grade, aggressive lymphoma with a poor response to therapy. Many patients present with clinically high stage at diagnosis, associated with progressive disease, while patients with low stage and small tumors at diagnosis have a more favorable course.

Histiocytic Sarcoma of the Hepatobiliary Tract

Extranodal histiocytic sarcoma can rarely involve the liver and/or the biliary tract. Infiltration of the liver is rare and is present as a focal to diffuse infiltration causing hepatomegaly or in the form of tumor nodules/masses (Hornick et al. 2004; Hayase et al. 2010). In case of an ill-defined-non-nodular infiltrate, the histiocytoid or epithelioid cells form a non-cohesive monomorphous infiltrate that can efface the portal tracts and replace the parenchyma. Within lobules, the neoplastic cells can grow within hepatic sinusoids, forming a distinct intravascular infiltrate. Hepatic infiltrates show a cellular morphology similar to that in other organs and tissues, containing oval, polygonal, spindled, and multinuclear giant cells with an abundant eosinophilic and often vacuolated cytoplasm and round to ovoid or reniform nuclei with a mostly open chromatin structure. Histiocytic sarcoma can show evenly distributed multinucleated CD68(+)CD163(+) giant cells scattered among polygonal mononuclear cells

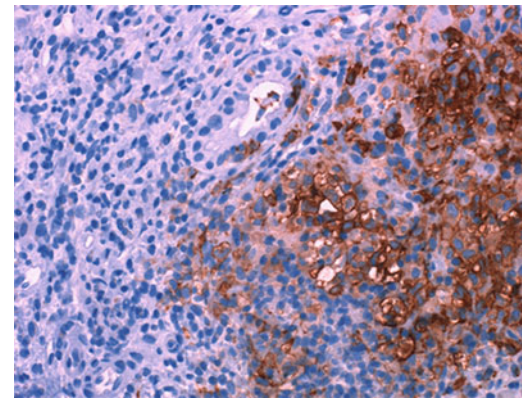

Fig. 1 Histiocytic sarcoma of the liver. The medium-sized to large neoplastic cells form a diffuse growth and are positive for CD68 (CD68 immunostain)

with epithelioid features (Copie-Bergman et al. 1998; Miliauskas 2003; Huang et al. 2007). The neoplasms show small numbers of background lymphocytes and reactive histiocytes/macrophages (Miliauskas 2003). The cells are immunoreactive for histiocyte-associated markers, i.e., CD68, CD163, lysozyme, and alpha-1-antitrypsin (Fig. 1), and for CD45 or CD45RO, but are consistently negative for CD1a/langerin, CD21, CD35, CD13, CD33, and markers of B-cell and T-cell lineages. Both CD68 and lysozyme show a markedly granular immunostaining, while CD163 shows a membrane and/or cytoplasmic staining (Hanson et al. 1989; Copie-Bergman et al. 1998; Sato et al. 2002; Vos et al. 2005). Part of the cells may express S100 protein (Copie-Bergman et al. 1998). The proliferation fraction varied considerably in published observations but may exceed 80 %. In one analysis, two distinct populations of cells were recognized. Oval cells were CD68(+)lysozyme(+) CD163(−), while spindle-shaped cells with abundant cytoplasm were CD68(+)lysozyme(−)CD163(−) (Wakahashi et al. 2010).

Nodular involvement of the liver is characterized by grayish white, solid, and soft tumors (Hayase et al. 2010). Involvement of the liver can result in hepatic dysfunction and peliosis hepatis (Fine et al. 1995). In an old male patient,

this type of neoplasm was found in the extrahepatic bile duct, causing stenosis and obstructive jaundice (Miyabe et al. 2014).

Differential Diagnosis

Cytomorphologically, histiocytic sarcoma can be confounded with malignant lymphoid neoplasms that have previously been classified as "true histiocytic," i.e., mainly high-grade B-cell, T-cell, and anaplastic non-Hodgkin's lymphomas. Immunohistochemistry, in particular CD68, CD163, and lysozyme immunostains, is mandatory for diagnosis.

Pathogenic Pathways

Etiology and pathogenesis of histiocytic sarcoma are still largely unknown. Histiocytic sarcoma or "true histiocytic lymphoma" was found to develop following other lymphoid or myeloid malignancies (so-called lineage conversion), including acute lymphoblastic neoplasms (Soslow et al. 1996; Bouabdallah et al. 2001; Dictor et al. 2009; Castro et al. 2010), hairy cell leukemia (Michonneau et al. 2014), low-grade follicular lymphoma (Stoecker and Wang 2013), chronic lymphocytic leukemia (Wang et al. 2010; Stoecker and Wang 2013), chronic myelomonocytic leukemia (Mori et al. 2010), or autoimmune lymphoproliferative syndrome and associated Rosai-Dorfman disease (Venkataraman et al. 2010). Interestingly, part of the tumors occurred in association with non-seminomatous germ cell tumors, mostly of the mediastinum and less often gonadal germ cell tumors, and usually malignant teratoma with or without yolk sac differentiation and embryonal carcinoma (Pileri et al. 1985; Ladanyi and Roy 1988; Koo et al. 1992; Margolin and Traweek 1992; Sasou et al. 1996; Suenaga et al. 2006). Histiocytic sarcoma often occurs within 1 year of germ cell tumor diagnosis. In addition to this sarcoma, other lymphoid malignancies are associated with germ cell tumors of the mediastinum and gonads. It has been suggested that embryonal progenitor cells occurring in certain germ cell tumors, such as teratocarcinoma, and capable to differentiate along a hematopoietic lineage may be involved in the emergence of histiocytic sarcoma.

Histiocytic sarcoma cells may show various cytogenetic abnormalities of several chromosomes, including chromosomes 3, 4, and 8 (Alonso-Dominguez et al. 2012). Recent investigations uncovered frequent BRAFV600E mutations in histiocytic sarcoma. In one study, these mutations were detectable in 62.5 % of the neoplasms and were more common than in Langerhans cell tumors and dendritic cell neoplasms (Go et al. 2014). A BRAFV600E mutation was also found in a histiocytic sarcoma arising from hairy cell leukemia (Michonneau et al. 2014). Human histiocytic sarcoma showed, similar to its murine counterpart, genetic or epigenetic inactivation of PTEN, p16(INK4A), and p14(ARF) (Carrasco et al. 2006).

"Reticulum Cell Sarcoma" of the Liver

Introduction

Reticulum cell sarcoma ("reticulosarcoma"; "retothelial sarcoma") is a now almost obsolete term. It denoted a mesenchymal malignant neoplasm that was formerly often diagnosed as a neoplastic lesion derived from reticulum cells and also appears in old references on hepatic sarcomas. It was described as a highly cellular sarcoma composed of small- to medium-sized spindle cells with pale cytoplasm and ovoid to slightly elongated nuclei and characterized by a high content of reticulin fibers as shown in silver stains. As a function of the redefinition of mesenchymal cells and tumors derived thereof, many if not most of the tumors previously diagnosed as "reticulum cell sarcoma" are now classified as other mesenchymal malignancies, in particular true malignant histiocytomas, and what the relatively few remaining cases really are remains to be clarified in more detail. However, for reasons of history and comparison, cases formerly diagnosed and reported as hepatic reticulum cell sarcoma are briefly discussed in this chapter. Based on the

description (although often very detailed) and the published figures, it is in many cases very difficult, or impossible, to transform the original diagnosis of reticulum cell sarcoma into a modern tumor category. However, at least part of the neoplasms may now represent dendritic cell neoplasms, neoplasms of the histiocyte lineage, or fibroblastic reticulum cell tumors.

Liver Involvement

Relatively few older reports described primary reticulum cell sarcoma or reticulosarcoma of the liver (Gasser 1955; Jozsa and Lusztig 1961; Leite 1963; Mastella and Paduano 1960; Ata and Kamel 1965; Markiewicz and Brzezinska 1965; Torres and Bollozos,1971; Portmann et al. 1976).

Macroscopy

The necropsy case reported by Gasser (1955) showed multiple tumor nodules that involved the entire organ. The white and firm nodules were isolated or clustered, and the largest nodule had the size of a fist.

Histopathology

Reticulum cell sarcomas were described as neoplasms composed of medium-sized to large, elongated, or polygonal cells with pale, ill-defined cytoplasm and pleomorphic nuclei. Part of the cells formed syncytia, and some cells were reported as histiocyte-like. There was a striking abundance of argentophilic reticulin fibers, forming a dense network, single tumor cells being surrounded by these fibers (Gasser 1955).

Differential Diagnosis

Some of the previous reticulum cell sarcomas of the liver may now be classified as metastatic fibroblastic reticulum cell sarcomas (Yaman et al. 2009) or as neoplasms of the dendritic cell and histiocytoid cell systems.

"Kupffer Cell Sarcoma" of the Liver

Several older reports describe so-called Kupffer cell sarcoma of the liver (Baker et al. 1956; Burston 1958; Pizzolato and Kistler 1959; Linquette et al. 1960; Matturi and Rossi 1963; Miller et al. 1964; Galup et al. 1965; Kwittken and Tartow 1966; Blackwell and Joske 1970; Mölleken 1973; Gentili et al. 1974; Greenberg 1977; Evans and Grasso 1978). In part of the cases, the tumors may have been angiosarcomas, because the authors employed the terms hemangioendothelioma ("reticulosarcoma angioplasticum"), hemangioendotheliosarcoma, or angioblastic reticuloendotheliomas as synonyms for Kupffer cell sarcoma (Matturi and Rossi 1963; Miller et al. 1964; Gentili et al. 1974). The macroscopy of a multinodular liver malignancy depicted by Baker et al. (1956) is that of a typical multinodular angiosarcoma. The figure shown in the report of Mölleken (1973) shows a neoplasm strongly resembling angiosarcoma, and the author diagnosed it as a special form of hemangioendothelioma classified as Kupffer cell sarcoma. Hepatic sarcomas thought to derive from Kupffer cells have also been observed in rats, in part following exposure to chemical carcinogens (Kendrey and Németh 1967; Chopra et al. 1979). In humans, Kupffer cell sarcoma is now an obsolete entity, part of the cases probably representing neoplasms of the macrophage/histiocyte and dendritic cell lineages.

"Histiocytoid Cell" Proliferations of Uncertain Cell Lineage

Introduction

There are several non-Langerhans cell proliferative "histiocytoid" disorders with an uncertain cell lineage and still unknown etiology. In regard to their biology, the lesions range from self-limited to progressive behavior. Part of these disorders

show multiple nodular or eruptive skin lesions but may also involve mucosal surfaces, inner organs, and the articuloskeletal system. Cutaneous forms can show a progressive course but may also exhibit regression.

ALK+ Histiocytosis

General Remarks

Histiocytic disorders in the pediatric age group mainly comprise Langerhans cell histiocytosis, several types of self-healing Langerhans cell and non-Langerhans cell disorders, EBV-associated hemophagocytic syndrome, and hemophagocytic lymphohistiocytosis. ALK+ histiocytosis is a novel systemic disorder that has been added to this list. The disease, characterized by a proliferation of morphologically distinctive histiocytes with unique expression of ALK, was described in three female infants who presented with pallor and prominent hepatosplenomegaly, but without fever. There was marked anemia and thrombocytopenia, but no leukopenia. Bone marrow showed no hemophagocytosis, but scanty ALK-positive cells or solitary or in tiny aggregates. The histiocytic process mainly involved the liver, but one patient developed a cutaneous infiltration morphologically resembling juvenile xanthogranuloma. In one patient, a TPM3-ALK fusion was detected. The disease in these three patients (two with chemotherapy) resolved slowly over many months (Chan et al. 2008).

Liver Involvement

Liver biopsies showed sinusoidal infiltration by single or small aggregates of very large histiocytes with and eosinophilic, vacuolated cytoplasm and irregularly folded or lobulated nuclei, a fine chromatin structure, and small nucleoli. Few cells contained two to four nuclei. Part of the cells revealed phagocytosis of lymphocytes, granulocytes, normoblasts, erythrocytes, or hemosiderin granules. In one patient, the histiocytes also infiltrated portal tracts. Ultrastructurally, Birbeck granules were not detectable. Immunohistochemically, the cells were strongly reactive for CD68, CD163, and lysozyme and heterogeneously for S100 protein. The cells were uniformly reactive for ALK in a membranous and weak cytoplasmic staining pattern. Immunostaining with anti-phospho-ALK antibody displayed granular cytoplasmic staining suggesting ALK fusion protein phosphorylated on tyrosine 664. There was no reactivity for CD1a and langerin (Chan et al. 2008).

Multicentric Reticulohistiocytosis

Multicentric reticulohistiocytosis (MRH; synonyms: generalized giant cell histiocytosis; lipoid dermatoarthritis; lipoid rheumatism; reticulohistiocytic granuloma; reticulomatosis with histiocytic giant cells; histiocytosis giganto-cellularis) is a rare condition characterized by widespread papulonodular skin and mucosal lesions, periungual coralliform nodules, periarticular nodules, severe symmetrical erosive to destructive and sometimes mutilating arthritis, and eventual involvement of inner organs, including bronchopulmonary system and the liver. MRH was described in the late nineteenth century (Targett 1897) and then in 1936 (Weber and Freudenthal). The disease starts with polyarthritis in at least half of patients, followed by skin lesions months to years later. Males and females are equally involved, and the disorder manifests between 40 and 45 years in most cases. Very rare pediatric cases are known. The skin lesions, which may grow to several cm of size, consist of proliferating histiocyte-like cells and multinucleated giant cells with an eosinophilic "ground-glass" cytoplasm (reviews: Holobar and Mach 1966; Rooney et al. 1975; Bach 1983; Liu and Fang 2004; Sroa et al. 2010; Islam et al. 2013). Liver involvement presented in the form of scattered nodules histologically showing the typical infiltrate including giant cells (Yang et al. 2009).

Progressive Nodular Histiocytosis

Introduction

Progressive nodular histiocytosis (PNH; synonyms: progressive nodular histiocytoma) is a rare form of non-Langerhans cell histiocytosis characterized by a progressive multinodular proliferation of dermal dendrocytoid cells of the macrophage/histiocyte lineage. The disorder had first been described in 1978 (Taunton et al. 1978), with relatively few cases having been described later (Burgdorf et al. 1981; Glavin et al. 2009; Lloyd et al. 2010; Nofal et al. 2011). The main cell lineage involved in PNH is a spindle-shaped histiocyte which also characterizes spindle cell xanthogranuloma (Zelger et al. 1996). The skin lesions in PNH are clinically characterized by multiple brown-yellowish papules or nodules. Superficial nodules are usually up to 5 mm in diameter, while deep nodules and tumors may reach a diameter of 3 cm. The disorder occurs in older patients (aged 40–20 years), in contrast to solitary spindle cell xanthogranuloma, which shows solitary lesions with a very similar morphology, but occurs in a younger age group (20–40 years; Zelger et al. 1995). PNH rarely involves inner organs, including the pharynx, larynx, lung, and liver (Lloyd et al. 2010). Patients with PNH usually follow a serious clinical course with progressive disfiguring skin lesions.

Vacuolated, lipidized/xanthomatized, scalloped, or oncocytic cells are often seen, as are multinucleated macrophages of the Touton type (Zelger et al. 1995). The cells are immunoreactive for a macrophage/dendritic cell lineage, mostly positive for CD68 and HAM56 but negative for S100 protein. At electron microscopic examination, no Birbeck granules are found. Pathogenetically, the neoplastic lineage that consists of dendritic-like spindled histiocytes that preferentially home to the dermis may in some patients also home to mucosal structures or even to deep-seated organs, the latter probably populated via hematogenous spread of macrophages or their precursors.

Liver Involvement

Liver involvement in patients with PNH is very uncommon (Gonzalez Ruiz et al. 2000; Lloyd et al. 2010). The development of hepatic lesions may follow a course similar to that observed in patients with multicentric reticulohistiocytosis (see above). In one male patient with multiple and in part confluent skin lesions, abdominal ultrasound examination revealed hepatosplenomegaly, with the spleen measuring 16 cm, suggesting marked visceral involvement, but a liver biopsy was not performed (Gonzalez-Ruiz et al. 2000).

Tumors of the Dendritic Cell System 102

Contents

Abstract

The hepatobiliary tract can be involved by members of the dendritic cell tumor group. Follicular dendritic cell tumor/sarcoma is a rare neoplasm of young and middle-aged individuals, presenting with nodal and extranodal manifestations. The term follicular dendritic cell sarcoma (FDCS) is now proposed by the WHO classification. The main feature of FDCS is a proliferation of rather large fusiform or spindled cells arranged in the form of fascicular, storiform, or whorled patterns. These cells consistently express CD21, CD35, CAN-42, and variably S-100 protein and epithelial membrane antigen. FDCS develops in the liver as sometimes large mass lesions that can express EBV markers. A variant of FDCS displays inflammatory pseudotumor-like features. A second neoplasm of dendritic cells that can occur in the hepatobiliary tract is interdigitating dendritic cell sarcoma, a tumor that usually develops in lymph nodes of elderly subjects. It is characterized by a proliferation of CD1a-negative histiocyte-like cells with nuclear pleomorphism and expression of CD68 and S-100 protein. The liver may be the site of reticulum cell-related tumors (fibroblastic reticular cells tumors).

Follicular Dendritic Cell Tumor/ Follicular Dendritic Cell Sarcoma of the Liver

ICD-O code 9758/3

Introduction

Follicular dendritic cell tumor (FDCT) is an uncommon neoplastic lesion usually developing in young to middle-aged individuals. According to the WHO classification of tumors, the former follicular dendritic cell tumor (FDCT) is now classified as follicular dendritic cell sarcoma (FDCS) and is defined as a neoplastic proliferation of spindled to ovoid cells showing morphologic and immunophenotypic features of follicular dendritic cells. FDCS exhibits both, lymphonodal and extranodal, manifestation patterns (review: Kairouz et al. 2007). After the initial description (Monda et al. 1986), only about 50 cases of extranodal FDCT/FDCS have been reported so far (Perez-Ordonez and Rosai 1998; Tu et al. 2007; Zhang et al. 2008). The proliferating target cell is an ovoid to spindle cell sharing an immunophenotype with follicular dendritic cells/ FDC (Chan 1997; Perez-Ordonez and Rosai 1998; Tu et al. 2007). CD21 (C3d receptor; positive in 93 % of cases) and CD35 (C3b receptor; positive in 89 % of cases) are the most commonly used FDC tumor markers. Based on literature data, other markers employed comprise R4/23 (63 %), Ki-M4, CAN.42, CD68, EMA (41 %), desmoplakin, CD45 (21 %), S-100 protein (31 %), and clusterin. The cells of FDCS are consistently negative for CD1a and cytokeratins (reviewed by Martins et al. 2011). Some novel FDC markers have recently been identified and may be useful for the diagnosis of FDCS, including podoplanin/ D2-40 (Yu et al. 2007; Xie et al. 2008; Marsee et al. 2009), Glut-1 and claudin-1 (Jorge-Buys et al. 2008), gamma-synuclein (Zhang et al. 2011), and CXCL13 (Vermi et al. 2008).

FDCT makes part of the so-called accessory cell tumors. The accessory or dendritic cell (DC) compartment comprises (1) the follicular dendritic cells (FDC) of the germinal centers; (2) the Langerhans cells (LC) of the skin and certain mucosas; (3) the interstitial dendritic cells (IDC), LC-like cells of parenchymal organs; (4) veiled or indeterminate cells, derived from IDC or LC and migrating to lymphoid tissues subsequent to antigen contact; and (5) interdigitating dendritic cells (IDC) located in the T-cell zone of lymph nodes. Tumors derived from these cells types (accessory cell tumors) have recently been discussed together with tumors of histiocytes. These neoplasms comprise histiocytic sarcoma, tumors, and sarcoma of Langerhans cell type, interdigitating dendritic cell tumor/sarcoma, follicular dendritic cell tumor/sarcoma, and eventually further lesions (Pileri et al. 2002). The characteristic features of FDCT include a growth of rather large neoplastic cells of mostly fusiform or spindle shape, arranged in the form of fascicular, storiform, or whorled patterns, exhibiting indistinct borders and an abundant and markedly eosinophilic cytoplasm, nuclei being ovoid, with a finely dispersed chromatin, but a prominent nucleolus. Binucleate or even multinuclear cells occur. Ultrastructurally, the cells lack Birbeck granules, but show desmosomes. At electron microscopy, the indistinct cell borders manifest as villosities at the cell surface, the convoluted interdigitating cell processes being joined by desmosomes. The target cells consistently express FDC markers, most frequently CD21, CD35, and CAN-42, whereas S-100 protein and CD68 were more variably expressed. Positivity for EMA was observed in slightly less than 50 % (Pileri et al. 2002).

Hepatobiliary Follicular Dendritic Cell Tumor/Follicular Dendritic Cell Sarcoma

FDCSs have been reported to occur in the liver, and part of these cases were initially classified as FDCTs of the previous nomenclature or as inflammatory pseudotumors. In one patient, a recurrent tumor after resection of an "inflammatory pseudotumor" revealed the morphologic, ultrastructural, and immunohistochemical features of FDCS. Interestingly, ISH for EBV-encoded RNA was positive in the tumor cells, and the cells

showed identical episomal clonal EBV on Southern blot analysis, indicating a clonal proliferation of EBV-positive neoplastic FDC, a cell type known to express the EBV receptor CD21 (Shek et al. 1996). Few similar cases of EBV-related intra-abdominal/hepatic FDCT were reported (Selves et al. 1996; Shek et al. 1998; Arber et al. 1998; Chan et al. 2001; Cheuk et al. 2001; Bai et al. 2006). PCR studies on two liver tumors revealed a characteristic 30-bp deletion of the EBV latent membrane protein-1 (LMP-1) gene, corresponding to the B95-8 sequence (Chen et al. 2001). Apart from hepatic EBV-FDCS, few FDCS primary to the liver did not show EBV expression or were not tested (Torres et al. 2005; Wang et al. 2006; Tu et al. 2007; Zhang et al. 2008; Liu et al. 2009; Xu et al. 2009; Tsunemine et al. 2010; Wang et al. 2010; Martins et al. 2011; Shrinagare et al. 2011). Other such cases include intra-abdominal FDCS with liver metastases (Li et al. 2005). Hepatic FDCS are usually single neoplasms not associated with other neoplastic disorders. In one patient, however, FDCS of the liver was preceded by a history of hyaline-vascular type of Castleman's disease (Fritzsche et al. 2010).

Epidemiology

The number of FDCT primary to the liver is small and amounts to about 20 cases. Both FDCT and follicular dendritic cell sarcoma have been employed to denote these neoplasms (Khalid and Folman 2005; Torres et al. 2005; Wang et al. 2006, 2010; Yuan et al. 2007; De Pas et al. 2008; Granados et al. 2008; Zhang et al. 2008, 2010; Liu et al. 2009; Xu et al. 2009; Fritzsche et al. 2010; Li et al. 2010; Tsunemine et al. 2010; Yin et al. 2010; Martins et al. 2011; Shinagare et al. 2011). In a series of 13 published cases reported in 2011 (Martins et al. 2011), the majority of patients were female (11 F, 2 M), with an age range at diagnosis of 19–82 years. However, this review also contained nine cases of tumors that are now classified as EBV-related FDCT (see above). In the group of EBV-associated inflammatory pseudotumor-like lesions, female predominance is known (see the respective chapter).

Clinical Features

Hepatic FDCS presents as a mass lesion causing abdominal pain and distension, malaise, fever, weight loss, and eventually anemia and jaundice. Serum AFP, carcinoembryonic antigen, and CA19-9 levels are within normal limits (Martins et al. 2011). Hepatic EBV-FDCS may be associated with polyclonal gammopathy and cutaneous leukocytoclastic vasculitis with purpura (Chen et al. 2001). The tumors develop in a previously normal liver. In one patient, hepatic FDCS developed in a 76-year-old woman with a history of hyaline-vascular type of Castleman's disease (Fritzsche et al. 2010).

Biology of Disease

FDCT are regarded as variably aggressive lesions considered as intermediate-grade malignancy. Extrahepatic tumors revealed overall rates of recurrence, metastasis, and mortality of 43 %, 24 %, and 17 %, respectively (Chan et al. 1997). A 78-year-old female patient treated with transcatheter arterial chemoembolization/TACE was alive 27 months after diagnosis with residual hepatic tumors favorably controlled by repeated TACE (Tsunemine et al. 2010).

Pathology

Macroscopy

Macroscopically, the tumors were usually solitary, circumscribed, and fleshy to rubbery lesions with a pushing border, ranging from 3.5 to 22 cm in diameter, with hemorrhage and necrosis.

Histopathology

In typical cases, histology revealed FDC-like spindle cells (sometimes in a fascicular pattern) in a tissue background with abundant

lymphocytes and plasma cells, the tumor cells sometimes forming syncytia-like structures between spindle cells and plump cells (Shek et al. 1998; Cheuk et al. 2001). Large and atypical, pleomorphic cells of polygonal shape can occur as well. Individual cells have a slightly eosinophilic and often fibrillary cytoplasm. The nuclei of these cells are ovoid to irregular shaped, with either small or prominent amphophilic or eosinophilic nucleoli and "empty" nucleoplasm and a delicate violaceous nuclear membrane, but usually with low or minimal mitotic activity. Part of the tumor cells are binucleated, the nuclei usually having enlarged nucleoli. The tumors also contain few multinucleated cells. These cells may resemble Reed-Sternberg cells. The spindled cells form diffuse sheets, fascicles, whorls, and sometimes a vaguely storiform pattern. The tumor tissue may be traversed by dense fibrous and in part sclerotic septa with areas of calcification (Martins et al. 2011). Focal coagulative necroses and small hemorrhages are noted. Characteristically, many tumors show sprinkling across the entire tissue of small lymphocytes, sometimes with perivascular cuffing and rarely dense and mimicking lymphoma.

Immunohistochemistry

Immunohistochemically, FDCT express FDC markers, including CD21 (C3d receptor; positive in 93 % of cases), CD35 (C3b receptor; positive in 89 %), Ki-M4, and CAN.42. The complement receptors CD21 and CD35, which recognize activated products of complements C3 and C4, are predominantly expressed on B lymphocytes and FDCs (review: Roozendaal and Carroll 2007). Other well-known markers expressed in variable rates comprise EMA (around 40 %), vimentin (around 60 %), HLA-DR, desmoplakin, and podoplanin. Podoplanin (D2-40) is a highly effective marker for FDC and FDCT (Xie et al. 2008; Marsee et al. 2009; Zhang et al. 2010). A comparative study revealed that podoplanin/D2-40 highlighted more FDC meshworks than CD21 in Castleman's disease, follicular lymphoma, nodular lymphocyte predominance Hodgkin's lymphoma, and residual reactive germinal centers in a variety of conditions (Xie et al. 2008). The homeostatic chemokine CXCL13, which is preferentially produced in B-follicles and attracts B lymphocytes that express the receptor CXCR5, is a marker for FDC and FDCT (Vermi et al. 2008). Expression of clusterin distinguishes FDCT from other dendritic cell neoplasms (Grogg et al. 2004). Gamma-synuclein is a novel marker for reactive FDC and cells of FDCT (Zhang et al. 2011). FDCT nuclei are reactive for p53 protein (Li et al. 2010). In one study all cases were EBV-RNA positive in ISH, whereas EBV-LMP (latent membrane protein-1) expression was more variable (Cheuk et al. 2001).

Inflammatory Pseudotumor-Like FDCT

Some authors proposed that inflammatory pseudotumor-like FDCT(IP-FDCT) is a variant of FDCT differing from conventional FDCT in several respects, including marked female preponderance, frequent presence of systemic symptoms, indolent behavior, prominent lymphocyte infiltration, and consistent association with EBV (Cheuk et al. 2001; Kiryu et al. 2009). In contrast to some inflammatory myofibroblastic tumors and part of inflammatory pseudotumors, these distinct lesions do not appear to express anaplastic lymphoma kinase/ALK (Chan et al. 2001). IP-FDCT has also been detected in the liver (Granados et al. 2008). In a study on 11 patients with inflammatory pseudotumor-like FDCT observed in 10 female and 1 male patients (age range: 19–61 years), seven lesions were documented in the liver (Cheuk et al. 2001). Hepatic IP-FDCS has been documented in another report (An et al. 2009). Pathologically, IP-FDCTs are characterized by loosely aggregated or dispersed spindle cells or ovoid cells intimately admixed with abundant lymphocytes (sometimes with lymphoid follicles) and plasma cells. The spindle cells have a pale to faintly eosinophilic cytoplasm with instinct cell borders. Nuclei are elongated or oval, with a vesicular chromatin and only minor atypia. The larger cells usually have an ovoid shape or are stellate shaped. Mitotic figures are rare. Some

tumors may contain Reed-Sternberg cell-like cells. All tumors show positive staining for at least one of the FDC markers, CD21/CD35, CD23, and CAN.42, and all tumor cells showed strong nuclear in situ labeling for EBER (Cheuk et al. 2001).

What Are Follicular Dendritic Cells (FDC)?

The development, proliferation, activation, and survival of B lymphocytes critically depend on the interaction with specific mesenchymal cells which are generally termed stromal cells and are operational in primary lymphoid organs already (Kincade 1991). In this network, dendritic cells are the highly specialized antigen-presenting cells of the immune system that play a central role in the regulation of innate and adaptive immune responses. The FDC is a unique stromal cell type operational in the complex cell interaction network in secondary lymphoid organs, and specifically in the lymph follicle (follicular stromal cells), and exhibits a distinct morphology with cell processes joined by desmosomes. Dendritic cells with a lymphocyte-stimulating activity differentiate from a lineage of CD133 precursor cells, i.e., primitive myeloid progenitor cells (Bonetti et al. 2011). During the differentiation process, dendritic cells express dendritic cell-specific transmembrane protein (DC-STAMP). During dendritic cell maturation, DC-STAMP relocalizes toward the Golgi apparatus, and DC-STAMP interacts with a partner in the endoplasmic reticulum, LUMAN (CREB3 or LZIP), and endoplasmic reticulum-resident transcription factor. LUMAN is activated in a process called regulated intramembrane proteolysis (RIP), which involves translocation to the Golgi apparatus and subsequent proteolytic cleavage. This proteolytically activated form of LUMAN is then translocated to the nucleus. The LUMAN/DC-STAMP is a regulatory circuit of dendritic cells (Eleveld-Trancikova et al. 2010). FDCs mostly occur in nodal and extranodal lymph follicles, but they can develop ectopically, e.g., in autoimmune reactions, even though their precursor cell has not yet been identified (Imai and Yamakawa 1996; Kasajima et al. 1997; Van Nierop and de Groot 2002).

Dendritic cell shaves the distinct ability to cross-present exogenous antigens in association with major histocompatibility complex (MHC) class I to CD8+ T cells, whereby an immune-related GTPase called Igtp (Irgh3), located to the membranes of endoplasmic reticulum and lipid bodies, plays a significant role (Bougnères et al. 2009). Generally, dendritic antigen-presenting cells possess distinctive mechanisms to sense pathogen-derived and other foreign molecules such as lipopolysaccharides, non-self nucleic acids, and an enormous host of environmental antigens to trigger defense reactions. These sensors include the RIG-l-like helicase (RLH) family that specifically recognizes viral RNA, as well as the cytoplasmic, nucleotide-binding oligomerization domain (NOD)-like receptors and Toll-like receptors (TLR) pathways. Plasmacytoid dendritic cells utilize TLR9 to detect pathogen-associated DNA and trigger cytokines to stimulate immune cells. This response involves AIM2 (absent in melanoma 2) and an endoplasmic reticulum-associated protein, STING (stimulator of interferon genes (review: Barber 2011). Functionally, FDC are non-phagocytic but have the ability to trap and retain antigens for longer time periods in the form of immune complexes, thus acting as antigen depots during germinal center response. They express molecules involved in the proliferation and differentiation of lymphocytes, especially B cells, and in cell adhesion. FDCs appear to play a pivotal role in the germinal center response associated with the cellular events of anamnestic humoral immune responses, in particular the selection of memory B lymphocytes: FDC presents native antigens to potential memory cells, of which only B lymphocytes with high-affinity B-cell receptors can bind. In this context, the primary function of FDC seems to prevent apoptosis and support proliferation of germinal center B cells (via two newly identified FDC-signaling molecules; Li and Choi 2002), hence playing a central role in the organization of the follicle structure and supporting survival of long-lived

memory B cells (Cyster et al. 2000), whereas activated T cells induce the differentiation of germinal center B cells (Liu and Arpin 1997). The function of dendritic cells critically depends on Ca2+ signaling, which directs the dendritic cell responses to diverse antigens, including Toll-like receptor ligands, intact bacteria and their products, and microbial toxins. Calcium signaling is involved in dendritic cell activation, differentiation, migration, and the construction of immunological synapses with T lymphocytes. The dendritic cell instrumentarium for Ca2+ handling consists of calcium trafficking in the endoplasmic reticulum, the plasma membrane, and the inner mitochondrial membrane, where Ca2+ pumps, Ca2+/Na1+ antiports, and Ca2+-permeable channels or uniporters are expressed (review: Shumilina et al. 2011).

The molecular basis for the FDC-B cell interaction remains poorly characterized, but several FDC products have recently been identified, including a splicing isoform of the complement receptor CD21 (Liu et al. 1997); a transmembrane protein involved in FDC-B cell interaction (8D6; Zhang et al. 2001); chemokine B lymphocyte chemoattractant (BLC; CXCL13; Gunn et al. 1998), which is a strong FDC chemoattractant for B cells; a distinct serpin which may protect essential proteins from degradation (Mueller et al. 1997); and the secreted protein, FDC-SP, suggested to act upon B cells (Marshall et al. 2002).

Interdigitating Dendritic Cell Sarcoma

ICD-O code 9757/3

Introduction

Interdigitating dendritic cell sarcoma (IDCS; interdigitating reticulum cell (IRC) tumor, IRCT) is a rare neoplasm arising from the antigen-presenting interdigitating dendritic cell (Nakamura et al. 1988; review: Fonseca et al. 1998). IDTS or interdigitating dendritic cell tumors have been classified as group IV, interdigitating dendritic cell tumor/sarcoma in the approach from the International Lymphoma Study Group (Pileri et al. 2002). In exceptional cases, IDCS may overlap with true histiocytic sarcoma (Porter et al. 2004).

IDCS usually develops in peripheral lymph nodes of patients in the sixth to eighth decades. Extranodal presentations, including the skin, soft tissues, parotid gland, tonsil, lung, duodenum, small intestine, spleen, testis, and liver, have been reported. Clinically, patients usually present with an asymptomatic mass, but systemic symptoms and signs, such as fever, fatigue, and night sweats, may occur. IDCS is an aggressive neoplasm. According to a SEER analysis, only 55 % of IDCS presented with localized disease at diagnosis. Overall survival time was significantly worse than those for follicular dendritic cell sarcoma, with a median survival time of 35 months (Perkins and Shinohara 2013).

Distinctive histologic features are proliferation of histiocyte-like cells with nuclear polymorphism and occasionally multinucleated elements, in lymph nodes involving the paracortical area sparing the B lymphocyte compartments. The neoplastic proliferations commonly form fascicles, storiform patterns, or whorls of spindled to ovoid cells, and some tumors show nests or sheets of round cells. The cytoplasm of the neoplastic cells is pale or slightly eosinophilic and the nuclei are ovoid or spindle shaped, with no or only minor atypias. The mitotic rate is usually low or very low, less than 5/10 HPF (Liu et al. 1998). Sinusal infiltration, fibrosis, and dense infiltrates of eosinophils and plasma cells are frequently noted. The neoplastic cells lack Birbeck granules (Nakamura et al. 1988, 1994). At EM examination, distinct intracytoplasmic membrane complexes have been detected, representing profiles related to microtubuloreticular complexes (Nakamura et al. 1989). In series of IDCS, all were immunoreactive for S-100 protein, CD68, lysozyme, and vimentin; three-fourths were positive for CD45. The tumor cells are usually positive for fascin. Negative results were obtained for CD1a, langerin, CD3, CD20, CD21, CD30, actin, and cytokeratin (Nakamura et al. 1988; Gaertner et al. 2001).

Interdigitating Dendritic Cell Sarcoma of the Liver

IDCS is a very rare neoplasm in the liver (Figs. 1 and 2). IDCS has been observed as primary tumors in the liver and lung in the same patient (Radovic et al. 2012). Apart from primary hepatic IDCS, extensive liver infiltration can occur in the setting of intra-abdominal and/or lymphonodal IDCS (Turner et al. 1984; Chan and Zaatari 1986; Weiss et al. 1990; Miettinen et al. 1993; Olnes et al. 2002).

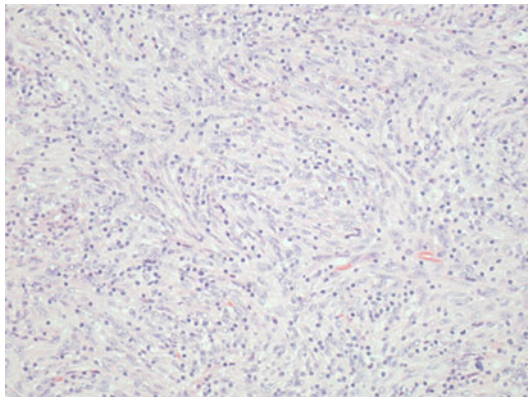

Fig. 1 Interdigitating dendritic cell sarcoma of the liver. The neoplasm is characterized by fascicles of spindle cells with a sparse lymphocytic infiltration (hematoxylin and eosin stain)

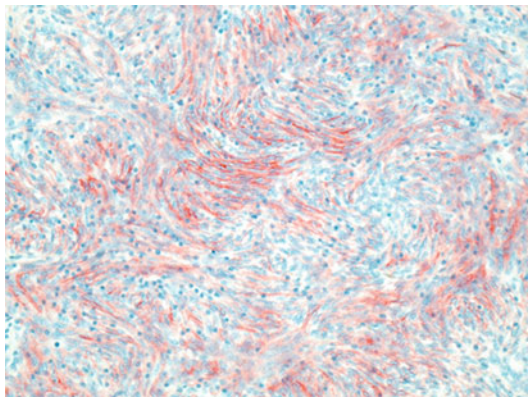

Fig. 2 Interdigitating dendritic cell sarcoma of the liver with reactivity of neoplastic spindle cells for S100 protein (S100 protein immunostain)

Overlap IDCS

Histiocytic sarcoma can show signs of interdigitating cell differentiation, representing an overlap lesion or a hybrid sarcoma (Yang et al. 2010). True histiocytic sarcoma with interdigitating cell differentiation was found in the liver and spleen of a 3-month-old boy presenting with hepatosplenomegaly and abdominal distention. In a liver biopsy, liver involvement was predominantly sinusoidal with some cellular nodules in portal tracts and invasion of terminal/central veins. The ovoid to elongated and in part large neoplastic cells showed large vesicular nuclei. Some of the nuclei were bean shaped, while others were indented. Many nuclei exhibited a large basophilic nucleolus. In EM pictures, no Birbeck granules were detectable. Immunohistochemically, the tumor cells were reactive for CD68, S100 protein, lysozyme, CD45, CD43, and vimentin. No reactivity for CD1a or CD21 was found (Porter et al. 2004).

Fibroblastic Reticular Cell Tumors (Reticulum Cell-Related Tumor, Including Fibroblastic Reticulum Cell (FBRC)-Related Neoplasms and Cytokeratin-Positive Interstitial Cell (CIRC) Neoplasms)

ICD-O code 9759/3

Introduction

Together with follicular dendritic cells and interdigitating reticulum cells, fibroblastic reticulum cells (FBRC) form a group of accessory cells of peripheral lymphoid tissues. FBRC are located in the parafollicular areas and the deep cortex of lymph nodes, where they are associated with the network ensheathing the postcapillary venules and nodal architectural structures, such as cords, channels, corridors, and conduits (Tykocinski et al. 1983; Gloghini and Carbone 1993; Gretz et al. 1997). FBRC are immunoreactive for vimentin, SMA, and desmin, suggesting a

myofibroblastic cell lineage (Tykocinski et al. 1983; Toccanier-Pelte et al. 1987). FBRC are thought to produce reticular/reticulin fibers and build a reticular framework in their biologic niche.

In contrast to paracortical dendritic cells that are in close contact with FBRC within the cellular framework of T-cell nodal areas, FBRC are negative for the 55 kDa actin-bundling protein, fascin (Hiroi et al. 2004). FBRC contain bundle filaments and dense bodies (Hiroi et al. 2004). Later, a subpopulation of cells was identified in the extrafollicular regions of the lymph nodes, spleen, and tonsils, showing immunoreactivity for cytokeratins 8 and 18 (cytokeratin-positive reticulum cells, CIRC; Franke and Moll 1987). CIRC already occur in fetal lymphoid organs (Doglioni et al. 1990). These cells can co-express smooth muscle actin (SMA) and desmin (more frequently SMA; Doglioni et al. 1990; Gould et al. 1995). CIRC are observed in both the outer and inner cortex of lymph nodes, as well as along the blood vessels in the node medulla (Gould et al. 1995). They have cytoplasmic processes connected by desmosome-like junctions and contain intermediate filaments, tonofilaments, and light bundles (Franke and Moll 1987; Doglioni et al. 1990). The cellular origin and the exact functions of FBRC and CIRC are not yet known; a mesenchymal stem cell has been taken into consideration. Apart from FBRC and follicular dendritic cells, secondary lymphoid organs show a third stromal cell that has recently been identified, the marginal reticular cell (Katakai 2012).

FBRC and CIRC Tumors

Neoplasms derived from FBRC or CIRC are very rare lesions. Reticulum cell neoplasms of the FBRC type have been characterized, and these tumors in fact share many features with FBRC (Andriko et al. 1998; Martel et al. 2003; Suarez-Vilela et al. 2012). The neoplasms may occur admixed with follicular dendritic cells (Jones et al. 2001). Cytokeratin-positive interstitial cell neoplasms (CIRC tumors) have also been characterized, mainly occurring in lymph nodes (Gould et al. 1990; Chan et al. 2000; Schuerfeld et al. 2003; Dong et al. 2008), but do not yet make part of the current classifications for histiocytic tumors, such as the ILSG classification. The tumors consist of spindle cells with elongated to round nuclei and prominent nucleoli, and these cells are arranged in a diffuse fascicular and vaguely whorled growth pattern. The mitotic activity is rather low, but necrosis may be seen. The neoplastic cells are immunoreactive for vimentin, desmin, S100 (inconstant), and lysozyme and focally for CD68 (inconstant); cytokeratins 7, 8, and 18; and AE1 and CK-pool. Ultrastructurally, the cells share the features known for normal CIRC (Chan et al. 2000; Schuerfeld et al. 2003). A progression of a FBRC tumor to cytokeratin-positive interstitial reticulum cell (CIRC) sarcoma has been reported (Lucioni et al. 2003), suggesting a common lineage of these two cell types.

FBRC Tumors of the Liver

Fibroblastic reticulum cell sarcoma metastatic to the liver has been reported (Yaman et al. 2009). In the older literature, several reports described so-called reticulum cell sarcoma of the liver (Torres and Bollozos 1971). Reticulum cells as they were classified in these times were slender and fusiform cells that were in close association with reticulum fibers and thought to be the producers of these fibers. Based on these reports, it is very difficult or even impossible to judge to which cell lineage the "reticulum cells" making up the neoplasms belonged.

Histiocytic Syndromes 103

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_103

Abstract

In addition to Langerhans cell histiocytosis and its variants, and histiocytic sarcoma, the hepatobiliary tract can be involved by a wide spectrum of other histiocytic neoplastic and nonneoplastic disorders. Rosai-Dorfman syndrome (sinus histiocytosis with massive lymphadenopathy), a polyclonal monocyte/macrophage/histiocyte disorder which involves various organs and tissue systems, can also present in the liver in the form of an atypical histiocytic infiltration, but hepatobiliary involvement is a rare event. Involvement of the liver, sometimes severe, is known for adult xanthogranulomatous disease, of which Erdheim-Chester disease is a prominent member. The liver frequently participates in various forms of hemophagocytic syndromes, including macrophage activation syndromes. Hemophagocytic lymphohistiocytosis is a heterogeneous group of inherited and acquired disorders of monocyte/macrophage function. The disorders include hereditary forms (familial hemophagocytic histiocytosis) and a broad array of histiocyte/macrophage disorders associated with or induced by autoimmune processes, collagen vascular diseases, tumors, and infections. In the liver, these disorders produce important macrophage accumulation associated with hemophagocytosis and sometimes destruction of small bile ducts, similar to biliary autoimmune diseases. A reactive histiocytosis associated with immunoglobulin-producing lymphomas is crystal-storing histiocytosis.

Introduction

In addition to Langerhans cell histiocytosis and its variants, and histiocytic sarcoma, there are several neoplastic and reactive histiocytic disorders of various etiology and pathogenesis that may involve the hepatobiliary tract (Table 1). Part of the novel immune-dysregulatory disorders, in particular those that are associated with macrophage activation syndromes, have recently been reviewed (Kaufman et al. 2014; Schulert and Grom 2014; Zhang et al. 2014b; de Jesus and Goldbach-Mansdky 2015; Put et al. 2015; Schulert and Grom 2015). These monogenic disorders result in dysregulated cytokine signaling and are therefore termed cytokinopathies (Moghaddas and Masters 2015).

Table 1 Neoplastic and reactive histiocytic disorders not related to Langerhans cell histiocytosis or histiocytic sarcomas

Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy)
Adult xanthogranulomatous disease and Erdheim-Chester disease
Weber-Christian disease
Cytophagic histiocytic panniculitis
Hemophagocytic lymphohistiocytosis
Familial hemophagocytic lymphohistiocytosis (Farquhar-Claireaux disease)
Secondary forms of hemophagocytic lymphohistiocytosis
Monogenic immune-dysregulatory disorders associated with macrophage activation syndrome/MAS (hereditary autoimmune disorders associated with MAS)
Monogenic systemic-onset juvenile idiopathic arthritis caused by mutations in LACC1
Inflammasome disorder caused by NLRP3 mutations
Inflammasome disorder caused by NLRC4 mutations
Immune-dysregulatory syndromes with chronic type I interferon signature caused by mutations in TMEM173/STING IFIH1/MDA5 and DDX58/RIG-I
Immune-dysregulatory syndromes caused by mutations in ADA2, TRNT1 and COPA, AP1S3, and TFNRSF11A
Immune-dysregulatory syndromes caused by mutations in PRKDC, STAT3, CTLA4, and PIK3R1
Crystal-storing histiocytosis

Rosai-Dorfman Disease (Sinus Histiocytosis with Massive Lymphadenopathy)

Introduction

Sinus histiocytosis with massive lymphadenopathy (SHML) has first been described in 1965 (Destombes 1965), later established as a distinctive entity (Rosai and Dorfman 1969), and then termed Rosai-Dorfman disease (RDD) or Destombes-Rosai-Dorfman disease. The typical

clinical features of SHML include painless lymphadenopathy with considerable lymph node enlargement, fever, leukocytosis, and polyclonal hyperglobulinemia/gammopathy. The manifestation time of SHML ranges from congenital SHML to very old age, with a mean age of onset of 20.6 years; males outnumber females (Foucar et al. 1990). The disorder most probably represents a reactive rather than a neoplastic process, usually resolving spontaneously, with involvement of a polyclonal monocyte/macrophage/histiocyte proliferation. A familial form of SHML (Faisalabad histiocytosis, H disease) is caused by germline mutations in the SLC29A3 gene (Morgan et al. 2010; Melki et al. 2013).

The condition may present with extranodal manifestations in up to more than 40 % of the patients (reviews: Veinot et al. 1998; Esquivel et al. 1999; Gaitonde 2007; Haroche and Abla 2015). A detailed list of extranodal manifestations is found in the review of Foucar and coworkers (Foucar et al. 1990). In more detail, lymph node involvement alone is found in 57 % of patients, 15 % present with extranodal disease only, and in 28 % of patients, both nodal and extranodal sites are involved. The most common extranodal sites are the skin and the upper respiratory tract, each involved in approximately 11 % of the cases (Foucar et al. 1990). In a study of 423 examples of SHML, the most common sites of extranodal manifestations were the skin, upper respiratory tract, and bone. In general, prognosis had been found to correlate both with the number of nodal groups and with the number of extranodal systems involved by SHML, the prognosis being worse in case of extranodal disease (Foucar et al. 1990). The histologic features of SHML in extranodal sites are, at least in principle, similar to those seen in involved lymph nodes. But extranodal SHML tends to exhibit more fibrosis, fewer typical histiocytes, more angiocentric plasma cells, and less lymphocytophagocytosis (Foucar et al. 1990).

Liver Involvement in SHML

The digestive system, including the liver, is not often affected in SHML, about 15 cases having been reported (Buchino et al. 1982; Foucar et al. 1990; Antonius et al. 1996; Lauwers et al. 2000; Anders et al. 2003; Iwabuchi et al. 2003; Krok et al. 2007; Chow et al. 2009; Maheshwari et al. 2009; Di Tommaso et al. 2010). In a study of 423 cases of the Rosai-Dorfman disease registry, hepatic involvement was only seen in 1 % (Foucar et al. 1990). Among 11 patients with GIT manifestation, this involved the liver in 5 patients, and most patients also had evidence of disease in other extranodal sites as well as in one or more lymph node groups (Lauwers et al. 2000).

SHML involving the GIT system does not seem to spontaneously resolve the patients for which follow-up was available (eight patients; reviewed by Anders et al. 2003) beyond 1 year were either alive with continuing disease (five cases) or dead of disease. Involvement of the liver is rare; among 423 examples, the liver was considered to be abnormal in 27 patients (Foucar et al. 1990), in most cases manifested as mild hepatomegaly; only 4 patients had biopsy evidence of hepatic involvement by SHML. All of these four patients had lymph node disease and had a mean age lower than that of the remainder of registry patients, and the combination of manifestations was found to be a poor prognostic sign. In a 68-year-old man with lymphadenopathy and elevated liver function tests, liver biopsy showed a nodular portal tract infiltration typical for SHML (Krok et al. 2007). A case of congenital SHML showed anemia, thrombocytopenia, and hepatomegaly. Liver biopsy revealed essentially preserved normal architecture of the liver tissue including the portal tracts. The sinusoids and portal tracts were infiltrated by atypical histiocytic cells that showed abundant granular and pale eosinophilic cytoplasm and medium- to large-sized vesicular nuclei. These cells were reactive for CD68 and S100 protein, but were CD1a negative. Some of the histiocytoid cells displayed emperipolesis or lymphocytophagocytosis (Chow et al. 2009). In one report, a patient with hepatic involvement in SHML had coincidental follicular non-Hodgkin's lymphoma (Di Tommaso et al. 2010). SHML of the pancreatic head has been shown to cause obstructive jaundice (Zivin et al. 2009). SHML has been found in association with giant cell hepatitis (Suarez-Vilela et al. 2004).

Macroscopy

Macroscopically, SHML of the liver in these four patients was characterized by the following features: a 1.5 cm well-circumscribed white nodule (depicted in Figs. 1, 2, and 3a of the work of Lauwers et al. 2000); several areas of decreased radioactivity in a liver scan; a congested liver at autopsy without focal lesions; a hepatomegaly; and multiple pinpoint-sized yellow foci, respectively; thus illustrating the gross presentation may be highly variable (Foucar et al. 1990). In a more recent study, a 3-year-old female child revealed cervical, mediastinal, retroperitoneal, and perihepatic lymph node enlargement, and liver imaging showed a hypodense lesion 1.9 × 1.0 cm in the right liver lobe (Maheshwari et al. 2009). In another study, liver involvement was observed in at least one pediatric patient claimed to have died from SHML (Buchino et al. 1982).

Histopathology

The accumulation of the histiocytic elements mainly takes place within the lobular parenchyma, in sinusoids, and in the portal tracts, which are expanded and form nodular infiltrate-rich structures (Figs. 1 and 2). Histiocytoid cell-rich interface lesions may develop. Lymphophagocytosis/emperipolesis is a characteristic feature. In the stable phase of the disease, the hepatic infiltrate consists of a mixture of histiocytes (in part with foamy cytoplasm), lymphocytes, and plasma cells located in the sinusoidal spaces (Buchino et al. 1982). A granuloma-like morphology may also occur. The parenchymal infiltration may be accompanied by hepatic steatosis, hypertrophy, and hyperplasia of Kupffer cells, erythrophagocytosis, and siderosis (Brown and D'Cruz 1987). Apart from red blood cells, histiocytes engulf lymphocytes and plasma cells, i.e., emperipolesis (Buchino et al. 1982). The infiltrates may be accompanied by considerable fibrosis. Eosinophilia of the liver has been observed in a patient with SHML, but was associated with concurrent hypereosinophilic syndrome (Hernandez et al. 1987).

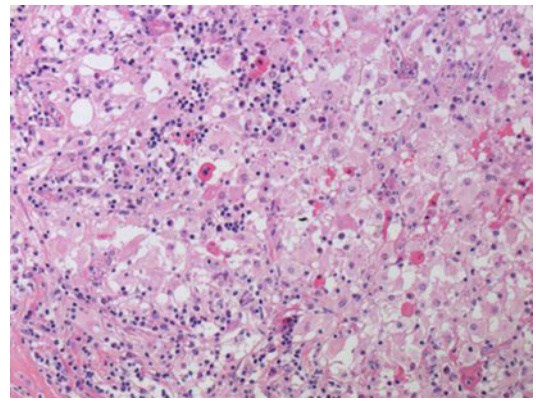

Fig. 1 Rosai-Dorfman disease of the liver. There is a diffuse growth of large histiocytoid and in part foamy cells, intermingled with lymphocytes. The eosinophilic cells are abnormal cells undergoing apoptosis (hematoxylin and eosin stain)

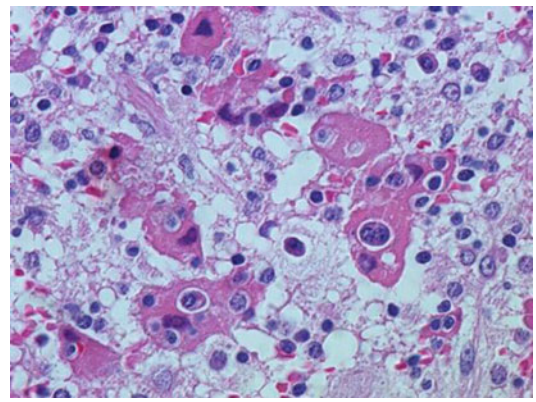

Fig. 2 Rosai-Dorfman disease in the liver. Large eosinophilic histiocytes display emperipolesis of lymphocytes (lymphocytophagocytosis; hematoxylin and eosin stain)

Morphology

General Morphology of Rosai-Dorfman Disease

In typical lymph node disease, the nodal sinuses are expanded by numerous histiocytes that occasionally can efface the nodal architecture. The involvement of a given node can be focal or diffuse, homogeneous, or multinodular. The cells have round to ovoid, vesicular nuclei, usually containing a single prominent nucleolus. Few nuclei are multilobulated, and rather slight nuclear atypia may be seen. Mitotic figures are usually

sparse. The cytoplasm of the histiocytes is predominantly abundant and slightly eosinophilic, but cells with glassy eosinophilic cytoplasm and distinct cellular margins can occur. A variable amount of foamy cells is in evidence. Electron microscopically, three types of histocytoid cells are recognized: (a) type I cells, with smooth cytoplasmic borders and moderate cytoplasmic lipids; (b) type II cells, cells with numerous interdigitating filopodia; and (c) type III cells, large cells with abundant lipid and formation of myelin figures. Emperipolesis of lymphocytes and plasma cells may be observed. This is the phenomenon of lymphophagocytosis (or better lymphocytophagocytosis), defined as lymphocyte penetration of an movement within another cell (review: Rastogi et al. 2014). In histiocytoid cells of SHML, the lymphocytes are often situated within vacuoles and thus seem to escape cell death and degradation (Colmenero et al. 2012). Sometimes, several lymphocytes are present in the cytoplasmic body of large histiocytoid cells. Emperipolesis may also involve neutrophils, plasma cells, and erythrocytes. Emperipolesis of neutrophils can be followed by neutrophil apoptosis in cutaneous SHML (Kusutani et al. 2011). The histiocytoid cell population is often accompanied by numerous, mature plasma cells which are arranged around postcapillary venules. The involved lymph nodes may, in addition to histiocytes, be infiltrated by neutrophils, sometimes with formation of microabscesses. Eosinophils are rare in SHML, in contrast to Langerhans cell histiocytosis.

Histogenesis of SHML

Currently, SHML is classified among the histiocytoses, one reason being the morphologic and clinical overlap between SHML and the prototypic idiopathic histiocytosis, i.e., LCH (Foucar et al. 1990), although the two respective cell types involved are clearly different with respect to their origin, lineage, immunophenotype, and function. Generally, results from immunohistochemical studies indicate that SHML cells belong to activated members of the monocyte/macrophage cell family. SHML cells consistently express S-100 protein; the monocyte/macrophage-associated antigens CD14, HAM 56, EBM11, CD33, CD64, and CD68; and the cellular adhesion molecule CD31/PECAM-1 (Eisen et al. 1990; Paulli et al. 1992; Slone et al. 2003). The SHML histiocytes express a pattern of further adhesion molecules that characterize circulating monocytes, i.e., CD11b, CD11c, CD18, CD62L, and CD103. A fraction of the cells are medium-sized mononuclear cells expressing an antigen pattern typical for recently immigrated monocytes, suggesting this cell as the main cell of origin of SHML cells (Paulli et al. 1992). Like Langerhans cells, SHML cells express aspartic proteinases, including cathepsin D (normally present in antigen-presenting cells) and cathepsin E, a macrophage marker. It has been suggested that stimulation of monocytes/macrophages via macrophage colony-stimulating factor (M-CSF) leading to immune suppressive macrophages represents a mechanism in the pathogenesis of SHML (Middel et al. 1999), hence the target cells of SHML making part of a polyclonal cell population. Polyclonality in SHML is supported by findings from the analysis of X-linked polymorphic loci by use of the HUMARA assay (Paulli et al. 1995).

Differential Diagnosis

In immune stimulated locoregional lymph nodes, marked accumulation of macrophages in sinus can be induced by primary and metastatic liver tumors. In a patient with hepatocellular carcinoma, this macrophage reaction in portal hepatic lymph nodes closely mimicked Rosai-Dorfman disease (Takagi et al. 2012).

Adult Xanthogranulomatous Disease (Including Erdheim-Chester Disease)

Introduction

Adult xanthogranulomatous disease (AXGD) is a group of four syndromes of non-Langerhans cell histiocytosis (type II) characterized by the development of inflammatory lesions

containing numerous lipid-laden foamy histiocytes/macrophages. AXGD includes adult-onset xanthogranuloma (AOX), adult-onset asthma, and periocular xanthogranuloma (AAPOX), necrobiotic xanthogranuloma (NBX), and Erdheim-Chester disease (ECD).

Erdheim-Chester Disease

Erdheim-Chester disease (ECD; synonyms: Erdheim-Chester syndrome; polyostotic sclerosing histiocytosis; lipid/cholesterol granulomatosis) is a multisystemic form of non-Langerhans cell histiocytosis that has been described in 1930 (Chester 1930). ECD is characterized by a proliferation of histiocytes/macrophages, sometimes lipid-laden, in the marrow cavities of tubular bones, adipose tissues, and less commonly visceral organs (reviews: Abdelfattah et al. 2014; Haroche et al. 2014; Cives et al. 2015; Haroche and Abla 2015). ECD can develop in any age, but is mostly diagnosed in patients between 40 and 60 years of age. ECD clinically presents with fever, weight loss, malaise, asthenia, and permanent juxtaarticular bone pain, and sometimes with signs of retroperitoneal disease. In case of specific organ infiltration, alterations such as exophthalmos, diabetes insipidus, and signs of pachymeningosis may occur. Symmetrical involvement of long bones, mainly of the lower extremities, is an almost universal alteration. Bone marrow infiltration leads to an osseous reaction characterized by a bilateral, metaphyseal, and diaphyseal, symmetric cortical osteosclerosis of long bones. In flat bones, the infiltrate can induce osteolytic foci. Extraosseous organ involvement mainly includes the lungs (in 20 % of cases), kidneys and/or perirenal fat, skin (often eyelid xanthomas), retroorbital adipose tissue (sometimes with exophthalmos), retroperitoneal adipose tissue, heart and pericardium, large arteries ("coated aorta"), adrenal glands, dura mater, and pituitary gland/sellar region. ECD can be a life-threatening condition, with a reported global 5-year mortality of 30–40 %.

In regard to the question as to whether ECD is a reactive or a neoplastic process, results of mutational studies are important. More than 50 % of patients with ECD show the BRAFV600E mutation (see below; Blombery et al. 2012; Haroche et al. 2012; Hervier et al. 2014). It has recently been suggested that the histiocytosis ECD is an inflammatory myeloid neoplasm (Allen and Parsons 2015; Haroche et al. 2015).

Liver Involvement in Erdheim-Chester Disease

So far, only few studies have documented severe liver involvement in ECD (Ivan et al. 2003; Gupta et al. 2007; Dickson et al. 2008; Pan et al. 2011; Arabadzhieva et al. 2015; Shu et al. 2015). In the young male patient with ECD-related vertebral osteolytic lesions reported by Ivan et al. (2003), a mild cholestatic syndrome and signs of hepatic cytolysis were detected. Liver biopsies revealed an extensive infiltration and replacement of the hepatic tissue by foamy, lipid-laden histiocytes/macrophages, and a diffuse lymphocyte infiltration, fibrosis, and scattered Touton-like giant cells without a granulomatous reaction were also present. Electron microscopy disclosed numerous secondary lysosomes and phagolysosomes, but no Birbeck granules, in the target cells, supporting the macrophage lineage of the cells involved (Ivan et al. 2003). The necropsy of a further patient with ECD showed a white-yellow fibrous tissues that had bilaterally encased kidneys and adrenals and had extended along vessels and portal tracts into the liver (Dickson et al. 2008). The patient described by Pan et al. (2011) revealed xanthogranulomatous foci within the liver parenchyma, characterized by foamy, CD68+/CD1a- macrophages, multinucleated giant cells, and inflammatory cells. ECD can involve the large intrahepatic and extrahepatic bile ducts, causing biliary obstruction that may mimic Klatskin tumor (Gundling et al. 2007).

Pathology of Erdheim-Chester Disease

At autopsy, soft and fat-like yellow masses have been described in organs, measuring up to several

cm in diameter (Sheu et al. 2004). Histologically, the often extensive infiltrate in ECD is dominated by macrophages rich in finely granular cytoplasm, often with lipid storage and formation of foam cells. The macrophages can be accumulated in the form of small nodular structures, sometimes with formation of conglomerate nodules or small tumor-like masses. The infiltrate also contains multinucleated giant cells of the Touton type, lymphocytes, and rarely other leukocytes. The infiltrate is often surrounded by a sheath of fibrosis ("fibroxanthomatous granulomas"). The leading cells, the ECD histiocytes, are immunoreactive for CD68, but, in contrast to Langerhans cell histiocytosis, do not stain for CD1a or S-100 protein (the CD68+/CD1a- phenotype; Ono et al. 1996; Ota et al. 2012). Birbeck granules are absent (Ono et al. 1996).

Differential Diagnosis

Clinically, ECD can mimic Langerhans cell histiocytosis or collagen vascular diseases. In some patients, autoimmune disorders with arthritis and polyserositis may be difficult to distinguish from ECD. Isolated involvement of the pituitary gland with ECD has to be distinguished from other forms of xanthomatous or xanthogranulomatous hypophysitis (Folkerth et al. 1998; Yokoyama et al. 2004).

Pathogenic Pathways

Etiology and pathogenesis of ECD have only partially been clarified so far. Morphologically and on a molecular level, ECD is related to Langerhans cell histiocytosis (LCH), but the relationship between these two disorders is complex. In a recent investigation, ECD followed or was diagnosed simultaneously with, but never preceded, LCH (Hervier et al. 2014). It seems that the progressive infiltration by a macrophage-dominated cell population is caused by an abnormal, persistent immune response with defective termination mechanisms rather than by a true neoplastic process. The distinctive composition of the infiltrate in ECD suggests that there will be an intricate and complex interaction between macrophages and lymphocytes. In fact it was shown that tumor necrosis factor alpha is a master regulator of inflammation in ECD (Dagna et al. 2012). The disease is linked to a network of pro-inflammatory cytokines and chemokines involved in the recruitment of macrophages/histiocytes into ECD lesions (Cavalli et al. 2014). Novel findings have shown that ECD is associated with the BRAF V600E mutation, similar to Langerhans cell histiocytosis (Blombery et al. 2012; Haroche et al. 2012; Emile et al. 2013; Hervier et al. 2014; Bosco et al. 2015; Haroche and Abla 2015). In one study 13/24 patients with ECD (54 %) harbored the BRAF V600E mutation, in comparison with 11/29 patients (38 %) with Langerhans cell histiocytosis (Haroche et al. 2012). BRAF oncogene-induced senescence may represent the link between oncogenic mutation and the pathologic inflammatory response (Cavalli et al. 2014). In BRAF wild-type patients with ECD recurrent RAS and PIK3CA mutations were observed (Emile et al. 2014).

Necrobiotic Xanthogranuloma: Liver Involvement

Necrobiotic xanthogranuloma (NBX; synonym: necrobiotic xanthogranuloma with paraproteinemia) is a rare, destructive non-Langerhans cell histiocytic disorder with formation of lipid-rich granulomas, a distinct type of collagen degradation/necrosis, and a usually indolent progressive course. In rare cases, the liver is involved by NBX, associated with formation of tumor-like nodular transformation with non-cirrhotic portal hypertension (Hunter and Burry 1985; Novak et al. 1992). One NBX patient showed syncytial giant cell hepatitis (Amer et al. 2005).

The condition was first distinguished from normo- or hyperlipemic plane xanthomas in 1980 (Kossard and Winkelmann 1980). NBX is strongly associated with monoclonal gammopathy (paraproteinemia) with or without concomitant B-cell neoplasms, including plasmacytoma/

multiple myeloma. The latter develop before the skin lesions or later in the course of disease (Ugurlu et al. 2000). Monoclonal gammopathy, usually of the IgG type and much less commonly of the IgA type, is found in 80 % of patients. Clinically, NBX most often manifests as yellowish skin plaques and nodules, most commonly in the periorbital region and sometimes defigurating. Large plaques may ulcerate (Ugurlu et al. 2000). Inner/visceral organs may be affected, including the lung, pericardium, myocardium, salivary glands, larynx, kidney, and liver (Hunter and Burry 1985; Fortson and Schroeter 1990; Bara et al. 2003; Zainal et al. 2010). Amyloidosis may develop as a late complication. Histologically, the granulomatous reaction is characterized by hyaline band-like necrobiosis of collagen, emergence of collagen fiber bundle fragments acting as foreign bodies associated with bizarre angulated giant cells, a macrophage-rich infiltrate with numerous lipid-laden foam cells, Touton giant cells (sometimes with so-called Touton cell panniculitis), cholesterol clefts, and infiltrates of lymphocytes and plasma cells, sometimes with lymphoid follicles (Finan and Winkelmann 1987).

Panniculitis-Associated Histiocytic Disorders: Weber-Christian Disease

Introduction

Weber-Christian disease (WCD; synonyms: Pfeifer-Weber-Christian disease; idiopathic relapsing febrile lobular non-suppurative panniculitis; relapsing nodular non-suppurative panniculitis; Weber-Christian syndrome) is a form of acute to chronic, relapsing inflammation of subcutaneous adipose tissue, characterized by a distinct phenotype of lobular and later nodular panniculitis. The disorder was first described by Pfeifer in 1892 (Pfeifer 1892), and a second patient was documented in 1916 (Gilchrist and Ketron 1916). In 1925, Weber referred to these two patients in his publication on "Relapsing non-suppurative nodular panniculitis" (Weber 1925), and in 1928, Christian added the word "febrile" (Christian 1928). In 1936, Brill coined the term "Weber-Christian disease" (Brill 1936; reviews: Oram and Cochrane 1958; Steffen 2002). WCD prevails in females 30–60 years of age, but it also occurs in infants (Hendricks et al. 1978) and children (Wu and Zou 2007).

Clinical and Morphologic Features

Clinically, WCD is characterized by recurrent subcutaneous inflammatory tender to painful nodules, erythematous skin lesions, fever, arthralgia, weight loss, and malaise due to systemic inflammatory reactions. The process can result in fibrosis/scarring and atrophy of the adipose tissue (lipoatrophy). Part of patients revealed hyperlipidemia, anemia, or leukemoid reactions. Inner organs and tissues may be involved, including the pancreas (pancreatitis), lung (pleuritis and lipogranulomatous pneumonitis), mediastinum (mediastinitis/periaortitis), mesenterium (mesenteritis), and liver. The clinical course of WCD is variable, cases with skin involvement only having a good prognosis, while systemic variants often result in complications and eventually fatal outcome.

In the subcutaneous lesions of WCD, three histopathological stages can be identified. In stage 1, adipose lobules are infiltrated by neutrophils, macrophages, and lymphocytes, associated with adipocyte damage and death. Stage 2 is characterized by a strong phagocytic reaction, with macrophages phagocytosing damaged and dead adipocytes, leukocytes, red blood cells, and debris, with formation of so-called bean-bag cells. In this stage, foamy macrophages develop. In stage 3, the macrophage accumulations are progressively replaced by a fibroblastic reaction followed by fibrosis and lipoatrophy.

Liver Involvement

Suspected liver involvement with WCD, manifest as hepatomegaly and elevated serum transaminases, has been documented in several reports

(Friedman 1945; Kinmont 1952; Schwartz et al. 1952; Steinberg 1953; Oram and Cochrane 1958; Stanoeva and Miovski 1972; Edge et al. 1986; Amarapurkar et al. 2005; Wu and Zou 2007). In patients with verified liver involvement, the histology is characterized by several patterns. Similar to other histiocytoid disorder with lipid storage, foamy macrophages can accumulate in the liver (Miyazaki et al. 1977). In one case with fatal outcome, the liver macroscopically showed numerous rice grain-sized yellow nodules (Bjornstad 1951). Some patients have shown hepatic steatosis and/or steatohepatitis (Hanrahan et al. 1951; Oram and Cochrane 1958; Miyazaki et al. 1977; Wasserman et al. 2001). Steatotic hepatocytes may show Mallory-Denk bodies (Kimura et al. 1980), thus mimicking alcoholic or nonalcoholic steatohepatitis (ASH/NASH). In one patient with WCD who died of hepatic failure, necropsy revealed acute focal necrosis of the liver (Miller and Kritzler 1943). Steatonecrosis of the liver in WCD was described in another patients (Jones et al. 1950). In a pediatric patient with WCD, chronic active hepatitis associated with an LKM variant autoantibody was found, suggesting that autoimmune mechanisms are involved in pathogenic pathways of WCD (Edge et al. 1986).

Differential Diagnosis

In patients with WCD-associated steatohepatitis, ASH and NASH due to other causes have to be considered. Hepatic foamy macrophages in portal tracts occur in other histiocytic disorders, including xanthoma disseminatum. Various forms of panniculitis resembling WCD occur in the setting of autoimmune disorders (in particular systemic lupus erythematodes), pancreatic diseases, lymphoproliferative disorders, infections, and trauma. WCD can be mimicked by cytophagic histiocytic panniculitis, discussed in the following paragraph. A panniculitis resembling WCD has been detected in patients with rare mutations in the tumor necrosis factor receptor superfamily (TNFRSF) 1A gene (Lamprecht et al. 2004). TNFRSF 1A gene mutations are known to cause TNFR-associated periodic syndrome/TRAPS.

Panniculitis-Associated Histiocytic Disorders: Cytophagic Histiocytic Panniculitis

Introduction

Cytophagic histiocytic panniculitis (CHP; panniculitis associated with hemophagocytic syndrome) was described in 1980 as a form of severe lobular and nodular panniculitis, characterized by a strong phagocytic activity of histiocytes/macrophages (cytophagy of leukocytes and erythrocytes) in the lesions, a high rate of systemic manifestations, and a high mortality (Winkelmann 1980; Winkelmann and Bowie 1980). Some authors employ the term CHP to describe two different processes, one being a variant of lobular panniculitis ("classical" CHP), the other neoplastic, i.e., subcutaneous panniculitis-like T-cell lymphoma (reviews: Requena and Sanchez Yus 2001; Aronson and Worobec 2010). CHP is often associated with an underlying infectious (in particular viral), autoimmune, or neoplastic disease, but in some patients, no such predisposing condition can be identified. CHP has also been observed following bone marrow transplantation or interferon-alpha therapy. In some patients, an overlap between Weber-Christian disease and CHP was found (Steininger and Missmahl 1988).

Clinical and Morphologic Features

The cutaneous manifestations of CHP are characterized by plaques and nodules that occasionally are ecchymotic and ulcerated. Histologically the lesions are dominated by a dense infiltrate of large histiocytes/macrophages with marked cytophagic features. The cells are engaged in vigorous phagocytosis of dead adipocytes and fragments thereof, leukocytes, erythrocytes, and debris, with formation of "bean-bag cells" (Alegre and Winkelmann 1989). In systemic CHP, fever, pancytopenia,

jaundice, mucosal ulcers, coagulation disorders, and serositis are common signs. Classic CHP not associated with lymphoma is not associated with EBV infection and often has a first phase with a benign course, unless terminal hemophagocytic syndrome develops, leading to disease acceleration and often fatal outcome associated with terminal hemorrhagic diathesis. Hemorrhagic diathesis is caused by thrombocytopenia and massive coagulation disturbances due to liver failure (Crotty and Winkelmann 1981). Many cases of hemophagocytic syndrome in the setting of CHP are considered a natural disease progression of subcutaneous panniculitis T-cell lymphoma (Craig et al. 1998), such patients being prone to have a fatal outcome (Huilgol et al. 1998). Pediatric CHP has been found in a patient with fatal hemophagocytic lymphohistiocytosis caused by a perforin gene mutation (Chen et al. 2007).

Liver Involvement

Many patients with CHP exhibit signs of liver dysfunction mimicking hepatitis (Winkelmann and Bowie 1980; March et al. 1986; White and Winkelmann 1989; Pettersson et al. 1992; Tsukahara et al. 1995), often associated with hepatomegaly or hepatosplenomegaly (Guitart et al. 1998). Hepatomegaly and hepatopathy, sometimes severe, is mainly seen in patients with CHP complicated by hemophagocytic syndrome (Huilgol et al. 1998). In liver biopsies, the dominant features consist of histiocyte infiltrations in portal tracts (Winkelmann and Bowie 1980; Willis et al. 1985) and signs of hemophagocytosis (Hilton et al. 1990). In fatal systemic CHP, infiltration of the liver with numerous histiocytes together with T lymphocytes was found (Perniciaro et al. 1994). CHP can lead to liver failure (Crotty and Winkelmann 1981).

Differential Diagnosis

The main differential diagnoses include other forms of hemophagocytic syndromes and atypical or aggressive variants of Weber-Christian disease.

Hemophagocytic Syndromes

Hemophagocytic lymphohistiocytosis (HLH): A heterogeneous group of inherited and acquired disorders of monocyte/macrophage function

HLH comprises two different conditions, i.e., (a) *primary hemophagocytic lymphohistiocytosis* (*familial or sporadic*) and (b) *secondary hemophagocytic lymphohistiocytosis* (Henter et al. 1997). Although the primary form is usually termed familial HLH (FHLH), it often appears sporadic with a negative family history, since the disorder is autosomal recessive. Familial HLH may be elicited by, or associated with, infections. Secondary HLH is an exaggerated, reactive proliferation and activation of the lymphocytic and histiocytic/macrophage cell systems induced by several factors, including severe infection (*infection-associated hemophagocytic syndrome*, *IAHS*); viral infection in immunocompromised hosts (*virus-associated hemophagocytic syndrome*, *VAHS*; *distinct variant*: *EBVHS or EBV-HLH*); immune system activation during malignancies (*malignancy-associated hemophagocytic syndrome*, *MAHS*, *and lymphoma-associated hemophagocytic syndrome*, *LAHS*); and prolonged intravenous nutrition with administration of soluble lipids (fat overload syndrome) (Henter et al. 1991c). Secondary HLH with its several variants is also termed *macrophage activation syndrome* (*MAS*), or *reactive macrophage activation syndrome* (*rMAS*). However, it is still questioned whether reactive hemophagocytic lymphohistiocytosis and macrophage activation syndrome are the same or different entities (Grom 2003). What appears settled is that, as discussed below, MAS has strong clinical similarities with FHLH and reactive VAHS. In addition, similar pathogenic pathways seem to involved, in that abnormal NK cell function and depressed perforin expression are not only crucial features of FHLH but also of MAS, especially MAS developing in systemic-onset juvenile arthritis.

Secondary hemophagocytic syndromes: Sporadic hemophagocytic lymphohistiocytosis and macrophage activation syndrome

Introduction

Hemophagocytic lymphohistiocytosis is a syndrome characterized by extreme immune system activation causing massive inflammatory reactions, related to an exaggerated reaction to antigenic stimulation (review: Allen and McClain 2015). Most patients with a secondary hemophagocytic disorder have in fact what is now more frequently termed *macrophage activation syndrome* (MAS; reactive macrophage activation syndrome, rMAS; secondary hemophagocytic lymphohistiocytosis, HLH; hemophagocytic syndrome; histiocytic medullary reticulosis). MAS was first described in 1939 under the term histiocytic medullary reticulosis (Scott and Robb-Smith 1939). MAS is a serious complication of systemic inflammatory reactions, occurring in children and adults, probably caused by excessive activation of T lymphocytes, natural killer cells, and macrophages (review: Ravelli 2002). In principle, MAS is a secondary or reactive hemophagocytic syndrome (hence, the alternative term rMAS). MAS has to be considered in patients with a systemic inflammatory response syndrome (SIRS) – or Still's disease-like clinical presentation (Emmenegger et al. 2002). According to the Histiocyte Society, the diagnosis of MAS/HLH requires the fulfillment of five criteria: (1) fever; (2) cytopenia (two of three lineages); (3) splenomegaly; (4) hypertriglyceridemia and/or hypofibrinogenemia; and (5) hemophagocytosis (Henter et al. 1991a), but there are also patients with atypical presentations. It is recognized that the main features of MAS are in part those also observed in familial hemophagocytic lymphohistiocytosis (see above).

MAS: Causes and Associations

MAS is associated with a number of underlying diseases such as viral, rickettsial, bacterial, or fungal infections, parasitic infestations, hematological and other malignancies (in particular lymphomas), autoimmune conditions, inflammatory bowel disease, Kikuchi's disease, metabolic disorders, liver transplantation, Kawasaki disease (Cummings et al. 2008), and rarely after viral vaccinations (Kumakura et al. 1997; Tsuda 1997; Janka et al. 1998; Corbeel 1998; Mahadeva et al. 2000; Otagiri et al. 2002; Ohno et al. 2003; Bhatia et al. 2003; Dhote et al. 2003; Karasu et al. 2003). In a systematic review based on a PubMed search, most cases of MAS associated with bacterial infections were brucellosis, rickettsial diseases, and Q fever. For viral infections, most of the cases were reported in patients with avian influenza A subtype H5N1, while the most common protozoal disease was visceral leishmaniasis (Cascio et al. 2012). Viral infections associated with rapidly progressive and life-threatening MAS, e.g., include human herpesvirus 8 reactivation in HIV-infected patients (Fardet et al. 2003). Among noninfectious disorders, active systemic disease associated with systemic lupus erythematodes, rheumatoid arthritis, and adult Still's disease are predominant causes of MAS (Dhote et al. 2003; Félix et al. 2009; Atteritano et al. 2012). MAS is also a well-known complication of systemic juvenile idiopathic arthritis (Davi et al. 2011; Minoia et al. 2014).

Particularly impressive secondary hemophagocytic syndromes occur in patients with viral infections, and specifically EBV infections (Maakaroun et al. 2010), similar to what has been discussed for XLP (virus-associated hemophagocytic syndrome, VAHS; Daum et al. 1987; Dharancy et al. 2008). In fatal cases of H1N+ influenza, MAS is suggested to be a secondary event and is in fact related to mutations in hemophagocytic lymphohistiocytosis genes (Schulert et al. 2015). Per definition, VAHS is a nonneoplastic, generalized histiocyte/macrophage proliferation with prominent hemophagocytosis associated with a systemic viral infection. Even though a benign lesion per se, VAHS in the context of EBV infection may follow a malignant and fatal

course (Kikuta et al. 1993), with a relatively high mortality, not only in those patients having XLP. The majority of EBV-VAHS cases develop in apparently immunocompetent children and adolescents (Imashuku 2002). The severe disease manifestations seem to be related to unrestricted release of cytokines produced by EBV-infected lymphocytes (reviews: Favara 1992; Fisman 2000; Kikuta 1995). The reason why some, but not all, patients with EBV infection develop VAHS is not clear. However, recent investigations have shown that there may be distinct EBV-infected cell populations in EBV-related VAHS that exhibit different patterns of EBV latent gene expression and a different EBNA promoter methylation status (Yoshioka et al. 2003).

Pathogenic Pathways

Pathogenetically, an non-controlled T lymphocyte or natural killer cell activation with induction of a "cytokine storm" is thought to give rise to potentially life-threatening macrophage activation, the final common pathway of rMAS, and associated with the infiltration of many tissues by T lymphocytes and activated macrophages. A central role is played by granule-dependent cytotoxic activity following cell activation, polarization of cytotoxic granules toward the conjugated target cell, and fusion of granules with target cell membranes, with release of granule contents (reviews: Janka 2007a,b; Filipovich 2008; de Saint Basile et al. 2011; Usmani et al. 2013). The macrophage populations in MAS in fact show an activated phenotype, and they express major histocompatibility complex class I and II molecules and macrophage colony-stimulating factor receptors (Arico et al. 2001b). Several cytokines are markedly elevated in serum of patients with MAS, including INF-gamma, TNF-alpha, IL-10, IL-12, and the IL-2 receptor (Henter et al. 1991b). This is accompanied by a profoundly decreased cytotoxic T-lymphocyte function and hampered or even absent NK cell function, being a hallmark of the immune dysregulation characterizing MAS, in some way similar to FHLH (Egeler et al. 1996). It has been shown that soluble Fas/CD95 (sFas) and Fas ligand (sFasL) were significantly elevated in the serum of patients with MAS episodes, decreasing again during convalescence, suggesting that sFas and sFasL, via interfering with activation-induced cell death (AICD), might contribute to the pathogenesis of MAS (Emmenegger et al. 2000). In patients with EBV-associated MAS, infection of T lymphocytes with EBV appears to be a typical feature, irrespective of the clinical course (Beutel et al. 2009).

Hemophagocytosis in MAS

Activation of macrophages/histiocytes in MAS is typically associated with hemophagocytosis that involves the pathologic finding of activated macrophages engulfing erythrocytes, leukocytes, platelets, and their precursor cells (Favara 1992). The organs and tissues most frequently showing hemophagocytosis are the spleen, liver, lymph nodes, and bone marrow, but the CNS and the skin may also be affected.

Clinical Features

Patients with MAS/rMAS present with persistent fever unresponsive to antibiotics, malaise, arthralgia, fatigue, rash, cytopenia, hepatosplenomegaly, and signs of multiorgan dysfunction (reviews: Pradalier et al. 2004; Gupta et al. 2009; Larroche 2012). In addition, part of patients exhibit signs and symptoms of the underlying disease that has caused MAS, resulting in complex diagnostic situations. The serum ferritin is typically elevated in rMAS (Esumi et al. 1987). The combination of a high serum ferritin concentration and a low glycosylated ferritin concentration is a particularly potent marker of rMAS (Lambotte et al. 2003). Particularly in children, HLH can cause multiorgan failure as a presenting syndrome or early in the disease course (Nahum et al. 2000).

Pathology of the Liver in Macrophage Activation Syndrome

Hepatic effects of MAS are both structural and functional, and in some patients, various forms of histopathologic alterations have been observed. In infants and children, liver involvement with MAS is common and was found in up to 91.7 % of patients (Karapinar et al. 2009; Amin et al. 2014). In adults, hepatomegaly was present in 50 %, and serum aminotransferases, ferritin, alkaline phosphatase, and triglycerides were elevated in all (De Kerguenec et al. 2001; Larroche et al. 2007). MAS may closely mimic acute or chronic hepatitis (Favara 1992; King et al. 1994) and may end up with acute hepatic failure (Parizhskaya et al. 1999). Histologically, acute lobular hepatitis with an infiltrate rich in T lymphocytes and macrophages is a typical feature (Bihl et al. 2006). Large and activated Kupffer cells are found within sinusoids (Figs. 3 and 4). Kupffer cells are often increased in number, interpreted as diffuse Kupffer cell hyperplasia. Part of these activated macrophages contain red blood cells in their cytoplasm as sign of hemophagocytosis (Andreopoulos et al. 2007). The liver sinusoids may be dilated, sometimes markedly so. The portal tracts contain a usually minor cellular infiltrate composed of lymphocytes (mainly T cells) and CD68-positive macrophages, but cases with marked portal tract histiocytosis have also been reported (Terada et al. 1999). The lymphocytes accumulating in the liver in MAS are mostly CD8+ cells that produce interferon gamma, while macrophages were shown to produce IL-6 and TNF-alpha (Billiau et al. 2005). Canalicular and/or intracellular cholestasis is found in part of cases (Tsui et al. 1991). In part of the patients, cholestasis is caused by a severe injury of small bile ducts, similar to vanishing bile duct syndrome and sometimes resulting in secondary biliary cirrhosis (Fig. 5). It has been suggested that the hepatocyte and cholangiocyte

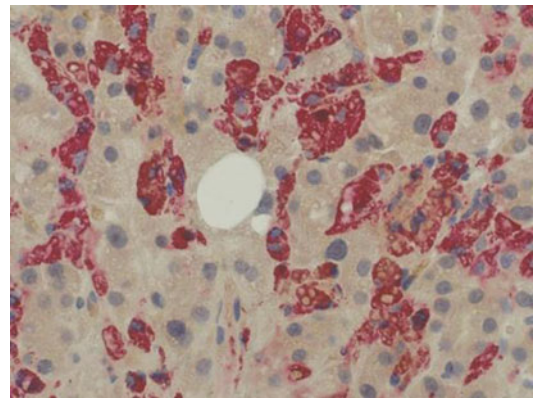

Fig. 4 Reactive macrophage activation syndrome of the liver. The sinusoids contain accumulations of activated macrophages (CD68 immunostain)

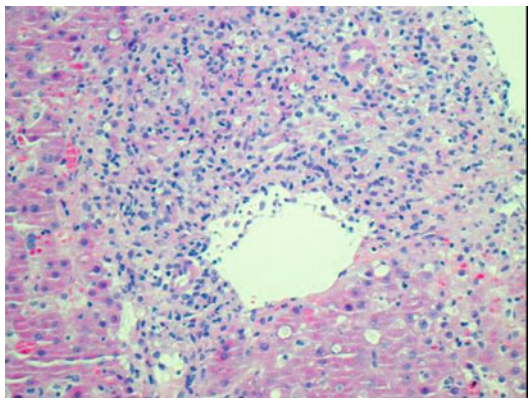

Fig. 3 Reactive macrophage activation syndrome of the liver. An enlarged portal tract is infiltrated with histiocytoid cells/macrophages and lymphocytes. The portal vein branch reveals signs of florid endotheliitis (hematoxylin and eosin stain)

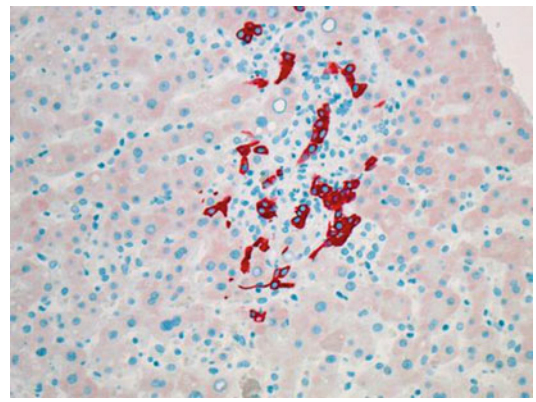

Fig. 5 Reactive macrophage activation syndrome of the liver. This disorder may be associated with injury and eventual destruction of small intrahepatic bile ducts, lymphohistiocytic cells invading and damaging the cholangiocyte lining (cytokeratin 19 immunostain)

injury are caused by a macrophage-lymphocyte-NK cell network attacking hepatic cells (Bihl et al. 2006). In the course of hemophagocytosis, marked siderosis of the liver can develop, an alteration which is also visualized in MR images (Zilkha et al. 1998).

Familial Hemophagocytic Lymphohistiocytosis (FHL; Farquhar Disease; Familial Erythrophagocytic Lymphohistiocytosis; Familial Hemophagocytic Reticulosis)

Introduction

Familial hemophagocytic lymphohistiocytosis (FHL; OMIM 267700) is a rare, autosomal recessive disease of infancy and early childhood. FHL was originally described in 1952 under the term "familial hemophagocytic reticulosis" (Farquhar and Claireaux 1952), and the specific hereditary features were outlined in 1984 (Gencik et al. 1984; review: Henter 1990). The estimated incidence is about 1 in 50,000 live births. In a large study on HLH in children (122 patients), a positive family history was detected 49 % of cases including two pairs of affected male twins; the median age at disease onset was 2.9 months, with the majority of patients being less than 1-year-old at onset, with no difference between familial and sporadic cases, and an associated infection (usually by common viral pathogens) was reported in 41 % of cases (Arico et al. 1996). Rarely, there are families with late onset of disease, i.e., between 9 and 17 years (Allen et al. 2001).

Clinical and Diagnostic Features

The presentation of the disorder is the same for bona fide familial HLH and the sporadic form, except the identification of distinct gene mutations in affected families, as briefly discussed below. The main features comprise malaise, intermittent fever, a rash, hemocytopenia (anemia and thrombocytopenia), lymphadenopathy, hepatosplenomegaly, signs of liver dysfunction, and a multivisceral accumulation of T lymphocytes and macrophages (Henter et al. 1991, 1993). Patients with FHL typically show hyperlipidemia. Hypofibrinogenemia in FHLH has been suggested to be caused by a direct action of activated histiocytes/macrophages on factor X via Mac-1 receptors, subsequent activation of the common pathway of the coagulation protease cascade, and uptake of fibrin/fibrinogen by these cells (Ooe 1991). More than half of the patients suffer from CNS involvement ranging from confusion to seizures and severe neurologic impairment (Horn et al. 2002). The involved organs and tissues are infiltrated by a reactive population of lymphoid cells and histiocytes/macrophages, with signs of hemophagocytosis. The latter is particularly evident in bone marrow biopsies (Cho et al. 1997). Rarely, the infiltrates involve the lung, causing a disorder resembling interstitial pneumonia and resulting in respiratory failure (Popper et al. 1994).

Etiology and Pathogenesis

In regard to the etiology of FHL, genetic studies have uncovered several altered gene functions in at least part of the patients with FHL indicating genetic heterogeneity of FHL (Dufourcq-Lagelouse et al. 1999a,b; Ohadi et al. 1999; Graham et al. 2000; Cicocki et al. 2014; Zhang et al. 2014a). The five types of FHL (FHL1 to FHL5) comprise alterations of perforin, Munc13-4/Unc13, syntaxin11, and SH2D1A genes.

The pathogenic pathways operational in all types of FHL are complex and only partially known. They are thought to involve an impaired lymphocyte- and NK-mediated cytotoxicity and defective triggering of apoptosis (Fadeel et al. 1999, 2001). This is thought to be related to lack of perforin expression in cytotoxic cell types in patients having a perforin gene mutation (Kogawa et al. 2002), while the mechanism is unclear in those patients disclosing a normal perforin phenotype. Effects of a systemic

hypercytokinemia, including IFN-gamma, TNF, and IL-6, have been proposed to be a common final pathway (Henter et al. 1991). The natural killer cell (NK) cytotoxic activity is markedly decreased in children with primary HLH (Kataoka et al. 1990), what may play a role in the disordered activity of the lymphohistiocytic network. Whole-exome sequencing revealed an overlap between MAS in systemic juvenile idiopathic arthritis and familial hemophagocytic lymphohistiocytosis (Kaufman et al. 2014).

In FHL patients with perforin mutations, the pathogenic pathways involve an altered function of cytotoxic T lymphocytes and natural killer (NK) cells. These two cell systems share a common cytotoxic pathway that is required for defense against virus-infected or transformed cells. Specifically, cytotoxic cells eliminate their target cells primarily via the secretion of granules containing perforin and granzymes (Shresta et al. 1998), and this multistep process involves target cell recognition, adhesion, formation of an immunologic synapse, reorientation of the Golgi complex and the microtubule-organizing center (MTOC), and the polarization of the lytic granule compartment toward the target cell contact site (Kupfer and Singer 1989). After establishing a synapse with the target cell, perforin-containing lytic granules are rapidly transferred to the target cell interface, followed by their docking and fusion with the respective plasma membrane, and release, whereupon the cell is destroyed. This interaction process requires the local concentration of talin and adhesion molecules (including LFA-1) at the contact site, forming a ring-like structure to which the polarized MTOC anchors. This ring surrounds a central supramolecular activation complex (cSMAC) containing the signal molecules, Lck and PKC delta. Polarized lytic granules then insert into the cSMAC before being secreted (Vyas et al. 2002). Which factors control the secretion process? Late in the exocytic pathway, the small GTPase, Rab27a, is an essential compound, as seen in respective human and animal mutation states (human Griscelli syndrome and the ashen mutant mouse; see below), but other factors remain to be identified.

Liver Involvement in Familial Hemophagocytic Lymphohistiocytosis

At autopsy, the enlarged liver shows hypertrophy of the Kupffer cells which exhibit erythrophagocytosis and a lymphocytic infiltration of portal tracts and the hepatic parenchyma, these cells predominantly expressing T-lymphocyte markers (Cho et al. 1997). In an autopsy study on 27 cases, infiltration of hepatic portal tracts of lymphocytes and histiocytes was present in 81 %, and the infiltrates were dense in 13/27 patients, sometimes resembling chronic hepatitis of low activity. This mixed infiltrates was also noted within liver lobules, albeit to a lesser degree. The number of Kupffer cells was moderately increased (Ost et al. 1998). In this study, hemophagocytic activity was only occasionally seen in the liver (3/27 patients; 11 %). The chronic hepatitis-like presentation was interpreted to probably represent the sequelae of a general lymphocyte activation in FHLH (Ost et al. 1998). Similar changes have been reported in other studies (Henter 1990; Favara 1992, 1996), and the pattern is very similar to that observed in sporadic hemophagocytic lymphohistiocytosis, with the apparently only distinguishing feature is the expression of CD21, CD30, and CD35 antigens by histiocytes (Boissy et al. 1997). Similar to reactive MAS, patients with FHLH can show severe loss of intrahepatic bile ducts (Kapelari et al. 2005).

Liver Pathology in Hemophagocytotic Forms of Griscelli Syndrome/GS (GS2; Rab27a Mutations)

A hemophagocytic syndrome has been described for GS several times, but chiefly in GS2 (Baumeister et al. 2000; Kumar et al. 2001; Sanal et al. 2002). Similar to FHLH, this disorder may be associated with decreased NK activity and hypertriglyceridemia (Baumeister et al. 2000). Recurrent hemophagocytosis can be severe and cause pancytopenia, already in neonates (Kumar et al. 2001). In GS associated with such reactions,

specifically in the so-called accelerated phase of GS, hepatomegaly with or without jaundice can occur (Sanal et al. 1993; Mancini et al. 1998; Baumeister et al. 2000). In one patient, hepatosplenomegaly was associated with hepatitis (Mancini et al. 1998). In pediatric patients with hepatomegaly, autopsy revealed lymphohistiocytosis and erythrophagocytosis of the liver (Sanal et al. 1993; Gögüs et al. 1995). In more detail, the liver is densely infiltrated by small lymphocytes and histiocytoid cells/macrophages, some of the engulfing erythrocytes (Gögüs et al. 1995), but in an autopsy study, erythrophagocytosis was particularly prominent in bone marrow and the spleen (Gögüs et al. 1995).

Liver Involvement in Chediak-Higashi Syndrome

In the accelerated phase of CHS, a syndrome develops that may be very similar to FHLH or to virus-induced hemophagocytic syndromes, including multivisceral lymphohistiocytosis, hemophagocytosis causing pancytopenia, hypertriglyceridemia, and eventual fatal outcome (Bejaoui et al. 1989; Shome et al. 2002). The lymphoid cell infiltrates are sometimes both very dense and atypical, leading to the differential diagnosis of malignant non-Hodgkin's lymphoma. The infiltrates may contain large histiocytoid cells and bona fide macrophages. Hemophagocytosis in lymph nodes, bone marrow, and visceral organs has consistently been reported (Donohue and Bain 1957; Efrati and Jonas 1958; Padgett et al. 1967; Bedoya et al. 1969; Krüger et al. 1971; Ito et al. 1972; Valenzuela et al. 1976). The presence of massive lymphohistiocytic infiltrates cannot only induce generalized lymphadenopathy but also hepatomegaly and splenomegaly (Krüger et al. 1971; Ahluwalia et al. 2003). In one study, the liver of each of four autopsied patients weighed 1.5–2 times normal (Rubin et al. 1985). Histologically, the typical hepatic changes consist of lymphohistiocytic infiltrates chiefly localized to the portal tracts (Valenzuela et al. 1976), but accumulation of lymphocytes and histiocytoid cells is also seen, albeit to a lesser degree, in the hepatic sinusoids. In some instances, the infiltrate extends between the hepatic lobules bridging the portal tracts (Rubin et al. 1985). Both the infiltrating histiocytoid cells and the resident Kupffer cells reveal prominent hemophagocytosis and nucleophagocytosis (Valenzuela et al. 1976). Among the phagocytosed elements, erythrocytes are by far the most numerous, but usually without significant phagocyte iron overload. At electron microscopic examination, giant lysosomal structures are also detectable in hepatocytes (Valenzuela et al. 1976). The hepatic infiltration may be associated with portal fibrosis (Krüger et al. 1971).

Hemophagocytic Lymphohistiocytosis and Liver Involvement in Wiskott-Aldrich Syndrome

Patients with WAS can develop EBV-associated hemophagocytic lymphohistiocytosis (EBV-HLH; Pasic et al. 2003) that induces liver alterations similar to those found in reactive MAS (see above).

Liver Changes in X-Linked Lymphoproliferative Disease

Liver pathology in XLP is dominated by infiltration by lymphoid cells, massive hemophagocytosis (Arico et al. 2001a), and other changes related to EBV infection. In the SAP-deficiency mouse model, hemophagocytosis has been documented (Yin et al. 2003). The marked hemophagocytosis observed in patients with XLP is strongly linked to massive EBV infection (predominantly fulminant infectious mononucleosis FIM) with virus-associated hemophagocytic syndrome (VAHS). EBV is a major triggering factor producing hemophagocytic syndromes, probably via hypercytokinemia caused by mono- or oligoclonal lymphocyte proliferation induced by EBV (Imashuku 2002). In a postmortem study of a boy with XLP-related FIM, the liver showed prominent polymorphous infiltrates (small and large, blast-like lymphocytes; plasma cells; macrophages; Reed-Sternberg-like cells) associated

with confluent zone 1 necrosis in the liver and hemophagocytosis (Maia and Garwacki 1999). The complex cellular infiltrate mainly involves the expanded portal tracts, but extends beyond the limiting plate to reach the periportal zone 1. Erythrophagocytosis is mainly accomplished by Kupffer cells (the hepatic macrophage system), but also by histiocytoid cells infiltrating the liver.

Localized and Generalized Crystal-Storing Histiocytosis

Introduction

Crystal-storing histiocytosis (CSH) occurs in conjunction with disorders associated with the production of monoclonal/monotypic immunoglobulins (paraproteins, Apitz 1940; multiple myeloma; extramedullary plasmacytoma; lymphoplasmacytic lymphoma; monoclonal gammopathy of undetermined significance, MGUS), but sometimes also in the context of other lymphoproliferative diseases (e.g., MALT lymphoma, low-grade B-cell NHL, extranodal marginal B-cell NHL, or large cell NHL) and even polyclonal disorders (e.g., in rheumatoid arthritis or in association with plasma cell granuloma). The hallmark of CSH is the accumulation of pinocytosed paraproteins (immunoglobulin light-chain proteins) in macrophages/histiocytes (the so-called "pseudo-pseudo-Gaucher cells," PPGC; Schaefer 1996) with subsequent formation of numerous intracytoplasmic crystals within lysosomes/pinosomes (Glaus 1917; Hamperl and Kalkhoff 1953; Ito et al. 1970; Jenkins et al. 1994; Papla et al. 2004; Keane and Gill 2008; Yang et al. 2010). The crystal-storing phenomenon in myeloma with associated amyloidosis has already been recognized in 1917 (Glaus 1917).

Immunoglobulins of light-chain-type kappa have been almost exclusively involved (lambda chain reported only about five times) without a consistent association with a particular Ig heavy chain. Crystal formation in CSH appears to be chiefly related to the type of light chain (kappa>>>lambda); kappa light chains are also involved in light-chain deposition disease and adult Fanconi syndrome with only rare exceptions (Maldonado et al. 1975; Ganeval et al. 1984).

Epidemiology

About 80 cases have been reported as of 2012, and most situations were detected together with myeloma or lymphoplasmacytic lymphoma. In a review of the literature, the mean age at presentation was 59 years for men and 61 years for women. Fifty-eight percent had localized CSH and 42 % had generalized CSH (Dogan et al. 2012). The latter mainly involved the bone marrow, liver, lymph nodes spleen, and/or kidney. The vast majority of the patients (90 %) had an underlying lymphoproliferative or plasma cell disorder, in particular myeloma, lymphoplasmacytic lymphoma, or MGUS. Tumor-like localized forms of CSH (crystal-storing histiocytoma) are rare and involved, e.g., the lung, heart, stomach, kidney, breast, central nervous system, and tongue (Dogan et al. 2012). In a more recent study, generalized involvement was detected in only 8 % (Kanagal-Shamanna et al. 2015).

Pathology of CSH

Morphologically, the inclusions present as eosinophilic needle-like structures in the cytoplasm of macrophages/histiocytes, frequently in a proportion of 30–50 % of the total cell volume (Lebeau et al. 2002). The crystals stain pink in hematoxylin-eosin preparations, reddish brown in Elastica van Gieson, and dark blue in Giemsa preparations (Lebeau et al. 2002). Ultrastructurally, rectangular and rhomboid crystal shapes predominate; the crystals do not reveal a periodic organization and have been shown to be located within lysosomes (Terashima et al. 1978). Immunohistochemistry may detect the Ig light-chain (kappa) character of the crystalline protein, although the staining may be weak and restricted to the crystals' periphery, owing to coverage of epitopes in the densely packed structures. Light-chain

crystal deposition can be confirmed by use of immunoelectron microscopy (immunogold labeling). The technique lacks the drawbacks of immunohistochemistry for crystalline deposits and seems to detect the disorders earlier; therefore, this method has been advocated to be employed in the diagnostic workup (Gu et al. 2003). The density of storing cells may sometimes exceedingly high, to the point that the underlying neoplastic disease may be camouflaged and the crystal-storing macrophages may adopt the appearance of Gaucher cells, suggesting the erroneous diagnosis of Gaucher's disease/glucocerebrosidosis (Ito et al. 1970).

CSH in the Hepatobiliary Tract

Liver manifestations of generalized CSH can be caused by the underlying lymphoproliferative disorder and its sequelae (Figs. 6 and 7). In one patient with multiple myeloma associated with CSH and amyloidosis, nodular myeloma cell infiltrates were scattered in the liver, spleen, and kidneys, accompanied by crystal-storing macrophages Takahashi et al. 1987). In generalized CSH involving the liver, crystals are mainly seen in the hepatic macrophage system, but in one case, crystals were also observed within hepatocytes (Papla et al. 2004). In a minority of cases of CSH, crystal-storing macrophages/histiocytes may represent the main pathologic liver finding. In one study, swollen Kupffer cells (hepatic macrophages) were found to contain crystalline inclusions, apparently obstructing the sinusoidal spaces. The cells involved were predominantly observed in central areas of the lobules, but crystal-storing macrophages are also located in the portal tracts (Terashima et al. 1978; Lebeau et al. 2002; Zioni et al. 2004). These macrophages exhibit positive immunoreactivity of kappa or lambda chains, IgA, IgG, or IgM, depending on the type of underlying lymphoproliferative disorder (Papla et al. 2004). At electron microscopic examination, the Kupffer cells may harbor an enormous amount of crystalline structures, sometimes displacing the nucleus to the periphery. Interestingly, these examinations also revealed intracytoplasmic crystals in hepatocytes, intermingled with mitochondria (Lebeau et al. 2002). Crystalline inclusions were also detected in hepatocytes in a case of multiple myeloma associated with generalized CSH (Kjeldsberg et al. 1977).

Differential Diagnosis

CSH should morphologically not be confounded with other disorders resulting in generalized

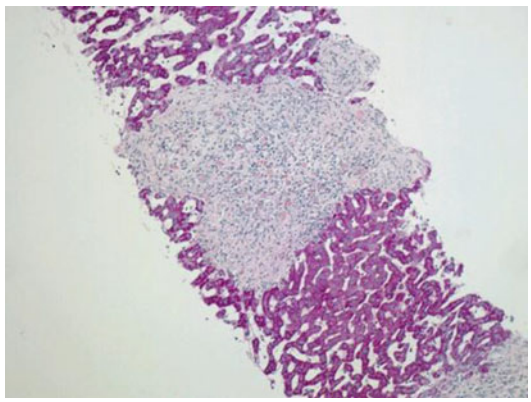

Fig. 6 Localized crystal-storing histiocytosis of the liver. The enlarged portal tracts are transformed into micronodular structures with a dense infiltrate containing PAS-positive cells (PAS stain)

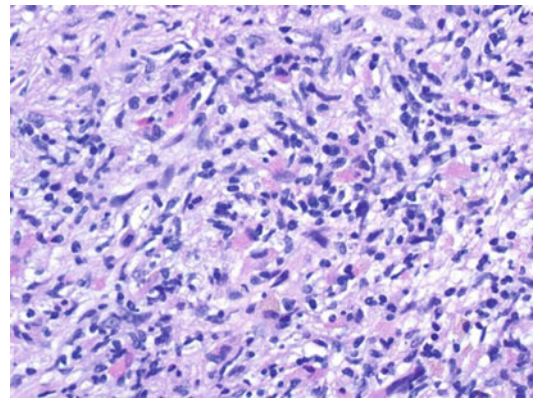

Fig. 7 Localized crystal-storing histiocytosis of the liver. The mixed cellular infiltrate contains large histiocytes/macrophages with bundles of immunoglobulin crystalloids (*pink structures*; Giemsa stain)

crystal deposition in the macrophage system, e.g., clofazimine-induced crystal-storing histiocytosis; clofazimine crystals are red in the frozen section and are brightly-red birefringent, but dissolve upon preparation of paraffin sections, leaving empty spaces, in contrast to the crystals of CSH (Sukpanichnant et al. 2000). Furthermore, Ig-containing crystals may accumulate in lymphoid cells of NHL, e.g., in follicular lymphoma, without involvement of the macrophage/histiocyte system (Wada et al. 2002).

Pathogenic Pathways

What are the pathogenic mechanisms of crystal formation in CSH? Overproduction of Ig light chains does not seem to be the key mechanism, because CSH has been observed in situations of minimal or no paraproteinemia or of low numbers of monoclonal Ig-producing cells. It has therefore been proposed that the stored paraproteins/light chains have sequence anomalies at specific sites promoting crystallization within target cells or adversely affect the cellular light-chain degradation pathway (Lebeau et al. 2002). Possible explanations surfaced from studies on the proximal renal tubular disorder, adult Fanconi syndrome, occurring in plasma cell dyscrasias, and caused by nephrotoxic Ig light chains. Diseases with production of abnormal immunoglobulin light chains (LC) can cause cast nephropathy or an accumulation of intracellular crystals in proximal tubular cells, a disorder termed myeloma-associated Fanconi syndrome with LC crystallization (Lajoie et al. 2000; Messiaen et al. 2000). In the latter disorder, proximal renal tubular cells carry numerous phagolysosomal inclusions with occasional crystalline periodic striation (Decourt et al. 2003).

Several studies have investigated molecular changes of LC in adult Fanconi syndrome (Rocca et al. 1995; Leboulleux et al. 1995; Deret et al. 1999; Decourt et al. 2003). In one study analyzing the molecular characteristics of LC, all three kappa chains responsible for crystal storage were encoded by the LCO2/O12 germline gene and had an unusual nonpolar residue in the CDR-L1 loop (Deret et al. 1999). A further study on patients with adult Fanconi syndrome showed that the variable domains of kappa chains were resistant to proteolytic cleavage in vitro, suggesting that crystal accumulation in lysosomes may result from resistance to degradation (Leboulleux et al. 1995). Unusual features restricted to the variable region of the kappa1 sequence were identified by another group, likely resulting from somatic hypermutation and probably altering the catabolism of the internalized proteins (Decourt et al. 2003). In murine models for LC-associated Fanconi syndrome, limited molecular changes introduced through site-directed mutagenesis in the variable domain may suppress formation of intracellular crystals within renal tubular cells (Decourt et al. 1999). In the light of these findings, it is of particular interest to note that, recently, an abnormal kappa LC has been characterized in CSH, showing unusual amino acid substitutions in the variable region of the stored LC and thought to be involved in pathogenesis of crystal storage (Lebeau et al. 2002).

Mesenchymal Hamartoma and Related Neoplasms

Mesenchymal Hamartoma of the Liver

104

Contents

Abstract

Mesenchymal hamartoma of the liver (MHL) is a rare primary hepatic tumor composed of a complex mixture of immature mesenchyme interspersed with small abnormal bile ducts, aberrant blood vessels, small hepatocyte islands, formation of stromal nodules, and frequently extramedullary hematopoiesis. MHL is usually a solitary tumor that typically develops in the pediatric age group, mainly in the first year of life. Fewer than 5 % present after the age of 5 years. Large tumors with numerous arteriovenous shunts can induce heart failure. MHL is associated with placental mesenchymal dysplasia. Apart from solid lesions, which may be associated with elevated serum alpha-fetoprotein levels, many tumors show extensive cystic change.

Large cysts (macrocysts) can undergo hemorrhage or purulent inflammation. Rare tumors exhibit satellite lesions or daughter nodules, but this does not indicate metastatic disease. MHL rarely occurs in older children or even in adult individuals.

The lesion is associated with distinct chromosomal translocations, mainly t(11;19).

Introduction

Mesenchymal hamartoma of the liver (MHL, hepatic mesenchymal hamartoma) is defined as hepatic tumor composed of a hamartomatous

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_104

mixture of immature mesenchyme interspersed with small abnormal bile ducts, aberrant blood vessels, and small hepatocyte islands (reviews: Siddiqui and Mckenna 2006; Baboiu et al. 2008; Rosado et al. 2013).

The first case was apparently reported in 1903 by Maresch under the term, lymphangioma of the liver, and this case has subsequently been cited several times as being MHL (Maresch 1903). However, when reading this report (in German) and studying the figures (which are drawings), there remains some doubt whether the lesion was in fact MHL. Maresch described a large hepatic tumor observed in a 5-year-old female patient (an unusual age group for MHL) with marked and progressive upper abdominal distension. The lesion was clinically suspected to be a huge ovarian cyst, and the mass had caused lumbar lordosis. At surgery, the tumor was pedunculated, being connected to the right liver lobe via an about 5 cm thick pedicle containing liver substance. Upon puncture of the tumor, a clear and yellowish fluid was oozing from the interior of the lesion. The tumor was completely removed, with an uncomplicated and recurrence-free follow-up. Grossly, the well-delimited mass measured up to 20 cm and contained numerous larger and smaller cystic cavities with a usually smooth inner surface. Histologically, the larger cavities had no cellular lining, while the microscopic cysts exhibited a lining with flat cells. No marked ductular proliferations were found in the tumor, but the lesion showed marked perilesional liver atrophy. It remains, therefore, unclear whether this mass did in fact represent lymphangioma, as the author concluded, or whether this represents the first case of MHL. Few reports described similar lesions between the 1940s and 1960s of the twentieth century (Benson and Penberthy 1942; Kay and Talbert 1950; Symmers and Ward-McQuaid 1950; Christopherson and Collier 1953; Packhard and Palmer 1955; Edmondson 1956; Grime et al. 1959; Nixon 1965; Stephens and Jenevein 1965; Ishida et al. 1966; Sutton and Eller 1968).

Hamartoma was used to designate such lesions in 1942 already (Benson and Penberthy 1942), but the currently employed term, MHL, was coined in 1956 by Edmondson, who reviewed the then available literature (Edmondson 1956). Previously, the term hamartoma had been applied to both focal nodular hyperplasia (FNH) and mesenchymal hamartoma. Edmondson pointed out that these two lesions had no similarity in structure and should be clearly distinguished. Other terms which have been employed to denote these lesions include lymphangioma, large solitary bile-cell fibroadenoma (Lee 1942/1943), and large cavernous lymphangiomatoid lesion.

Epidemiology

Overall, MHL is a rare hepatic tumor, and even large centers usually do not encounter more than one new case every 2 years (Raffensperger et al. 1983; Kwok et al. 1989; DeMaioribus et al. 1990; Murray and Ricketts 1998). However, after hemangiomas, MHL is the second most common benign hepatic tumor in childhood. In a review of more than 1,200 pediatric liver tumors, MHL accounted for 6 % of all specimens (Weinberg and Finegold 1983). MHL is more common in the first year of life (around 55 % of all cases; de Maioribus et al. 1990), and about 15 % have been observed in the neonatal period (Mulrooney et al. 2001). In fact, over 90 % are manifest in infancy and fewer than 5 % present after the age of 5 years. In a study of 18 cases, the mean age at presentation was 16 months (DeMaioribus et al. 1990). Roughly 75 % of MHL involve the right liver lobe. There is one report of ectopic MHL (Sarihan et al. 1994). It is estimated that approximately 25 % of benign hepatic tumors in infants are MHL (Kwok et al. 1989). The lesion is usually reported as a sometimes large or very large circumscribed solid mass with a propensity to cystic or pseudocystic change.

Clinical Features

MHL typically presents with abdominal distension and an upper abdominal mass, although some cases are found incidentally on physical examination or imaging. In contrast to undifferentiated (embryonal) sarcoma (see below), pain is

rarely a dominant feature. Few patients show anorexia, vomiting, or failure to thrive. Among 18 patients retrospectively studied, 13 patients were symptomatic, presenting with increasing abdominal distention (DeMaioribus et al. 1990). Abdominal distention may rapidly progress owing to increasing fluid accumulation in the stroma and in cysts (Srouji et al. 1978; Chandramouleeswari et al. 2012). Large MHL in neonates and young infants may compromise circulation and may evolve into life-threatening lesions (Silber et al. 1970; Smith et al. 1978). Intraabdominal pressure exerted by large tumors may cause engorged veins in the abdominal wall or edema of the lower limbs. Specifically, tumoral arteriovenous shunts may induce heart failure (Smith et al. 1978). In a neonate, a huge mass was shown to induce vascular steal with subsequent renal insufficiency (Mulrooney et al. 2001). MHL has also been reported to be associated with disseminated intravascular coagulation (Rao et al. 1984; Wan et al. 2009). An exceptional complication of macrocystic MHL is cyst rupture, with production of neonatal ascites (George et al. 1994).

In the neonatal period, MHL can result in respiratory distress or apnea (Srouji et al. 1978; Raffensperger et al. 1983; Lennington et al. 1993; Balmer et al. 1996; Kitano et al. 2000). Massive abdominal distension owing to rapid expansion of the tumor has been reported (Silber et al. 1970). High-output heart failure was observed in several infants, also in the presence of relatively small tumors (Smith et al. 1978; Lanuza et al. 1980; Ehren et al. 1983; Alkalay et al. 1985). There are few reports documenting pulmonary hypertension, vascular steal, and thrombocytopenia (Mulrooney et al. 2001). Rare complications in neonatal MHL comprise perinatal tumor rupture (George et al. 1994), compression of bile ducts with obstructive jaundice (Ehren et al. 1983), torsion of pedunculated MHL (Vazquez-Lima et al. 2009), and fatal hemorrhage in the tumor following birth trauma (Singh et al. 1996). MHL in infants and older children presents with a similar clinical configuration. Complications in the age group include obstructive jaundice (Heller et al. 1992), hemorrhage, anemia (Salisbury et al. 1986), abscess formation (Salisbury et al. 1986), pyrexia (Salisbury et al. 1986), constipation (Wholey and Wojno 1994), and disseminated intravascular coagulation (Rao et al. 1984).

In MHL, liver function tests are usually normal. Maternal serum AFP and/or betaHCG may be elevated (Foucar et al. 1983; Dickinson et al. 1999; Kitano et al. 2000). However, MHL may also be associated with slightly to moderately elevated alpha-fetoprotein (AFP) concentrations in the serum of the patient (Justrabo et al. 1998; Murray and Ricketts 1998; Boman et al. 2004; Cajaiba et al. 2007; Gunes et al. 2008; Unal et al. 2008; Fretzayas et al. 2009), but this may take up to a year because of ongoing hepatocyte regeneration (Justrabo et al. 1998). This elevation of serum AFP is thought to be caused by proliferating hepatocytes immunoreactive for AFP within the loose myxoid stroma of the tumor (Ito et al. 1984) or be caused by AFP overexpression of peritumoral hepatocytes (Boman et al. 2004). AFP levels in serum drop following tumor resection (Fretzayas et al. 2009). In a patient in whom MHL mimicked hepatoblastoma, serum AFP levels decreased after preoperative chemotherapy (Unal et al. 2008).

A fraction of MHL is already detectable prenatally (fetal MHL), usually diagnosed in the last trimester of pregnancy by fetal ultrasonography and/or CT owing to the multicystic aspect of the liver mass. So far, less than 20 reported cases of MHL diagnosed or detected prenatally by ultrasound examination are known (Foucar et al. 1983; Hirata et al. 1990; Bartho et al. 1992; Hansen and Ragavendra 1992; Ruiz et al. 1995; Bessho et al. 1996; Bejvan et al. 1997; Tovbin et al. 1997; Littlewood Teele et al. 1998; Dickinson et al. 1999; Kitano et al. 2000; Kamata et al. 2003; Ramirez-Garrido et al. 2003; Laberge et al. 2005; Heyer et al. 2007; Ruhland et al. 2011). The antenatal appearance of the tumor may be either solid (echogenic) or multiloculated cystic (Stanley et al. 1986). In a review of 13 reported cases (Kamata et al. 2003), two were solid, eight were cystic, and three were mixed, and the size of the masses varied from 5 to 14 cm. As a characteristic feature of this tumor, rapid tumor growth was observed in five cases,

four of them with a cystic morphology (Bessho et al. 1996; Bejvan et al. 1997; Tovbin et al. 1997; Dickinson et al. 1999), but signs of spontaneous regression were also seen in two cases (Littlewood Teele et al. 1998). Among 13 cases, perinatal complications were encountered in five. MHL manifest in the fetal liver can cause nonimmune hydrops (Alkalay et al. 1985; Bessho et al. 1996; Dickinson et al. 1999), sometimes followed by stillbirth or early postnatal death. Rapid tumor growth of fetal MHL seems to more frequently cause hydrops. Based on the sometimes impressive size, also MHL manifest in newborns (Balmer et al. 1996) has begone their growth in the fetal period already.

MHL is sometimes associated with malformations, including common mesentery with cecocolonic malposition (Sanchez Blanco et al. 1989), malrotation of the bowel (Ramareddy and Alladi 2012), Bochdalek diaphragmatic hernia (Ortiz Otero et al. 2012), and mesenchymation defects, such as protrusion through the chest wall and thus producing an extrathoracic lesion (Yesildag et al. 2004), or gastroschisis (Bulhak-Guz et al. 2005). MHL has also found to arise in an intrathoracic heterotopic liver (Antoniou et al. 2012).

Imaging Features

Ultrasound and computed tomography appearances reflect the main gross components of the tumors, ranging from a predominantly cystic or multicystic mass to a complex solid mass. Sonographically, round hyperechoic parietal nodules within the cystic spaces of MHL have been described. CT and MR of cystic forms reveal a multicystic, septated mass within the liver or on a pedicle.

Selected References Razek et al. 1973; Gilbert et al. 1978; Donovan et al. 1981; Rosenbaum and Mindell 1981; Egawa et al. 1983; Raffensperger et al. 1983; Schumacher and Westfechtel 1983; Giyanani et al. 1986; Stanley et al. 1986; Faleski and Ghiatas 1987; Roberts et al. 1989; Bovis et al. 1990; Federici et al. 1992; Kaufman 1992; Megremis et al. 1994; Wholey and Wojno 1994; Lai et al. 1996; Motiwale et al. 1996; Vandendriessche et al. 1996; Alwaidh et al. 1997; Meinders et al. 1998; Murray and Ricketts 1998; Koumanidou et al. 1999; Locham et al. 1999; Sato et al. 2000; Konez et al. 2001; Cetin et al. 2002; Arfa et al. 2003; Jaswal et al. 2003; Kamata et al. 2003; Yen et al. 2003; ye et al 2000; Millard et al. 2006; Gosset et al. 2008; Zhang et al. 2008; Ammor et al. 2009; Gow et al. 2009; Moore et al. 2009; Nakajo et al. 2009; Anil et al. 2011; Salihoglu et al. 2013.

Multicystic MHL can clinically and radiologically mimic lymphangioma (Arfa et al. 2003). A heterogeneous imaging pattern with varying signal intensities on MR is thought to correspond to different concentrations of proteinaceous material within the cysts (Wholey and Wojno 1994; Helmberger et al. 1999). Rarely, septal calcification visualized by imaging has been reported in cystic lesions (Kenney et al. 1986; Konez et al. 2001), and multifocal calcification has also been noted in the solid variant (Chung et al. 1999). Calcification may be detectable as a peripheral alteration (Steiner and Giles 2008). Large solitary cysts in MHL can grow to giant dimensions (Dooley et al. 1983) and may mimic hepatic hydatid disease (Smith et al. 2001). After contrast medium administration, solid components of MHL are enhanced, but there is no significant change in the density of cystic portions (Ros et al. 1986; Wholey and Wojno 1994; Alwaidh et al. 1997). Angiographically, abnormal blood vessels (Grases et al. 1979; Alanen et al. 1987) and multiple focal avascular areas are recognized, representing the cystic components (Wendth et al. 1976). The abnormal vasculature of MHL may mimic hemangioma in MRI (Andronikou et al. 2006). In addition to cystic tumors, solid or mixed morphologies are also recognized. In a study on 13 children with MHL, 31 % had a multiseptated cystic tumor, 38 % had a mixed solid and cystic tumor, and 31 % had a solid tumor (Kim et al. 2007).

Pathology

Macroscopy

The right lobe is preferentially involved (about 75 %); the remaining tumors occur in the left lobe or involve both lobes (Martinez-Mier et al. 2012). MHL is frequently large tumors, resected specimens weighing between 400 and in excess of 1,800 g, and tumors showing a diameter sometimes exceeding 30 cm and weighing 3 kg or more (Silber et al. 1970; Dehner et al. 1975; Weinberg and Finegold 1983; DeMaioribus et al. 1990; Shuto et al. 1993; Chau et al. 1994; Otal et al. 1994; Bove et al. 1998; Murray and Ricketts 1998; Orlowski and Breborowicz 2011). Some of the very large lesions occupy almost the entire liver (Shuto et al. 1993; Alwaidh et al. 1997). Similar to cavernous hemangiomas and FNH, MHL may grow in the form of pedunculated masses, up to 20 % and usually arising from the inferior surface of the liver (Raffensperger et al. 1983; Stocker and Ishak 1983; Bejvan et al. 1997; Rakheja et al. 2004). Exceedingly large lesions have been termed giant MHL (Narasimharao et al. 1988; Shuto et al. 1993; Narasimhan et al. 2004; Vargas-Vallejo et al. 2005). In a series of eight cases, the mean weight was 651 g, although the weights for three of the largest lesions were not recorded (Otal et al. 1994). MHL is usually solitary, spherical, dark red or reddish-brown tumors with smooth surfaces. On cut section, the outstanding feature in most cases is their irregular cystic appearance. Macroscopically, solid and macrocystic forms are recognized. In a series of 17 cases, seven (41 %) were solid and ten (59 %) cystic, and the solid variants showed a higher serum level of AFP (Chang et al. 2006). The tumor cysts, which do not communicate with the biliary tree, vary in size from few millimeters to more than 15 cm. In one case, almost 700 ml of fluid could be aspirated from the lesion (Stephens and Jenevein 1965), and in a neonate, MHL presented as giant intraabdominal cyst (Ramareddy and Alladi 2012). The macrocysts mostly contain clear or pale yellowish serous fluid or, less commonly, a mucoid fluid. The composition of the cyst fluid is similar to blood plasma except that the concentrations of protein, glucose, and cholesterol are lower (Dooley et al. 1983; Yandza and Valayer 1986; Mascarello and Krous 1992). Large cysts may show secondary changes, such as bleeding or empyema formation in case of infection, but intracystic bleeding is, overall, a rare event in MHL (Salisbury et al. 1986; Kwok et al. 1989; DeMaioribus et al. 1990; Lennington et al. 1993). In the stromal-predominant variant, the solid component with small cysts produces a Swiss-cheese pattern (Ros et al. 1986; Helmberger et al. 1999). Numerous small to tiny, in part confluent and bulging, whitish nodules of ovoid to irregular shape may be recognized to be interspersed with liver parenchyma (Bove et al. 1998). Gross examinations commonly reveal the presence of a gray white to red purple and usually edematous connective tissue between the cysts.

MHL is predominantly a solitary lesion, but there are several reports describing multifocality (review: Stringer and Alizai 2005). Small satellite lesions at the margin of the main tumor have been described (Stocker and Ishak 1983; Lack 1986; Stocker 2001). These lesions have also been termed daughter nodule (Fukahori et al. 2007). Such satellites may cause recurrence after apparent complete resection (Bejarano et al. 2003). In addition to satellites immediately related to the tumor periphery, more remote nodules have also been noted. In two adult patients with MHL, satellite nodules were found separate from the main lesion. In one of these cases, multiple small and cystic lesions with the histology of the principal tumor and measuring less than 1 cm were seen throughout the liver (Cook et al. 2002). In a neonate who died soon after birth showed at autopsy to have a large discrete MHL in the right and left lobes of the liver (Stringer and Alizai 2005).

Histopathology

The histopathology of MHL has been specified in detail (Dehner et al. 1975; Cooper et al. 1989; Figs. 1, 2, 3, 4, and 5). Depending on the

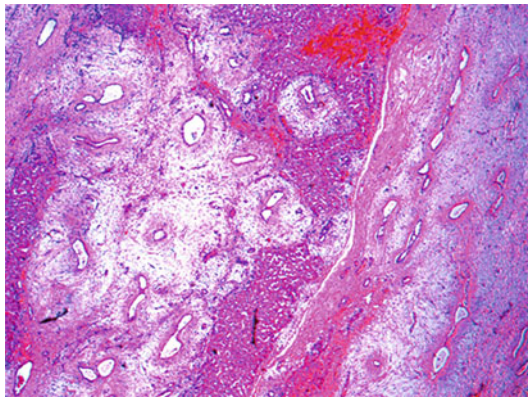

Fig. 1 Mesenchymal hamartoma of the liver. The tumor consists of nodular mesenchymal structures that contain abnormal bile duct-like profiles (hematoxylin and eosin stain)

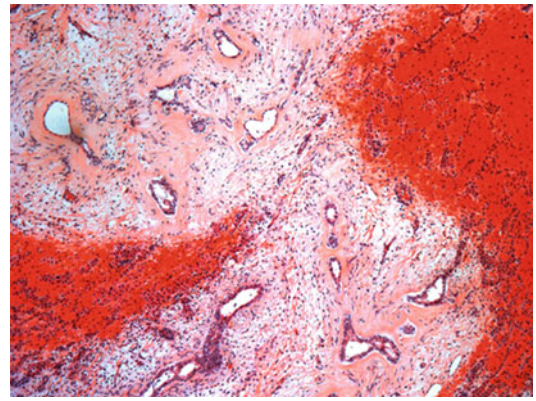

Fig. 3 Mesenchymal hamartoma of the liver. In part of mesenchymal nodules, bile duct equivalents are surrounded by hyaline connective tissue (hematoxylin and eosin stain)

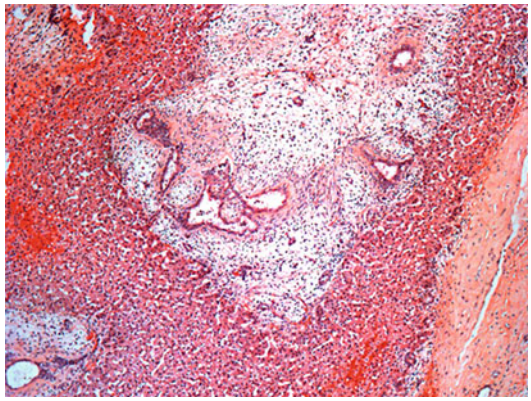

Fig. 2 Mesenchymal hamartoma of the liver. At higher magnification, the tissue surrounding bile duct equivalents is composed of immature, partly myxoid mesenchyme with spindle cells and stellate cells (hematoxylin and eosin stain)

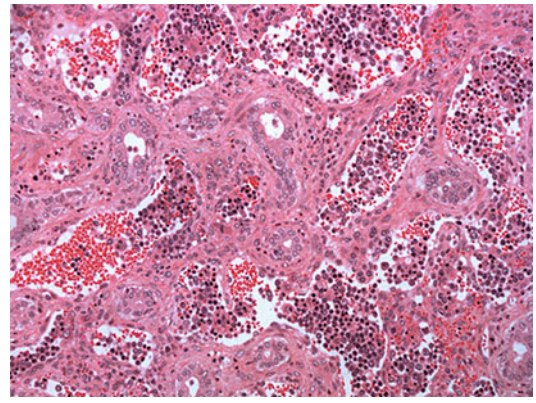

Fig. 4 Mesenchymal hamartoma of the liver with vigorous extramedullary hematopoiesis. The blood-forming cells are situated within vascular channels between mesenchymal septa with embedded bile ducts (hematoxylin and eosin stain)

contribution of tissue components, is has been proposed to histologically divide MHL into two forms, i.e., cystic predominant and stromal predominant (Cetin et al. 2002). The stromal component presents in the form of a paucicellular fibromyxoid tissue that appears to expand within the liver substance, sometimes having structures that mimic portal tracts, but without the normal portal vein architecture. Within this tissue bile duct-like profiles surrounded by a dense connective tissue are seen. This ductal/ductular compartment is usually more dense at the periphery of the tumors. It has been suggested that these small bile duct-like structures derive from dysplastic bile ducts (Ishida et al. 1966; Stocker an Ishak 1983; Lack 1986; DeMaioribus et al. 1990; de Chadarevian et al. 1994). The matrix is typically more condensed around the ducts and becomes more loose or even myxoid toward the neighboring liver substance. Within this myxoid stroma, macrocystic, microcystic, or cystoid change may develop. Large cysts are commonly devoid of an epithelial lining and may thus represent fluid-filled cystic spaces within a matrix rich in

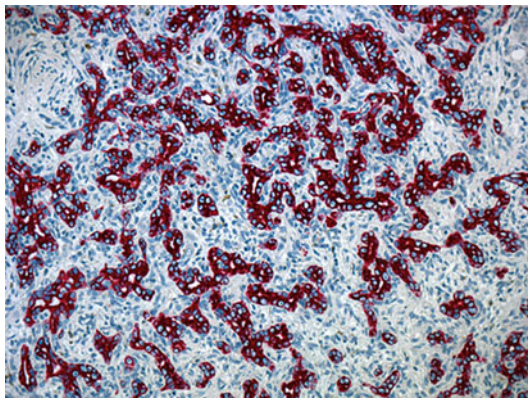

Fig. 5 Mesenchymal hamartoma of the liver. The tumor can contain areas with a high density of ductular structures (cytokeratin 7 immunostain)

interstitial fluid containing glycosaminoglycans (Stocker and Ishak 1983; Drachenberg et al. 1991). Some cysts exhibit a flat cellular lining that has, based on ultrastructure, been proposed to be mesothelium (O'Sullivan et al. 2001). In addition to bile ducts, the myxoid stroma contains small clusters of in part proliferating hepatocytes (Dehner et al. 1975). These hepatocytes are commonly smaller than normal, and they may be vacuolated (Stocker and Ishak 1983; Boman et al. 2004). At the interface between the portal tract-like compartments and the adjacent liver parenchyma, ductules in an arrangement resembling ductal plate malformation are sometimes in evidence. The epithelium of the ducts is irregular and may show signs of atrophy or at least flattening. The stroma frequently contains hemopoietic foci (Lack 1986; DeMaioribus et al. 1990; Otal et al. 1994), considered to be part of the fetal hepatic hemopoiesis that occurs in the hamartoma (Chau et al. 1994). There seems to exist a relationship between the gross presentation of MHL and the histology. The solid variant showed smaller bile ducts and more frequent proliferation of vessels, and in some solid tumors, larger amounts of evenly distributed hepatocytes were found, probably associated with a higher level of serum AFP in solid lesions (Chang et al. 2006). The vascular supply of MHL is only partially known. In one dissecting microscopic examination, analysis revealed a single vascular supply in one case, and this phenomenon was suggested to be the cause of early ischemic changes leading to cystic change (Lennington et al. 1993). There seem to be biliary connections between MHL and the adjacent liver (Senyuz et al. 1988). The liver parenchyma surrounding the tumor may show compression atrophy with ductular reaction (Chau et al. 1994), but there may also be interdigitation of MHL tissue with parenchyma, without signs of invasive growth. Specifically, small nodules of residual hepatic parenchyma may be found at the periphery of cystic spaces (Lennington et al. 1993).

Histologic Variants

Some MHL shows histologic features different from what is seen in "standard" MHL. One variant is termed stromal-predominant MHL (Mansour et al. 2005; Gunes et al. 2008). Few MHl show angiomatous elements, first described by Edmondson (Edmondson 1956). An uncommon but highly interesting phenotype is MHL combined with hemangioendothelioma, first reported by Lack (1986) and subsequently noted by other authors (Smith et al. 1978; Lanuza et al. 1980; Singh et al. 1996; Mulrooney et al. 2001). Such combinations suggest a fundamental disorder in mesenchymation and angiogenesis, also supported by the occurrence of placental mesenchymal dysplasia in some patients with MHL (see below).

Cytology

Relatively few MHL have been examined by fine-needle aspiration. Aspiration cytology of MHL revealed the presence of small groups and isolated benign-appearing spindle cells admixed with scarce amounts of myxoid stroma and normal ductal cells and hepatocytes. Although nonspecific, such findings are helpful to preoperatively exclude other liver tumors occurring in this age group (Al-Rikabi et al. 2000; Jimenez-Hefferman et al. 2000).

Ultrastructure

At electron microscopy, the tumor cells are stellate, oval to spindle shaped, with interconnected cytoplasmic processes encircling small and sometimes slit-like intercellular cystic spaces, which appeared to be the precursors of larger cysts (Dehner et al. 1975; Drachenberg et al. 1991). Tumor cells may reveal pinocytotic vesicles, a well-developed Golgi apparatus, and a moderately developed rough endoplasmic reticulum (Chau et al. 1994).

Immunohistochemistry

MHL exhibits a complex immunohistochemical phenotype, due to the various cellular components present (Table 1). In some respects, the phenotype is similar to that of undifferentiated embryonal sarcoma (see below).

Immunohistochemically, the mesenchymal tumor cells are consistently reactive for vimentin and, in a subset, for smooth muscle actin, suggesting a contribution of myofibroblastoid cells. Reactivities for desmin and alpha-1-antitrypsin were also detected in the mesenchymal cells (Von Schweinitz et al. 1999; Stocker 2001; Cook et al. 2002; Abdulkader et al. 2004). The mesenchymal cells also express fibroblast growth factor receptor, which may play a role in growth of the tumors (Von Schweinitz et al. 1999). Expectedly, the cells of the bile duct-like profiles and of epithelium-lined cysts are reactive for cytokeratins 7 and 19 (Chau et al. 1994; Justrabo et al. 1998; Cook et al. 2002; Yesim et al. 2005). Glypican-3 is expressed in a subset of MHL, what may cause differential diagnostic difficulties (Levy et al. 2012). One group detected Ki-67-positive proliferating mesenchymal cells in liver tissue at the margin of MHL but not within the tumor (Von Schweinitz et al. 1999), while another group found a low proliferative activity within the lesions, but with a prominent bcl-2 reactivity in the mesenchymal and epithelial components of the tumor, associated with a low apoptotic index (Abdulkader et al. 2004).

Table 1 Immunohistochemical phenotype of mesenchymal hamartoma of the liver

Mesenchymal cells positive for:
Vimentin
Smooth muscle actin (in part)
Desmin (in part)
Alpha-1-antitrypsin
Glypican-3 (in part)
Fibroblast growth factor receptor
Bcl-2
Cells of bile duct-like structures positive for:
Cytokeratin 7
Cytokeratin 19

Mesenchymal Hamartoma and Placental Mesenchymal Dysplasia

In some cases of prenatally diagnosed MHL, the liver tumor was associated with mesenchymal stem villous hyperplasia of the placenta (Alwaidh et al. 1997; Kitano et al. 2000; Carta et al. 2005; Laberge et al. 2005; Francis et al. 2007; Reed et al. 2008; Mack-Detlefsen et al. 2011; Harris et al. 2013). In one patient, the placenta was noticed to have multiple cysts at 16 weeks' gestation, and elevated maternal serum AFP was present (Kitano et al. 2000). In an infant with MHL associated with placental mesenchymal dysplasia, androgenetic/biparental mosaicism was detected, suggested to play a pathogenetic role in MHL (Reed et al. 2008). Mesenchymal stem villous hyperplasia of the placenta (MSVHP, mesenchymal dysplasia of the placenta) is an uncommon anomaly characterized by edema and stromal extension of the placental stem villi with relatively normal terminal villi, secondary to vascular malformations of the fetal plate (Takayama et al. 1986; Moscoso et al. 1991; Gibson et al. 2004). It has been described in phenotypically normal fetuses, illustrating that this disorder can coexist with normal fetal development, but may be occasionally associated with fetus anomalies (Lage 1991; Chen et al. 1997; Jauniaux et al. 1997), in particular intrauterine growth restriction and fetal demise (Pham et al. 2006).

MSVHP can coexist with chorangioma (Hojberg et al. 1994; Chen et al. 1997; Matsui et al. 2003). MSVHP is sometimes accompanied by omphalocele (Lage 1991; Pridmore et al. 1994), and an association of MSVHP and Beckwith-Wiedemann syndrome (BWS) has been observed several times (Lage 1991; McCowan and Becroft 1994; Hillstrom et al. 1995; Paradinas et al. 2001).

Mesenchymal Hamartoma of the Liver in Older Children

As outlined above, MHL typically occurs in children younger than 2 years of age or in the adult population. Only 5 % of MHL are diagnosed in children older than 5 years or in adults. Recently, a variant of MHL has been reported in an 11-year-old boy. This variant of MHL was characterized by a solid phenotype, i.e., without cystic structures, a predominantly myxoid stroma, and a minimal bile ductular component. It was suggested that this phenotype occurring in an older child might be reflected by a different biology of disease (Virgone et al. 2015).

Mesenchymal Hamartoma of the Liver in Adults

In addition to the classical MHL developing in the pediatric age group, MHL forms a group of tumors occurring in adults. They are more frequent in females, with an age range 21–69 and a reported size range 5–24 cm.

Selected References Grases et al. 1979; Dooley et al. 1983; Jennings et al. 1987; Gramlich et al. 1988; Gutierrez and Burgener 1988; Ito et al. 1989; Drachenberg et al. 1991; Wada et al. 1992; Megremis et al. 1994; Yamamoto et al. 1994; Bilge et al. 1996; Turlin et al. 1996; Fashir et al. 1998; Murray and Ricketts 1998; Chung et al. 1999; Papastratis et al. 2000; Cook et al. 2002; Brkic et al. 2003; Kim et al. 2003; Yesim et al. 2005; Ayadi-Kaddour et al. 2006; Hernandez et al. 2006; Mori et al. 2008; Klaassen et al. 2010.

In one patient, MHL was associated with pancreas divisum (Ito et al. 1989). Is the pathomorphology of adult-type MHl similar or the same as pediatric MHL? In a study of only three cases, it was found that, in contrast to childhood cases, the stromal component consisting of fibroblastoid cells and myofibroblasts was fibrotic with areas of dense hyalinization and only focal myxoid areas (Cook et al. 2002). It has also been described that adult-type MHL shows a series of histologic modifications, including progressive loss of hepatocytes, degeneration of bile duct epithelium, and cystic change of the mesenchymal component. In the infantile cases of MHL, bile duct-like structures and hepatocytes are abundant, while in adult-type tumors, hepatocytes were encountered preferentially at the periphery of the tumors and may be absent in the interior (Gramlich et al. 1988; Drachenberg et al. 1991; Chau et al. 1994). Some of these differences between pediatric and adult MHL may be caused by progression of the lesion toward a mesenchymal-predominant phenotype associated with progressive loss of epithelial lineages. In fact, sequential CT scans in childhood MHL have shown initial expansion of the lesion with subsequent involution (Barnhart et al. 1997).

Biology of Disease

As a rule, MHL has a benign course with good prognosis if the tumor is resected (Yen et al. 2003; Pandey et al. 2011). It has, therefore, been suggested that asymptomatic MHL can be managed by observation alone (Gottschalk et al. 1988; Roebuck 1998). In the perinatal period, however, the course may be complicated by hemodynamic instability and respiratory distress (Cornette et al. 2009), and complications may develop, in part caused by wrong diagnosis (Karpelowsky et al. 2008). Only a few cases with local relapse or metastatic spread have been reported, and such lesions are difficult to judge in regard to their hamartomatous nature.

Malignant Neoplasms Developing from Mesenchymal Hamartoma

As discussed in the respective chapter, undifferentiated (embryonal) sarcoma of the liver can develop from MLH (Begueret et al. 2001; O'Sullivan et al. 2001). In a 20-year-old male patient, hepatic angiosarcoma arose in MHL. The patient had a well-circumscribed mass on the undersurface of the right liver lobe, and histology revealed angiosarcoma with areas of MHL (Kulkarni et al. 2010). A second case of angiosarcoma arising in adult MHL was reported (Li et al. 2007).

Associated Hepatic Lesions

MHL can synchronously occur with other space-occupying lesions of the liver. In a cohort of 112 children with liver hemangioma, three of them (0.027 %) had concurrent MHL (Behr et al. 2012). MHL can occur in combination with infantile hepatic hemangioendothelioma (Hsiao et al. 2007; Behr et al. 2012) and congenital solitary nonparasitic liver cyst (Azar et al. 2003). The potential connection between MHL, MSVHP, and BWS is of interest in the light of hepatic tumors and tumor-like lesions occurring in BWS, including hepatoblastoma (Fukuzawa et al. 2003; Hamada et al. 2003; Rump et al. 2005), hepatic hemangioendothelioma (Drut et al. 1992), mixed hamartoma of the liver (which is different from FNH; Rhodes et al. 1978; Fukuzawa et al. 2001), focal nodular hyperplasia (FNH) of the liver (Bordeianou et al. 2005), liver cysts (Takano et al. 1997), and biliary dysgenesis (Steigman et al. 1990; Coppin et al. 1997).

Differential Diagnosis

Entirely intrahepatic MHL with prominent cystic changes should be distinguished from simple hepatic cysts (George et al. 1994), undifferentiated (embryonal) sarcoma of the liver, cystic alterations in hepatoblastoma (Ros et al. 1986), abscesses (Ros et al. 1986; Stanley et al. 1986), and echinococcosis, while pedunculated tumors with an important extrahepatically growing component may be confounded with cystic duplication (Ros et al. 1986), choledochal cyst (Stanley et al. 1986), lymphatic malformations or lymphangioma (Tzen et al. 1998), or loculated ascites (Ros et al. 1986; George et al. 1994).

Cytogenetic Alterations, Molecular Features, and Pathogenesis

So far, few reports have documented chromosomal aberrations in MHL (Table 2), including a balanced translocation between chromosomes 15 and 19 (Speleman et al. 1989); a balanced translocation between chromosomes 11 and 19 with a breakpoint at 19q13.4 as the most frequent recurrent anomaly (Mascarello and Krous 1992; Bove et al. 1998; Rakheja et al. 2004; Sugito et al. 2010); a complex translocation between chromosomes 11,17 and, 19 at bands q12, p11, and q13.3 (Murthi et al. 2003); and an inversion of chromosome 197. The involvement of chromosomes 11 and 19, Shetty et al. 2011; being a recurrent anomaly, with the breakpoint at 19q13.4 a common clonal abnormality potentially serving as a diagnostic feature of MHL (Bove et al. 1998; Sharif et al. 2006). A role of chromosome 19q is furthermore suggested by the finding of an interstitial deletion involving band 19q13.4 in MHL (Talmon and Cohen 2006). However, part of the MHL has been demonstrated, through flow cytometry, to be hyperdiploid (Otal et al. 1994), a feature that suggests the possibility of the involvement of a neoplastic cell lineage and that has also been found in undifferentiated (embryonal) sarcoma (UES) of the liver (see below; Chou et al. 1990).

Table 2 Cytogenetic aberrations in mesenchymal hamartoma of the liver

Balanced translocation t(11,19)
t(11,19)(q13;q13.4)
t(2;19)(q31.1;q13.42)
Inversion of chromosome 19
inv(19;19)(q13.42;q13;43)

By use of capture-based next-generation sequencing targeted to loci, chromosome rearrangements involving the MHLB1 (mesenchymal hamartoma of the liver B1) locus were identified in MHL, including the translocation 1 (11;19)(q13.1.; q14.42) involving the MALAT gene1 gene; the translocation t(2;19)(q31.1; q13.42) involving AK023515, an uncharacterized noncoding gene; and the inversion inv(19;19)(q13.42;q13.43) involving the PEG3 gene encoding a Kruppel-type zinc-finger protein (Mathews et al. 2013). The first translocation type is shared with undifferentiated embryonal sarcoma of the liver. A histogenetic relationship between MHL and UES has first been suggested by Stocker and Ishak (1978), subsequently challenged (Gallivan et al. 1983; Finegold 1986; Lack 1986; Chou et al. 1990; Aoyama et al. 1991), and later revived (de Chadarevian et al. 1994; Lauwers et al. 1997; Bove et al. 1998; Ramanujam et al. 1999; Begueret et al. 2001; O'Sullivan et al. 2001; Rajaram et al. 2007; Lahmar-Boufaroua et al. 2008). UES was also found to arise from MHL in adult patients (Tucker et al. 2012). There is histologic evidence that UES might evolve from preexisting MHL (malignant transformation of MHL; Ramanujam et al. 1999). In a more recent investigation, a single example of a UES arising in MHL with a complex karyotype including add (19q)(13) was reported (Lauwers et al. 1997), all these findings suggesting a pathogenetic link between MHL and UES. Similar to few instances of MHL, flow cytometry in UES revealed hyperdiploid cell lines (Chou et al. 1990). Among 14 structural chromosomal anomalies found in one study of UES, one case exhibited a breakpoint at 19q11, as in MHL (Sawyer et al. 1996). The breakpoint of the critical 11q13 region has been cloned and the sequence determined. The breakpoint at 11q13 occurred in the MALAT1 gene, and the breakpoint at 10q13.4 occurs at a locus termed, MHLB1, for mesenchymal hamartoma of the liver breakpoint 1 (Rajaram et al. 2007). MALAT1 (metastasis-associated lung adenocarcinoma transcript 1, synonym, NEAT2) is a conserved long noncoding RNA which is highly expressed in nuclei. Long noncoding RNAs (lncRNAs), with a size larger than 200 nt, are a group of RNA species that have no protein coding ability, but not only act as the intermediary between DNA and proteins but also regulate gene expression in many ways, including chromosome remodeling. lncRNAs, in particular MALAT1, HOTAIR, and ANRIL, contribute to cancer development and progression through their action on several critical carcinogenic pathways, including the expression of metastasis-associated genes (Tano and Akimitsu 2012; Li and Chen 2013; Qiu et al. 2013; Shi et al. 2013). MALAT1 is an important lncRNA, of which two alternative modes of action have been proposed, i.e., regulation of gene expression or alternative splicing (Gutschner et al. 2013). MALAT1 regulates alternative splicing by modulating SR splicing factor phosphorylation (Long et al. 2009; Tripathi et al. 2010). MALAT1 cooperates with MALAT1-associated small cytoplasmic RNAs (mascRNAs). mascRNA is processed from the much longer nuclear MALAT1 by the action of RNAse P. However, under normal condition, knockout of MALAT1 in mice is compatible with cell viability and normal development (Eissmann et al. 2012). MALAT1 controls cell cycle progression by regulating the expression of the oncogenic transcription factor B-MYB (Tripathi et al. 2013). It positively regulates cell motility through transcriptional regulation of motility-associated genes.

The pathogenesis of MHL is unknown. Based on a low proliferative activity in the lesions, it has been suggested that most of the growth in MHL takes place before or just after birth, while cyst expansion is later responsible for postnatal tumor growth (Stocker and Ishak 1983). The lesion is conventionally classified as a tumor-like, nonneoplastic process, hence the name, hamartoma. Therefore, one hypothesis of pathogenesis refers to a developmental disorder. According to this hypothesis, MHL may be related to a ductal plate malformation and reflects features known from congenital hepatic fibrosis and Caroli's disease (Dehner 1975; Von Schweinitz et al. 1999; Stocker et al. 2002). A pathway characterized by aberrant development of hepatic tissues is further suggested by the

observation of MHL developing in an arrested liver in conjunction with infantile hemangioendothelioma (Bejarano et al. 2003).

A second hypothesis considers ischemia as a cause of MHL. That ischemia which can induce abnormal hepatic growth patterns is known from regenerative nodular hyperplasia and from FNH-like lesions that may develop in hepatic venous outflow disorders. Based on the comparison of the histology of MHL with that of a torsioned accessory liver lobe, it was suggested that MHL may be a consequence of reactive changes to regional ischemia within a sequestered hepatic lobe (Lennington et al. 1993). However, the distinct vascular supply pattern of MHL, characterized by the presence of commonly multiple feeding vessels, renders this hypothesis unlikely. Biliary maldevelopment and cystic changes in MHL have also been suggested to be caused by a fetal vascular insult (Okeda 1976).

The third hypothesis holds it that a neoplastic process is involved, albeit with a so far unknown cellular origin. The presence of cells sharing features with hepatic stellate cells (HSC) led to the hypothesis that MHL might be an HSC-derived tumor (Shintaku and Watanabe 2010). Is there evidence that MHL may in fact not be a hamartoma, but rather a true neoplasm? Theoretically, this would not be expected, owing to the involvement of several and apparently unrelated cell lineages. On the other hand, the often dominant mesenchymal component might be neoplastic, in some way inducing the biliary and, eventually, hepatocytic component (Bove et al. 1998), in the sense of a neoplastic disorder of mesenchymal to epithelial transition. Based on cytogenetic and DNA analysis findings, there is some evidence that a neoplastic process may be involved, and the possibility of MHL being a disorder of imprinting has been discussed (Reed and Kapur 2008).

Undifferentiated (Embryonal) Sarcoma (UES)

105

ICD-O code 8991/3

Contents

Abstract

Undifferentiated embryonal sarcoma (UES) is defined as a highly malignant mesenchymal neoplasm of the liver. UES mainly occurs in the pediatric age group and is characterized by the presence of an immature and myxoid mesenchyme that contains numerous pleomorphic and giant cells with distinct eosinophilic globular cytoplasmic inclusions. UES is the third most common malignant hepatic tumor in children, whereby about 50 % of patients are 6–10 years old at diagnosis. In contrast to hepatoblastoma, only a minority of UES is diagnosed in children younger than 5 years. UES is a highly aggressive neoplasm that forms large liver tumors mainly in the right liver lobe, typically undergoing cystic change, sometimes mimicking hydatid disease. Spontaneous hemorrhage and tumor rupture may occur. Apart from a basic histologic pattern, several variants are known, including small cell, anaplastic and rhabdoid phenotypes, and tumors with various heterologous components. The abnormal mesenchyme of UES may surround abnormal and dilated intratumoral bile

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_105

duct-like structures. There is a pathogenetic relationship between UES and mesenchymal hamartoma of the liver.

Introduction

Undifferentiated (embryonal) sarcoma (UES) is defined as a highly malignant mesenchymal neoplasm of the liver, predominantly in children, characterized by the presence of an immature and myxoid mesenchyme containing pleomorphic and giant cells with globular eosinophilic cytoplasmic inclusions.

UES was first described in 1978 as a separate pathologic entity, based on 31 observations (Stocker and Ishak 1978). This tumor type may have first been reported in 1946, under the term, mesenchymoma, based on an observation in a 6-year-old boy, but the fact that this patient survived well for 13 months in a pre-chemotherapy era and based on the two histologic figures in the article leaves some doubt whether this tumor was not rather mesenchymal hamartoma (Donovan and Santulli 1946). Several terms had been employed to denote this neoplasm, including primary sarcoma of the liver (Willeford and Stembridge 1950), malignant mesenchymoma, embryonal sarcoma (Lagacé et al. 1974; Blattner et al. 1977; Forster and Berman 1977; Cornut-Sipido 1979; Cozzutto et al. 1981), primary mesenchymoma (Lorimer 1955), fibromyxosarcoma, primary malignant mesenchymal tumors, or simply sarcoma (Anderson 1951; Keeling 1971; Stanley et al. 1973). Prior to the 31 cases described by Stocker and Ishak (1978), the largest series of this lesion was that by Foster and Berman (1977) with 12 cases. The term, undifferentiated sarcomas of the liver, had however previously been employed to denote a primary hepatic sarcoma in an adult patient (Esposito et al. 1977). Within few years after the first description, several further cases have been reported (Abramowsky et al. 1980; Kinjo et al. 1980; Gallivan et al. 1983; Gonzalez-Crussi 1983; Weinberg and Finegold 1983; Parichatikanond and Parichatikanond 1985).

Epidemiology

UES is the third most common malignant tumor of the liver in the pediatric age group, accounting for about 9–15 % of childhood hepatic malignant neoplasms (Stocker and Ishak 1978; Weinberg and Finegold 1983). Among the 31 patients reported by Stocker and Ishak (1978), 51.6 % of the children were 6–10 years of age, followed by the groups 11–15 years (19.4 %), 0–5 years (16.1 %), 16–20 years (6.5 %), and >20 years (6.5 %). Four patients of this series were not in the pediatric age group and were 19, 20, 22, and 28 years old at diagnosis. In some reports, there was a male preponderance, but in a larger study of 20 patients, the male to female ratio was 1:1 (Nicol et al. 2007). As already specified in a report of 31 cases (Stocker and Ishak 1978), the majority of patients present between 6 and 10 years of age, i.e., clearly later than patients with hepatoblastoma. The neoplasm is not related to preexisting liver disease (literature reviews: Aghajanzadeh et al. 2003; Sakellaridis et al. 2006; Iqbal et al. 2008; Pachera et al. 2008; Mohapatra and Krisnanand 2007; Boybeyi et al. 2009; Pathirana et al. 2010).

Albeit typically a tumor of older children, there are numerous reports documenting UES in adult patients. Adult primary UES is a rare disease that, similar to cases in the pediatric age group, develops in livers without preexisting disease, in particular without liver cirrhosis.

Clinical Features

The patients commonly present with an abdominal mass and upper abdominal pain. Among 31 patients, 12 had an abdominal mass only, 10 abdominal pain only, and 6 abdominal mass and pain (Stocker and Ishak 1978; Wei et al. 2008). Abdominal discomfort and pain were experienced for periods of 3 days–1 month. Asymptomatic abdominal masses had been noted for periods of 2 weeks–6 months. Jaundice and systemic signs such as fever, malaise, lethargy, and weight loss may occur, and sometimes the patient is referred to the hospital in a severely ill state, e.g., owing to tumor rupture with abdominal crisis (Weinberg and Finegold 1983; Lack et al. 1991). In UES, serum AFP is in the normal range (Stocker and Ishak 1978; Kanamaru et al. 1991; Lack et al. 1991; Wei et al. 2008), but lectin-reactive AFP (AFP-L3) may be elevated in a minority of patients (Okuda et al. 2005). UES tends to invasion and tissue destruction, including extension of the neoplasm along the inferior vena cava to the heart (Gallivan et al. 1983; Bassly et al. 2008). Bronchobiliary fistula has been observed in a child suffering from UES (Corapçioglu et al. 2004). In adult patients, the frequently cystic tumor may mimic hepatic hydatid disease (Faraj et al. 2010; Yoon et al. 2010; Kalra et al. 2011). In one 46-year-old female patient, UES was associated with systemic lupus erythematosus (Jia et al. 2013). In one adult case, UES radiologically mimicked Klatskin tumor (Lee et al. 2010). Complications of UES comprise hemorrhage (Suarez et al. 2000; Küpeli et al. 2008),spontaneous rupture followed by hematoperitoneum and eventually hemorrhagic shock (Stocker and Ishak 1978; Lack et al. 1991; Yedibela et al. 2000; Uchiyama et al. 2001; Hung et al. 2007; Yu et al. 2009), or rupture following abdominal trauma (Ida et al. 2009). Exceptionally, UES is associated with paraneoplastic syndromes or disorders. In a single reported patient, UES was associated with peripheral eosinophilia (Zaheer et al. 1994), and another adult patient revealed an erythropoietin-secreting tumor (Lin et al. 2013). One patient experienced fever of unknown origin, secretory diarrhea, refractory long QT syndrome, and torsades de pointes, resolved following surgical resection (Fricchione et al. 2013).

Imaging Features

The imaging features of UES have been studied in detail, also with respect to radiologic-pathologic correlations and treatment response. Ultrasonography reveals large masses which are hyperechoic or isoechoic. Predominantly solid variants with many small anechoic spaces may be seen (Ros et al. 1986). On the other hand, a true cystic change of the tumor has already been described for one patient in the original series of 31 cases as of 1978, whereas in more than half of the cases of this series, there were multiple cystic areas containing necrotic debris, clotted blood, or gelatinous material (Stocker and Ishak 1978). Overall, CT usually shows large solid low-attenuating masses with cystic areas, with varying degrees of enhancement of the solid component and formation of hyperdense septa of variable thickness and a dense peripheral rim. Irregular high-density lesions exhibiting hemorrhage may occur. Cystic UES may show multiple internal septations (Ros et al. 1986; Joshi et al. 1997). The cystic changes may vary considerably both in size and shape and may cause a pitfall diagnosis in endemic hydatidosis areas (Joshi et al. 1997; Aggarwal et al. 2001; Charfi et al. 2008; Faraj et al. 2010). Large cysts in UES may also mimic complicated hepatic cysts at imaging (Tsukada et al. 2010). The cystic changes in UES may be the result of liquefied hemorrhage and/or necrosis, because hemorrhagic fluid in the cyst cavities suggested

that cystic "degeneration" was related to hemorrhage. However, the finding that the inner wall of the cysts in UES may be rather smooth led to the view that the cysts develop spontaneously (Dai et al. 2005). At MRI, T1-weighted images reveal well-defined hypointense masses, sometimes with scattered high signal intensities, while T2-weighted images show high signal intensity in most of the tumor volumes. MRI clearly displays the cystic space of the tumors, the septations, and often substantial central necrosis (Marti-Bonmati et al. 1993; Buetow et al. 1997; Woong et al. 1997; Yoon et al. 1997; Psatha et al. 2004). Angiographically, UESs are usually hypovascular tumors, although hypervascular areas may also occur (Stocker and Ishak 1978; Ros et al. 1986).

Selected References Ros et al. 1986; Marti-Bonmati et al. 1993; Urban et al. 1993; Moon et al. 1994, 1995; Sano et al. 1995; Buetow et al. 1997; Yoon et al. 1997; Helmberger et al. 1999; Chuang et al. 2002; Psatha et al. 2004; Goncalves-Matoso et al. 2005; Kim et al. 2008; Iqbal et al. 2008; Yu et al. 2008; Zhao et al. 2008; Crider et al. 2009; Lashkari et al. 2009; Yang et al. 2009; Kowalczyk and Carr 2010; Sodhi et al. 2010

Pathology

Macroscopy

Similar to other malignant hepatic tumors, UES develops more frequently in the right liver lobe (right lobe localization in 11/16 patients in one study, with contiguous involvement of the left lobe in three; Lack et al. 1991). UESs are usually large or even huge tumors that present as solitary and mostly well-delineated masses with variable areas of hemorrhage, confluent necrosis and sometimes macrocytic changes, resulting in a highly variegated cut surface. UES often grows to a very impressive size. In the series of Stocker and Ishak, tumor size was assessed in 20 cases, among which four were less than 10 cm in diameter, 10 were between 10 and 20 cm, and 6 exceeded 20 cm in diameter, the largest measuring 30 cm. The weight of the tumors varied from 90 to 3,375 g (average of 16 tumors, 1,310 g). In a study of 28 cases, the mean transverse diameter of the tumors was 14 cm (range, 10–25 cm). In a study of 16 patients, the average tumor diameter was 21 cm (range, 10–35 cm; Lack et al. 1991). The masses were predominantly solid (83 % of tumor volume), and pathologic and sonography findings were concordant (Buetow et al. 1997). The solid variants are globular in shape and are usually well demarcated from the rest of the liver. Typically, the tumors are nonencapsulated. Some tumors may show a pseudocapsule, but this impression is usually produced by compression and atrophy of adjacent liver substance.

The neoplasms are soft or fluctuant, with a glistening or variegated cut surface, colors ranging from gray-reddish to yellowish or even tan. Hemorrhage and necrosis may comprise up to 80 % of the tumor (Stocker and Ishak 1978; Ros et al. 1986; Leuschner et al. 1990; Lack et al. 1991; Parham et al. 1991; Kadomatsu et al. 1992; Walker et al. 1992; Buetow et al. 1997). The issue of macrocytic changes in UES has already been addressed above. In a minority of cases, "true" cystic cavities containing a mucoid fluid are in fact encountered. Mucoid or gelatinous areas are also observed. Together with necrosis cavities and spaces containing liquid or clotted blood, these can produce multiple cyst-like areas, seen in more than half of the cases in the series of 31 cases described by Stocker and Ishak (1978), but such lesions should not be confounded with the much rarer "true" cysts. Smaller cysts often contain a brownish mucoid fluid. UES may present as a single (solitary, unilocular) cyst of the liver (Chowdhary et al. 2004; Kim et al. 2009; Massani et al. 2010). Intravascularly growing tumors show a glistening, transparent quality with bosselations. Pedunculated tumors are very uncommon lesions, in contrast to mesenchymal hamartoma (Stanley et al. 1973; Stocker and Ishak 1978). In the case of Stanley and coworkers (1973), a 10-year-old boy had a partially cystic and solid pedunculated mass (17 cm diameter)

that was attached to the posterior inferior surface of the left liver lobe.

Histopathology

The histologic features of UES have been described in detail (Stocker and Ishak 1978; O'Sullivan et al. 2001; Bliuznikov et al. 2007). The tumors are often surrounded by a compressed fibrous pseudocapsule of varying thickness, with atrophy of the adjacent liver parenchyma. The interior of the masses is composed by various types of tissue components (Table 1).

The bulk of the tumor consists of a loose but cellular tissue consisting of immature-looking or undifferentiated mesenchymal cells. These appear in several types, dominated by stellate and spindle cells, and followed in frequency by giant and polymorphic cells and by round cells. Most of these cells display very indistinct cell borders, sometimes suggesting the formation of syncytia. These types of cell seem to reflect various pathways of differentiation (Aoyama et al. 1991). Most of the stellate and spindle cells are scattered loosely in a matrix rich in Alcian blue-positive mucopolysaccharides, but part of these cells may also form fascicles or whorls or are packed in sheets. Such cases resemble malignant fibrous histiocytoma or fibrosarcoma (Keating and Taylor 1985), or hemangiopericytoma/solitary fibrous tumor. Spindle cells with myoid differentiation occur (Walker et al. 1992) (Figs. 1, 2, 3, 4, 5, 6, 7, and 8).

Table 1 Histologic phenotypes of undifferentiated (embryonal) sarcoma (UES)

Standard morphology
Bimodal type with prominent cholangiocellular differentiation
Fibrous histiocytoma-like variant
Hemangiopericytoma-like variant
Anaplastic variant
Small cell variant
Rhabdoid features
Marked myoid differentiation
Marked lipomatous differentiation
Angiosarcomatous differentiation
Chondroid or osteoid differentiation

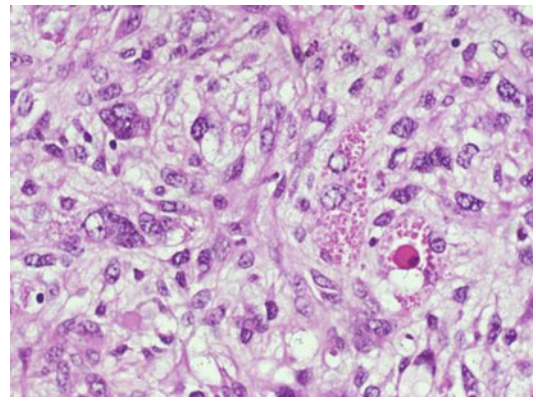

Fig. 1 Undifferentiated (embryonal) sarcoma of the liver. The hypercellular tumor consists of spindle cells and stellate cells with marked nuclear pleomorphism. Note the intracellular eosinophilic inclusions (hematoxylin and eosin stain)

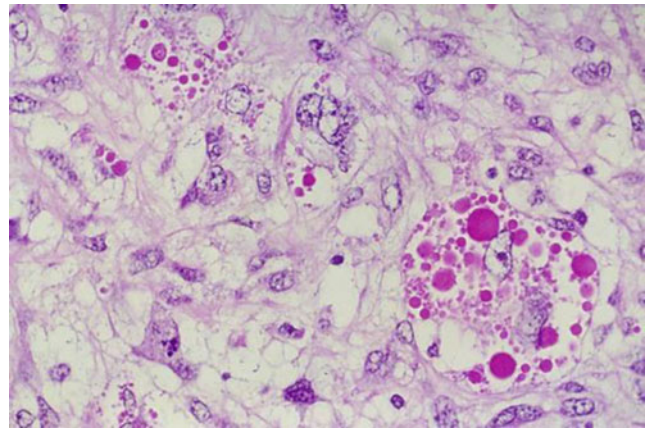

Fig. 2 Undifferentiated (embryonal) sarcoma of the liver. Tumor giant cells contain dense eosinophilic globular inclusions with a heterogeneous size distribution (PAS stain)

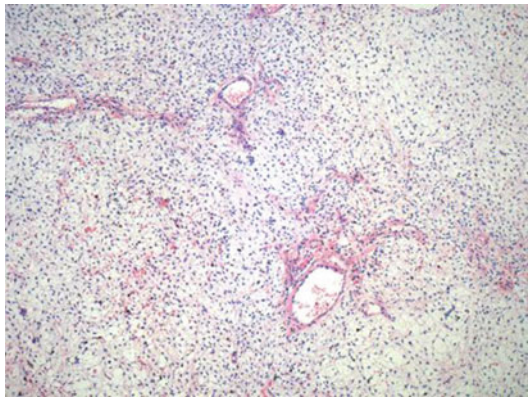

Fig. 3 Undifferentiated (embryonal) sarcoma of the liver with a markedly myxoid aspect and predominance of stellate tumor cells (hematoxylin and eosin stain)

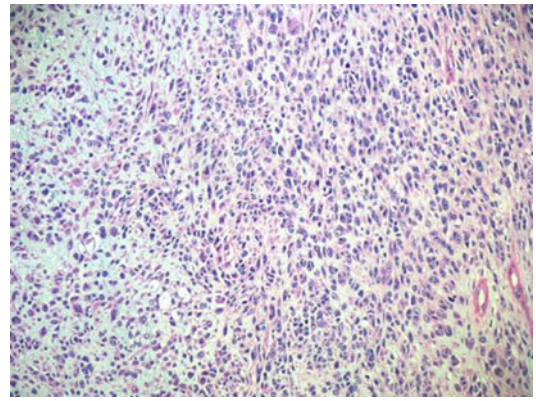

Fig. 5 Undifferentiated (embryonal) sarcoma of the liver with predominance of spindle cells and polygonal cells (hematoxylin and eosin stain)

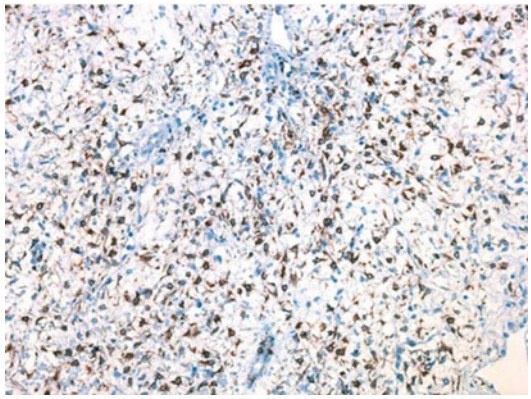

Fig. 4 Undifferentiated (embryonal) sarcoma, myxoid variant. The stellate aspect of tumor cells is well recognizable in a stain showing vimentin expression (vimentin immunostain)

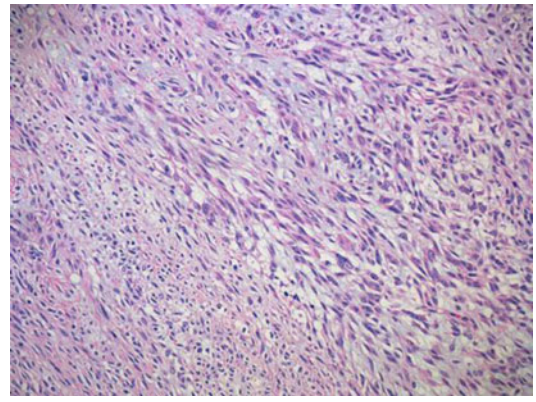

Fig. 6 Undifferentiated (embryonal) sarcoma of the liver. In this tumor, fascicles or interlacing bundles of spindle cells with an eosinophilic cytoplasm are present (myoid variant; hematoxylin and eosin stain)

In a minority of cases, a contribution of anaplastic or small cells is seen (Walker et al. 1992). It was suggested that an anaplastic component is more commonly encountered in UES arising in adults (Nishio et al. 2003). Osteoid formation in UES has been described (Lack et al. 1991). This abnormal mesenchyme of UES often surrounds abnormal and dilated intratumoral, CK 19-positive bile duct-like profiles, and the cellularity of the tissue may be higher close to the epithelial lining, forming a "cambium." This predominant component of UES shows high mitotic activity. The giant cells are either multinucleated or contain highly polyploidy and in part bizarre nuclei, with segregation of micronuclei, formation of nuclear bridges, and complex lobulations. Part of the large cells or giant cells contain few to numerous intracytoplasmic eosinophilic globules, measuring 2–40 μm in diameter, and sometimes hiding the nucleus. These globules are variably PAS-positive, but resistant to diastase digestion. In the Masson trichrome stain, they are blue to red, purple with PTAH, and positive with the Danielli staining method (Stocker and Ishak 1978). Globule-containing cells release the globules into the extracellular space upon cell death. The tumor tissue contains a fine network of reticulin fibers. Focally, dense bundles of partly hyalinized

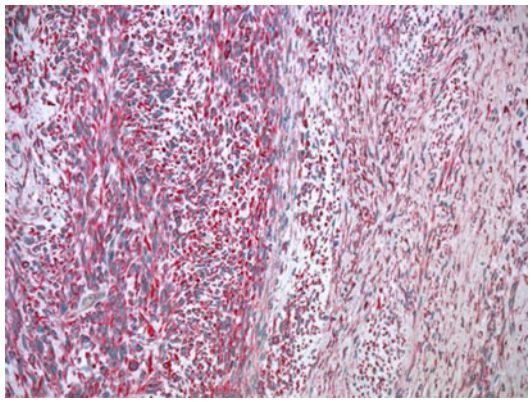

Fig. 7 Undifferentiated (embryonal) sarcoma of the liver, myoid variant. Numerous spindle cells are reactive for smooth muscle actin (alpha-SMA immunostain)

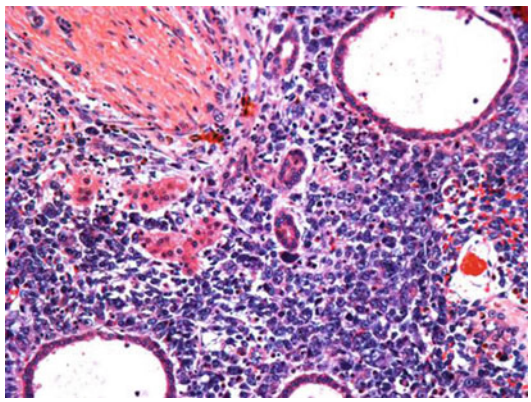

Fig. 8 Undifferentiated (embryonal) sarcoma of the liver, anaplastic variant. Small- to medium-sized cells with poor cytoplasm result in a "blue cellular tumor." Note the dilated bile duct within the tumor tissue (hematoxylin and eosin stain)

collagen are in evidence. Mainly in regions of necrosis, an infiltrate composed of lymphocytes, macrophages, and plasma cells is often present. UES has been diagnosed by the use of fine-needle aspiration cytology (Pieterse et al. 1985; Sola-Pérez et al. 1995; Krishnamurthy et al. 1996; Garcia-Bonafé et al. 1997; Allen et al. 1998; Pollono and Drut 1998; Sharifah et al. 1999; Anavi et al. 2001; Gupta et al. 2010; Kaur et al. 2010). Metastases of UES usually show the same histopathologic presentation as the primary lesion, but there are deviations from this presentation. Peritoneal metastases of UES in an adult patient were found to present as leiomyosarcomatous nodules (Fievez et al. 1983). This phenomenon may be linked to the fact that UES has been shown to undergo smooth muscle cell differentiation (Nishio et al. 2003), and such a cell lineage may then also evolve in metastatic disease.

A distinct feature of some UES is the focal differentiation along myoid (leiomyoid and/or rhabdomyoid) lineages or along an adipocyte-like lineage. Ultrastructural studies suggested a leiomyoblastic differentiation (Gonzalez-Crussi 1983), and features suggesting a leiomyoid cell lineage have been observed by previous investigators as well (Lagacé et al. 1974; Cozzutto et al. 1981 9) and supported by more recent findings (Walker et al. 1992; Nishio et al. 2003). A differentiation along a lipoblastoid lineage has chiefly been suggested based on the presence of oil red O staining (Stocker and Ishak 1978) and ultrastructural presence of lipid droplets in subsets of tumor cells (Cozzutto et al. 1981; Chang et al. 1983; Ellis and Cotton 1983; Gallivan et al. 1983; Parham et al. 1991). Lipid droplets in UES cells were detected in six out of seven neoplasms in one analysis (Parham et al. 1991). Morphologically, typical lipoblasts in UES have also been described (Lagacé et al. 1974). Whether this phenotype reflects liposarcomatous features of some, UES is not ascertained. In rare instances, aberrant differentiation patterns can occur, e.g., chondroid differentiation with formation of chondrosarcoma-like lesions (Kinjo et al. 2010), production of tumor osteoid (Chen et al. 2013), or lesions resembling telangiectatic hepatic adenoma (Tanaka et al. 2012). In one adult patient, UES arising from mesenchymal hamartoma exhibited peripheral angiosarcomatous differentiation (Tucker et al. 2012).

At the interface between the tumor and the liver, trapped and damaged hepatocytes, and abnormal and in part cystic bile ducts are seen (Figs. 9, 10, 11, and 12; Stanley et al. 1973; Stocker and Ishak 1978; Walker et al. 1992). The duct-like structures are sometimes markedly dilated and deformed; they may contain an eosinophilic material, but bile is consistently lacking. Only rarely were parenchymal cells seen deeper

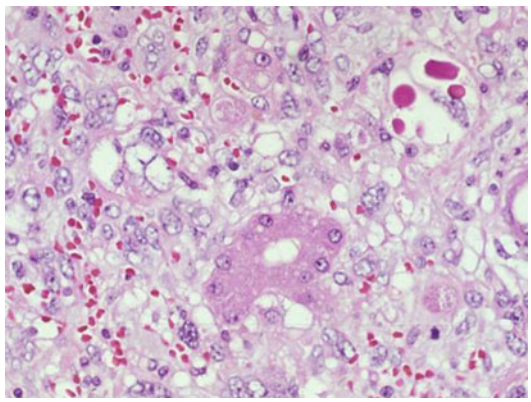

Fig. 10 Small bile ducts embedded in pleomorphic tissue of undifferentiated (embryonal) sarcoma. Cholangiocyte cytoplasm shows eosinophilia (hematoxylin and eosin stain)

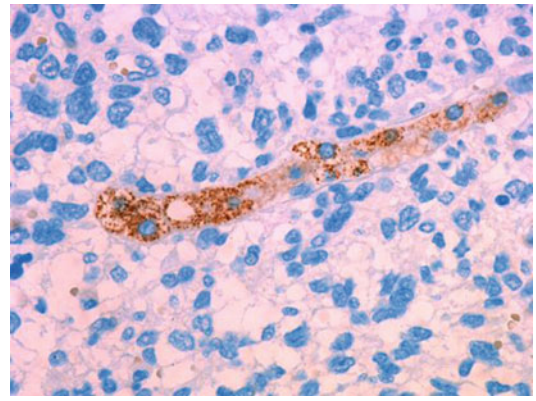

Fig. 12 Undifferentiated (embryonal) sarcoma with embedded intratumoral hepatocytes and no intervening cells. Hepatocytes are strongly positive for Hep Par1 (Hep Par1 immunostain)

than 0.5–1.0 cm from the edge of the tumor (Stocker and Ishak 1978). The dilated bile duct-like structures are separated from the tumor tissue by a thin, PAS-positive lamella which may represent a basement membrane, but focally this lamella is broached by sarcoma cells. The cholangiocyte lining is typically not atrophic, the cells being cuboid instead of flat, but some cells show signs of damage, with irregular arrangement of the cell within the single layer and hyperchromatic nuclei as a frequent feature (Stanley et al. 1973). As the sarcoma tissue directly encroaches upon these ducts, the absence of atrophy is striking. The marked cystic dilatation also requires the production of more cholangiocytes to cover this large surface. In a thin zone immediately surrounding the ducts, round tumor cells are sometimes more frequent, a phenomenon also depicted in Figs. 11 and 12 of the Stanley et al. publication (1973). Stocker and Ishak (1978) noted that there are tumor areas where the epithelial cells seem to be separated from one another and blended with the sarcomatous cells. This phenomenon may be striking and may either represent and transient contact between malignant mesenchymal and

nonneoplastic epithelial cells or eventually epithelial-mesenchymal transition. Whether these bile duct-like profiles are really entrapped bile ducts, as suggested by several authors (Stanley et al. 1973; Stocker and Ishak 1978), or represent neoplastic elements themselves has not been clarified (see below). An argument for entrapped bile ducts is their concentration in the area of the tumor closest to the interface between the involved liver and the tumor mass. Sections from central parts revealed only an occasional duct (Stanley et al. 1973).

Hepatocytes located within the tumor occur as single cells, small clusters, or even cell plates resembling those in the normal liver. The cells can show signs of damage or regeneration, and sometimes the hepatocytes are in direct contact with bile duct cells, suggesting differentiation of cholangiocytes from hepatocytes or their precursors.

The gelatinous center of the tumor may contain thrombosed vessels, sometimes with organization of the thrombi. Autopsy observations specifying the histology of metastases are available from the study of Stocker and Ishak (1978). All extrahepatic tumor manifestations contained sarcomatous cells, some of which had the typical PAS-positive globules. In one case, epithelial elements (bile duct-like structures) were found in the tumor adjacent to the stomach and bowel but in continuity with the hepatic lesion. But another case showed epithelium-lined structures in metastatic lesions in the lung. Stocker and Ishak (1978) argued that the epithelium-lined structures found in a tumor adjacent to the stomach and diaphragm, though still in continuity with the primary liver tumor, represent entrapped bile ducts carried along with the tumor mass as it extended beyond the boundaries of the liver. Furthermore, the epithelial structures these authors found in pulmonary metastases were interpreted as entrapped bronchioles. Hepatocytes (solitary cells, clusters, or even cords/plates) are sometimes found in UES. Stocker and Ishak (1978) observed parenchymal cells within the tumor's pseudocapsule and at the periphery of the neoplasm, but only rarely were hepatocytes found deeper than 0.5–1.0 cm from the edge of the tumor. Such intratumoral hepatocytes have been interpreted as entrapped parenchymal cells, because of their position near the tumor margin (Walker et al. 1992; their patient 2). However, we have found that morphologically abnormal hepatoid cells also occur in central parts of large tumors, these cells not showing signs of damage or atrophy caused by entrapment.

Electron Microscopy Findings

Relatively few UESs have been examined ultrastructurally (Lagacé et al. 1974; Cozzutto et al. 1981; Chang et al. 1983; Keating and Taylor 1985; Pieterse et al. 1985; Chou et al. 1990; Parham et al. 1991; Agaram et al. 2006). At electron microscopy, spindle and stellate cells including both single and multinucleated forms are embedded in a loose collagenous stroma. Neighboring cells may be connected by poorly formed desmosome-like junctions. The cytoplasm of the tumor cells contains relatively few mitochondria, but is rich in free ribosomes and RER profiles. The lumens of the RER may be dilated and contain an amorphous material. Golgi apparatus is rare and not prominent. The presence of tonofilament-like bundles of intermediate filaments and cell junctions in some cases has suggested epithelial differentiation of a subset of tumor cells (Miettinen and Kahlos 1989). Some of the cells contain lipid droplets. In some cases, a myoid differentiation ("leiomyoblastic" cells) has been detected (Gallivan et al. 1983; Gonzalez-Crussi 1983), rarely with signs of rhabdomyoblastic differentiation (Vetter et al. 1989).

Immunohistochemistry

UES usually displays a complex immunohistochemical pattern, with many markers being positive in a variable pattern (Parham et al. 1991; Table 2).

The mesenchymal tumor cells are consistently reactive for vimentin (Lack et al. 1991; Diedhiou et al. 2002; Kiani et al. 2006; Zheng et al. 2007; Wei et al. 2008; Shehata et al. 2011). In one study, all tumors were vimentin positive, and part of the

Table 2 Immunohistochemical profile of undifferentiated embryonal sarcoma

Positivity of tumor cells for:
Vimentin (consistently)
Smooth muscle actin (in part)
Desmin (in part)
Cytokeratins (in part)
CD56 (membranous staining)
Alpha-1-antitrypsin
Glypican-3 (in part)
Adipophilin (in part)

cases were reactive for Bcl-2 (Kiani et al. 2006), cytokeratin AE1/AE3, CD10, calponin, p53, and exceptionally desmin (Kiani et al. 2006), illustrating the polyantigenic features of this immature neoplasm. Focal cytokeratin expression has been documented in some reports (Chou et al. 1990; Lack et al. 1991), sometimes with formation of a paranuclear dot-like staining pattern (Pérez-Gomez et al. 2010). Part of the tumor cells is reactive for alpha-1-antitrypsin (Abramowsky et al. 1980; Miettinen and Kahlos 1989; Shehata et al. 2011). In particular, the typical PAS-positive intracellular globules were shown to contain alpha-1-antitrypsin, but these structures are ultrastructurally different from the inclusions found in hepatocytes of some forms of alpha-1-antitrypsin deficiency (Abramowsky et al. 1980). Diffuse membranous immunostaining of tumor cells for CD56 has been found (Pérez-Gomez et al. 2010). Rarely, clusters of spindle cells are positive for smooth muscle actin and desmin, suggesting muscle cell differentiation (Diedhiou et al. 2002; Nishio et al. 2003). In contrast, myogenin and myogenic regulatory protein D1 (MyoD1) were uniformly negative in UES (Nicol et al. 2007). The tumor cells do not express epithelial membrane antigen (EMA; Miettinen and Kahlos 1989), and nuclear accumulation of beta-catenin was not detected in UES (Yamaoka et al. 2006). UES, similar to mesenchymal hamartoma, shows cytoplasmic expression of glypican-3 (Levy et al. 2012). A part of the cells appear to share features with hepatic stellate cells, e.g., positivity for alpha-SMA and adipophilin-positive vesicles (Tanaka et al. 2012).

Cytogenetic Features

DNA ploidy studies revealed highly aneuploidy patterns as a sign of marked genomic instability (Chou et al. 1990; Leuschner et al. 1990). A DNA ploidy study demonstrated a single G0/G1 peak indicating a diploid DNA content, and only one tumor showed a hypodiploid DNA content (Leuschner et al. 1990). Another investigation found an aneuploidy cellular component (Chou et al. 1990). UES exhibits complex cytogenetic alterations. Both gains and losses of components of several chromosomes were detected, indicating extensive chromosomal rearrangements in UES (Iliszko et al. 1998). In one case, near-triploid and near-hexaploid clones with several chromosomal rearrangements were detected (Iliszko et al. 1998); this polyploidization probably reflected in the bizarre giant nuclei typically seen in this tumor. Aneuploidy of the cell population, usually with high S phase, is a typical feature of UES (Chou et al. 1990). Comparative genomic hybridization revealed multiple chromosomal amplifications and deletions in UES, including gains of 1q, 5p, 6q, 8p, and 12q and losses of 9p, 11p, and 14 (Sowery et al. 2001). UES is associated with a recurrent translocation t(11;19)(q11; q13.3–q13.4) or add(19)(q13.4) (see below).

Differential Diagnosis

As the clinical, radiological, and histologic presentations are highly characteristic and the tumor predominantly occurs in children beyond the hepatoblastoma age, this neoplasm can hardly be confounded with other tumors.

Biology of UES

UESs are aggressive tumors that so far implied a dismal outcome. However, new combined surgical and chemotherapy treatments have improved prognosis (Harris et al. 1984; Horowitz et al. 1987; Perilongo et al. 1987; Ware et al. 1988; Steiner et al. 1989; Orozco

et al. 1991; Walker et al. 1992; Urban et al. 1993; Douglass 1997; Webber et al. 1999; Bisogno et al. 2002; Kim et al. 2002; Almogy et al. 2004, 2005; Baron et al. 2007; Kim et al. 2007; McCarthy et al. 2007; Pachera et al. 2008; May et al. 2012; Gao et al. 2013; Geel et al. 2013; Ismail et al. 2013; Plant et al. 2013). In a study of 17 patients enrolled by the Italian and German Soft Tissue Sarcoma Cooperative Groups and treated by surgery at diagnosis followed by multi-agent chemotherapy and second-look surgery in case of residual disease, 12 patients were alive with follow-up ranging from 2.4 to 20 years (Bisogno et al. 2002). Liver transplantation has been successfully performed in pediatric patients with UES (Kelly et al. 2009; Okajima et al. 2009; Plant et al. 2013; Walther et al. 2013).

Relation to Mesenchymal Hamartoma of the Liver and to Other Tumors

In few cases, UES seems to have arisen from preexisting hepatic mesenchymal hamartoma (see below; de Chadarévian et al. 1994; Lauwers et al. 1997; Begueret et al. 2001; O'Sullivan et al. 2001; Rajaram et al. 2007; Lahmar-Boufaroua et al. 2008; Shehata et al. 2011). In the case of a 15-year-old girl, mapping of the tumor demonstrated a typical mesenchymal hamartoma transforming gradually into UES. Cytometrically, the hamartoma component was diploid, while the UES component showed a prominent aneuploid peak. Karyotypic analysis revealed structural alterations of chromosome 19 (Lauwers et al. 1997). More than ten cases have been reviewed from the literature, and in part of them, transition zones between mesenchymal hamartoma and UES have been identified (Shehata et al. 2011). UES has been found to be associated with tumors other than hepatic mesenchymal hamartoma. A teenage girl with UES developed metachronous vaginal rhabdomyosarcoma, and a middle-aged woman developed metachronous B-acute lymphoblastic leukemia (Gasljevic et al. 2011).

Pathogenesis

A pathogenic or histogenetic link between UES and mesenchymal hamartoma of the liver has been suggested as early as 1978 (Stocker and Ishak 1978), but has been challenged previously or later (Stanley et al. 1973; Dehner et al. 1975; Donnelly et al. 1978; Cozzutto et al. 1981; Gallivan et al. 1983; Finegold 1986; Lack 1986; Chou et al. 1990; Aoyama et al. 1991). However, there are in fact few observations suggesting that UES may develop within mesenchymal hamartoma of the liver (de Chadarévian et al. 1994; Lauwers et al. 1997; Ramanujam et al. 1999; Begueret et al. 2001). In a 15-year-old female patient, mapping of the hepatic tumor demonstrated an atypical mesenchymal hamartoma transforming gradually into UES composed on anaplastic stromal cells. Flow cytometry revealed that the cells of the mesenchymal hamartoma were diploid, while UES cells showed a prominent aneuploidy peak, and cytogenetic analysis of UES exhibited structural alterations (translocation) of chromosome 19q13.4 (Lauwers et al. 1997), implicated as a potential marker of mesenchymal hamartoma (Speleman et al. 1989; Mascarello and Krous 1992; Bove et al. 1998; Rakheja et al. 2004). Based on these constellations, a pathogenetic link between these two tumors was suggested (Lauwers et al. 1997). Mesenchymal hamartoma of the liver is associated with a distinct chromosomal translocation, i.e., t(11;19q)(q11;q13.4) (Mascarello and Krous 1992; Bove et al. 1998; Hu et al. 2012), and this abnormality is thought to play a role in the pathogenesis of both this benign tumor and UES which may develop from it. Analysis of the translocation breakpoints showed that, in one case, the breakpoint occurred in the MALAT1 gene, and the breakpoint was termed MHLB1, for mesenchymal hamartoma of the liver breakpoint 1 (Rajaram et al. 2007).

MALAT1 (metastasis-associated lung adenocarcinoma transcript 1; NEAT2, noncoding nuclear-enriched abundant transcript 2; gene located on chromosome 11q13.1) is a long noncoding RNA species which is highly expressed in

nuclei (Hutchinson et al. 2007) and whose expression correlates with the development and invasive behavior of several tumors (Ji et al. 2003; Diederichs 2010; Tani et al. 2010; Tano et al. 2010; Lin et al. 2011; Xu et al. 2011). In hepatocellular carcinoma, MALAT1 overexpression predicts tumor recurrence (Lai et al. 2012). MALAT1-associated small cytoplasmic RNA (also termed mascRNA) is roughly 53–61 nucleotides in length and is processed from the much longer noncoding (nc) RNA, MALAT1, by the enzyme RNAase P. MALAT1 regulates alternative splicing by controlling the activity of the SR protein family or splicing factors via phosphorylation (Tripathi et al. 2010; Ankö and Neugebauer 2010). Alternative splicing of pre-mRNA is employed to achieve increased transcriptome and proteome complexity. Alternative splicing utilizes specific serine/arginine (SR) splicing factors, which act in a cell-specific phosphorylation-dependent manner. SRs and several SR-related proteins interact with and process mRNA precursors and thus are master regulators of gene expression (reviews: Blencowe et al. 1999; Long and Caceres 2009). MALAT1 is localized to nuclear speckles and does not shuttle between the nucleus and cytoplasm, the localization to speckles being regulated by RNPS1, SRm160, and IBP160 (Miyagawa et al. 2012).

There is evidence that changes in p53 are involved in UES (Chuang et al. 2002; Lepreux et al. 2005; Sangkhathat et al. 2006). At least part of UES shows nuclear immunohistochemical reactivity for p53 protein (Chuang et al. 2002). Mutation analysis of UES revealed missense mutations of TP53 (Kusafuka et al. 1997; Hu et al. 2012). In one study of UES in adults, immunohistochemistry showed overexpression of p53 protein in more than 80 % of tumor cells, and mutations of the TP53 gene were observed in two cases, involving the sequence-specific DNA-binding domain (Lepreux et al. 2005). Missense mutations of TP53 were found in three tumors of another study, and the mutations were found specifically in tumor tissue and not detected in the surrounding normal hepatic tissue and were associated with strong p53 immunoreactivity. Mutation points were localized in exon 7 (Gly245Ser), exon 6 (Arg196Pro), and exon 8 (Arg273Pro) (Sangkhathat et al. 2006).

Metastatic Liver Disease

Metastatic Liver Disease: Pathological Aspects

106

Contents

Abstract

Liver metastases represent a highly important issue in hepatobiliary oncology. In Europe and North America, metastases of various cancers to the liver predominate over primary hepatic neoplasms in a ratio of over 40:1. the majority of liver metastases in adult patients are carcinomas and malignant melanoma, followed by non-Hodgkin's lymphomas, other hematological neoplasms, germ cell tumors, and sarcomas. In the pediatric age-group, neuroblastoma and other small cellular blue tumors, PNETs, and hematological neoplasms metastasize to the liver. Hepatic metastases present in the form of several characteristic macroscopic growth patterns, including macronodular patterns, micrometastases, diffuse intrasinusidal metastasis, inductal growth metastasis, intraportal metastasis and other intravascular manifestations, and the rarer neoplastic lymphangiosis. Liver metastases occur as solitary or multiple lesions. In part of cases, a large solitary metastasis can be the source of secondary lesions through intrahepatic spread. Metastases in the subcapsular area of the liver cause umbilicated nodules and tumors that may involve adjacent structures, such as the diaphragm. Distinct metastatic growth patterns occur in cirrhotic livers.

Introduction

Metastatic liver disease is a very important issue in liver oncology, as in Europe and North America, metastases to the liver predominate over primary hepatic neoplasms in a ratio of over 40:1 (reviews: Pack and Brasfield 1955; Willis 1973; Schulz and Hort 1981; Weiss and Gilbert 1982; Kumar and Weaver 2009; Iacobuzio-Donahue and Ferrelll 2010). Conversely, there are regions where primary hepatic malignancies are more common than liver metastases, e.g., Southeast Asian and sub-Saharan African areas, mainly due to the high incidence of hepatocellular carcinoma, the rarity of certain cancers that are common Western countries, and a short life span that renders certain extrahepatic malignancies less frequent.

Epidemiology

The majority of liver metastases in adult patients are carcinomas and malignant melanomas, followed by malignant non-Hodgkin's lymphomas and other hematologic disorders, germ cell tumors, and sarcomas (Olubuyide and Odunfa 1989; Engels et al. 2002; Iacobuzio-Donahue and Ferrelll 2010). Based on clinical and surgical data, the most common liver metastases in adults are from carcinomas of the breast, colorectum, and stomach, whereas autopsy studies which more often include older patients more frequently listed testicular, pancreatic, gallbladder, and uveal tumors (DiSibio and French 2008). In certain western countries, metastatic liver disease is dominated by colorectal cancer metastasis (Faivre et al. 2003; Manfredi et al. 2006). Non-Hodgkin's lymphomas and Hodgkin's lymphoma involve the liver in up to 20 % of patients (Jaffe 1987). In the pediatric age-group, neuroblastoma and other small cellular "blue" tumors, PNETs, and hematologic malignancies often metastasize to the liver, whereas important liver malignancies producing intrahepatic metastatic disease comprise hepatoblastomas and pediatric hepatocellular carcinoma.

General Features of Hepatic Metastases

Based on the particular microenvironment, the distinct vascular system, and specific pro-metastatic features of the liver, hepatic metastases present with complex macroscopic and histopathological patterns, which are summarized in this paragraph before describing a selection of specific tumor metastases (Table 1).

Table 1 Growth patterns, secondary alterations, and effects of hepatic metastases

Growth patterns
Macronodular patterns
Micrometastases, including miliary metastases
Diffuse intrasinusoidal metastatic tumors
Intraductal growth of metastases
Intraportal metastasis
Metastasis in the hepatic vein system
Hepatic lymphangiosis carcinomatosa
Tumor-in-tumor metastasis
Secondary alterations of hepatic metastases
Necrosis, hemorrhage and infarction of liver metastasis
Calcifications
Metastasis infection and abscess formation
Tumor fibrosis
Cyst formation
Hepatic alterations caused by liver metastases
Hepatomegaly
Liver atrophy
Atrophy hypertrophy complex (AHC)
Perifocal changes
Perifocal fatty change
Perifocal clear cell change
Perifocal microvascular changes
Perifocal ischemia
Perifocal parenchymal atrophy
Perifocal bile duct changes
Perifocal immune reactions
Perifocal fibrosis
Metastasis-induced pseudocirrhosis
Hepar lobatum carcinomatosum
Chemotherapy-induced alterations

Growth Patterns of Hepatic Metastases

Hepatic Macrometastases

Hepatic macrometastases are those that can be detected macroscopically (Figs. 1, 2, 3, 4, 5, 6, and 7). In advanced tumor disease, most hepatic metastases are multiple lesions, although certain and frequent neoplasms can produce solitary, sometimes huge or massive metastases, e.g., colorectal carcinoma, renal cell carcinoma, and certain sarcomas. As discussed in more detail below, peripherally located hepatic metastases can show umbilication ("cancer navel") caused by tumor necrosis, tissue collapse, and capsular retraction. Several growth patterns occur, the most important being an expanding pattern with pushing borders, an infiltrative pattern with highly irregular borders, and metastases surrounded by satellite nodules. Less common patterns comprise intraductal growth and production of a tumor pseudocapsule. On sections, a majority of metastases appear as whitish or creamy-white masses of variable consistency, friable tumors found in lesions of high cellularity and poor stroma formation, and firm tumors in case of marked desmoplasia. Mucin-rich cancers display glistening or gelatinous masses of increased tissue transparency. Apart from this whitish color, certain metastases exhibit colors that can direct the observed to the type of neoplasm involved. The most evident example is of course malignant melanoma with its black metastases. Yellowish or tan metastases suggest neuroendocrine tumors, but a yellow color is also found in metastases undergoing fatty change. Intrahepatic metastases of hepatocellular carcinoma can be greenish due to bile deposition. A dark red color caused by marked hemorrhage mainly characterizes angiosarcoma, certain other sarcomas, choriocarcinoma, and renal cell carcinoma. Lymphomas, highly cellular carcinomas, and part of sarcomas may show an opaque, "fish flesh" appearance. Calcifications present as white to yellow speckles, grains, or irregularly shaped areas of gritty consistency (reviews: Engels et al. 2002; Centeno 2006).

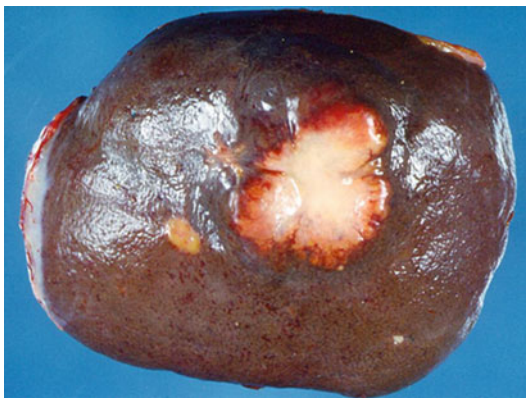

Fig. 1 Colorectal carcinoma metastasis of the liver. The metastatic nodule (*center*) is situated in the subcapsular area and has a central depression, the "cancer navel" (umbilication). The periphery of the nodule shows hyperemia. A small, *yellow* pseudolipoma of Glisson's capsule is seen to the left of the metastasis

Miliary Hepatic Metastases and Other Micrometastases

Introduction

In the course of metastatic spread to the liver it can be expected that metastases starting from distributed single cells are first small clusters of cells gradually growing to lesions that will become visible to the naked eye. Usually, the diameter limit of small metastases visualized, e.g., on the hepatic capsular surface in the course of laparoscopy, is in the region of larger granulomas, i.e., 1–2 mm in diameter. Such metastatic lesions are called miliary metastases, a form of micrometastases. A milium is a millet seed which has a diameter in the 1 or 2 mm range and has been used in the classical medical literature to denote several lesion types of this size, the best known being the milium (pl. milia) in miliary tuberculosis.

As outlined in more detail in the chapter on tumor staging, micrometastases are, according

Fig. 2 Liver metastasis of pancreatic ductal carcinoma. The cut surface of this large mass reveals a nodular texture and numerous hemorrhages (fixed resection specimen)

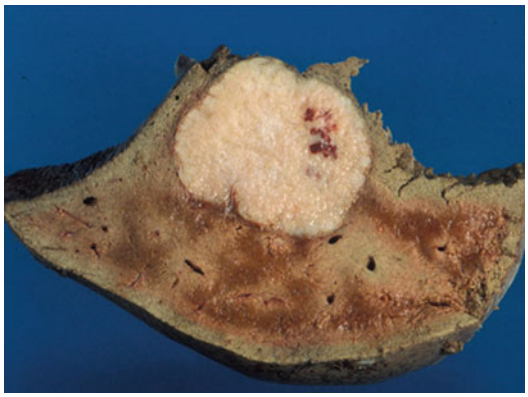

Fig. 3 Colorectal carcinoma metastasis of the liver. This metastasis has a finely granular structure and is close to the resection margin (fixed resection specimen)

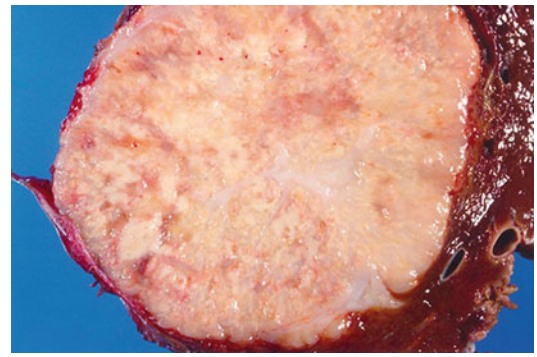

Fig. 4 Colorectal carcinoma metastasis of the liver. The mottled appearance of the cut surface, with *yellow* areas, is caused by multifocal necrosis associated with hemorrhage (non-fixed resection specimen)

to UICC 1992 and the guidelines of the 6th TNM classification, metastatic lesions with a diameter of 2 mm or less, indicated by the addition of the label "mi" in staging protocols (Hermanek 1999; Hermanek et al. 1999; Gusterson 2003; Sobin 2003). A main difference between micrometastases and miliary metastases is the type of distribution in involved organs. In miliary metastases, the small lesions are numerous and diffusely scattered throughout the organ, whereas micrometastases may show a discrete distribution, e.g., involving only part of an organ or being distributed perifocally around a macroscopic "mother" metastasis. It is assumed that, in most instances, miliary metastases represent a certain stage in the growth of metastases from small to larger lesions (the "miliary window"). However, there may be metastases that are as such characterized to grow with this pattern and metastases remaining small, owing to inherent growth limitations of the tumor or factors of the stromal-vascular bed. On the other hand, development and growth of micrometastases are modulated by neoadjuvant chemotherapy (NAC). In patients with CRC, NAC reduced the incidence of intrahepatic micrometastases but did not affect their distribution when such micrometastases were present (Wakai et al. 2012). The presence of micrometastases in resection specimens, which may only be detectable by immunohistochemistry, affects biology of disease and predicts

high risk for intrahepatic tumor recurrence after metastasectomy (Yokoyama et al. 2002).

Miliary Hepatic Metastases, Micrometastases, and the Problem of Early Detection of Metastatic Liver Disease

The interest in miliary metastases is based, apart from theoretical questions regarding tumor growth, on the clinically important aspect of hepatic lesions being too small to be identified as metastases at CT and other imaging methods (the "missed metastases" problem). Specifically, what is the risk that very small lesions seen on CT images will develop into miliary or micrometastases? Tumors metastasizing to the liver may produce micrometastases, and these lesions are thought to be responsible for at least part of recurrences post hepatectomy, because they may be located close to the resection margin (Schimanski et al. 2010). But initial staging CT scans in patients with colorectal carcinoma (CRC) may also show small, "indeterminate" hepatic lesions. In a study on 419 patients with CRC, 16.7 % of the patients had small liver lesions on their initial liver CT that could be definitely characterized. Among the 65.7 % of patients who underwent follow-up imaging, 10.9 % showed progression of the lesions suggestive of early metastases (Lim et al. 2009). In breast cancer patients, tiny hepatic lesions of indeterminate significance are termed TSTC (deemed too small to characterize). In a study on 7692 women with breast cancer, 1012 (13.2 %) underwent contrast-enhanced CT including liver assessment. The presence of at least one hepatic lesion deemed TSTC was detected in 277 of 941 women (29.4 %) in whom no definite hepatic metastasis was reported. At a median follow-up time of 54 weeks, the lesions were unchanged in 91.6 %, no longer visible in 4.2 %, and larger in 3.1 %. The enlarging hepatic lesions deemed TSTC were metastatic breast cancer in three, metastatic pancreatic cancer in one, and cysts in one patient (Khalil et al. 2005).

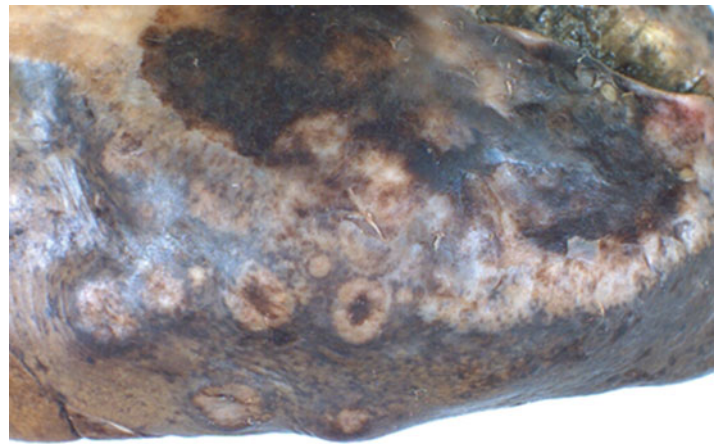

Fig. 6 Carcinoma metastasis of the liver. Even small subcapsular metastatic nodules can undergo tumor umbilication

Fig. 7 Liver metastasis of colorectal carcinoma metastasis. The tumor has invaded the diaphragm (*left* of the *middle*), causing adherence of the liver surface to the diaphragm

Epidemiology

Miliary hepatic metastases and micrometastases in general have been described for several types of tumors, including colorectal carcinoma (Hosch et al. 2002; Yokoyama et al. 2002; Votrubova et al. 2006), breast carcinoma (Khalil et al. 2005), pancreatic carcinoma (Suwa et al. 1999; Yokoyama et al. 2012), malignant melanoma (Pichon et al. 2004), including uveal melanoma (Servois et al. 2010; Borthwick et al. 2011), neuroendocrine carcinoma (Fazio et al. 2008), carcinoid tumors (Rixen et al. 1998), medullary carcinoma of the thyroid (Yanardag et al. 2003), and certain sarcomas (Probst-Cousin et al. 1997). In a study on liver metastases of endocrine tumors, the median size of depicted metastases was 12 mm for CT and 10.5 mm for MRI. A miliary pattern with numerous small hepatic lesions scattered throughout the liver was present in nine patients (22.5 %; Dromain et al. 2005). Micrometastases may dominate the metastatic pattern or occur in close vicinity of large hepatic metastases. The frequency of the latter phenomenon varies considerably among different cancer types, and was rather common in gastric cancer metastases (Nomura et al. 2009), but uncommon in CRC metastases (Kokudo et al. 2002).

Clinical Features

The clinical presentation of diffuse hepatic miliary metastatic spread differs from that of the much more frequent "classical" metastatic liver. Patients with miliary liver spread may show hepatomegaly associated with jaundice and signs of hepatocellular insufficiency, owing to the multifocal destruction of parenchyma by the innumerable small tumor nodules (Pichon et al. 2004). The presence of micrometastases and their detectetion has an important impact on the definition of the minimal distance to the resection margin in case of metastasectomy (Zhou et al. 2007).

General Histopathology

Micrometastases are also found in the vicinity of macroscopic metastases, e.g., of gastrointestinal primary tumors. Such lesions were, e.g., observed around 48 % of liver metastases of gastric carcinoma (Nomura et al. 2009). They may be found in relation to portal vein branches up to 29 mm distant from the macroscopic metastasis, what has an impact on the distance of the resection margin in hepatectomy (Isono et al. 1990). In CRCs metastasizing to the liver, micrometastases around macrometastases were not common and most were confined to the immediate vicinity of the tumor border. This observation has an impact on the selection of minimal resection margin distances (Kokudo et al. 2002). In some situations, growth of very small metastatic lesions is localized to the sinusoids. Such patients, e.g., those with breast cancer, may then present with occult micronodular pseudocirrhosis (Fournier et al. 2010; see also the respective paragraph).

Pathogenesis

In a murine tissue explant model, two-photon microscopy revealed that injected mammary tumor cells showed a greater extravasation tendency in liver than in lung, with 56 % of tumor cells in the liver having extravasated by 24 h, compared with only 22 % of tumor cells in the lung that had extravasated. In the liver, imaged tumor cells continually transitioned from an intravascular location to an extravascular site, while extravasation in lung slowed down after 6 h. Interestingly, micrometastases growing out from extravasated cells were heterogeneous in composition, containing tumor cells and endothelial cells (Martin et al. 2010).

Diffuse Intrasinusoidal Metastatic Tumors of the Liver

Introduction

A subset of carcinomas metastasizing to the liver show a distinct intrahepatic growth pattern characterized by diffuse growth of cancer cells within the sinusoidal channels, accompanied by an often discrete stromal reaction (Watson 1955). This chapter exclusively focuses on intrasinusoidal metastases caused by solid tumors, albeit the most common cause of acute hepatic failure secondary to malignant infiltration are lymphohematologic malignancies, treated in other chapters. Diffuse intrasinusoidal metastatic growth is mostly known from metastasizing carcinoma of the breast, including the lobular variant (Allison et al. 2004; Rajvanshi et al. 2005), and may occur in case of radiologically occult primary tumors (Allison et al. 2004).

Clinical and Imaging Features

Diffuse neoplastic infiltration of the liver can cause acute liver failure (ALF) but overall is an uncommon complication. In some patients with hepatic metastatic disease, tumors may replace up to 90 % of the liver without any manifestation of jaundice or other signs of hepatic malfunction. Among 4020 cases of acute liver failure over an 18-year period, only 0.44 % were attributed to malignant hepatic infiltration (Rowbotham et al. 1998). In another investigation, 7.2 % of 292 patients with metastatic liver disease developed hepatic coma (Bernuau et al. 1986), such large differences in prevalences likely to be caused by the type of hepatic metastases. In fact, diffuse and massive colonization in the hepatic microvascular bed by cancer cells may cause failure of perfusion resulting in ALF, including breast carcinoma, small cell carcinoma of the lung, nasopharyngeal carcinoma, gastric carcinoma, colorectal carcinoma, malignant melanoma, prostatic carcinoma, and urothelial carcinoma (Rajvanshi et al. 2005). It is proposed that ALF in this infiltration pattern is caused by a combination of hepatic microcirculation failure mainly compromising portal venous blood inflow, followed by ischemia of hepatocyte parenchyma and hepatocyte loss. However, as only a rather small fraction of patients develop ALF, other and more complex pathogenic pathways may be involved, including a direct effect of homing, adhering, and growing cancer cells on liver cell function. Dense accumulation of carcinoma cells in the sinusoidal bed may induce portal hypertension due to a sinusoidal block. Helical CT scanning of liver with intrasinusoidal metastases revealed marked hepatomegaly without any visible nodular lesions in the liver (Miyaaki et al. 2010). Owing to the development of ischemic areas, a mottled liver scan can result (Lin and Donati 1981). Diffuse sinusoidal cancer infiltration can also cause a contracted liver mimicking liver cirrhosis.

Pathology

In an autopsy study of three breast carcinomas having diffusely and intrasinusoidally metastasized to the liver, all livers were homogeneously firm, tan-yellow, without metastatic nodules (Allison et al. 2004). However, also grossly normal livers have been found at necropsy (Schneider and Cohen 1984).

Liver biopsies and necropsy specimens show a diffuse accumulation of carcinoma cells within

the sinusoids. The carcinoma cells often stick together, form intravascular Indian files, or small aggregates, associated with focal or diffuse dilatation of the vascular channels. The tumor cells may be surrounded by a thin fibrin layer and granular thrombotic material containing altered thrombocyte indicating local tumor cell-induced thrombosis. These tumor thrombi may extend into small portal venous branches, into sublobular veins, and even into larger veins of the vascular exit tract. The endothelial lining of the sinusoids may lack or no longer be visible owing to atrophy and encroaching tumor cells. But the sinusoidal architecture may in fact be destroyed, associated with decay of liver cell plates, apoptosis, and hepatocyte necrosis. Liver cell necrosis was related to the degree of sinusoidal involvement by tumor cells (Henrion et al. 1996). Following destruction of the sinusoidal wall, carcinoma cells may overrun hepatic cell plates, somewhat analogous to piecemeal necrosis (Krauss et al. 1979). A fine stromal reaction may follow the infiltrating tumor cells, this phenotype forming the transition to cases with more pronounced stromal formation and termed cancerous pseudocirrhosis, discussed in another chapter.

Immunohistochemistry

In case of diffuse accumulation of cancer cells in the lumina of sinusoidal vascular channels, lineage determination may be very difficult and hence requires immunohistochemistry. Cytokeratin markers will in most cases allow the diagnosis of carcinoma, even in case of poorly differentiated neoplasms. In metastatic breast carcinoma, which is well known to show a sinusoidal spreading pattern, gross cystic disease fluid protein-15 (GCDFP-15) was the most reliable marker, while BCA-25 is also positive in part of cholangiocarcinomas and metastatic carcinomas other than breast tumors (Akasofu et al. 1993). Histologically and cytologically, diffusely growing hepatic metastases of lobular breast carcinoma and signet ring cell carcinoma of the gastrointestinal tract may be difficult to distinguish. Immunohistochemically, all metastatic GIT signet ring cell carcinomas proved to be CK20 positive, while only 5 % of metastatic lobular breast carcinomas were CK20 positive. None of GIT signet ring cell carcinomas but the majority of lobular breast carcinomas were estrogen receptor positive (Tot 2000).

Pathogenesis

The mechanisms of a preferential growth within the sinusoidal vascular compartment are not known, but it is assumed that distinct homing mechanisms mediated by differential expression of adhesion molecules and their receptors are involved. Within sinusoids, circulating carcinoma cells are in close contact with endothelial cells, Kupffer cells/macrophages, perisinusoidal stellate cells, and Pit cells. Intrasinusoidal growth also requires that carcinoma cells engage in contact among themselves to form cellular aggregates. Local pericellular activation of the coagulation system may play an important role. The fine stromal reaction accompanying intrasinusoidal carcinoma growth, particularly in case of breast cancers, seems to be a condition necessary for cancer growth, as in other locations. Stromal cells may either derive from circulating mesenchymal stem cells or locally recruited from activated stellate cells and hepatic myofibroblasts.

Intraductal Growth of Metastases

Jaundice developing in patients with colorectal and other carcinoma and sarcoma metastases to the liver is usually caused by diffuse or multifocal parenchymal lesions that interfere with hepatocyte function. In part of the patients, however, jaundice is caused by obstructive lesions of the biliary tract, predominantly due to extrahepatic duct compression or stenosis, a situation first described in 1946 based on two cases (Herbut and Watson 1946). In the latter case, duct obstruction is either caused by duct wall invasion, intraluminal growth, or compression by enlarged lymph nodes harboring metastases, situated behind the duodenum, along the common bile duct, or at the liver hilus. But part of carcinomas metastasizing to the liver can invade the intrahepatic biliary tree and form intraductal growths that may cause duct stenosis or duct obliteration. This phenomenon has most commonly been observed with colorectal carcinoma

(CRC) metastases and several reports have documented this distinct clinical-pathological entity, but intraductal growth also occurs with metastases from other primary tumors.

It seems that CRC metastases have a distinct propensity or are predisposed to intraepithelial/intramucosal spread along intrahepatic bile ducts and their intact basement membranes, replacing the preexisting normal epithelial lining. But CRC also has a tendency to metastasize to the extrahepatic bile ducts (Nagler and Rochwarger 1977; Warshaw and Welch 1978; Gray et al. 1982; Morelli et al. 2007). Overall, intrahepatic intraductal growth of colorectal metastases is a phenomenon of variably frequency as based on the literature (Riopel et al. 1997; Nakanuma et al. 2011). One study reported a prevalence of 12 % of gross extension of colorectal metastasis into bile ducts (Okano et al. 1999), while a later study found that 3.7 % of resected colorectal liver metastases extended predominantly along the intrahepatic bile duct system without forming a relevant extraductal mass (Kubo et al. 2002). One investigation showed that more cases were recognized at exploration for hepatic resection than clinical or radiographic recognition (Povoski et al. 2000). It seems that the prognosis of disease with macroscopic bile duct invasion is better than that in patients with microscopic intraductal invasion, which tends to aggressively involve portal tracts (Okano et al. 1999; Kubo et al. 2002). Less often, other types of carcinomas metastatic to the liver show intraductal growth, the most frequent cancer being renal cell carcinoma (Ueda et al. 2002; Masuda et al. 2009; Simunek et al. 2011). Renal cell carcinoma is also well known to form polypoid and stenosing intraluminal metastases in the extrahepatic bile ducts (Kauffmann et al. 1992; Letessier et al. 1994; Miyagishima et al. 1996) and in the lumen of the gallbladder (Satoh et al. 1991; Nojima et al. 2008). Rarer examples of malignancies that cause intraductal growths include malignant melanoma (however mostly at the level of extrahepatic ducts; Kohler and Riemann 1987; Parquier et al. 1991) and pancreatic acinar cell carcinoma (Nagata et al. 2012). Melanoma metastatic to the common bile duct can clinically present as obstructive jaundice (England and Sarr 1990; Colovic et al. 2007).

Intraportal Metastasis of Solid Tumors

Introduction

Tumor thrombi are well-known and prognostically relevant complications of hepatocellular carcinoma, but metastatic deposits with or without thrombus formation in the portal vein and its branches also occur in extrahepatic tumors metastasizing to the liver, although portal vein thrombus as a complication of metastatic liver disease is much less common than HCC-induced portal vein thrombosis (Marn and Francis 1992; Ito et al. 1997). In a prospective study of 100 patients with liver metastasis using real-time ultrasound, 8 % of the patients were found to have portal vein thrombosis (Atri et al. 1990). However, the true incidence of portal vein metastasis remains unknown, because the mere fact that portal vein thrombosis is detected at imaging will not mean that this thrombus contains malignancy. The intraportal manifestations of tumors can result from direct metastatic translocation along the portal venous system (direct origin from the primary tumor) or indirectly via local transmural ingrowth from hepatic metastases followed by formation of an intravascular metastasis. Tumor thrombus in the portal vein system may be associated with tumor manifestations in the splenic vein and other veins communicating with the portal vein.

Metastatic Tumor Masses in the Portal Vein Trunk and Its Major Branches

Tumors metastasizing to the liver may produce intraportal metastases with formation of macroscopically visible tumor thrombi (Figs. 8 and 9). This phenomenon has been observed for several neoplasms, including colorectal carcinoma, gastric carcinoma, renal cell carcinoma, non-small cell carcinoma of the lung, ductal tumors of the pancreas, neuroendocrine tumors of the pancreas, malignant melanoma, and cholangiocarcinoma. The formation of a metastatic portal vein tumor thrombus can destroy even a large vein branch or the main PV trunk, sometimes resulting in a

cord-like portal vein remnant embedded in the tumor mass (Senda et al. 1995).

Macroscopic tumor thrombus in the portal vein (PV) from colorectal cancer is an uncommon event. In a retrospective review of the charts of 142 consecutive patients who underwent hepatic resection for colorectal liver metastasis it turned out that 2.8 % had macroscopic PV invasion (Tada et al. 2003). In a literature review of 15 cases of colorectal cancers inducing PV tumor thrombus, the main PV was involved in three cases, the left PV in six, the right PV in three, the posterior PV in two, and the anterior PV in one case. No specific clinical features typified patients with colorectal liver metastasis of PV tumor thrombus with respect to age, gender, or the primary tumor site. The interval from colorectal resection to diagnosis of PV tumor thrombus ranged from 4 to 141 months. In 12/15 cases (80 %), liver metastasis was accompanied by PV tumor thrombus, and 12/15 cases were metachronic metastases (Tomimaru et al. 2010). In a compilation of 15 published cases, PV tumor thrombosis was synchronous in 3 and metachronous in 12 patients (Tomimaru et al. 2010).

PV thrombus from colorectal carcinoma can rarely occur in the absence of a hepatic parenchymal metastasis (Matsumoto et al. 2009; Yamamoto et al. 2011), and the same phenomenon has been found with gastric carcinoma (Ishikawa et al. 1995). The pathways from an extrahepatic primary tumor to an intraportal metastasis are sometimes complex and involve more than one localization step. In case of renal cell carcinoma, PV tumor thrombus may be the second metastatic manifestation after a pancreatic metastasis (Kawakami et al. 2008). Radiologically, PV tumor thrombosis is generally characterized by enlargement of the involved vein segment, decreased density mass without intraluminal enhancement of the involved part, and nonvisualization of the portal venous branch in the involved lobe (Ishikawa et al. 1995). In cases with indirect metastatic involvement of the PV, tumor encasement of the vein may be seen on CT and MR images. Tumor-induced thrombosis of the PV can be followed by cavernous transformation of this vein (Ishikawa et al. 1995). Relevant stenosis or obstruction of the PV and its large branches cause ischemia of liver parenchyma and can result in hepatic infarctions seen as more or less extended well-defined homogeneous

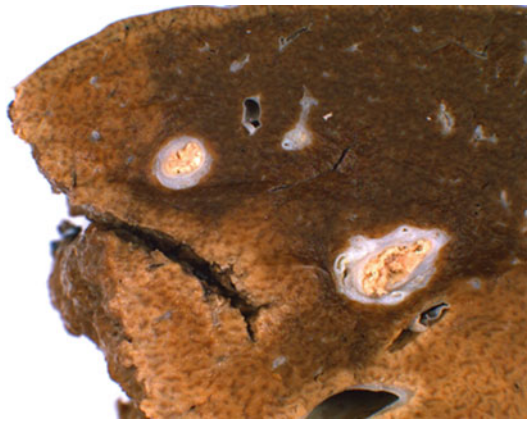

Fig. 8 In this liver with carcinoma metastases (not shown), cancer tissue has invaded portal venous branches in the vicinity of metastasis

Fig. 9 Hepatic metastases with portal vein involvement (non-fixed specimen)

low-density areas on CT scans (Ogawa et al. 2009).

Metastatic Tumors in Small Portal Venous Branches

Microscopic tumor invasion into the small intrahepatic portal vein branches is detectable in about 20 % of cases with liver metastases from colorectal cancer (Yamamoto et al. 1995). In contrast, intravascular metastatic carcinomatous spread to small portal venous branches with formation of multiple tumor emboli is a rare event that may result in acute and sometimes fatal liver failure. In one study, tumor emboli were present within portal vein branches ranging from 0.12 to 2.9 mm in diameter and were freely floating or attached to the vascular walls, with or without varying degrees of superimposed organization (Bégin et al. 2001). Extensive metastatic deposits in small portal vein branches can massively compromise portal venous flow followed by parenchymal ischemia, hepatocyte necrosis, or even parenchymal infarction (Harrison et al. 1981; Fig. 10).

Macroscopy

Development of metastasis in the PV trunk and in the large PV branches is macroscopically visible as tumor thrombi. This alteration has most commonly been seen in metastasizing colorectal cancer. Tumor thrombi are friable or firm structures that may occlude the PV lumen and contain a significant proportion of coagulated blood, even with the striation typical for recent appositional thrombosis. Gray to whitish and in part necrotic tumor components are seen already from the surface of the thrombus or are then visualized when cutting through the thrombus. Tumor thrombi may adhere to the portal vein wall, and sometimes the tumor tissue itself mediates adhesion or has already invaded the venous wall. Segments of the PV containing tumor thrombi are usually dilated. In the majority of cases of colorectal cancer, PV thrombosis is associated with metastases in the liver parenchyma. These metastases may be situated close to the thrombosed PV or may be distant from it. In case the parenchymal metasdtatic nodule is closely associated with the PV tumor thrombus, outgrowth of cancer from the tumor thrombus through the PV wall has to be considered. With time, part of the thrombus organizes, and in case of slow-growing tumors, cavernous transformation of the PV may ensue. Marked stromal reaction taking place when the tumor has engaged with the venous wall may induce obliteration of the involved part of the PV, leaving a firm string.

Obstruction of the PV and its large branches can cause marked ischemia of the liver substance, ending up with Zahn's infarcts. Zahn's infarcts present as sharply demarcated pale to yellowish areas that may, in early stages, slightly bulge from the cut surface and exhibit a lobular texture that is coarser than normal, while in later stages the lobular architecture is effaced owing to confluent necrosis, edema, and exsudation.

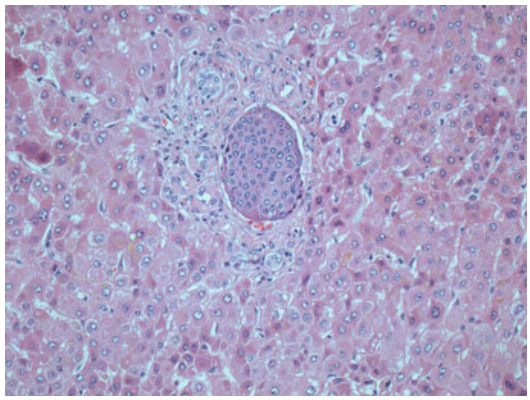

Fig. 10 Liver metastasis of neuroendocrine carcinoma. The tumor has invaded a small portal vein branch (hematoxylin and eosin stain)

Histopathology

Histologically, PV tumor thrombi show a mixture of fresh and older thrombotic material and cancer tissue embedded in the thrombus masses. Tumor cells are suspended as small clusters or even single cells in the thrombotic background, or form cohesive masses. Even in the latter, thin trabecula of fibrin often traverse the tumor tissue. With time, the thrombus will organize, with normal blood vessels sprouting from the venous wall, accompanied by fibroblasts/myofibroblasts and leukocytes, including macrophages. The interaction

between this non-neoplastic organizing granulation tissue and the tumor tissue is complex and not yet well studied. It may be assumed that the tumor recruits blood vessels and stromal cells from this organizing tissue, facilitating its further growth and invasion.

Invasion of the Sinusoidal Vascular System

Apart from primary intrasinusoidal metastasis (see above), cancer cells released from the periphery of a metastatic nodule can invade adjacent sinusoidal vascular channels (Fig. 11). In part of cases, intrasinusoidal invasion is extensive and causes marked obstruction of the sinusoidal bed, followed by parenchymal atrophy. In addition to direct tissue invasion of cancer cells, spread along the microvascular system is one mechanism causing involved resection margins (Fig. 12).

Metastases/Tumor Invasion of the Hepatic Vein System

In contrast to the portal vein system, which can be reached by tumor cells through a metastatic hematogenous pathway, involvement of the hepatic vein system by tumor much more results from direct intravascular growth of tumor following macrovascular invasion in the primary tumor. The typical model of this pathway are renal cancers, invading the inferior vena cava and then producing a cohesive tumor plug that may grow upward to the ostial region of hepatic veins and to the right atrium. This intravascular growth mode is a variant of metastatic spread that does not completely meet the definition of true metastasis. In a patient with a small hepatic colorectal metastasis, a microscopic tumor embolism was detected in the hepatic vein around the metastatic tumor nodule (Nakayama et al. 2005).

Budd-Chiari Syndrome Induced by Invasive-Metastatic Tumors

Malignant neoplasms growing into and within the hepatic veins can induce tumor thrombi analogous to those in the portal vein. Similar to hepatocellular carcinoma, metastatic tumor thrombi can cause Budd-Chiari syndrome, sometimes with a fulminant course. This complication has most often been observed in patients with renal carcinoma, which is well known to invade the inferior vena cava and to involve the hepatic veins and their ostia (Yanagizawa et al. 1983; Nakajima et al. 1989; Kume et al. 1999; Ciancio and Soloway 2001; Zisman et al. 2003; Sarwar and Khan 2008; Shih et al. 2009; Marangoni et al. 2010). Other metastatic tumors that have been found to be associated with Budd-Chiari syndrome include malignant melanoma, uterine carcinoma, PNET of the kidney, and sarcomas originating from the inferior vena cava, including leiomyosarcoma and rhabdomyosarcoma. As in other forms of Budd-Chiari syndrome, tumor-

induced Budd-Chiari syndrome can cause Zahn's infarct of the liver.

Hepatic Lymphangiosis Carcinomatosa

Lymphangiosis Carcinomatosa of the Liver: A Rarely Examined Lesion

Lymphangiosis carcinomatosa (LC) or lymphatic invasion, which has been studied in detail in other organs involved by cancer, has been much less investigated in the liver, although the lymphatic system of the liver has been analyzed in detail (Fig. 13; Szabo et al. 1975; Yamamoto and Phillips 1986). Pathways leading to lymphangiogenesis have also been investigated for several tumor systems (Achen and Stacker 2006; Achen and Stacker 2008). Among a total of 762 cases of malignancies, LC of the liver was found in 10 cases out of 250 cases with liver metastases. In eight cases, the primary tumor was gastric carcinoma (Itoh et al. 1988). The result of LC can be so-called lymphangitic liver metastasis. The intravascular cancer cell depositions located within low-flow lymphatics can undergo necrosis; this may be followed by dystrophic calcifications with a distinct branching pattern (Matsumoto et al. 2004). Carcinomatous thrombi located in portal tract lymph vessels can exert pressure on intrahepatic bile ducts and cause progressive jaundice (Tada et al. 1996; Ishizaki et al. 2001). The presence of intrahepatic lymphatic invasion by CRC cells predicted poor survival and recurrence after hepatectomy (Sasaki et al. 2002; Korita et al. 2007).

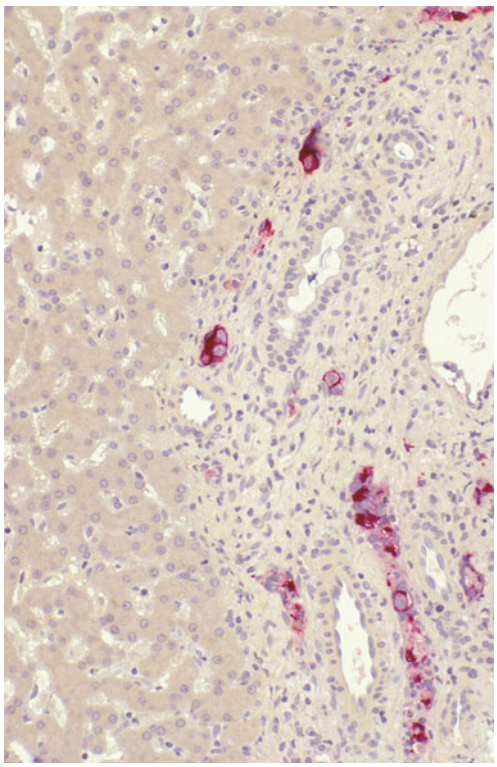

Fig. 13 Liver metastasis of poorly differentiated adenocarcinoma. The cancer cells are located in lymphatic vessels of a portal tract (lymphangiosis carcinomatosa; cytokeratin immunostain)

Lymphangitic Hepatic Metastasis

Lymphangiosis carcinomatosa, which is mostly located in the compartment of portal tracts of the liver, can give rise to a distinct variant of hepatic metastases (lymphangitic liver metastasis). On sonography and CT images, enlargement of the portal tracts with maginal obscurity was found, while cholangiograms revealed narrowing and dilatation of the intrahepatic bile ducts, and angiograms distortion, displacement, and occlusion of the hepatic artery and portal vein (Itoh et al. 1991).

Veno-Occlusive Lesions Associated with Lymphangiosis Carcinomatosa of Hepatic Veins

LC can involve the lymphatic vessels located to the wall of sublobular and hepatic veins. The subsequent lymph vessel obstruction may be associated with intimal proliferative lesions of terminal hepatic venules to larger hepatic veins, possibly induced by intimal lymph stasis and causing focal veno-occlusive disease (Shibayama et al. 1991).

Tumor-in-Tumor Metastasis

Tumors metastasizing into other tumors is a rare phenomenon that has, however, been described for a wide variety of cancers, with examples of carcinomas metastasizing to both other carcinomas or benign tumors (Elmaci et al. 2001; Sakai et al. 2010). Hepatocellular carcinoma has been found to metastasize into a medullary carcinoma of the thyroid (Sung et al. 2011).

Hepatic Metastasis in Fatty Liver

Whereas the prevalence of metastases of extrahepatic tumors to the liver in chronic hepatic disease, and in particular cirrhosis, has been studied in detail, relatively few data are available concerning other liver disorders and their potential impact on the hepatic metastasizing process. There is evidence that liver metastases are rare in patients with fatty liver (Murono et al. 2013). Among 839 patients with colorectal carcinoma who underwent resection, 121 patients were designed to have fatty liver based on ultrasonography, and 718 had no fatty liver. There were only 2 patients who had liver metastases in the fatty liver group in comparison with 115 patients with liver metastasis in the nonfatty liver group (Hayashi et al. 1997). In an investigation of 747 patients undergoing surgical treatment for colorectal cancer, synchronous hepatic metastases were present in 32 % of patients with normal liver, but only 15 % of patients with fatty liver (Iascone et al. 2005). These findings are also of interest on the background of liver changes caused by neoadjuvant chemotherapy. It has been found that this therapy administered prior to liver surgery for CRC metastases can cause marked steatosis and nonalcoholic steatohepatitis (Kampfenkel et al. 2011; Urdzik et al. 2012). On the other, there is more recent evidence that fatty liver in a rat model produces a pro-metastatic microenvironment for hepatocellular carcinoma via activation of heatic stellate cells whch secrete VEGF, interleukin-1alpha, and TGF-beta (Mikuriya et al. 2015).

The pathogenesis of a potential protective effect of hepatic steatosis against part of liver metastases is not clarified. The effect has been reproduced in a rat model. Rats with fatty liver seldom had experimental liver metastases (injection of a rat colon cancer cell line) compared to normal rats (Tamura et al. 1999). In rats, fatty liver suppresses angiogenesis in metastatic lesions, and this effect may play a role in the suppression of metastatic growth in fatty livers (Karube et al. 2000).

Metastases in Chronic and Cirrhotic Liver Disease

Introduction

Old observation and a series of studies suggest that metastatic carcinoma is rarely encountered in patients with liver cirrhosis, leading to the concept that the chronically damaged livers with remodeling and fibrosis are partially protected from metastasizing malignancies. Recent investigations confirmed that patients with chronic liver injury, including chronic viral hepatitis, have a significantly lower occurrence of hepatic CRC metastasis than patients with a healthy liver (Zeng et al. 2012; Augustin et al. 2013).

Epidemiological Considerations

The finding of the rarity of metastases in cirrhotic livers had led to the publication of cases with metastases in a cirrhotic liver, probably to document the uniqueness of such an event, either as single case reports or as small series. These reports might also have been stimulated to be published on the background of the marked contrast between the high frequency of primary liver cancer in cirrhosis in comparison with the uncommon metastases of extrahepatic primary malignancies. The first case of cancer metastasis in a cirrhotic liver was published in 1888 (Hanot and

Gilbert 1888), followed by numerous later reports. On the other hand, several reports have described the rarity of even absence of carcinoma metastases in cirrhotic livers, e.g., colorectal carcinoma/CRC (Uetsuji et al. 1992).

Selected References Poulain 1899; White 1897; Achard and Laubry 1902; Colwell 1905; Rolleston and McNee 1929; Lisa et al. 1942; Wallach et al. 1953; Lieber 1957; Gall 1960; Ruebner et al. 1961; Wegener 1961; Goldstein et al. 1966; Berge and Saldeen 1968; Goldstein 1969; Peichl et al. 1978; Mirouze and Michel 1982; Pérez Flores et al. 1987; Melato et al. 1989; Siu et al. 1999; Gervaz et al. 2003.

In the study of Ruebner and coworkers (1961), 399 patients with liver cirrhosis were selected from autopsies. Among these cirrhosis patients, only 20 % of malignancies had metastasized to the liver, in comparison with 36 % in the noncirrhotic control group. The distribution of types of cancer metastases to the liver in cirrhotic patients was very similar to that in the control group. It was concluded that the relative rarity of hepatic metastases could therefore not be attributed to a greater proportion of tumors a small propensity for metastatic spread to the liver. In a Japanese autopsy study, 8798 cases of liver cirrhosis were identified among 240′377 patients (3.66 %). Of these, 737 (8.4 % of the cirrhotics) had coexistent extrahepatic malignancy; 26.3 % of these had metastases in the cirrhotic liver, in comaprison with 38.3 % and 43.2 % in control groups of the time periods 1958–1959 and 1967–1968, respectively (Hamaya et al. 1975). In a study of consecutive autopsies comparing Italian (5241 autopsies; 500 cases of cirrhosis) and Japanese (6511 autopsies; 529 cases of cirrhosis) cases matched for sex and age, the results were similar in both areas and confirmed the opinion that metastases in the cirrhotic liver are rare (Melato et al. 1989). In the CRC study of Uetsuji and coworkers (1992), analyzing 250 patients with CRC, liver cirrhosis was not found among the 40 patients with metastases, but was present in 46 (21.9 %) of the 210 nonmetastatic patients. An investigation of 2162 consecutive autopsies performed during a 12.5-year period showed that the cirrhotic liver was less often affected by metastases than the noncirrhotic liver (33.3 % vs. 46.4 %). In cirrhotic livers, metastases from neuroendocrine tumors were predominantly localized within the parenchymatous nodules, whereas nonendocrine carcinomas had metastasized more often to the fibrous septa of cirrhotic livers (Van Boekrijck and Klöppel 1992). A later autopsy study confirmed that liver metastases of extrahepatic cancers are less frequent in cirrhotic patients (Pereira-Lima et al. 2003). Among 747 patients undergoing surgical treatment for colorectal cancer, synchronous hepatic metastases at the time of surgery amounted to 32 % of patients with a normal liver, 15 % of patients with fatty liver, and 4.7 % of patients with cirrhotic livers (Iascone et al. 2005).

Some authors questioned the concept of rarity of metastases in cirrhotic liver (Fisher et al. 1960; Norkin et al. 1962; Zotti et al. 1986). Fisher and coworkers (1960) analyzed 2865 autopsy cases, including 213 cases of liver cirrhosis, and did not find a difference in the frequency of hepatic metastases of extrahepatic cancers between cirrhotics and noncirrhotics, but detected a significant difference in the frequency of extrahepatic malignancies between these two groups. According to Ruebner and coworkers (1961), the rarity of hepatic metastases in patients with cirrhosis of the liver was, at least in part, due to a significant decrease in extrahepatic cancer in this group of patients compared with matched controls. In fact, extrahepatic malignant tumors in cirrhosis patients were found to be rare by all previous authors who had studied this problem (Hall and Sun 1951; Lieber 1957; Gall 1960; Fisher et al. 1960). If confirmed, the lesser prevalence of extrahepatic cancer in cirrhotics may be due to the reduced life span of cirrhotic patients, hence leaving less time for the development of extrahepatic malignancies. Such a mechanism has been proposed for other situations, e.g., the diminished prevalence of cancer in patients with tuberculosis or diabetes

mellitus (Pearl 1929; Cornfield 1959; Rockstroh and Schröter 1960). Some of the differences that have been published in several reports may be biased by the difficulties arising in the interpretation of autopsy data, eventually leading to fallacious conclusions (Mainland 1953). It has been pointed out that "even if two fatal diseases had no relationship in a living population, there would nevertheless be a negative association between them in an autopsy population. The autopsy incidence of one lethal disease (e.g., cancer) among patients affected by a second fatal disease (e.g., cirrhosis) would therefore, always be reduced in comparison with the rest of the necropsy material. The higher the mortality of the second disease, the smaller would the proportion of patients who, at autopsy, were affected by both diseases" (Cornfield 1959; quoted from Ruebner et al. 1961).

Pathogenetic Hypotheses

Liver cirrhosis is characterized by massive remodeling of the hepatic architecture, associated with a deranged microcirculation and arteriovenous shunting. The change in the structure and function of microvessels in cirrhosis may affect the homing and adhesion of circulating carcinoma cells. Also the capillarization that takes place in hepatic sinusoids in cirrhosis (Schaffner and Poper 1963; Neubauer et al. 2001) may affect the metastatic process, as tumor cells homing to sinusoids may face greater difficulties to egress from vessels due to the new basement membrane barrier characterizing sinusoidal capillarization. Fibroblast and myofibroblast functions are altered in the fibrotic process of cirrhosis, and this may have an impact on stromagenesis of metastasizing carcinomas, because myofibroblasts have a central role in tumor stroma remodeling (Otranto et al. 2012). There are differences between the findings obtained with studies on humans in comparison with findings in laboratory animals. In an experimental rat model of liver cirrhosis (induction of cirrhosis by the administration of carbon tetrachloride), an increased proportion of animals producing liver metastases following injection of Walker carcinosarcoma cells was observed, suggesting that, in this model, the cirrhotic liver is a "fertile soil" for hepatic metastases (Fisher and Fisher 1960).

Biopsy of Hepatic Metastases

For histological diagnosis, fine-needle aspiration (FNA)/fine-needle aspiration cytology (FNAC) and needle core biopsy (NCB) employing either transabdominal ultrasound or computed tomography scanning guidance are frequently used techniques to provide diagnostic samples with a high yield, particularly when FNA and NCB are combined (Jacobsen et al. 1983; Bell et al. 1986; Kern and Haber 1986; Cochand Priollet et al. 1987; Sautereau et al. 1987; Seitz et al. 1990; Lin et al. 1991; Tsai et al. 2002; Sanz and del Valle 2004; Larsen et al. 2007). In one study using FNA, 90 % of cases were positive on rinse, 78 % on smear, and 69.6 % on both rinse and smear (Axe et al. 1986). In a comparative study of 141 consecutive cases, FNA cytology was more sensitive and accurate than NCB, but the combination of these sampling techniques increased diagnostic sensitivity (Stewart et al. 2002).

In situations of increased risk of bleeding and/or the presence of small hepatic tumors, endoscopic ultrasound-guided fine-needle aspiration biopsy (by the transgastric route) may be performed and is a powerful, reliable, and safe procedure (Hollerbach et al. 2003). Use of FNA/FNAC in abdominal tumors has been reported to be fatal in 0.006–0.031 % of cases (Fornari et al. 1989; Smith 1991). The majority of biopsy-associated deaths occured with liver tumors and were due to fatal hemorrhage. A further complication which is well established for several types of liver malignancies is biopsy track seeding, including the skin. Metastatic disease can emerge subsequent to both FNA and NCB (Smith 1984; Denton et al. 1990; Roussel et al. 1989; Roussel 1990; McGrath et al. 1991) and has an overall estimated frequency of 0.005–0.009 % quoted for large series of fine-needle abdominal biopsies (Livraghi et al. 1983;

Smith 1991). For the liver, most cases have been reported after biopsy of hepatocellular carcinoma (review and meta-analysis: Silva et al. 2008). The complication has been reported to be less common in CRC metastases than in hepatocelular carcinoma (Glaser et al. 1989; Gayral et al. 1990; Scheele and Altendorf-Hofmann 1990; McGrath et al. 1991; Goletti et al. 1992; John and Garden 1993; Vergara et al. 1993; Abdelli et al. 1994; Herszenyi et al. 1995; Jourdan and Stubbs 1996; Ohlsson et al. 2002; Metcalfe et al. 2004), but a more recent study described needle track deposits as common and with an adverse effect on long-term survival (Jones et al. 2005). But the issue has raised critical voices in regard to indications versus contraindications of hepatic FNA and/or NCB in case of CRC metastases.

Neoplastic needle track seeding has, albeit very seldom, been observed following percutaneous radiofrequency ablation of hepatocellular carcinoma (with an estimated risk of 0.6–0.9 %; Livraghi et al. 2005; Stigliano et al 2007), and after percutaneous ablation of CRC liver metastases, sometimes with growth of cutaneous ulcerated cancer nodules (Bonatti et al. 2003; Charalampopoulos et al. 2007; Liu et al. 2009).

Prognostic Factors for the Outcome of Patients with Liver Metastases

Numerous studies comparing prognostic factors involved in primary tumor biology versus metastases have been performed and the results compiled (Gayowski et al. 1994; Shirabe et al. 1997; Bakalakos et al. 1998; Ohlsson et al. 1998; Ambiru et al. 1999; Iwatsuki et al. 1999; Nagashima et al. 1999; Minagawa et al. 2000; Seifert et al. 2000; Heslin et al. 2001; Imamura et al. 2001; Yamada et al. 2001; Aldrighetti et al. 2005; Schindl et al. 2005). Prognostic scoring systems have been developed (Iwatsuki et al. 1999; Schindl et al. 2005).

The disease-free interval (time interval between resection of primary tumor and metastatic disease) has been associated with an increased risk of liver recurrence (Logan et al. 1982; Registry of Hepatic Metastases 1988). Stage and site of CRCs are important prognosticators (Nordlinger et al. 2005). A prognostic effect of initial CRC stage has been reported several times (Butler et al. 1986; Iwatsuki et al. 1986; Doci et al. 1991; Scheele et al. 1995; Nordlinger et al. 1996; Jaeck et al. 1997; Minagawa et al. 2000). The presence of synchronous liver metastases is a high-risk factor in CRC (Scheele et al. 1995; Beckurts et al. 1997; Jenkins et al. 1997), as is tumor size (Registry of Hepatic Metastases 1988; Doci et al. 1991; Pedersen et al. 1994; Scheele et al. 1995; Nordlinger et al. 1996), number of metastases. Prognosis becomes worse as a function of the number of hepatic metastatic foci (Registry of Hepatic Metastases 1988; Gayowski et al. 1994; Elias et al. 2005; Onodera et al. 2005). The presence or absence of four or more hepatic metastases was a predominant prognostic determinant with a 5-year survival rate of 20 % in patients with less than four liver metastases, and no 3-year survivor among patients with four or more metastases (Ekberg et al. 1986). Unilateral lesions do better than bilateral lesions (Gayowski et al. 1994; Wanebo et al. 1996; Bakalakos et al. 1998). Tumor satellitosis affects outcome (Gibbs et al. 1998). In a study of 127 patients treated at a single center, the 3- and 5-year survival for patients with concomitant EHD were 47 % and 26 %, respectively, compared with 67 % and 49 % for those without EDH (a significant difference; Carpizo et al. 2009). In resected patients, the status of the resection margin has an impact on tumor biology (Ekberg et al. 1986; Iwatsuki et al. 1986; Nordlinger et al. 1996; Scheele et al. 1996; Jaeck et al. 1997; Shirabe et al. 1997; Bakalakos et al. 1998). A resection margin of less than 10 mm has an adverse effect (Ekberg et al. 1986). In CRC liver metastases, a positive hepatic resection margin was associated with a higher incidence of postoperative recurrence and lower survival rate. In a study of 293 consecutive CRC patients undergoing hepatic resection, the width of the resection margin did, however, not influence the postoperative recurrence rate or pattern of recurrence, suggesting that the "1 cm rule" should be abandoned (Hamady et al. 2006). Pushing invasion margins

are prognostically more favorable than infiltrating invasion margins (Cianchi et al. 1997). Incomplete resection is clearly associated with an elevated recurrence rate (Gayowski et al. 1994; Pedersen et al. 1994; Beckurts et al. 1997; Jenkins et al. 1997; Bakalakos et al. 1998). The prognosis of liver metastases is also markedly influenced by certain parameters of metastasis morphology and biology. Similar to hepatocellular carcinoma, the presence of a fibrous pseudocapsule around coloractal metastases is a favorable prognostic factor (Yamamoto et al. 1999). In a clinicopathological study conducted in 152 patients who underwent initial hepatic resection for metastatic colorectal cancer, presence of fibrous tissue between the tumor and the surrounding parenchyma was detected in 61 %. Presence of a microscopic fibrous pseudocapsule was identified in 28 % of metastases in another study (Ambiru et al. 1999). Pathologically, the presence and thickness (thin vs. thick, according to the number of collagen fiber bundles) of a pseudocapsule were related closely to less invasiveness into adjacent vessels. The postresection survival was significantly better in patients with thick or thin pseudocapsules than in those without a pseudocapsule (Okano et al. 2000). In an univariate survival analysis (N: 221), the presence of a fibrous pseudocapsule around metastatic nodules was found to a significant positive prognostic factor (Weber et al. 2001). An aggressive biology of CRC metastases may be reflected by the invasion mode and in particular by the incorpation of preexisting liver tissue and cells in the metastatic growth. In was shown that a high frequency of hepatocyte entrapment in metastasis is associated with lower 5-year survival rates (Koike et al. 2000). Angioinvasion in metastases is a high-risk facor (Gayowski et al. 1994).

In regard to the risk of extrahepatic metastasis in CRC, lymphatic permeation of the primary tumor has been shown to be a predicting factor (Sasaki et al. 2005a). The metastatic tumor doubling time was an important prehepatectomy predictor of survival and nonrecurrence of hepatic colorectal cancer metastases (Tanaka et al. 2004). The proliferative index of CRC metastases determined by Ki-67 immunohistochemistry was the most reliable prognostic factor of survival in one retrospective study (Weber et al. 2001). Concerning the significance of apoptosis of metastatic cells, the Fas/CD95 index determined in resected CRC liver metastases correlated with postoperative CEADT, number of metastases, and survival (Onodera et al. 2005). Nuclear p53 protein expression in resected hepatic CRC metastases is an independent prognostic factor for survival (Nitti et al. 1998; Heisterkamp et al. 1999) and is, together with DCC (deleted in colonic cancer), a positive prognosticator of survival after resection of hepatic CRC metastases (Saw et al. 2002). There is a higher expression of the oncoproteins, c-myc, c-erbB-2/neu, PCNA, and p53 in metastasizing colorectal cancer than in nonmetastasizing tumors (Yang et al. 1996). However, a later study on several genetic markers revealed that the DNA content and expression of c-myc, c-erbB-2, EGFR, H-ras, p53, PCNA, and nm23 do not predict survival after potentially curative resection of hepatic metastases, but that immunoreactivity for p53 protein may be an important marker of local recurrence in the liver (Crowe et al. 2001). By multivariate analysis, p53 and EGFR expression of colorectal liver metastases were the best predictors of disease-free survival after partial liver resection (De Jong et al. 1998).

Relatively few markers are available for CRC and its metastases. Serum levels of carcinoembryonic antigen (CEA) and carbohydrate antigen 19–9 (CA19-9) are often elevated in patients with CRC. CEA, a complex glycopotein, is produced by about 90 % of CRC and is known to contribute to the malignant phenotype of this tumor. Serum levels of CEA are used as a marker of disease, and failure of serum CEA to return to normal levels after surgical resection is indicative of inadequate resection or occult systemic disease. Furthermore, CEA levels after salvage surgery appear to predict survival in patients undergoing resection of liver or lung metastases (review: Goldstein and Mitchell 2005). Patients with colorectal liver metastases and a preoperative CEA $<$ or $=$

30 ng/mL are more likely to be resectable, and they have the longest survival (Bakalakos et al. 1999). A multivariate analysis of 90 patients revealed that, in patients with CRC liver metastases, elevation of serum CA19-9 is a risk factor for extrahepatic metastasis, whereas elevated CEA could not predict extrahepatic metastatic disease (Sasaki et al. 2005b). In contrast, CA19-9 serum levels did not predict the prognosis and did not allow for detecting recurrence of CRC (Morita et al. 2004). Expression analysis of CEA (assessed via immunohistochemistry and PCR) revealed that patients with a lesser CEA expression score in the livermetastasis margin appeared to have a longer disease-free survival period than did those with a greater CEA expression score (Kim et al. 2003).

Metastatic Liver Disease: Colorectal Carcinomas

107

Contents

Abstract

Among tumors causing hepatic metastatic disease, colorectal carcinoma (CRC) plays a very important and distinct role, both clinically and pathologically. The liver is the first and most common of CRC metastasis. CRC metastases to the liver occur in synchronous or metachronous manner, whereby synchronicity of CRC hepatic metastasis is a risk factor associated with poorer outcome. CRC metastatic to the liver has a complex molecular signature that will be employed for risk stratification and new treatment modalities. CRC metastasis to the liver presents a solitary or multiple lesions. The metastases involve the liver lobes with different frequencies, the right being involved more frequently. Typical solitary CRC metastases are bulky masses with a usually expanding growth pattern. The pattern of nodularity and growth patterns have resulted in classification systems for metastases. Large CRC nodules often reveal secondary changes, central necrosis being a very common feature. The tumors can invade the liver capsule and extend into adjacent structures, mainly the diaphragm, resulting in characteristic imaging findings. The metastatic nodules are associated with a distinct peritumoral immune reaction and may elicit formation of a pseudocapsule.

Introduction

The liver is the first and most common site of colorectal cancer (CRC) metastasis; at autopsy, more than 50 % of patients dying with CRC will have hepatic metastases (Dionne 1965; Willis 1973; Bengmark and Hafstrom 1969; Pickren et al. 1982; Bird et al. 2006). About 25 % of patients who underwent CRC resection have liver metastases diagnosed presurgery or during surgery (synchronous liver metastases). CRC metastases are confined to the liver in 30–40 % of the patients at the time of their detection (Oxley and Ellis 1969; Ruers and Bleichroth 2002; Simmonds et al. 2006; Ong and Leen 2007). CRC metastases to the liver occur in a synchronous or metachronous manner, two groups which differ in their biology of disease (Slesser et al. 2013). Synchronicity of CRC hepatic metastases is a risk factor associated with poorer outcome (Adam 2007). Synchronous hepatic CRC metastasis can occur in the absence of regional lymph node metastasis (Fujii et al. 2013). CRC metastatic to the liver has a complex molecular signature (Jin et al. 2012; Murakami et al. 2013) that will result in distinct molecular signatures usable for tumor and therapy stratifications.

Clinical Features and Biology of Disease

The clinical presentation of colorectal liver metastases is highly variable, depending on the number and size of metastases, the growth patterns, the modes of vascular and/or bile duct invasion, and complications. The clinical features therefore range from an asymptomatic situation to nonspecific abdominal pain and discomfort and to fulminant hepatic failure. The clinical picture is also modified by the presence or absence of local colorectal recurrence and remote extrahepatic metastatic disease.

Hepatic resection is generally accepted as the best treatment for hepatic colorectal cancer metastases, although the resectability rate is reported to be only 25 % (Scheele et al. 1995; systematic review of published studies: Simmonds et al. 2006). Five-year survival rates achieved by this technique approach 50 %. But about 60 % of the patients undergoing this treatment develop tumor recurrence, up to more than 40 % in the liver (Hughes et al. 1986; Doci et al. 1991; Rees et al. 1997; Ohlsson et al. 1998; Minagawa et al. 2000; Carpizo et al. 2009). Recurrence at the level of the surgical margin was found in around one quarter of these patients with recurrent disease (Wang et al. 1996). Among extrahepatic recurrences after liver resection, pelvic recurrence amounted to 16.3 % in one study, and most patients with pelvic recurrence also developed recurrence in the liver (Assumpcao et al. 2008).

Principal Macroscopic Growth Patterns

The number of CRC metastases of the liver (solitary vs. few vs. numerous) varies markedly as a function of the material examined. Autopsy investigations have shown solitary lesions in 16 %, most livers having several to numerous nodules (Schulz et al. 1985). This paucity in solitary lesions is probably related to the far advanced disease encountered in autopsies of patients with treatment failure. Conversely, surgical resection specimens are expected to have more solitary lesions due to earlier intervention. CRC metastases involve the liver lobes with different frequencies. In a study of 26 metastasis-containing autopsy livers from patients with CRC, the overall incidence of metastases located in the right lobe was 61.2 % compared to 38.8 % on the left side (Schulz et al. 1985).

Most hepatic metastases of CRCs show a nodular growth pattern, with presence of either a solitary, often large nodule, or several to numerous nodules (Fig. 1). CRC metastases of the liver can, however, also present with one of the non-nodular growth patterns that have been described above. Typical solitary CRC metastases present as bulky, rather well-circumscribed masses with most often an expanding growth pattern, but lesions with a highly irregular

Fig. 1 Hepatic colorectal carcinoma metastasis with satellite nodules (fixed specimen)

contour and an invasive phenotype with few to numerous satellite nodules are also encountered. On cut surfaces, the tumors appear as cream-white to gray-white lesions that are often soft and friable in the center, due to marked necrosis, and more firm in peripheral parts, the high consistency mainly depending of the viability state of cancer cells and the amount of stroma present. In part of the cases, spotty to large hemorrhages are seen. The nodules may also show other secondary changes as discussed above. Based on macroscopic presentation, several gross classifications of CRC metastases have been proposed. In the Yasui classification (Yasui et al. 1997), a simple nodular (SN) type and a confluent nodular (CN) type are distinguished. The SN type has a smooth distinctive border and medullary structure with or without necrotic foci. The CN type is, in contrast, a multinodular tumor with an irregular border. The applicability and significance of this classification system was critically reassessed (Nanashima et al. 2002). Hepatic CRC metastases are also classified as pushing (expanding) vs. invading (infiltrative) lesions, whereby the pushing mode is associated with superior disease-free survival (Pinheiro et al. 2014). The peritumoral liver substance often shows a rim of atrophy, visualized as a slightly depressed zone of parenchyma having a reddish discoloration. A yellow rim surrounding the metastatic nodule indicates perifocal hepatic fatty change.

Penetration of the Liver Capsule and the Diaphragm

Large metastatic tumors and those located in the organ's periphery will frequently contact the liver capsule and grow beyond the organs' contour, with a dome-shaped tumor covered by thinned capsule and showing dilated and engorged blood vessels surrounding the lesion. In an autopsy study, CRC metastases reached to the liver surface in 49 % (Schulz et al. 1985). In case of large central necrosis within the nodule, a typical umbilication occurs, with a central or excentric dimple of sometimes several cm diameter (the so-called cancer navel). Contact of several types of metastatic carcinomas with the capsule can cause capsular retraction (Fennessy et al. 2004). On CT images, two types of capsular retraction can be found. In the first type, the retracted capsule is smooth and regular, while in the second type, the retracted capsular part is eroded or even ulcerated. Both lesion types were specific for malignant hepatic tumors (Soyer et al. 1994).

These growth modes can be associated with penetration of the liver capsule (Josephson and Wallace 1978). In early phases of this process, the liver capsule overlying the metastasis loses its glistening aspect and becomes dull, turbid, or opaque, due to loss of the mesothelial covering and deposition of an exudate rich in fibrin. In the superior part of the liver, this early inflammatory reaction can cause adhesion between the organ surface and the inferior aspect of the diaphragm, but this adhesion is easily removed, as it is only due to a fibrin "glue" and not fibrous tissue. In later phases, metastatic tissue invades the falciform ligament, or infiltrates the diaphragm, first by growing through adhesions into the adjacent subserosal space of the diaphragm and then into its muscle tissue (Figs. 2, 3, 4, and 5). Radiologically it may be difficult to distinguish between mere adhesion between the liver surface and the diaphragm and true invasion. Although metastatic CRC often reach to the liver capsule, invasion and penetration of this organ limit do not seem to be very frequent. The phenomenon was studied in 163 human autopsies showing metastatic

Fig. 2 Hepatic colorectal carcinoma metastasis with invasion of the diaphragm. A part of the muscular diaphragm (to the *left*) adheres to an umbilicated peripherally located metastasis. Note the growing tumor nodules forming a collar around the depressed tumor area

Fig. 3 Hepatic colorectal carcinoma metastasis with invasion of the diaphragm. This distinct mode of invasion is associated with typical imaging features (fixed resection specimen)

Fig. 4 Hepatic colorectal carcinoma metastasis with invasion of the diaphragm. On this cut surface, an epicapsular tumor mass is seen above the umbilicated part. A cancer nodule is located within the diaphragmatic muscle

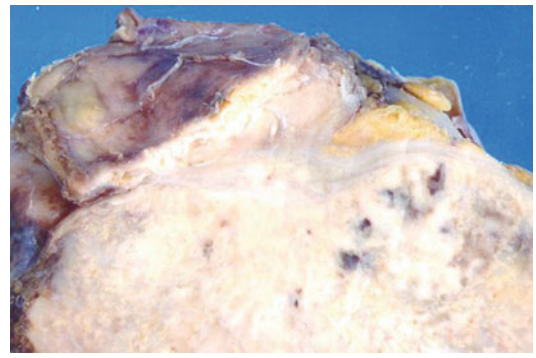

Fig. 5 Hepatic colorectal carcinoma metastasis with invasion of the diaphragm. In this case, the adherent part of the diaphragm is extensively infiltrated by tumor (fixed resection specimen)

subcapsular tumor nodules in the liver. In the majority (153/163 cases), there was some stretching and distortion of the hepatic capsule but no evidence of capsular infiltration by the tumor. Only ten cases showed small foci of tumor within the capsule proper, and in two cases only were tumor cells seen to have breached the capsule and overlying mesothelium and to be on the peritoneal surface. The rarity of penetration was also observed in scanning electron microscope, where subcapsular/capsular tumor nodules (sometimes umbilicated) bulge from the surface, however, mostly covered by mesothelium (Josephson and Wallace 1974, 1978).

The phenomenon of capsular invasion has been studied in detail by use of animal experimentation. In experimental hepatic metastases in rats (injection of Walker 256 carcinosarcoma cells into the mesenteric vein), it was found that hepatic subcapsular nodules penetrated the liver capsule in all animals and the tumor cells lodged on the peritoneal surface (Josephson and Wallace 1978). Scanning electron microscopy revealed that the mesothelial cell layer of the capsular peritoneum was distorted over the penetrating tumor nodules. This was followed by a local fibrinous reaction, loss of mesothelial cells, and lodging of tumor cells (single or clusters/clumps) in these gaps (Josephson and Wallace 1978).

Histopathology

Colorectal adenocarcinoma is somewhat unique because it has a highly characteristic morphology among adenocarcinomas, rendering it diagnosable in biopsies with high reliability (Figs. 6 and 7). In fact, most instances of metastatic colorectal cancer disease in the liver may be correctly diagnosed in biopsies using standard morphology (Centeno 2006; Van den Eynden et al. 2014). Most cases show the "classical" cylindrocellular adenocarcinoma pattern with variable expression of tubular, papillary, cribriform, and solid components, the cells having ovoid or elongated nuclei either placed basally or higher up in the cell body.

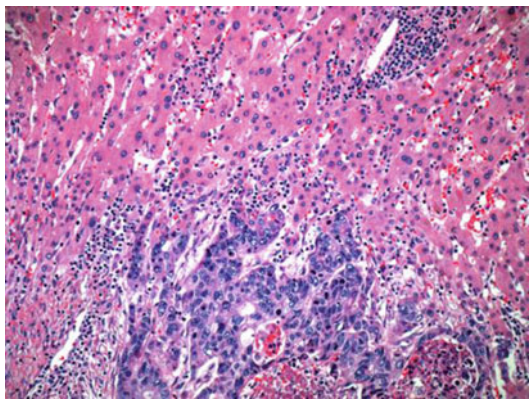

Fig. 6 Peripheral invasion pattern of hepatic colorectal carcinoma metastasis (hematoxylin and eosin stain)

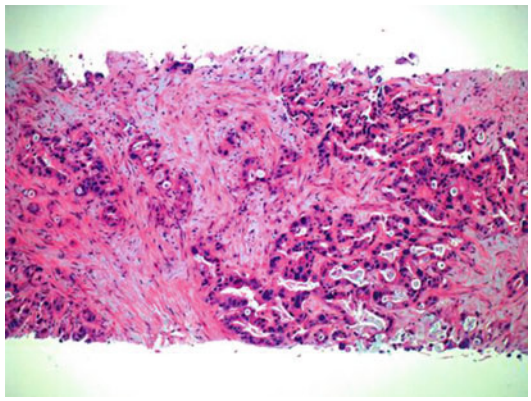

Fig. 7 Liver metastasis of colorectal carcinoma, needle biopsy. Note the abundant desmoplastic stroma (hematoxylin and eosin stain)

It is typical that the histologic differentiation (grade) of hepatic colorectal metastases is practically the same as that of the primary tumor. In case of the rarer mucinous, colloid, signet ring-cell, or poorly differentiated CRCs, the assignment of a metastasis to the colorectal origin is much more difficult or impossible, as the histologic presentation is the same as in other primaries having these features. Distinct histologic growth patterns have been defined for metastatic carcinomas of the liver. Small metastases with a size less than 1 mm show a replacement growth pattern in about two thirds of CRC cases, while metastatic nodules exceeding a diameter of 20 mm predominantly exhibit an expansive growth pattern. In contrast to other primary tumors, a sinusoidal growth pattern is less common in small CRC metastases (Terayama et al. 1996a). Macronodular CRC metastases typically display necrosis, sometimes extensive and involving most of the tumor mass. A type of necrosis that occurs in CRC metastasis and is highly characteristic for these neoplasms is so-called "dirty" or intraacinar necrosis/IAN, characterized by a focus of coagulation necrosis containing nuclear debris and a peripheral rim of preserved cylindrical tumor cells (Bizjak-Schwarzbartl 1987; Lash and Hart 1987). Necrosis can be followed by dystrophic calcification (Sanchez-Pérez et al. 1995). In a systematic comparative analysis, IAN was much more frequently encountered in CRC metastases than in metastases of other carcinomas (Wong and Neville 2007).

Immunohistochemistry

Immunohistochemically, expression patterns of certain antigens may be useful in typing of established or suspected liver metastases of carcinomas (Tot and Samii 2003), although the histomorphological presentation of CRC is so typical that the tumor can often be diagnosed with ease in H&E-stained preparations with high reproducibility. Hepatocellular carcinoma and cholangiocarcinoma can be distinguished from CRC metastasis by differences in staining patterns of HepPar1, pCEA, and of MOC31, the latter

labeling a cell surface glycoprotein (Niemann et al. 1999; Porcell et al. 2000; Proca et al. 2000; Morrison et al. 2002; Siddiqui et al. 2002; Lamps and Folpe 2003; Shiran et al. 2006). It has been shown that intrahepatic cholangiocarcinomas can more reliably be distinguished from colorectal cancer metastases by use of cytokeratin 7, 19, and 20 immunostaining (Maeda et al. 1996; Rullier et al. 1999, 2000; Shimonishi et al. 2000). CK20 seems to be a very useful marker for distinguishing gastrointestinal adenocarcinomas from adenocarcinomas of other primary sites (Moll et al. 1992; Chu et al. 2000; Rullier et al. 2000; Park et al. 2002; Tot 2004); in particular, the CK20[+] CK7[−] phenotype is characteristic for CRC metastasis (in more than 75 % of cases; Wauters et al. 1995; Tot 1999, 2002, Tot and Samii 2003). Reactivity for CK19 was not useful in differentiating cholangiocarcinoma from CRC metastasis (Lau et al. 2002). Das-1 immunostaining can discriminate between CRC metastasis and hepatocarcinoma (Zimmerman et al. 2002). Certain molecules expressed in CRC metastases affect outcome. For example, expression of folate receptor-alpha is present in a subset of resected hepatic CRC metastases, and this marker was independently associated with survival after resection (D'Angelica et al. 2011). Expression of the E-cadherin-catenin complex was also associated with tumor progression (Nanashima et al. 1999; Ikeguchi et al. 2001). Presence of certain cytokeratins has also been documented in CRC liver metastases at the RNA level, e.g., cytokeratin 20. It has been suggested that a high incidence of clinically inconspicuous lymph node and liver samples tested positive for cytokeratin 20, together with guanylyl cyclase, emphasizes the function of these two organs as primary filters for epithelial cells possibly shed from colorectal carcinomas (Conzelmann et al. 2003, 2005).

Fibrous Pseudocapsule of CRC Metastases

Parts of hepatic colorectal metastasis show a lamina of stromal tissue interposed between the tumor's periphery and adjacent liver parenchyma, termed a pseudocapsule (Yamamoto et al. 1995). Macroscopically, this pseudocapsule is sometimes visualized as a gray-white band or line, completely or incompletely surrounding the tumor nodule. Formation of a fibrous pseudocapsule is well known in various forms of hepatocellular carcinoma (HCC) and is a typical feature of one subset of small HCC. The incidence of a pseudocapsule in this tumor type varies considerably (in the literature ranging from less than 5–86 %), probably related to definitions used and subtypes of tumors studied. In non-small HCC, encapsulation has been reported to be associated with a less aggressive tumor biology and less frequent vascular invasion and tumor microsatellites (Ng et al. 1992). A fibrous pseudocapsule (FPC) has been noted in other epithelial and mesenchymal liver tumors, including various metastases. In liver metastases of CRC, an FPC can be observed in both small and large tumors (Yamamoto et al. 1995). At gross examination of fresh (unfixed) resection specimens, the FPC may be visualized as a whitish band of variable thickness, separating the tumor from the liver substance, and sometimes with retraction of liver parenchyma immediately outside the FPC. The retraction effect becomes more pronounced after fixation of the specimen and is probably caused by a rim of perifocal parenchymal atrophy, also recognized by flattening of the liver lobules in this area, associated with effacement of the terminal vein lumina and an elliptical shape of the lobules. In cases where the metastasis is located underneath the liver capsule, the FPC blends into the capsule, resulting in a thick encapsulation of the tumor where it may bulge from the surface (with or without umbilication). In deep-seated metastases, the FPC may either surround the entire lesion (complete FPC) or may only be present in certain sectors of the lesion (incomplete FPC). It has not been defined so far how much of a tumor circumference must show a fibrous interface to call this an FPC, but fibrous tissue between tumors and the liver substance was found in 67 % of surgically resected CRC liver metastases (Okano et al. 2000).

Histologically, the FPC varies markedly in relation to its thickness, geometry of separation from either the tumor or the adjacent liver, degree

of completeness, cellular composition, and amount of collagen layers. The FPC may present, on one end of the spectrum, as a thin layer of collagen, blending with the tumor's stroma, but usually distinguishable from stroma by the presence of delineated collagen bundles and the lower (myo)fibroblastic cellularity and lower content of glycosaminoglycans of the FPC in comparison with stroma. On the other end of the spectrum are thick pseudocapsules having ten or more layers of collagen bundles, rendering the FPC visible at naked eye examination. Based on the number of collagen bundles, a grading system has been proposed (none, no fibrous tissue observed; thin, tumor separated by several layers of collagen bundles; thick, tumor separated by ten or more layers of collagen bundles; Yamamoto et al. 1995; Okano et al. 2000). The cellularity of a given FPC is determined, on the one hand, by the amount of resident connective tissue cells (higher cellularity in "young" or active FPC vs. "old" and inactive, collagenized FPC) and on the other on the amount of infiltrate cells. Some FPC may contain lymphocytes, macrophages, and plasma cells in high densities, and the macrophage population may contain lipid-laden foam cells subsequent to phagocytosis of necrotic tumor cells and granulocytes. Often the peripheral half of the FPC, facing the adjacent liver parenchyma, exhibits a higher infiltrate density, with spillover of lymphocytes in the hepatocyte parenchyma, and collagenization seems to advance from the stromal compartment of the tumor toward the liver. Owing to the expansive growth of the metastasis, the FPC may be pushed to portal tracts, and these may then be integrated into the FPC, sometimes associated with ductular proliferations. Immunohistochemically, the (myo)fibroblastic cells located in the FPC are reactive for both vimentin and alpha-smooth muscle actin, supporting a myofibroblastic lineage.

Similar to HCCs, the presence of well-developed FPC in CRC liver metastases is a predictor of the post-resection outcome (Yamamoto et al. 1999). By a univariate analysis, the positive prognostic effect of a FPC was thickness dependent: a thicker (grade 3) pseudocapsule was associated with less frequent recurrence of disease and better patient survival. Interestingly, 63 % of patients with intra-bile ductal growth had a thick (grade 3) FPC, indicating that these features were common to a special subgroup with an excellent prognosis (Okano et al. 2000). The desmoplastic reaction surrounding CRC metastases was shown to favor tumor growth via alphaV integrin ligation (Conti et al. 2008).

Angiogenesis in CRC Metastases

Hepatic metastases are predominantly supplied by arterial blood, a finding having a strong impact on therapeutic measure such as arterial chemotherapy and chemoembolization (Breedis and Young 1954; Healey 1965; Ackerman 1974; Ridge et al. 1987; Archer and Gray 1989; Lin et al. 1984; Casillas et al. 1997; Liu and Matsui 2007). On the other hand, it has been emphasized numerous times that the portal vein contributes to the process of vascularization of metastases, either directly or through the sinusoids (Lin et al. 1984; Ackerman 1986; Haugeberg et al. 1988; Paku and Lapis 1993; Terayama et al. 1996; Kuruppu et al. 1997; Nikfarjam et al. 2003; Paku et al. 2005).

Similar to other malignancies, CRC metastases elicit a more or less vigorous angiogenic response in the tissue surrounding the tumor nodules. Histologically, angiogenesis is visualized as a dense network of small and in part sinusoid-like vessels in close spatial relationship with the stroma embedding the invasive cancer cells. Many newly formed blood vessels in and around CRC metastasis of the liver are lined with sinusoidal endothelial cells that differ from endothelia of larger vessels (Gervaz et al. 2000). These sinusoid-like channels can undergo capillarization (Terayama et al. 1996a). These endothelial cells may originate from endothelial progenitor cells located in the highly angiogenic tissue surrounding hepatic tumors (Yu et al. 2010). In and around metastases, angiogenesis is promoted by vascular endothelial growth factor/VEGF and E-selectin, but is suppressed by Netrin-4 and LK-68 (Xu et al. 2013). Angiogenesis driven by angiogenic factors may progress stepwise as a function

of enlarging metastatic nodules (Terayama et al. 1996b). An increase in number and density of microvessels is required for providing oxygen and nutrients to the growing tumor and is expected to exert an influence on progression and biology of disease. In human CRC liver metastases, a higher microvessel count was associated with decreased disease-free and overall survival (Nanashima et al. 2009).

In the rat, the liver lobule as homing area of circulating cancer cells shows arterioportal anastomoses and arterial terminations at the base of the lobule. These terminations supply one hepatic microcirculatory subunit per lobule, the so-called arterial hepatic microcirculatory subunit (aHMS). The sequence of ongoing arterialization of experimental metastasis includes the distortion of the aHMS by the growing metastatic nodule; the initial fusion of the sinusoids of the aHMS at the tumor-parenchyma interface; the fusion of sinusoids located at the base of the aHMS, leading to disruption of the vascular sphincter (burst pipe); the incorporation of the dilated artery and the fused sinusoids into the growing tumor; and the further development of the tumor vasculature (arterial tree) of metastasis larger than 2,000 μm by proliferation, remodeling, and continuous incorporation of fused sinusoids at the tumor-parenchyma interface. In this rat model, only half of the metastases of colon carcinoma were arterialized at the size of about 1,500 μm, but the arterialization process accelerates with increasing metastasis size (Dezsö et al. 2009). The size has also an impact on the number of arteries supplying a given nodule, in that smaller nodules were supplied by one artery branch, but acquired more branches as they became larger nodules (Ackerman 1974; Dezsö et al. 2009).

Immune Reactions in Primary CRCs and Their Liver Metastases

A relationship between local immune reactions, visualized as lymphocyte-rich intra- and peritumoral infiltrates, and survival advantage in primary CRC is well documented (Fig. 8). Patients with dense lymphocytic infiltration

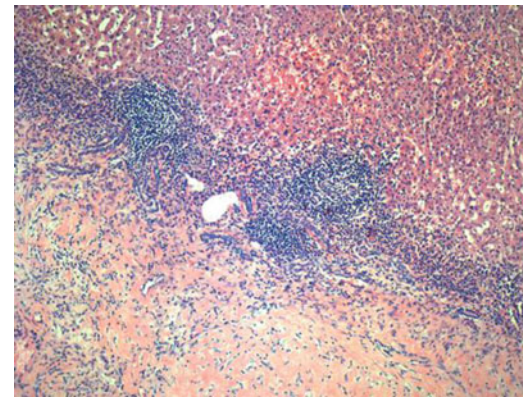

Fig. 8 Hepatic colorectal carcinoma metastasis with immune reaction. The metastatic nodule (*lower part of figure*) has undergone regression and fibrosis. At the tumor-liver interface, dense lymphocytic infiltrates with lymph follicles are found (hematoxylin and eosin stain)

(tumor-infiltrating lymphocytes) at the advancing margin of CRC have a favorable prognosis (Svennevig et al. 1984; Jass 1986; Ropponen et al. 1997).

In primary CRC, several pattern of lymphocyte-rich infiltrates can be distinguished. A rather common phenomenon is the presence of a discontinuous or, less often, a continuous band of lymphocytes located in the region of the advancing margin. Sometimes, this infiltration band is found between the epithelial front of the carcinoma and the adjacent liver, i.e., within the interposed stromal lamella. Here, the lymphocyte infiltrate may be admixed with plasma cells, macrophages, and granulocytes. In other cases, the lymphocytes predominate in the compartment of the invading carcinoma proper, i.e., intermingled with cancer cells and their intratumoral stroma. This phenomenon is only seen in viable-looking (chiefly peripheral) parts of the metastasis, whereas more deeply seated and often necrotic parts of the metastasis show few or no lymphocytes. Small lymphocytes are seen to infiltrate the epithelial formations themselves, whereby the lymphocytes are located between adjacent tumor cells and sometimes also in the lumina of tubular or cribriform structures. Foci of intraepithelial lymphocytes may be associated with tumor cell apoptosis, with formation of cell debris and typical, eosinophilic apoptotic bodies. Emperipolesis

of leukocytes may occur. In areas of dense intratumoral infiltrates, lymphocytes are observed within small tumor vessels, sometimes directly attached to the endothelium, probably representing effector cell homing. This phenomenon may also be noted within tumor stroma (particularly in the stroma interposed between the tumor front and the liver) and in hepatic sinusoids close to the invading tumor. Increased peritumoral lymphocytes and tumor-infiltrating lymphocytes are associated with tumor cell budding in primary CRC (Zlobec et al. 2007). Tumor-infiltrating lymphocytes are mainly T lymphocytes with cytotoxic activity directed against autologous tumor cells (Hom et al. 1993; Fossum et al. 1994). A further important class of T lymphocytes engaged in antitumor activity are regulatory T cells (Tregs) which accumulate within metastases. In CRC metastases, Tregs suppress the development and progression of these metastases through overcoming IL-17-producing T cells (Wang et al. 2014). Immunohistochemically, CD3+ and CD8+ small lymphocytes clearly prevail, and the intra-cancer and specifically intraepithelial infiltration is well demonstrable with these immunostains. The tumor-infiltrating T cells secrete cytokines in response to tumor stimulation in CRC (Diederichsen et al. 1999), and their antitumor effects may be mediated by this cytokine secretion. It has been shown that secretion of interleukin-4 and tumor necrosis factor-alpha by tumor-infiltrating lymphocytes in CRC confers improved survival (Barth et al. 1996). There are, however, also local factors that may blunt the antitumor T cell response. Reduced CD3-zeta chain, an important signaling component of the T cell receptor, is involved in incomplete cellular activation and antitumoral cytotoxicity of tumor-associated lymphocytes in CRC metastases (Yoong and Adams 1998). Another pathway for inhibiting lymphocyte-mediated antitumor immune responses is the induction of lymphocyte apoptosis and subsequent local lymphocyte depletion by tumor cells. Various cancer cell types have been shown to express Fas ligand (FasL) and to kill lymphoid cells by Fas-mediated apoptosis, thus causing apoptotic lymphocyte depletion within the Fas ligand-expressing tumors (Bennett et al. 1998). In CRC, expression of FasL was detected on the surface and within the cytoplasm of carcinoma cells in 61 % of the cases and was associated with apoptosis of tumor-infiltrating lymphocytes (Okada et al. 2000). Immunohistochemically, marked apoptotic death of T cells within the tumor is sometimes visualized in the form of CD3+ tiny apoptotic bodies or cellular debris or, in case of dense decaying infiltrates, a CD3+ granular material.

Apart from lymphocytes of several classes, macrophages are also present in hepatic CRC metastases, often located in the peripheral invasion front and/or in the stromal tissue surrounding the metastasis. Morphometric studies revealed that the macrophages are accumulated and activated in peritumoral regions of CRC metastases (Miyagawa et al. 2002). Parts of these macrophages home to the tumors as circulating monocytes and monocytoid cells. Hepatic macrophages mediate the adhesion of CRC cells to sinusoidal endothelial cells by cytokines (Gangopadhyay et al. 1998). A second population of CRC metastasis-associated macrophages is recruited from hepatic Kupffer cells (Meterissian et al. 1994; Paschos et al. 2010; Dent 2013; Wen et al. 2013). Kupffer cells are detectable in close spatial association as vimentin-positive spider-shaped cells (Wu et al. 1996) and play a role in arresting circulating tumor cells in hepatic sinusoids (Bayon et al. 1996). In an orthotopic murine model of CRC liver metastasis, it turned out that Kupffer cells have a bimodal role in determining tumor growth, in that these macrophages had an early inhibitory and late stimulating effect (Wen et al. 2013).

The survival advantage of pronounced lymphocytic infiltration in primary CRC is known for many years and has already been commented in 1931 (McCarthy 1931), and the phenomenon has since been reported several times (Zamcheck et al. 1975; Watt and House 1978; Thynne et al. 1980; Carlon et al. 1984; Svennevig et al. 1984; Jass 1986). In primary CRC, multivariate analysis showed that tumor-infiltrating lymphocytes were an independent prognostic factor of overall and recurrence-free survival in all cases ($N = 276$), as well as in patients with

T1-4N0-3M0 and T1-4N1-3M1 (Ropponen et al. 1997). Absence of CD8+ tumor-infiltrating lymphocytes was predictive of an adverse prognosis in patients with lymph node-negative, mismatch repair-proficient CRC (Zlobec et al. 2008). Similarly, CRC liver metastasis-associated lymphocytic infiltration is a significant prognostic factor for cancer-related survival after hepatectomy (Nagashima et al. 1999). Among 41 patients who underwent initial hepatic resection for hepatic CRC metastases, 44 % of the tumors showed a dense lymphocytic infiltration between the metastases and adjacent liver. Histologically, tumor invasion of the portal vein was rare in patients with dense infiltrates (12 %) compared with patients with weak infiltrates (36 %). Patients with dense lymphocytic infiltration phenotype exhibited a longer survival (Okano et al. 2003). There are, however, also studies failing to show a significant difference in survival between patients with conspicuous peritumoral infiltrate and those without it (Cianchi et al. 1997). An important role played by immune reactions is supported by the observation of rapid metastatic spread of CRCs following immunosuppression, e.g., due to solid organ transplantation (Lin et al. 2010). Although there is strong evidence that immune reactions located to CRC metastases have a protective effect, there are also findings that show a metastasis-promoting effect. For example, a host inflammatory response promotes liver metastasis through increasing intravascular tumor cell arrest and extravasation (Auguste et al. 2007).

Intraductal Growth of CRC Metastasis

Introduction

In primary liver cancers, intrabiliary invasion and growth are well-known growth patterns and have been documented for both hepatocellular carcinoma and cholangiocarcinoma (Lin et al. 1975; Kojiro et al. 1982; Yamamoto et al. 1997; Iyomasa et al. 1999; Suh et al. 2000; Nishio et al. 2002). The frequency of gross biliary tract invasion of hepatic colorectal cancer metastases is less frequently described in the literature, but the reported data depend on the demonstration of macroscopic vs. microscopic bile duct invasion. The phenomenon has been shown in one report to occur in about 10 % of surgically resected specimens (Okano et al. 1999), while other authors regard this pattern as rare (Tomizawa et al. 2003). In another investigation, 6 of 103 patients undergoing hepatectomy for colorectal liver metastases had macroscopic intrabiliary tumor growth (Sugiura et al. 2006). However, massive bile duct invasion by colorectal cancer metastases is much rarer. Intrabiliary cancer thrombi associated with biliary tract dilation is visualized by imaging techniques, including CT imaging (Okano et al. 2002). In one study, macroscopic intrabiliary tumors were detected pre- or intraoperatively by use of CT, ultrasonography, and intraoperative ultrasonography (Sugiura et al. 2006). Percutaneous transhepatic cholangiography reveled typical and circumscribed filling defects with the morphology of bulging masses (Sugiura et al. 2006). In case of involvement of the common bile duct or the confluence region by cancers, obstructive jaundice can be the leading sign (Thompson et al. 1993).

Selected References Herbut and Watson 1946; Nagler and Rochwarger 1977; Warshaw and Welch 1978; Gray et al. 1982; Sung et al. 1988; Riopel et al. 1997; Okano et al. 1999; Rullier et al. 1999; Povoski et al. 2000; Kubo et al. 2002; Tomizawa et al. 2003; Takamatsu et al. 2004; Uehara et al. 2004; Sugiura et al. 2006; Tokai et al. 2006; Estrella et al. 2013; Coppola et al. 2014; Peungjesada et al. 2013.

It has been proposed that intrabiliary extension of hepatic colorectal cancer metastases is associated with better prognosis (Okano et al. 1999; Kubo et al. 2002), but whether this is in fact a reproducible effect has to be investigated in systematic studies in more detail. For example, intraductal growth may be associated with an increased rate

of portal vein invasion (Sugiura et al. 2006), what will have an impact of prognosis.

Pathology

Macroscopy

The main features of the lesions have been compiled in a landmark article (Riopel et al. 1997). The intraductal component presents in one of several gross growth patterns, i.e., polypoid, papillary, and nodular patterns. The intraductal tumor is sometimes in direct contact with a mass of extraductal metastasis, but in part of the cases, only an intraductal tumor is seen macroscopically, closely resembling intraductal cholangiocarcinoma. In a study of 149 patients with first colorectal liver metastases, the 18 patients with gross intraductal extensions showed intraductal tumors measuring 4–42 mm in diameter (median: 17 mm; Okano et al. 1999). The duct stenosis caused by intraductal metastases can induce marked intrahepatic bile duct dilatation (Jhaveri et al. 2009). The wedge-shaped area seen on CT images in part of the cases was visualized as a well-demarcated dark red-brown region in the cut surface of resected specimens (Okano et al. 2002).

Grossly, intrabiliary manifestations of metastasis were described as prominent and soft papillary masses that extend into the intrahepatic ducts (Takamatsu et al. 2004). These lesions are usually more friable than intraparenchymal metastases and may show the morphology of a sessile polyp. They are usually more circumscribed than intraductal cholangiocarcinoma and commonly are not adhesive to the bile duct wall (Takamatsu et al. 2004). The cut surface of a fresh resection specimen may also show a whitish nodule of metastatic carcinoma within a large portal triad, bulging from the surface, sometimes misinterpreted as a satellite nodule (Riopel et al. 1997). In such a situation, intraductal growth is easily demonstratable by use of the points as small forceps that can be introduced between the tumor and the mucosal surface of the bile duct. Some metastases with intrabiliary growth show only a minimal invasion of adjacent liver parenchyma (Uehara et al. 2004).

Histopathology

Histopathological detection of intraductal growth of colorectal liver metastasis is much more frequent than the gross detection of this type of lesion. In one analysis, bile duct invasion was histologically observed in 42 % of 149 patients (Okano et al. 1999). A second study documented histological bile duct involvement of colorectal metastases even in 81 % of 151 patients, mostly intraepithelial ductal spread of CRC cells confirmed with CK7/CK20 immunohistochemistry (Wakai et al. 2011). Metastatic adenocarcinomas with intraductal growth may present both extraductal and intraductal manifestations, or be restricted to the intraductal space without evidence of extraductal disease. As in other intraluminally growing carcinomas, a papillary structure is common. Colorectal carcinoma invading intrahepatic bile ducts can show an exophytic, papillary growth resembling that of cholangiocarcinomas, but the cytologic features of the metastatic tumor differs from cholangiocarcinoma cells (Colagrande et al. 2004). Histologically, these villous growths may involve larger parts of the intrahepatic biliary tree, extending into peripheral branches distal to a bifurcation. The metastatic carcinoma may replace the epithelial lining of the invaded duct and extends along the epithelium (Tokai et al. 2006). In part of these cases, the intramucosal growth pattern closely resembled high-grade dysplasia or carcinoma in situ (Riopel et al. 1997). Intraductal metastases sometimes exhibit only minimal invasion of liver parenchyma (Uehara et al. 2004). In intramucosal or intraepithelial extension, carcinoma cells advance along the intact-looking basement membrane and replace the nonneoplastic biliary ductal epithelium. Interestingly, no intraepithelial extension advanced beyond the intraluminal extension, whereas in the proximal direction, the distance between the end of the macroscopical intraluminal extensions and intraepithelial extensions ranged

from 4 to 10 mm (Sugiura et al. 2006). The macroscopic friability of intraductal lesions of metastases is caused by poor stroma formation in contrast to intraparenchymatous metastatic foci. In contrast to intraductal cholangiocarcinoma, the transition between tumor cells and the nonneoplastic bile duct epithelium is abrupt (Takamatsu et al. 2004). Whereas extraductal metastatic tumor tissue usually reveals a marked stromal reaction, desmoplasia is mostly poor in the intraductal tumor part, but vascular stalks accompanied by stromal cells are sometimes noted.

Immunohistochemistry

CRC metastases to the liver generally reflect the immunophenotype of the primary colorectal lesions. In one patient with an intraductal colorectal metastasis, the tumor cells were CK7 negative but CK20 positive, supporting the immunophenotype of colorectal adenocarcinoma (Uehara et al. 2004; Kayashima et al. 2008; Seshadri and Majhi 2009; Wakai et al. 2011) and rendering cholangiocarcinoma much less likely (Tot 1999; Rullier et al. 2000). There are, however, certain differences in expression pattern between primary and secondary tumors. Claudin-1 and E-cadherin expressions were elevated in CRC metastatic lesions (Kinugasa et al. 2012).

Differential Diagnosis

Adenocarcinoma metastasis with intraductal growth closely mimics intrahepatic cholangiocarcinoma radiologically, macroscopically, and histologically (Riopel et al. 1997; Wenzel et al. 2003; Colagrande et al. 2004; Seshadri and Majhi 2009). Part of intraductally growing CRC metastases showed marked mucin production (Tokai et al. 2006), a feature that may suggest primary intraductal mucinous tumors. However, cholangiocarcinomas have cytological and nuclear features clearly different from those of metastatic adenocarcinomas, in particular colorectal tumors. On the other hand, intraductal papillary cholangiocarcinoma may be misinterpreted to be intraductal colorectal metastasis (Itatsu et al. 2007). In cases of doubt, immunohistochemistry will be helpful to distinguish the tumors in question, specifically cytokeratins 7 and 20.

Colorectal Liver Metastases in the Pediatric Age Group

Introduction

Colorectal carcinoma (CRC) is rare in children with an estimated incidence of one child per one million/year. CRC has been observed in children younger than 1 year of age (adenocarcinoma in a 9-month-old infant; Kern and White 1958). The first case was probably reported by Clar in 1885, who recorded a case of carcinoma of the colon in a 3-year-old boy (Clar 1885). The literature documents several series and case reports, amounting to more than 300 reported cases. Hoerner (1958) was able to collect 73 cases of carcinomas of the colon and 189 of carcinoma of the rectum occurring in individuals under 20 years of age and published between 1865 and 1958. A Japanese review published 1991 listed 41 Japanese cases reported in this country so far (Taguchi et al. 1991). In a study of 21 patients with CRC younger than 30 years of age, only 4 patients (19 %) were less than 20 years old (Shahrudin and Noori 1997). In a large series of patients (77 patients covering ages 7–19 years), 76 patients had one or more signs or symptoms of CRC, such as abdominal pain, altered bowel habits, weight loss, and anemia. However, pediatric CRCs seem to more often present with signs of obstruction. Johnston (1947) estimated that at least 70 % of cases in children present with intestinal obstruction. The reason for this clinical manifestation is thought to be the more rapid progression of CRC in children (Salem and Postlethwait 1960) and the higher risk that diagnosis is missed in comparison with adults, owing to the rarity of the lesion in the pediatric age group. The tumors were evenly distributed between the right and left colon. At presentation, 86 % of patients had advanced-stage

disease, and more than half had distant metastases (Hill et al. 2007). Pediatric CRC can also develop in the setting of ulcerative colitis (Wilcox and Beattie 1956).

Selected References Saner 1946; Scholefield 1946; Johnston 1947; Buchman and Calhoun 1958; Hoerner 1958; Salem and Postlethwait 1960; Donaldson et al. 1971; Rao et al. 1985; Koh and Johnson 1986; Lamego and Torloni 1989; Brown et al. 1992; Ameh and Nmadu 2000; Kravarusic et al. 2007; and Ferrari et al. 2008.

The histopathology of pediatric CRC differs from that in adults. Parts of the tumors are classical adenocarcinomas of the colorectal type, but mucinous or colloid carcinoma (Buchman and Calhoun 1958; Tandon et al. 1985; Brown et al. 1992; Redkar et al. 1993; Malik and Kamath 2011) and signet ring-cell carcinoma (Takai et al. 1988; Pandey et al. 2008) also occur, the mucinous variant being particularly common in several studies, amounting to 50 % (Hoerner 1958; Ladd and Grosfeld 2006). In adolescents, the tumor was a poorly differentiated adenocarcinoma in the majority of cases (Odone et al. 1982). In a study of 110 CRC patients from Japan younger than 20 years of age, there was a high incidence of poorly differentiated carcinoma (51.5 % for poorly differentiated adenocarcinoma, signet-ring-cell carcinoma, and undifferentiated carcinoma) and a high proportion of advanced stage at diagnosis (67.1 % for clinical stages IIIb and IV) (Yamamoto et al. 1996).

Liver Metastases in Pediatric Colorectal Carcinoma

CRC in younger individuals is an aggressive disease that often presents with high stage at diagnosis and has a poor survival. This distinct feature has already been documented in the old literature (Scholefield 1946; Hoerner 1958). Several cases of liver metastases in pediatric colorectal carcinoma have been reported (Ko et al. 1995; Karnak et al. 1999; Ameh and Nmadu 2000; Kam et al. 2004; Hill et al. 2007; Pandey et al. 2008). Due to the small number of cases observed in children, it is currently not known whether the propensity to metastasize to the liver is similar to or different from CRCs of the adult age group, but CRC in young individuals is rapidly progressive, with a high rate of recurrence, both local and remote. In adolescents, the natural history of CRC was found to be characterized with extensive disease at diagnosis and unresponsiveness to medical management. In a study of 24 adolescent patients, this was reflected in an 8-month median survival from diagnosis (Odone et al. 1982). In a Turkish study on 20 patients, all presented with advanced stages of disease. Peritoneum was the most common site of extensive intraabdominal disease, followed by omentum majus and liver (Karnak et al. 1999). An investigation from Taiwan (28 patients 20 years old or less) demonstrated that proportion of mucinous adenocarcinoma was higher than that in the older population and that most cases were advanced at diagnosis (Dukes stages C or D), with an overall survival rate of only 21 % (Chen et al. 2001). In a study of Argentina, patients with CRC of the group covering 0–20 years of age revealed a high-risk group in comparison with older patients, in that this group had significantly more advanced disease and poorer prognosis (Chantada et al. 2005). In a subset of patients with CRC younger than 18 years, six out of seven had tumor progression or relapse, and five died of their tumor (Ferrari et al. 2008).

Abstract

Apart from the common colorectal carcinoma (CRC) metastases, malignancies that relatively often metastasize to the liver include small cell carcinoma of the lung, breast cancers, thyroid carcinoma of various types, gastric cancer, malignant melanoma of the skin and eye, and cancers of the genitourinary tract. In addition to the type, anatomic location, and local stage of a malignancy, its differentiation grade markedly influences propensity to metastasize to the liver. As in CRC, molecular and in particular genomic features will in the future be important means to predict metastatic disease. There is a large group of malignancies that metastasize to the liver less commonly than CRC and the cancers listed above. They mainly comprise squamous cell carcinoma of the skin and mucous membranes, ovarian carcinomas, and salivary gland tumors. Almost any type of sarcoma can metastasize to the liver, but hepatic sarcoma metastasis is generally less common than that of carcinomas. Very rarely, meningeal tumors and neoplasms of the central nervous system (CNS) produce liver metastases, sometimes via a shunt. A challenging group of hepatic metastases are those without, or not yet, identifiable primary tumor (cancer of unknown primary location, CUPL).

Common Hepatic Metastases of Non-sarcomatous Malignancies other than CRC

Non-CRC carcinomas that typically metastasize to the liver, sometimes in a massive manner, include small cell carcinoma of the lung, breast cancer, thyroid cancer of various types, gastric cancer, malignant melanoma of the skin, uveal melanoma, and cancers of the genitourinary tract (Figs. 1 and 2). Carcinoma of the prostate can metastasize more often than previously thought (Pouessel et al. 2007). It is still very difficult to estimate which primary tumors will be prone to produce metastases. For example, analysis of a series of recurrent breast cancers uncovered that

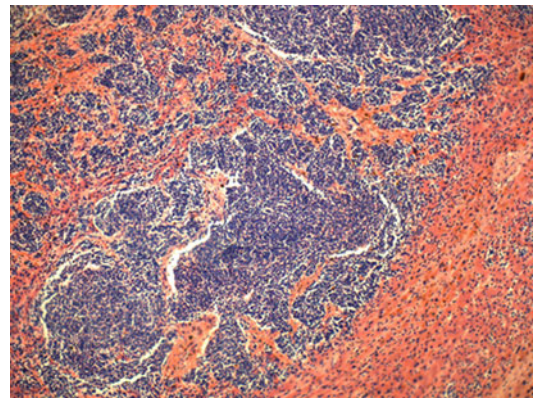

Fig. 1 Liver metastasis of bronchial small cell carcinoma (hematoxylin and eosin stain)

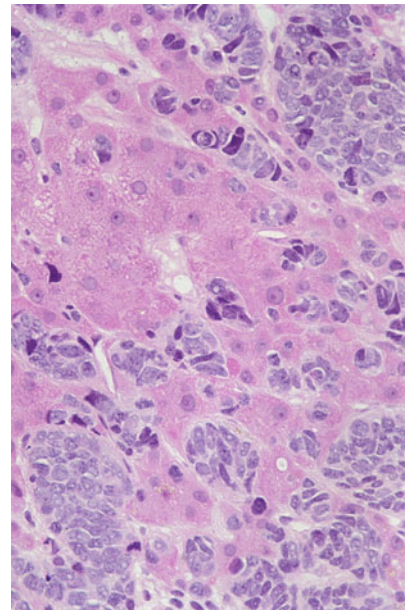

Fig. 2 Intrasinusoidal metastatic spread of bronchial small cell carcinoma (hematoxylin and eosin stain)

the presence of liver metastases was not associated with patient age, menopausal status, size of primary tumor, regional lymph node status, or the length of the recurrence-free interval, but patients with liver metastases were significantly closer to menopause than those without (Kamby et al. 1987). The propensity to metastasize to the liver is often dependent on the differentiation grade of the neoplasms in question. For example, anaplastic thyroid carcinomas were found to have

metastasized in 20 % of patients, whereas hepatic metastases of differentiated carcinomas of the thyroid are an uncommon event. A well known of malignancies metastasizing to the liver is neuroendocrine tumors, mainly originating from the gastrointestinal tract and the pancreas, whereby midgut carcinoid tumors are a particularly important example of metastasizing neoplasms. Although the appendix is an important location of carcinoids, it only rarely gives rise to hepatic metastases. Similarly, rectal carcinoids less than 2 cm in diameter rarely metastasize to the liver (Que et al. 1995; Chamberlain et al. 2000). Hepatic metastases of carcinoids and islet cell tumors are usually multiple, of varying size, and bilobar in the majority of cases (Chamberlain et al. 2000; Ihse et al. 2001). It is of interest to note that not only established types of cancers have different propensities to metastasize to the liver but that also subtypes differ in their hepatotropism. For example, ductal carcinoma of the breast more frequently metastasizes to the liver than its lobular counterpart (Fondrinier et al. 1997).

Similar to CRC metastases, several types of hepatic metastases can elicit intrahepatic complications, such as biliary obstruction due to extrinsic compression or direct invasion of bile ducts (Papo et al. 1996; Enomoto et al. 2006). Metastases other than CRC can also invade large hepatic venous branches, including multifocal intraportal invasion (Nakajima et al. 2005).

Epithelial Tumors that Less Often or Rarely Metastasize to the Liver

Skin Carcinomas

Basal cell carcinoma of the skin (basalioma) is a very common invasive neoplasm that however rarely metastasizes, with a metastasis rate of 1 in 1,000–35,000 patients (von Domarus and Stevens 1984). The most common sites of metastasis are the lungs, followed by the bone, lymph nodes, liver, and spleen (Farmer and Helwig 1980; Di Lernia et al. 2013). Hepatic metastasis can develop more than 20 years after primary therapy of the skin tumor (Postlethwaite et al. 1990). Squamous cell carcinomas primary to the skin or mucous membranes have a low metastatic potential, but can give rise to hepatic metastases (Warren and Hoerr 1939; Swanbeck and Hillstrom 1969; Lazarus et al. 1980; Chaux et al. 2011). Merkel cell carcinoma of the skin metastasizes to the liver (Sharma et al. 1991; Gollub et al. 1996).

Salivary Gland Tumors

Certain types of salivary gland tumors are well recognized to metastasize to distant organs. The likelihood of remote metastases is associated with high-grade neoplasms, including adenoid cystic carcinoma, salivary duct carcinoma, high-grade mucoepidermoid carcinoma, and tumors located in the submandibular gland, posterior tongue, and pharynx (Schwentner et al. 2006). Adenoid cystic carcinoma is the most common type of salivary gland tumors that gives rise to liver metastasis, and hepatic metastatic disease may be the initial presentation of this tumor (Spolverato et al. 2014). Exceptionally, also low-grade salivary gland mucoepidermoid carcinoma metastasized to the liver (Herd et al. 2012). Rarely, pleomorphic salivary gland adenoma, mostly of the parotid gland, can metastasize to the liver, even in the absence of histologic signs of malignancy, sometimes with a delay of many years (Youngs and Scheuer 1973; Olsha and Gottschalk-Sabag 1995; Singhal et al. 2010; Abou-Foul et al. 2014).

Ovarian Carcinomas

Parenchymal liver metastases of epithelial ovarian malignancies are relatively rare, ranging in frequency from 4 % to 9.4 % of patients (Dauplat et al. 1987; Loizzi et al. 2005; Lim et al. 2009; Alvarado-Cabrero et al. 2013). More often, subcapsular liver metastases of ovarian carcinomas are found (Triller et al. 1985). In contrast to liver parenchyma, the biliary tract was involved with metastases in 15 % of patients (Alvarado-Cabrero et al. 2013).

Carcinomas of Endocrine Glands

Carcinomas of the pituitary gland are rare, but well-known causes of liver metastasis, whereby ACTH-and prolactin-producing neoplasms prevail (Lormeau et al. 1997; Arias et al. 2000; Suzuki et al. 2002; van der Klaauw et al. 2009). Relatively rarely, adrenocortical carcinomas metastasize to the liver (Gaujoux et al. 2012), sometimes with a delay of more than 10 years after primary diagnosis and therapy (Maywardi et al. 2012). The uncommon parathyroid carcinomas are also known to produce hepatic metastases (Albertini et al. 1953).

Hepatic Metastases in the Pediatric Age Group

As outlined above, certain cancers occurring in adults, such as CRC, can also produce liver metastases in children. In addition, several types of malignancies that preferentially develop in infants and children frequently produce hepatic metastatic disease. These neoplasms mainly include neuroblastoma, Primitive neuroectodermal tumors (PNETs) nephroblastoma, cellular blue tumors of various types, pediatric soft tissue and bone sarcomas, and lymphomas. Also malignancies originating in the pediatric liver can cause intrahepatic metastases, including hepatoblastoma, pediatric hepatocellular carcinoma, and undifferentiated embryonal sarcoma. The prevalence of the diverse tumor types varies somewhat from one investigation to the other. In a study of 15 patients undergoing hepatic metastasectomy, seven patients had neuroblastoma, three Wilms' tumor, two osteogenic sarcoma, one GIT carcinoma, and two desmoplastic small round cell tumor (Su et al. 2007).

Hepatic Metastases of Sarcomas and Other Mesenchymal Tumors

Almost any type of sarcoma has been found to metastasize to the liver, but generally, sarcoma metastases are less common than those of carcinomas. The most common primary sites for hepatic sarcoma metastases are soft tissues and the gastrointestinal tract (GIT) (Hafner et al. 1995; Jaques et al. 1995; Lang et al. 2000; Rehders et al. 2009; Chua et al. 2011; Zacherl et al. 2011). Sarcomas with a relatively high incidence of hepatic metastases include malignant gastrointestinal stromal tumor and leiomyosarcoma of the gastrointestinal and genital tracts and of soft tissues (Merimsky et al. 1999; Lang et al. 2000), liposarcomas (Pisters and Sondack 2002; Estourgie et al. 2002), and angiosarcoma (Tateishi et al. 2003). In a series of 331 patients with sarcoma metastatic to the liver, 68 % had intra-abdominal sarcoma; 14 % retroperitoneal, 9 % extremity/trunk, and 9 % head/neck lesions; and 61 % gastrointestinal stromal tumor or GIT leiomyosarcoma (DeMatteo et al. 2001). Among 981 patients with soft tissue sarcoma, 65 patients showed hepatic metastases, and 61 of them had an intra-abdominal primary site, 85 % of the neoplasms being high-grade leiomyosarcomas (Jaques et al. 1995). The gross metastatic patterns vary markedly, in part depending on the type of sarcoma involved. In a study of 45 patients with soft tissue sarcoma metastasis to the liver, 59 % had a solitary metastasis, 22 % had two metastases, and 18 % had three or more metastatic nodules (Rehders et al. 2009).

Granulosa cell tumors of the ovaries have a certain tendency to metastasize to the liver, sometimes with cystic changes of the lesions (Margolin et al. 1985; Neste et al. 1996; Ali 1998; Madhuri et al. 2010). Metastases of malignant melanoma are discussed in a separate chapter.

Rare and Unusual Hepatic Metastases Produced by Intracranial and Intraspinal Tumors

Introduction

Apart from diverse types of carcinomas and sarcomas known or expected to metastasize to the liver, there are diagnostically difficult situations of neoplasms of the intracranial and intraspinal

compartments sometimes giving rise to liver metastases. Interestingly, part of these neoplasms is regarded as benign or low-grade malignant in their primary site, to later behave as highly malignant cancers as soon as they have produced metastatic disease. As such neoplasms are not extensively treated in many texts, and give rise to differential diagnostic problems, pertinent examples of these lesions are therefore discussed in more detail in the following paragraphs.

Meningioma Metastatic to the Liver

Meningiomas account for about 15–20 % of all primary CNS tumors and present with a complex spectrum of histologic phenotypes that have been defined in the WHO tumor classification (Louis et al. 2007a, b). Meningiomas usually grow in an expansive, space-occupying manner, but invasive growth is also known for certain types of this tumor. The prevalence of a malignant histology of meningiomas ranges from 2 % to 10 %. Invasive meningiomas can invade the bone, venous sinuses, brain, soft tissues of the scalp, and paranasal sinuses. In contrast, metastatic spread to remote organs is a rare event in meningiomas and is estimated to be less than 1 in 1,000 patients with meningioma (Enam et al. 1996). The most common metastatic site is the lung (60 % of cases), followed by the abdomen and liver (34 %), cervical lymph nodes (18 %), skeletal long bones, pelvis and skull (11 %), pleura (9 %), vertebrae (7 %), CNS (7 %), and mediastinum (5 %) (Kepes 1982; Bondy and Ligon 1996).

Only relatively few cases of meningiomas metastatic to the liver have been reported. The range of histologies includes meningothelial meningioma (Ku et al. 2005), fibroplastic meningioma (Ishibashi et al. 1983; Cerda-Nicolas et al. 2003; Rampurwala et al. 2011), atypical meningioma (Asqhar et al. 2009), transitional meningioma (Figueroa et al. 1999), rhabdoid meningioma (Wang et al. 2011), or anaplastic meningioma (Garcia-Conde et al. 2009; Lambertz et al. 2011). Rhabdoid meningioma (Perry et al. 1998; Matyia et al. 2010) and anaplastic meningioma are highly aggressive malignant neoplasms with a prominent tendency for invasion and metastatic spread. In histologically benign variants, liver metastasis may occur after a long delay, e.g., 31 years in a case of fibroplastic meningioma (Rampurwala et al. 2011).

A variety of factors have been associated with metastatic spread of meningioma. The estimation of factors favoring extracranial metastasis is complicated by the fact that metastasis is rare, with usually single cases being reported, and that histologic types and meningioma grading have been revised several times in recent years (review: Figueroa et al. 1999). What are the potential pathways of spread for an intracranial meningioma to reach the liver? Tumor may spread through the venous system of the sinuses or tumor veins. Penetration of the dura mater of venous sinuses favors the invasion of neoplastic cells into the jugular venous system and then the pulmonary venous system, the system of the vena azygos and hemiazygos, and vertebral venous plexuses (Shimanskii et al. 2011). A very rare pathway involves the spread of meningioma cells via a ventriculoperitoneal shunt, with seeding to the liver and subsequent growth of implantation metastases. In one case, a 61-year-old woman was diagnosed with intracranial atypical meningioma which twice recurred 2 and 4 years after the first resection. The recurrent tumors were resected and a ventriculoperitoneal shunt was installed. At age 68 years, the patient had developed a liver metastasis of meningioma, situated in segments 4 and 5 and measuring 8.3 cm in diameter (Moir et al. 2010).

Meningeal Hemangiopericytoma Metastatic to the Liver

Meningeal hemangiopericytoma (MHPC; hemangiopericytomatous meningioma) was formerly regarded as a form of angioplastic meningioma, but has been shown to be a neoplasm that clearly differs from meningiomas in both its histologic phenotype and its biology. The neoplasm accounts for about 1 % of all primary intracranial tumors. In a series of 44 cases, the average age of the patients

at diagnosis was 42 years, and 55 % of these tumors occurred in men (Guthrie et al. 1989).

MHPC is an aggressive tumor which, in its biological behavior, is clearly different from true meningiomas. In the study of Guthrie et al. (1989), the average time before the first recurrence was 47 months, with the recurrence rates at 1, 5, and 10 years after primary surgery being 15 %, 65 %, and 76 %, respectively. The 10- and 15-year rates of metastasis were 33 % and 64 %, respectively. MHPC has a marked tendency for local invasion, including skull bones, and for multiple metastatic progressions. Distant metastases may occur several years after initial treatment (Chang et al. 2004; Shi et al. 2009). Similar to other hemangiopericytomas, MHPC may be associated with paraneoplastic hypoglycemia. Histologically, the tumor is characterized by marked cellularity, vascularity, and dense net of reticulin fibers. Cells are medium-sized or large, in part spindled cells with large nuclei and often rather sparse cytoplasm. These cells form nests and fascicles, but also may be arranged as proliferating elements around endothelium-lined vascular channels with a staghorn pattern (Fabiani et al. 1980; Kochanek et al. 1986). MHPC is either grade II or grade III lesion. Immunohistochemically, MHPC lacks strong expression of cytokeratins, while vimentin is at least focally positive (Moss 1987; Chang et al. 2004). In one study, focal CAM 5.2 expression was noted in 26 % of MHPC (Rajaram et al. 2004). MHPC is strongly positive for CD99 and Bcl-2, and all cases showed individual cell factor XIIIa reactivity (Rajaram et al. 2004). Typically – and in contrast to meningothelial meningioma – MHPCs are negative for diffuse epithelial membrane antigen (EMA) expression, and also expression of S100 protein is not detectable (Chang et al. 2004; Sundaram et al. 2010). However, MHPC cells can show focal EMA positivity, and a minor EMA reactivity does therefore not preclude a diagnosis of this tumor (Rajaram et al. 2004).

Several reports have documented the occurrence of liver metastases of MHPC. Liver metastases can develop with a long delay after primary diagnosis, e.g., 9 years (Soares et al. 2003). Also MHPC metastasizing to the liver can be associated with hypoglycemia (Ferguson and Flinn 1995; Nabeya et al. 1998; Miyamoto et al. 2004), in one case with high blood levels of an abnormal form of insulin-like growth factor type 2/IGFII (Grunenberger et al. 1999).

Selected References Chakravarty et al. 1991; Kaneko et al. 1993; Ferguson and Flinn 1995; Nabeya et al. 1998; Davies et al. 1999; Grunenberger et al. 1999; Soares et al. 2003; Chang et al. 2004; Miyamoto et al. 2004; Spatola and Privitera 2004.

Glioblastoma

Extracranial metastases of glioblastoma are very rare, with a reported frequency of only 0.44 %. The predominant metastatic sites are the locoregional lymph nodes, lungs and pleura, and skeletal system (review: Pasquier et al. 1980). Glioblastoma can invade blood vessels and is capable to produce extracranial hematogenous metastases, also to the liver (Leifer et al. 1989; Shuto et al. 1995; Widjaja et al. 2000; Saad et al. 2007; Piccirilli et al. 2008; Robert and Wastie 2008; Schönsteiner et al. 2011). Liver metastases may be multiple and sometimes very large (Robert and Wastie 2008). It has been proposed that metastasis to the liver may occur via vascular anastomoses between the vertebral and portal venous systems (Shuto et al. 1995).

Several reports have demonstrated the spread of intracranial glioblastoma to the peritoneal cavity through a ventriculoperitoneal shunt. Shunt-mediated tumor seeding can result in multiple, sometimes coalescent implants or large proliferating tumor masses that compromise adjacent abdominal organs and the omentum (Newton et al. 1992a; Fecteau et al. 1998; Kumar et al. 1999). Peritoneal glioblastoma implants can involve the liver and induce hepatic metastases (Kayama et al. 1981).

The transmission of donor-related malignancies by solid organ transplantation is a well-known, albeit rare, event. In a study of 342 donor hepatectomies, 13 cases had primary cerebral neoplasia. Among these, four were glioblastoma. Recurrent malignancy related to CNS neoplasia was observed once. The donor of the liver had undergone surgical resection of an intracerebral multiform glioblastoma and died from tumor relapse. The female recipient of the liver developed, 4 months after transplantation, intraperitoneal and intrahepatic masses identified as glioblastoma metastases (Jonas et al. 1996). In a retrospective review of 1,173 liver transplants performed between 1992 and 2006, 42 donors with a CNS tumor were identified. Thirty-two CNS tumors were malignant (20 of them had glioblastoma multiforme) and 10 tumors were benign. The rate of recurrence for the entire group was 2.4 % (all CNS tumors; Kashyap et al. 2009).

Malignant Astrocytoma

High-grade astrocytoma is known to sometimes metastasize to extracranial remote sites (LoRusso et al. 1988). Very few examples of malignant (non-glioblastomatous) astrocytomas metastatic to the liver in the absence of a shunt have been published (Schuster et al. 1976; Pasquier et al. 1980).

Similar to glioblastoma, grade III astrocytoma can spread via ventriculoperitoneal shunts, producing peritoneal seeding (Declercq et al. 1992). The intraperitoneal implants may form a tumor ascites with numerous suspended, GFAP-positive tumor cells (Wakabayashi et al. 1985).

Pilomyxoid Astrocytoma

Pilomyxoid astrocytoma of the spinal cord was found to spread to the peritoneal cavity through a ventriculoperitoneal shunt, producing widespread peritoneal gliomatosis and confirming the sometimes aggressive biology of this neoplasm (Arulrajah and Huisman 2008).

Oligodendroglioma and Oligoastrocytoma

According to the WHO classification of brain tumors, oligodendroglial tumors are separated into oligodendrogliomas WHO grade II, anaplastic oligodendrogliomas WHO grade II, oligoastrocytomas WHO grade II, anaplastic oligoastrocytomas WHO grade II, and glioblastomas with an oligodendroglioma component WHO grade IV. These neoplasms have distinct molecular features (review: Hartmann and von Deimling 2009). Oligodendroglial tumors of higher grade rarely cause metastatic disease (James and Pagel 1951; Jellinger et al. 1969; review: Zustovich et al. 2008). Few cases of oligodendroglioma liver metastases have been observed (Spataro and Sacks 1968; Macdonald et al. 1989; Uzuka et al. 2007; Yokosuka et al. 2007; Han et al. 2008), mostly with an anaplastic histology. Massive peritoneal metastasis of pediatric oligodendroglioma was noted in one patient after ventriculoperitoneal shunting (Becker et al. 1978).

Ependymoma

Ependymomas rarely metastasize outside the central nervous system. Among 81 ependymomas evaluated in the Memorial Sloan-Kettering Cancer Center between 1956 and 1989, five (6.2 %) had extraneural metastases. Two of the tumors were anaplastic and three histologically benign. Metastatic sites included the lung, thoracic lymph nodes, pleura, peritoneum, and liver (Newton et al. 1992b). Metastasis of ependymoma may occur with impressive timely delay. In one case, liver and lung metastases were diagnosed 40 years after primary diagnosis of cerebral ependymoma (Graf et al. 1999). Peritoneal seeding of high-grade ependymoma (ependymoblastoma) via ventriculoperitoneal shunt has been described (Shibasaki et al. 1977) and may result in liver metastasis (Kayama et al. 1981).

Ependymoma can also occur in the ovaries and metastasize to the liver (Fan et al. 2006). There are few anecdotal reports of primary extraneural "ectopic" ependymomas. These lesions were

mostly localized close to the neural axis, i.e., sacrococcygeal region, posterior mediastinum, or ovaries. One single case of apparently primary hepatic ependymoma has been reported, a tumor detected in 41-year-old female without any evidence of a CNS primary tumor (Wiendl et al. 2003).

Gliosarcoma

Gliosarcoma is a rare primary CNS neoplasm characterized by a biphasic pattern consisting of glioblastoma and fibrosarcomatous and/or MFH-like components. Gliosarcomas have a temporal lobe predilection and infrequently show EGFR mutations (Sreenan and Prayson 1997; Han et al. 2010). Gliosarcoma may arise in oligodendroglial tumors (oligosarcoma; Rodriguez et al. 2007). Gliosarcoma has a strong propensity for hematogenous metastasis, sometimes with intravascular gliomatosis. Metastasis to the liver has been demonstrated (Smith et al. 1969; Yokoyama et al. 1985; Matsuyama et al. 1989; Beaumont et al. 2007).

Intracranial Germinoma

Intracranial germ cell tumors form a distinct group of neoplasms that predominantly develop in the suprasellar and pineal regions. The major types comprise germinoma, teratomas, yolk sac tumor, embyronal carcinoma, and choriocarcinoma (Matsutani et al. 1997). The rarest type in these locations is pure embryonal carcinoma (Maruki et al. 2000). The histologic typing of intracranial germ cell tumors is sometimes difficult owing to the fact of internal heterogeneity of the neoplasms. For example, suprasellar embryonal carcinoma was found to undergo differentiation into yolk sac tumor and choriocarcinoma (Wang et al. 1995), and embryonal carcinoma of the pineal gland can undergo yolk sac differentiation (Iwanowski et al. 1997).

Intracranial germinomas are usually located to the pineal gland region. These neoplasms often carry a good prognosis owing to their radiosensitivity. Recurrence is rare, but few patients may develop neural and extraneural metastases, including arachnoid, dural and extradural spaces, spines, skin, lymph nodes, heart, lungs, adrenal, kidneys, pancreas, and liver (Motomochi et al. 1980; Adachi et al. 1991). In one young male patient, suprasellar germinoma metastasizing to the liver contained syncytiotrophoblastic giant cells and was associated with elevated serum chorionic gonadotropin levels (Adachi et al. 1991). Metastasis in the sense of peritoneal implants can occur via ventriculoperitoneal shunt, in part of the cases showing infiltration of the omentum and displacement of the liver (Triolo and Schulz 1980; Haimovic et al. 1981; Kun et al. 1981; Devkota et al. 1984; Talamo and Mendelow 1985; Pallini et al. 1991; Blasco et al. 1993; Ung et al. 1993; Wong et al. 1996; Uchino et al. 1999; Altundag et al. 2002). In the intraperitoneal implant metastases, differentiation of the tumor may change, reflecting the differentiation plasticity of germ cell tumors. In a male patient who had pineal germinoma, the tumor spreads to the peritoneal cavity via shunt where it changed into yolk sac tumor, with formation of a large liver tumor (Uchino et al. 1999). Transformation of germinoma into yolk sac tumor in intraperitoneal implants was detected in another patient (Back et al. 1997). In another case, pineal germinoma transformed into a mixed germ cell tumor with teratoma components in the large intraperitoneal tumor that was located close to the shunt tip (Saibara et al. 1991). In a 10-year-old patient, teratocarcinoma of the pineal gland region which had spread to the abdominal cavity through a ventriculoperitoneal shunt had transformed into pure germinoma (Iwamuro et al. 2002).

Intracranial Yolk Sac Tumor

Intracranial yolk sac tumors typically occupy either the suprasellar region or the pineal gland. These malignancies can spread to the peritoneal cavity through ventriculoperitoneal shunts (Wilson et al. 1979; Bamberg et al. 1984; Kimura et al. 1984).

Intracranial Choriocarcinoma

Parts of germinomas have been shown to contain syncytiotrophoblastic cells (Adachi et al. 1991), but choriocarcinoma sensu stricto is a very uncommon intracranial malignancy. Suprasellar choriocarcinoma was described in a 19-year-old male patient, causing the patient's death. Autopsy revealed remote metastases in the skin, lungs, kidney, intestine, and liver (Shinmura et al. 1983).

Intracranial Teratocarcinoma

Cerebral teratocarcinoma of a young adult patient metastasized to the abdominal cavity via a ventriculoperitoneal shunt, resulting in a massive abdominal tumor (Rickert et al. 1998).

Pineoblastoma (Pinealoblastoma)

Pineoblastoma is the main member of the pineal parenchymal tumor group, which comprises a spectrum of lesions ranging from pineocytoma of intermediate differentiation pineal parenchymal tumor to the less-differentiated pineoblastoma (Lutterbach et al. 2002; Han et al. 2011). Pineoblastomas, which represent the most aggressive of pineal parenchymal tumors (Tate et al. 2011), occur in the pediatric age group, but also form a distinct group of adult tumors. In adults, the median age at diagnosis was 36 years, and in one series all patients presented with hydrocephalus (Chang et al. 1995). Osseous metastases from primary central nervous system tumors are rather rare, except for medulloblastoma and glioblastoma, and also pineoblastoma is well known to metastasize to the skeletal system (Jacobs and Rosenberg 1989; Fraser et al. 2000; Charafe-Jauffret et al. 2001; Constantine et al. 2005). Peritoneal seeding can occur via ventriculoperitoneal shunt, characterized by peritoneal implants and sometimes large intra-abdominal tumor masses (Pfletschinger et al. 1986; Cranston et al. 1992; Gururangan et al. 1994). Tumor-induced ascites may develop (Cranston et al. 1992).

Choroid Plexus Carcinoma

Peritoneal dissemination via a ventriculoperitoneal shunt has been observed in pediatric choroid plexus carcinoma, causing death with widespread metastasis (Donovan and Prauner 2005).

Medulloblastoma

Medulloblastoma is an aggressive and mostly infratentorial tumor that is known to produce extracranial metastases, mostly to the skeletal system (in particular pelvis, femur, and vertebrae; Kleinman et al. 1981; Rickert 2003). Also in adult with medulloblastoma, bones are the predominant metastatic site (Rochkind et al. 1991). Systemic metastases occurred earlier in patients with ventriculoperitoneal shunts (Kleinman et al. 1981). In a series of 103 patients, eight developed extra-CNS metastases (7.7 %). In one of these eight patients, metastasis was located to the liver (Kochbati et al. 2006). But in an autopsy study, liver metastases hold the third place in frequency (28 %) after bone metastases (82 %) and lymph node metastases (65 %) (Kleinman et al. 1981). In a comparison of pediatric and adult cases of medulloblastoma, liver metastases were more frequent in children (15 %), while adults had more often lung metastases (Rochkind et al. 1991). Medulloblastoma can spread to the abdominal cavity via ventriculoperitoneal shunts (Makeever and King 1966; Hoffman et al. 1976; Oemus et al. 1992; Jamjoom et al. 1993; Carrasco Torrents et al. 2001; Magtibay et al. 2003; Loiacono et al. 2006).

Atypical Teratoid/Rhabdoid Tumor

Atypical teratoid/rhabdoid tumors (AT/RT) of the CNS are rare and extremely aggressive malignancies. These tumors usually occur in early childhood, but adult cases are also known (Lutterbach et al. 2001). AT/RT can spread to the peritoneal cavity through ventriculoperitoneal shunts (Ingold et al. 2009).

Chordoma

Chordoma, a tumor derived from notochordal remnants, occurs mostly in patients in the fifth to seventh decade and is an aggressively growing tumor causing metastatic disease in up to 30 % of cases. Liver metastases of intracranial chordoma are, however, rare (Ashwood et al. 1994; Chopra et al. 2010). The same holds true for liver metastasis of sacrococcygeal chordoma of adults (Raguin et al. 1987; Tavernaraki et al. 2003). Also sacrococcygeal chordoma of childhood has been shown to sometimes have an aggressive course with generalized metastases, including the liver, and histologically with predominance of "pink" cells over physaliform cells (Shinmura et al. 2003). In childhood, subsets of sacrococcygeal chordomas are highly proliferative lesions with nuclear atypia, classified as either dedifferentiated chordoma with anaplastic histology or atypical chordoma with sarcomatoid appearance (Iwasa et al. 1998). It has been reported that also adult cases of sacrococcygeal chordomas can undergo an aggressive course, associated with a change in differentiation to sarcomas with variable cell lineages, including fibrosarcoma or osteosarcoma (dedifferentiated chordoma).

Apparently Locally Growing Neoplastic Lesions Metastasizing to the Liver

There are few examples of apparently reactive, or locally growing, lesions that metastasize to the liver. One of these unusual lesions is aneurysmal bone cyst. Aneurysmal bone cysts (ABCs) account for 1–2 % of all primary bone tumors and are predominantly diagnosed in the first two decades of life. Histologically, ABCs consist of blood-filled spaces lined by a cellular tissue composed of densely packed spindle cells and numerous multinucleated giant cells. Giant cells in ABCs express an osteoclast-like phenotype and are formed from CD14+ macrophage precursors, while CD14- mononuclear stromal cells express osteoclastogenic factors and interact with CD14+ cells to form osteoclast-like giant cells by a RANKL-dependent mechanism (Taylor et al. 2012). ABCs are rapidly growing and locally aggressive/recurrent lesions that have been regarded as reactive processes. However, subsequent cytogenetic and molecular studies revealed a neoplastic basis of at least part of ABCs by the demonstration of clonal chromosome band 17p13/16q22 translocations that place the USP6 (TRE2 or TRE17) oncogene under the regulatory influence of the active CDH11/osteoblast cadherin 11 gene promoter (Oliveira et al. 2004). Metastasizing ABC was detected in a 48-year-old woman with a giant ABC of the left ilium. The patient died 2 years after diagnosis, and at autopsy, metastases of ABC were found in both lungs, both kidneys, and the liver. There was no evidence for telangiectatic osteosarcoma having developed from ABC (van de Luijtgaarden et al. 2009).

Liver Metastases from Cancer of Unknown Primary Site/Location (CUPL)

Introduction

In part of patients with liver metastasis, even detailed clinical investigations will not elucidate their origin. This situation is termed liver metastases from cancer of unknown primary site or location (CUPL; synonyms, hepatic metastases from an unknown primary neoplasm, UPN). CUPL is the hepatic manifestation of CUP (cancer of unknown primary origin). CUP is usually defined as histologically proven malignancy for which the primary site could not be found after anamnesis, complete physical examination, imaging, and routine chemistries. CUPL is a diagnostic challenge in clinical practice even in the face of the advanced diagnostic technologies currently available (Mousseau et al. 1991; Hogan et al. 2002; Pouessel et al. 2005; Shaw

et al. 2007). This also generally holds true for CUP as a group (reviews: Gaber et al. 1983; Perchalski et al. 1992).

Epidemiology

Cancer of unknown primary origin (CUP; synonyms, neoplasms of an unknown primary site (NUPS); metastasis of unknown origin (MUO); metastases of undetermined source) is estimated to account for 2–10 % of all malignant neoplasms at presentation (Fizazi 2006). About 2 % of more than one million cases of cancer diagnosed in residents of SEER areas for the 15-year period 1973–1987 were designated as being CUP (Muir 1995). By reviewing 1,656 autopsies performed on adults, 43 cases of NUPS were found (Mayordomo et al. 1993). In a review of 9,436 consecutive autopsies performed between 1984 and 1999 at the Mayo Clinic and matched with 177,167 cancer patients treated in the same time period, there were 64 patients who died of CUP. Autopsy located the primary site in 35 patients (55 %; Blaszyk et al. 2003). Also another study showed that primary sites could be identified by autopsy in 51 % of cases (Al-Brahim et al. 2005), but it is seen that roughly half of the cases remain MUO even after necropsy. In a large retrospective study, 3.7 % of all referrals to the cancer center were CUP. The three most common CUP subgroups were CUPL (25 %), CUP-bone (21 %), and CUP-brain (16 %). The remaining subgroups occurred at frequencies of less than 10 % each (Shaw et al. 2007). Generally, patients with CUP show an unfavorable biology of disease, however, with markedly variable data concerning survival time (Pimiento et al. 2007). The median survival for all 1,000 consecutive CUP patients analyzed at the Anderson Cancer Center in Houston was 11 months (Hess et al. 1999), while for 1,285 patients from the Netherlands, the median survival was only 11 weeks, and only 15 % of the CUP patients were still alive 1 year after diagnosis (van der Wouw et al. 2002). There may be subsets of "unfavorable" CUP that may profit from targeted treatments based on molecular profiling (Amela et al. 2012).

CUPL Histology at the Time Point of Diagnosis

Clinicopathologic and morphologic approaches to classify metastatic neoplasms in regard to the primary site have been worked out and reviewed (Marchevsky et al. 2010). In a group of 100 CUPL patients from a single French center, 66 had adenocarcinoma, 19 undifferentiated carcinoma, and 11 squamous cell carcinoma in their hepatic metastases (Culine et al. 1998). Another study of 88 patients included adenocarcinoma in 70, neuroendocrine in 4, squamous cell carcinoma in 4, small cell carcinoma in 4, and some rarer types (Hogan et al. 2002). Among 118 patients with CUPL, the most frequent histologic types observed were adenocarcinoma, undifferentiated, neuroendocrine, and squamous cell carcinomas. In a retrospective study of 49 CUPL patients, the commonest histologic types encountered were adenocarcinoma ($N = 34$) and undifferentiated carcinoma ($N = 12$). In 38 % of cases, the liver was the only metastatic site (Lazaridis et al. 2008). Adenocarcinomas were the most frequent type of carcinoma in a series of 1539 CUP (Altman and Cadman 1986), and poorly differentiated carcinomas and poorly differentiated adenocarcinomas may account for roughly a third of all CUP cancers (Lenzi et al. 1997). These results illustrate what is generally known from liver metastases, i.e., that adenocarcinomas are the most common metastatic tumors, mainly caused by the high incidence of metastasizing tumors of the gastrointestinal tract and the breast. This has led to the concept of adenocarcinoma of unknown primary site (ACUPS; Moertel 1979; Markman 1982; Hamilton and Langlands 1987). A synonym of this term is unknown primary adenocarcinoma or UPA (Speel et al. 2008). In the group of CUP, ACUPS is a dominant histology, accounting to 42.8 % of all cases in one investigation (Pimiento et al. 2007). Among patients with ACUPS, the

most common sites of metastases were the lymph nodes, liver, lung, and bone in order. In 60.5 % of patients, the dominant tumor location was below the diaphragm (Song et al. 2002). Patients having their major sites of disease above the diaphragm experienced a significantly longer survival than patients whose disease was below the diaphragm (Markman 1982).

Clinical Features and Biology of Disease of CUPL

For patients with CUP, strategies to be followed in order to arrive at diagnosis and identification of the primary site have been standardized in sets of guidelines (Bugat et al. 2003; Lesimple et al. 2003). According to general views, CUPL are not expected to present in a manner different from that of other hepatic metastases. Liver metastases from unknown primary site are often multiple and often hypervascular on MRI images, whereas solitary metastases are more often hypovascular (Braga et al. 2003). However, novel concepts suggest that at least part of tumors that present as CUP or CUPL differs in their biology and molecular features from other malignancies with a similar or the same histologic type. Overall, patients with CUPL have a dismal prognosis (Ayoub et al. 1998). Among 47 patients who had received first-line chemotherapy (42 platinum-based), only six showed an objective response, and median survival was 10 months (Lazaridis et al. 2008). In a study on 107 patients who had received at least a front-line of chemotherapy (74 platinum-based), the overall response rate was 19.4 %, and the overall median survival was 6.6 months (Pouessel et al. 2005). CUPL patients with adenocarcinoma seem to carry a particularly dismal prognosis (Hogan et al. 2002).

Assignment of Primary Tumors: The Significance of Histopathology and Immunohistochemistry

As at least a subset of patients with CUPL may profit from chemotherapies, attempts should be undertaken to identify the primary site by the use of optimal histological classification and immunohistochemistry (review: Krishna 2010). In the course of histologic evaluation, it is good practice to first allocate the CUPL case in question to one of the major tumor categories, as in any diagnostic approach, i.e., carcinoma vs. sarcoma vs. melanoma vs. neuroendocrine vs. hemolymphatic vs. others (Oien 2009). For carcinomas, and in particular adenocarcinomas, experience will often allow to suspect or even reliably identify colorectal carcinoma or breast carcinomas. Conversely, the presence of squamous cell carcinoma will not permit the identification of the primary site, owing to the similarity of all squamous cell tumors in any locations they occur. In case of undifferentiated tumors, distinct marker panels applied to biopsies may identify small cell carcinoma vs. poorly differentiated adenocarcinoma, PNET, and other anaplastic tumors (van der Gaast et al. 1996). For fine-needle aspiration cytology approaches, a panel including CK5/6, CK7, CK20, CA125, thyroid transcription factor 1/TTF-1, and CDX2 was proposed (Onofre et al. 2007). For colorectal carcinoma metastases, the CK20+/CK7- pattern showed a specificity of 98.7 % in predicting colorectal primary localization, superior to that of CDX2 expression (Tot and Samii 2003; Tot 2004). In contrast, the CK7+/CK20- phenotype favors a lung primary adenocarcinoma (Rubin et al. 2001). In addition to immunohistochemical analysis, molecular approaches for the identification of tissue of origin can successfully be employed (review: Monzon and Koen 2010). Established methods include gene expression profiling and several commercially available molecular test systems, e.g., including Theros CancerTYPE ID, Pathwork tissue-of-origin test, miRview mets, CupPrint, and CUP assay.

Molecular Assignment of Origin in CUPL

Gene expression profiling methods (multiple expression signatures) were shown to accurately assign CUP to a primary tissue of origin (Bloom

et al. 2004; Ismael et al. 2006; Staub et al. 2010). cDNA- and oligonucleotide-based classifiers accurately predicted the known primary site of origin for an independent set of metastatic lesions (Bloom et al. 2004). Classifiers trained on combined expression data from both normal tissue data sets were able to predict the site of origin in a cohort of 652 primary tumors with approximately 90 % accuracy (Staub et al. 2010). In a systematic literature review, it was found that molecular assignment may not predict response to therapy and outcome, suggesting that CUP may harbor molecular traits distinct from tumors of known primary sites (Pentheroudakis et al. 2009).

Pathogenesis

Apart from CUP cases where the primary tumor could not be identified due to diagnostic difficulties or limitations, CUP tumors may tend to present in this distinct manner owing to inherent biologic characteristics (review: van de Wouw et al. 2003). It was suggested that CUP tumors may show a clonal relationship between multiple tumors within individual CUP patients. A molecular resemblance would argue for an early clonal outgrowth of tumor cells from the primary neoplasm, a mutual feature observed within this group of neoplasms (Speel et al. 2008). By the use of genomic hybridization, it was found that primary tumors and multiple metastases sampled at autopsy of CUP patients are clonally related, independent of the anatomical origin of the cancer. The findings suggest that tumor progression is particularly rapid in CUP patients, limiting the chance of clonal divergence (Speel et al. 2008).

Abstract

Hepatic metastases undergo several types of secondary changes. Part of these alterations is mainly observed in tumor progression, when neoplasms increase in size and are subject to decreasing vascular supply and oxygenation. Large and rapidly growing hepatic metastases typically show necrosis. This necrosis is commonly of the coagulation type and is, in the absence of chemotherapy, caused by tumor hypoxia. Hypoxic necrosis mainly involves central parts of a metastatic nodule, while blood circulation in peripheral parts is preserved. Usual necrosis can also be induced by chemotherapy, which in addition can elicit infarct-like necrosis. Necrotic tumor tissue often undergoes dystrophic calcification. Rupture of tumor blood vessels in necrotic areas may result in massive hemorrhage, and involvement of adjacent bile ducts induces bile impregnation of necrotic areas. Large necrosis may undergo sequestration, can burst, or become infected by circulating or ascending bacteria. Infection of necrotic tissue may result in large collections of pus and, in case of infection with gas-producing microorganisms, show pneumatic lesions. In necrotic metastases, anaerobic bacteria can elicit hepatic necrobacillosis. A rare secondary alteration of metastases is spontaneous regression, known for several types of tumors.

Necrosis and Infarction of Hepatic Metastases

Introduction

Large and rapidly growing hepatic metastases typically undergo necrosis, sometimes extensive, causing characteristic secondary phenomena with an impact on clinic-radiological diagnosis and changing the biology of the metastasis. In diagnostic surgical pathology, necrosis of metastases is a difficult challenge, because it may be very demanding to answer the question as to whether viable tumor still exists in a given metastatic nodule. Approaches to solve this question are discussed in a separate chapter.

Necrosis of hepatic metastases, and specifically of carcinoma metastases, presents as one of several patterns, which reflect the dynamics of necrosis and secondary phenomena modifying the necrosis' morphology.

Coagulation Necrosis (So-Called Usual Necrosis or Dirty Necrosis)

Coagulation necrosis of a carcinoma metastasis is the most common phenotype. In the absence of chemotherapy, it is caused by hypoxia and thus reflects the morphology of other ischemic necroses (Figs. 1, 2, 3, and 4). Macroscopically, the center of a metastatic nodule is occupied by a whitish to "dirty-looking" mass with a finely granular texture on cut surfaces. When cutting through this mass, artifacts may occur, e.g., slit-like spaces caused by shearing forces in a tissue with a markedly reduced coherence or the falling off of entire

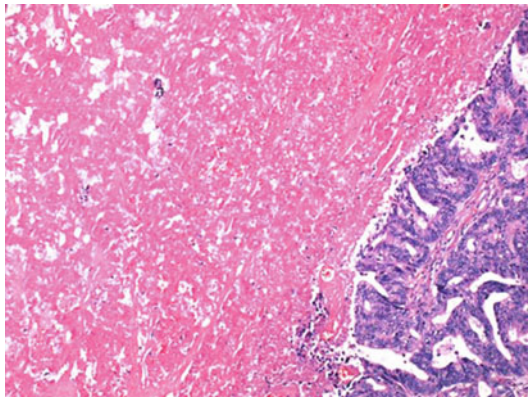

Fig. 2 Massive necrosis of colorectal carcinoma metastasis of the liver. The original structure of adenocarcinoma is still seen in the form of shadow tumor cells (hematoxylin and eosin stain)

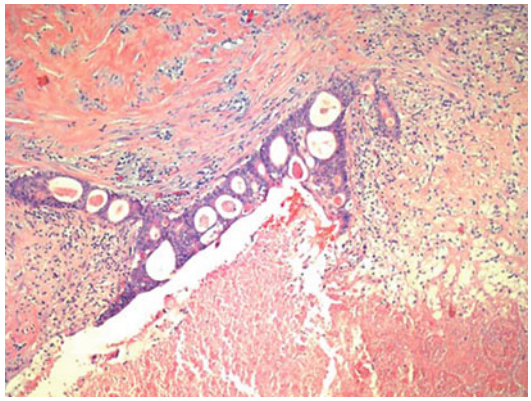

Fig. 3 Extensive necrosis of hepatic colorectal carcinoma metastasis. Note that the tumor stroma remains intact (left upper corner; hematoxylin and eosin stain)

tumor fragments following cutting. Greasy masses are typically left on the knife's blade. The transition between the necrosis and viable tumor tissue at the nodules periphery is often abrupt. In some tumors, the color of the necrotic area deviates from the common whitish tinge, e.g., being yellowish or pink or blackish in the case of malignant melanoma. Coagulation necrosis causes a reduction in tissue mass. This is best seen in necrotic nodules situated in the subcapsular area of the liver. Necrosis in such nodules typically causes the development of depressed central zone or dimple, called umbilication. The center of this tumor umbilicus is often pale or

yellowish, caused by the necrotic area which is here very close to the capsular surface.

Histologically, coagulation necrosis is characterized by an eosinophilic acellular mass with densely packed granular structures representing ghost cells and cytoplasmic debris. Nuclear debris are often seen in the form of basophilic dots clearly smaller than nuclei. As reticulin fibers resist decay within a necrotic tissue for longer time periods, a reticulin stain will be of great diagnostic help, because it usually depicts the original reticulin network and often still shows the shape and size of the necrotic tumor cells and their characteristic arrangement and relation to stroma. In case of doubt, it is therefore strongly recommended to perform such stains.

Liquefactive Necrosis

In a minority of necrotic metastases, the necrotic tissue mass undergoes liquefaction, causing the accumulation of a turbid fluid with suspended necrotic fragments in the core of metastasis. The pathogenesis of liquefactive necrosis is not yet fully known, but the action of proteolytic enzymes generated by tumor cells and/or leukocytes was suggested.

Necrosis of Metastases Following Chemotherapy

There are two general patterns of necrosis present in hepatectomy specimens with colorectal metastases preceded by perioperative chemotherapy – one type representing the so-called "dirty" or usual necrosis and the other type consisting of larger zonal areas of necrosis with surrounding fibrosis, designated infarct-like necrosis. In the latter, a rim of fibrotic tissue with numerous foamy macrophages is present. In a systematic study, infarct-like necrosis was significantly associated with perioperative chemotherapy and was associated with improved disease-free survival compared with metastases having usual or coagulative necrosis (Chang et al. 2012). Colorectal liver metastases may contract centripetally as a response to chemotherapy. Central necrosis was prominent in untreated metastases but disappeared after chemotherapy, where discrete islands of viable tumor cells outside of the main tumor mass can be seen. The shrinkage of central necrosis subsequent to chemotherapy can be followed by central tumor fibrosis (Ng et al. 2008).

Hemorrhage of Necrosis

The rupture of necrotic blood vessels within the metastasis can cause extensive bleeding (La Fianza et al. 1999). Several patterns of intrametastatic and intranecrotic hemorrhage can be distinguished. In part of the tumors, several foci of hemorrhage develop, causing roundish bloody spots on the cut surface. Histologically, these hemorrhages are situated around intranecrotic blood vessels having undergone rupture and identified in connective tissue stains. A second pattern is characterized by larger hemorrhages that may dissect the necrotic tissue, with isolation of individual necrotic areas. In a third situation, the entire necrotic area is imbibed with blood, causing a morphology mimicking a hematoma. After lysis, a central blood clot may remain. A fourth pattern shows liquefaction and lysis of hemorrhage, with accumulation of a reddish liquid in the center of the necrosis.

Calcification of Necrosis

In part of necrotic metastases, calcifications are found within the necrotic masses. This alteration is discussed in more detail below.

Mummification of Necrosis ("Putty Necrosis")

In rare cases of complete necrosis of a metastasis with no remaining viable tumor cells, the necrotic tissue may undergo marked shrinking with progressive loss of tissue fluid. This process, which may be associated with calcification, results in roundish mass of sticky material grossly resembling putty used for windows ("putty necrosis"). This phenomenon is better known from the caseiform coagulation necrosis occurring in tuberculosis.

Mucin-Rich Necroses

In hepatic metastases of colloid carcinomas characterized by a very high amount of mucin, mucin will remain within necrotic areas following decay of viable tumor tissue (Fig. 5). These mucin masses of "mucin lakes" are situated within the extracellular space of necrosis and present as amphophilic or slightly basophilic, thready or

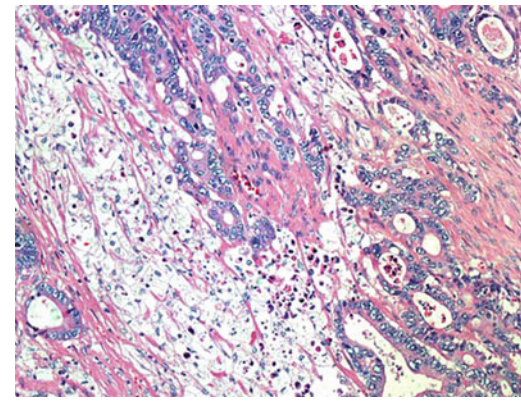

Fig. 5 Hepatic colorectal carcinoma metastasis with necrosis and release of mucinous matter (hematoxylin and eosin stain)

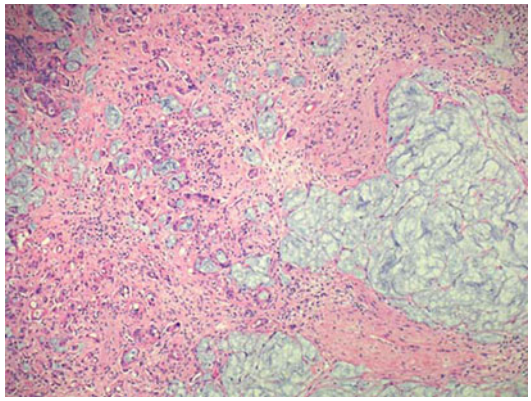

Fig. 6 Hepatic metastasis of mucin-rich adenocarcinoma. Leakage of tumor mucus has caused so-called mucin lakes, characterized by large amounts of extracellular mucin accumulating in stroma and liver tissue (right half of figure; hematoxylin and eosin stain)

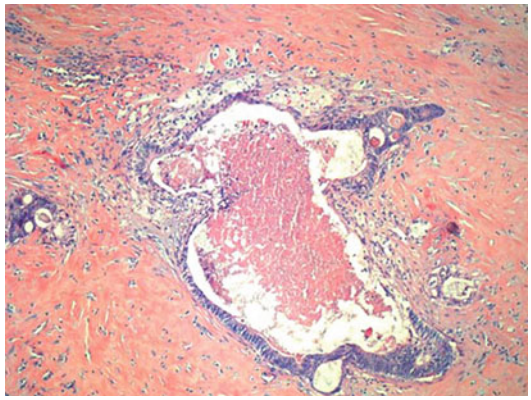

Fig. 7 Liver metastasis of colorectal carcinoma. The dilated tubular structure is focally surrounded by clear cells (upper aspect of tubule) representing mucophage nests (hematoxylin and eosin stain)

clumpy, striated masses in an eosinophilic and granular background. Mucin stains (PAS, alkaline acian blue) will clearly show the mucin material, which is often intermingled with dead tumor cells and connective tissue fiber fragments of the preexisting stroma. In bursting necrotic metastases, the mucin masses may spill over into adjacent liver tissue and cause mucinous tissue dissection associated with the accumulation of mucophages and even mucus granulomas with foreign body-type giant cells (Figs. 6, 7, and 8).

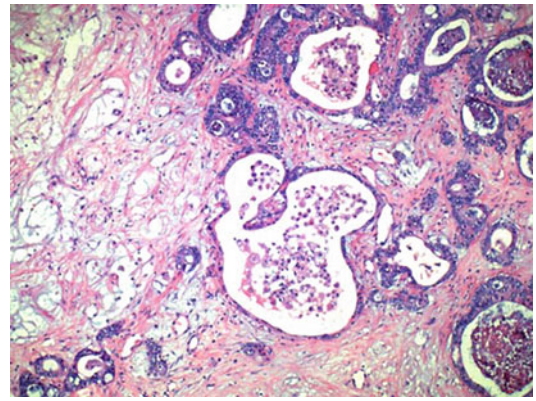

Fig. 8 Liver metastasis of mucin-producing carcinoma with intratubular accumulation of mucophages (hematoxylin and eosin stain)

Bile Impregnation of Necrotic Metastases

In case a necrotic metastasis encroaches upon intrahepatic bile ducts or invades such a duct, bile leaks may ensue, causing bile to infiltrate the necrotic mass. Histology shows small deposits of brightly yellow bile admixed with the necrotic tissue, sometimes with bile accumulations situated within slit-like spaces probably represented original perivascular spaces.

Mural Nodules and Other Signs of Cancer Regrowth After Necrosis

In some markedly necrotic liver metastases, marginal nodules of viable tumor tissue are noted. These nodules are situated at the border of metastases and, like satellite nodules, seem to grow from the original peripheral part of the metastasis into the adjacent liver substance. It is suggested that this pattern of apparent regrowth may be related to the emergence of favorably neovascularized zones, where angiogenesis at the tumor border has taken place as a response to tumor damage. In some metastases with necrosis, regrowth can be found deep within the necrotic area itself. In these instances, careful search will almost always reveal the presence of new blood vessels that have sprouted into the area concerned,

and among which surviving, dormant cancer cells have started to proliferate again. In cases where granulation tissue is interposed between the periphery of a necrotic metastasis and the liver, a similar phenomenon may be encountered, characterized by growth of carcinoma in close relationship with the granulation tissue's vascular compartment.

Bursting Metastasis and Liver Rupture

Hepatic metastases with rapid growth and extensive necrosis may burst, associated with laceration of the liver capsule, organ rupture, and sometimes massive bleeding. Postnecrotic rupture of liver metastasis can develop with several types of metastasizing cancers, but it predominantly occurs in tumors known to have a tendency for necrosis and rupture, including small cell carcinomas, colorectal carcinoma, renal cell carcinoma, choriocarcinoma, and squamous cell carcinoma (Mittleman 1987; Murakami et al. 2000; Tung et al. 2002; Gulati et al. 2009; Duan et al. 2014). Delayed hepatic rupture after radiofrequency ablation for colorectal hepatic metastasis was observed (Chang et al. 2014).

Sequestration of Necrotic Metastasis

In older and large necroses of metastases of long duration and poor vascularization, the necrotic tissue mass may undergo contraction, with detachment of the necrotic core from a peripheral rim of variable thickness, resulting in a more or less spherical sequester of necrotic tissue separated from the remaining nodule by a circular slit-like space. At macroscopic examination, this sequester may easily be removed from the nodule following cutting through the metastasis.

Infection of Tumor Necrosis

The necrotic tissue of tumors, including hepatic metastases, is a favorable substratum for the growth of diverse bacteria and fungi, due to the availability of low-molecular-weight energy sources and large amounts of proteins. Thus, necrotic metastases may become infected, the type of infection being strongly influenced by the oxygenation and the iron resources of the tissue. Expectedly, large necroses with poor oxygenation will favor the replication of anaerobes. Growth of bacteria within necroses is easily detectable in H&E-stained sections already, due to the characteristic regular and invariant morphology of bacteria and fungi in comparison with the irregular nuclear debris. Gram and fungus stains will help to identify the microorganisms involved. In case bacterial growth takes place in peripheral parts of the necrosis, i.e., closer to still perfused tumor vessels, the chemotactic and chemokinetic activity of bacteria will cause granulocyte immigration. This may lead to suppuration of the necrotic metastasis, typically starting in the mantle zone of metastasis, eventually followed by liquefaction of necrotic tissue through granulocyte proteases (the "suppurative liquefaction" or in German "puriforme Erweichung" of older pathology texts). Histolysis caused by bacterial or fungal infection may cause bursting of metastasis, invasion into adjacent structures, or even fistulation.

Immune Reactions Directed Against Necrotic Tumor Tissue

In the devascularized tissue composing the center of necrosis, no cellular infiltrate suggesting a cellular reaction of the host is found, except nuclear debris of neutrophil granulocytes. In contrast, variable degrees of leukocytic infiltrations are regularly found around necrotic metastases. These infiltrates consist mostly of T lymphocytes, both of the CD4+ and CD8+ classes, usually, however, with a predominance of the latter. Relatively few B lymphocytes are noted, while plasma cells may be encountered in larger numbers. These immune cells either form small collections of cells in the liver tissue surrounding the metastasis, with some of the cells scattered within the tumor tissue itself, or form a band-like infiltrate following to peripheral contour of the tumor. Macrophages and

eosinophil granulocytes are often seen in these infiltrates. There is no obvious difference in the type and density of these infiltrates between metastases with extensive vs. minor necrosis. However, for some colorectal metastases with extensive necroses and particularly those where the necrotic tumor tissue reaches near the intact adjacent liver tissue, a macrophage reaction may be more prominent, sometimes with an epithelioid cell component, suggesting a cell-bound immune reaction directed against tumor-associated antigens released in the course of necrosis. In few hepatic carcinoma metastases, the formation of granulation tissue starting to organize the necrotic mass is seen.

Calcification of Hepatic Metastases

Introduction

Hepatic metastases of carcinomas (mainly adenocarcinomas), neuroendocrine tumors, and some other epithelial neoplasms are known to undergo calcification (mineralization). This type of calcification in metastases is of the dystrophic type and has to be distinguished from calcium salts making part of osteoid, representing apatite and found in the liver, e.g., in metastasizing osteosarcoma. These calcifications are often visualized on radiographic images (Green and Stephens 1971; Easson et al. 1996; Hale et al. 1998) and are apparently not clearly related to the type of underlying histology. However, calcified hepatic metastases are most often found in colorectal carcinoma (CRC), especially the mucinous variety (Stoupis et al. 1998). It is estimated that calcification occurs in 12–28 % of hepatic CRC metastases (Wells 1956; Appleby and Hacking 1958; Karras and Cannon 1960; Green and Stephens 1971; Takahashi et al. 1971; Franca et al. 1978; Bernardino 1979; Rubaltelli et al. 1983; Ferrozzi and Rossi 1991; Easson et al. 1996; Hale et al. 1998). In a retrospective analysis of patients with CRC, 11 % had calcified liver metastases at presentation and 4 % developed calcification during chemotherapy (Hale et al. 1998). Other malignancies that have been reported to show calcifications in their liver metastases comprise lung carcinoma, breast cancer, stomach carcinoma, renal cell carcinoma, carcinoma of the prostate, medullary thyroid carcinoma, and neuroblastoma. In medullary carcinoma of the thyroid, calcifications are typically seen in primary tumors and are often encountered in lymph node and liver metastases (McDonnell et al. 1986). In a retrospective study of 230, CT analyses of hepatic masses yielded 28 cases (12.2 %) which contained calcifications. Calcifications were found in 15.3 % with hepatocellular carcinoma, 18.3 % with CRC metastases, 2.8 % with non-colonic liver metastases, and 11 % with a benign liver mass (Scatarige et al. 1983). Calcifications of hepatic CRC metastases sometimes occur in the course of systemic chemotherapy or hepatic infusion chemotherapy (Rubaltelli et al. 1983; Aoki et al. 1987; Hale et al. 1998).

Pathology

In most cases where calcifications are seen at histologic examination, this change is not visible at gross examination. In case of marked calcification, cut surfaces of tumors, and in particular CRC metastases, show single or clustered, gray-white to cream-colored speckles within necrotic areas of the tumor. In fixed specimens, the necrosis sometimes displays fissures or slits as artifacts where macroscopic deposits of calcifications are seen. Rarely, the amount of granular calcium salt deposits is such that the cut surface of the tumor is gritty, and the deposits are felt when cutting through the metastasis. In part of the lesions, coalescent calcium-containing deposits develop, with the formation of firm or even "stony" conglomerates. However, dry calcified necroses ("chalky necroses") as seen in tuberculomas do not develop in calcified metastases. Exceptionally, the entire metastasis appears as a stone-hard lesion. Calcifications may follow the branches of tumor vessels. In some CRC metastases, calcifications are predominantly localized at the interface between central necrotic tumor tissue and the peripheral viable parts of the tumor.

Histologically, calcifications of metastases present with several patterns. The most frequent morphology is that of multiple to numerous basophilic calcium salt deposits localized within necrotic tumor areas. These deposits may show an internal gradient of basophilia, depending on the age of the lesions and the local concentration of calcium salts. The deposits stain black in the von Kossa stain. In some of the lesion, a faint PAS positivity is seen in the deposits, caused by the accumulation of glycoproteins serving as the calcification matrix or the deposition of remnant mucin components of the tumor. A second type of calcification is characterized by sickle-shaped basophilic calcifications seen in peripheral parts of the tumor. In a third type, large conglomerates of dense calcium-containing deposits are present, without necrosis or tumor. This is an end stage of extensive dystrophic calcification, and the tissue samples may require decalcification prior to sectioning and staining. Within these larger deposits, ossification with osteoid and mature lamellar bone may develop (osseous metaplasia; metaplastic ossification; orthoplastic calcification), sometimes even with hematopoietic bone marrow. A fourth type of calcification is characterized by calcium salt deposits along the tumor vascular tree, mainly along the adventitia of tumor arteries.

In some reports it was claimed that the mucinous type of CRC was more often associated with calcification of hepatic metastases. This view was not confirmed in other investigations. In a group of 31 patients with calcified metastases, calcification occurred independent of the degree of tumor differentiation, the presence of mucinous adenocarcinoma, or the hepatic tumor burden (Easson et al. 1996). In a study of 22 cases of calcified hepatic CRC metastases, there was no correlation between calcification and the pathologic subtype of primary CRCs (Xu et al. 2010).

Differential Diagnosis

The main differential diagnoses comprise primary hepatic tumors that are well known to mineralize, including hepatocellular carcinoma, fibrolamellar carcinoma, cholangiocarcinoma, and liver cell adenoma. In liver cell adenomas, calcifications may be solitary or multiple and are commonly located eccentrically. Calcifications in cholangiocarcinomas are seen in around 18 % of CT images and are typically associated with a marked desmoplastic reaction. In fibrolamellar carcinomas, calcifications are detectable in 15–25 % of cases (Stoupis et al. 1998). Less common situations comprise calcified mixed tumors and primary osteosarcomas of the liver. Hepatic hemangiomas, especially large ones (giant hemangiomas) may contain large and coarse calcifications that are usually centrally placed, within the tumor's fibrotic core. These calcifications are seen on CT images in about 20 % of cases. Multifocal hepatic calcifications have been reported in epithelioid hemangioendothelioma (den Bakker et al. 1998).

Biological Significance of Calcifications in Hepatic Metastases

There are few data regarding the eventual impact of metastasis calcification on tumor biology and prognosis. In a retrospective study, the survival of patients with calcified hepatic CRC metastases was compared with those without calcification. The two groups were comparable with respect to sex, age, time to calcification, time to metastasis, and treatment type. The presence of calcification had a statistically significant improvement in survival, independent of other variables (Easson et al. 1996).

Pathogenesis

It has been proposed that calcification in metastases arises through a double mechanism: primary, characterized by calcified osteoid formation (orthoplastic calcification), and secondary as a result of necrosis and other regressive changes (dystrophic calcification) or through calcification of mucoid material or tumor amyloid. Mucins produced by adenocarcinomas appear to trap calcium salts (Habighorst 1963). Part of cases

showing calcification in metastases has been observed during local or systemic chemotherapy (Rubaltelli et al. 1983; Hale et al. 1998). As the extent of calcifications in metastases of colorectal cancer changes under chemotherapy (Hale et al. 1998), it may be assumed that the increasing mass of necrotic tissue acting as a calcium salt sink is involved in this phenomenon. On the other hand, calcification of tumor metastases may represent inherent features related to distinct metabolic characteristics of the neoplastic cell lineage. For example, it was found that recurrent tumors following lumpectomy of hepatic CRC metastases develop calcification and that calcification in newly developing tumor masses was similar to that of their primary counterparts (Xu et al. 2010).

Hepatic Metastases Complicated by Liver Abscesses, Puriform Liquefaction, and Pneumatic Tumors

Abscess Formation

Hepatic metastases can undergo necrosis followed by suppuration and abscess formation. Abscess formation within or around tumors has also been seen in primary hepatic tumors (Yu et al. 2007). Pure abscesses, i.e., lesions not associated with gas-forming bacteria (see below), are rare alterations that are either solitary or multiple (Josef 1979; Pisano et al. 2007). As in liver abscesses not associated with hepatic metastases, infection with a broad array of microorganisms is pathogenically involved (Brook and Frazier 1998). Liver metastasis undergoing abscess formation may rupture due to the puriform destruction of the tissue (Josef 1979). More common are liver abscesses that are indicators of silent or manifest colorectal cancer, a tumor that is well known to be associated with solitary or more often multiple pyogenic liver abscesses (Cohen et al. 1989; Lonardo et al. 1992; Pierrugues et al. 1994; Teitz et al. 1995; Tzur et al. 2003; Alvarez et al. 2004; Yokota et al. 2005; Giuliani et al. 2007; Hiraoka et al. 2007; Lee et al. 2008). This type of abscess can be caused by several bacterial species, including *Streptococcus milleri* (Tzur et al. 2003) and anaerobic germs such as *Bacteroides* and *Peptostreptococcus* (Lonardo et al. 1992; Alvarez et al. 2004; Lieuw-a-Fa et al. 2008). Abscesses caused by anaerobic bacteria including *Bacteroides* tend to have a liquid consistency in contrast to necrotic liver metastases (Lieuw-a-Fa et al. 2008). The pathogenic pathways involved in liver abscess formation in patients with CRC and other gastrointestinal cancers not having liver metastasis are not elucidated, but transfer of intestinal bacteria from ulcerated tumor surfaces to the liver via the portal circulation, with or without pylephlebitis, is considered. In fact, portal pyemia secondary to carcinoma of the rectum has been described (Ritchie, 1975). Multiple sterile liver abscesses may as such mimic metastatic disease during imaging workup (Acharya 2012).

Abscess-Like Lesions in Hepatic Metastases Caused by Anaerobic Bacteria ("Hepatic Necrobacillosis")

"Hepatic necrobacillosis" is a condition characterized by solitary or multiple liver abscesses caused by anaerobic bacteria. In part of the cases, necrotic metastases, mostly of CRC, have been identified as a background alteration favoring infection with anaerobic germs. Bacteria cultivated from such lesions comprise *Bacteroides* species, *Fusobacterium nucleatum*, and *Peptostreptococcus* species (Young et al. 1977; Trump et al. 1978; Tweedy and White 1987; Hagelskjaer and Pedersen 1993; Katzenstein et al. 1994; Athavale et al. 2002; Sarmiento and Sarr 2002; Le Roux et al. 2006; Kim et al. 2011). Pathologically, the centers of the lesions exhibit extensive coagulation necrosis, while peripheral parts display a purulent exudate sometimes demarcated by granulation tissue. The latter may develop wedge-shaped necroses due to microvascular/capillary damage induced by toxic products of the anaerobic bacteria. The necrosis may later undergo liquefaction caused by enzymes of bacteria and leukocytes ("puriform liquefaction"). Due to their destructive features, abscesses developing in the context of "hepatic necrobacillosis" may

mimic primary hepatic malignancy (Athavale et al. 2002).

What Are the Essential Features of Bacteria Causing "Hepatic Necrobacillosis"?

Bacteroides is an obligately anaerobic, Gram-negative, saccharolytic bacterium which comprises at least ten valid species. Bacteroides species organisms are the predominant commensal bacteria in the human gut and are now considered to be reservoirs of antibiotic resistance genes due to their capacity to harbor and disseminate these genes in the course of homologous and heterologous conjugation through mobile transmissible elements occurring in great variety (Nguyen and Vedantam 2011). The original *Bacteroides* genus described in 1898 was later partitioned into three genera, i.e., *Bacteroides sensu stricto*, *Prevotella*, and *Porphyromonas*. The species of the latter two genera generally are associated with the oral cavity and rumen. *B. fragilis* and other intestinal *Bacteroides* species play an important role in the enterohepatic circulation of bile acids. Primary bile acids entering the GIT via bile are deconjugated and transformed into 15–20 secondary bile acids by these bacteria. As very well-adapted gut symbionts, *Bacteroides* species possess membrane-spanning sensor histidine kinases to sense complex carbohydrates which the bacteria degrade (Lowe et al. 2012). The *Bacteroides fragilis* species group is one of the most important pathogens in polymicrobial infections, linked to a complex and variegated spectrum of virulence factors (Brook 1989; Wexler 2007). In patients with *B. fragilis* bacteremia, malignancy was the most common comorbidity, and intra-abdominal infections accounted for approximately half of the infection sources (Cheng et al. 2009). Patients with colorectal cancer reveal changes in the composition of the gut flora, a condition termed microbial dysbiosis. *Bacteroides* species are associated with colorectal carcinoma (Sobhani et al. 2011). In a study of ten patients, *B. vulgatus* and *B. fragilis* and B. ovatus were the least frequently isolated *Bacteroides* species in the feces (Namavar et al. 1989). In contrast to CRC, patients with colorectal adenomas show, among mucosal adherent bacteria, more often species of the genera *Dorea* and *Faecalibacterium* and less often *Bacteroides* and *Coprococcus* (Shen et al. 2010). *Fusobacterium* species (*F. necrophorum*, *nucleatum*, *mortiferum*, and *varium*) are associated with several clinical conditions. In a review of 52 consecutive patients with *Fusobacterium bacteremia*, 10 % showed Lemierre's syndrome, 27 % were previously healthy patients who had *F. necrophorum* sepsis without vascular thrombosis, 12 % were women who had puerperal infections, and 52 % were older patients who had cardiovascular, pulmonary, or neoplastic diseases (Nohrström et al. 2011). Lemierre's syndrome is a disorder chiefly affecting young healthy adults. This syndrome usually develops after bacterial purulent tonsillitis and peritonsillitis. Purulent peritonsillar pockets and abscesses are then the niches where anaerobic *Fusobacteria* can survive and proliferate. These bacteria can invade the soft tissues of the neck and penetrate the jugular vein system to induce infected thrombosis, the source of subsequent bacteremia, sepsis, and all its complications. Sepsis following a throat infection was first reported in 1918 by Scottmuller, but it was Lemierre in 1936 who described the condition in detail based on 20 cases. Overall, *Fusobacterium bacteremia* is a rare disorder, accounting for approximately 0.9 % of patients with bacteremia, with *F. nucleatum* being the most common species accounting for 41.5 % in one study (Su et al. 2009). *Fusobacterium bacteremia* is encountered in patients with neutropenia, e.g., associated with leukemia and lymphoma (Candoni et al. 2003). In the course of F. *nucleatum bacteremia*, portal vein thrombosis (Bultink et al. 1999; Verna et al. 2004), pylephlebitis with liver abscess (Etienne et al. 2001), and multiple infected liver abscesses can develop (Scoular et al. 1992; Le Roux et al. 2006). This constellation has been proposed to be termed "digestive variant" of Lemierre's syndrome (Le Roux et al. 2006). *Peptostreptococcus* is a genus of Gram-positive

anaerobic non-spore-forming bacteria. The species of *Peptostreptococcus* (*P.*) identified in the setting of clinical infections were formerly part of the genus known as *Peptococcus*. Several *Peptostreptococcus* species (most commonly *P. magnus*, *asaccharolyticus*, *anaerobius*, *prevotii*, and *micros*) are commensal organisms in humans and predominantly colonize the oral cavity, skin, and the gastrointestinal and genitourinary tracts. Another clinically relevant bacterium, *Gaffkya anaerobia*, was renamed *P. tetradius. Peptostreptococcus* species become pathogenic in immunocompromised hosts and in situations where anaerobic niches are created in the body, e.g., necrotic tumors. In the course of septicemic *Peptostreptococcus* infections, abscesses can develop in several organs, including the liver. A recently identified member of the *Bacteroidetes* group that is associated with CRC is *Alistipes finegoldii*, a bacterium clustered with *Alistipes putredinis*, a member of the human gut flora (Fenner et al. 2007).

Infection of Hepatic Metastases with Gas-Forming Bacteria

The infection of hepatic and at least partially necrotic metastases with gas-forming bacteria, chiefly *Clostridium* species, has predominantly been found with metastases of CRC (Kahn et al. 1972; Kolbeinsson et al. 1991; Urban et al. 2000; Kurtz et al. 2005), but other tumors such as carcinoma of the breast (Thel et al. 1994), pancreatic carcinoma (Fondran and Williams 2005), and choriocarcinoma can also be involved (Lee and Hsieh 1999). This complication is typically found in hepatic CRC metastases that have outgrown their blood supply and hence provide an anaerobic microenvironment ideal for bacterial growth. In case of marked local gas production, the necrotic metastases can accumulate gas that is visible at imaging (intrahepatic pneumatic tumor; "pneumometastasis"; Tokita et al. 1988; Urban et al. 2000). Gas formation in hepatic metastases can develop in short time, e.g., within 3 days as seen in follow-up CTs (Urban et al. 2000). The accumulated gas can remain limited to metastases on CT and not extend into the healthy adjacent liver (Urban et al. 2000), but *Clostridium*-induced intrametastatic gas formation can also cause rupture of the lesion followed by pneumoperitoneum (Raghavendra et al. 2013).

Clostridium (*C.*) *septicum* was detected in most cases (Thel et al. 1994; Lee and Hsieh 1999; Kurtz et al. 2005), but *C. perfringens* was also isolated (Fondran and Williams 2005). *C. septicum* is as anaerobic Gram-positive bacillus that can cause infections which rapidly progress to sepsis. This bacterium is strongly associated with malignancy, especially of the gastrointestinal tract and in particular CRC (Alpern and Dowell 1969; Koransky et al. 1979; Kolbeinsson et al. 1991). Although widely spread in the environment, *C. septicum* germinates and proliferates predominantly in devitalized and necrotic tissues with failing blood supply and low oxygen tension, including tumors and their metastases.

Anaerobic Necrosis and Abscesses of Hepatic Metastases Following Nonsurgical Therapies

Extensive liver necrosis with inflammatory reactions has been observed after radiofrequency ablation of liver metastases (Kvitting et al. 2006). Marked necrosis and inflammation were found following intra-arterial chemotherapy for metastatic CRC (D'Orsi et al. 1979).

Cyst Formation in Hepatic Metastases

Introduction

Hepatic metastases of diverse types of extrahepatic malignant neoplasms can undergo secondary cystic change, sometimes resulting in large single cysts or multiple cysts distributed in both liver lobes. These alterations may cause significant differential diagnostic problems, some of the cystic metastases resembling simple benign cysts or parasitic cysts.

Epidemiology

Numerous types of extrahepatic malignancies have been reported to cause cystic hepatic metastases. Similar to metastases in other organs, squamous cell carcinomas seem to have a higher tendency to show cystic hepatic metastases than other carcinoma types. In malignant melanoma, cystic metastases may develop more than 10 years after surgical excision of the primary lesion (Takauji et al. 2005). Massive cystic change of hepatic metastases of malignant melanoma may occur following transarterial chemoembolization (Ataergin et al. 2009). In the pediatric age group, PNETs (Shah and McHugh 2000) and neuroblastomas are well known to cause cystic liver metastases, sometimes with the formation of numerous cysts (Lee et al. 1998; Chacko et al. 2007). Cystic liver metastases in neuroblastoma can be associated with a distinct clinical entity, i.e., bilateral cystic adrenal neuroblastoma, a rare condition (Cassady and Winters 1997). Among neoplasms metastasizing to the liver and forming cystic metastases, neuroendocrine tumors, including carcinoid tumors of the GIT, have been reported more often than other tumors, suggesting that these lesions have a pronounced tendency to undergo cystic change in their metastases (Saubier et al. 1970; Dent and Feldman 1984; Bremer et al. 1986; McDermott 1987; Isomura et al. 1980; Salamone et al. 2010; Wijesuriya et al. 2010). The cysts may become large and eventually mimic *Echinococcus* cysts (Krohn et al. 2011). The reason why neuroendocrine tumors more often undergo cystic changes is not known.

Pathology

Macroscopically, cysts in liver metastasis are more prominent in large tumor masses. They produce a broad spectrum of changes ranging from small and ill-defined centrally placed cysts to large cysts that occupy most of the tumor mass, leaving only a thin rim of usually necrotic tissue. The cyst fluid is frequently turbid, with floating necrotic tissue fragments, and may show a hemorrhagic or yellowish color. In rare instances, the cyst lining is smooth and the lesion then mimics a benign nonparasitic cyst or a cystadenoma. Following cyst hemorrhage, masses of coagulated blood are found in the cyst lumen.

Cystic Changes in Treated Gastrointestinal Stromal Tumor Metastases

A distinct situation is the development of cysts in metastatic gastrointestinal stromal tumors (GIST) following treatment with imatinib mesylate/IM (Joensuu et al. 2001; Chen et al. 2002; Bechtold et al. 2003; Reichardt et al. 2004; Vanel et al. 2005; Linton et al. 2006; Phongkitkarun et al. 2008; Ulusan et al. 2008). IM is a specifically designed tyrosine kinase receptor inhibitor, which targets, among others, the KIT receptor and interrupts neoplastic growth messages to the cell. Liver metastases from GIST are often hypervascular prior to treatment and therefore not easily visualized on conventional portal venous phase CT images (Sandrasegaran et al. 2005). The development of cystic metastases was a consistent finding in several studies. In an investigation of four GIST patients who had received IM, follow-up CT showed that all hepatic metastases resembled cystic lesions after 8 weeks of treatment (Chen et al. 2002). In the review of seven patients with unresectable metastases from GIST who were treated with IM, hepatic metastases showed significant decreased attenuation in the first 2 months and continued decreasing attenuation at the 12-month follow-up. These metastases resembled simple cysts (Bechtold et al. 2003). In a retrospective, another study investigated the serial histological changes in GIST treated with IM and showed that therapy-induced cystic change of tumors is associated with tumor response and that cystic metastases had a lower mitotic count and lower proliferation indices and shrinkage of tumor tissue (Reichardt et al. 2004). In 13/39 patients with GIST who developed hepatic metastases, a cyst-like appearance was noted (Vanel et al. 2005). However, cystic liver metastases from GISTs have also been noted before any

treatment (Zonios et al. 2003; Jain et al. 2009). The pathogenesis of cyst formation in metastases following IM therapy is still uncertain, because such imaging changes are not typical cancer response patterns to conventional cytotoxic chemotherapy. Tumor shrinkage may follow cystic change; in one case report, hepatic metastases of GIST became cystic in MR appearance after 4 weeks of IM and became smaller after 8 weeks of treatment (Joensuu et al. 2001). GISTs showed myxoid changes and pycnotic nuclei in an eosinophilic myxoid background (Berman and O'Leary 2001), suggesting apoptotic cell decay. In a c-KIT-dependent GIST cell line, inhibition of c-KIT with IM triggers the upregulation of the proapoptotic protein BIM via both transcriptional and posttranslational mechanisms, suggesting a mechanism for IM-induced apoptosis (Gordon and Fisher 2010).

Tumor Fibrosis

Part of slowly growing hepatic tumor metastases undergoes progressive fibrosis that can rarely result in advanced scarring. As a spontaneous process, advanced fibrosis is an uncommon phenomenon and may be induced by marked immune reactions of the host, organization of necrotic tumor tissue, or a late change of tumor stroma. The fibrosis can rarely be associated with reactive ossification. A marked fibrosis overgrowth of CRC liver metastasis occurs in tumors that regress after chemotherapy (Rubbia-Brandt et al. 2007).

Spontaneous Regression of Hepatic Metastases

Introduction

Exceptionally, apparently spontaneous regression of hepatic metastases has been reported for renal cell carcinoma (Deweerd et al. 1977), colorectal carcinoma (Serpick 1976), malignant melanoma (Kalialis et al. 2008), and gastric carcinoma (Rosenberg et al. 1972). Renal cell carcinoma has shown metastasis regression following surgical removal of the primary lesion (Deweerd et al. 1977; Ritchie et al. 1988).

In an exemplary historical case report, a 44-year-old patient with familial polyposis, reported by Rankin and coworkers (1965), underwent resection of a rectal adenocarcinoma (poorly differentiated), and four metastatic liver nodules of 1 cm diameter each were detected, colorectal metastases confirmed through biopsy. Without further treatment, the patient was found to be well 7 years after rectal surgery. Three years later, a second carcinoma was found in the ascending colon, which was resected. During this operation, there was no evidence of the previously observed liver metastases.

Pathology

The histopathology of regressing metastases is characterized by the decay of preexisting carcinoma structures, such as disintegration of trabecules and acini, tumor cell necrosis and apoptosis, detachment of tumor cells from stromal elements, hemorrhage, and variable amounts of infiltrating leukocytes, mainly lymphocytes. Metastasis shrinkage may be associated with fibrosis, stellate scars, and finally a fibrosclerosed stroma (Figs. 9, 10, 11, 12, and 13). Spontaneous development of host immunity directed against

Fig. 9 Hepatic colorectal carcinoma metastasis with marked necrosis and shrinkage. The center of the metastasis consists of yellowish necrotic tissue. Shrinkage of the tumor has caused a stellate aspect of the nodule, in part reflecting tumor vessel patterns

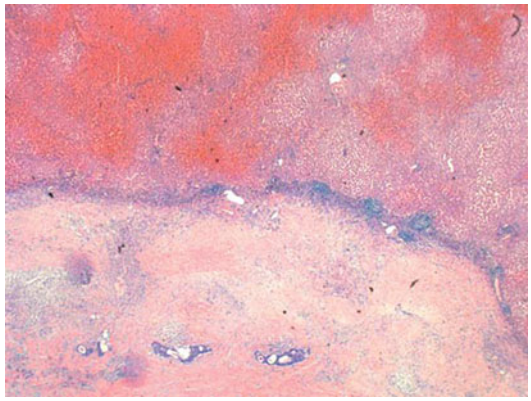

Fig. 10 Marked regression of hepatic colorectal carcinoma metastasis. Most of the tumor nodule consists of fibrosed stroma, with few remnant carcinoma tubules. At the interface between tumor and adjacent liver, an immune reaction is seen (hematoxylin and eosin stain)

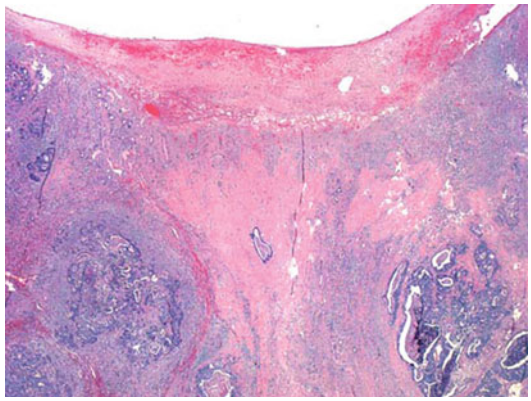

Fig. 11 Shrinkage and retraction of hepatic colorectal carcinoma metastasis at a site of capsular invasion and umbilication (hematoxylin and eosin stain)

tumor-associated antigens has been suggested as a regression-inducing mechanism (Bulkley et al. 1975). In regression induced by chemoembolization, a foreign body reaction can be observed (Fig. 14).

Tumor Alterations Caused by Bioptic Procedures

The trauma induced within metastatic and other tumor manifestations by biopsy needles can result in hemorrhage and necrosis. This alteration

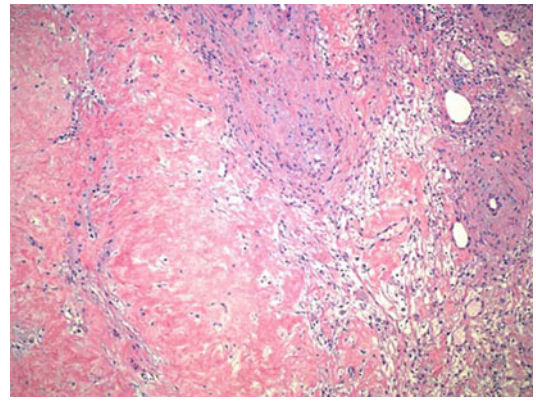

Fig. 12 In regression of hepatic metastases, tumor stroma can undergo sclerosis and hyalinization (hematoxylin and eosin stain)

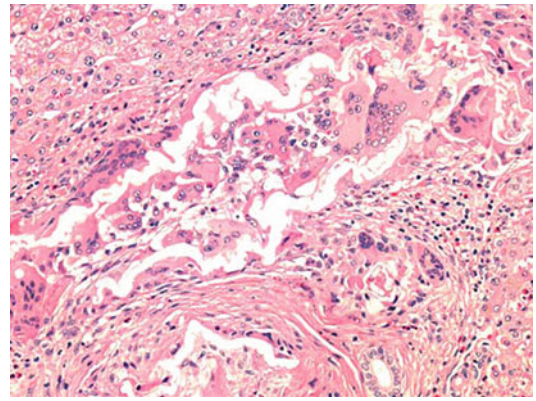

Fig. 13 Chemoembolization of hepatic carcinoma metastasis. This therapy can induce a vigorous foreign body reaction with multinucleated giant cells derived from fused macrophages (hematoxylin and eosin stain)

Metastatic Liver Disease: Hepatic Lymph Node Involvement

110

Contents

Abstract

Metastatic cancers of the liver can undergo further spread via the liver lymph drainage system, reaching lymph nodes close to the liver and the retroperitoneal space. Hepatic lymph is drained to a rather large group of locoregional lymph nodes. A first lymph node station is located very close to the liver, in the transverse fissure, associated with the left hepatic artery. Liver-associated lymph nodes are less common and smaller on the right side. The main lymphatic drainage route for hepatic cancer cells, including cells released from metastases, is along the hepatic artery to hepatic nodes at the hilum, from here to the celiac group; along the falciform ligament to right phrenic nodes and then to mediastinal nodes; through the esophageal hiatus and the caval foramen and transdiaphragmatically to right phrenic and mediastinal nodes; to paracardial upper gastric lymph nodes; and along the phrenic arteries directly to celiac nodes. Overall, the prevalence of hepatic pedicle lymph node metastases in diverse liver malignancies ranges from 10 % to 20 %, but the rate of macroscopically visible hepatic locoregional lymph node metastases is less, around 7 %. Involvement of liver-associated lymph nodes in hepatic metastatic disease has an impact on outcome. For hepatic colorectal

DOI 10.1007/978-3-319-26956-6_110

carcinoma metastasis, intrahepatic lymphatic vascular dissemination is associated with increased risk of recurrence and poor survival, and involvement of liver-associated nodes confers a poorer result following metastasis resection.

General Remarks and Anatomy

The lymphatic drainage of the liver is notable for its volume and flow to a rather large number of lymph node groups. Within the liver, the lymph vessel system is arborized and forms a network with unhindered communication from one area to another (Huth 1974; Wolodjko 1967; Szabo et al. 1975; Sapin and Usovich 1983; August et al. 1985). A first lymph node system is located close to the liver, i.e., in the transverse fissure (very small nodes, about 2 mm diameter), posterior to the portal vein, posterior to the pars transversa of the left portal vein, and associated with the left hepatic artery. Generally, lymph nodes are less common and smaller on the right side, and lymph nodes are not found or are seldom found between the portal vein, hepatic artery, and bile ducts in the fissures (Hardy et al. 1976). The main drainage routes from the liver comprise (August et al. 1985):

1. Along the hepatic artery to the hepatic nodes at the hilum and from here to the celiac node group
2. Along the falciform ligament to supradiaphragmatic right phrenic lymph nodes and then to mediastinal or internal mammary lymph node chains
3. Through the esophageal hiatus and the caval foramen and transdiaphragmatically to supradiaphragmatic right phrenic and mediastinal lymph nodes
4. Along the superior border of the lesser omentum to the paracardial upper gastric lymph nodes
5. Along the phrenic arteries directly to the celiac lymph nodes

The common hepatic node group is connected with the nodes on the anterior surface of the pancreatic head, and this pathway terminates in the node situated to the right of the origins of the celiac trunk and the superior mesenteric artery (Deki and Sato 1988). The convergence system of lymphatics is also connected with the lymphatic drainage of the gallbladder. The first node is the cystic node or pericholedochal node. The further drainage comprises at least three pathways: (1) the cholecysto-retropancreatic (main) pathway (This pathway has two routes, one running spirally and posteriorly from the anterior surface of the common bile duct to the right and the other running almost straight down from the posterior surface of the common bile duct. At the retroportal segment, these routes converge at a large lymph node being the terminal node of this pathway.), (2) the cholecysto-celiac pathway terminating in the celiac nodes, and (3) the cholecysto-mesenteric pathway, by which some lymphatics run to the left in front of the portal vein and connected with the nodes at the superior mesenteric root (Ito et al. 1991; Uesaka et al. 1996). The spread of CRC to hepatic locoregional lymph nodes is well documented and, as outlined below, has a marked impact on disease progression and survival (Gayowski et al. 1994; Beckurts et al. 1997; Ohlsson et al. 1998; Kokudo et al. 1999; Rodgers and McCall 2000; Ishibashi et al. 2006). The phenomenon is biologically interesting, because it is an example of cancer spread from metastasis to metastasis, described long ago (Vines 1949; Viadana and Au 1975; Viadana et al. 1978).

Frequency and Distribution of Hepatic Lymph Node Involvement

Overall, the prevalence of hepatic pedicle lymph node metastases ranges from 10 % to 20 % (August et al. 1985; Jaeck 2003; Viana et al. 2009). The rate of macroscopic hepatic lymph node metastasis has been reported to be 7 % and the incidence of macroscopic and

microscopic node metastasis 19 % (Elias and Ouellet 2003). As periportal/hilar and celiac lymph nodes are rather commonly involved, routine periportal/celiac lymph node biopsies have been advocated (Gibbs et al. 1998). Among 100 consecutive patients undergoing curative hepatectomy for CRC metastases with extensive lymph dissection of the hepatic pedicale in the absence of macroscopic node involvement, microscopic lymph node involvement was found in 14 patients. Node metastases involved very different lymph node sites and was related only to the number of metastases, extent of liver involvement, and carcinoembryonic antigen level (Elias et al. 1996). In one series, hepatic lymph node sampling was done in 78/182 cases of hepatic resections for colorectal metastases. Twelve percent showed secondary lymph node metastases in the hepatoduodenal ligament. There was a tendency for liver metastases in the right liver lobe to metastasize to lymph node No. 12b (or node of the foramen of Winslow, lymph nodes along the common bile duct) and liver metastases in the left liver lobe to metastasize to No. 8a (anterosuperior group of the lymph nodes along the common hepatic artery). In another study, a total of 111 hepatic lymph nodes were removed from 33 patients with synchronous CRC liver metastases during the resection of the primary tumor. Hepatic lymph node metastasis was found in nine patients (27 %). The node sites involved were three along the hepatic artery, three in the hepatoduodenal ligament, and three in both (Ishibashi et al. 2006). Among 156 patients undergoing curative liver resection for RCR metastases, microscopic hepatic lymph node involvement occurred in 15 % of the patients and was associated with a poor 5-year survival (Laurent et al. 2004). In a retrospective series of 62 patients who were deemed not resectable at laparotomy, 11 % were found to have positive portal or celiac nodes as the only site of extrahepatic disease (Gibbs et al. 1998). It was reported that, based on CT and PET scans, routine sampling of perihepatic lymph nodes will have a low yield in patients without some evidence of disease on preoperative CT or PET scans or at the time of exploration (Grobmyer et al. 2006).

Impact on Disease Progression and Outcome

For hepatic colorectal metastasis, intrahepatic lymphatic vascular dissemination was associated with increased risk of intrahepatic recurrence and poorer overall survival (review: Lupinacci et al. 2014). In the presence of hepatic lymph node involvement, it has previously been suggested that liver resection for metastasis is not contraindicated (Nims 1984; Yasui et al. 1995; Beckurts et al. 1997). Specifically, it has been proposed that positive nodes located near the hilum and along the hepatic pedicle (area 1) should not be considered an absolute contraindication to resection of hepatic metastasis (Jaeck 2003). One study has reported a survival benefit of hepatic lymph node dissection for some patients, provided a potentially curative (R0) resection is feasible (Wakai et al. 2009). On the other hand, the involvement of the hepatic lymph nodes has been a contraindication for resection for other authors, because it is considered as tertiary metastasis (Ohlsson et al. 1998; Minagawa et al. 2000). The outcome of patients with positive nodes is or was generally regarded as poor in comparison with node-negative patients and one of the most significant prognostic indicators (Nakamura et al. 1992; Scheele et al. 1996; Elias and Ouellet 2003; Pandey 2008; Ishida et al. 2011; Cardona et al. 2013). However, the unfavorable progression of disease depends on the node group involved in the era of new chemotherapy strategies. Formerly, when the positive nodes reach the celiac trunk (area 2), there was no survival benefit after metastasis resection (Jaeck 2003), whereas with new therapies, node involvement of area 1 or 2 does not anymore affect survival after CRC metastasis resection (Oussoultzoglou et al. 2009). Even the presence of microscopic lymph node metastases may have an impact on outcome in patients submitted to

curative hepatectomy (Lupinacci et al. 2013). Currently, there seems to be no convincing evidence of a survival benefit for routine or selective lymphadenectomy, and survival rates are low in patients with positive lymph nodes draining the liver irrespective of whether they are detected by routine lymphadenectomy or by macroscopic involvement (Gurusamy et al. 2008, with review). So far, there are a few 5-year survivors after liver resection for hepatic CRC metastases involving the hepatic lymph nodes, with or without lymph node dissection (Nakamura et al. 1992, 1999; Yasui et al. 1995; Ambiru et al. 1999; Rodgers and McCall 2000). The most common sites of tumor recurrence in the node-positive patients are the remnant liver and again the hepatic lymph nodes (Kokudo et al. 1999). The cell subpopulations giving rise to lymph node metastases of cancers also spreading to the liver are not yet well defined. From genetic and epigenetic studies, it surfaced that lymph node and liver metastasis appear to originate in clonally different processes. Specifically, remote organ metastases harbor more molecular abnormalities than those located in lymph nodes (Miranda et al. 2013).

Immune Reactions in Metastasis-Draining Lymph Nodes: Tumor-Draining Lymph Nodes (TDNLs), Metastasis-Draining Lymph Nodes (MDLNs), and the Concept of Metinel Nodes

As in lymph nodes draining primary tumors, metastatic tumors can elicit distinct patterns of immune reactions in locoregional lymph nodes. For the liver, tumor-draining lymph nodes (TDLNs) can undergo reactive enlargement mimicking metastatic disease. Lymphadenomegaly is in these situations caused by expansion of the follicular cortex and/or the paracortical area; the accumulation of other immunologic effector cells, including plasma cells and macrophages; and the recruitment of myeloid and other dendritic cells and of granulocytes, mainly eosinophils, all these alterations representing a concerted immune response directed against tumor-associated antigens. With time, locoregional immune reactions lead to an important change in the nodal microarchitecture (Heys and Eremin 1992; Chandrasekaran and King 2014). Markedly activated TAMs in TDLNs can result in the development of epithelioid macrophages which form a granulomatous reaction (review: Bhatia et al. 2009), which may sometimes mimic sarcoidosis. In addition to humoral and cell-bound immune reactions, lymph nodes under changes are linked to secondary alterations of primary tumors of their metastases. In case of tumor hemorrhage, lymph nodes contain fresh blood translocated by lymphatics, macrophages with erythrophagocytosis, and hemosiderin deposition, while tumor necrosis can induce the accumulation of numerous macrophages and lipid-rich foamy cells in dependent nodes.

Immune reactions in TDLNs as a main element of tumor surveillance are both of the innate and adaptive type. Adaptive immune responses to cancers are mainly directed against tumor-associated antigens (TAAs) that are shed from neoplastic cells to be presented by antigen-presenting dendritic cells. Adenocarcinomas (primary tumors and metastases) promote a vigorous B lymphocyte reaction in TDLNs. An increased number of B cells in locoregional lymph nodes suggest antitumor immune responses characterized by interactions between activated T lymphocytes and B cells, whereby nodes draining adenocarcinomas often show B lymphocytes with expression of CD80 (Lores et al. 1998; Contassot et al. 2009). The CD8(+) T-cell response is regulated not only by antigen presentation by dendritic cells and interaction with B cells but also by the expression of regulatory factors. The T-box transcription factor eomesodermin controls CD(8+) cells activity and lymph node metastasis in CRCs (Atreya et al. 2007). TDLNs also contain specific populations of immunologic effector cells that exert an important effect on tumor growth and progression. TDLNs draining colorectal cancer contain variable number of regulatory T cells (TREGS) with a FOXP3-positive phenotype, and it is expected that also metastasis-draining lymph nodes (MDLNs) exhibit this distinct cell

population. FOXPs(+)TREG infiltration was associated with more advanced colorectal cancer disease and lymph node metastasis (Gai et al. 2013). These TREGs potentially influence CD8(+) T-cell functions in that FOXP3(+) TREGs can impair CD8(+) cell function (Deng et al. 2010). An important role in immune defense directed against spreading cancer cells is played by the first nodes that drain a metastasis. These nodes were termed metinel nodes, and they contain interferon-gamma-producing lymphocytes that show clonal expansion, suggesting the presence of tumor-reactive lymphocytes (Dahl et al. 2008). Apart from cellular reactions, TDLNs and MDLNs express several proteins that are associated with nodal metastasis. In sentinel lymph nodes of colorectal cancers, upregulation of four metastasis-associated proteins was found, including hnRNP A1, ezrin, tubulin beta-2C, and annexin A1 (He et al. 2010).

Adenocarcinoma cells metastasizing to lymph nodes induce intranodular epithelial-mesenchymal transition (EMT) and recruit mesenchymal cells to become stromal cells, induced nodal stroma providing a critical microenvironment (niche) for metastatic tumor growth. In a first phase, the nodal pro-metastatic niche is characterized by a predominance of monocytes and macrophages (tumor-associated macrophages (TAMs)), associated with T and B cells, TREGs, myeloid dendritic cells, natural killer cells, and eosinophils. The complex interactome of these niche cells can induce the transformation of local mesenchymal cells or homing mesenchymal stem cells into cancer-associated fibroblasts (CAFs) and myofibroblasts as most important cell populations of stroma (review: Horst and Horny 1988). After the homing of cancer cells to the lymph node niche, a complex cross talk between CAFs of the stroma and carcinoma cells takes place, a process markedly modulated by STAT1 signaling (Kaler et al. 2014). There is evidence that carcinoma cells and CAFs are cooperative in the metastatic spread, in that, e.g., they show co-migration induced by TGF-beta1, a process enhancing metastasis (Gonzalez-Zubeldia et al. 2015). Cells making part of the premetastatic nodal niche also operate in the induction of angiogenesis and lymphangiogenesis that facilitate metastatic growth. Nodal lymphangiogenesis induced by tumor cells increases lymph flow and tumor metastasis (Harrell et al. 2007). TAMs and CAFs are engaged in a cellular prolymphangiogenic cross talk that is important for the initiation of a distinct vascular bed within the metastatic site (Schlereth et al. 2014).

Abstract

The presence and progression of hepatic metastases elicit a spectrum of secondary changes in the liver. Many metastases induce, due to their progressive growth, hepatomegaly, which often involves both liver lobes. However, in cases where metastatic disease compromises the portal venous system and/or bile duct system of one lobe, enlargement can involve only one liver lobe, the other undergoing shrinkage, the so-called atrophy/hypertrophy complex. Metastases in the liver induce various perifocal alterations in the parenchyma. Perifocal fatty change of hepatocytes is a common change and may be caused by tumor-induced microvascular obstruction and hypoxia. In the case of severely compromised microcirculation, perifocal ischemia with necrosis or perifocal atrophy ensues. Hepatocytes situated around metastatic nodules sometimes exhibit clear cell change. Cancer cells of metastases can induce activation of adjacent hepatic stellate cells, followed by matrix production and stroma induction. This may, in certain cancers such as metastasizing breast cancer, result in metastasis-related liver remodeling and pseudocirrhosis. Sinusoids in liver harboring metastases undergo a complex spectrum of alterations, including peliosis-like changes and microthrombangiopathy.

Hepatomegaly, Liver Atrophy, and the Atrophy/Hypertrophy Complex (AHC) in Metastatic Liver Disease

Gross hepatic metastases, a particular multiple metastases, cause hepatomegaly, sometimes to a very impressive degree, with liver weights exceeding 8 kg in some patients. On the other hand, a compromised hepatic circulation caused by even discrete metastatic liver disease can induce changes in liver mass and volume. It has been shown that the reduction of portal blood flow in patients with occult hepatic metastases may cause a decrease in liver volume (Ishizawa et al. 2005). This is related to the pathophysiological effect that any reduction in portal venous flow will compromise liver maintenance and cause atrophy due to lack of hepatotropic effects (Rous and Larimore 1920; Bax et al. 1956; Rozga et al. 1986; Takayasu et al. 1986). The pathogenesis of portal venous flow changes in the presence of metastases is unknown, but they do not seem to only depend on effects of mechanical vessel obstruction but also on the effects of humoral mediators.

In a study of 63 consecutive patients undergoing curative resection of hepatic CRC metastases, the CT-estimated liver volume (Kawasaki et al. 1993) was 841 ml in 8 patients who subsequently developed overt hepatic metastases during a 2-year follow-up and 1,145 ml in 55 patients without (occult) metastases. The results suggested that the liver with occult metastases decreases in size before overt metastatic tumors develop to be detectable (Ishizawa et al. 2007). It is known that even small hepatic metastases may lead to subtle changes in liver blood flow detected by hepatic flow scintigraphy (Leveson et al. 1985; Huguier et al. 1993; Kopljar et al. 2004), a phenomenon also detectable in experimental metastasis models in animals (Hemingway et al. 1991, 1993; Nott et al. 1989, 1991). Using Doppler ultrasonography, the Doppler perfusion index (DPI) was defined as the ratio of hepatic arterial flow to total liver blood flow and found to be useful in assessing tumor effects on liver circulation (Leen et al. 1993; Oktar et al. 2006). Changes in DPI are sensitive indicators for occult hepatic metastases (Leen et al. 1995; review: Leen 1999). In the context of such measurements, it has been taken into account that patient age has an effect on liver volume and liver blood flow. There is a significant negative correlation between age and both liver volume and apparent liver blood flow, whether expressed in absolute terms or per unit body weight. Similarly, a significant negative correlation is observed between apparent liver blood flow per unit of liver volume (i.e., liver perfusion) and age (Wynne et al. 1989). What is not clarified is the question as to why metastasis/portal hypoperfusion-induced atrophy in deprived parts is not compensated by reactive hypertrophy of the

uninvolved parts, because this a well-known response to atrophy in other situations, in the form of a so-called atrophy/hypertrophy complex (Bax et al. 1956; Lambotte et al. 2000; Ueda et al. 2004).

In some patients having massive and diffuse hepatic metastatic disease, and particularly those with breast cancer, the process can end up with liver atrophy. This alteration may represent the end stage of pseudocirrhosis or be an early response circumventing the pseudocirrhotic stage. Progressive liver atrophy can cause liver failure (Shitara et al. 2008). Mainly in cases where the metastatic tumor encroaches upon large bile ducts, causing stenosis or even obstruction, atrophy/hypertrophy complex (AHC) of the involved area may develop. As described in more detail in chapters of cholangiocarcinoma, AHC is characterized by the combination of parenchymal atrophy, hypertrophic changes with formation of nodular structures, and biliary-type fibrosis (review: Lory et al. 1994).

Perifocal Liver Changes in Hepatic Metastatic Disease

Introduction

Hepatic metastases can be associated with, or induce, a wide spectrum of changes in adjacent liver tissue, mostly in close vicinity to metastases. These alterations may, in the case of numerous metastases, compromise the function of the normal liver. On the other hand, the changes may exert an influence on the further growth of metastases within the hepatic environment or may affect the development of new metastatic nodules or satellite nodules. In what follows, the most important perifocal changes are briefly discussed.

Perifocal Fatty Change

Perifocal fatty change of hepatocytes located close to the periphery of metastases is a rather common alteration. It mostly presents as macrovesicular fatty change and less often as microvesicular fatty change. Macrovesicular fatty change is most commonly observed in liver parenchyma surrounding metastases of carcinomas and particularly those of colorectal cancer. In part of the cases, this change is macroscopically visualized as a brightly yellow of whitish-yellow rim of variable width directly adjacent to the metastatic nodules. The peripheral border of the rim facing the parenchyma is sharply demarcated in most cases, but may display an interdigitating interface. Histologically, hepatocytes in this rum show the typical large cytoplasmic vacuoles as seen in other forms of triglyceride fatty change. In a minority of cases, infiltrates of leukocytes, including neutrophils, lymphocytes, and macrophages, are present, causing a histology sometimes resembling that of nonalcoholic steatohepatitis/NASH, but fibrotic changes are not observed. Few apoptotic bodies (apoptosis of damaged hepatocytes) may be encountered. Accumulation of stainable iron is lacking. In the rare instances of microvesicular perimetastatic fatty change of hepatocytes, the alteration is only detectable histologically and is characterized by slightly enlarged liver cells showing a foamy cytoplasm. Inflammatory changes are not seen in this type of fatty change. The pathogenesis of perifocal fatty change has not been elucidated. It may be assumed that a deranged energy supply to hepatocytes localized just outside the growing tumor, e.g., due to poor oxygenation of tissue, causes accumulation of neutral fat and lipids in hepatocytes.

Perifocal Clear Cell Change

This rare alteration presents either as clusters or larger areas of clear hepatocytes rich in glycogen or as a ballooning (so-called hydropic degeneration) of liver cells without formation of Mallory-Denk bodies. Clear cell change may be associated with macrovesicular fatty change. Similar to pericentral ballooning found in toxic or other types of hepatocyte damage, peritumoral clear cell change is sometimes associated with cholestasis of the tissue concerned.

Perifocal Ischemic Change

The vascular bed of the liver and blood flow can be markedly compromised by tumor metastasis and particularly those of large size and with an invasive growth front. Due to pressure effects, microvascular/sinusoidal damage, and induction of intravascular coagulation, perifocal hepatic parenchyma may suffer severe ischemia resulting in perifocal necrosis of the coagulative type. These necrosis are commonly focal and form small patches reflecting the vascular architecture, but larger and rim-like zones of necrosis are also encountered. Within the eosinophilic necrosis, nuclear shadows of former liver cell plates and hepatocytes are seen. The necroses may be demarcated by a leukocyte reaction on the sides facing liver parenchyma. In very rare instances, infarctoid necroses resembling Rattone-Zahn infarct are detectable, probably caused by obstruction of larger portal venous branches by the invasive metastasis. Apart from frank ischemic necrosis, apoptosis of hepatocytes, necroptosis, and other ischemic cellular changes (including the so-called cloudy swelling; "trübe Schwellung" or "tropfige Entmischung" in German; Schilling 1894; Albrecht 1903; Findlay 1927) are encountered. Similar to ballooning, cloudy swelling is caused by an energy supply disorder (Shibayama et al. 1991), including deranged phosphorylation steps (Fonnesu and Severi 1954), and is thought to mainly involve defective functions of cellular membranes and mitochondrial membranes in toxic stress and hypoxia (Abdelhalim and Jarrar 2011). The membrane changes are associated with macromolecular crowing which contributes to hepatocyte swelling (Del Monte 2005).

Perifocal Atrophy

Atrophy of liver parenchyma surrounding tumors including metastases is a well-known phenomenon (Figs. 1, 2, and 3). It is, however, more commonly found in expanding tumors with low growth than in markedly invasive and rapidly growing tumors, because the latter destroy the tissue before it can undergo visible atrophy. Perifocal atrophy seen at gross examination is the form of a rim-like area surrounding the tumor, characterized by a pale color and a crowding of terminal veins. In fresh non-fixed specimens, the atrophic zone may exhibit a slightly higher consistency in comparison with normal liver substance. On cut surfaces of formalin-fixed specimens, the atrophic zone may display as a sunken area clearly contrasting with the usually bulging tumor. Histologically, liver lobules in the atrophic zone are undersized and elliptically deformed, the longer axis of the ellipse being oriented more or less parallel to the peripheral contour of the pushing tumor. Liver cell plates are thinned, associated with sinusoidal dilatation. Increased lipofuscin deposition in hepatocytes is usually not observed.

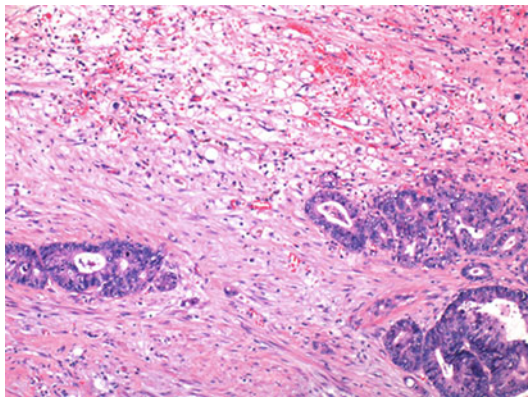

Fig. 3 Liver metastasis of colorectal carcinoma. Peritumoral hepatocytes exhibit dissociation, atrophy, and ballooning (hematoxylin and eosin stain)

Perifocal Alterations of Bile Ducts

Hepatic tumors, including metastases, are known to induce complex alterations of intermediate and small bile ducts and ductules in parenchyma surrounding the tumors and in adjacent portal tracts. The changes include bile duct compression and obliteration, acute cholangitis and cholangiohepatitis, secondary sclerosing cholangitis, bile duct erosion and fistulas, induction of biliary leaks, and ductular proliferations. Ductular proliferations with or without associated fibrosis may be marked and can involve both tissues directly surrounding the metastases and/or adjacent portal tracts. CK7- and CK19-positive ductules or ductular cells may be integrated in the growing, invasive metastases. Apart from cholangiocytes of the ductules, hepatocytes located to perimetastatic parenchyma may also show CK7 positivity. The pathogenic pathways leading to ductular proliferations in association with hepatic metastases are not fully known, but biliary obstruction caused by tumor has been implicated.

Perifocal Hepatic Stellate Cell Activation, Stroma Induction, and Fibrosis

Metastatic tumor can induce activation of perifocal hepatic stellate cells (HSCs), with differentiation into alpha-SMA-positive myofibroblasts. This alteration may be associated with circumscribed capillarization of the sinusoids, with formation of a basement membrane in the Disse space between the sinusoidal endothelium and the hepatocytes plates, visualized as a type IV collagen- and laminin-positive membrane.

Interactions between metastatic tumor cells and HSCs play a role in the generation of tumor stroma required for further growth and invasion of metastases. In a nude mouse model, it was found that intrasplenically injected human CRC cells migrated into the spaces of Disse and underwent proliferation, in close associated with hepatocytes and HSCs. In this model, HSCs were accumulated at 14 days after injection around the tumor mass and started to express alpha-SMA. Conditioned medium of activated HSCs contained PDGF-AB, hepatocyte growth factor, and TGF-beta, augmenting proliferation and migration of the CRC cells (Shimizu et al. 2000). Myofibroblasts as the differentiated offspring of hepatic stellate cells affect the biological behavior of cancer cells. It is, e.g., known that human hepatic myofibroblasts increase the invasiveness of HCC cells, mediated by motogenic hepatocyte growth factor secreted by the myofibroblasts (Neaud et al. 1997). Tumor cells themselves produce factors that induce hepatocyte growth factor in

fibroblasts of stroma (Nakamura et al. 1997). The activation process of fibrogenic cells is also thought to be involved in the development of perimetastatic fibrosis and formation of myofibroblast-containing tumor pseudocapsules, which are however seen only in the minority of metastatic nodules and which are usually less pronounced than those of primary liver tumors.

Perifocal Sinusoidal Changes

Liver tissue surrounding metastatic nodules reveals a variety of alterations of the microvascular system and in particular of sinusoids. The latter show collapse or obliteration, dilatations (focal segmental, diffuse, saccular), peliosis-like changes, and microthrombangiopathy. Peliosis-like changes may be difficult to distinguish from hemorrhages in perimetastatic liver tissue. Microthrombi in perifocal sinusoids, both hyaline and granular, may be caused by the procoagulative effects of some tumors.

Perifocal Obliterative Changes of Veins

Hepatic metastases may be associated with thrombosis and fibrous obliteration of small- to medium-sized portal vein branches ("perifocal portal phlebopathy"). Around metastases, sublobular and terminal veins/venules can rarely develop endophlebitis followed by fibrous obliteration, resulting in a complex of alterations resembling veno-occlusive disease/VOD. Classical VOD can develop following chemotherapy, but is then not restricted to perimetastatic liver tissue.

Tumor Cell Scattering and Perifocal Invasion

In the liver tissue surrounding metastases, scattering of tumor cells as an early step in the invasion cascade can be noted. It is seen as single tumor cells or tumor cell clusters in small vessels, in particular sinusoids. It is likely that these cells form the origin of satellite nodules developing in the vicinity of larger metastatic nodules. The current concept in fact is that the process of hepatic invasion by carcinoma cells originates in the sinusoids, where intrasinusoidal cells (Kupffer cells/macrophages), perisinusoidal cells (HSCs/myofibroblasts), and hepatocytes interact with metastasizing cells, through the expression of numerous cell adhesion molecules (CAMs) (Paschos et al. 2009). The differential and dynamic expression of CAMs in this distinct microenvironment of early invasion and spread is crucial for cancer cell homing mechanisms. The scattered intravascular tumor cells may be associated with microthrombi.

Some of the scattered cells are situated within hepatic lymph vessels, but these cells are less easily recognizable owing to the difficulty of identifying lymph vessels. Podoplanin immunostaining should be used to detect lymph vessels, mainly in portal tracts adjacent to metastatic nodules, and to test whether cancer cells are really located in the lumen of podoplanin-positive vascular profiles. Starting from the periphery of an established hepatic metastasis, extravascular invasion of tumor into the perimetastatic parenchyma can occur. Cohesive carcinoma cells grow into adjacent liver cell plates, replace and eventually destroy the hepatocyte population of the plates, and apparently employ the plate matrix as a scaffold. In a nude mouse model of metastasizing human CRC cells, injected tumor cells adhered to the endothelial layer of terminal portal venules and periportal sinusoids, followed by deep invasion of hepatocyte plates. The tumor cells were linked with each other or with adjacent hepatocytes by desmosomes, these desmosomes being maintained during mitosis. When invading tumor cells were exposed to bile canaliculi, they generated microvilli on the surface. After adhesion of tumor cells to endothelial cells, the latter retract rapidly and cancer cells bind to hepatocytes. In carcinoma cell-hepatocyte cocultures, CRC cells formed long cytoplasmic protrusions toward hepatocytes in their close vicinity and these protrusions attached to microvilli of hepatocytes. Then, adhering membrane areas were formed by both

cell types, and a distinct set of integrin subunits was expressed in carcinoma cells (Mook et al. 2008). In a rat model, occlusion of sinusoids by metastasizing CRC tumor cells was not sufficient to establish stable tumor cell arrest, suggesting that adhesion molecules and homing receptors play an important role (Gassmann et al. 2009).

Immune and Other Defense Reactions Around Liver Metastases

The parenchymal liver zone surrounding metastases harbors distinct sets of cells that are involved in antitumor defense, including Kupffer cells, various classes of lymphocytes, plasma cells, dendritic cells, and granulocytes, in particular eosinophils (Phillips 1989; Roh et al. 1990; Zhang et al. 1993; Van der Bij et al. 2005; Gulubova et al. 2008; Paschos et al. 2010). More details on the morphology and function of these cell systems around metastases are treated in a separate paragraph.

Metastasis-Related Pseudocirrhosis and Related Alterations of the Liver

Introduction

A variety of structural and contour changes can develop in patients with metastases to the liver, mainly after chemotherapy of metastasizing breast cancer, characterized by fine, diffusely nodularity that resembles liver cirrhosis and the development of non-cirrhotic portal hypertension. This spectrum of alterations is called pseudocirrhosis (synonyms: metastatic carcinomatous liver cirrhosis, diffuse desmoplastic metastatic cancer of the liver; Amtrup 1971). Pseudocirrhosis in metastatic liver disease is almost exclusively seen in treated carcinoma of the breast (Amtrup 1971; Sonnenblick et al. 2011), but is also observed in metastatic liver disease in the absence of breast cancer chemotherapy. It has also been found in occult breast cancer. Relatively few other cancers have been found to cause pseudocirrhosis including medullary thyroid cancer (Harry et al. 2012), esophageal cancer (Kobashigawa et al. 2010), carcinoma of the pancreas (Kang et al. 2008), and colorectal carcinoma (Theophilidou et al. 2012). In metastasizing breast cancer, pseudocirrhosis has been found subsequent to treatment with various agents, including Adriamycin, cyclophosphamide, cisplatin, 5-fluorouracil, vinblastine, vincristine, ifosfamide, navelbine, paclitaxel, and tamoxifen.

Epidemiology

Depending on the imaging criteria used, metastasis-associated pseudocirrhosis is a relatively frequent change of the liver. Hepatic capsular retraction as an indicator of pseudocirrhosis was observed in 29/58 patients with hepatic breast cancer metastases (50 %; Fennessy et al. 2004). Among 91 women with breast cancer metastatic to the liver who received chemotherapy, hepatic contour abnormalities were seen in 75 %, and portal hypertension was detected in 6 out of 16 patients with diffuse nodularity (Qayyum et al. 2007).

Clinical Features

The marked remodeling of liver substance and the vascular system of the liver often causes portal hypertension based due to blood shunting through abnormal vascular communications between liver and tumor nodules and angiogenesis (Viguier et al. 2006; Sass et al. 2007). Non-cirrhotic portal hypertension in pseudocirrhosis is associated with splenomegaly and ascites (Viguier et al. 2006). In one study, ascites was noted in 52 % and splenomegaly in 27 % of the patients (Young et al. 1994). Less commonly, hepatic encephalopathy and/or variceal bleeding has been found (Qayyum et al. 2007). In the case of massive metastasis and advanced remodeling of the liver parenchyma by multiple metastatic nodules, liver failure can ensue (Sonnenblick et al. 2011). Liver failure has also been observed in massive diffuse liver metastasis of occult breast carcinoma

(Morrison and Pennington 1984). Pseudocirrhosis due to metastasizing pancreatic cancer was found to be reversible with early recognition and management (Kang et al. 2008).

Pathology

Macroscopically, livers with pseudocirrhosis are either of normal weight or may have lost substance. The contour is irregular, and the organ has a nodular aspect both from the capsular surface and on cut surfaces, but the consistency is not increased to the degree found in cirrhosis. The condition sometimes resembles macronodular cirrhosis (Wallace et al. 2003), with large regenerative nodules embedded in a fibrous tissue background. Histologically the vascular relationships are preserved, in contrast to true cirrhosis. Specifically, true cirrhotic nodules are consistently lacking. The fibrosis is often associated with capsular retraction causing a lobular deformation, which is sometimes massive and will be further discussed in a subsequent paragraph. In some cases, mainly those with incomplete treatment response, preserved carcinoma nodules are closely intermingled with regenerating liver parenchyma. The fibrous tissue reaction in the liver may blend into preserved stromal areas of the carcinoma, resulting in a very complex picture of hepatic remodeling. In cases with remaining cancer, carcinoma cells may grow within sinusoids or abnormal vascular communications, also within stroma-containing septa.

Differential Diagnosis

The main differential diagnosis is liver cirrhosis, characterized by cirrhotic nodules (pseudoacini) and deranged vascular relationships, both lacking in pseudocirrhosis.

Pathogenic Pathways

Pathogenically it is assumed that chemotherapy induces inflammatory changes directed against damaged or necrotic cancer cells followed by a fibrogenic response that, together with desmoplasia of the tumor, leads to fibrous remodeling of the liver. Alternatively, nodular regenerative hyperplasia (NRH) as a well-known reaction to chemotherapy has been proposed to contribute to the pathogenesis of pseudocirrhosis (Key et al. 1987; Rosen et al. 1991; Young et al. 1994). Definite NRH was seen in 3 out of 22 patients with breast cancer-induced pseudocirrhosis (Young et al. 1994). It is assumed that the sometimes large nodules of NRH compress parenchyma and the sinusoidal network, followed by atrophy. A vascular factor promoting NRH is suggested by the observation that marked pseudocirrhosis was observed in patients who had received either intra-arterial infusions of chemotherapeutic agents or hepatic arterial embolizations, causing parenchymal damage and/or bile duct injury (Shirkhoda and Baird 1994).

Hepar Lobatum Carcinomatosum

Introduction

Hepar lobatum carcinomatosum (HLC) is a very rare acquired structural alteration of the liver characterized by the secondary development of deep fissures and retractions of the liver surface causing coarse lobulations of the liver substance. There are multiple cancer-bearing scar-like alterations and compensatory nodular hyperplastic changes of the spared parenchyma. The picture closely resembles that seen in end-stage tertiary syphilis of the liver (Honma 1987). HLC may represent an uncommon, excessive variant of metastasis-associated pseudocirrhosis ("forme majeure").

Epidemiology

HLC has predominantly been observed in patients with metastasizing breast cancer after chemotherapy, i.e., in the same context as pseudocirrhosis (Chin et al. 1987; Honma 1987; Graber et al. 2010). In fact, there seems to be a continuum from capsular retraction seen in breast cancer-

induced pseudocirrhosis, with incipient lobulation, to the fully developed HLC. Among 22 breast cancer patients showing retraction of the capsular surface of the liver causing a lobular margin, marked retraction with coarse lobule formation developed over 1–3 months on serial CT images (Young et al. 1994). In part of the cases, HLC may result from a general shrinkage process of the tumor and fibrosed liver, because HLC has been seen after complete chemotherapeutic regression of hepatic metastases (Chin et al. 1987). Apart from treated breast cancer, HLC has rarely been noted in other cancers metastasizing to the liver, including colorectal carcinoma (Teke et al. 2011).

Pathology

At gross examination, the liver may be underweight or looking shrunken and shows a coarsely lobulated contour associated with multiple capsular indentations, crevices, and fissures, from which scar-like fibrous septa extend deeply into the parenchyma. These septa divide the liver substance into several macronodules of variable size, whereby a predominant centrifugal distribution of the lesional areas is seen. Many of the septa abut on the centers of regressed tumor nodules (Gravel et al. 1996) and extend to the roots of fissures or crevices. The portal venous system does usually not contain tumor, but old organized thrombi or signs of phlebosclerosis may be noted.

Histologically, the macronodular areas causing the coarse lobulation of the liver consist of hepatic parenchyma with signs of regeneration (liver cell plates exceeding three cells in width) and deformation of liver lobules. However, lobules and vascular relationships are preserved in the nodules and nodes, and cirrhotic nodules are consistently lacking. Partially or completely necrotic tumor tissue is found interspersed between parenchymal nodules and scar-like septa. A macrophage reaction, foam cells, iron pigment deposition, and a lymphocytic infiltrate may be present in close association with regressed tumor tissue. The septa themselves consist of two components. First, part of the septa show collagenous fibrous tissue of variable fibroblastic/myofibroblastic cellularity. This component of septa results from tissue collapse associated with a fibrogenic response. Second, scar-like septa may contain stroma from infiltrating carcinoma, and in these stromal areas, regrowth of carcinoma and tumor-induced angiogenesis can take place.

Pathogenesis

The pathogenesis of HLC seems to be related to chemotherapy-induced regression of tumor nodules, followed by tissue collapse, inflammation, fibrosis, coalescence of fibrotic areas with remaining tumor stroma, and eventual regrowth of tumor in the stromal areas making part of scars. HLC is often associated with multifocal carcinomatous obstruction of portal venous branches and the hepatic venous tract (Honma 1987). These changes will cause ischemic injury to parenchyma and result in infarctoid changes. Part of the fibrous retractions may in fact be postnecrotic scars.

Chemotherapy-Associated Steatosis and Steatohepatitis (CASH) in Patients with Liver Metastases

Introduction

Chemotherapy of liver metastases, in particular of colorectal carcinoma, has proved to be an efficient therapy. It can reduce the size of metastases that are unresectable rendering them resectable (downstaging) and decreases the postoperative recurrence rates in patients with initially resectable tumors. However, chemotherapy of hepatic metastasis bears the risk of hepatotoxicity.

Selected references: Fong and Bentrem 2006; Abdalla and Vauthey 2008; Tannapfel and Reinacher-Schick 2008; Choti 2009; Chun et al. 2009; Cleary et al. 2009; Aloia and Fahy 2010; Baumgaertner et al. 2010; Tannapfel et al. 2011; Pilgrim et al. 2012.

An emerging chemotherapy-associated hepatotoxic entity is hepatic steatosis/steatohepatitis. Nonalcoholic fatty liver disease (NAFLD) may develop after therapy with 5-fluorouracil (Norum

1995; Sorensen et al. 1995) or chemotherapy of breast cancers (Shirkhoda and Baird 1994), while nonalcoholic steatohepatitis (NASH; chemotherapy-associated steatohepatitis, CASH), a serious complication of NAFLD, is known to occur after irinotecan treatment, specifically in obese patients (Fernandez et al. 2005; Pawlik et al. 2007; Morris-Stiff et al. 2008; Benoist and Nordlinger 2009; Khan et al. 2009). BMI correlates with the frequency of hepatic steatosis after chemotherapy (Kampfenkel et al. 2011; Makowiec et al. 2011).

5-FU-induced steatosis can be diagnosed by the use of CT imaging (Peppercorn et al. 1998; Miyake et al. 2005). Irinotecan-induced CASH affects hepatic functional reserve and increases both morbidity and mortality after hepatectomy for metastasis (Callery 2005; Fernandez et al. 2005; Fong and Bentrem 2005; Zorzi et al. 2007; Sotiropoulos et al. 2009; Pessaux et al. 2010; Kneuertz et al. 2011; Vigano et al. 2012). Steatohepatitis as such, but not simple steatosis, increases morbidity after liver resection. In a series of 248 patients having received preoperative chemotherapy (fluorouracil [FU] alone, irinotecan plus FU, and oxaliplatin plus FU), 36 patients (8.9 %) had NAFLD, and 22 (5.4 %) had NASH. In this study, irinotecan was significantly associated with CASH compared with no chemotherapy, and patients with CASH had an increased 90-day mortality compared with patients who did not have steatohepatitis (Vauthey et al. 2006; comment: Gentilucci et al. 2006). In patients treated with irinotecan alone, steatosis >30 % was found in 27.3 % of patients (Pawlik et al. 2007). Among 146 patients who had post-chemotherapy liver resection for CRC metastases, 32 patients developed NAFLD (steatosis > or = 30 %) and 15 had CASH. In multivariate analysis, a BMI >27 was the only risk factor for steatosis or NASH (Brouquet et al. 2009). A high prevalence of steatosis was also detected in combination chemotherapies. Of 54 patients having neoadjuvant chemotherapy with FOLFOX-4 (folinic acid/5-FU/oxaliplatin), 68 % showed steatosis of the liver surrounding the metastases even in the absence of obesity (Aloysius et al. 2007). However, the main hepatic lesion induced by preoperative 5-FU/oxaliplatin chemotherapy in patients with colorectal liver metastases was vascular and not steatosis in an analysis investigating 92 randomly selected patients, of whom 75 had received preoperative chemotherapy (Aloia et al. 2006). Steatosis and steatohepatitis as complications of preoperative chemotherapy were not detected in other studies (Kandutsch et al. 2008; Ryan et al. 2010). In the study of Ryan and coworkers (2010), moderate to severe fatty injury was uncommon among 334 patients with CRC hepatic metastases, CASH being detectable in only eight cases/2.4 %, 7 of whom did not receive chemotherapy. The prosteatotic effects of 5-FU and irinotecan were reproduced in C57BL/6 mouse model, but steatosis had no adverse effect on liver regeneration after partial hepatectomy (Rickenbacher et al. 2011). In the same mouse strain, oxaliplatin was found to induce CASH (Keizman et al. 2010).

Pathology

Steatosis and CASH are histologically not different from the respective alterations occurring in other settings. As in alcoholic steatohepatitis and NASH, liver tissue in CASH can show hepatocyte ballooning, liver cell apoptosis, and eventually Mallory-Denk bodies. Quantification of steatosis in NAFLD and NASH associated with chemotherapy may be supported by modern digital techniques and imaging methods. In the assessment of steatosis in chemotherapy-treated patients with CRC hepatic metastases, classical histopathology was less reliable than digital quantification of steatosis (DQS), and proton MR spectroscopy ([1] H MRS) showed very similar steatosis levels and high reliability compared with DQS. [1] H MRS was able to predict steatohepatitis with 100 % sensitivity and 89 % specificity (Urdzik et al. 2012).

Differential Diagnosis

Steatosis occurring in chemotherapy of liver metastases is usually a diffuse alteration, but it may also present as a lesion with focal predominance. In such situation, focal steatosis/

steatohepatitis may radiologically mimic metastasis (Yates and Streight 1986; Choi and Kim 2011).

Portal Venous Gas Following Metastasis Chemotherapy

Introduction

Patients with synchronous colorectal liver metastases are at risk for septic complications following chemotherapy. Necrotic metastasis tissue can be superinfected by various bacterial taxa, including gas-forming germs. The latter infection can result in gas accumulation in the necrotic tumor tissue itself and/or the transit of gas into the portal venous system. Gas in metastatic liver lesions is as such not an uncommon finding.

Not all situations of gas within metastases are caused by gas-forming bacteria. Apart from gas produced by complicating anaerobic bacterial infection, external air may be entrapped in the lesions during a surgical procedure. Furthermore, a hepatic and partially necrotic metastasis can be superimposed with a pyogenic infection, resulting in a pyogenic abscess with an air-fluid level rather than central gas accumulations. In the absence of bacterial infections causing gas formation, gas accumulation is typically restricted to the metastatic lesions, while in the former situation, gas accumulation is often also seen outside the metastatic lesion (review: Bozkurt et al. 2012). Pneumatosis cystoides intestinalis and portal venous gas have also been observed secondary to CRC chemotherapy (Clemente et al. 2010), neoadjuvant radiochemotherapy (Duchon et al. 2011), and targeted molecular cancer therapies (Lee et al. 2012).

Pathology

In the case of gas-producing bacterial infections of hepatic metastasis, the tumors usually show extensive necrosis and/or suppuration, the necrotic tissue crackling upon palpation and eventually showing a foamy cut surface, with gas bubbles of various sizes, some of them collapsing following incision. Gas bubbles may also be seen in the parenchyma surrounding the lesion, but usually not in more remote parts of the liver, this phenomenon being important in the differential diagnosis of diffuse clostridial gangrene of the liver. Conversely, hepatic abscesses with an air-fluid level are more difficult to diagnose macroscopically, because the central air-containing space immediately undergoes collapse following incision. Free gas in large portal venous branches are mostly recognizable during necropsy and less easily in resection specimens. Following incision of the portal vein during dissection, gas bubbles and blood mixed with gas foam may be found, a foul smell being characteristic for gas-forming infections in contrast to the non-smelling artificially entering ambient air. The only histological landmark of gas in the portal venous system is the presence of "empty holes" within the properly fixed blood masses seen in the venous lumina.

Pathogenic Pathways

In patients with colorectal carcinoma with or without hepatic metastatic disease, gas can enter the portal venous system through various mechanisms. A rapid response to chemotherapy may cause extensive necrosis of the primary tumor, followed by necrotizing enterocolitis with dissecting gas in the bowel wall, gas then entering the portal circulation. Gastrointestinal perforation following cancer therapy can also result in portal venous gas (Ortega et al. 2009). Following chemotherapy of metastasis, almost complete or complete necrosis of the tumor can subsequently turn into a liver abscess, which may then fistulize into the portal vein system (Zalinski et al. 2009). The process may progress into fulminant abdominal gas gangrene, with gas-containing liver metastases and involvement of locoregional lymph nodes (lymphonodal gas gangrene) and portal vein branches (Bozkurt et al. 2012).

Pathogenic Features of Liver Metastasis: Growth, Regrowth, Stem Cells, and Circulating Tumor Cells

112

Contents

Abstract

Growth and regrowth of hepatic cancer metastases depend on distinct cell kinetic features of the various tumors involved, on tumor stem cell characteristics, and on the biology of circulating tumor cells. Hepatic metastases display distinct growth patterns, the most common being expanding, replacement, desmoplastic (stroma-rich), and frankly invasive patterns. There is a relationship between these patterns and proliferative, invasive, and angiogenic features of tumors involved. The progressive growth of hepatic metastases not only depends on the proliferative and invasive capacities of the tumor cells but also on the biology of the so-called metastatic niche in the liver, involving complex interactions between tumor cells and cells of the microenvironment, including stromal cells, cancer-associated fibroblasts, stellate cells, and several cell types of the immune system. Metastatic cancer cells can, in turn, modulate the function of cells in the hepatic metastatic niche. Metastases in the liver can release tumor-initiating cells, in part with stem cell features, that enter circulation and give rise to further intrahepatic and extrahepatic metastases. These circulating cells and their remote metastatic offspring are capable to re-home to the liver and to induce new metastatic foci in programmed pre-metastatic niches.

Growth of Liver Metastases

Growth Patterns

Hepatic metastases show various growth patterns, the most common being expanding ("pushing"), desmoplastic, replacement, or frankly invasive patterns. There is a relation between these growth patterns and angiogenesis, in that CRC liver metastases with a replacement pattern were non-angiogenic, while those with a using pattern were most angiogenic, the latter situation associated with poor survival (Van den Eynden et al. 2012). In contrast to other malignant neoplasms, biologically more aggressive CRCs do not seem to have a higher proliferative capacity (Anjomshoaa et al. 2008). There is evidence that hepatic CRC metastases are sometimes slow growing (Agui et al. 2002; Kitabatake et al. 2002; Seong et al. 2004). Based on a study of 73 primary CRCs and 27 CRC hepatic metastases, it was found that, compared with the primary tumors, metastases had a significantly lower expression of multigene proliferation signature and a lower Ki-67 proliferative activity, whereas the M30 apoptotic index was similar in primaries and metastases. It was suggested in this study that a low relative proliferation appears to be a biological feature of CRCs with a high metastatic potential (Anjomshoaa et al. 2009). The CDX-2 gene product is a transcription factor that is involved in the proliferation and differentiation of intestinal epithelial cells and is a marker for gastrointestinal adenocarcinomas (Werling et al. 2003; Li and Folpe 2004), in particular also for colorectal adenocarcinoma (Barbareschi et al. 2003). In metastatic gastrointestinal adenocarcinoma, CDX-2 demonstrated nuclear staining in 86 % of the cases (Saad et al. 2004).

Effects of Tumor Size at Metastasis

There is a relation between the size of a primary malignancy and the probability of metastatic spread. Although large tumors contain much more cells than small ones, there is generally a tendency that large lesions produce less metastases than smaller ones (Martinez et al. 1956; Kimmel and Flehinger 1991; Xu and Prorok 1998), probably due to a lesser content in metastasis-producing tumor cells. On the other hand, a critical tumor size must be achieved in order to produce micrometastases (Liotta et al. 1977; Withers and Lee 2006).

Growth of Colorectal Carcinoma Metastases Following Hepatic Resection (Growth in the Regenerating Liver) and Regrowth After Chemotherapy

Liver resection for hepatic metastasis is sometimes followed by a significant surge of tumor recurrence. There is evidence that the regenerating liver exerts stimulatory effects on tumor growth (reviews: Christophi et al. 2008; Krause et al. 2013). In colorectal carcinoma metastases, macrophage inflammatory protein-2 contributes to liver resection-induced acceleration of growth (Kollmar et al. 2006). Liver resection for hepatic metastases is sometimes followed by a significant surgery of tumor recurrence. There is evidence that the regenerating liver exerts stimulatory effects on metastatic tumor growth (review: Christophi et al. 2008).

Tumor Stem Cells, Tumor-Initiating Cells, and Circulating Tumor Cells

Introduction

The evolution of cancer is now considered to be driven by cells with stem-like features. These cells are commonly termed tumor stem cells (TSCs) or cancer stem cells (CSCs), but most studies now utilize the term tumor-initiating cells (TICs; synonym: cancer-initiating cells, CICs; Zhou et al. 2009; Garvalov and Acker 2011). Some authors used the term tumor-propagating cells. TICs form a fraction of the circulating cells identified as circulating tumor cells (CTCs), whereby CTCs form a heterogeneous population of cells consisting of TICs and other stem cells, and post-

stem cell-differentiated tumor cells that have escaped from the primary tumor. It is important to note that the concept of a "cancer stem cell" or now TIC does not imply that these cells are derived from normal, i.e., non-transformed stem cells. Cancers can originate from transformed stem cells characterizing the tissue of origin, but such cells must not necessarily be the cells that are later identified as TICs, although both cell types share the important features of low proliferation activity, unlimited self-renewal, and longevity. It is currently unknown whether part of the original transformed stem cells become TICs ("sneaking-through TICs") or whether all TICs evolve in a post-initiation phase of cancer. According to a current model, TICs emerge through mutations either from stem cells, multipotent progenitor cells, or even primed progenitor cells (Zhou et al. 2009). TICs were identified as cells capable of initiating and sustaining growth of tumors in immunodeficient mice (Lapidot et al. 1994; Singh et al. 2004) and are characterized by apparently unlimited self-renewal, stress resistance (in particular resistance to chemotherapy), special homing features, and the capability for the establishment of distant metastases. TICs/CICs represent a subset of rare, hierarchically organized cancer cells that cannot only accomplish tumor onset but also progressive accumulation of mutations followed by tumor cell maintenance and metastatic spread. The identification of TICs/CICs uncovered that cancers show a previously unknown hierarchical structure, involving several sets of neoplastic cells acting in an ordered interaction and interdependence pattern. The concept of TICs has rendered to original and too simplicistic view of tumors releasing more or less differentiated cancer cells into an "invasion and metastasis cascade" obsolete. There is evidence that in order to assume a self-renewal state, cells to become TICs acquire expression of a stem cell gene map that possesses an embryonal stem cell-like transcriptional program (Wong et al. 2008). TICs can stay dormant for certain and sometimes long time periods (so-called dormant cancer cells), to be activated and mobilized in a later phase (McCubrey et al. 2011, 2012). The mechanisms that shift dormant TICs to an active state characterized by "moving" the cancer process ahead are critical for cancer progression but are not yet well known. An important role in the control of TICs and their activation state is the immune system of the host. A competent immune system of the host may recognize TICs and destroy them as soon as they shift from the dormant state (Maccalli et al. 2014).

Tumor-Initiating Cells (TICs): Important Mediators of Cancer Metastasis and Progression

Progression of cancer and in particular metastatic spread involve distinct populations of TICs. Part of TICs can, in the setting of their circulation in the body, home to distinct sites, probably the pre-metastatic niches discussed above. According to this concept, TICs coerce host tissue to cancer spread (Malanchi 2013). TICs engaged in metastatic spread are sometimes termed metastatic cancer stem cells or tumor-propagating cells/TPCs (Lau et al. 2014). Metastatic TICs derived from CRC primary tumors express a stem cell marker present in CRC stem cells, Musashi-1, regulated by Notch3 signaling (Pasto et al. 2014). After having settled at the future metastasis sites, TICs can undergo epithelial-to-mesenchymal transition (EMT) induced by the transcription factor Snail1. EMT is an important step for TICs to initiate metastatic growth (Sun and Qiu 2013), and EMT itself enriches for TICs to again release these cells into circulation. Therefore, TICs and EMT form a potent engine that employs TICs to undergo EMT, to produce TICs via a complex to-and-fro mechanism, and to prime TICs to develop metastatic tumor cells. EMT involving TICs results in two populations of cells, i.e., TICs with epithelial features (E-TICs) and those with mesenchymal features (M-TICs). It was shown that E-TICs derived from carcinoma can elicit metastasis, while M-TIC cells were nonmetastatic. These two cell populations cooperated, in that M-TICs enhanced the invasiveness of M-TICs and promoted the escape of E-TICs from primary implantation sites to accelerate their metastatic colonization (Celia-Terrassa et al. 2012). EMT

involving TICs and their differentiated offspring induces complex rearrangements of the cytoskeleton, including upregulation of vimentin in epithelial lineage cells, detyrosination of alpha-tubulin, and the production of cell projections important for niche attachment, such as microtentacles (Charpentier and Martin 2013).

Role of Stem Cells in the Development of Metastases

Migrating cancer stem cells (MCSCs) are now considered to play a significant role in the pathogenesis of metastases (Dalerba and Clarke 2007; Li et al. 2007). In the case of CRC, MCSCs can be isolated from primary tumors. Among these cells, a CD110+ and CDCP11 subpopulation was shown to mediate organ-specific metastasis, specifically to the liver and lung (Gao et al. 2013). Primary CRCs and their metastases contain a subset of colony-forming CD133+ cells, where a higher percentage of these cells was detected in metastases in comparison with primary tumors. CD133+ in CRCs are considered to be cancer stem cells (Puglisi et al. 2009).

Circulating Tumors Cells

The liver is a major metastasis-susceptible site (review: Vidal-Vanaclocha 2008). CRC reach the liver via the venous splanchnic circulation and chiefly through the portal vein. There is a relation between venous invasion in the primary tumor and the emergence of hepatic metastases. The average number of foci of venous invasion by CRC with metachronous liver metastasis did not differ significantly from that with synchronous ones, and invasion into extramural large veins appeared to be associated with liver metastases (Mori et al. 2009). In rat experiments, in vivo microscopy has revealed that the numbers of intracardially injected cells arrested in the hepatic sinusoidal circulation did not depend on the sinusoidal diameter, whereas more lumen-occluding arrested cells were seen in a rat strain with a narrower sinusoidal bed. Cell arrest was partly impaired by inhibition of beta-1 or beta-4 integrins (Gassmann et al. 2009).

Apart from cancer stem cells and TICs that can circulate in blood and lymph, more differentiated tumor cells also circulate in blood and lymph and are the "classical" cells that mediate spread and metastasis (circulating tumor cells, CTCs; review: Mavroudis 2010). CTCs have also been termed the "leukemic phase" of solid cancers (Mocellin et al. 2006). As outlined above, settling and growth of CTCs are more complex than previously thought and depend on distinct tissues niches that are also programmed and prepared by cells other than established tumor cells, including TICs. The presence and the levels of CTCs are strongly associated with tumor disease relapse and metastatic rates. CTCs therefore form a non-invasive window to screen disease progression and outcome for various cancer types (Paterlini-Bréchot and Benali 2007; Cohen et al. 2009; Allen and El-deiry 2010). CTCs express organ-specific markers (Paterlini-Bréchot 2011) and share with their parent tumor genomic and microRNA profiles (Smirnov et al. 2005; Sieuwerts et al. 2011), allowing the determination of their origin and possible fate. Long after their discovery is, however, still not clarified as to how many of CTCs are capable to survive, proliferate, and give rise to metastases. Viable CTCs have invasive features (Friedlander et al. 2014). The fate of CTCs is strongly influenced by their interaction with endothelium and other cells of pre-metastatic niches, immune responses of the host, mechanisms of epithelial-mesenchymal transition (EMT), factors inducing apoptosis, and their intrinsic survival engine modulated by genomic instability. Similar to cancer stem cells, more mature CTCs are subject to EMT, a factor that exerts a strong influence on the development of metastasis (Kallergi et al. 2011; Lecharpentier et al. 2011; Gorges et al. 2012). Circulating breast cancer cells simultaneously expressed epithelial and mesenchymal markers, but cells with mesenchymal features were highly enriched in CTCs, these mesenchymal cells occurring as both single cells and multicellular clusters expressing known EMT regulators (Yu et al. 2013). Subsets of CTCs are in an apoptotic status (apoptotic circulating

tumor cells, apoCTCs). In breast cancer patients, apoCTCs could be detected irrespective of the clinical status, although these cells are more frequent in patients with early disease compared with those having metastatic disease (Kallergi et al. 2013). apoCTCs correlated with the total number of CTCs in patients with small-cell lung cancer (Hou et al. 2012). In patients with CRC, apoCTCs were associated with liver metastasis (Allen et al. 2014).

Circulating Tumor Cell Clusters, Circulating Tumor Fragments, and Tumor Emboli

Part of CTCs can form multicellular aggregates in circulation, termed circulating tumor cell clusters (CTC clusters; Molnar et al. 2001). CTC clusters may form through intercellular adhesion, adhesion mediated by platelets, or EMT (see above), or represent original tiny tissue fragments released from the primary tumors. That CTC clusters may escape as such from primary tumors is supported by the observation that CTC clusters found in the blood of prostate cancer patients can contain circulating fibroblast-like cells. The presence of circulating fibroblast-like cells correlated with a more aggressive course of tumors (Jones et al. 2013). The exact biology of CTC clusters is, however, not yet known in more detail.

In addition to CTC clusters, larger multicellular tumor cell aggregates associated with activated and aggregated platelets and clotted plasma occur, the tumor microthrombi and tumor microemboli. Tumor microemboli can circulate in blood and correlate with the total CTC number (Hou et al. 2012). Clusters and tumor microemboli can be arrested in microvessels and eventually obturate these vascular channels. Even larger circulating structures are circulating tumor tissue fragments containing stromal cells and vascular cells and resulting from invasion of entire tumor tissue parts into the vascular bed (Kats-Ugurlu et al. 2009). Tumor embolism mediated by such fragments is a source of metastatic disease (Hart 2009) but is less well documented than that occurring with CTCs and TICs. A distinct mode of metastasis is the invasion-independent entry or intravasation of tumor cell nests through gaps in sinusoid-like vascular channels of certain tumors, resulting in the release of small nests enveloped by endothelial cells (Sugino et al. 2004).

Abstract

Homing of circulating cells to pre-metastatic niches of the liver and their subsequent growth to a metastasis requires a complex interaction between tumor cells and various normal cellular and matrix components of the future metastatic site. In the course of homing to endothelial surfaces of hepatic blood vessels and vascular invasion, tumor cells interact with platelets and induce platelet adhesion and aggregation. Tumor cell-induced thrombocyte aggregation facilitates early steps of metastasis through increased tumor cell arrest and formation of tumor cell emboli. Platelets participating in tumor cell aggregates promote cell adhesion and invasion and release growth factors for cancer cells. Following their exit from blood vessels, tumor cells engage in complex interactions with stromal cells. The stromal microenvironment profoundly influences growth and invasion of tumor cells in the metastatic site. Stromal cells interacting with tumor cells include cancer-associated fibroblasts and myofibroblasts, vascular cells, tumor-associated macrophages/TAMs, myeloid suppressor cells, and other cells of local immune responses. Cancer cells in turn constantly modulate the cellular composition of stroma, promote angiogenesis, and are subject to epithelial-mesenchymal transition.

Platelet Interactions, Platelet Aggregation, and the Formation of Tumor Metastasis

Introduction

In the course of vascular invasion and the associated endothelial cell damage, cancer cells having contact to streaming blood can induce platelet homing and thrombocyte aggregation. These thrombocyte aggregates, being in contact with the subendothelial space following endothelial cell loss, form a distinct niche for tumor cells that promotes growth and the formation of metastases. Tumor cell-induced platelet aggregation facilitates hematogenous metastatic spread by increasing the arrest of tumor cell clusters and tumor cell emboli in the microcirculation and is also involved in differential homing of platelet-tumor cell aggregates to distinct vascular beds (reviews: Honn et al. 1992; Tsuruo and Fujita 2008; Sharma et al. 2014). Generally, platelets can exert pro-metastatic effects. Platelet-tumor cell interactions are sufficient to prime tumor cells for subsequent metastasis, involving TGF-beta/Smad and NF-kB pathways via platelet-derived TGF-beta (Labelle et al. 2011). Platelets possess a complex granule proteome (Koseoglu and Flaumenhaft 2013) that contains numerous factors that can affect neoplastic cells. Through secretion of granule proteins, platelets modulate growth of tumor cells and the associated angiogenesis (Dovizio et al. 2014; Riedl et al. 2014). Thrombocyte alpha-granules of platelets also contain chemokines that can affect tumor cell behavior (Karshovska et al. 2013). In addition, platelets store laminins 411/421 and 511/521 in non-alpha- or dense-granule compartments and secrete these proteins via microvesicles (Pook et al. 2014).

Thrombocyte-Tumor Cell Interactions

It is known for long that patients with solid cancers can show elevated platelet blood counts in the absence of a paraneoplastic thrombocythemia. This thrombocytosis varies widely in its severity but may be associated with shorter patient survival (review: Buergy et al. 2012) and is associated with a higher metastatic load, e.g., in hepatocellular carcinoma. Elevated circulating thrombocytes enhance cancer cell migration and promote hematogenous metastasis in patients with lung cancer (Li et al. 2014). Neoplastic cells of solid cancers can undergo complex interactions with thrombocytes, whereby these interactions are capable to induce platelet aggregation favoring homing of cancer cells after intravascular spread (see below; Chang et al. 2009) or to affect the biological behavior of neoplastic cells, e.g., promoting their proliferation, cell-matrix adhesion, and/or invasive features. Cancer cells, also those of metastases, can internalize thrombocytes

or thrombocyte fragments (Panasci et al. 1980; Bhatia and Dey 2013), a process probably inducing complex signaling pathways mediated by platelet granule factors.

Platelets and Platelet Aggregates as Pacemakers of Metastatic Spread

In the setting of metastatic spread, thrombocytes play a pro-metastatic role involving several steps of the invasion and metastatic cascade (Karpatkin and Pearlstein 1981; Gasic 1984; Mehta 1984; Falanga et al. 2003; Borsig 2008; Erpenbeck and Schön 2010; Jain et al. 2010; Bambace and Holmes 2011; Gay and Felding-Habermann 2011). Interactions between platelets and tumor cells are important for metastatic spread and are mediated by adhesive receptors expressed by both partners of the interaction (Oleksowicz and Dutcher 1995). Thrombocytes promote the adhesion of spreading tumor cells to endothelial cell surfaces (Nierodzik et al. 1995), form aggregates that can store growth factors to be delivered to tumor cells, mediate access to the subendothelial space via collagen-induced viscous metamorphosis, slow down the streaming blood through induction of coagulation, induce a focal angiogenic response, and shield tumor cells from attack of host cells, in particular natural killer cells (Table 1; Yahalom et al. 1985; Eldor et al. 1987; Honn et al. 1992; Tsuruo and Fujita 2008; Gil-Bernabé et al. 2013; Reymond et al. 2013). Promotion of tumor angiogenesis by platelet products is an important mechanism that is not only dependent on VEGF and is the result of a combined action of several molecules that form the angiogenic payload of platelets (Battinelli et al. 2011; Sabrkhany et al. 2011; Radziwon-Balicka et al. 2012; Etulain et al. 2013). Platelet extracts induced growth, migration, and invasion in human hepatocellular carcinoma in vitro (Carr et al. 2014). Direct signaling between thrombocytes and tumor cells also induces epithelial-mesenchymal transition/EMT, an alteration that is critically involved in tumor metastasis (Labelle et al. 2011). Important steps in the process of platelet-induced tumor cell adhesion, homing, and transendothelial migration are mediated by P-selectin. P-selectin plays an important role in liver metastasis even in the absence of natural killer cell function (Coupland et al. 2012).

Table 1 Effects of platelets on malignant neoplastic cells

Induction of platelet aggregation (via Aggrus/podoplanin-CLEC-2 pathway)
Promotion of adhesion to endothelial cells
Induction of tumor cell motility and migration
Vessel wall transmigration
Stimulation of tumor cell growth
Induction of epithelial-mesenchymal transition
Signaling of platelet-tumor cell interactions (in part through platelet internalization)
Induction of angiogenesis

Tumor Cells Can Promote Platelet Aggregation and Release of Microvesicles and Exosomes

Several tumor types have been shown to produce and secrete the platelet aggregation-inducing factor Aggrus, a protein also termed podoplanin. Aggrus is secreted by various tumors, including CRC (Kato et al. 2003). Aggrus released by tumor cells interacts with a platelet receptor termed CLEC-2, and the ligand-receptor binding induced thrombocyte aggregation (Takagi et al. 2013). Aggrus-induced aggregate formation plays an important role for the changes in blood rheology required for tumor cell homing in the microvascular bed (Jurasz et al. 2004). Platelet aggregates and thrombocyte-induced local blood coagulation cause slowdown of streaming blood in microvessels, enabling tumor cells to engage with endothelia and adhere to the inner vessel wall. In fact, platelet-derived Aggrus/podoplanin was shown to promote metastasis (Kunita et al. 2007; Suzuki-Inoue 2011; Fujita and Takagi 2012; Lowe et al. 2012). One mechanism of metastasis promotion by podoplanin involves an induction of tumor cell migration (Shen et al. 2010; Kunita et al. 2011), whereby serine moieties in the intracellular tail of podoplanin regulate cell motility (Krishnan et al. 2013). In addition, contacts between platelet aggregates

induced by tumor cells permit the transfer of granule and nongranule proteins of platelets and of exosomes to adjacent endothelial cells and tumor cells. Platelet-derived microvesicles or microparticles are important participants in intercellular communication and play a role in cancer progression (Varon and Shai 2009; Aatonen et al. 2012). Activated platelets secrete granule proteins and parallel release two types of membrane microvesicles, namely, simple microvesicles by surface shedding and more complex exosomes derived from multivesicular bodies and alpha-granules (Heijnen et al. 1999). Platelet-derived microvesicles (microparticles) possess membrane domains that contain adhesion molecules and diverse receptors and contain signal substances that can stimulate angiogenesis (Varon and Shai 2009) and tissue regeneration (Varon et al. 2012).

Platelet Mimicry of Cancer Cells

Certain cancer cell types acquire a geno-phenotype the closely resembles that of thrombocytes/platelets. Such tumor cells express megakaryocyte genes, including adhesion receptors alpha IIb beta 3, thrombin receptor and PECAM/Cd31, and/or platelet-type 12-LOX. These acquired expression patterns enable the cancer cells to activate the coagulation cascade. It is currently considered that these platelet-like features of cancer cells affect their capability to spread and metastasize (Timar et al. 2005).

The Metastatic Stromal and Vascular Environment of the Liver

Introduction

The liver is known to provide a tissual microenvironment that favors the establishment of metastases of various malignancies, but specifically carcinomas. Part of the tumor cells transported into the liver via the vascular system resists antitumor defense mechanisms and can adhere as viable cells to endothelium of blood vessels, chiefly endothelia of hepatic sinusoids. Here, they start to respond to growth factors produced and secreted by neighboring hepatocytes, perisinusoidal cells, and vascular cells. In the first step, this results in avascular micrometastases in periportal areas of liver lobules. The next step is characterized by stroma formation, a prerequisite for angiogenesis, because newly formed blood vessels depend on being embedded within a mesenchymal matrix with its specific extracellular matrix (ECM) proteins. Fibroblasts from portal tracts become cancer-associated fibroblasts (CAFs) as an important component of stroma, and stromal myofibroblasts are recruited from activated hepatic stellate cells and portal tracts. Together, these cells generate a "private" tumor microenvironment that has a pro-metastatic effect (Vidal-Vanaclocha 2008, 2011).

The Pro-metastatic Effect of Stromal Interactions

The stromal microenvironment profoundly influences many steps of cancer progression, including the ability of cancer cells to metastasize (the 'stromal factor'; Wernicke et al. 2011). Within stroma, influences of this distinct and complex microenvironment are mediated by bidirectional interactions between epithelial tumor cells and the neighboring stromal cells, these interactions referring to adhesion, migration, proteolysis, angiogenesis, homing strategies, epithelial-mesenchymal transition, immune escape mechanisms, and survival (reviews: Bogenrieder and Herlyn 2003; Orimo and Weinberg 2006).

What are the pathways leading to stromal formation in metastases? Early in the outgrowth phase of murine colorectal carcinoma micrometastases, hepatic Kupffer cells and fibroblasts are recruited and start to invade the metastatic nodules. These transitional metastases are connected by protrusions of fibroblast-rich tissues co-localized with collagen-rich matrix and CD31-positive cells. The latter step is characterized by the generation of a pro-angiogenic niche and the switch of a transitional metastasis to an established, vascularized metastasis (Higashi et al. 2002). Stromal components, including

fibroblasts, myofibroblasts, endothelial and other vascular cells, mesenchymal stem cells, granulocytes, and cells of the immune system, interact with carcinoma cells to promote growth, invasion, and metastasis (reviews: Li et al. 2007; Aharinejad et al. 2009; Finger and Giaccia 2010; Pietras and Ostman 2010; Udagawa and Wood 2010). Stroma-derived growth factors and cytokines produced by stromal-resident lymphoid cells and macrophages activate autocrine and paracrine oncogenic signaling pathways, which in turn promote proliferation or spread of epithelial cancer cells. Stromal cell can produce matrix metalloproteinases (MMPs) which are known to operate within the invasion cascade. However, whereas MMP-9 is upregulated in primary CRCs, it is expressed mainly by macrophages in the invasion zone of hepatic metastases and there generally less expressed than in primary tumors (Illemann et al. 2006). Both mesenchymal cells and macrophages are active in the procoagulative environment of tumors, coagulation factors such as fibrinogen and thrombin affecting tumor cell growth and differentiation. Components of stromal cells may also promote the locomotor and migratory activity of carcinoma cells. The intermediate filament protein, vimentin, a constituent of mesenchymal cells, is an AKT1 target mediating motility and invasion (Zhu et al. 2011a). Factors regulating epithelial-mesenchymal transition (EMT) affect the metastatic process. The developmental transcription factor, Six1, induces EMT in dependence of TGF-beta signaling. Six1 is a critical mediator of the switch in TGF-beta signaling from tumor-suppressive to tumor-promotional activity, the TGF-beta type I receptor being the target of Six1 and a critical effector of Six1-induced TGF-beta signaling and EMT (Micalizzi et al. 2010).

Cancer-Associated Fibroblasts

Cancer-associated fibroblasts (CAFs) seem to regulate many aspects of tumorigenesis and cancer spread (reviews: Orimo and Weinberg 2006; Cirri and Chiarugi 2012). Stromal fibroblasts in CRC metastases originate from resident fibroblasts and create an inflammatory microenvironment characterized by TNF-alpha-mediated upregulation of IL-8 via nuclear factor kappaB (Mueller et al. 2007). Colorectal cancer-associated fibroblasts represent a genetically distinct population of stromal cells (Mrazek et al. 2014). Activated CAFs residing in tumor stroma are a source of growth factors for carcinoma cells, factors promoting angiogenesis and lymphangiogenesis, cytokines mediating tumor immunity, and factors involved in epithelial-mesenchymal transition (Räsänen and Vaheri 2010). Primary CAFs from colorectal liver metastases express several inflammatory, tumor-enhancing factors, including IL6 and monocyte-chemoattractant protein (MCP)-1. Both factors are induced by TNF-alpha, which also upregulates ICAM-1. A similar reaction pattern was found for liver-resident, non-tumor-associated fibroblasts (Mueller et al. 2010), which may therefore constitute a cell type playing a role in the generation of a pro-metastatic stroma. The stroma of carcinomas exerts an influence on angiogenesis and antiangiogenesis and by this affects the development of metastases. The growth of metastases is dependent on the growth of blood vessels into the tumor mass. The extracellular matrix of the stroma and its specific proteins, including basement membrane laminin, fibronectin, and tenascin, is a source of both pro-angiogenic factor activation and endogenous angiogenesis inhibitors, such as endostatin (review: Nyberg et al. 2008). Multicellular spheroids of murine colorectal cancer cells mimic micrometastases and their growth pattern activates the pro-angiogenic phenotype of the carcinoma cells (Valcarcel et al. 2008). Antiangiogenic effects and hypoxia-dependent signaling pathways are counteracted by semaphorin 3A produced by cancer cells in metastases (Maione et al. 2012).

Lymphangiogenesis in Hepatic Metastasis: Does It Play a Role?

For the metastatic spread of cancer cells, generation of a lymph vessel network (lymphangiogenesis) plays a crucial role. A dynamic lymph vessel system has an active role

in metastatic dissemination, and metastasizing tumor cells are capable to synthesize and secrete factors that promote lymphangiogenesis. In a mouse model of breast cancer, tumor cells produced the homeodomain-containing transcription factor SIX1, which induces lymphangiogenesis and metastasis via upregulation of VEGF-C (Wang et al. 2012a).

Interactions of Metastatic Carcinoma Cells with Hepatic Stellate Cells (HSC)

As stroma plays a significant role in homing and growth of carcinoma metastasis, cells potentially producing stroma in the liver are of specific interest. Apart from fibroblasts and myofibroblasts in portal tracts and vessel walls, the only cell type of the liver capable of producing extracellular matrix is the hepatic stellate cell (HSC). We have shown that HSCs can interact and form tight adhesions with hepatocytes during the early regeneration phase of the normal rat liver (Mabuchi et al. 2004a, b), suggesting that HSCs can form a epithelial-mesenchymal interactome in the liver. By the use of a nude mouse model, it was demonstrated that intrasplenically injected colon carcinoma cells migrated into the space of Disse and underwent proliferation, in close association with hepatocytes and HSCs. At 14 days, HSCs were accumulated around the emerging small tumor mass and showed transformation into alpha-SMA-positive myofibroblasts. The growing colon carcinoma cells produced PDGF-AB, enhancing proliferation and migration of HSCs, while HSCs produced PDGF-AB, HGF, and TGF-beta and could augment proliferation of carcinoma cells, suggesting complex bidirectional interactions between metastasizing carcinoma cells and activated HSCs (Shimizu et al. 2000). This interaction may result in an "amplification loop" to further metastatic growth in the liver (review: Kang et al. 2011). The transition from HSCs to myofibroblasts in pro-metastatic hepatic stroma is regulated by the fibrillar collagen receptor discoidin domain receptor 2 (DDR2). Downregulation of DDR2 promotes myofibroblast transition and predisposes hepatic tissue to colorectal carcinoma metastasis in mice (Badiola et al. 2011).

Stroma-Associated Inflammatory and Immunologic Effector Cells Control Metastasis Formation: TANs, TAMs, Myeloid-Derived Suppressor Cells (MDSCs), Myeloid Angiogenic Cells (MACs), and Lymphocytes

The stroma of many tumors contains leukocytic infiltrates/inflammatory cells which are instrumental in immune reactions that either inhibit tumors or produce factors that stimulate growth and metastasis. An inflammatory microenvironment induced by myeloid cells is key alteration for promoting tumor invasion and metastatic spread (Grugan et al. 2012; Capece et al. 2013; Smith and Kang 2013; Keskinov and Shurin 2014). A specific role is attributed to tumor-associated macrophages (TAMs), tumor-associated neutrophils (TANs), and myeloid-derived suppressor cells/MDSCs. The presence of TAMs and TANs has been linked to poor clinical outcomes in solid tumors, as these cells can switch from a tumor-suppressing to a tumor-promoting phenotype (review: Alphonso and Alahari 2009). TANs can play a role in tumor cell detachment (tumor cell individualization as a prerequisite for motility and migration), have a pro-angiogenic activity, and secrete MMP-9 playing a role in tumor invasion (Benson et al. 2012).

TAMs form a major component of tumor stroma, consist of several functionally different subsets, and originate from distinct circulating monocytes that home to the tumor microenvironment (Movahedi et al. 2010). But accumulation of TAMs in stroma is also accomplished by in situ proliferations of TAMs in tumors (Tymoszuk et al. 2014). Local accumulation of monocytes differentiating into TAMs is promoted by the TGF-beta superfamily member, Nodal, which is an embryonal morphogen that is upregulated in numerous tumors (Wang et al. 2014a). The interaction of stromal cells with TMAs results in differential macrophage programming in the tumor microenvironment (Ruffell et al. 2012). TAMs are

major players in the tumor microenvironment and exert a strong influence on progression and metastatic spread of cancer (Hao et al. 2012; Galdiero et al. 2013). In the course of tumor progression, TAMs and their hematogenous precursors, the monocytes, are actively recruited into tumor tissue, and particularly its stroma. In their interaction with tumor and stromal cells, TAMs can undergo several functional changes. Whereas classical M1 macrophages are engaged in inflammatory responses, antitumor immunity, and antigen clearance, alternative M2 macrophages are active in anti-inflammatory reactions, wound healing, stroma formation, and tumor progression (reviews: Chanmee et al. 2014; Van Overmeire et al. 2014). TAMs most closely resemble polarized class two macrophages/M2 and are cells that markedly modulate the composition and function of tumor microenvironments (Mantovani et al. 2002). TAMs have upregulated expression of CD206 and CD163 markers of alternative activation but do not have increased expression of classically activated macrophage markers, CCR2 and CCR5. Monocytes as precursors of M2 TAMs are recruited to metastatic sites by distinct homing mechanisms. A major ligand facilitating monocyte accumulation is P-selectin glycoprotein ligand-1/PSGL-1 (Hoos et al. 2014).

The interaction of TAMs with tumor cells is mediated by adhesion molecules and glycosaminoglycans. Hyaluronan synthase HAS2 stimulates the interaction between cancer cells and TAMs and promotes tumor progression and metastasis (Okuda et al. 2012). The interactome of TAMs, lymphoid cells (mainly T cells), and myeloid-derived suppressor cells is active in pro-angiogenic reactions and the preparation of homing vascular surface facilitating tumor cell and platelet adherence and cancer cell transmigration (reviews: Labelle and Hynes 2012; Smith and Kang 2013).

M2 TAMs exhibit a distinct functional profile characterized by the (stimulated) production of a wide array of factors. Activated TAMs can produce a host of cytokines that can modulate tumor cell behavior and affect stromal cell production function. TAMs strongly express interleukin receptor-associated kinase (IRAK)-M, a serine/threonine kinase that is a potent negative regulator of Toll-like receptor signaling (Kobayashi et al. 2002). In tumors, IRAK-M is induced by TGF-beta1 from stromal cells and regulates tumor growth (Standiford et al. 2011). TGF-beta1 plays a central role in myeloid cell regulation (Pang et al. 2013). TAMS can secrete matrix metalloproteinases (MMPs), including MMP-9, whereby differentiation-related expression of MMP depends on an interaction of the ECM component, laminin.-5, with monocytes (Kamoshida et al. 2014). TAMs produce oncostatin M and VEGF (Benson et al. 2012). Tumor-infiltrating monocytes/macrophages produce and secrete the innate immune response mediator, human beta-defensin-3, a factor that inhibits cancer cell migration through downregulation of metastasis-associated 1 family, member 2 (MTA2 9 expression (Uraki et al. 2014)). TAMs are involved in the progression of HCC, as M2 type macrophages can modulate the composition of HCC stroma and modify immunosuppressive functions of immune effector cells (Shirabe et al. 2012). In HCCs, TAMs can promote a stem cell-like property of cancer cells through TGF-beta1-induced epithelial-mesenchymal transition (Fan et al. 2014), a mechanism that favors a metastatic phenotype. TAMs can also induce the expression of the macrophage receptor, CD163, in malignant cells, thus resulting in some sort of "induced receptor sistership". CD163 expression in a subpopulation of cancer cells may constitute a phenotypic shift associated with epithelial-mesenchymal transition, increased invasion, and a metastatic phenotype (Maniecki et al. 2012). Part of TMAs are involved in the promotion of angiogenesis (Owen and Mohamadzadeh 2013). These specialized cells are termed myeloid angiogenic cells (MACs). MACs are in part Tie-2 expressing monocytes and significantly contribute to angiogenesis and vascular repair through paracrine mechanisms as they lack the capacity to differentiate into endothelial cells (Chambers et al. 2013). Experimental selective ablation of TAMs with MAC features suppresses angiogenesis and metastatic tumor spread (Lin et al. 2013). MAC-induced angiogenesis depends on the expression of the myeloid cell receptor LRP1/

CD91 that regulates monocyte recruitment and VEGF availability in tumors (Staudt et al. 2013).

In addition to TAN and TAM, myeloid-derived suppressor cells (MDSCs) play a significant role in the function of tumor microenvironment, tumor progression, and metastasis (reviews: Schmid and Varner 2012; Brandau et al. 2013; Diaz-Montero et al. 2014). MDSCs are bone marrow-derived myeloid cells that are recruited to tumors, where they are transformed to potent immunosuppressive cells, which, however, also have functions other than blunting immune reactions (reviews: Mantovani et al. 2009; Dumitru et al. 2012; Schmid et al. 2012; Diaz-Montero et al. 2014). Apart from their role in mediating immunosuppression via strong inhibition of antitumor immune reactions produced by T cells, MDSCs strongly stimulate tumorigenesis, tumor growth, and metastasis (Umansky and Sevko 2013), probably by modulating the cellular composition of stroma in pro-metastatic niches. MDSCs enhance the stemness of cancer cells by inducing micron-101 and suppressing the corepressor CtBP2 (C-terminal binding protein-2, a protein that directly targets stem cell core genes resulting in cancer cell stemness and an invasive and metastatic phenotype (Cui et al. 2013)). The function of MDSCs is regulated by microRNA-155. Downregulation of the miR enhances the recruitment and function of MDSCs in the tumor microenvironment (Wang et al. 2014d).

Interactions of Carcinoma Cells with Hepatic Blood Vessel Cells and Vascularization of Metastases

Successful growth of metastases requires the generation of a stroma harboring blood vessels produced in the setting of tumor-induced angiogenesis. The mode of neovascularization of metastases originating from various tumors varies itself considerably, suggesting an "individualized" mode of angiogenesis. A corrosion case study of 22 livers with multiple metastases from different primary neoplasms showed the development of an individual pattern of vascularization in all metastases. The majority of metastase displayed a distinct blood supply by branches of the hepatic artery and portal vein branches, whereby all metastases of the same liver showed an identical vascularization pattern (Strohmeyer et al. 1986). Intra- and peritumoral connections between vessels fed by the arteries and portal vein branches are mediated by sinusoidal connections (Nikfarjam et al. 2003). Also a Microfil injection study in human autopsies with liver metastases showed both an arterial and portal mode of vascularization, although the hepatic artery mode was more important (Lin et al. 1984). Injection studies of human liver metastases exhibited a highly abnormal mode of vascularization, never imitating the normal angioarchitecture of the liver (Strohmeyer et al. 1987). Gelatine-injected specimens of human hepatic metastases also revealed that vascularized micrometastases in the vicinity of macrometastases are more common than anticipated from routine preparations (Haugeberg et al. 1988). A gamma camera imaging study of colorectal hepatic metastases revealed that more than twice as much of test substrate was delivered per volume of tumor relative to liver by the hepatic artery as by the portal vein (Ridge et al. 1987). Portal vein blood played a minor role in a rat model of liver metastases (Archer and Gray 1989). In a murine model, blood feeding metastases was distributed from arteries to capillaries of the metastasis center, from where it flowed to a superficial venous network and then further to hepatic veins (Voboril 2005).

In a murine hepatic metastasis model, sinusoidal endothelial cells are activated by interaction with colon carcinoma cells. These activated endothelial cells display an increased expression of mannose receptor (ManR) and ManR-mediated endocytosis. This effect depends on a two-step mechanism: (1) release of COX-2-dependent IL-1 stimulating factors by LFA1-expressing C26 cells in response to ICAM1, which is expressed by activated sinusoidal endothelial cells and (2) widespread upregulation of ManR in endothelia through tumor cell-induced IL-1. ICAM-1-induced tumor COX-2 decreases antitumor activity during hepatic metastasis through Il-1-induced ManR in endothelial cells, ManR therefore constituting a common mediator

for the pro-metastatic effect of Il-1, COX-2, and ICAM-1 (Arteta et al. 2010).

Features of Hepatic Parenchyma That Can Promote Metastatic Growth

Ischemia/reperfusion injury to liver parenchyma can accelerate the outgrowth of preestablished colorectal micrometastases (van der Bilt et al. 2005). With increasing ischemia times, tissue necrosis, and ischemia/reperfusion injury-accelerated tumor growth in mice increased, and in this murine model, outgrowth of micrometastases was further increased by increasing the age of the mice and steatosis of the livers (van der Bilt et al. 2008).

Actions of miRNAs in the Tumor Stroma

In breast cancer metastases, it has been found that miRNA-31 inhibits metastatic growth through the pleiotropic suppression of pro-metastatic target genes that include integrin alpha(5), radixin, and RhoA (Valastyan et al. 2010). Heparanase, a potent protumorigenic and pro-metastatic enzyme which is produced by stromal cells, is targeted and suppressed by miRNA-1258 (Zhang et al. 2011). Epigenetic alterations of miRNA deregulation are common in various tumors. Enhancer of zeste homolog 2 (histone H3 lysine 27 trimethylating enzyme), frequently upregulated in malignancies, epigenetically silences multiple tumor suppressor miRNAs to promote liver cancer metastasis (Au et al. 2012).

Pathogenic Features of Liver Metastases: Epithelial-Mesenchymal Transition (EMT)

Introduction

Epithelial-mesenchymal transition (EMT) is a major process involved in the construction of tissues in early stages of ontogenesis. There, EMT is characterized by the internalization of epithelial cells to give rise to mesodermal/mesenchymal tissues. To arrive at this result, epithelial cells must undergo dramatic changes, including the disconnection of junctions, undergoing polarization and shape change to become migrating cells, and altering cell surface adhesion molecule complements (the "adhesome"). Specifically, distinct expression patterns of integrins are involved in EMT, described as an integrin adhesome (Zaidel-Bar et al. 2007; Zaidel-Bar and Geiger 2010; Winograd-Katz et al. 2014). Other adhesion platforms involved in EMT generation comprise the cadherin adhesome (Zaidel-Bar 2013) and dystroglycan adhesome (Bello et al. 2014). EMT in cancer is characterized by dysregulation of several molecules that comprise, apart from adhesion molecules, intermediate filament proteins, calcium-binding proteins, and transcription factors. Tumor cells in EMT show loss of E-cadherin expression, upregulation of vimentin, induction of alpha-SMA, and expression of Snail1 and Snail2/Slug (Maeng et al. 2014). Typically, cells engaged in EMT fail to express E-cadherin, an important adhesin. The dissolution of the E-cadherin-mediated adherens junction is an important early step in EMT in epithelial malignancies. Downregulation of E-cadherin is accomplished by the action of several transcription factors forming a hierarchical system. Initial transcriptional inducers of EMT are Snail1 and Snail2/Slug, which lead to the activation of ZEB family members, TCF3, TCF4, Twist, Goosecoid, FOXC1, FOXC2, H-Ras, CD44, claudin-1, TGF-beta1, and TNF-alpha. Upregulation of Snail2/Slug and FOXC2 by either Snail1 or Twist does not depend in TGF-beta1 signaling (Taube et al. 2010; Hugo et al. 2011; Qin et al. 2012; Xu et al. 2012; Suh et al. 2013; Caja and Vannucci 2014; Liu et al. 2014b; Okabe et al. 2014). Slug (or now Snail2) is a transcriptional repressor of E-cadherin and is a downstream target of SPARC/osteonectin (Fenouille et al. 2012). Twist1, a basic helix-loop-helix protein transcription factor involved in EMT both in ontogenesis and cancer, is regulated by phosphoregulation (Firulli and Conway 2008) and stabilized by autophagy deficiency via

binding of SQSTM1 to Twist1 in order to prevent autophagosomal Twist1 degradation (Qiang and He 2014). A negative regulator in EMT-related TGF-beta signaling is Smurf2, a protein that interacts with the HCV viral protease NS3-4A (Verga-Gérard et al. 2013). The factors activated by the master EMT inducers Snail1 and Slug have themselves distinct targets that mediate their effects in the EMT molecular pathway. For example, ZEB1 has the collagen receptor tyrosine kinase, discoidin domain receptor 1/DDR1 as its transcriptional target, whereby ZEP1 downregulates DDR1 and contributes to an invasive cancer cell phenotype (Koh et al. 2014). Twist1, having a central role as an effector for EMT induction, can also induce endothelial transdifferentiation of cancer cells through a Jagged1-Krüppel-like factor/KLF-4 signaling axis (Chen et al. 2014a). A further transcription factor involved in EMT and metastasis I a cytotoxic T-lymphocyte agonist epitope of brachyury. EMT is also regulated by the Wnt/beta-catenin signaling cascade, which is activated in the setting of EMT by stromal cell-derived factor 1/SDF-1 and its receptor, CXCR4 (Hu et al. 2014). EMT induced by TNF-alpha requires stabilization of Snail1 mediated by Akt/GSK-3beta signaling, GSK-3beta being a Wnt signaling component (Wang et al. 2013a). EMT can be induced by extravasated platelet aggregation, one critical molecular being CD42b coexpressed with Snail1 (Miyashita et al. 2014).

In addition to factors promoting EMT, there are pathways counteracting EMT generation, and it may be anticipated that failure of such inhibitory pathways in tumors might be involved in metastasis. Protocadherin 9, frequently lost in HCC, inhibits EMT and cell migration through activation of the Wnt signaling component, GSK-3beta (Zhu et al. 2014). EMT can be repressed expression of SMAR1 which represses Snail2/Slug transcription and inhibits E-cadherin degradation in cancer cells (Adhikary et al. 2014). SMAR1 is a nuclear protein involved in chromatin homeostasis that binds to nuclear matrix attachment regions/MARs, regions crucial for proper periodic chromatin arrangement.

Epithelial-Mesenchymal Transition as a Metastasis-Promoting Alteration in Cancer

EMT plays a central role in the generation of a proinvasive tumor microenvironment and metastatic spread of cancer (reviews: Chaffer and Weinberg 2011; Jing et al. 2011; Meng and Wu 2012; Jung et al. 2015). EMT provides cancer cells with migratory, invasive, stroma interactive, and stem cell properties that enable them to disseminate and settle at remote sites. Advanced cancer stage and metastatic spread in HCC are associated with a typical EMT-related cellular alteration, i.e., downregulation of E-cadherin (Zhai et al. 2014). Abnormal expression of EMT-related proteins in HCC, i.e., loss of E-cadherin and overexpression of vimentin and S100 proteins, is correlated with an aggressive metastatic phenotype of this tumor (Zhai et al. 2014). EMT in HCC is related to hepatitis virus infection, viral proteins promoting EMT pathways by various mechanisms (Wang et al. 2014d). For example, HCV-induced expression of osteopontin, a pro-metastatic phosphoprotein overexpressed in HCC, is associated with EMT via the activation of the GSK-3beta signaling pathway (Iqbal et al. 2013).

EMT promoting invasion and metastatic spread in cancers, including liver cancer, is induced by aberrant expression of various pro-EMT factors. Metastasis in HCC is strongly promoted by overexpression of the pro-EMT transcription factor, Snail2/Slug (Sun et al. 2014). TGF-beta1 plays a central role in EMT induction and metastasis in HCC (Reichl et al. 2012). TGF-beta1, which induces EMT in HCC, is induced in these tumors by tumor-associated macrophages/TAMS which also promote cancer stem cell-like features in HCC cells (Fan et al. 2014). Tumor-derived secretory clusterin, a protein involved in the regulation of TGF-beta1-Smad3 signaling, facilitates HCC metastasis via induction of EMT (Wang et al. 2012b). Another member of the TGF-beta family of proteins, bone morphogenetic protein-9/BMP-9, also induces EMT in HCC (Li et al. 2013). Upregulation of hepatocyte growth factor/HGF promotes

carcinogenesis and EMT in HCC through Akt and COX-2 pathways, whereby HGF causes loss of cell surface E-cadherin (Ogunwobi and Liu 2011). Expression of the Hedgehog signaling effector, Gli1, in HCC promotes EMT, invasion, and metastasis (Chen et al. 2014b). ZEB1, a second rank effector of EMT-inducing factors, reduces E-cadherin expression in HCC cells and increased expression of N-cadherin and vimentin, promoting EMT and metastasis in HCC (Zhou et al. 2012). Forkhead box Q1/FOXQ1, a master regulator of tumor metastasis, promotes HCC metastasis by transactivating the EMT inducer ZEB2 (Xia et al. 2014). Loss of expression of functional p53 in HCC is correlated with EMT via regulation of the beta-catenin signaling pathway (Wang et al. 2013b). Downregulation of lipocalin-22 by TGF-beta1 is associated with Tist1 expression and EMT in HCC (Wang et al. 2013b). Stress-activated protein kinase (SAPK)-interacting protein1 or SIN1 which is a key regulator of Akt is overexpressed in HCC and promotes metastasis via induction of EMT (Xu et al. 2013). Activated Wnt/beta-catenin signaling enhances hypoxia-induced EMT in HCC via crosstalk with hypoxia inducing factor-1alpha signaling (Zhang et al. 2013b). Hypoxia and hypoxia-inducible factor-1alpha as such induce EMT in HCCs through activation of Snail1 (Zhang et al. 2013c). EMT-related upregulation of hypoxia-inducible factor-1alpha induces the transcription factor PROX1, resulting in HCC metastasis (Liu et al. 2013). Sirtuin 1/SIRT1, a protein implicated I telomere maintenance and growth in HCC, can mediate EMT in these neoplasms by GSK-3beta/beta-catenin signaling (Chen et al. 2013). Metastasis of HCC induced by EMT is promoted by elevated expression of myeloid differentiation factor 88/MyD88, a protein interacting with p85, a regulatory subunit of phosphoinositide 3-kinase/PI3-K, causing Akt activation, subsequent GSK-3beta phosphorylation, and stabilization of the pro-EMT factor Snail1 (Jia et al. 2014). HCC expresses mortalin, a member of the HSP70 heat shock protein family involved in stress response regulation. Overexpression of mortalin is associated with EMT, angiogenesis metastasis in HCC (Yi et al. 2008; Chen et al. 2014c). In HCC, EMT is induced metadherin, a protein known to increase metastasis in these tumors (Zhu et al. 2011b). In various cancer types, including HCC, EMT as a mechanism involved in metastasis is modulated through the expression of members of a calcium-binding family, the S100 proteins. S100 proteins are critically involved in tumor cell-stromal cell interactions, promotion of EMT, and the generation of a proinflammatory tumor microenvironment promoting invasion and spread (Lukanidin and Sleeman 2012). Induction of EMT by S100A4 is regulated by the Sonic Hedgehog-Gli1 signaling pathway, whereby the Hedgehog effector Gli1 modulates S100A4 expression via cis-acting elements (Xu et al. 2014). S100A4 induces migration and invasion in HCC cells through the induction of an NF-kappaB-dependent MMP-9 signal (Zhang et al. 2013d). In HCC, abnormal expression of EMT-related S100A4 is correlated with an aggressive tumor biology (Zhai et al. 2014). The metastasis-associated protein S100A4 induces a network of inflammatory cytokines that activate stromal cells to have protumorigenic features (Bettum et al. 2014). In addition to S100A4, a second S100 protein can induce EMT, i.e., S100A2, acting through functional interaction with Smad3 which is enhanced in the presence of high calcium and TGF-beta activity (Naz et al. 2014). In HCC, ectopic expression of metastasin, a further calcium-binding protein, induces typical EMT with decreased E-cadherin and upregulation of vimentin via upregulation of SNAI1 (Zheng et al. 2013). Several EMT-associated proteins are regulated by BTB/POZ domain-containing protein 7/BTBD7 in HCC (Tao et al. 2013). In cancers, EMT is connected with the induction of an inflammatory microenvironment that plays a role both in favoring invasion and spread and tumor control by immune mechanisms. TGF-beta1 contributes to an inflammatory niche through promotion of immune cell homing and switching the phenotypes of tumor-infiltrating immune cells (Fuxe and Karlsson 2012).

Regulation of Epithelial-Mesenchymal Transition

EMT as a motor of the metastatic pathway is regulated by several mechanisms that control expression of pro- and anti-EMT factors. Numerous factors are regulated by epigenetic promoter methylation, with a complex EMT-related or even EMT-specific DNA methylome. EMT factors are controlled by microRNAs. MiR-29c mediates EMT in human CRC metastases via modulation of beta-catenin signaling (Zhang et al. 2014a). MiR-424-5p can reverse EMT in HCC by targeting the beta-catenin inhibitor, ICAT (Zhang et al. 2014b). MiR-122 triggers EMT and suppresses HCC cell motility, migration, and invasion via targeting RhoA (Wang et al. 2014b). Downregulation of microRNA-30a in HCC facilitates migration and invasion through promotion of EMT (Liu et al. 2014a). This miR can, however, also inhibit EMT via targeting the pro-EMT factor Snail1/Snai1, an effect circumvented by its downregulation in cancers (Kumarswamy et al. 2012). MicroRNA-26b inhibits EMT by targeting USP9X, a protein which in turn affects EMT through Smad4 and the TGF-beta signaling pathway (Shen et al. 2014). MicroRNA-148a suppresses EMT and metastasis of HCC by targeting Snail signaling (Zhang et al. 2014c). MiR-491 is involved in the regulation of HCC metastasis by blocking EMT via increase of surface E-cadherin expression (Zhou et al. 2013). Overexpression of microRNA-106b promotes cell migration and metastasis in HCC via promoting EMT via overexpression of the RhoGTPases, RhoA, and RhoC (Yau et al. 2013). Micro-RNA-490-3p modulates HCC cell growth and EMT by targeting endoplasmic reticulum-Golgi intermediate compartment protein 3/ERGIC3 (Zhang et al. 2013). The invasive and metastatic behavior of HCC is suppressed by microRNA-612 which inhibits EMT (Tao et al. 2013). Metastasis regulated by EMT is also subject to modulation by long noncoding RNAs that affect transcriptional and posttranscriptional steps in synthesis of critical factors (Serviss et al. 2014). A long noncoding RNA activated by TGF-beta promotes the invasion-metastatic cascade in HCC (Yuan et al. 2014).

The Concept of the Pre-metastatic Niche

Introduction

The establishment of a microenvironment that favors homing and growth of cancer cells is a critical condition for the generation of metastasis. The biogenesis of metastases requires a distinct tumor cell-host organ interface in early phases of the metastatic process (Gassmann and Haier 2008). The cellular basis for this pathway of metastasis has been reviewed (Oppenheimer 2006) and has resulted in the concept of the pre-metastatic niche (pre-MN). A pre-MN is defined as a distinct variant of microenvironment that is induced in target organs of metastasis and facilitates homing, adhesion, growth, invasion, and survival of metastatic tumor cells (Kaplan et al. 2006; Perelmuter and Manskikh 2012; Zoccoli et al. 2012). In this sense, the pre-MN is a structure that precedes, and eventually anticipates, the generation of a metastasis, a novel concept for the understanding of a metastasis cascade. Also for the liver, which is a major metastasis-susceptible organ, a pre-or pro-metastatic microenvironment has been discussed (review: Vidal-Vanaclocha 2008).

The Cellular Preparation of the Pre-metastatic Niche

It was demonstrated that bone marrow-derived cells/BMDC home to the pre-MN via the action of adhesion molecule and chemokine signaling, and there establish clusters that precede the arrival of even single metastasizing cancer cells. Interaction of these BMDC with local cells promotes the upregulation of several factors that will be important for cancer cell growth, including signaling chemokines, stromal differentiation factors, and angiogenic factors (review: Kaplan et al. 2006). Bone marrow-derived myeloid progenitor cells can induce mesenchymal-epithelial transition/MET in remote tissues (Gao et al. 2012b).

Cancer Progenitor/Stem Cells in a Pre-metastatic Niche

Cancer stem cells are thought to possess distinct tissue and cell selection capabilities allowing them to home to a pre-MN (Malanchi et al. 2011). In their interaction with microenvironmental structures, cancer stem cells are not a fixed set of cells but rather a flexible population of cells that can differentiate to typical tumor cells and revert to a stemlike state. There is strong evidence that this switching is regulated by interactions with mesenchymal cells of the niche (Fessler et al. 2013), these cells themselves being programmed to later become true stromal cells, including cancer-associated fibroblasts and myofibroblasts. Within a pre-MN, cancer stem cells dwell in some sort of a "CSC niche" which controls their self-renewal, differentiation, and departure for other niches (Borovski et al. 2011).

Cross-Talk Between Tumor Cells and Elements of the Pre-metastatic Niche

In addition to several classes of stem cells that can prepare the pre-MN, differentiated tumor cells themselves interact in a complex manner with elements of the pre-MN. The interaction with cells of the pre-MN can induce genetic and epigenetic alterations in the homing tumor cells, changes that can themselves promote a metastatic phenotype of the cancer cells (Carlini et al. 2011). The offspring of tumor cells that have undergone such pre-MN-induced changes may be primed to transfer these acquired changes to other potential metastatic sites, eventually to induce novel pre-MNs. On the other hand, tumor cells that have settled in the niche can prime the further development of cells active in the niche (Deng et al. 2012) and induce the evolution of the pre-MN to a complete and active, vascularized stroma (the concept of induced stromal progression).

Programming of the Pre-metastatic Niche by Exosomes

The mechanisms as to how homing cells induce resident cells to become a pre-metastatic microenvironment and then a tumor stroma and an angiogenic field are still not well known. It is assumed that direct contact of homing bone marrow-derived cells and cancer stem cells and differentiated tumor cells with tissue can elicit a differentiation switch of mesenchymal and vascular cells in situ. On the other hand, exosomes delivered by tumor cells and harboring genetic information or signaling molecules can drive pre-MN formation (Alderton 2012). Exosomes contain membrane anchors that allow them to attach to target cells in a niche, to deliver their information cargo (Pant et al. 2012). Exosomes released from melanoma cells and transported to sentinel lymph nodes prepare these nodes for metastasis through remodeling of the lymphonodular microenvironment (Hood et al. 2011). Exosomes released from malignant cells, e.g., melanoma cells, can also educate noncancer progenitor cells toward a pre-metastatic phenotype through the action of the receptor tyrosine kinase Met (Peinado et al. 2012). For this pathway to work, certain conditions must be present in resident cells to interact with exosomes, such as expression of the CD44v6 isoform of CD44, this factor assembling a soluble matrix for exosomes to allow cell embedding and growth (Jung et al. 2009).

Programming the Pre-metastatic Niche by Soluble Factors from Progenitor Cells and Tumor Cells

Apart from direct interaction with future stromal cells and release of exosomes, tumor cells can also secrete various factors that "prepare" the future niche, and in particular its endothelial cells, for cancer cell homing. Such secreted factors include vascular endothelial growth factors, TGF-beta and TNF-alpha. These molecules can elicit the release of secondary signal substances from the

niche, e.g., the chemokines S100A8 and S100A9 (Rafii and Lyden 2006). The latter two chemokines are also produced by macrophages, including those located in pre-MNs (Maru 2007). Proteins of the S100A family, including S100A4, are metastasis-associated proteins (Hemandas et al. 2006). Myeloid progenitor cells from the bone marrow can secrete the proteoglycan, which is capable to regulate remote microenvironments to become of pre-MN (Gao et al. 2012a). Carcinoma cells secreting vascular endothelial growth factor C into lymph, draining the cancer, can induce characteristic changes in locoregional lymph nodes, including an increase in lymphatic vessels and the induction of high endothelial venules, before the arrival of tumor cells (Chung et al. 2012).

Counteracting the Function of the Pre-metastatic Niche

There are several mechanisms that may abolish the generation and functions of pre-MN. Mesenchymal cells and endothelial cells in certain tissues and organs may be refractory to pre-MN-inducing cells and factors, being one explanation why certain tissues are only seldom involved by metastases, e.g., skeletal muscle. Tumor cells having settled and grown in the area of the pre-MN can later destroy this microenvironment (Bidard et al. 2008), rendering it non-functional. A third mechanism depends on the formation of tumor-entrained neutrophils (TENs), cells that circulate in the blood as a response to malignancies but are absent in healthy subjects. TENs inhibit metastatic seeding by blunting the function of pre-MNs via secretion of hydrogen peroxide (Granot et al. 2011).

Abstract

In order to enter an invasive and metastatic cascade, cancer cells must be released and individualized. Cell budding is a process characterized by single cells or small clusters of cancer cells that leave the invasion front. These individualized cells are capable to invade blood vessels and lymph vessels, a process which requires cell motility, differential cell-matrix adhesion, production of invadopodia, and the secretion of lytic enzymes, including metalloproteinases. The invasion armamentarium of cancer cells is not only an inborn feature of these cells but is also modulated by nonneoplastic cells encountered by cancer cells on their invasive track. For example, stromal cell-derived factor 1/CXCL12 stimulates motility and migration of cancer cells that express the respective receptor, CXCR4. Apart from budding cells that are prone to become invasive cells, malignant neoplasms can release, already in early phases, cells that will evolve independent from the primary tumor. These so-called premalignant cells or circulating tumor cells (CTCs) have a fate of their own and possess a high degree of plasticity. There is evidence that such cells are capable to induce premetastatic niches in target organs and to generate a cancer field within the body. Along their metastatic spread and within the premetastatic niche, cancer cells can fuse with normal cell partners of the microenvironment, forming chimeras that play a role in the regulation of growth and epithelial-mesenchymal transition (EMT).

Tumor Cell Budding, Motility, and Invasion as Driving Forces for Liver Metastases

Tumor Cell Budding as a Mode of Tumor Cell Individualization

Colorectal Carcinoma (CRC) cells exert distinct growth patterns that affect disease progression and prognosis, in particular tumor cell budding at the invasive margin. Budding (or sprouting) is defined as small clusters of individualized and poorly differentiated carcinoma cells in or outside the invasion front. The presence of such dissociated, dedifferentiated tumor cells at the tumor-host interface is predictive of lymphatic involvement of CRC (Ogawa et al. 2009), lymphovascular invasion (also in early stage N0 CRC; Wang et al. 2009), predicts local and distant metastases (Nakamura et al. 2005; Zlobec et al. 2008; Suzuki et al. 2009), including lymph node metastasis (Yamauchi et al. 2008), and is correlated with an enhanced malignant potential in CRC (Okuyama et al. 2002; Prall 2007; Kanazawa et al. 2008). These budding cells have undergone epithelial-mesenchymal transition (EMT) and are growth-arrested due to increased expression of p16 and other mechanisms (Jung et al. 2001). Low cellular proliferation at the invasion front, the niche of budding cells, has been associated with poor prognosis in CRC (Palmqvist et al. 1999). Loss of expression of the adhesion molecule, E-cadherin, and APAF-1 were independent predictors of budding, and the loss was associated with more frequent peritumoral lymphocytes and tumor-infiltrating lymphocytes (Zlobec et al. 2007).

Motility, Migration, and Invasion of Tumor Cells: The Role of Invadopodia

The dissociation process of budding cells at the invasion front requires distinct modes of motility/cell locomotion linked to the tumor cells' cytoskeleton. Individualized cancer cells are capable to migrate through the extracellular matrix (ECM) and can form ECM-degrading, actin-rich ventral membrane protrusions called invadopodia, similar to the podosomes of macrophages. These dynamic organelle-like structures adhere to, and proteolytically digest, collagens, laminin, and fibronectin located in the ECM (Yamaguchi et al. 2006; Stylli et al. 2008).

The formation of invadopodia requires WAVE2 expression but seems to be independent of the tubulin system (Kikuchi and Takahashi

2008). In the regulation pathways programming the conversion between rounded and elongated modes of cancer cell movement, DOCK3, NEDD9, WAVE2, and ARHGAP22 are key factors regulating Rac and Rho signaling (Croft and Olson 2008). The formation of diverse types of lamellipode with actin reassembly at the leading edge requires the membrane transport of WAVE2. The membrane transport of WAVE2 requires the association between the constitutive complex of betaPIX and GIT1 with WAVE2 (Morimura et al. 2009) and a small GTPase, Rac1, the motor protein kinesin, and microtubules (the latter not of importance in invadopodia). The p21-activated kinase Pak1 is a downstream effector of Rac1 and binds to WAVE2 and is transported with WAVE2 to the leading edge by stimulation with hepatocyte growth factor. Concomitantly, phosphorylation of tubulin-bound stathmin/Op18 at serine 25 and serine 38, microtubule growth, and stathmin/Op18 binding to the kinesin-WAVE2 complex are induced (Takahashi and Suzuki 2009). The human ortholog of mammalian enabled (hMena), an actin regulatory phosphoprotein involved in the control of cell motility, is expressed at the invasion margin of CRC and here particularly in budding cells (Toyoda et al. 2009).

Immunohistochemical staining for the cytoskeletal component, beta(III)-tubulin, was evident in budding CRC cells, suggesting that changes in tubulin isotypes could modulate the invading activity of these cells (Portyanko et al. 2009). 14-3-3 sigma is frequently expressed in budding tumor cells in the invasive area, and overexpression of the protein modulates cell migration in the presence of the ECM protein, tenascin-C (Ide et al. 2007). As motile dissociated cancer cells (including budding/sprouting cells) with a decreased level of differentiation play a crucial role in carcinoma invasion, the actin remodeling system critically participating in the locomotion machinery is studied in cancer, including CRC. At the leading edge of migrating cells (lamellipodia and invadopodia), protrusive forces are developed by the assembly of F-actin filaments organized in dendritic array at the front and a more distal lamellar linear array. Production and remodeling of F-actin depends on several proteins acting in a highly orchestrated fashion. Tropomyosin markedly inhibits lamellipodium formation and facilitates the distal lamellar linear array, in that it competes with the actin nucleator, actin-related protein 2/3 (Arp2/3) during filament branching, and counteracts the effects of the neural Wiskott-Aldrich syndrome protein, N-WASP (Bugyi et al. 2010). Cortactin is an F-actin-binding protein that stabilizes F-actin networks and promotes actin polymerization by activating the Arp 2/3 complex. Overexpression of cortactin stimulates cell migration in cancer cells, and in CRC cells, cortactin interacts with the zona occludens-1(ZO-1) protein, and expression of this complex favors an invasive and spreading/metastasizing phenotype (Hirakawa et al. 2009). Actin-related protein 2 (Arp2) colocalizes with WAVE2 in CRC cells and this is correlated with liver metastasis (Iwaya et al. 2007). Two CARMIL (capping protein, Arp2/3, and myosin-I linker) family proteins exert important regulatory functions. CARMIL1 localizes to lamellipodia and macropinosomes, and loss of its function causes loss of lamellipodial actin, along with defects in protrusion, ruffling, and macropinocytosis. CARMIL2 colocalizes with vimentin, and loss of its function causes a distinct multipolar phenotype, associated with decreased levels of myosin-IIB (Liang et al. 2009). An important group of regulating factors are members of the TOCA family of F-BAR-containing proteins. These proteins bind to and remodel lipid bilayers in a clathrin-dependent manner via their conserved F-BAR domains and regulate actin dynamics via their N-WASP binding SH3 domains. In mammalian cells, TOCA1 is associated with N-WASP and WPS-1 directly or WAVE2 indirectly via ABI-1 (Giuliani et al. 2009). Generally, BAR (Bin-Amphiphysin-Rvs) domain proteins can sense membrane curvature and recruit actin to membranes. They are also critically involved in clathrin-mediated endocytosis, in which actin polymerization mediated by the Arp2/3 complex is essential for membrane tubulation and vesicle formation and fission. The tubulated membrane between the future endocytic vesicle and the plasma membrane seems to form

an arc upon scission of the endocytic vesicle, and the formation of this structure depends on arc sensing mediated by the RFC/F-BAR domain protein, FBP17 (Suetsugu 2009). In endocytosis, BAR proteins also interact with other components of the endocytic and cytoskeletal machinery, including the GTPase dynamin (which mediates vesicle fission), N-WASP (an Arp2/3 complex regulator), and synaptojanin (a phosphoinositide phosphatase). Three classes of BAR proteins have been defined, i.e., BAR, N-BAR, and F-Bar (Dawson et al. 2006).

Stromal Factors Exerting an Influence on Tumor Cell Migration and Invasion

CXCL12 (stromal cell-derived factor 1) is an important factor for the stimulation of cancer cell motility and migration. CXCL12 promotes motility in neoplastic cells that express the receptor, CXCR4 (Do Carmo et al. 2010). CXCL12+ tumor budding in CRC is a significant prognostic factor (Akishima-Fukasawa et al. 2009). CXCR4 is also known to enhance the proliferation of certain cancer cells via AKT and ERK-dependent pathways (Shen et al. 2010). The liver has high concentrations of CXCL12 (Kim et al. 2005) that could provide a specific homing target and promoting factor for CXCR4-expressing CRC cells. CXCL12 is a constitutively expressed chemokine which orchestrates a large array of functions. Six different isoforms exist in humans (α, β, γ, δ, ε, and ϕ), all differing in their C-terminal domain (Yu et al. 2006). CXCL12 binds to the receptor, CXCR4, which is transcriptionally regulated by HIF-1alpha and a constitutively activated EGFR variant, EGFRvIII (Rahimi et al. 2010). Angiogenesis is promoted by attraction of motile endothelial cells by CXCL12. The axis markedly affects the migration of tumor cells to metastatic sites, allowing cancer cells to access cellular niches expressing the CXCR4 receptor favoring cell survival and growth ("metastatic homing" of cancer cells; Murphy 2001; Burger and Kipps 2006; Dewan et al. 2006). In CRC, CXCR4 expression was found to increase the risk for recurrence, liver metastasis, and poor survival (Kim et al. 2005). The role of the microvascular bed in mechanisms of tumor cell spread surfaced in the observation that concomitant overexpression of CXCR4 and vascular endothelial growth factor (VEGF) in the tumors predicts early distant relapse in stage II-III CRC patients (Ottaiano et al. 2006).

Pathogenic Features of Liver Metastases: Dissemination and Evolution of Premalignant Cells (Circulating Tumor Cells, CTCs) and the "Wandering Field"/"Cancer Field" Hypotheses

In the previous paragraph, it was outlined that the settling of tumor cells and their progenitors at future metastatic sites requires the establishment of a premetastatic niche that permits circulating cells to home to tissues and to interact with the host organ (Sleeman 2012). On the other hand, the early metastatic process also requires that subpopulations of cells are released that are capable to home to a niche and to produce a metastatic growth. The capacity of tumor cells to escape from the primary tumor, individualize, migrate, invade, and spread to remote tissues was described as a phenomenon resembling Darwinian selection (Klein 2013). However, this may represent a simplistic view, as the so-called invasion and metastasis cascade does not seem to exactly work that way. Rather, there is recent evidence that tumor cells and particularly their progenitors (cancer stem cells) individualize and disseminate in very early and primordial malignant neoplasms already, having a still not well-studied status of "premalignant" cells (PMCs), single disseminated tumor cells (DTCs), or circulating tumor cells (CTCs) (Klein 2000; Diamond et al. 2012) that will evolve almost or completely independent from the primary tumor (Ansieau et al. 2008). These individualized cells have a fate of their own and possess a high degree of plasticity (Bednarz-Knoll et al. 2012). It is these PMCs that will acquire, by progressive genomic instability and

selection pressures, distinct genomic signatures, and these alterations will render PMCs capable to induce, and interact with, future premetastatic niches. In this setting, spread of cancer may be described by the features of a "wandering field hypothesis," meaning that PMCs and their induced premetastatic niches form a cancer field that is distributed within the host. The generation and distribution of tumor cells that can finally give rise to metastases in "field-like" body structure has been addressed by methods of systems biology, discussing selection-driven independence, invasion, and so-called swarm intelligence (Tarabichi et al. 2013).

Pathogenic Features of Liver Metastases: Parallel and Nonparallel Progression of Tumor and Metastases

Introduction

An older view of metastatic spread identified the primary tumor as the single important engine determining metastasis through the production and release of fully metastasis-capable cells. A second hypothesis, termed the parallel progression model (Klein 2009), proposes parallel, independent progression of metastases arising from early disseminated cells (single disseminated tumor cells (DTCs); see above). Clonal expansion mechanisms and a marked genetic disparity between primary tumors and disseminated tumor cells (Stoecklein and Klein 2010) support this hypothesis. Other findings were not compatible with the parallel progression model, but the linear progression model in this hypothesis works when it is assumed that tumors harbor two types of cells, i.e., metastasis-forming cells (MFCs), likely to derive from tumor stem cells, and a second set that is not capable to produce metastases. There is evidence that the proportion of MFCs decreases as a function of increasing tumor size, one possible explanation for the observation that at least part of large tumors have a lesser probability to produce metastases (review: Koscielny and Tubiana 2010).

Do Primary Tumors and Their Metastases Share a Parallel Evolution?

Animal experimentation had already shown that removal of a primary malignancy can be followed by rapid outgrowth of metastases. This observation illustrates that primary tumors might exert an effect on growth of their metastases and that primary tumor and metastases may not have parallel growth patterns. In human CRCs, resection of the primary tumor was associated with a modest increase in cancer cell proliferation of synchronous hepatic metastases and a significant decrease in metastatic tumor cell apoptosis. These findings suggest that primary tumors can inhibit growth of their metastases (Peeters et al. 2006).

Pathogenic Features of Liver Metastases: Tumor Self-seeding and Cross-seeding in Metastasis

Introduction

According to classical concepts, metastasis has been considered to be a unidirectional process, whereby cancer cells are released by, or actively emigrate from, the primary tumor and seed cells into lymph nodes and to remote organs. This pathogenetic view, oriented on a mode "as the river flows," has not been questioned for a long time. There is now evidence that metastasis is a multidirectional process, whereby cancer cells can not only seed to distant sites but also back to the primary tumor. The process of recolonizing of the primary tumor and its premetastatic niche is termed, tumor self-seeding. This hypothesis is based on the presence of tumor cell-supporting noncancerous cells not only in remote tissues but also in the primary tumor. The self-seeding model may answer many open questions regarding the complexity of the metastatic process (Norton and Massagué 2006; Norton 2008; Kim et al. 2009; reviews: Leung and Brugge 2009; Aguirre-Ghiso 2010; Hahnfeldt 2010; Norton 2011; Comen et al. 2011; Sleeman et al. 2011; Comen 2012; Comen and Norton 2012). In mice tumor models, it was shown that the self-seeding process can

select more aggressive cells involved in cancer progression (Kim et al. 2009). Circulating tumor cells were found to enhance primary tumor growth, probably through stromal paracrine effects (Hahnfeldt 2010).

Homing Mechanisms in Tumor Self-seeding

How are tumor cells attracted to reinfiltrate primary tumors? Circulating tumors studied in mice secrete factors ("seed-derived factors") that favor stromal recruitment and angiogenesis also in the primary lesion, including the chemokine CXCL1 (Kim et al. 2009). It has been shown that the protein chromogranin A inhibits the shedding of cancer cells into circulation from primary tumors, as well as the reinfiltration of primary tumors, via decreased vascular leakage in tumors and inhibition of transendothelial migration of cancer cells (Dondossola et al. 2012).

Pathogenic Features in Liver Metastases: Cell Clone Ecology Hypothesis

In the cell clone ecology hypothesis, it is assumed that the survival and fate of cell clones that behave like "parasites" in the organism and result in cancer are governed by the principles of ecology. The hypothesis is based on the concept that mutated and aneuploid cell clones undergoing progressive genomic instability are prone to degradation rather than becoming "successfully progressing clones," with an inherent risk to become extinct or enfeebled to become a benign condition. In order to establish a "fit" clone, the cells of a so-called transient clone must undergo cell-cell fusion (the cell fusion model of cancer progression and metastasis). Cell-cell fusion provides, according to this hypothesis, a sex-like mode of reproduction essential for an ecologically fit parasite organism, provides the opportunity required by tumors to rejuvenate cell lines containing abnormal and instable genomes, and serves to overcome erosion of telomeres during clone expansion (Parris 2006a, b).

Pathogenic Features in Liver Metastases: Cancer Cell-Normal Cell Fusion Theory of Metastasis

Introduction

Invasion and spread of cancer cells require an intricate interaction between the tumor cells and normal cells of their invaded tissue environment, involving complex patterns or mutual cross talk between tumor cells, stromal cells, and leukocytes (the so-called seed and soil theory; review : Mareel and Madani 2006). In this complex interplay, cells involved create close contacts through cell-to-cell adhesion and enter a complex interactomics (van der Bij et al. 2005). This may potentially lead to the secretion of factors involved in tumor-stromal interactions (e.g. the matricellular protein SPARC; Podhajcer et al. 2008) and mutual signaling via exchange of signaling substances between normal cells and tumor cells. For example, secreted activated leukocyte adhesion molecule (sALCAM) attenuates melanoma cell invasion (van Kilsdonk et al. 2008). Leukocytes infiltrating tumors facilitate dissemination in that they disrupt intercellular junctions and cell surface adhesion molecules (Man et al. 2011). Leukocytes in contact with tumor cells can create a premetastatic niche (Oppenheimer 2006), but they may also act as myeloid-derived suppressor cells (review: Nardin and Abastado 2008). Furthermore, information may be exchanged between stem cells and cancer cells via horizontal genomic transfer (large-scale transfer of DNA and chromatin; Glinsky 2005). This has been suggested for cancer cells expressing antigen of tumor-associated macrophages (TAMs) (Shabo and Svanvik 2011). However, there is evidence of a more intimate interaction between normal cells and cancer cells (Lagarde 1986). It has been found that macrophages and other bone marrow-derived cells can fuse with cancer cells forming heterologous

chimeras (Vignery 2005; Vignery 2008). Cell-to-cell fusion results in a complex sharing of several cellular features by the chimeras and the eventual emergence of novel types of behavior, including a metastatic phenotype (Lagarde and Kerbel 1985; Parris 2008). Somatic cell fusion is a potent source of genetic rearrangement leading to potentially metastatic cell variants (Larizza and Schirrmacher 1984; Carter 2008). In vitro fusion of a nonmetastatic tumor cell type with a bone marrow-derived macrophage results in the tumor cell's high metastatic capacity (Larizza et al. 1984a). In animal tumor xenograft models, this phenomenon was associated with tumor metastasis (review : Pawelek and Chakraborty 2008).

Macrophage-Tumor Cell Chimeras

It is known that diverse types of malignant neoplastic cells acquire distinct sets of macrophage properties, including morphological appearance, surface adhesion, phagocytosis, motile behavior, and membrane lipid composition (Huysentruyt et al. 2008). This phenomenon has led to the concept of "cancer as a macrophage-mediated autoaggressive disease" (Muntarova and Kovarik 1987). It has been observed that such features may be acquired through heterologous cell-to-cell hybridization (Kerbel et al. 1983; Lagarde and Kerbel 1985). Tumor cell fusion with leukocytes is a source of myeloid traits in cancer, including the acquisition of typical motile behaviors (Rachkovsky et al. 1998; Pawelek 2005). Also the distinct features of tumor-associated macrophages (TAMs) may be acquired by tumor cells via cell fusion (review: Pawelek et al. 2006). Fusion of melanoma cells with macrophages results in acquired melanocyte stimulating hormone-inducible chemotaxis in the tumor cells (Rachkovsky and Pawelek 1999). Macrophage-melanoma cell fusion-induced hybrids upregulate N-acetylglucosaminyltransferase V (beta 1,6-branching; Gnt-V) (Chakraborty et al. 2001), acquire specific motility patterns, are highly metastatic in vivo, and express macrophage-associated traits of increased Gnt-V (Chakraborty and Pawelek 2003; Chakraborty and Pawelek 2007). Gnt-V forms beta 1,6 branching on the trimannosyl terminus of N-glycans, causing the production of beta 1,6 Glc-NAc-bearing oligosaccharide, important for the adhesion and motile behavior of both normal granulocytes and tumor cells. In macrophage-melanoma cell hybrids, these oligosaccharides colocalize with coarse melanin granules (Rupani et al. 2004). It has been proposed that mechanisms allowing escape from the extracellular matrix are important for migration and invasion, and such escape strategies may be acquired through cell fusion (review: Parris 2006b). Macrophages are capable to fuse with epithelial cells of murine intestinal tumors, resulting in nuclear reprogramming with the expression of unique subsets of transcripts (Powell et al. 2011). There is suggestive evidence that the highly metastatic variant ESb of the T cell lymphoma Eb is derived from spontaneous fusion with a host macrophage (Larizza et al., 1984b). Leukocyte-cancer cell fusion might act as the initiator for the use of aerobic glycolysis as a metabolic energy source of cancer cells, the Warburg effect (Lazova et al. 2011).

Tumor Cell-Normal Cell Chimeras

Native or damaged tumor cells can fuse with nonneoplastic host cells, e.g., following irradiation (Wiener et al. 1974a; Ber et al. 1978). Heterospecifc chimeras are a mechanism for horizontal transmission of malignancy (Goldenberg 2012). Normal diploid cells fused to malignant neoplastic cells can suppress the malignant phenotype in the chimeras (Harris et al. 1969; Wiener et al. 1974b). On the other hand, murine melanoma–macrophage hybrids showed enhanced metastatic behavior (Rachkovsky et al. 1998). A fusion-induced alteration in the cell surface structure, involving N-glycosylation of membrane proteins mediated by N-acetylglucosaminyltransferase V, is involved in this mechanism (Sodi et al. 1998; Chakraborty et al. 2001).

Tumor Cell-Tumor Cell Chimeras

There is strong evidence that tumor cells can form hybrids/chimeras among each other by cell fusion. The capability to fuse is not restricted by the type of cell origin or cell lineages involved, in that epithelial cells can form somatic hybrids with mesenchymal cells or germ cell tumor cells (Peterson and Weiss 1972; Litwack and Croce 1979; Fortuna et al. 1989). Fusion of tumor cells, also in vivo, can alter the biological behavior of the cells and effect invasion and spread. Spontaneous fusion of two mouse tumor cell subpopulations resulted in a more aggressive tumor cell variant (Miller et al. 1989), in part with enhanced metastatic potential (Mi et al. 2012), but loss of malignancy of hybrids derived from two murine malignant cell lines has also been observed (Jami and Ritz 1975). A predominance of a metastatic phenotype has been observed in hybrids formed by fusion of mouse and human melanoma cells (van Golen et al. 1996). Certain oncogenic features expressed in tumor cell chimeras can behave in a switchable dominant manner (Zimmermann et al. 1981).

Fusion of Intact Cancer Cells with Cancer Cell Components

Cells can not only fuse with intact partner cells but also with parts of the partner cell body, e.g., organelles and plasma membrane vesicles. Fusion of plasma membrane vesicles from highly metastatic cancer cells affect arrest and metastasis of blood-borne tumor cells (Poste and Nicolson 1980). Fusion of plasma membrane vesicles from highly metastatic cancer cells with blood-borne tumor cells can modify the arrest and mestatatic behavior of the recipient cells (Poste and Nicolson 1980).

Stem Cell-Tumor Cell Chimeras

As a mechanism of pathogenesis of cancer it has long been hypothesized that cancer cells might arise from a hybrid cell which derives from normal somatic cell fusion but obtains a proliferative advantage (Qian 1993). On the other hand, it has been suggested that distinct features of stem cells can be transferred to tumor cells through cell fusion. According to this concept, cancer can result from a fusion between an "altered" premalignant cell and a bone marrow-derived stem cell, aneuploidy as a typical feature of tumor cells being the direct result of this fusion process. This model might explain striking similarities between stem cells and cancer cells (He et al. 2005).

Organelle Chimeras of Normal Cells

Through cell fusion, cells can uptake organelles from partner cells. The resulting organelle chimera is heteroplasmic (heteroplasmy). On a genomic level, heteroplasmy denotes a situation characterized by the presence of a mixture of more than one type of organelle genomes, mainly mitochondrial DNA and plastid DNA, within a cell or individual. However, the term heteroplasmy is most often employed to describe a distinct state of the mitochondrial genome. Mitochondrial heteroplasmy results from mutations in the mitochondrial genome, whereby microheteroplasmy with numerous independent mutations is normally found in organisms. There is evidence that the most dramatic effects of heteroplasmy on the fate of the chimeric cells are obtained in case of mitochondrial chimeras, which contain two or more sets of mitochondrial DNA (Hua et al. 2012). Very low-level heteroplasmy mitochondrial DNA variations are an inherited trait in humans (Guo et al. 2013). Normal mammalian cells can even be propagated after integration of organelles as foreign as those of plants, e.g., chloroplasts (Nass 1969).

Heterosis

Heterosis or hybrid vigor (synonym: outbreeding enhancement) denotes the phenomenon that hybrids of two genetically pure cell lines grow more rapidly or give rise to more cells than the

parental pure lines. The phenomenon of heterosis results in increased yield of cellular offspring and therefore increased biomass (Shull 1948; McDaniel and Sarkissian 1966; Baranwal et al. 2012; Groszmann et al. 2013). Effects of gene dosage imbalances play a significant role in heterosis. The underlying mechanisms seem to involve cumulative positive effects in the differential expression of sets of genes on yield-producing metabolic pathways (reviews: Kamb 2003; Baranwal et al. 2012). For a heterotic phenotype to occur, genetic and genomic studies have shown that gene expression in hybrids is regulated by the interactions of the two parental epigenetic systems and their genomes (review: Groszmann et al. 2013).

Cell Chimeras and Nuclear Alterations

Fusion of two contiguous tumor cells will increase the chromosome content of the resultant chimera, and this increase of ploidy could facilitate and heighten the inherent genomic instability of the lineage. This phenomenon has been observed as spontaneous fusion between metastatic mammary tumor subpopulations (Miller et al. 1988; review: Hart 1983). Murine fusion-derived hepatocytes showed ploidy reductions (Duncan et al. 2009).

Cancer Cell Chimeras and Cell Differentiation

Progression of cancer, including the establishment of a metastatic phenotype, depends on the proliferative status and the differentiation of the neoplastic cells. It is known that hybrid formation between cells affects differentiation of the fusion partners. In hybridization experiments using cells of defined and different histotypes, it turned out that both parental determinations are retained by hybrid cells and that parental differentiation modes are repressed only in a mutually exclusive fashion (Fougère and Weiss 1978). On the other hand, fusion of interspecific cells (rat and mouse) demonstrated that one specific function of one of the fusion partners can be expressed in the hybrid cells (Peterson and Weiss 1972). In hybrids between murine melanoma and teratocarcinoma cells, the formation of "supermelanotic chimeras" depends on the activation of genes involved in differentiation (Watanabe 1984).

Fusion of Human Cells with Cells of Nonhuman Organisms

It has been theorized that normal cells might acquire "dangerous" genetic information by integration of genetic information other than that of viruses. One hypothesis suggests that tumorigenic cells in part originate from fusions between normal human cells and bacteria, the fusion product termed "bactocytes" (Shaw 2003).

Pathogenic Features of Liver Metastases: Transfer of Cell-Free Genomic and Signaling Components Between Metastatic Cells and Between Normal Cells and Tumor Cells. An Extended Concept of Metastasis

Introduction

There is evidence that genetic and signaling information can spread from cancer cells to other cancer cells or normal, nontransformed cells (review: Garcia-Olmo et al. 2012). Through such mechanisms, metastasis of cancer has lived a conceptual extension from spread of malignant cells to spread and intracorporeal distribution of subcellular elements and components.

Exosomes

Exosomes are defined as small membrane-bound vesicles which cells can release into their microenvironment and from there to blood and lymph. The morphogenesis and biogenesis of exosomes involve a process of inward budding of membrane compartments into the lumen of late endosomes, followed by the fusion of the proto-multivesicular bodies

with the plasma membrane. The cargo of exosomes consists of noncoding RNAs (including microRNAs and onco-miRs), signaling substances, adhesion molecules, and lipids (Rak 2010; Ludwig and Giebel 2012). As exosomes carry and transport bioactive lipids, and are enriched in cholesterol and sphingolipids in comparison with their parental cells, exosomes can serve as structures mediating intercellular communication dependent on lipid signaling (Record et al. 2014). The transfer of this exosomal cargo may induce pathologic alterations at the exosomal terminals (so-called exosomopathies; Korc 2015). Circulating exosomes and their cargo can successfully be employed as molecular biomarkers for diagnosis, classification, and monitoring of various malignant neoplasms.

Circulating Nuclear DNA (fcDNA)

In cancers, release of intact nuclear DNA or of DNA fragments from cancer cells is a common phenomenon, due to ongoing decay of neoplastic cells and their nuclei caused by apoptosis and necrosis. This DNA enters circulation in the form of free circulating DNA (fcDNA; circulating nucleic acids in plasma and serum, CNAPS; Schwarzenbach et al. 2011; Garcia-Olmo and Garcia-Olmo 2012; Garcia-Olmo et al. 2012; Gonzalez-Masia et al. 2013). In addition to cancer cells, also normal cells and cells of benign tumor release fcDNA. Assessments of fcDNA can be used as diagnostic markers, molecular characterization of primary and metastatic tumors, and design of personalized therapies (Goessl 2003; Fleischhacker and Schidt 2010; Vlassov et al. 2010; Ulivi and Silvestrini 2013).

Circulating Nucleosomes (cNUCs)

Nucleosomes as complexes of nuclear DNA and histone proteins can be released as intact particles from stressed, dying, or dead cells, including cancer cells. In patients with various malignancies, plasma and serum concentrations of nucleosomes are frequently elevated (Gezer et al. 2013). This "nucleosomics" can serve as a biomarker, e.g., for the detection of colorectal cancer (Holdenrieder et al. 2014) and the prognostication in cancer patients undergoing chemotherapy (Stoetzer et al. 2012). Nucleosomes are released from cells stimulated intrinsically or extrinsically to undergo apoptotic cell death, but in certain cells, e.g., neutrophils, nucleosomes can also be released by an active secretion process (Holdenrieder et al. 2012). Increased circulating nucleosomes (cNUCs) are also detected in autoimmune diseases, psoriasis, sepsis, trauma, and situations of large tissue necrosis. As a vehicle for DNA, circulating nucleosomes in cancer patients can be employed similar to fcDNA for diagnostic and monitoring purposes (Holdenrieder et al. 2001; Holdenrieder et al. 2008, Holdenrieder and Stieber 2009; Stoetzer et al. 2012; Wittwer et al. 2013). Nucleosomes and in particular their histones can also form the cargo of exosomes. Interestingly, cancer patients show distinct posttranslational modifications, including trimethylated histone tails, of histones carried by exosomes (Gezer et al. 2012; Leszinski et al. 2012; Gezer and Holdenrieder 2014).

Circulating Mitochondrial DNA (ccfmtDNA)

Similar to nuclear DNA, also mtDNA can escape from damaged normal and cancer cells and enter circulation, either as free mtDNA or in the setting of mitochondria. Circulating mtDNA (circulating cell-free mtDNA, ccfmtDNA) increases with age and can act as so-called damage-associated molecular pattern (DAMP) agents and are considered to be a pathogenic component for a low-grade chronic inflammatory status occurring in elderly subjects, a condition termed "inflamm-aging" (review : Pinti et al. 2014). mtDNA can undergo characteristic mutational changes in various tumors. Circulating cancer-derived mutant mtDNA can therefore be used as a predictive biomarker in several neoplasms

(Ellinger et al. 2012; Uzawa et al. 2012; Yu 2012).

microRNAs (miRNAs) and Other Noncoding RNAs

Micro-RNAs play an important role in the pathogenesis of metastases, as they control the expression of stem cell molecules and molecules involved in invasion and spread (Nicoloso et al. 2009). All examined biological fluids in the body contain extracellular miRNAs that are nuclease resistant. In patients with cancer, neoplastic cells can release miRNA and via this mechanism transfer part of their molecular signature into the organism. In addition to represent a cancer marker, extracellular miRNA are considered molecules with an important cell-to-cell communication function (Turchinovich et al. 2013). Part of miRNAs released into the extracellular space enter blood and lymph circulation and thus become circulating miRNAs. As these miRNAs are highly stable, they are suitable as diagnostic cancer markers that can easily be detected and measured. Circulating miRNAs have now been utilized as markers for several solid neoplasms and hematologic malignancies (Zheng et al. 2013). In particular, plasma miRNA have been identified and evaluated for the early detection, monitoring, and outcome prediction of CRCs and their metastases (Giraldez et al. 2013; Luo et al. 2013; Kjersem et al. 2014). Certain species of miRNA are characteristic for CRCs, such as circulating miRNA-106a, −130b, −378, and −484 (Kjersem et al. 2014; Zanutto et al. 2014). MicroRNA signatures can discriminate between colorectal cancer recurrences to lymph nodes and liver and between CRC metastases and primary hepatic tumors (Drusco et al. 2014). Lymph node metastases of colorectal cancer express distinct patterns of long noncoding RNAs (lncRNAs) (Han et al. 2014), a phenomenon that might, similar to microRNAs, be transferred to remote areas in the body. Apart from microRNAs, other types of noncoding RNAs can be released into circulation, including small interfering RNA (Valiunas et al. 2015).

Exosome-Derived MicroRNAs (miRNAs)

Apart from miRNAs freely circulating in blood and lymph following their release from normal and cancer cells, miRNA can also travel in circulation as cargo located within exosomes (Camacho et al. 2013; Kosaka et al. 2013). Exosomal miRNAs (exomiRNAs) are thought to have a significant role in intercellular communication and transfer of specific signals, as circulating exomiRNA can be taken up by recipient cells to alter gene expression in these cells via RNA interference. This mechanism can induce several functional changes in recipient cells, including induction of pro-inflammatory cytokine expression (Mobergslien and Sioud 2014); exomiRNAs are increasingly employed as noninvasive biomarkers for diagnosing and screening of malignancies (Cazzoli et al. 2013).

Pathogenic Features of Colorectal Liver Metastasis: Prometastatic and Antimetastatic Genes

115

Contents

Abstract

The metastatic spread of various malignancies is regulated by prometastatic genes and antimetastatic genes and their products. In addition to the function of these metastasis-associated genes, numerous epigenetic mechanisms affecting the metastatic cascade have been observed. By this approach, a molecular portrait or molecular signatures of cancers prone to metastasis are identified. In metastasizing hepatocellular carcinoma (HCC) and liver metastases of extrahepatic cancers, alterations of several metastasis suppressor genes have been found. In HCC, well-known members comprise KAI1(CD82) and nm23. Both in HCC and metastasizing colorectal carcinoma, downregulation of KAI1 occurs, thus abolishing the antimetastatic function of this gene. The expression patterns of KAI1 are modulated by various factors, including hepatitis B virus-mediated epigenetic silencing. Nm23, a second antimetastatic protein, acts through its function as a protein that removes prometastatic proteins from the cytosol. In several malignancies, both upregulation and downregulation of this protein were observed.

Metastasis Promoting and Suppressing Genes

Genetic and Epigenetic Mechanisms Controlling Metastatic Spread: Identification of a Molecular Metastasis Portrait

There is increasing evidence that a tumor's proclivity for distinct remote metastatic sites may be encoded in genetic, epigenetic, and transcriptional programs that are expressed in early phases of tumor evolution already and which might allow predictions as to patterns of metastatic sites (reviews: Ramaswamy 2006; Nadal et al. 2007; Chiang and Massagué 2008). DNA microarray-based gene expression profiling has identified specific transcriptional signatures in primary tumors that destine involved cells to perform a metastatic spread (Hunter et al. 2003; Ramaswamy et al. 2003; Minn et al. 2005; Eltarhouny et al. 2008; Kroon et al. 2008; Molloy et al. 2012). These analyses identify what is called a "molecular portrait" of cancers prone to produce metastases. In breast cancer, e.g., a 70-gene prognosis signature has been found, which represents a classifier for the metastatic process and prognosis (Weigelt et al. 2005).

Prometastatic Genes and Gene Products

The search for metastasis-related genes is accomplished by primary-secondary tumor comparisons from large-scale databases (Kim and Lee 2009). By use of expression profiling experiments, a signature of 115 genes was established that differentiated metastatic from nonmetastatic primary CRC. Among these, the TGFbeta inhibitor BAMBI (bone morphogenetic protein and activin membrane-bound inhibitor) was highly expressed in about half of metastatic primary tumors and metastases but not in nonmetastatic tumors. BAMBI is a transmembrane TGFR1/BMPR1-related pseudoreceptor which antagonizes TGF-beta/BMP signaling by inhibiting the formation of functional authentic receptor complexes. BAMBI is a target of canonical Wnt signaling in colorectal tumor cells (Sekiya et al. 2004). This involves the beta-catenin coactivator BCL9-2, and it is suggested that BAMBI regulates CRC metastasis by connecting the Wnt/beta-catenin and TGFbeta signaling pathways (Fritzmann et al. 2009; comment: Carethers 2009). BCL9, the mammalian ortholog of Drosophila Legless, and its homolog BCL9-2 are essential components of canonical Wnt signaling (Brack et al. 2009). BAMBI also undergoes epigenetic regulatory changes, including silencing via hypermethylation of its gene, a mechanism thought to play a role in cancer invasiveness (Khin et al. 2009). Detection of DNA mutations has been accomplished by PCR restriction fragment length polymorphism or mutant-specific amplification K-ras and p53 genes (Hayashi et al. 1995) and has augmented the diagnosis rate of colorectal liver metastases (Schimanski et al. 1999). K-ras codon 12 and 13 mutations are correlated with differential patterns of tumor cell dissemination in CRC patients, in that CRC with codon 12 mutation showed the same pattern of tumor cell dissemination as their K-ras wild-type counterparts, while codon 13 mutants had higher rates of circulating epithelial cells (Conzelmann et al. 2004). Overexpression of fibrinogen-like protein 2 in cancer cells promotes metastatic tumor progression via induction of EMT (Qin et al. 2014).

Metastasis Suppressors: KAI1 (CD82)

Both in metastasizing HCC and metastases of extrahepatic primary tumors, a group of potent metastasis suppressor genes has been identified (reviews: Cook et al. 2011; Hurst and Welch 2011). In HCC, well-known members are KAI1 and nm23. The gene KAI1 (also termed CD82) is a general suppressor of metastasis in numerous types of cancer. The expression of KAI1, encoding a membrane scaffold protein, is reduced in advanced colon cancer and its liver metastasis (Maurer et al. 1999; Zheng et al. 2007), similar to hepatocellular carcinoma metastases (Guo et al. 1998). The antimetastatic actions of KAI1 are as yet

incompletely known. As a membrane scaffold, KAI1 regulates cell adhesion by altering alpha4 integrin stability and regulating spatial integrin arrangement (Termini et al. 2014). KAI1 expression is greater in HCC without intrahepatic metastases (Sun et al. 1998). The expression of KAI1 is modulated by several factors involved in hepatocarcinogenesis. Hepatitis B virus inhibits KAI1 expression via epigenetic hypermethylation of its promoter in HCC cells (Yu et al. 2014). KAI1 expression is downregulated by microRNA-197 which directly targets CD82 (Dai et al. 2014).

Metastasis Suppressors: Nm23

Another protein involved in the metastatic pathway is the nm23 protein group (NDPK-A; Sarris and Lee 2001; Marino et al. 2012). Nm23 (Nm23-H1) was established as the first metastasis suppressor gene (An et al. 2010), while the closely related isoform, Nm23-H2, has antimetastatic functions (Boissan and Lacombe 2006). The gene encodes a protein with multiple functions of which only part are implicated in metastasis suppression. Nm23-H1 is a multifunctional enzyme with nucleoside diphosphate kinase, histidine protein kinase, and exonuclease activities. Owing to the latter function, it was assumed that Nm23 reduces the acquisition of mutations that may promote a transition to a metastatic phenotype. Through protein-protein interactions, Nm23 may remove prometastatic proteins from the cytosol (Marino et al. 2011). In fact, Nm23 can bind numerous proteins that are involved in cancer cell invasion and metastasis, including proteins of Rho, Ras, TGF-beta and ERK-signaling pathways, cytoskeletal components (tubulin, vimentin), cell adhesion proteins, and proteins involved in transcription regulation (Marino et al. 2012). Nm23-H1 suppresses HCC cell adhesion and motility/migration by modulating glycosylation of integrin beta1 (She et al. 2010). Nm23 is expressed in part of HCCs and affects metastasis and prognosis (Nakayama et al. 1992; Yamaguchi et al. 1994; Huang et al. 1998; Guo et al. 2010). In contrast to Nm23-H1, Nm23-H2 can exert a prooncogenic potential in hepatocarcinogenesis and is positively associated with telomerase activity (Iizuka et al. 2003). Low expression of the homeobox gene Barx2 in HCC correlates with metastasis (Zhang et al. 2014), suggesting that Barx2 may act as a HCC tumor suppressor.

Colorectal Carcinoma Metastasis as an Example for Molecular Pathways

Introduction

Investigations regarding distinct gene expression patterns (transcriptomics) characterizing metastasizing colorectal cancers aim at defining predictive models of metastatic spread and personalized treatment strategies (reviews: Ki et al. 2007; Welsh et al. 2008; Jin et al. 2012). In a study on colorectal cancers using array comparative genomic hybridization (aCGH) to assess DNA copy number changes in primary tumors, it turned out that primary tumors which subsequently produced liver metastases had genomic aberrations on chromosome 20q (Bruin et al. 2010). Most colorectal liver metastases harbor the genetic abnormalities also observed in the primary tumors. But liver metastases from many cases showed, in addition, acquisition of genetic aberrations not found in the primary. These aberrations included genetic lesions associated with metastatic colorectal carcinoma, and the acquisition of new chromosomal abnormalities, e.g., losses of chromosomes 4 and 10q and gains of chromosomes 5p and 6p (Munoz-Bellvis et al. 2012). Chromosome 20p11 gains were associated with liver-specific metastasis in patients with CRC (Mekenkamp et al. 2013). The molecular characterization of circulating colorectal carcinoma cells resulted in the identification of 410 genes that formed a signature for these cells (Barbazan et al. 2012).

The Wnt/Beta-Catenin Signaling Pathway in Metastasis

In the initiation phase of colorectal carcinogenesis, dysregulation of the Wnt/beta-catenin

pathway linked to progressive genomic instability plays a significant role (Grady 2008). In early colorectal carcinogenic steps, Wnt signaling is often deregulated by acquired mutations and loss of heterozygosity (LOH) of the adenomatous polyposis coli (APC) tumor suppressor gene, the protein product of which regulates cellular beta-catenin via control of the respective degradation pathway. APC mutation abrogates the colonocyte's capability to regulate intracellular compartmental beta-catenin concentration and causes transport of beta-catenin in the nucleus. In fact, both sporadic and familial APC-associated adenomas show high nuclear concentrations of beta-catenin (Grady 2008). The function of beta-catenin is closely linked with the cell surface adhesion molecule, E-cadherin. In colorectal carcinomas, changes in E-cadherin expression have been correlated with tumor size, histopathology, and differentiation, but the results are still inconsistent (review: Tsanou et al. 2008).

Notch Signaling

A second signaling branch involved in the pathogenesis of metastases is Notch signaling (review: Ishii and Saito 2008). Notch signaling pathways are implicated in the maintenance of self-renewal potential in stem cells, binary cell fate determination in progenitor cells, and induction of terminal cell differentiation (Artavanis-Tsakonas et al. 1999). The Notch receptor is also linked to Wnt/beta-catenin-mediated tumorigenesis (Radtke and Raj 2003). Ligands for the several Notch receptors (NOTCH1, NOTCH2, NOTCH3, and NOTCH4) comprise Delta homologs (DLL1, DLL3, DLL4) and Serrate homologs (JAG1, JAG2).

Ligand binding induces the cleavage of Notch receptors by metalloproteinase and gamma secretase to induce nuclear translocation of the Notch intracellular domain (NICD). Notch signaling inhibitors, NUMB and NUMB-like (NUMBL), are docking proteins that modify distinct pathways of cellular differentiation (Katoh and Katoh 2006a). Gamma secretase is an intramembrane aspartyl protease complex that mediates Notch cleavage and the production of amyloid beta-proteins (reviews: Iwatsubo 2004; Li et al. 2009). The metalloproteinases active in Notch cleavage are a disintegrin and metalloproteases, ADAMs. ADAM proteases have complex functions that include shedding of proteins from cells and matrix contact sites, including matrix proteins (matrix protein sheddases; Franzke et al. 2009) and cytokines such as TNF (TNF sheddases; ADAM17 as a TNF convertase; Black et al. 1997; Moss et al. 1997; ADAM10, Mezyk-Kopec et al. 2009). ADAM10 and ADAM17 are involved in Notch receptor cleavage (Bozkulak and Weinmaster 2009), and ADAM10 is the rate-limiting protease of regulated intramembrane proteolysis, its ectodomain itself processed by ADAM9, ADAMS5, and gamma secretase (Tousseyn et al. 2009). The ectodomain of bound Jagged1 itself is cleaved by an ADAM17-like activity, similar to the cleavage of Drosophila Delta by Kuzbanian. The ectodomain shedding of ligand can be stimulated by Notch and yields membrane-tethered C-terminal fragments of Jagged and Delta accumulating in cells. Presenilin (PS) forms stable complexes with Jagged and Delta and their C-terminal fragments. PS/gamma secretase then mediates the cleavage of the latter to release the Jagged and Delta intracellular domains, a portion of which can enter the nucleus to act as signaling fragments (LaVoie and Selkoe 2003). Intranuclear NICD forms a nuclear complex with CSL (RBPSUH), Mastermind (MAML), p300, and histone acetyltransferase, and this complex induces transcriptional activation of Notch target genes, including HES1, HES5, HES7, HEY1, m HEY2, and HEYL. Overexpression of hes 1 and other Notch targets have been associated with sporadic CRCs. In colorectal cancer cells, the Notch effector is downstream of Wnt/beta-catenin, and it has been shown that Jagged1 is the pathological link between Wnt and Notch pathways (Rodilla et al. 2009). This is of specific interest because it has been shown that Jagged1 is expressed on several progenitor cell systems due to canonical Wnt signaling activation, and this induces self-

renewal of stem cells due to activated Notch signaling (Katoh and Katoh 2006b).

TGF-Beta Signaling in Metastatic Pathways

A third pathway involved in colorectal carcinogenesis is the TGF-beta system, which is now known to be linked to Wnt/beta-catenin signaling. TGF-beta belongs to a ligand-receptor family which also includes several members of the bone morphogenetic protein (BMP) family, and BMPs are involved in carcinogenesis of the colon (Jung et al. 2004). Advanced malignancies often exhibit increased concentrations of TGF-beta, which has been suggested to promote invasion, spread, and metastasis of tumor cells. Inhibition of cell proliferation by TGF-beta is mainly mediated by the Smad pathway; epithelial focal complex formation is independent of Smad. In contrast, focal complex formation of epithelial cells in response to TGF-beta is mediated by two mitogen-activated protein kinases (MAP kinases), extracellular signal-regulated kinase (ERK), and Jun N-terminal kinase (JNK), thus mediating cell migration of epithelial cells in an Smad4-independent manner (Imamichi et al. 2005; Giehl et al. 2007). The TGF-beta pathway is linked to the activin/activin receptor signaling system. The activin type II receptor (ACVR2) gene is a member of the TGF-beta type II receptor (TGFBR2) family and is a putative tumor suppressor gene which is frequently mutated in microsatellite-unstable colorectal cancers (MSI-H colorectal cancers). TGFBR2- and ACVR2-signaling pathways share distinct cellular effectors, the SMAD proteins. ACVR2 transmits the growth effects of activin via phosphorylation of SMAD proteins to affect gene transcription.

Tumors and Tumor-Like Lesions of the Hepatic Ligaments

Tumors and Tumor-Like Lesions of the Hepatic Ligaments

116

Contents

Abstract

Several types of tumors, tumor-like lesions, and cysts can develop in the hepatic ligaments, mainly in the falciform and round ligament. Among mesenchymal tumors, lipoma is a well-known, albeit rare primary neoplasm of hepatic ligaments. These neoplasms take their origin from adipocytes localized between the peritoneal folds of ligaments. Lipomas have to be distinguished from the properitoneal fat pad associated with the falciform ligament. Other rare benign tumors of ligaments include perivascular epithelioid cell tumors, fibroma, lymphangioma, gastrointestinal stromal tumor, paraganglioma, and mature teratoma. There are very rare malignant neoplasms primary to hepatic ligaments, e.g., malignant mesothelioma, leiomyosarcoma, and several other types of sarcoma. Hepatic malignancies can extend into the ligaments and thus mimic primary tumors of these structures. In addition, the hepatic ligaments can be the site of metastatic tumor spread. Cysts located to ligaments include congenital mesothelial or epithelial cysts and hydatid cysts. Mass-forming lesions of ligaments that may be confounded with neoplasms comprise hematomas, abscesses, bilomas, and soft tissue necrosis in pancreatitis.

DOI 10.1007/978-3-319-26956-6_116

Introduction

Various types of benign and malignant neoplasms, cysts, and tumor-like lesions can develop in hepatic ligaments, mainly in the falciform and round ligament (ligamentum falciforme hepatis and ligamentum teres hepatis, respectively). Due to their topographic relationship with the liver, tumors of the ligaments can be confounded with neoplasms originating from the liver substance proper. The anatomy and ontogenesis of hepatic ligaments are discussed in a paragraph at the end of this chapter.

Lipoma of the Hepatic Ligaments

Overall, the hepatic ligaments are considered to be a low potential source of intraabdominal tumors, and in fact, only few bona fide neoplastic lesions originating from these structures have been reported so far, adipose tissue tumors being the most frequently described. The knowledge of such lesions is, however, of interest insofar as several mass-producing lesions of the liver may develop close to the hepatic ligaments and hence result in differential diagnostic difficulties. This question in principle arises in any situation of masses or cystic lesions detected in the left hepatic intersegmental fissure.

Several reports have documented lipomas in the falciform (Honda et al. 1983; Bruneton et al. 1987; Kakitsubata et al. 1993;) or round (Adamsen 1983; Budarin 1988; Farkas et al. 1991) hepatic ligaments. These neoplasms may take their origin from the adipocyte population localized between the peritoneal folds of these structures, and being richly developed mainly in the round ligament, here being in continuity with the adipose tissue of the perihilar hepatic area. Ligamentary lipomas may grow to a large size, in one report resulting in a mass of 20 cm diameter (giant lipoma; Farkas et al. 1991). Similar to lipomas in other locations, regressive changes or even infarction can occur (Adamsen 1983). On imaging, adipose tumorous lesions of the falciform ligament have to be distinguished from focal fatty change of the liver, which frequently occurs close to this ligament, and may result in a diagnostic pitfall on CT, MR, and sonography (Yoshikawa et al. 1987; Ohashi et al. 1995; Soyer et al. 1996; Spelle et al. 1997). Fatty pseudolesions in segment IV adjacent to the falciform ligament have been observed to be caused by drainage of the paraumbilical vein, related to the vascular connections discussed above (Kobayashi et al. 2001). The properitoneal fat pad associated with the falciform ligament (see above; Feldberg and van Leeuwen 1990) may radiologically be confounded with a ligamentary lipoma. Finally, extraperitoneal lipomatous appendages of the falciform ligament can undergo twisting and thus result in differential diagnostic problems on US and CT (Coulier et al. 2001).

Other Rare Benign or Semimalignant Tumors of the Hepatic Ligaments

Only very few other rare benign tumors have been reported as primary ligamentary neoplasms, including angiofibroma (Spay et al. 1973), cystic lymphangioma (Zaev 1989; Morgan and Ricketts 2004), mature cystic teratoma (Abe et al. 1976; Ayyappan et al. 2007; Gangopadhyay et al. 2009; Srivastava et al. 2011), perivascular epithelioid cell tumor (Choi et al. 2009), gastrointestinal stromal tumor (Abedalthagafi 2012), and paraganglioma (Delbridge and Connolly 1982).

Primary Malignant Tumors of the Hepatic Ligaments

The very rare malignant tumors primary to the hepatic ligaments described so far include leiomyosarcoma (Yamagiwa et al. 1967; Mital and Bazaz-Malik 1971; Adachi et al. 1979; Tomaszewski et al. 1986; Morita et al. 1987; Yamaguchi et al. 1996), malignant mesothelioma (Marubayashi et al. 1998), malignant fibrous histiocytoma (Toughrai et al. 2007), fibromyxoid sarcoma (Harish et al. 2003), solitary fibrous tumor with malignant change (Gidwani

et al. 2004), stromal tumor (Poilblanc et al. 2006), and hemangiopericytoma (Majnarich and Stout 1960). These tumors may grow to impressive size; the hemangiopericytoma reported by Majnarich and Stout (1960) had a weight of 3 kg at surgery. The single report of malignant mesothelioma in the falciform ligament (Marubayashi et al. 1998) is of some theoretical interest, because approximately 30 % of mesotheliomas involve the peritoneal cavity, either solely or in combination with a pleural neoplasm. The patient described by Marubayashi and coworkers had a 10 cm-sized, encapsulated mass with no evidence of diffuse mesenteric thickening or multiple nodules, suggesting that the falciform ligament tumor either originated from cells of the mesothelial peritoneal covering of the ligament or from a precursor cell system located within the ligamentary tissue itself.

Malignant neoplasms of the hepatic ligaments also develop in the pediatric age group. Leiomyosarcoma of the ligamentum teres has been found in a 10-year-old girl (Tomaszewski et al. 1986). In a 14-month-old boy, an endodermal sinus (yolk sac) tumor was observed in the falciform ligament (Atkinson et al. 1992). Clear cell myomelanocytic tumors of the falciform and round ligaments are discussed in the chapter on pediatric liver tumors.

Extension of Primary Hepatic Malignancies into the Hepatic Ligaments

The hepatic ligaments are sometimes involved by primary hepatic neoplasms extending into these structures, e.g., hepatocellular carcinoma (Miyazaki et al. 1989), the spreading pathways probably employing the vascular network connecting the liver with its ligaments (Solomon and Rubinstein 1984). Owing to its distinct angioarchitecture and the vascular connections, the round ligament may offer a particularly efficient spreading pathway for hepatic cancer cells; it has, e.g., been demonstrated that HCC can extend along the round ligament to finally reach the umbilical area (Kim and Lim 1985).

Metastases to the Hepatic Ligaments

Malignant neoplasms of the abdominal cavity can metastasize to the hepatic ligaments, mostly in the setting of peritoneal carcinosis (Missalek 1993; Saida et al. 1994).

Cystic Lesions of the Hepatic Ligaments

Apart from solid neoplastic lesions, cystic space-occupying lesions rarely evolve in the ligaments of the liver and can result in focal porta hepatis scintiscan defects (Karabin 1951; McClelland 1975). Congenital or acquired ligamentary cysts (mesothelial or rarely epithelial), which may produce upper abdominal pain, occur in both ligaments (Motolese Lazzaro 1966; Krylov and Shurkalin 1968; Tessari 1970; Seniutovich et al. 1976; Enterline et al. 1984; Smirnov and Pravdin 1989; Bryan and Pillarisetty 1992; Lagoudianakis et al. 2008; Patel et al. 2009). These cysts probably have a malformative cause, although this has so far not been investigated in a conclusive manner. The hepatic ligaments can be involved by echinococcosis resulting in cystic lesions of variable size (Vadala et al. 1985). Cystic lesions originating in the falciform ligament may radiologically be mimicked by internal herniation of small intestine through a primary or iatrogenic defect ("window") of this ligament (Kobayashi et al. 1999; Vorburger et al. 2000; Sourtzis et al. 2002; Charles et al. 2005). A cyst-like phenomenon may also result from fluid collections in hepatic fissures caused by normal anatomic variations or pathologic furrows (e.g., in cirrhosis and liver atrophy) and recesses (Auh et al. 1994).

Tumor-Like Lesions of the Hepatic Ligaments

Tumorous lesions of the hepatic ligaments may also be suspected in case of other reactive changes occurring in these structures. Rarely, primary abscesses develop in the falciform ligament (Doscher et al. 1980; Sones et al. 1981; Lipinski

et al. 1985; Laucks et al. 1986; Kaneko et al. 1990; Pratap et al. 2006). In acute pancreatitis, diffusion of blood into the falciform ligament, and from here to the subcutaneous umbilical tissues (Cullen's sign; Bem and Bradley 1998), or causing necrosis of the round ligament (Lange and Rozentale 1995) can develop and induce a ligamentary mass effect. Tumor-like expansion by edema and hemorrhage of the round and falciform ligaments has been demonstrated to occur in isolated gangrene of the ligaments, a rare cause of peritonitis (Charuzi and Freund 1976; Watson et al. 1988; Pans et al. 1999; Losanoff and Kjossev 2002; Tison et al. 2005), and similar alterations may result from strangulation of the round hepatic ligament (Turkina et al. 1990) and in the so-called idiopathic segmental fatty tissue necrosis of the round ligament (Goti et al. 2000). Furthermore, abscesses, biliomas, and hemorrhages of the liver and the pericholecystic area can spread along the hepatic ligaments and cause a mass effect (Mori et al. 1989; Pratap et al. 2006). The falciform ligament can undergo torsion and induce a local peritonitis with edema and exudation (Llyod 2006). Falciform ligament hernia after cholecystectomy, fundoplication, or blunt abdominal trauma has been reported (Charles et al. 2005; Lakdawala et al. 2009; Sykes et al. 2010). A neoplastic mass may be suspected in certain malformations of the liver (Parke et al. 1996). Owing to abnormal hepatic fixation, the liver moves to an unusual site ("wandering liver," "hepatic vagrancy"). In persistence of the primitive ventral mesogastrium and congenital absence of the coronary and triangular ligaments, the liver and spleen may freely be mobile (Susani et al. 1983; Siddins and Cade 1990). In the congenital absence of the falciform and the triangular hepatic ligaments, hepatic torsion with complete dislocation of the liver into the left upper quadrant can ensue, resulting in an unusual mass effect (Tate 1993). Congenital defects of the falciform ligament may cause small bowel herniation through this gap (falciform ligament window) followed by obstruction of the bowel and falciform ligament deformation through traction (Gaster 1948; Miller 1981; Vorburger et al. 2000; Bedioui et al. 2008; Gingalewski and Lalikos 2008; Coulier et al. 2009; Shiozaki et al. 2012). The gallbladder may be situated within the coronary ligament, and thus produce a retrohepatic mass (Principe et al. 1979).

Ontogenesis and Anatomy of the Hepatic Ligaments

The hepatic ligaments serve to connect the liver with the abdominal wall and the diaphragm. The falciform ligament (ligamentum falciforme hepatis) and the round hepatic ligament (ligamentum teres hepatis) are the so-called ventral mesohepaticum. Peritoneal attachments of the liver to the diaphragm include the falciform ligament, the left triangular ligament, and the coronary ligament with the right triangular ligament. The latter is the lateral unification of the layers of the coronary ligament. The liver is posteriorly connected to the diaphragm, and thus the coronary ligament has superior and inferior layers rather than anterior and posterior layers (Umidon 1967; Mirilas and Skandalakis 2002). These authors proposed to employ the term "peritoneal attachment," instead of "ligament," but the established term is used throughout the present text. These ligaments are the ontogenetic remnants of the development of the liver within the septum transversum.

The anatomy of the hepatic ligaments has been investigated to considerable detail (Li et al. 2004), chiefly also in the light to better understand the pathogenesis of the abnormal venous flow occurring in portal hypertension, including the mechanisms operational in the development of caput medusae (Krahn 1974). The imaging anatomy of the falciform ligament is important in the echocardiographic diagnosis of ascites, as this structure helps to distinguish ascites from pericardial effusions, pleural effusions, and pericardial cysts (Cardello et al. 2006). The falciform ligament is characterized by a duplication of the peritoneum connecting the upper abdominal wall and the inferior surface of the diaphragm with the anterior surface of the liver. This structure is visualized also in ultrasonic examinations (Hillman et al. 1979). At its inferior end, the ligament is in

continuation with the round hepatic ligament, where also vascular connections are present (see below).

The presence of a hepatic falciform artery (HFA) may clinically manifest in situations where, following hepatic artery infusion chemotherapy, a supraumbilical skin rash developed (Williams et al. 1985). The HFA is a rather small vessel usually arising as a terminal branch of the middle or left hepatic artery. It had first been described by Albrecht von Haller in 1753 as Ramulus ad appendicem ensiformem et lineam albam to denote the arterial vessels located within the anterior abdominal adipose tissue body in the midline between the posterior layer of the rectus sheath and the peritoneum, and extending to the falciform ligament (Merklin 1971; Feldberg and van Leeuwen 1990). The artery provides partial blood supply around the umbilicus and communicates with branches of the internal thoracic and superior epigastric arteries, and its terminal branches end in the midline rectus sheath and the peritoneum, extending into the base of the falciform ligament. The HFA is usually single, but may branch early and course along the falciform ligament as two vessels side by side, but the falciform ligament itself may be supplied by multiple vessels rather than one or two larger vessels (Williams et al. 1985). In a systematic angiographic study on 53 patients, this artery was detected in 24.5 % of the patients by use of celiac or common hepatic angiograms, with no difference in the incidence between patients with normal livers and patients with chronic liver disease (Gibo et al. 2001). In this study, the blood flow of the HFA was slower than that of the peripheral hepatic arteries. Conversely, only 25 among 1,250 patients (2 %) who underwent celiac or hepatic arteriography showed an HFA. Among these patients, the HFA arose as a terminal branch of the middle hepatic artery in 56 % and of the left hepatic artery in 44 %. The vessel was single in 72 % and double in 28 %. The HFA ran within the falciform ligament and the branches were connected with the liver around the falciform ligament (Baba et al. 2000). In another investigation, the origin of the HFA was analyzed in more detail. In a total of 340 liver cirrhosis patients undergoing hepatic artery chemoembolization for HCC, the angiographic incidence of an HFA was 7.6 % (26/340). The origin was the middle hepatic artery (A4) in 16, the superior branch of the middle hepatic artery in 3, the inferior branch of the middle hepatic artery in 2, the inferior branch of the left hepatic artery (A3) in 3, and the confluence of A3 and A4 in 3 cases. Anastomoses between the HFA and the subcutaneous artery were either direct or via the ensiform branch of the internal thoracic artery, located at the lower and upper part of the falciform ligament, respectively (Ibukuro et al. 1998). In contrast to angiographic findings, the anatomic incidence of an HFA was clearly higher, amounting to 38/55 (68 %) anatomic dissections (Michels 1955). By use of computed tomography hepatic arteriography (CTHA), the detection rate of the HFA was 77 % (Tajima et al. 2009).

The ligamentum teres hepatis (round hepatic ligament) has an average length of 17.6 $\pm$ 5.5 cm and a mean diameter of 1.8 $\pm$ 0.4 cm (Ying et al. 1997). The round ligament consists of three parts: (a) the distal part, situated in a subperitoneal niche of the abdominal wall and reaching from the navel to the root of the falciform ligament; (b) the part situated within the peritoneal duplication of the caudal area of the falciform ligament; and (c) the part located under the liver in the sagittal fissure between the left liver lobe and the quadrate lobe, frequently covered by connective tissue or by a bridge of liver substance. Portions of the round ligament are situated within the properitoneal fat pad which is also associated with the falciform ligament and contains the ensiform vessels (Merklin 1971; Feldberg and van Leeuwen 1990). The adipose tissue within this fad pad, which had a mean thickness of 1.2 cm in a CT study in 103 patients (Feldberg and van Leeuwen 1990), is in direct continuation with the variably developed fatty tissue of the round ligament. The distal insertion of the round ligament varies considerably: in a study on 220 patients submitted to laparoscopy, 50 % of the patients showed a round ligament not directly running from the porta hepatis to the umbilicus, but to a point of insertion cranial to the umbilicus in the median

line of the anterior abdominal wall, resulting in the potentially significant situation that, in case of portal hypertension with Cruveilhier-Baumgarten syndrome, large-caliber porto-femoral "umbilical" vessels might in fact be running a course to the left of the umbilicus and thus be prone to injury at laparoscopy (Friedrich et al. 1988). The central venous rudiment in the round ligament derives from the umbilical vein keeping its potential to be recanalized (Gonzales-Carbalhaes 1959; Chevrel et al. 1982; Ying et al. 1992). Under normal conditions, the round ligament proper is characterized by a connective tissue string being round to ovoid on cross sections. The central vein (zone 1 of Krahn) is enveloped by a sheath of fibrillar tissue containing small blood vessels and few myocytes, followed by a rim of myocyte fascicles and more loose connective tissue (zone 2 of Krahn) The periphery of the bundle consists of connective tissue with longitudinally oriented muscle cells, the adventitia (zone 3 of Krahn). Between the bundle or string itself and the peritoneal covering is a sheath of adipose tissue of variable thickness, traversed by blood and lymph vessels and nerves (zone 4 of Krahn). It has to be emphasized that this ordered construction may vary considerably, some of the three zones being poorly distinguishable or even lacking (Krahn 1974). The small central vein of the bundle takes its origin at the pars umbilicalis of the left portal vein branch. The diameter of its lumen varies markedly, the diameter sometimes decreasing from proximal parts to distal parts of the round ligament, whereas in other situations the residual lumen in the cranial and middle segments is larger (Ying et al. 1997). Distally, the vein branches into several small veins or venules. The vein exhibits, already after its origin from the left portal vein and in the hepatic part of the round ligament, numerous venous anastomoses with neighboring veins, resulting in loose or dense venous networks connecting intraligamentous and extraligamentous veins (Krahn 1974). The intraligamentous veins form two groups, one located within the muscle layer and another with an extramuscular location. The extraligamentous veins correspond to Sappey's paraumbilical veins (Sappey 1893), and a second connecting system links the round ligament veins to the veins of the falciform ligament. The latter form a connection between the convexity of the liver and the abdominal wall or the diaphragm (the upper venous group of Sappey). The largest of these veins is thought to represent the persistence of the so-called Burow's vein in adults (Burow 1838). Most of the veins accompanying the round ligament and connecting the liver with the abdominal wall follow the ligament in a more or less parallel fashion (Sappey 1893). Sometimes, the distal veins spread in a delta-like manner to form a fan-like network in the abdominal wall ("Schaltvenen"; Baumgarten 1881). Small arteries are usually found in peripheral parts of the round ligament and along the paraumbilical veins, whereas the central parts of the ligament are poor in arteries. Stereologic measurements have shown that the overall vessel number is higher and the vessel transverse sectional area is larger in the cranial and middle segments of the round ligament than in the caudal segment (Ying et al. 1997).

The lymphatic system of the hepatic ligaments has been studied in detail (Borisov 1968; Golab 1972; Mielke 1972). Both large hepatic ligaments contain a dense network of lymphatic channels/vessels. Similar to the peritoneal covering of the diaphragm (Bettendorf 1978; Li and Jiang 1993), the mesothelial surface of the ligaments contains so-called stomata, i.e., holes which are considered to be connections between the peritoneal cavity and the subperitoneal lymphatic vessels and capable to allow the transperitoneal traffic of both fluid and particulate matter (Tesch et al. 1990). Whether these openings also permit the migration of malignant neoplastic cells and are therefore involved in local tumor spread has to our knowledge not yet been studied so far.

Nodular Hyperplastic Lesions of the Liver

Focal Nodular Hyperplasia (FNH) of the Liver

117

Contents

A. Zimmermann, *Tumors and Tumor-Like Lesions of the Hepatobiliary Tract*,
DOI 10.1007/978-3-319-26956-6_117

Abstract

Focal nodular hyperplasia (FNH) of the liver is a reactive mass-forming regenerative hyperplastic response of hepatocytes, secondary to localized vascular and circulatory abnormalities. FNH has a predilection for young females and represents, after hemangioma, the second most common benign hepatic tumorous lesion of the liver in adults. Many FNH are asymptomatic and detected by chance, but a minority of FNH are associated with various symptoms mainly related to large size or atypical location. Most FNH are solitary lesions that are predominantly located in the right liver lobe. In a minority of patients, multiple lesions, sometimes exceeding 30, are present. Macroscopically, FNH are well-circumscribed nodular, yellowish to tan masses with a characteristic nodular texture, radiating septa, and a central stellate scar-like fibrotic structure. Part of the lesions protrude from the liver and can become pedunculated masses. The diameter of FNH may exceed 20 cm. Histologically, FNH is characterized by nodules that consist of normal-looking hepatocytes forming thin plates. These nodules are separated from each other by fibrous septa and interspersed portal tract-like structures. The latter lack interlobular bile ducts but contain ductular proliferations. The fibrous tissue areas contain abnormal thick-walled blood vessels.

Introduction

According to the 2010 WHO classification, focal nodular hyperplasia (FNH; synonyms: hamartoma of the liver; hepatic pseudotumor; solitary hyperplastic nodule; lobar cirrhosis) is a regenerative hyperplastic response of hepatocytes, secondary to localized vascular abnormalities. The process is not neoplastic.

Ewing mentioned that typical cases of FNH were already described by Rokitansky, Salter, Engelhardt, and Wegelin (Ewing 1940). One of the first detailed descriptions emphasizing the septal architecture and the lack of bile ducts is that by Wegelin. In his thesis as of 1905 (in German, under the tutorship of Professor Theodor Langhans, Berne, the discoverer of the Langhans giant cell), Karl Wegelin described a solitary, well-circumscribed liver tumor, histologically characterized by a solid growth of hepatocyte plates with intervening sinusoids. Beginning at the periphery of the lesion, thin septa entered the nodule, dividing the tumor into irregular subunits of variable size. In the nodes of the septa, large vessels, including arteries and veins, were seen, but no bile ducts (Wegelin 1905; Walthard 1968). In later studies, the lesions were called "adenoma" (Branch et al. 1945), or "benign hepatoma" (Hoffman 1942). In the following years, the criteria of the entity and issues of nomenclature and classification and of pathology and pathogenesis have been developed step by step, ending up with a standardized diagnosis of FNH (Patton 1948; Greinacher 1950; Kay and Talbert 1950; Bartlett and Shellito 1951; Benz and Baggenstoss 1953; Wilson and Macgregor 1969; Knowles and Wolff 1976; Kerlin et al. 1983; Shortell and Schwartz 1991; Bartlett et al. 1996; Kondo 2000; Bioulac-Sage et al. 2001b, 2007)

Epidemiology

FNH occurs in both men and women, but shows a predilection for young women, with a ratio F:M of up to 8:1 (Reddy et al. 2001). After hemangioma, FNH is the second most common benign hepatic tumorous lesion in adults, with an incidence in adult autopsies of about 0.8 %. However, the diagnosis of FNH in the general population is now more frequently done, mainly due to improved imaging techniques, and the reported incidence is up to 3 %. FNH is diagnosed in wide age range, from small children to old age. In a study of 305 cases, median age at diagnosis was 38 years (Nguyen et al. 1999). Male patients may show multiple FNH in the absence of associated liver disease or medications (Cadranel et al. 2003).

FNH is an unusual hepatic lesion in children (Schmelling 1934; Benson and Pemberthy 1942; Maier 1955; Rhodes et al. 1978; Lack and

Ornvold 1986; Feng et al. 2000; Hung et al. 2001; Al-Attar et al. 2004; Chen et al. 2010; Towbin et al. 2011; Franchi-Abella and Branchereau 2013; Valentino et al. 2014). In a retrospective study examining 14 cases of FNH in children who previously had been treated for a malignancy, it turned out that FNH appears to be a late complication of a iatrogenic vascular disease, alkylating agents, veno-occlusive disease, and hepatic radiotherapy possibly playing a role in the generation of endothelial/vascular damage (Bouyn et al. 2003). Pediatric FNH has also been observed in an infant antenatally exposed to steroids (Prasad et al. 1995) and has been found in identical twins (Mindikoglu et al. 2005), suggesting a genetic background of an underlying vascular hepatic anomaly.

Clinical and Imaging Features

Many FNH are asymptomatic lesions that are detected by chance, but a minority of FNH are associated with various symptoms that are mainly related to large or huge size, atypical location, or unusual growth such as pedunculation (Chun Hsee et al. 2005). In a study of 305 lesions, 35.4 % were discovered incidentally (Nguyen et al. 1999). 57.7 % of patients with symptomatic FNH experienced abdominal pain, while an abdominal mass was detected in only 3.8 % and hepatomegaly in 0.8 % (Nguyen et al. 1999). FNH can undergo a variety of complications. In contrast to liver cell adenoma, spontaneous hemorrhage and rupture of FNH are a rare event (Becker et al. 1995; Li et al. 2007), but may result in life-threatening acute intraabdominal bleeding (Ishak and Rabin 1975; Knowles et al. 1978; Koch et al. 2006). As unusual as hemorrhage is central necrosis of FNH that results in sudden upper abdominal pain and fever (Cimmino and Scott 1978). Necrosis of FNH can result from infarction (Bathe et al. 2003), and the mechanisms may be similar to infarction of cirrhotic nodules (Kim et al. 2000). FNH can cause hepatic vein obstruction in case of large and centrally placed lesions (Arrive et al. 1999; Rangheard et al. 2002). In very rare instances, FNH was associated with elevated serum alpha-fetoprotein/AFP levels (Mneimneh et al. 2011), probably caused by regenerating hepatocytes in the lesion.

Numerous imaging features characterizing FNH have been described on CT and MR images. FNH are well-delineated mass lesions with a typical internal structure revealing an epithelial mass having the features of hepatic parenchyma, a radiant array of septa, and a central stellate scar-like fibrosis (Shamsi et al. 1993). An important diagnostic radiological feature is the so-called central scar (review: Elsayes et al. 2007), an alteration that is, however, not really a "true scar", but rather a complex fibrovascular structure resulting from remodeling during FNH growth and having a distinct pathophysiology. The central scar (the "scar sign"; Wenzel and Winters 1983) that is in evidence particularly in larger lesions, and is frequently seen in both CT and MRI pictures, can even more efficiently be visualized by more specific techniques, e.g., as the "star sign" on gadolinium-enhanced MR angiography (Ko et al. 2002). An enhancing scar has, overall, been reported to occur in 14–43 % of cases (Vilgrain et al. 1992). There are rare examples of FNH lacking a central scar (Matsushita et al. 1995). Part of FNH shows a spoke-wheel arterial pattern related to the architecture of septa originating from the central scar (Ungermann et al. 2007). FNH is viewed as a hyperplastic reaction by the liver parenchyma to a preexisting abnormal hypertrophic artery system without significant blood supply from the portal vein (Wanless et al. 1985a; Reddy and Schiff 1993; Namasivayam et al. 2007).

Macroscopic Pathology

Most FNH are solitary lesions (about 75 %) that predominantly develop in the right liver lobe. In approximately 30 %, three to five nodules are found, whereas more than five nodules (multiple FNH) occur in a minority of patients, however sometimes exceeding 30 nodules, either in one lobe or with a diffuse distribution (Knowles and Wolff 1976; Vilgrain et al. 1992; Colle et al. 1998; Kim et al. 2004; Finley et al. 2005;

Shen et al. 2007; Cordeiro et al. 2009). The size varies from few mm to more than 20 cm in diameter. In a study of 305 lesions, the median diameter of lesions was 3 cm; 26.3 % were 2 cm in diameter or less, 38 % measured 2–5 cm, and 35.7 % had a diameter of more than 5 cm (Nguyen et al. 1999). Macroscopically, most FNH are well-circumscribed, expanding intrahepatic lesions with a typically lobulated contour (Figs. 1, 2, 3, 4, 5, 6, 7, and 8). Pedunculated lesions with a defined vascular stalk occur, but are rare (Maier 1955; Brouquet et al. 1985; Sawhney et al. 1992; Nguyen et al. 1999; Wasif et al. 2008). In the study of Nguyen and coworkers, pedunculated lesions were found in 7/305 cases (Nguyen et al. 1999). "Classical" FNH are mostly of yellowish to tan color, rarely red congested areas are seen. On cut section, several patterns of nodularity are in evidence. The most common pattern is that of elongated or oval nodules arranged along septa in a more or less radiated fashion. In a second pattern, more elongated and sometimes bent or hook-shaped nodules form a "cerebriform" pattern or a pattern resembling the cut surface of a truffle. In a third pattern, the nodules are arranged in a haphazard fashion. The mass is usually composed of subunits each measuring 2–3 mm, causing the multinodular aspect on cut surfaces. Especially in large lesions, one dominant nodule is sometimes seen, associated with a rim of smaller nodules at the periphery or a cluster of small nodules at one place, suggesting that one nodule started earlier with growth or was subject to a stronger growth stimulation. Subcapsular lesions may bulge and often exhibit a geographical pattern or a regular checkerboard-like or

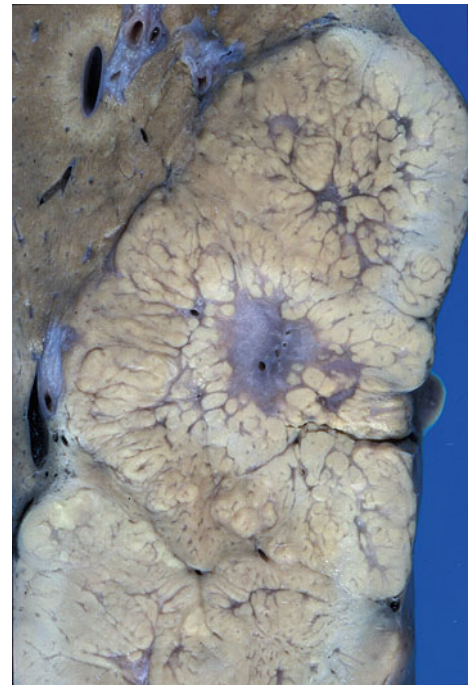

Fig. 5 Focal nodular hyperplasia of the liver with stellate scars (cut surface of a fixed resection specimen)

cobble-stone pattern, caused by the network of fibrous septa anchored to the capsule. On cut sections, the central stellate scar as a leading alteration in FNH can often be visualized with naked eye. It was found in 45.4 % among 305 lesions, and 3.6 % of lesions revealed more than one scar (Nguyen et al. 1999). Rarely, the central scar can extend, via fibrous septa, to the liver capsule, causing capsular retraction (Ko et al. 2003).

FNH can undergo several secondary changes, including central necrosis, infarction, hemorrhage, and calcification. Central necrosis of FNH can produce sudden onset of abdominal pain. Necrosis may be large and mimic parenchymal infarction (Bathe et al. 2003). Bleeding can produce blood-filled cysts that may later show fibrous obliteration (Langman and Hall 2001). Apart from necrosis or even infarction, FNH can rarely develop other changes, such as cluster-like internal cysts due to fibrinoid necrosis (Kottke et al. 2007).

Histopathology

The histopathologic presentation has been described and reviewed in detail in numerous reports (Orda et al. 1973; Lepreux et al. 2002;

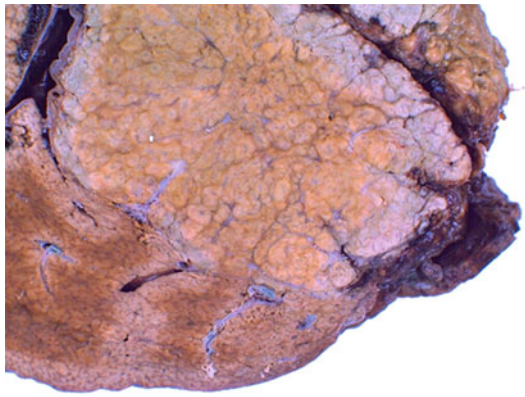

Fig. 7 Focal nodular hyperplasia of the liver with a micronodular pattern

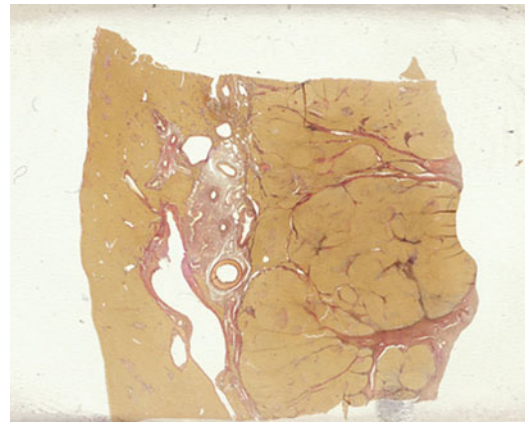

Fig. 9 Focal nodular hyperplasia of the liver. Nodular subunits are separated from each other by fibrous septa (Elastica van Gieson stain)

Fig. 8 Focal nodular hyperplasia of the liver, exophytically growing variant

Pan et al. 2004; Bioulac-Sage et al. 2007), including precursor lesions of FNH or "pre-FNH" (see below; Bioulac-Sage et al. 2008).

Parenchymal Nodules

Generally, typical and fully established FNH is characterized by a conglomerate of hepatocyte nodules separated by fibrous bands or septa (Fig. 9). The hepatocytes forming the nodules are arranged in a pattern reflecting normal hepatic parenchyma, i.e., liver cell plates that are two cells thick (couplets), although plates seemingly being one cell thick only may be seen. The hepatocytes forming the parenchyma of FNH do not differ morphologically from normal hepatocytes. Hepatocytes of FNH can undergo fatty change/steatosis, thought to be an extension of fatty liver to fatty FNH (Mitchell et al. 1991; Mortelé et al. 2000). Steatosis or granulocytic steatohepatitis has also been found in FNH-like lesions developing in the setting of alcoholic liver disease (Kim et al. 2008). In a subset of lesions, Mallory-Denk body formation has been reported (Wetzel and Alexander 1979). The nodules are separated by atrophic parenchyma and abnormal, portal tract-like structures. These abnormal portal tract-like structures almost always exhibit a marked ductular reaction, and this reaction is also found at the interface between nodular parenchyma and the periphery of the septa (Butron Vila et al. 1984). Typically, an interlobular bile duct is not found in the portal tract-like areas, which, therefore, per definition are not true portal tracts, as a triad (bile duct, artery, portal venous branch) is not present. In variable densities, lymphocytic infiltrates occupy these spaces. A fibrous capsule is lacking (Knowles and Wolff 1976). The characteristic deficiency of bile ducts has led to the term, "nodular hyperplasia with ductopenia" (Wanless; cited in Kageyama et al. 1998).

Central Scar and Abnormal Blood Vessels

Most lesions show a central fibrous scar (stellate or star-shaped scar), or several of these, the largest scar usually being situated close to the central part of the mass, and the other stellate scars being situated at variable distances from the center, and sometimes being connected to the major scar by fibrous septa (Figs. 10, 11, 12, and 13). These scars, and chiefly the central one, disclose malformed vascular structures, in particular large arteries and arterialized veins, but a bona fide portal venous branch is lacking. Large vessels have an irregular, markedly thickened intima with focal medial attenuation. Typically, the internal elastic lamina is poorly developed or duplicated. In the area of the central scar-like fibrosis, activated hepatic stellate cells are present, thought to contribute to fibrosis and being activated due to oxidative stress caused by arterial hyperperfusion in central parts of the lesion (Sato et al. 2009). The centers of FNH typically exhibit an abnormal compartment of arterial vessels. Most lesions are supplied by one or more anomalous arteries larger than expected for the target area. These arteries tend to branch and to form a spider-like structures or a complex network (Wanless 1987), seem

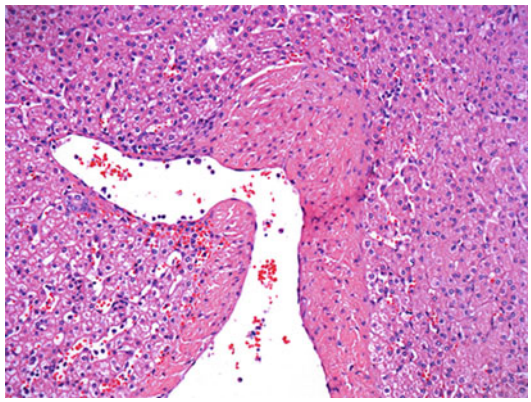

Fig. 13 Abnormal blood vessel in focal nodular hyperplasia at higher magnification (hematoxylin and eosin stain)

to take their origin in the central fibrous scar (Fechner and Roehm 1977), and are not accompanied by an interlobular bile duct and a portal venous branch.

It has been described that each artery branch feeds a separate nodule of about 1 mm diameter (Wanless et al. 1985a), and adjacent nodules then coalesce to form a compound nodular lesion. The arterial blood drains directly into sinusoids and into hepatic veins. In a study on 29 resected FNH, the vascular pattern of the masses was investigated by use of colored gelatin injection. No orientation with respect to portal tracts and central/terminal veins was evident in any of these lesions. Anomalous arteries were in connection with capillaries located to the fibrous septa, and the latter drained into CD34-and vWF-positive sinusoids adjacent to the septa. venous vessels were connected to central or hepatic veins surrounding the nodular lesions, and intranodular sinusoids were connected to the sinusoids in the adjacent normal liver. Gelatin injected at autopsy into the hepatic artery appeared not only in the anomalous arteries, but also in capillaries and in sinusoids adjacent to the fibrous septa, and CT during arterial portography disclosed no portal flow in the lesions. It was concluded that arterial blood in FNH flows from the anomalous arteries via the capillary bed into sinusoids adjacent to the fibrous septa (Fukukura et al. 1998). In rare situations, the abnormal vascular network in the center of FNH reveals angioma-like features (Saito et al. 2005; Glas et al. 2008). FNH can be diagnosed by needle biopsy, especially in the knowledge that the sample comes from a mass, and when the tissue shows the characteristic interface between abnormal portal tract-like structures with ductular profiles, abnormal arteries and lack of a bile duct, and the normal-looking parenchyma (Fabre et al. 2002; Makhlouf et al. 2005). These hallmarks are not usually found in fine needle aspiration preparations. In cytological preparations of histologically verified FNH, spindle cell fragments have been observed, potentially leading to misinterpretation as a mesenchymal tumor (Krishnamurthy and Nerurkar 2002).

Other Histologic Features

Calcifications have been noted in FNH (Langman and Hall 2001) and may be related to postnecrotic calcium salt deposition (so-called dystrophic calcification). They are in evidence by use of imaging in 1.4 % (5/357; Caseiro-Alves et al. 1996), in another study in 1/78 cases (Brancatelli et al. 2001), and they are visualized histologically. They were evident in the form of small, solitary spots located centrally or peripherally within the lesions and resemble calcified lesions seen in fibrolamellar carcinoma. Sometimes, the abnormal, thick-walled vessels of FNH exhibit tiny calcifications. Apart from calcifications, focal ossification of FNH has been described (Langman and Hall 2001). Whereas the number of Kupffer cells is reduced in HCCs, specifically in large tumors and those of low differentiation, Kupffer cell numbers are increased in FNH in comparison with extranodular liver in up to 46.2 % of cases (Tanaka et al. 1996), this phenomenon being one reason for the selective uptake of superparamagnetic iron oxide by these lesions. Iron-poor FNH can occur in iron-storing livers in hemochromatosis. In a patient with peripheral portal vein tumor thrombosis, segmental hepatic iron deposition of the parenchyma peripheral to the occluded portal venous branch was noted, and it was suggested that the absence of portal blood flow may cause this focal change (Kawamori

et al. 1991). On the other hand, it has been proposed that FNH can accumulate iron in situation of intralesional hemolysis (Mahfouz et al. 1999).

Immunohistochemistry

The pertinent immunohistochemical features of FNH and their position in the differential diagnosis of hepatocellular adenoma have been reviewed (Bioulac-Sage et al. 2012, 2014; Balabaud et al. 2013; Sempoux et al. 2013, 2014). In cytokeratin immunostains, hepatocytes in the periphery of lobules of FNH may show a mild CK7 immunostaining, while, expectedly, the proliferated ductular profiles in portal tract-like structures are strongly reactive for both CK7 and CK19 (Fig. 14; Iyer et al. 2008; Ahmad et al. 2009). The ductular cells are also reactive for Bcl-2, as ductules in normal liver (Charlotte et al. 1994).

Upregulation of hypophosphorylated activated beta-catenin is present in FNH in the absence of activating mutations and regulates the overexpression of six perivenous genes, including glutamine synthetase. Hepatocytes in FNH are immunoreactive for glutamine synthetase/GS, a beta-catenin target (Rebouissou et al. 2008a; Bioulac-Sage et al. 2008, 2009; review: Bioulac-Sage et al. 2011). The expression of GS is a sensitive and specific marker for diagnosing FNH (Tsai et al. 2012) and is helpful specifically in needle biopsies, where diagnosis of FNH is sometimes difficult as the typical architecture of FNH is not easily seen, but after GS immunostaining the diagnosis was certain in 86.7 % of cases (Bioulac-Sage et al. 2012). Positive cytoplasmic staining formed large areas, anastomosed in a map-like pattern, often surrounding hepatic veins, but GS was not expressed in hepatocytes close to fibrotic bands containing arteries and ductules (Bioulac-Sage et al. 2009; Sempoux et al. 2014). There are forms of FNH that lack a map-like staining pattern for GS, but rather display a patchy GS pattern along with expression of serum amyloid-associated protein (Joseph et al. 2014). A further maker of mature hepatocytes that stains all FNH cases is arginase-1 (McKnight et al. 2012). The expression of E-cadherin, N-cadherin, and alpha-catenin of normal hepatocytes is preserved in liver cells of FNH (Kozyraki et al. 1996). FNH can be reactive for fatty acid-binding protein and serum amyloid A protein.

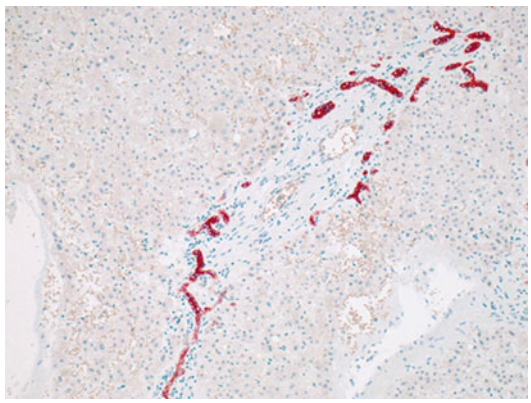

Fig. 14 Ductular proliferations in focal nodular hyperplasia. No interlobular bile ducts are seen (cytokeratin 19 immunostain)

In CD34 immunostains, FNH revealed various patterns of endothelial cell staining, ranging from CD34 inflow staining to mixed inflow-diffuse, to diffuse staining patterns (Kong et al. 2000; Iyer et al. 2008; Ahmad et al. 2009). FNH show a downregulation of CD143, in that the number of CD143+ sinusoidal endothelial cells was significantly reduced in FNH in comparison with extralesional liver and hepatocellular adenoma, suggesting that CD143 immunostaining might be of diagnostic use (Grantzdorffer et al. 2004). The capillarized sinusoidal channels in FNH express podocalyxin-like protein 1, a CD34-related sialomucin that is also expressed in tumor-associated microvasculature endothelial cells in HCCs (Heukamp et al. 2006). Fibrillin-1 and elastin as components of the microfibrillar system show a distribution and expression in FNH that is different from normal extralesional liver. Fibrillin-1 was more strongly expressed in the perisinusoidal space of FNH than normal liver, but showed a similar continuous expression along the perisinusoidal space, while expression was discontinuous in liver cell adenomas (Lepreux et al. 2004). We showed that, in contrast to hepatocellular carcinoma, liver cells in FNH are not reactive

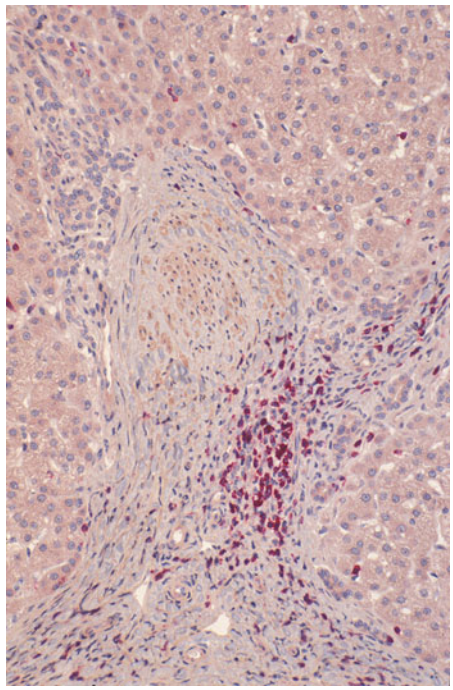

Fig. 15 Focal nodular hyperplasia of the liver with focal T-cell infiltrates in a stellate scar (CD3 immunostain)

for glypican-3 (Zhu et al. 2001), a finding confirmed by several subsequent studies (Libbrecht et al. 2006a; Ligato et al. 2008; Wang et al 2008; Nassar et al. 2009). FNH do no express agrin (Tatrai et al. 2009). In contrast to HCC, nuclei of FNH do not express p53 protein (Ojanguren et al. 1995; Schaff et al. 1995). FNH possess a distinct extracellular matrix produced by fibroblastoid cells, myofibroblasts, and activated stellate cells. Immunohistochemically, the matrix of central scars resembled that of portal tracts, but contained more vitronectin. The fibrous zone surrounding the scar itself was rich in laminin and thrombospondin, suggesting a strong fibrogenic response. The matrix lining the sinusoid-like vessels in the FNH parenchyma retained the features of hepatic perisinusoidal space, including the presence of tenascin. The perisinusoidal fibrosis developing in FNH is accompanied by the induction of integrin receptors on hepatocytes and sinusoidal endothelial cells (Scoazec et al. 1995). In contrast to hepatocellular carcinoma, FNH is not immunoreactive for the marker aldo-ketoreductase family 1B10/AKR1B10 (Matkowskyj et al. 2014).

In the tissue forming portal tract-like structures and fibrous septa, lymphoid cell infiltrates may be found, usually of low density and mostly consisting of CD3-positive T-cells (Fig. 15).

FNH Variants and Possible Precursor Lesions of FNH

Introduction

Apart from classical FNH, several variants of this lesion have been described and classified over the years under various, not yet standardized or generally accepted names. Future consensus studies will clarify and standardize these lesions further.

FNH with Microvascular Abnormalities and So-called Telangiectatic FNH

There are variants of FNH showing marked dilatations of the sinusoidal vascular bed. This change may involve large sectors of the nodule and is already visualized at low magnification. It was proposed to denote such lesions, FNH with major sinusoidal dilatation, whereby the regions with sinusoidal ectasia may not stain for GS (Sempoux et al. 2014). Currently, telangiectatic FNH (TFNH) is defined as a lesion different from classical FNH and to represent a variant of liver cell adenoma rather than FNH (Paradis et al. 2004; Bioulac-Sage et al. 2005). Telangiectatic nodular liver lesions previously termed TFNH are, therefore, treated in a separate chapter. Previously, TFNH was described as an uncommon lesion that has been defined as FNH with one cell-thick hepatic plates separated by markedly dilated sinusoids, lacking a central scar, few fibrous bands/septa, few reactive ductules, and with subtle or even no architectural distortion. Occasional hemorrhagic and necrotic centers are noted (Wanless et al. 1989; Nguyen et al. 1999; Fabre et al. 2002; Lepreux et al. 2003b). TFNH frequently presents with multiple lesions (MTFNH), described under the term multiple FNH syndrome (Wanless et al. 1989).

Steatotic FNH

Part of FNH shows marked steatosis of hepatocytes, whereby small to large triglyceride droplets are visualized in the target cells (steatotic FNH). Accumulation of fat in lesional hepatocytes is also known for true liver cell neoplasms, including hepatocellular adenoma and HCC. Steatotic FNH has characteristic imaging features, specifically MR (Ronot et al. 2013).

Pre-FNH

Bioulac-Sage and coworkers described a "pre-FNH" by use of glutamine synthetase/GS (Bioulac-Sage et al. 2008). In this early lesion, GS-reactive hepatocytes occupied a wider area than in the surrounding perilesional liver and tended to extend outwards. Portal tracts bordering the nodule were more fibrotic, lacked portal vein branches and interlobular bile ducts, but with arterial proliferation often in proximity with large draining veins. There were rare isolated arteries and hepatic veins were rare. The findings of this early lesions confirmed that, according to the "Wanless hypothesis," there is an initial portal tract injury in FNH morphogenesis leading to local portal vein damage, resulting in abnormal circulation, arteriovenous shunts, scar formation, ductular reaction, and compensatory liver cell hyperplasia.

Small FNH and "Subtle" FNH

Owing to the more refined imaging techniques, more and more small hepatic nodules are detected where the diagnosis may be difficult to achieve, also with respect to histologic examination. By "small" one usually refers to nodular lesions not exceeding a diameter of 2 cm. Such small nodules, due to their probably early stage of development, may lack the key features of FNH as defined in larger lesions (Schilling et al. 2000; Bioulac-Sage and Balabaud 2001), and differentiation from small liver cell adenoma becomes a demanding task (Bioulac-Sage et al. 2001a). It seems to be safe to assume that nodules larger than 3 cm in most instances show the features described as typical for *bona fide* FNH in daily practice. Small lesions with a somewhat ambiguous morphology have, in the sense of a working formulation, arbitrarily been classified into four types, a fifth type representing fully developed FNH (Lepreux et al. 2003a), as follows: (1) Type 1 lesion: Tiny nodules, steatotic or not, with mildly disorganized liver architecture and dilatation of thin-walled vessels in the immediate vicinity of portal tracts; (2) Type 2 lesion: Nodules with mildly disorganized liver architecture and enlarged or tortuous arteries (with tortuosity identified by finding multiple cross-sections of the same vessel) in portal tracts or in septa. Portal tracts sometimes lack a bile duct or portal vein; (3) Type 3 lesion: Nodules like those of type 2 that also include hyperplastic foci; (4) Type 4 lesions: Minor or "subtle" forms of FNH with incomplete or very small fibrous scar, inconstant ductular reaction, and incomplete nodular organization; and (5) Type 5 lesion: Full-blown FNH. Macroscopically, small FNH-like lesions are distinguished from the surrounding normal liver tissue by a slight change in color, in that these nodules are usually paler (Lepreux et al. 2003a). In the latter study, nonclassified nodules detected by imaging techniques corresponded to type 1 and 2 lesions, and subtle FNH (type 4 lesions) occasionally had type 2 or 3 lesions at their periphery. On the other hand, small FNH showing in the center cirrhotic-like nodules may be surrounded with type 1 and type 2 lesions. The hyperplastic foci seen in type 3 (hyperplasia required for this type) were fed by arterioles accompanied by slight cytokeratin 7-positive ductular reaction (poor or no staining for cytokeratin 19). Via formation of thin fibrous bands tending to approximate neighboring hepatic veins, the morphology of type 4 lesions emerges (minor form of FNH, subtle FNH). It is reasonable to assume that at least part of these lesions represent changes along the pathway leading from simple nodules to established FNH, although the four types described reflect single steps within a pathogenic continuum (Lepreux et al. 2003a). Lepreux and coworkers theorized that communications of arterioles with

various blood vessels (terminal portal vein branches, inlet venules, and even sinusoids) may lead to dilatation of the latter and to an abnormal local circulation.

Histopathology of the Extralesional Liver

In at least part of livers harboring FNH, several types of abnormalities have been detected. In one investigation, abnormal small arteries not accompanied by portal tracts were found more often in FNH livers, as were CD34-positive sinusoids around portal tracts. In addition, small uniform nodule formations with ring-like siderosis were noted (Motosugi et al. 2009). In a further study, the extranodular liver area in 73 % of FNH cases revealed alterations that were similar to but milder than those in the FNH nodule (Kondo et al. 1998).

FNH in Livers with Preexistent Chronic Liver Disease

FNH usually occurs in normal or, at least, noncirrhotic livers. In fact, the International Working Party formulation of nodular hepatic lesions defines FNH as "a nodule composed of benign-appearing hepatocytes occurring in a liver that is otherwise histologically normal or nearly normal" (International Working Party 1995). This observation as such suggests that FNH is not a simple, exaggerated regenerative response. However, there are situations where FNH, either solitary or multiple, or FNH-like lesions, develop in abnormal livers, including livers with chronic fibrosing hepatopathy/cirrhosis, livers with sequelae of hepatic venous outflow disorders, and associations of FNH with other synchronous liver tumors (see below). Relatively few studies have reported the occurrence of FNH in chronic liver disease. Adenomatous hyperplasia, as it was previously termed, resembling FNH (Terada et al. 1993), and FNH-like hyperplastic nodular lesions (Sugihara et al. 1990; Nakashima et al. 1996; Kageyama et al. 1998; Libbrecht et al. 2001, 2006b) were described in cirrhotic livers. The lesions described by Terada and coworkers were small (approximately 1 cm) and contained portal tracts, but a large number of arteries were present in central star-like fibrotic areas (Terada et al. 1993). It has been suggested that FNH-like lesions in cirrhosis can be histologically distinguished from bona fide FNH by the finding that FNH-like lesions containing a central stellate fibrosis exhibit, in contrast to FNH, a fibrous capsule, and they lack signs of hepatocyte hyperplasia and may show iron deposition (Sugihara et al. 1990). Typically, FNH lacks a fibrous capsule (Knowles and Wolff 1976). Among the published cases with available histologic figures, the case of Kageyama and coworkers reveals a marked resemblance to "true" FNH, with a diameter of 4.5 cm, a central stellate-like scar and radiating septa, and lacking portal tracts, but again with a fibrous capsule (Kageyama et al. 1998; their Fig. 3). In a retrospective study on 146 liver transplants with cirrhosis, five patients showed a total of 12 nodules (size range: 4–23 mm; median: 10.5 mm; 1.2 % of a total of 240 nodular lesions) with histologic features suggestive of FNH (FNH-like nodules; Quaglia et al. 2003). All these small lesions showed a nodular architecture with mildly inflamed vascular fibrous septa and fibrous scar-like areas containing a predominantly lymphocytic infiltrate with ductular proliferations, as seen in FNH. Unpaired small arteries were found in the liver parenchyma of three lesions. The majority of the nodules exhibited a predominantly marginal sinusoidal pattern of CD34 expression, as seen in cirrhotic livers; all lesions revealed canalicular cholestasis, and large-sized arteries adjacent to the lesion were detected in the majority of the cases (Quaglia et al. 2003). Together, these observations suggest that nodular lesions with many features of FNH can, albeit rarely, occur in the context of hepatic cirrhosis. These small nodular lesions should not be confounded with macroregenerative nodules developing in cirrhosis (Theise et al. 1992; Ferrell et al. 1992

FNH: Association with Other Hepatic Tumors or Disease States

FNH and Hepatocellular Adenoma

A synchronous/simultaneous presentation of FNH and hepatocellular adenoma in the same liver has been documented several times (Casarella et al. 1978; Reichlin et al. 1980; Grange et al. 1987; Nguyen et al. 1999; Di Carlo et al. 2003; Laurent et al. 2003). In a series of 168 patients with 305 FNH lesions, the association of FNH with liver cell adenoma was observed in 3.6 % of the cases (Nguyen et al. 1999). In another study, liver cell adenoma together with FNH was found in 5 out of 30 cases of "multiple benign hepatocytic nodules," and all five patients were women on oral contraceptives (Laurent et al. 2003). Three patients exhibited additional small nodules that could not be classified with certainty. In most situations, the two lesions have developed sequentially (metachronically), but in some of these it is difficult to judge whether one of the lesions was in fact FNH (Antoniades et al. 1975; Goldfarb 1976). In one instance with apparently bona fide FNH, an adenoma was resected; 23 months later three new 2-cm lesions were detected via angiography, and two of them fulfilled the criteria of FNH (McLoughlin et al. 1973). Data on the occurrence of this combination may be controversial due to the difficult assessment of small lesions, the features of FNH versus adenoma sometimes being overlapping; for example, a liver cell adenoma may be modified be recurrent hemorrhage with subsequent scarring, thus grossly resembling FNH. On the other hand, a small sample of an FNH may look like an adenoma histologically. The association of liver cell adenoma and FNH could be coincidental or then related to a common cause, such as contraceptive-induced angiogenic abnormalities, tumor-induced growth factors, or thrombosis and local arteriovenous shunting (Laurent et al. 2003). A common pathway may be considered in those rare situations where hepatocellular adenoma develop within FNH (Guntz et al. 1983). There is few reports describing mixed adenoma-focal nodular hyperplasia of the liver (Handra-Luca et al. 2006; Chen et al. 2011).

FNH and Hepatocellular Carcinoma

Several reports have described the synchronous occurrence of hepatocellular carcinoma (HCC) and FNH (Kobayashi et al. 1993; Chen et al. 2001; Coopersmith et al. 2002; Cucchetti et al. 2003; Kellner et al. 2003; Zhang et al. 2004). In a carefully performed autopsy study on 11 patients having HCC in noncirrhotic and nonfibrotic livers, four exhibited FNH (Kobayashi et al. 1993). In one study, the two masses were closely associated within one tumorous lesion, and clonal analysis (based on HUMARA) suggested that FNH and HCC derived from the clonal expansion of two different clones (Chen et al. 2001). In another patient, the two synchronously detectable tumors were not spatially related, and no chromosomal aberrations (based on comparative genomic hybridization) were found in the FNH occurring synchronously with the HCC (Kellner et al. 2003). Lesions fulfilling the criteria of FNH may be difficult to discern from larger regenerative nodules in cirrhotic livers with HCC, because such hyperplastic foci can aggregate to form larger units of hyperplastic parenchyma with a rearrangement of fibrous tissue septa (Kato et al. 2001).

FNH and Nodular Regenerative Hyperplasia

A complex relationship between HCC and nonneoplastic hyperplastic hepatocyte reactions is further illustrated by the observation that HCC may be associated with nodular regenerative hyperplasia (NRH). Among 342 noncirrhotic livers with HCC, 23 showed NRH (Nzeako et al. 1996). In an autopsy study on 11 patients with HCC without cirrhosis, NRH occurred in one

instance (Kobayashi et al. 1993). Apart from ordinary HCC, FNH has also been found to be associated with fibrolamellar carcinoma in the same liver (Saul et al. 1987; Davidson et al. 1990). In one reported patient, nodular hyperplasia resembling FNH surrounded fibrolamellar carcinoma (Saxena et al. 1994). In this patient, there was an apparently direct transition between the two lesions, whereas in another report, FNH was adjacent to but distinct from FL-HCC (Saul et al. 1987). The nodules may represent a hyperplastic response to the high vascularity of FL-HCC.

FNH and Hepatic Vascular Tumors

Further published associations comprise FNH with hemangioma (Mathieu et al. 1989; Wanless 2000; Vilgrain et al. 2003), hemangioma and multiple liver cysts (Toshikuni et al. 2001), hepatic adenoma and hemangioma (Di Carlo et al. 2003), and angiomyolipoma, bile duct adenoma, and hemangioma (Langner et al. 2001). FNH occurring with hemangioma of the liver is of particular practical and theoretical interest. In the older literature, hepatic hemangiomas in association with FNH were observed in 7 of 34 patients (20 %; Benz and Baggenstoss 1953), 6 of 23 patients (26 %; Mathieu et al. 1989), and 4 of 23 autopsied patients (17 %; Wanless et al. 1989). In a more recent and larger study, among 148 patients with FNH, 29 (20 %) had FNH with one or more associated hepatic hemangiomas, in comparison with 9 % in a control group without FNH, indicating that patients with FNH are in fact more likely to have an associated liver hemangioma in a significant and nonrandom manner (Vilgrain et al. 2003). The association of FNH with hemangioma has been suggested to be related to a common vascular-mediated pathogenic pathway, because hemangiomas have also been observed together with other regenerative nodules of the liver (Ndimbie et al. 1990). Furthermore, it has been noted that FNH and liver cell adenomas occur more often patients who have coexisting vascular tumors, portal venous absence or occlusion, or portohepatic venous shunts (Ishak and Rabin 1975; Grazioli et al. 2000). Multiple FNH have been observed together with two different types of hepatic vascular tumors: cavernous hemangioma and epithelioid hemangioendothelioma (EHE) (Bralet et al. 1999; comment: Wanless 2000). In this young woman taking oral contraceptives, EHE affected both liver and lung. The authors suggested that, as EHE typically infiltrates liver sinusoids and intrahepatic veins with polypoid projections, this tufted intravascular growth pattern may have caused decreased perfusion of the liver in EHE areas, with consequent increased blood flow to other hepatic areas; this nonuniformity of blood flow eventually favors the emergence of FNH (Bralet et al. 1999). This hypothesis is supported by the observation that epithelioid hemangioendothelioma of the liver occurred together with hepatic nodular regenerative hyperplasia (Malamut et al. 2001).

Other Associations

Multiple FNH have been observed to occur in conjunction with hepatic leiomyosarcoma with epithelioid features (Iordanidis et al. 2002), the FNH lesions proposed to have been emerged owing to abnormal hepatic blood supply. The coexistence of FNH and hepatic focal fatty change producing so-called pseudotumor has been reported (Wu et al. 2003). FNH has been observed in association with familial glioblastoma (Everson and Fraumeni 1976).

Differential Diagnosis

The main differential diagnoses comprise liver cell adenoma, macroregenerative nodules, and other hepatocellular nodular lesions (review: Hytiroglou and Theise 1998). Furthermore, other liver cell masses with a central scar-like structure have to be distinguished, e.g., hepatocellular carcinoma with a central scar (Yamamoto et al. 2006). Nodules resembling FNH occur in alcoholic liver cirrhosis (Lee et al. 2007) and are discussed in another paragraph.

The Natural History of FNH and Biology of Disease

Growing FNH

FNH may develop rapidly, mainly in cases with vascular disorders, but after their initial phase, growth may vary considerably among the lesions. By use of an MRI follow-up, interval growth was seen in 15 % of lesions over 7–48 months, with increase in size of 2–1.7 cm and percentage change of 105–340 % (mean: 64 %; Halankar et al. 2012). A significant proportion of FNH exhibit slow growth or seemingly remain stable in size. Rarely, FNH show accelerated or rapidly expanding growth, due to unknown reasons ("progressive type of FNH"; Sadowski et al. 1995). There are also situations where the number of lesions will suddenly increase (Sato et al. 2006). Progression of multiple lesions of FNH has been observed, associated with an angiographically documented increase in artery diameter, suggesting a role of arterial hyperperfusion of the target area (Kaji et al. 1998). Relatively few observations have so far suggested that there is no direct relationship of FNH growth and oral contraceptive intake (Kubota et al. 2001). In case of progressive growth, FNH may compromise large intrahepatic vessels, such as the hepatic veins, and hence produce a clinically dangerous behavior (Papanikolaou et al. 2009).

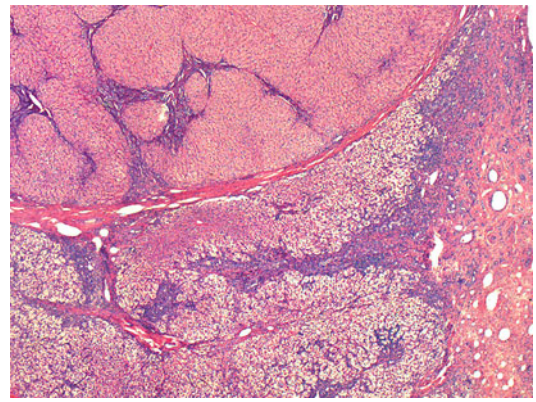

Fig. 16 Focal nodular hyperplasia with circumscribed regressive changes (lower half of figure; hematoxylin and eosin stain)

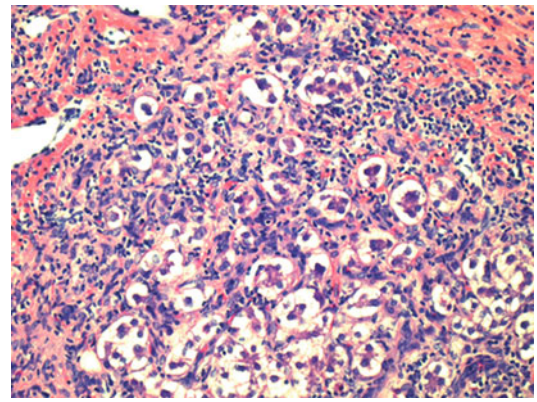

Fig. 17 Focal nodular hyperplasia with regressive changes. Part of the cells exhibit marked ballooning (hematoxylin and eosin stain)

Regressing FNH

FNH can undergo regressive changes, characterized by a distortion of the nodular arrays, generation of dense fibrotic tissue in a focal distribution, crowing of blood vessels, and collapse of GS-positive areas (regressing FNH; Sempoux et al. 2014; Figs. 16 and 17). FNH can regress partially or completely (Ohmoto et al. 2002; Kuo et al. 2009; Laumonier et al. 2010). One case of regressing FNH was histologically studied based on a resection specimen. Part of the 4-cm-sized nodule was still recognizable FMH, with glutamine synthetase-positive hepatocyte nodules surrounded by fibrous bands, inflammatory infiltrates, and mild ductular reaction. A second part of the nodule was more fibrotic, with numerous arteries showing extremely thick walls and a very narrow lumen. This part was devoid of GS-positive hepatocytes and of ductular reaction (Laumonier et al. 2010). In an ultrasound study of 16 cases with a mean follow-up of 33 months, the size was reduced in 7/16 at the end of the follow-up, and in 1/16 the lesion had disappeared (Di Stasi et al. 1996). The process of regression may extend over long time periods, e.g., 10 years (Aufort et al. 2003). In the investigation of Kuo et al. (2009), the significant factors associated with regression or even disappearance of FNH were older age, nodule diameter less than 2 cm,

and longer follow-up time. Multiple regression analysis showed that older age and longer follow-up time were the independent factors associated with regression/disappearance of FNH. In a retrospective MRI study of 120 consecutive patients with FNH, interval regression was noted in 8 % of nodules over a period of 7–63 months, with decrease in size of 0.2–0.9 cm (mean: 0.5 cm; Halankar et al. 2012). There few observations suggest that regression of FNH may ensue subsequent to discontinuation of oral contraceptives (Ross et al. 1976; Aldinger et al. 1977; Scott et al. 1984; Cote 1997), but a role of sex steroids is still disputed.

Pathogenesis of FNH

Abnormal Vascularization in FNH

Distinct patterns of vascular abnormalities, and a disordered local blood flow caused by them, are in the center of pathogenetic pathways leading to FNH. The frequent presence of obstructive vascular lesions not only in established FNH, but also in early FNH and putative FNH precursor lesions, and the finding of abnormally structured and abnormally large vessels in FNH has led to the hypothesis that FNH is a parenchymal response to focally increased blood flow (Kondo 2001, 2003; Kondo et al. 2004). There is increasing evidence that an abnormal blood circulation in the liver is a major etiologic factor for the development of FNH, but the mechanisms leading from an early focal regenerative or hyperplastic response to a sometimes large lesion with a distinctive architecture are far from clear. Theories relating to a "vascular factor" in the pathogenic pathway focused both at the inflow tract and the outflow tract of the liver. Wanless and his group suggested that a local portal vein injury, e.g., caused by thrombotic occlusion or pylephlebitis/portal vein endophlebitis, is an initial step in a pathogenetic cascade of events (Wanless et al. 1985a; the "Wanless hypothesis"). This initial PV lesion leads to secondary large arteriovenous shunts, followed by arterialization of the local PV system associated with irregular thickening of the vascular intima, resulting in highly abnormal thick-walled vessels resembling dystrophic arteries. The authors also proposed that the loss of interlobular bile ducts as a typical feature of FNH and followed by reactive ductular proliferation is related to portal tract changes, but this has to be studied in more detail, as bile ducts are not fed by the portal vein, but by branches of the hepatic artery. Another hypothesis has it that the primary lesion is situated in the outflow tract, outflow obstruction (e.g., hepatic vein thrombosis) causing congestion with fibrosis, parenchymal collapse, arteriovenous shunting, and subsequent portal vein and bile duct loss. In both the "primary inflow variant" and the "outflow variant" of mechanisms, the end result is a local rearrangement of vascular structure and an abnormally increased local flow of partially arterialized blood.

Based on the finding of abnormal and supernumerary arteries and arterioles in FNH, it has been proposed that an increased arterial flow might cause hyperperfusion of the target parenchyma, thus leading to subsequent hepatocellular hyperplasia (Wanless et al. 1985a). In fact, in addition to the typical centrifugal flow, a centripetal shift of arterial blood from hepatic arteries directly to sinusoids and hepatic veins has been demonstrated with single-level dynamic CT during hepatic arteriography (Miyayama et al. 2000). However, the risk of FNH and other hyperplastic liver lesions is obviously also increased in hepatic circulation disorders not primarily related to changes in arterial perfusion, including venous malformations, and disorders of the hepatic venous outflow tract. The idea has therefore emerged that FNH, similar to NRH, might be a rather nonspecific reaction to any type of focal ischemia induced by various mechanisms. If so, this hypothesis would however require an explanation as to why FNH and its putative precursors are single lesions in some, and multiple lesions in other patients, and why FNH lesions never occur to such an amount and in such a distribution as, e.g., the lesions in NRH. A distinctive situation with formation of a pathologic vascular "field effect" favoring multiple and synchronous FNH lesions might be represented by FNH occurring in oral contraceptive users, because these livers show an

abnormal hepatic vascular bed also outside the nodules themselves (Lepreux et al. 2003b). In what follows, several entities causing abnormal hepatic blood flow and known to be associated with FNH and FNH-like lesions are discussed.

Hepatocyte Hyperplasia in Hepatic Inflow Disorders

Portal Vein Thrombosis

There are several situations supporting a pathogenic role of venous inflow disorders of the liver for the development of hepatic nodular hyperplastic changes. FNH is a complication of long-standing portal vein thrombosis (Chiti et al. 1992; Bureau et al. 2004), and FNH can develop around a portal vein cavernoma (Ribera Cano et al. 2007; Marin et al. 2011).

Congenital Absence of the Portal Vein

Congenital absence of the portal vein (CAPV; for classification, see Morgan and Superina 1994; Badler et al. 2002), with visceral venous return to the suprahepatic inferior vena cava, is sometimes associated with hyperplastic hepatocyte nodules, including FNH (Okuda et al. 1988; Matsuoka et al. 1992; Guariso et al. 1998; Altavilla and Guariso 1999; Kinjo et al. 2001; De Gaetano et al. 2004; Koizumi et al. 2006; Schmidt et al. 2006; Chandler et al. 2011; Scheuermann et al. 2012) or nodular regenerative hyperplasia (Motoori et al. 1997; Arana et al. 1997; Grazioli et al. 2000; Tanaka et al. 2003; Kudo 2003). The hyperplastic nodular lesions can grow to impressive size (e.g., 10 cm diameter; Tanaka et al. 2003). Similarly, a hypoplasia of the intrahepatic portal venous system in congenital extrahepatic portocaval shunt can cause hepatic hyperplastic nodules (Yonemitsu et al. 2000). In other situations, intrahepatic portal venous obstruction due to failure of communication between the embryonic vitelline veins has caused abnormal gross hepatic lobulation already in utero, suggesting that pathologic venous flow can induce an early abnormal liver growth response (Johnson et al. 1979). The effects of portal vein agenesis can be mimicked by portal vein thrombosis that has been shown to be associated with nodular regenerative hyperplasia of the liver (Fukai et al. 1992) or with partial nodular transformation/PNT (Terayama et al. 1995). PNT has also been found around intrahepatic portal venous emboli of hepatocellular carcinoma (Hoso et al. 1996).

Congenital and Acquired Portocaval Shunts

First described by Abernethy in 1793, congenital vascular shunts between the main portal vein or its main central branches and the inferior vena cava (the "Abernethy malformation") are rare defects (Park et al. 1990; Howard and Davenport 1997; Lane et al. 2000) classified into Abernethy type 1 (usually in girls with other congenital anomalies; includes congenital absence of the portal vein with redirection of portal blood directly into the inferior caval vein) and type 2 (includes a side-to-side primarily extrahepatic connection between the inferior vena cava and an otherwise normal portal vein (Howard and Davenport 1997; Badler et al. 2002). The drainage sites of the splanchnic veins are the inferior vena cava, the left renal vein, the right atrium, and the azygos veins.

Congenital extrahepatic portocaval shunts can be associated with hepatic hyperplastic nodules (Yonemitsu et al. 2000), including large FNH nodules (Kitzing et al. 2011; Lisovsky et al. 2011; Pupulim et al. 2013). Sometimes, these lesions are of remarkable size; a large hyperplastic liver nodule has been noted in congenital portocaval shunt of Abernethy type 2 (Kanamori et al. 2003). In an animal model, congenital portacaval-shunt rats display focal hyperplastic changes of hepatocytes and even hyperplastic foci nodules, the latter mainly in the periportal zone (Vonnahme et al. 1984; Bioulac-Sage et al. 1985). Portocaval anastomosis in the rat can cause the emergence of hyperplastic foci in the otherwise atrophic liver (Dubuisson et al. 1985). Hyperplastic liver nodules after portacaval anastomosis have been described (Weinbren and Washington 1976). On the other hand, there are investigators who failed to produce hepatic hyperplastic nodules in rats by portacaval anastomosis and testosterone (Wanless and

Gledhill 1979). Multiple FNH have been observed after portocaval shunting (Scheuermann et al. 2013), and hyperplastic nodular hepatic lesions have been found following end-to-side portocaval shunting in childhood (Fukushima et al. 2007).

Spontaneous intrahepatic portosystemic shunts (SIPSS) are very rare, and less than 50 cases have been reported. SIPSS may be acquired, and they are then associated with liver cirrhosis and portal hypertension, taking the form of a large tubular vessel that connects the right portal vein to the retrohepatic vena cava (Masatoshi et al. 1993; Landen and Delugeau 2003). Congenital SIPSS usually result from patent ductus venosus (Arantii) or vitelline veins. Spontaneous intrahepatic portosystemic shunts (Lalonde et al. 1992; Landen and Delugeau 2003), spontaneous intrahepatic portohepatic shunts (Materne and Van Beers 1998), mesocaval shunts (Sakatoku et al. 1996), and intrahepatic porto-portal communications in the absence of the horizontal segment of the right portal vein and the umbilical portion of the left portal vein (Mignon et al. 1996) were associated with FNH.

Abnormal Branching of the Portal Vein

That an anomalous venous supply of the liver can provoke a circumscribed expansion of the hepatocyte population is shown by giant caudate lobe hyperplasia in case of anomalous caudate portal vein branching (Gabata et al. 1999; Kwak et al. 2000).

Hyperplastic Hepatocyte Reactions in Acquired Portal Vein Obstruction

In case of invasion of portal vein branches by malignancies, obstructive portal venopathy can induce a peritumoral hyperplasia of the liver. However, such hyperplasias lack the nodular aspect, the ductular reaction, and the central scar of FNH (Arnason et al. 2013).

Hepatoportal Sclerosis

Hepatocytic hyperplastic lesions also emerge in hepatoportal sclerosis, characterized by distal portal vein phlebosclerosis with the formation of portocaval shunts (Blanc et al. 2000), but FNH has apparently not yet been observed in this phlebopathy.

Hepatocyte Hyperplasia in Persistence of the Ductus Venosus and in Association with Umbilical Vein Anomalies

The ductus venosus connects the umbilical vein to the inferior vena cava in fetal life and subsequently closes rapidly after birth. About 50 % of umbilical venous blood passes through the ductus venosus, while the remainder is distributed to both lobes of the liver, the fetal liver exerting a major role in influencing venous return to the heart and in regulating oxygen distribution (Rudolph 1983). Predicted blood flows in humans through the ductus venosus and umbilical vein increase throughout gestation (from about 25 to 75 ml/min and from about 45 to 370 ml/min, respectively), while the flow fraction shunted via the ductus venosus diminishes (Edelstone 1980; Pennati et al. 2003). Persistence of a patent ductus venosus, which occurs sporadically or as a familial trait, results in an intrahepatic portosystemic venous communication from the portal venous system to the inferior vena cava (Barsky et al. 1989). A patent ductus venosus has been detected in infants with and without cardiac defects. In adults, the diagnosis is made as an incidental finding or in subjects presenting with hypoglycemia or portosystemic encephalopathy. Nodular hepatic lesions occur as a complication of a persistent ductus venosus, e.g., partial nodular transformation (PNT) of the liver (Wanless et al. 1985b), and other hepatocytic tumor-like lesions of the liver (Matsubara et al. 1996). PNT is a rare condition of unknown pathogenesis in which nodules composed of hepatocytes replace portions of the liver substance. PNT has also been observed in connection with portal vein thrombosis (Terayama et al. 1995). In familial patent ductus venosus, notable attenuation of the main portal vein with diminished intrahepatic branches was observed, and large hyperplastic liver lesions compatible with FNH were detected in one study (see below; Jacob et al. 1999).

Variations and malformations of the umbilical veins are extremely rare (Prust and Eskandari 1967; Theander and Karlsson 1978; Ricklan

et al. 1988). In the normal situation, the umbilical cord initially has two umbilical veins. Toward the end of the 4th gestational week, blood from the two vitelline and two umbilical veins passes directly into the sinus venosus. Subsequently, the growing hepatocyte cords interrupt the course of the vitelline veins, thus forming the sinusoidal network. After approximately 6 weeks, the umbilical vein system becomes connected to the hepatic sinusoids, the right umbilical vein obliterates and disappears by days 33–34, either by complete atrophy or by fusion with the left umbilical vein, whereas the part of the left umbilical vein between the body wall and the liver persists throughout fetal life, as does the ductus venosus. With the increase in blood flow from the placental circulation, a direct connection is established between the remaining left umbilical vein and the right hepatocardiac channel, which is the ductus venosus. Congenital anomalies of the umbilical veins can cause disorders of parenchymal development and hyperplastic reactions in the liver. They have been categorized into three groups (Ricklan et al. 1988). In the first group, the veins show normal attachment point to the abdominal wall and to the liver, but their intraabdominal course is abnormal, sometimes causing intestinal obstruction. The second group is characterized by anomalies of the umbilical vein itself. The neonatal umbilical cord can contain two veins instead of one; this accessory vein represents the persistent right umbilical vein. A persistent right umbilical vein compromises the placental blood flow achieved by the ductus venosus, with excessive placental blood returning to the fetal heart. The third group comprises abnormalities of the umbilical vein within the body and includes an umbilical vein bypassing the liver to enter the right atrium, the coronary sinus, the inferior vena cava, the iliac vein, or the right branch of the portal vein.

FNH or FNH-Like Lesions Developing in Hepatic Venous Outflow Disorders

In Budd-Chiari syndrome, several types of nodular hyperplastic lesion have been observed,

Fig. 18 Focal nodular hyperplasia (FNH) and FNH-like lesions in Budd-Chiari syndrome

including large regenerative nodules, lesions resembling FNH, and nodules that can histologically not be distinguished from bona fide FNH (Fig. 18; Ibarrola et al. 2004). In 23 patients followed up for Budd-Chiari syndrome, 19 patients developed multiple benign nodules, most of which were smaller than 4 cm in diameter (Vilgrain et al. 1999). Multiple macroregenerative nodules of the liver have been found to be caused by failure of hepatic venous drainage in Budd-Chiari syndrome (Zhou et al. 2000; Ibarrola et al. 2004). In a study of multiple nodular hepatic lesions occurring in the livers of four patients with Budd-Chiari syndrome, 15 of 32 nodules examined histologically displayed a central scar, and some nodules had other alterations typical for FNH (Maetani et al. 2002). FNH-like lesions subsequent to hepatic venous thrombosis have been reported (Schilling et al. 2000; Cazals-Hatem et al. 2003). However, not every nodular hepatic lesion developing in the setting of Budd-Chiari syndrome is a hepatocytic nodular lesion, but may also represent focal hemorrhage (Shapiro et al. 1993).

Nodular hyperplastic changes of the liver, mainly nodular regenerative hyperplasia, occur in stenosing lesions of small hepatic veins, in particular VOD/veno-occlusive disease (Russmann et al. 2001).

Hepatocyte Hyperplasia in Arterial and Other Vascular Malformations

Hereditary hemorrhagic telangiectasia (HHT; see the ▶ Chap. 58, "Tumor-Like Vascular Malformations") is sometimes associated with nodular transformation of the liver, the nodules being related to abnormally developed arteries and arteriovenous shunts (Wanless and Gryfe 1986; Ravard et al. 2004; Gincul et al. 2008; Khalid and Garcia-Tsao 2008). The prevalence of hyperplastic nodular lesions varies, however, considerably among different investigations. Among 52 HHT families who underwent a screening program for the detection of hepatic vascular malformations, FNH was found in 5 out of 274 subjects, with tumor diameters ranging from 2 to 9 cm (1.8 %; Buscarini et al. 2004). Thirty patients (19 women) with HHT studied in the setting of the Belgian Registry showed more nodular lesions: the authors observed a high prevalence (47 %) of asymptomatic hepatic tumors with radiologic and histologic characteristics of FNH for the majority of these tumors (Brenard et al. 2010). Among 171 consecutive HHT patients, hepatic nodular lesions were found in 6 (3.5 %; Scardapane et al. 2013). Pathogenetically, the complex intrahepatic arteriovenous shunts are likely to cause focal hyperperfusion with arterialized blood, causing a hyperplastic liver cell response. It has to be emphasized that hepatic arterioportal shunts themselves can radiologically mimic hepatic tumors (Matsuo et al. 2002).

Vascular malformations of the celiac axis and the hepatic artery branch in Klippel-Trenaunay syndrome can be associated with multiple FNH (Haber et al. 1995; Bathgate et al. 1999). There is a rare syndrome of FNH, neoplasia of the brain, and intracranial vascular malformations (Wanless et al. 1989; Goldin and Rose 1990).

Hepatocyte Hyperplasia in Disorders of Sinusoidal Perfusion

Sinusoidal obstruction is well established to cause nodular regenerative hyperplasia (Rubbia-Brandt et al. 2010), but can also be associated with larger hyperplastic lesions. FNH has been observed in patients with sinusoidal obstruction syndrome due to hematopoietic stem cell transplantation (Sudour et al. 2009). Two reports document children with sickle cell anemia (sickle cell disease, SCD) who developed FNH, possibly caused by the impairment of blood flow by sickling erythrocytes (erythrostasis) and the tendency for small vessel occlusion (Markowitz et al. 1980; Heaton et al. 1991). In fact, sickling in the sinusoidal vascular bed, making part of sickle cell hepatopathy, causes a nonuniform blood distribution. However, the effects of sickling on the microvascular bed are more complex. In SCD, microvascular flow is episodic, even in asymptomatic patients, so the effect of sickling is also modulated by factors other than mere sickling. The present concept is that SCD is also an inflammatory state associated with the activation of several cell types. Conduit vessels in SCD exhibit impaired vasodilation to endogenous and exogenous nitric oxide (Eberhardt et al. 2003). In SCD, blood microparticles derived from erythrocytes, thrombocytes, monocytes, and endothelial cells circulate, expressing tissue factor promoting blood coagulation (Shet et al. 2003).

Hepatocyte Hyperplasia in Portal Hypertension

FNH can develop in the context of idiopathic portal hypertension (IPH; Kondo et al. 1998). In some patients, multiple FNH emerged (Eda et al. 1999). Ten FNH were detected in a female patient with IPH, CREST syndrome, and protein S deficiency (Sanchez Manuel et al. 1997).

FNH Developing in Conjunction with Liver Hemangiomas

As outlined above, FNH can be combined with hemangioma in the same liver, but the relationship between these two lesions is not clarified. In one small child with a spontaneously shrinking liver hemangioma, follow-up showed that a nodule of FNH had emerged exactly at the site where previously the involuting hemangioma was situated, suggesting a causal relation between the two lesions (Turowski et al. 2009).

FNH and FNH-Like Nodules Associated with Steroid Hormones

Up to three quarters of females with FNH were found to be long-term users of oral contraceptives (OC). Therefore, prolonged OC intake and pregnancy have been suggested to be related to FNH pathogenesis (Davis et al. 1975; Bartok et al. 1980; Tajada et al. 2001). Low levels of estrogen receptors have been detected in FNH (Bojar et al. 1984), whereas expression of progesterone receptors was not demonstrated in FNH (Kubota et al. 2001). However, in a large study on 216 women, neither the size nor number of FNH lesions were influenced by OC use, and pregnancy was not associated with FNH changes or complications (Mathieu et al. 2000). A lack of effect of pregnancy on growth progression or complications of large FNH was confirmed in a recent study (Rifai et al. 2013). The question as to the pathogenetic significance of OC and other sex steroids has, therefore, to be tested in further studies. In the light of the important role played by vascular, and particularly portal venous alterations in FNH, thrombotic events induced by OC and related substances may theoretically be considered as pathogenetic elements. Few cases of FNH have also been found in association with androgenic substances (Cap et al. 1983; Serke et al. 1986; Helsing and Nielsen 2006) and intraconazole (Wolf et al. 2001).

FNH Developing Post-chemotherapy and/or Post-radiotherapy

FNH of the liver is increasingly diagnosed in children that had treatments for hematooncologic diseases, including leukemias and solid tumors, among the latter specifically neuroblastoma (Joyner et al. 2005; Marabelle et al. 2008; Benz-Bohm et al. 2010). The pathogenesis of these FNH is not known, but damage of hepatic vasculature by chemotherapeutic agents or ionizing radiation has been considered; for example, a role of endothelial damage by alkylating agents or radiotherapy has been suggested (Bouyn et al. 2003). Multiple FNH was found in association with oxaliplatin-based chemotherapy (Donadon et al. 2013).

Other and Rare Associations

FNH was found in grafted livers, possibly as a consequence of an altered hepatic circulation in the posttransplant liver (Ra et al. 2010). In children, FNH was detected following hematopoietic stem cell transplantation (Masetti et al. 2013). Interesting observations are also those where FNH was found within tumors showing hypervascularity; for example, FNH almost completely surrounded by metastatic renal cell carcinoma has been described, and the observers suggested that tumor-associated hyperemia may have played a pathogenic role (Nisar et al. 2002). FNH developed within 1 year after blunt abdominal trauma (Savoye-Collet et al. 2002). The pathogenic relationship is not clear, but traumatic injury to the liver can cause vascular lesions that might induce a hyperplastic response, such as hepatic artery pseudoaneurysms or arteriovenous fistulas (Schmidt et al. 1980). Rarely, FNH has been detected in the context of thorotrast liver disease (Sano et al. 1985). It has to be added that other reactive hepatocytic nodular changes, i.e., nodular regenerative hyperplasia of the liver (Dachman et al. 1987; Beer et al. 1998), and an ill-defined nodularity of the liver (Velasquez et al. 1985) have also been observed in association with thorotrastosis.

FNH was found in association with biliary atresia after Kasai hepatic portoenterostomy (Okugawa et al. 2008), Fanconi anemia (Nuamah et al. 2006), glycogenosis type I (Takamura et al. 1995), and glycogenosis type VI (Ogawa et al. 2010). Similar to liver cell adenoma (Beuers et al. 1991), FNH has been reported in association with Klinefelter syndrome (47, XXY), suggested to be related to the hormone imbalance present in this disorder (Santarelli et al. 2003) and in Turner syndrome (Roulot 2013).

Clonality of FNH, FNH Dysplasia, and Hepatic Malignancy

By use of several methods, it turned out in most studies that FNH are polyclonal lesions in 50–100 % of cases (Paradis et al. 1997; Nakayama et al. 2006; Cai et al. 2009; Gong et al. 2009), although results of monoclonality have also been published (Gaffey et al. 1996).

In a minority of cases, hyperplasic hepatocytes of FNH may undergo dysplastic changes (Fig. 19). Rarely, marked hepatocellular atypia interpreted as so-called large cell change has been found in FNH (Agaimy et al. 2003; Pai et al. 2009). In a 73-year-old male patient, this change was associated with formation of Mallory bodies in the atypical target cells, and it was suggested that these alterations characterize a distinct rare variant of FNH (Agaimy et al. 2003).

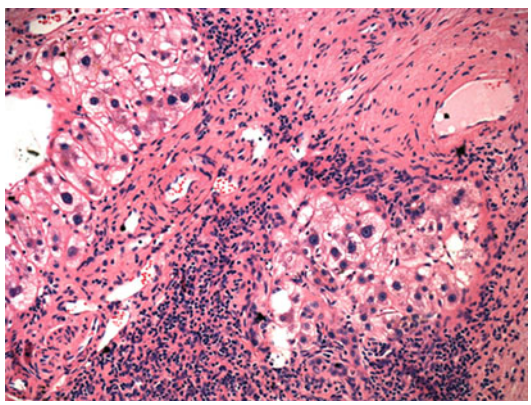

Fig. 19 Focal nodular hyperplasia with cellular/nuclear atypia (hematoxylin and eosin stain)

Dysplastic changes that develop in FNH are thought to be a first step in a carcinogenic pathway. In fact, there are relatively uncommon instances where hepatocellular carcinoma developed within preexisting FNH (Davis et al. 1975; Langrehr et al. 2006; Petsas et al. 2006; Haubert et al. 2010). Fibrolamellar carcinoma has also been reported to arise in FNH (Imkie et al. 2005). This has led some authors to assume that fibrolamellar carcinoma might be the malignant counterpart of FNH.

Cytogenetic and Molecular Features

Most FNH have no or relatively few genetic abnormalities. Chromosomal gains found in FNH mainly included 11q, 9q, 17q, and 22q (Chen et al. 2002). Trisomies of chromosomes 1 and 8 found in HCC were not found in FNH (Nasarek et al. 1995). In one child with FNH, a dup(8p)/(del(8q) recombinant chromosome had been found (Tokutomi et al. 2007). As outlined above, they show upregulation of activated beta-catenin in the absence of activating beta-catenin gene mutations (review: Rebouissou et al. 2008a).

Liver cell adenomas and FNH have been studied in detail in regard to molecular features (Rebouissou et al. 2008b). Based on the assessment of 209 selected genes in 14 FNH samples by use of RT-PCR, it was found that seven genes were significantly upregulated or downregulated in these lesions. Among these, the most informative were angiopoietin-1 and angiopoietin-2 (Paradis et al. 2003). In FNH, angiopoietin-1 was upregulated, and angiopoietin-2 was downregulated, and the Ang-1/Ang-2 ratio was highly and specifically increased in FNH compared with normal liver or other groups of lesions. Tie-2 mRNA, the receptor of Ang-1 and Ang-2, was detected at the same level in FNH as in normal liver. The specific increase of the Ang-1/Ang-2 ratio in the presence of a functional angiopoietin receptor may thus be involved in the pathogenesis of abnormal blood vessels in FNH (Paradis et al. 2003). In a recent study of nine FNH, a significant increase of angiopoietin-1 was found, whereas no significant changes in

angiopoietin-2, receptor tyrosine kinase with immunoglobulin-like and EGF-like domains 2, VEGF-A, or VEGFR-2 were observed. Based on a frequent history of vascular injury in FNH, it was concluded that angiopoietin-1 might exert different effects in FNH, such as stimulating the recruitment of myofibroblasts to result in dystrophic vessels (Gouw et al. 2010).

Abstract

Nodular regenerative hyperplasia (NRH) of the liver is a multilobular regenerative nodular lesion that develops in a noncirrhotic liver. NRH is characterized by the presence of nodules composed of normal-looking hepatocytes that form enlarged cell plates. These nodules are not surrounded by collagenous tissue, but a compressed reticulin network is present between the nodules and adjacent parenchyma. Cells within the nodules exhibit an increased proliferative activity. NRH is a major cause of noncirrhotic portal hypertension and develops in association with several systemic and local disorders, including autoimmune and related diseases, vascular disorders of the liver, myeloid neoplasms and various lymphoproliferative disorders, various drugs (mainly immunosuppressive agents), immunodeficiency syndromes, infections, and numerous other but rare conditions. There is evidence that, as a major pathogenic pathway, obliteration of small portal venous branches that causes atrophy of downstream liver lobules is followed by compensatory hyperplasia of adjacent lobules. There are other, less common forms of noncirrhotic nodular hyperplastic lesions of the liver, including partial nodular transformation.

Nodular Regenerative Hyperplasia (NRH) of the Liver

Introduction

Nodular regenerative hyperplasia (NRH) of the liver (synonyms: micronodular transformation; nodular transformation; nodular noncirrhotic liver; noncirrhotic nodulation of the liver) is multilobular regenerative nodular lesion developing in a noncirrhotic liver. NRH is morphologically characterized by the presence of nodules of regenerating, normal-looking hepatocytes, without fibrous septa, usually distributed diffusely across the liver parenchyma (Stromeyer and Ishak 1981). NRH is a major cause of noncirrhotic portal hypertension (review: Nakanuma et al. 2001). An important pathogenic mechanism, outlined in more detail below, is that obliteration of small portal venous branches causes atrophy of downstream liver lobules followed by compensatory hyperplasia of adjacent lobules with a still intact portal blood supply (reviews: Connolly 1977; Rougier et al. 1978; Smith 1978; Alperstein et al. 1981; Stromeyer and Ishak 1981; Mones and Saldana 1984; Moran et al. 1991; Tsui and So 1993; Pettei et al. 1995; Dall'Igna et al. 1996; Trenschel et al. 2000; Kondo et al. 2004).

Epidemiology

In several reports, Rauström is credited with being the first to describe a case of NRH of the liver in 1953, however by using the term *miliary hepatocellular adenomatosis* (Rauström 1953). In 1959, Steiner coined the term *nodular regenerative hyperplasia of the liver* (Steiner 1959). The prevalence of NRH may be as high as 0.6 % on the basis of autopsy series (Wanless et al. 1980). NRH is predominantly a disease of adult subjects but is also well recognized in the pediatric age-group (). In children, NRH may follow completion of solid tumor chemotherapy and may mimic hepatic metastases (Chu and Roebuck 2003; Citak et al. 2007). There are very rare instances of familial occurrence of NRH (Dumortier et al. 1999). A trimorphic syndrome with familial idiopathic pulmonary fibrosis, bone marrow hypoplasia, and hepatic NRH has been described (Talbot-Smith et al. 2009). The causes and pathogenic pathways of NRH are discussed in more detail at the end of this chapter.

Clinical and Imaging Features

NRH may be asymptomatic (Reshamwala et al. 2006), but in autopsy studies, NRH is associated with noncirrhotic portal hypertension in part of patients with this disorder (Wanless 1990). Noncirrhotic portal hypertension has been observed in at least half of patients with NRH (Sherlock et al. 1966; Classen et al. 1970; Rougier

et al. 1978; Stromeyer and Ishak 1981; Naber et al. 1991; Arvanitaki and Adler 2001; Gentilucci et al. 2011; review: Hartleb et al. 2011). Noncirrhotic portal hypertension is also caused by NRH in the pediatric age-group (Alperstein et al. 1981). Hemodynamic studies have suggested that portal hypertension in NRH is primarily sinusoidal, similar to that seen in liver cirrhosis (Ueno et al. 1996). In a more recent study of 24 NRH patients with symptomatic portal hypertension analyzing wedged hepatic vein, inferior vena cava, and portal vein pressures, findings were those of a presinusoidal component to portal hypertension, probably related to compression of portal venules by the regenerative nodules (Bissonnette et al. 2012). Rarely, NRH was associated with pulmonary arterial hypertension (Yutani et al. 1988; Bedossa et al. 1990). NRH may be associated with elevated serum AFP levels, caused by the regenerative hepatocyte response (Mneimneh et al. 2011). The prognosis of NRH is thought to be related more to the severity of underlying disease or systemic disorder than to the hepatic involvement itself (Colina et al. 1989).

The nodules of NRH have variable echogenicity on sonography, with hyperechoic or hypoechoic lesions (Casillas et al. 1997). In many cases, the reflexion pattern of the nodules is similar to that produced by cirrhotic liver, but in contrast to cirrhosis, the liver surface is smooth and free from the typical nodularity found in cirrhosis, and the coarsening or thickening of the lower edge of the liver is absent (Classen et al. 1970). By use of contrast-enhanced ultrasound (CEUS), distinct coral atoll-like lesions were detected in predisposed patients (Caturelli et al. 2011). Multiple small echogenic masses with occasional anechoic centers corresponding to hemorrhagic foci within the nodules may be encountered (Dachman et al. 1987). Radiologically, multiple small to medium-sized nodules and larger masses caused by conglomerate nodules on a background of a noncirrhotic liver are visible (Reynolds and Wanless 1984). The imaging features of multiple NRH lesions may mimic hepatic metastases (Clouet et al. 1999). These findings may be associated with splenomegaly and/or ascites on plain films or upper gastrointestinal series, and esophageal varices in barium studies, features of portal hypertension (Dachman et al. 1987). On CT images, the nodules are often hypodense without significant enhancement. The lack of enhancement is an important finding to distinguish NRH from large regenerative liver nodules which exhibit enhancement in a large proportion of cases (Ames et al. 2009). In a larger series, masses seen on CT images measured 0.2–10 cm in diameter, the latter representing conglomerate nodules (Dachman et al. 1987). Conglomerate lesions may produce a pseudotumoral aspect (Patriarche et al. 1988; Casillas et al. 1997). T1-weighted MR images of the liver show high-signal nodular lesions with central hypointense foci, while T2-weighted images reveal that the nodular lesions are isointense with central hyperintense foci (Siegelman et al. 1995; Horita et al. 2002; Wang et al. 2008; Leung et al. 2009). The nodules may take up technetium sulfur colloid (reviews: Dachman et al. 1987; Kobayashi et al. 2009). Angiographically, the findings were strikingly similar to what has been reported in cases of idiopathic portal hypertension (Shedlofsky et al. 1980). In splenoportography, an abrupt reduction in the contrast density of the smallest hepatic branches was seen, typical for a block at the level of hepatic microcirculation (Classen et al. 1970). Detection in intranodular Kupffer cells with superparamagnetic iron oxide enhanced MR imaging is an important indicator that a nodule is regenerative rather than neoplastic (Kobayashi et al. 2009).

Pathology

Macroscopy

At autopsy, livers with NRH often show a smooth capsule, in contrast to cirrhosis. However, in cases with advanced disease and formation of conglomerate nodules, the macroscopic features may resemble liver cirrhosis, also on small biopsy samples (Fig. 1; Qizilbash and Castelli 1980). On cut surfaces the picture varies considerably, ranging from an apparently preserved lobular

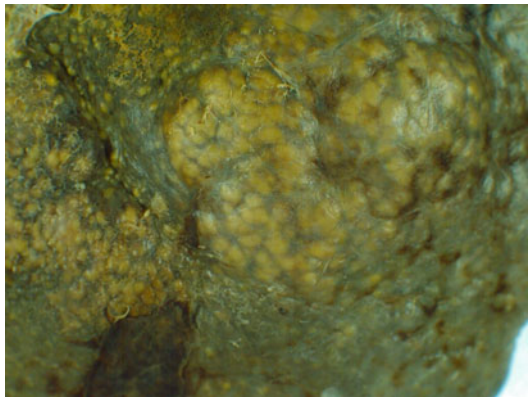

Fig. 1 Marked nodular regenerative hyperplasia of the liver

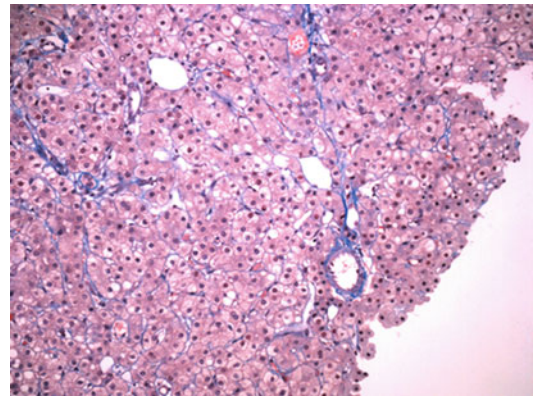

Fig. 3 Nodular regenerative hyperplasia of the liver. As seen in this collagen stain, the nodular lesion is not surrounded by fibrosis (CAB stain)

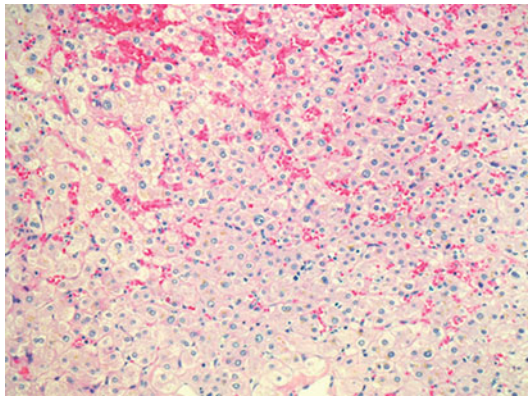

Fig. 2 Nodular regenerative hyperplasia of the liver. Hyperplastic areas show enlarged liver cell plates, darker cells and nuclear unrest (*center* of figure, hematoxylin and eosin stain)

architecture without visible nodular structures to multiple round to polygonal nodules, sometimes resulting in a picture resembling liver cirrhosis. The nodules typically measure 1–3 mm in diameter, but a macronodular aspect of the liver may also be found. In most instances, the nodules are more or less spherical, have a color identical or similar to the background parenchyma, and do not bulge from the cut surface. In contrast to cirrhotic nodules, the borders of the nodular structures are blurred or ill defined, because they are not delimitated by a fibrous shell (Stromeyer and Ishak 1981; Solis Herruzo et al. 1985; Wanless 1990; Forbes et al. 1991). Rarely, conglomerate nodules may be formed, resulting in lesions approaching 10 cm in diameter or even pseudotumoral presentation (Casillas et al. 1997). At abdominal surgery, granularity of the liver surface has been described (Blendis et al. 1970). Laparoscopically, histologically proven NRH grossly presented as a non-nodular undulated liver surface, a recognizable lobular pattern, and a hepatic consistency softer than normal to palpation (Cano-Ruiz et al. 1985).

Histopathology

The pertinent histological features of NRH have been described in detail (Weinbren and Mutum 1984). The salient presentation is that of well-circumscribed or vague hepatocyte nodules without associated fibrosis, whereby the nodularity is finer than the macroscopic appearance of granularity in cases of diffuse NRH (Figs. 2 and 3). NRH can develop in a focal pattern or may exist as diffuse NRH occupying the entire liver (diffuse regenerative hyperplasia, DNRH; Colina et al. 1989), depending on the underlying causes. The diameter of the nodules ranges from minute spherical hepatocyte clusters that may not be seen easily without a reticulin stain to macronodules that can be seen with naked eye (Trenschel et al. 2000). The hepatocyte plates within the nodules exhibit a characteristic thickening, the plates having three or four rows instead of two.

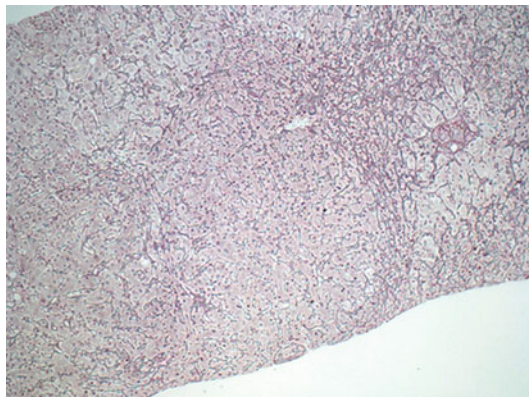

Fig. 4 Nodular regenerative hyperplasia of the liver. The nodular lesion is best visualized in reticulin stains (*middle* of figure; Gomori silver stain)

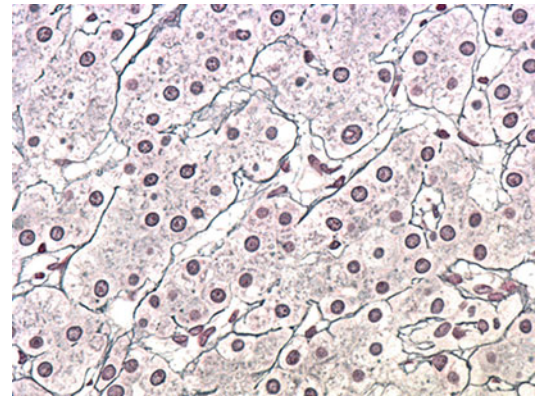

Fig. 6 Nodular regenerative hyperplasia of the liver. In this reticulin stain, an enlargement of hepatocyte plates (more than two cells in width) is seen (Gomori silver stain)

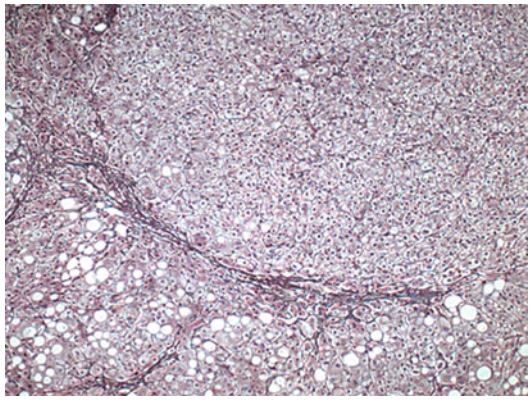

Fig. 5 Nodular regenerative hyperplasia of the liver may induce compression of adjacent liver tissue and condensation of reticulin fibers (Gomori silver stain)

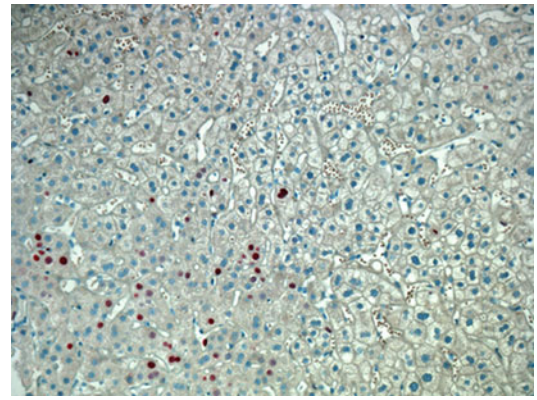

Fig. 7 Nodular regenerative hyperplasia of the liver. In areas with hyperplasia, hepatocytes exhibit an increased proliferative activity (*left half* of figure; MIB1 immunostain)

This feature is particularly well visualized in a reticulin stain (Figs. 4, 5 and 6). Thick hepatocyte plates are a constant and striking feature and represent the result of regenerative cell proliferation (Fig. 7; Weinbren and Mutum 1984). Within the nodules and their conglomerates, sinusoids are commonly narrow and the number of branches of the hepatic vein are reduced. Portal tracts may be trapped within nodules, producing a pattern of reversed lobulation, but this a rather rare finding. Portal tracts entrapped within regenerative nodules may show a mild lymphocytic infiltration and some fibrosis, even with incomplete septa. Obliterative portal phlebopathy may be in evidence (Nakanuma et al. 1996). Typically, the parenchyma adjacent to the nodules reveals a preserved lobular architecture, i.e., without any cirrhotic remodeling, but it manifests varying degrees of atrophy, with compression and thinning of hepatocyte plates, best seen in reticulin stains. Due to the expansion of nodules, the reticulin network is compressed and therefore more dense, a feature that has not to be confounded with true fibrosis. In and around the nodules of NRH, sinusoids may be significantly dilated in the absence of a hepatic venous outflow disorder (Kakar et al. 2004). Sinusoids of livers with NRH may contain increased

numbers of lymphocyte. CD8+ cytotoxic T lymphocytes were detected in 14 of 44 NRH patients. The cells were located near atrophic liver cell plates. Significantly more granzyme B+ and CD57+ lymphocytes were observed in NRH than chronic hepatitis C samples with quantitatively similar CD8+ lymphocyte infiltrates. It was suggested that CD8+ cytotoxic cells may damage sinusoidal endothelial cells and participate in the pathogenesis of NRH (Ziol et al. 2004). NRH may be associated with other histological liver alterations, depending on the type of underlying disease. In certain hematologic disorders, including myeloproliferative syndromes, obliterative portal venopathy is found in association with NRH (Wanless et al. 1980). NRH occurring in the setting of primary hypogammaglobulinemia was often associated with accumulation of lymphocytes in hepatic sinusoids (Malamut et al. 2008).

Immunohistochemistry

In one report, periportal immunostaining of hepatocytes for alpha-1-antitrypsin was more frequent in biopsies showing NRH than in non-NRH samples, suggesting that this staining may be useful in confirming the needle biopsy diagnosis of NRH (Nakhleh and Snover 1988).

Causes of Nodular Regenerative Hyperplasia

The causes of NRH cover a broad spectrum. Many if not most causative factors operate through a pathway involving vascular damage. The mode of progression or the reversibility of NRH are currently unknown. Known causes and associations of NRH are compiled in Table 1.

Drugs

Drug-induced NRH is common form of this disorder, probably amounting to more than 60 % of cases (Colina et al. 1989; Ghabril and Vuppalanchi 2014), but the underlying cause is
